To realize next-generation power devices and highly sensitive quantum sensors, heteroepitaxy of diamond on Si substrates is a key technology from the viewpoint of scalability and Si CMOS hybrid system [1-3]. We utilize 3C-SiC as an intermediate layer between Si substrates and diamond films because it can be directly grown on the Si and the lattice constant and the surface energy of the SiC are close to the diamond.

We would like to introduce the heteroepitaxial growth of diamond on both Si (001) and (111) substrates by original antenna-edge type microwave plasma CVD with in-situ bias current monitoring during bias enhanced nucleation (BEN). We show the properties of the diamond films, and then the potentials for both power devices (Schottky barrier diodes) and quantum sensors. Concerning the schottky barrier diodes (SBDs) on heteroepitaxial diamond (001) films, the specific on-resistance of 0.2 Ω·cm² and high rectification of 10⁵ (±5 V) were obtained which are comparable for SBDs on homoepitaxial diamond films.

The sensor devices using nitrogen-vacancy (NV) centers were formed in the heteroepitaxial diamond (111) films. The NV centers could be preferentially aligned of the NV axis to the one direction and be leading to improving the sensitivity was confirmed.

Thin CVD Diamond Films on AlGaN/GaN HEMTs Structures Ken Haenen1, 2, 1Institute for Materials Research (IMO), Hasselt University, Diepenbeek, Belgium; 2MOMEC, IMEC vzw, Diepenbeek, Belgium.

Diamond’s extreme properties make it a prime candidate for next-gen electronic devices, including high frequency and high power operation. While monolithic diamond devices based on doped monocrystalline layers, enabling both unipolar as well as bipolar design schemes, have great potential, the currently obtainable substrate size and quality leave several years of scientific and technological development. The fact that diamond has an extremely high thermal conductivity and can be deposited on non-diamond substrates, opens up an intermediate pathway for hybrid power devices that integrate diamond with other wide bandgap materials such as SiC or GaN. The main goal in such cases is to achieve an enhanced reliability of the latter active materials by providing superior cooling minimizing thermal hotspots and withstanding large break down electric fields.

Here, the case of diamond on GaN-based HEMT structures is considered. First, the deposition of thin CVD diamond layers will be discussed, including the surface chemistry governing the nanodiamond particle seeding, the deposition conditions, and the use of different microwave-based CVD techniques, including resonant cavity and linear antenna technology. Cross-sectional TEM and EELS mapping of the stacks are employed to discuss the structural and morphological properties and to extract possible changes in composition in the underlying Si,N/AlGaN/GaN interfacial layers induced by the substrate temperature during diamond deposition. Finally, the evaluation of the effective thermal conductivity of the thin diamond layers is discussed. The contactless transient thermoreflectance technique, used to study the heat spreading capabilities, shed light on the thermal conductivity and interfacial thermal boundary resistance.

4:30 PM EP09.09.05/EP08.07.05
Gate Oxide Stability in Diamond Power Transistors Loto Oluwasayo1, Matthieu Florentin1, Cedric Masante1, Nazareno Donato1, Marie-Laure Hicks4, Alex C. Pakpour-Tabrizi1, Richard B. Jackman4, Verena Zuerbig5, Philippe Godignon6, David Eon1, Julien Pernot1, Philippe Godignon6, David Eon1, Julien Pernot1, Philippe Godignon6

Semiconducting diamond is an attractive candidate for the next generation of high voltage and high frequency power devices, thanks to its exceptional properties in terms of wide bandgap, high breakdown field and thermal conductivity. In the literature, several diamond-based field-effect-transistors (FETs) have already revealed good on state performance and high blocking voltage capability (~2kV) in a wide range of operating temperatures. The possibility of generating an inversion regime in diamond metal-oxide-semiconductor FET (MOSFET), and the new Deep Depletion regime (D2MOSFET) specific to wide bandgap semiconductors pave the way for a new generation of power devices. The critical part of the transistor is the gate oxide, with electrical charge traps located within the oxide or at its interface with the semiconductor. These traps can screen the gate potential and shift the threshold voltage, making the devices unusable. The reduction of the trap density is a major concern in all MOS technologies, as well as its stability with time under bias stress.

The latest results about diamond MOS transistors prepared in the framework of the European GreenDiamond project will be presented, and the evolution of the diamond MOS properties with time will be reported for the first time.
The properties of diamond (high mobilities and ultra-gap) suggest different current transport modes that can support high current operation which is sustained and actually improved at high temperatures. This study presents experimental results of forward current density vs voltage which shows a $V^2$ dependence indicative of injection mode transport. The Schottky-PIN devices show high values of forward current density (> 500A/cm² at 3 V) that is stable and actually improves at elevated temperature. Perhaps the most stunning aspect of these results is that the diode specific on-resistance ($R_{on}$) decreases as the voltage increases. The results indicate a new mode of operation of high mobility diamond power devices where the high carrier mobilities and low phonon scattering will support current injection and drift with a reducing resistance as the current is increased. We present a comparison between diodes that operate in injection mode and the more conventional doped drift layer. We discuss modifications of the standard power electronics figure of merit for projecting the operation of diamond devices that operate in the injection transport mode. This research is supported through the NASA HOTTECH program.

Diamond electronics devices are probably the future of power electronics in comparison with other wide band-gap materials. This is due to the exceptional intrinsic properties of the diamond such as a wide band gap (5.45 eV), a high breakdown field (10 MV/cm), a large carrier mobility (2000 cm²/V.s) and a good thermal conductivity (22 W/cm.K).

The most promising device is the vertical Schottky diode, which has already been the subject to a lot of studies. Nevertheless, there are still some open questions, such as: why leakage current appears in some diodes? Is the leakage current linked to the material itself? Is the interface between the diamond layer and metallic contacts homogeneous and does it have an impact on the diodes characteristics? What is the effect of carrier injection at the p$^+$ interface? Finally, how is the breakdown through the stack? To answer these questions we imagined to observe vertically the structure, i.e. through the Schottky contact, the diamond, up to the heavily doped layer used as the back contact for the diode. Two ways are developed in order to have a view along this direction. First, by focused ion beam technic, a thin lamella is defined and reported on an external holder. Second, by a fine polishing of the edge of the plates, the stack can be directly observed. Thus, with these techniques, all interfaces can be investigated as well as the quality of the grown material. This first part gives us also information on growth and on how to optimize it.

Then, to correlate material properties to electrical properties of Schottky diode, the lamella is wired and studied by electron beam induced current (EBIC). This gives an image of the electric field distribution through all the stack, i.e metal, lightly doped and heavily doped diamond. It also provides access to the local electric properties of the device and the correlation with the material properties at the same location. The results of this first in-situ electrical measurement of diamond devices will be presented, and all the implications in the understanding of diamond Schottky diodes.

Diamond exhibits many outstanding properties such as good light transmission, effective resistance to radiation damage, large bandgap, high breakdown voltage, high thermal conductivity, high carrier mobilities etc., having potential applications in the fields of wide range optical transparent window material, coating tools, especially in the field of electron devices which can work in high frequency, high power, high temperature as well as corrosive environment [1-2]. Hydrogen-terminated diamond (H-diamond) devices have been widely researched due to its surface high carrier density and mobility of $10^{13}$ cm$^{-2}$ and 50-150 cm$^2$/V.s$^{-1}$, respectively. An excellent ohmic contact between electrode metal layer and H-diamond is needed. Recently, a new ohmic contact between iridium (Ir) and H-diamond has been reported. However, the barrier height between Ir and H-diamond was still not very clear. To obtain the barrier height value between metal and H-diamond, X-ray photoelectron spectroscopy (XPS) technique was used in this work, because it can directly measure the electronic levels, and used to obtain the barrier height value.

For this work, investigation of barrier height between Ir and H-diamond has been carried out using XPS technique. Firstly, 3X3X0.5 mm$^3$ (001) single crystal diamond with lightly boron doping ($10^{15}$/cm$^3$) was cleaned by acid and alkali to remove the non-diamond phase. Secondly, the sample was treated by hydrogen plasma to form the hydrogen-terminated diamond surface. Thirdly, 20 nm Ir was deposited on half part of the sample as reference by electron beam evaporation (EB) technique. Then, anodic aluminium oxide (AAO) with 50 nm hole and 20 nm spacing was transferred on the whole sample surface. After that, 3 nm Ir was deposited on sample by EB technique. Later, after the AAO was removed, 3 nm Ir island with diameter of 50 nm was formed on sample surface. Finally, XPS technique was used to measure the carbon and Ir electronic levels to obtain the barrier height between Ir and H-diamond.

Switching Speed Enhancement with Enlarge Gate width Diamond Cascade Application in High Voltage Half-Bridge Inverter

Robert J. Nemanich1, Raghuraj Hathwar1, Manpuneet Benipal2, Franz A. Koeck1, Mohamadali Malakoutian1, Srabanti Chowdhury1 and Stephen M. Goodnick1; 1Arizona State University, Tempe, Arizona, United States; 2Advent Diamond, Tempe, Arizona, United States; 3University of California - Davis, Davis, California, United States.
C-H (Hydrogen-Terminated) diamond MOSFETs show high breakdown voltage characteristics (over 1600 V) and wide temperature operations (10 K-673 K) [1, 2]. However, transport properties of C-H diamond MOSFETs show normally-on because 2DHG exists without gate bias voltage. In consideration of these devices and energy-saving the normally-off operation of devices is required. The cascode structure is based on using the normally-off silicon device to shift the threshold voltage of normally-on device to normally-off. It is successful in changing normally-on AlGaN/GaN HEMT to normally-off. We fabricated the diamond-cascode by the combination of the normally-off silicon p-MOSFET and normally-on C-H diamond FET. Characteristics show the gate of diamond FET is controlled by the silicon p-FET, and it shows normally-off characteristics and maximum transconductance has been drastically enhanced, and the diamond cascode show great breakdown voltage (over 1700 V) because the high voltage was blocked by diamond FET. We applied the diamond cascode in half-bridge inverter configuration as high side, and the GaN cascode (TPH3206PS) is application in low side in the half-bridge inverter. The diamond FET in diamond cascode with \( L_{GS} \approx 2 \mu m, L_{DS} \approx 4 \mu m, \) and gate width is 25 \( \mu m, \) the \( V_{GS,HD} \) characteristics shows the maximum current is \(-3,3 mA\) with \( I_{C,OFF} \approx 20 \mu A/m. \) After application in half-bridge inverter in the low operation voltage of 20 V, the switching time (\( T_{ON} \)) in the high-side is 40 \( \mu s. \) In the high operation voltage of 200 V, the \( T_{ON} \) is 60 \( \mu s, \) but the switching time (\( T_{OFF} \)) in the low-side are under 1 \( \mu s. \) We think the reason is the gate width (\( W_{G} \)) imbalance between the tiny size diamond FET and GaN cascode product, and the gate width imbalance is lead to difference current driving capability between the two sides in inverter. We enlarge the gate width of diamond FETs, and we fabricated the different gate width of diamond FETs from 50 \( \mu m \) to 500 \( \mu m, \) and \( V_{GS,HD} \) characteristics shows the maximum current of \( W_{G}=500 \mu m \) is 30 mA. After we application the larger \( W_{G}, \) diamond FET in the half-bridge inverter, the \( T_{ON} \) is 5 \( \mu s \) in high-side has been observed in the operation voltage of 20 V, and \( T_{OFF} \) is 14 \( \mu s \) in 200 V operation voltage, switching time is faster about 8 times in the low voltage and 4 times in the high voltage. At last, we confirmed the half-bridge inverter operated in 400 V operation voltage. Therefore, new structure of diamond FETs for higher frequency and high operation voltage half-bridge inverter has been discussed and designed.

To overcome the limitations and drawbacks of conventional technologies, light-based technologies are on the rise. Integrated optical systems offer the potential to realize optimized photonic building blocks into complex circuits exhibiting high stability and scalability. Successful applications of integrated optical systems are already found in telecommunication, metrology and sensing. Examples are also extended to quantum photonic platforms, benefiting mainly from the miniaturization’s capabilities that integrated approaches provide. Established methods to realize integrated circuits, inspired from microelectronics, are limited to quasi-planar geometries and require sophisticated multi-step fabrication routines. The most promising approach to solve these drawbacks and open the route to fast prototyped three-dimensional integrated circuits is femtosecond laser lithography. A femtosecond laser beam is tightly focused inside the volume of a transparent material, mounted on a high-precision translation stage. By translating the sample relative to the beam focus, permanent nanometer-sized structures are induced. Although femtosecond laser lithography is originally intended for waveguide fabrication in isotropic glasses it is not restricted to this host material. To date, femtosecond laser lithography is employed to structure, also organic polymers and the wide class of crystalline materials whereas nonlinear crystals belong to the most important. Here we report on the fabrication of Type III depressed cladding waveguides in extended polycrystalline diamond samples by femtosecond laser lithography. Previous studies were limited to waveguide fabrication by femtosecond laser in single crystal diamond substrates. Due to the optical properties of diamond, such as high refractive index, strong nonlinear and Raman coefficient, and the ability to host coherent color centers at room temperature, it is attracting increased interest in the fields of classical and quantum photonics. The waveguide structures were inscribed using a femtosecond Ti:sapphire laser system (Coherent Legend) with a central wavelength of 800 nm and pulse duration of about 120 fs at a repetition rate of 1 kHz. The laser beam was focused by a high numerical aperture microscope objective (NA=0.8) into a 300 \( \mu m \) thick polycrystalline diamond substrate in an absolute depth of 90 \( \mu m. \) We demonstrate waveguiding in the near-infrared telecommunication C-band for optimized processing parameters. The proposed approach combines the advantages of the versatile technique femtosecond laser lithography with the outstanding material properties of diamond enabling extended 3-dim integrated optical system based on diamond. Promising applications are on-chip diamond quantum photonics and the realization of high-quality single photon emitters.

9:45 AM EP09.10.06 Hydrogen-Terminated Diamond Field-Effect Transistor with YSZ Dielectric Layers Yanfeng Wang, Xiaohui Chang, Wei Wang, Dan Zhao, Jiao Fu and Hong-Xing Wang; Xi'an Jiaotong University, Xi'an, China.

Diamond exhibits many outstanding properties such as good light transmittance, effective resistance to radiation damage, large bandgap, high breakdown voltage, high thermal conductivity, high carrier mobilities, etc., making it having potential applications in the fields of wide range optical transparent window material, coating tools, especially in the field of electron devices which can work in high frequency, high power, high temperature as well as corrosive environment [1-2]. When diamond is treated by hydrogen plasma, a two dimensional hole gas (2DHG) layer will be formed under diamond surface with a sheet hole density of \( 10^{13} \) cm\(^{-2} \). However, this 2DHG layer is thermally and chemically unstable. In order to solve this problem, dielectric layer is often deposited on H-diamond surface in metal-oxide-semiconductor field effect transistor (MOSFET) field. Up to now, various dielectric layers have been used in H-diamond MOSFET such as SiO\(_2\), Al\(_2\)O\(_3\), HfO\(_2\), TaO\(_3\), and ZrO\(_2\), etc. Yttria-stabilized zirconia (YSZ) is an excellent dielectric material with high thermal stability, whose dielectric constant and band gap are 27 and 5 eV, respectively.

In this work, the investigation of H-diamond FETs with YSZ dielectric layer has been carried out. Firstly, gold electrodes were patterned on H-diamond by electron beam evaporation technique. Secondly, UV-ozone was used to insulate the device. Then, YSZ dielectric layer was deposited on p-type conduction channel by magnetron sputtering deposition technique. After that, Al gate was deposited on H-diamond by electron beam evaporation technique. The length and width of channel were 15 and 100 \( \mu m \), respectively. Finally, electrical properties of this H-diamond MOSFET had been investigated. The detail will be presented in the conference.

Diamond is considered as an attractive semiconductor to open up next-generation electronics based on its unique physical and electrical properties. For instance, the highest breakdown voltage among wide-band-gap semiconductors with high thermal conductivity and high saturation velocity potentially lead to a higher attainable power density. In addition, the excellent spin characteristics of nitrogen-vacancy complexes including long coherence time and optical initialization and read-out properties lead to a potential candidate for single photon source, magnetic sensors, and quantum applications. High quality single crystal diamond growth by plasma-enhanced CVD and precise control of impurity doping underlay the design of virtually all these applications. n-type Fermi controlling is still a challenging target, since diamond generally prefers to be p-type semiconductor even in an intrinsic diamond. Carbon vacancies including impurity-vacancy complexes are all acceptor-type defects that capture electrons. From the viewpoint of n-type semiconductor diamond, the suppression of these vacancies is one of the most important factors of Fermi controlling as well as suppression of boron acceptors. On the other hand, from the viewpoint of defect engineering, n-type donors can supply electrons to vacancy defects, leading to the stabilization of their charge states. Nitrogen-vacancy complexes have three charge states, and only NV- centers are required for quantum spin applications. In this presentation, we would like to discuss the engineering significance of n-type Fermi control from the viewpoints of following two targets. (1) Inversion channel control in diamond/AI2O3 configuration, (2) Phosphorus doping for charge-state control of nitrogen-vacancy complexes.

Boron Nitride is a wide band gap semiconductor with cubic and hexagonal phases that are isoelectronic to diamond and graphite respectively. The cubic phase of boron nitride has similar structural, electronic, and thermal properties with diamond. These similarities enable an integrated device design that can operate under extreme conditions. We present an approach to deposit boron nitride, as a neutron conversion layer, on a PIN diamond alpha radiation detector. Using plasma enhanced chemical vapor deposition, boron nitride is deposited on polycrystalline and single crystal diamond, with and without a gold contact interlayer. By tuning the hydrogen to fluorine ratio during the deposition, we can control the equilibrium between etching and film formation. In situ X-ray photoelectron spectroscopy is used to characterize the sp2:sp3 bonding of the surface, as well as to calculate the growth, etching, and regrowth rates. Our current growth rate is ~1nm/min. The optimal thickness for the neutron conversion layer is 1 to 3µm, therefore we are working toward increasing this growth rate of boron nitride.

Chemical Vapor Deposited Diamond High Power Capacitors Jim J. Davidson1, David Kerns2, John Fraley2, Stephen Minden2 and Brett Sparkman2; 1Management, International FemtoScience Incorporated, Nashville, Tennessee, United States; 2Wolfspeed, A Cree Company, Fayetteville, Arkansas, United States.

Utilizing the known dielectric properties of undoped polycrystalline CVD diamond films of > 10e12ohm-cm, capacitor structures were created to examine, for example, the capacitance, charge storage density, leakage and breakdown properties of capacitors whose dielectric layer is commercially procured CVD diamond. This paper will describe the test capacitor created, the testing procedures, and the electrical and physical characterization of the diamond capacitors, “D-Caps”.

For power electronics and/or energy storage scenarios, a better capacitor structure, particularly as regards the quality and strength of the dielectric utilized in these capacitors needs to be improved. While high coulomb/ cm3 values are cited by, e.g., electrochemical and electrolytic ultracapacitor type capacitors, their high voltage limitations are disappointing, and by virtue of their fundamental makeup cannot be enhanced. There are advantages to having truly solid, planar (layered) type of capacitor structure, such as presently achieved with, for example, ceramic type capacitors. There have been laboratory tests of the dielectric strength/ voltage breakdown characteristics of diamond layers – and those values (circa > 3(10e7) V/cm) are impressive - but no practical examination for capacitor applications derived directly from commercially deposited polycrystalline diamond films has been performed. This paper takes commercially procured undoped polycrystalline diamond films and fabricates them into practical conductor/diamond/conductor layered capacitor structures and examines their electrical behavior and their potential [figuratively and literally] for utilization as industrial capacitors for power or energy storage. MDM (metal/diamond/metal) layers, typically 1 to a few microns in thickness, were examined by SEM, Xray and Raman spectroscopy topologically and in cross-section. Aspects of multilayer “comb” type interlayer (“MDMDM” structures) were considered.

We will report pertinent electrical and physical characterization properties of planar diamond dielectric based capacitor test structures, including leakage characteristics, breakdown behavior, statistical distribution of yield and routes to practical packaging and applications.

Nitrogen and Oxygen-Terminated Diamond Electrolyte Solution-Gate FET for pH Sensing in Both Acidic and Alkaline Solutions in pH Solutions

Yu Hao Chang1, Shaili Falina1, Sora Kawai1, Mohd Syamsul1, Yutaro Iyama1, Yukihiko Shintani2 and Hiroshi Kawarada1, 2; 1Waseda University, Tokyo, Japan; 2Kagami Memorial Research Institute for Material Science and Technology, Tokyo, Japan.

We investigated pH sensitivity of nitrogen and oxygen-terminated diamond electrolyte solution-gate field effect transistors (SGFETs). Diamond has many appealing properties including chemical inertness, biocompatibility, and simple chemical modification on the surface that are suitable for pH sensing in SGFETs. Since 2001, we have reported diamond SGFETs where the semiconductor surface was directly immersed in electrolyte solution and the drain current was controlled by electric double layer at the diamond surface [1]. We conducted H-termination on diamond surface to obtain surface p-type conductivity and introduced O-termination to acquire pH sensitivity [2]. Amine-terminated diamond SGFETs has a pH sensitivity of 50 mV/pH; the amine termination was achieved by UV radiation treatment in NH3 atmosphere [3]. In recent research, N-termination can be achieved on diamond surface by nitrogen radical exposure with remote RF plasma [4]. In this work, we continued to utilize nitrogen and oxygen-termination on diamond SGFETs for pH sensing in both acidic and alkaline solutions as illustrated in Dr. Shaili Falina’s research [5], and increased coverage rate of N-terminated surfaces to optimize pH sensitivity.

Polycrystalline diamond surface was first hydrogenated by plasma treatment under hydrogen atmosphere. At room temperature, H-terminated diamond surface exhibited sheet resistance of 20-60 kΩ/sq and a high carrier density at 10^19 cm^-2. Source and drain electrodes were then formed with Au, connected with wires by conductive paste and sealed with epoxy resin to prevent leakage in pH solutions. The resulting channel length and width was 0.33 mm and 5.0 mm, respectively. As opposed to U/V ozone treatment, anodic oxidation was conducted to achieve O-termination [6]; the channel of diamond surface is applied up to 1.6 V while the Ag/AgCl reference electrode was grounded. Finally, N-termination was conducted by means of remote RF plasma at 300 W with nitrogen gas containing 4% hydrogen gas as radical source for 20 minutes. I_D-S-V_Ds characteristics and pH sensitivity were procured by Keithley Instrument source-measure unit from pH 2-12.

As a result, nitrogen and oxygen-termination on diamond SGFETs showed increased pH sensitivity compared with only O-termination in both acidic and alkaline solutions. While further investigation regarding the effect of N-terminated surface coverage rate in pH solution is required, by increasing the coverage rate of N-terminated surface, we suspect an enhancement in pH sensitivity of the device.

11:45 AM EP09.11.05

Electrical Properties of CMP Treated 1 inch Heteroepitaxial Diamond Substrates Seongwoo Kim1, Yuki Kawamata1, Yutaka Kimura1, Kokichi Fujita1, Kenjiro Ikejiri1 and Makoto Kasu1; 1Adamant Namiki Precision Jewel Co., Ltd., Tokyo, Japan; 2Saga University, SAGA, Japan.

Mass production technologies of CMP treated substrate are important to accelerate research and development activities of diamond semiconductor. Although there still exists some challenges, such as large substrate, high crystallinity and surface finishing, most of research resources are devoted to achieve high crystallinity. In order to overcome the other two tasks, we have developed heteroepitaxial diamond growth method and Chemical Mechanical Planarization (CMP) technologies.

Heteroepitaxial diamond growth method has a great potential to obtain a large diamond substrate compared to other growth methods. Because of the difference in the coefficient of thermal expansion between diamond and basal substrate material, crack and random delamination are generated in diamond film during the cooling down process. We have previously reported in details the fabrication of the freestanding heteroepitaxial diamond substrate via microneedles that prevent the crack generation and the delamination11. Following this technique, a diamond substrate with 1 inch diameter was successfully achieved. In order to demonstrate larger than 1 inch diameter diamond substrate, it is necessary to change the basal substrate material because of two reasons: (1) the diameter of the commercially available MgO substrate is limited to 1 inch. (2) MgO substrate cost exponentially increases with diameter. One of the most promising materials to replace MgO is sapphire. The crystal system of sapphire (hexagonal) is different from that of diamond and iridium (Cubic), whereas sapphire substrate is chemically inert, 8 inch substrate available and much cheaper than MgO. Therefore, standard hetero-epitaxial diamond growth procedure on MgO substrate was applied to the A-plane sapphire substrate with 10 mm × 10 mm square surface. The grown crystal was obtained without any cracks and breakage. The obtained thickness is 800 µm. As a result of X-Ray Rocking Curve measurement, crystallinities of both (400) and (311) planes were better than that achieved diamond grown on MgO substrate. Furthermore, 1 inch heteroepitaxial diamond substrate was successfully demonstrated on sapphire.

Surface finishing is important to obtain the best performance of a substrate. In the case of conventional semiconductor substrate, CMP is applied as a surface finishing technology. The influence of CMP treatment on heteroepitaxial diamond was investigated by MOSFET characteristics. The heteroepitaxial diamond substrates were all the same thickness, off angle and surface roughness by mechanical polishing. CMP was applied after mechanical polishing. MOSFET was fabricated on the heteroepitaxial diamond substrate with and without CMP. We found that the Id-Vd characteristics of MOSFET on CMP treated substrate is better than that without CMP. The details will be discussed at the symposium.

intermediate transformation of solar energy to electrical energy. In general, the photocatalytic transformation of carbon-based starting materials is attractive as such reactions environmentally friendly and can be carried out under mild conditions. Diamond is an attractive material for the photocatalytic transformations due to its unique electronic properties, e.g. the reduction of carbon dioxide. So far, the excitation of electrons into the conduction band requires UV light due to the large bandgap. Therefore, for the ability to use visible light, the introduction of unoccupied states in the band gap of diamond is a requirement to overcome this limitation. In this work we report our results on the photocatalytic activity of differently terminated and functionalized diamond materials. This includes not only direct interaction with suitable surface atoms but also the immobilization of transition metal complexes using different linker strategies. We were able to demonstrate the direct use of visible light for the transformation of CO₂ into methanol and formate and will discuss the influence of different parameters such as the medium, surface structure and type of diamond on the efficiency of the photocatalytic process. This project has received funding from the European Union's Horizon 2020 Program under Grant Agreement no. 665085 (DIACAT).

Len¹, Andres Arreola¹, Virginia Altoe⁶, Dennis Nordlund⁷ and Abraham Wolcott¹; ¹San Jose State University, San Jose, California, United States; ²The Molecular Foundry, Lawrence Berkeley National Laboratory, Berkeley, California, United States; ³SLAC National Accelerator Laboratory, Menlo Park, California, United States.

The interest in high-pressure high-temperature (HPHT) fluorescent nanodiamonds (FNDs) as an emerging probe for biosensing results from the unique photophysics of the nitrogen vacancy center (NVC). NVCs detect magnetic fields, electric fields, and may be realized as pH or voltage sensors. Attractive characteristics of the biosensing include their lack of cytotoxicity, infrared emission (575-800 nm) and long term photo-stability make FNDs an ideal bio-labeling tool. Challenges in modifying the inert diamond surface limit their development as a biological probe in cells and tissues. The synthesis of a silica shell using wet chemistry techniques encapsulating the FNDs allows for further functionalization and control of shape specific properties. Silica priming of the diamond surface proceeds by nucleophilic attack of the tetrahydroxysilane precursors forming a silyl ether bond (C-O-Si-OH) to the diamond surface. A realization of 2-20 nm thick shells of SiO₂ was achieved through variations in synthesis time and particle size analysis was conducted through DLS, SEM, and TEM. Molecular functionalization of polyethylene glycol (PEG) moieties onto the silica shell stabilizes the FNDs colloidal in biological environments while amine and sulfyl-hydryl moieties act as anchors for folic acid decoration. Other functionalization techniques employed include the use of 11-azido1undecyltrimethoxysilane, (3-Glycidoxypropyl)trimethoxysilane, (3,3,3-trifluoropropyl)-trimethoxysilane, carboxylic acid, and phosphonate moieties. Functionalization was verified through FTIR and synchrotron based X-ray techniques (XAS and XPS). We also demonstrated optimized targeted staining of unpegulated folate receptors in HeLa cells cultures. This work provides a wide range of surface and morphological tunability that can be used in magnetometry and electric field sensing applications.

Stable Ag-Diamond Core-Shell Nanostructures with Tunable Optical Properties
Shuo Li and Robert J. Hamers; University of Wisconsin-Madison, Madison, Wisconsin, United States.

Diamond is widely used in many applications like coatings, optical lenses & windows, high power laser optics, photocatalysts and imaging fields. Tuning the optical properties of diamond is needed for wider applications. However, diamond is a large bandgap material and is highly transparent from deep UV to infrared light across the electromagnetic spectrum, limiting its applications. Previously people use doping method by introducing impurities like nitrogen or boron into diamond crystal lattices, creating defect states which absorb visible light and generate colors. However, there are only limited choices of elements available to serve as donors, limiting the tunability of diamond optical properties. Moreover, the introduction of impurities would often result in the degradation of diamond quality. Plasmonic metal nanoparticles are highly efficient at absorbing and scattering light at certain wavelengths, and they exhibit size- and shape-dependent plasmonic features in a wide region of the spectrum. Therefore, by integrating metal nanoparticles like Ag into diamond would provide an alternative approach to tune the diamond’s optical properties in a more controllable way. Previous reports have shown the incorporation of Ag nanostructures with diamond would enhance the optical properties of diamond. Whereas for as-reported Ag-diamond hybrids, the Ag are exposed to the environment, which makes the structures not stable; the tunability of Ag plasmonic properties also needs to be increased.

Here we demonstrate a stable Ag-diamond core-shell structure can be made, in which the Ag core sizes and diamond shell thicknesses can be controlled precisely, resulting in the tunable optical properties of diamond. As Ag is embedded in diamond shells, this hybrid material has superior stability that can maintain the structure and properties even after high temperature annealing or acid boiling treatment. The Ag nanoparticles embedded within diamond films are grown by a three-step process: (1) a very thin film of Ag is deposited onto a diamond surface, (2) the Ag film is de-wetted into individual nanoparticles, and (3) a second diamond film is grown to encapsulate the Ag nanoparticles. Cross-sectional SEM clearly shows individual nanoparticles with sizes ranging from ~10 nm to 500 nm depending on experimental conditions. UV-vis spectra clearly show the plasmonic peaks in good correspondence of SEM. TEM analyses show the boundary between the diamond-Ag nanostructures, as well as the columnar growth of diamond extending radially from the Ag nanoparticle cores. We show that the unique Ag-diamond core-shell structure with great stability is a promising platform for diamond with tunable optical properties in various applications.

Black Diamond as an Antibacterial Surface—Interplay Between Chemical and Mechanical Bactericidal Activity
Paul W. May², Olivia Dunseath², Ed J. Smith¹, Tarik Al-Jeda², James A. Smith³, Angela Nobles¹, Gavin Hazell¹ and Colin C. Welch²; ¹Dental School, University of Bristol, BRISTOL, United Kingdom; ²School of Chemistry, University of Bristol, Bristol, United Kingdom; ³Plasma Technology, Oxford Instruments, Bristol, United Kingdom.

‘Black silicon’ (Si₃) samples with surfaces covered in nanoneedles of length ~5 μm were fabricated using a plasma etching process and then coated with a conformal uniform layer of diamond using hot filament chemical vapour deposition to produce ‘black diamond’ (BD) nanostructures. The diamond needles were then chemically terminated with H, O, NH₃, or F using plasma treatment, and the hydrophilicity of the resulting surfaces were assessed using water droplet contact-angle measurements. The effectiveness of these differently terminated BD needles in killing the Gram-negative bacterium E. coli was semi-quantified by Live/Dead staining and fluorescence microscopy, and visualised by SEM. The total number of adhered bacteria was consistent for all the nanostructured BD surfaces at around 50% of the value for the flat diamond control. This, combined with a chemical bactericidal effect of 20-30%, shows that the nanostructured BD surfaces supported significantly fewer viable E. coli than the flat controls. The BD surfaces were particularly effective at preventing the establishment of bacterial aggregates – a precursor to biofilm formation. The percentage of dead bacteria also decreased slightly as a function of hydrophilicity, with superhydrophobic F-terminated BD killing 50% of the adherent bacteria. These results are consistent with a predominantly mechanical mechanism for bacteria death based on the stretching and disruption of the cell membrane, combined with a smaller additional effect from the chemical nature of the surface.
Production and Manipulation of Diamond Nanoparticles

Laia Gines, Soumen Mandal and Oliver A. Williams; Cardiff University, Cardiff, United Kingdom.

The production of diamond nanoparticles containing colour centres has attracted increasingly interest in the last years for quantum computation applications. Particularly, the SiV colour centre has highlighted as a promising photon source among other colour centres in diamond, due to its interesting optical properties at room temperature. SiV colour centres acting as single photon emitters can be created through different approaches in-situ during CVD growth by introducing silicon as a solid source or in a gas phase.

In this work diamond nanoparticles with custom colour centres were produced from bulk material via milling strategies. First a diamond film containing NV/SiV centres was grown onto a passive substrate, followed by sacrificial etching of the substrate. The resulting diamond film was milled using a planetary mill based on either steel or SiN. The milled material was purified by acid reflux. To measure particle sizes, different slurries containing the diamond nanoparticles obtained were prepared and characterized by using Dynamic Light Scattering (DLS) and Nanoparticle Tracking Analysis (NTA). XPS was also used to qualify the milling process contamination. Colour centre incorporation was confirmed by Photoluminescence and Hanbury Brown and Twiss measurements. The control of surface sp3 and sp2 potential will also be demonstrated.

Applied Particulate Nanodiamond to Enhance Thermal and Mechanical Properties of Host Systems

Jim I. Davidson1, David Kerns2, Blake Branson1, Ethan Langone1, Farzin Mashahi2, Wayne Johnson1, Lino Costa1 and Kathleen Lansford1; 1FemtoSci Incorporated, Nashville, Tennessee, United States; 2Tennessee Technological University, Cookeville, Tennessee, United States; 3University of Tennessee Space Institute, Tullahoma, Tennessee, United States.

Conventional heat transfer fluids such as water, ethylene glycol, mineral oils and their mixtures are presently significantly compromised for their fundamental objective, cooling the heat generating system, because their inherent thermal conductivity is poor. Likewise, the inherent strength of, for example, polymer based solid systems could be enhanced by the addition of nanoparticles that improve bonding at the molecular level. In this paper, particulate nanodiamond, ND, ['detonation' nanodiamond] is examined as a low concentration additive to liquid and solid systems to enhance, e.g., their thermal conductivity and strength.

The criticality of sufficient deaggregation and compatible functionalization chemistry to successful outcomes will be addressed. We have prepared different functionalized nanodiamond, FND, samples, where the functional group is specifically intended to have its terminal chemical bonding couple with the host matrix resulting in their operating improvement. Because the effective diameters of molecular influence of the attached functional groups in the host matrix can be much greater than the 5 nanometers of the “core” ND, concentrations in the range of ppm of the FND can result in double digit improvements of key properties.

Examples of these FND applications will be presented, such as, many cooling loop systems, be they for electronic or engines, are water based. We have examined a FND formulation and evaluated it as an additive in a precisely controlled and monitored water cooling loop which allows the direct determination of the heat transfer coefficient, a more practical parameter than thermal conductivity, and an improvement of over 20% was observed at a FND concentration of 500ppm.

Further, an appropriate FND formulation to enhance the polymers used in composites was applied and improvement in the flexural strength was observed. Tensile strength testing of ox-ND/PAN (highly de-aggregated nanodiamond (ND) polyacrylonitrile (PAN)) and ox-UDD/PAN (aggregated ultra-dispersed (UDD) polyacrylonitrile (PAN)) thick-film composites was performed. Elastic modulus, tensile strength, and elongation measurements of these solid polymer samples as a function of ND addition were measured. The more highly dispersed de-aggregated ox-ND is more effective as a reinforcement additive than aggregated ox-UDD while the as-received UDD/PAN composite samples, having very poor dispersion characteristics [a configuration often examined and reported in none ND evaluations], exhibit tensile strengths even lower than those measured for pure PAN control films. The results of this work demonstrate the elastic modulus and tensile strength of de-aggregated ox-ND/PAN composites outperform those of aggregated ox-UDD/PAN composites at all additive concentrations above ~ 3 vol.%. At 10 vol.% ox-ND loading, elastic modulus is enhanced by nearly 80% and tensile strength increases by nearly 60% relative to pure PAN films.

Neural Adhesion on Diamond—Competition Between Polymer Treatment and Surface Morphology

Barbora Jakubcova1, Andrew Taylor3, Pavel Hubik1, Vaclav Petrak1 and Vladimir Petrakova1, 2; 1Institut for Experimental Physics, Freie Universitaet Berlin, Berlin, Germany; 2Faculty of Biomedical Engineering, Czech Technical University in Prague, Kládno, Czechia; 3Institute of Physics, The Czech Academy of Sciences, Prague, Czechia.

The ability to form an efficient interface between material and neural cells is a crucial aspect for construction of neuroelectrodes. Diamond offers material characteristics that could, to a large extent, improve the performance of neuroelectrodes. The greatest advantage of diamond is a large variety of material and surface properties such as electrical conductivity, surface morphology, and surface chemistry. Such a variety of material characteristics can lead to various cellular responses. Here we compare survival, adhesion, and neurite formation of primary neurons on diamond thin films of various morphologies and treatments with several types of polymers commonly used to enhance cell adhesion. We found that the variation of surface roughness of
High Self-Nucleation for Continuous Nano-Diamond Film Growth on Silicon Substrate

The nucleation occurs on the β-SiC intermediate layer (several nm) at high temperatures, when the carbon concentration on the substrate surface reaches its saturated value. The nucleation densities can then be enhanced by one to two orders, but this value is still far below the number suppression of carriers generated from sp² bonds, which contribute heat transport, and the existence of hydrogen atoms at grain boundaries in the hydrogenated film.

It was experimentally demonstrated that the thermal conductivity of UNCD/a-C:H films is strongly dependent on the grain size. The grain size dependent of thermal conductivity of diamond has been mainly studied for chemical vapor deposition (CVD), and it has been reported that thermal conductivity is strongly depends on the intrinsic properties of grain boundaries. Recently we have realized the formation of UNCD/hydrogenated amorphous carbon (a-C:H) composite (UNCD/a-C:H) films by coaxial arc plasma deposition (CAPD), which is a kind of physical vapor deposition. Note that CAPD does not necessarily require a hydrogen atmosphere during the deposition for the formation of diamond grains, in other words, UNCD/non-hydrogenated amorphous carbon (a-C) composite (UNCD/a-C) films can be grown under a base pressure. So far, hydrogenation effects on the thermal conductivity of UNCD/a-C:H films has never been studied because H atoms are unintentionally incorporated into the films from source gases in CVD. In this study, UNCD/a-C and UNCD/a-C:H films were deposited under a base pressure and in hydrogen atmospheres, and the hydrogenation effects on the interfacial thermal conductance at grain boundaries were studied.

UNCD/a-C:H and UNCD/a-C films were deposited on Si substrates at a substrate temperature of 550 °C by coaxial arc plasma deposition (CAPD) using a coaxial arc plasma gun equipped with a graphite target. Al films were deposited on the UNCD/a-C:H films by sputtering for the time-domain thermoreflectance (TDTTR) measurement. From the TDTTR measurement, the thermal conductivities of the non-hydrogenated and hydrogenated films were estimated to be 7.80 and 2.32 W/(m K), respectively, which are larger than those of a-C:H and a-C films, respectively. It might because of the existence of diamond crystallites in our films. As reasons for the small interfacial conductance value of the hydrogenated film as compared with that of the non-hydrogenated film, we consider that the number suppression of carriers generated from sp² bonds, which contribute heat transport, and the existence of hydrogen atoms at grain boundaries in the hydrogenated films that enhance from phonon scattering.

It was experimentally demonstrated that the thermal conductivity of UNCD/a-C:H films sensitively decreases by hydrogenation, in other words, the thermal conductivity of UNCD/a-C:H films is controllable with hydrogenation.

High Self-Nucleation for Continuous Nano-Diamond Film Growth on Silicon Substrate

Continuous diamond films grown on heterostructures are required for current technological applications, such as heat dissipation, nano/micro-electromechanical systems and even future potential many optic-electronic devices. Growth of thin coalesced diamond layers requires a very high density of nucleation sites (typically 10¹⁵ cm⁻²). However, very low nucleation densities (typically below 10¹⁵ cm⁻²) are obtained on non-treated substrates due to the high surface energy of diamond relative to heterostructures. Seeding process or surface pretreatment is believed to be the best choices to provide stable diamond seeds or nuclei for subsequent diamond CVD growth, but surface damage (microscopic defects or scratches) caused during seeding or pretreatment process has hindered its application on future potential optic-electronic devices. A promising alternative is to develop a high self-nucleation method for subsequent diamond growth on non-diamond surfaces.

It is a generally accepted fact, that the primary process responsible for diamond nuclei formation is heterogeneous nucleation on the substrate surface. In the case of Si substrates, the nucleation occurs on the β-SiC intermediate layer (several nm) at high temperatures, when the carbon concentration on the substrate surface reaches its saturated value. The nucleation densities can then be enhanced by one to two orders, but this value is still far below the minimum requirements for subsequent continuous film growth.

In this presentation, we will report our recent observations on high self-nucleation of continuous thin nano-diamond films growth on silicon substrate. The effect of the substrate orientation and seeding process will be compared. The possible cause for such self-nucleation phenomenon will be investigated and discussed.
Mechanism of High Ionic Conduction Paths in Composite Solid Electrolyte

Feifei Shi and Yi Cui; Material Science and Engineering, Stanford University, Stanford, California, United States.

As one of the most promising next-generation batteries, all-solid-state lithium battery is well known for its superior advantage of high energy density and nonflammability, as well as its intrinsic drawback poor ionic conductivity of solid electrolyte. Therefore, it is crucial to understand the ion conduction mechanism in solid electrolyte for optimized design to enhance ionic conductivity. Recently, composite solid electrolyte with aligned interface has been reported to achieve one order of magnitude enhancement on ionic conductivity. However, the mechanism accounting for the enhanced ionic conductivity at solid/solid interfaces remains unclear.

Here we unveil the diffusion path of the lithium in the composite electrolyte by tracking labeled lithium isotope, characterizing polymer crystal structure with both hard and soft X-ray diffraction, and mapping the electronic structure of lithium by electron spectroscopy. Further understanding of the correlation between interface structure and ion conduction mechanism has been obtained, which enables new solid electrolyte design with better ionic conductivity.

State-of-Charge-Dependent Space-Charge-Layer Formation in Solid-State Batteries

Michael W. Swift and Yue Qi; Michigan State University, East Lansing, Michigan, United States.

As all-solid-state lithium ion batteries develop as an alternative to traditional liquid-electrolyte cells, a thorough theoretical understanding of the driving forces behind battery operation is needed. We present a model of potential profiles in a generic all-solid-state battery, and apply the model to the Li/LiPON/Li$_x$CoO$_2$ system. The potentials yield valuable information about lithium distribution and transport, including the nature of electrical double layers which form at interfaces. The results suggest design rules to minimize interfacial lithium barriers and optimize device performance.

Mapping LLZO Grains and Grain Boundaries Through a Simple Thermal Etching Technique

Masumi Sato, Regina Garcia-Mendez and Jeff Sakamoto; University of Michigan, Ann Arbor, Michigan, United States.

LLZO is one of the most promising solid-state electrolytes due to its electrochemical and chemical stability against metallic Li and high ionic conductivity (1 mS cm$^{-1}$) at room temperature. However, it has been reported that Li metal still propagates along LLZO grain boundaries above a critical current density (CCD) (1).

It is known that the chemistry of grain boundaries and grains are typically different. In this study, we assume the same is true for polycrystalline LLZO. We hypothesize that grain boundaries etch faster than grains, thus enabling a technique to visualize and study the microstructure of LLZO. The proposed technique does not requiring extensive sample preparation such as what is required for electron backscattering diffraction (EBSD). Variables such as temperature, dwell time, atmosphere and flow rate were tuned to optimize the thermal etching method while maintaining phase purity, e.g., not decomposing LLZO grains.

AI-LLZO pellets were densified by rapid induction hot pressing, followed by grinding and polishing. Surface heat treatment was conducted to reduce the concentration of Li$_2$CO$_3$ and LiOH layers that readily form after LLZO is exposed to air (2) before thermal etching. Scanning Electron Microscope (SEM) was used to see the grain boundaries and determine the grain size of the surface of the thermal etched LLZO pellets and X-Ray Diffraction to analyze phase purity. EBSD was conducted to confirm that the features observed in thermally etched LLZO surface correspond to grain boundaries. Additionally, TGA-Mass Spectrometry was used to correlate the mass loss to the chemistry of the volatilized compounds during thermal etching of LLZO. Furthermore, Electrochemical Impedance Spectroscopy (EIS) measurements were conducted to evaluate that the ionic conductivity of LLZO remains unchanged after completing the thermal etching process.

It is believed that the thermal etching method developed and optimized in this work can be used as a simple technique to examine the microstructure of LLZO and perhaps other polycrystalline electrolytes.
Solid state electrolytes are currently being intensively investigated for the possible application in solid-state batteries. Among all known solid Li+ conductors, Li10GeP2S12 (LGPS) is one of the most promising candidates due to its unrivaled high ionic conductivity of 12 mScm−1 and successful implementation into solid state batteries. Therefore, there is a great interest to further optimize the Li+ mobility and to reduce the costly germanium content using different doping strategies in related structures. Unfortunately, increasing the Sn fraction in Li10Ge1−xSnxP2S12 leads – counter to chemical intuition – to a reduction in the ionic conductivity.

The present work reveals the structural and lattice dynamical reasons for the observed behavior. Solid solutions of Li10Ge1−xSnxP2S12 were synthesized and structural changes and their resulting impacts on the Li+ transport property were investigated using a combination of structural refinements, ultrasonic speed-of-sound measurements and AC impedance spectroscopy. It is shown that while the lattice volume and the c/a ratio of the compounds increase with increasing Sn4+ fraction, the ionic conductivity decreases. Taking a deeper look into the local bonding properties reveals that a bottleneck of the diffusion channels along the z-direction tightens. In addition, a softening of the lattice with the more polarizable Sn4+ cation was observed similar to other classes of lithium and sodium thiophosphate solid electrolytes. But in this case the softening of the anion backbone leads to stronger Li+ − S2− Coulombic interactions, that can be understood with the concept of inductive effects. Overall this work demonstrates, that chemical intuition can struggle in the understanding of structure property relationships and that a deeper look into the local bonding properties is necessary for the future design of solid electrolytes.
Solid polymer electrolyte has excellent processability although its ionic conductivity and mechanical strength needs to be improved. Here I will present our recent progress on nanoscale design of using nanomaterials to form composite polymer electrolyte to improve both ionic conductivity and mechanical strength. Nanomaterials include nanowires and porous anodized alumina. Organic-organic composite electrolyte is also explored. We use successfully these solid electrolytes for Li metal batteries.

Fabrication of Advanced Composite Cathodes in All-Solid-State Batteries Using 3D Reconstruction Analysis and Complementary Wet-Based Process Sangjun Choi, Wo Dum Jung, Minjae Jeon, Seong-Min Kim, Ji-Su Kim, Byung-Kook Kim, Byoung-In Sang and Hyoungchul Kim; 1High-Temperature Energy Materials Research Center, Korea Institute of Science and Technology, Seoul, Korea (the Republic of); 2Department of Chemical Engineering, Hanyang University, Seoul, Korea (the Republic of).

Next-generation Li-ion battery (LIB) applications such as electric vehicles, unmanned aerial vehicles, energy storage systems, and integrated power devices for the Internet of Things require the development of technologies that allow the storage of electrical energy at safer and higher energy densities over a wider range of operating temperatures. In this context, all-solid-state battery (ASSB) technologies have the advantage of eliminating the organic electrolyte from the existing secondary battery in addition to incorporating solid-state materials for all components, thereby meeting all requirements for next-generation LIB applications. The composite cathode of an ASSB composed of various solid-state components (i.e., the active material, electrolyte, conductive additive, and etc.) requires a dense microstructure and highly-percolated solid-state interface different from that of a conventional liquid-electrolyte-based Li-ion battery. Indeed, the preparation of such a system is particularly challenging.

In this study, quantitative analyses of composite cathodes by three-dimensional (3D) reconstruction analysis were performed beyond the existing qualitative analysis, and their microstructures and reaction interfaces were successfully analyzed. Interestingly, various quantitative values of structure properties (such as the volume ratio, connectivity, tortuosity, and pore formation) associated with material optimization and process development were predicted, and they were found to result in limited electrochemical charge/discharge performances. We also verified that the effective two-phase boundaries (TPBs) were significantly suppressed to ~23% of the total TPB, due to component dispersion and packing issues. In addition, we have developed a pore decomposition process (PDP) that tracks the origins of pore structures using quantitative values of a 3D reconstruction structure. The solid electrolyte and cathode active material showed a noticeable difference in the ratio of induced pore volume: 43% of the total pore from solid electrolyte and 56% from active material. To solve the observed problems such as formation of pores, we adopted a wet-synthesis process of sulfide solid electrolyte on fabricating composite cathode. The introduction of a new wet-based solid electrolyte improved the microstructure of the composite cathode by eliminating pores, increasing interfacial contact area, and mitigating inhomogeneous mixing. Therefore, the enhanced microstructure provide a better ionic conduction pathway, resulting in higher electrochemical cell performance. The pore formation, the powder characterstics, and the process optimization of composite cathode are closely related, and the quantitative analysis results from 3D reconstruction process provide relevant insights.

Effect of Microstructure on the Critical Current of Li7La3Zr2O12 Jeff Wolfenstine; Army Research Laboratory, Adelphi, Maryland, United States.

Li-ion conducting solid-state batteries based on a Li7La3Zr2O12 (LLZO) solid-state electrolyte combined with a Li-metal anode have attracted considerable attention because they offer the advantages of higher energy and enhanced safety compared to the current Li-ion batteries. One of the major issues the with Li/LLZO system is determining what LLZO microstructural variables influence the critical current (current at which lithium dendrites/filaments form on charging). For a single-phase material the major microstructural variables are porosity and grain size. For a solid-state electrolyte a high relative density is required thus, the major microstructural variable is the grain size. It is the purpose of this presentation to discuss the effect of grain size (5 to 600 mm) on the room temperature critical current of LLZO and by examining the effect of grain size on ionic conductivity and fracture toughness and determine which of these properties has a major influence on the critical current for hot-pressed high relative density (>97%) Li7La3Zr2O12.

Phase-Field Simulations of Lithium Dendrite Growth with Open-Source Software Zijian Hong and Venkatasubramanian Viswanathan; Mechanical Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania, United States.

Dendrite growth is a long-standing challenge that has limited the applications of rechargeable lithium metal electrodes. Here, we have developed a grand potential based nonlinear phase-field model to study the electrodeposition of lithium as relevant for a lithium metal anode, using open-source software package MOOSE. The dynamic morphological evolution under large/small overpotential is studied in 2-dimensions, revealing important dendrite growth/stable deposition patterns. The corresponding temporal-spatial distributions of ion concentration, overpotential and driving force are studied, which demonstrate an intimate, dynamic competition between ion transport and electrochemical reactions, resulting in vastly different growth patterns. Given the importance of morphological evolution for lithium metal electrodes, wide-spread applications of phase-field models have been limited in part due to in-house or proprietary software. In order to spur growth of this field, we utilize an open-source software package and make all files free available online to enable future studies to study the many unsolved aspects related to morphology evolution for lithium metal electrodes.

11:45 AM ET01.01.11
Crosslinked Poly(tetrahydrofuran) as a Loosely-Coordinating Solid Polymer Electrolyte David Mackanic1, Yi Cui2 and Zhenan Bao3; 1Chemical Engineering, Stanford University, Stanford, California, United States, 2Materials Science and Engineering, Stanford University, Stanford, California, United States.

Solid polymer electrolytes (SPEs) promise to improve the safety and performance of lithium ion batteries (LIBs). However, the low ionic conductivity and transference number of conventional poly(ethylene oxide) (PEO) based SPEs preclude their widespread implementation. Herein, we introduce crosslinked poly(tetrahydrofuran) (xPTHF) as a promising polymer matrix for "beyond PEO" SPEs. The crosslinking procedure creates thermally stable, mechanically robust membranes for use in LIBs. Molecular Dynamics and Density Functional Theory (DFT) simulations accompanied by Li NMR measurements show that the lower spatial concentration of oxygen atoms in the xPTHF backbone leads to loosened O-Li+ coordination. This weakened interaction enhances ion transport; xPTHF has a high lithium transference number of 0.53 and higher lithium conductivity than a xPEO SPE of the same length at room temperature. We demonstrate that organic additives further weaken the O-Li+ interaction, enabling room temperature ionic conductivity of 1.2*10^-4 S cm^-1 with 18 wt. % DMF in xPTHF. In a solid state LIB application, neat xPTHF SPEs cycle with near theoretical capacity for 100 cycles at 70 °C, with rate capability up to 1C. The plasticized xPTHF SPEs operate at room temperature while maintaining respectable rate capability and capacity. The novel PTHF system
Despite their high energy density, Li metal anodes have not been successfully commercialized due to dendritic Li plating during charging. However, recent developments in Li-ion conducting solid electrolytes have rekindled interest in the use of Li metal anodes. In particular, sulfide solid electrolytes (SSEs) are attractive materials due to their high ionic conductivities, low grain boundary resistance, and mechanical strength. However, SSEs are readily reduced by Li metal, calling into question their viability. Here, the interfacial stability between SSE and Li metal anodes is investigated computationally using the concept of band edge alignment. First-principles calculations were performed using many body perturbation theory to evaluate the position of the conduction band minimum (CBM) in various SSEs. These levels are compared with the Li/Li' electrochemical potential in order to evaluate the likelihood charge injection (i.e., reduction) from Li anodes. Our calculations reveal that reduction by Li is preferred for Li10GeP2S12, Li10SnP2S12, Li3PS4, Li4GeS4, and Li,S2O6. Although the position of the CBM is sensitive to the surface features of the SSE, varying the surface composition appears to be insufficient to prevent reduction. In addition to predicting CBM positions, the full band gaps of several SSEs were evaluated. Band gap values range from 4.0 eV in Li10SnP2S12 to 4.8 eV in LiPSs. Finally, we discuss the implications of our findings for interfacial reactions between SSEs and Li metal.

Epitaxial Li3Ti5O12 Thin Film as Model System for Li-Ion Conductivity

Francesco Pagani1,2, Evelyn Stilp1, Reto Pfanninger3, Eduard Cuervo Reyes1, Arnold Lemaitre1, Zoljan Balogh-Michels1, Antonio Neels1, Jordi Sastre Pellicer1, Michael Stiefel1, Max Dobelt2, Marta D. Rossell1, Rolf Enz1, Jennifer L. Rupp1, and Corsin Battaglia1
1Empa–Swiss Federal Laboratories for Materials Science and Technology, Dübendorf, Switzerland; 2Electrochemical Materials, ETH Zürich, Zürich, Switzerland; 3Department of Material Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 4Ion Beam Physics, ETH Zürich, Zürich, Switzerland.

Thin-film all-solid-state batteries provide a model system for the fundamental study of Li-ion transport, defect chemistry [1], and electrochemical stability [2] and find applications in smart cards, sensors, and radio-frequency identification tags [3]. Here we compare the Li-ion conductivity of epitaxial and polycrystalline Li3Ti5O12 thin films (≈ 125 nm thick) and investigate the impact of grain boundaries on Li-ion conductivity. Phase-pure epitaxial and polycrystalline Li3Ti5O12 thin films were grown on MgO(111), MgO(001), and MgO(100). In our calculations, the Li+ transport in Li3Ti5O12 is found to be suppressed compared to Li metal. Our calculations reveal that reduction by Li is preferred for Li10GeP2S12, Li10SnP2S12, Li3PS4, Li4GeS4, and Li,S2O6. Although the position of the CBM is sensitive to the surface features of the SSE, varying the surface composition appears to be insufficient to prevent reduction. In addition to predicting CBM positions, the full band gaps of several SSEs were evaluated. Band gap values range from 4.0 eV in Li10SnP2S12 to 4.8 eV in LiPSs. Finally, we discuss the implications of our findings for interfacial reactions between SSEs and Li metal.

References:
Electrochemical energy storage devices have attracted wide attention for energy conversion and storage. Over the past several decades, the success of the lithium-ion batteries (LIBs) has triggered the revolution of personal electronics and significantly changed our lifestyle. However, further progress in battery technology is still needed and great efforts are devoted to improve energy density, cycle life, cost and safety.

Among various kinds of rechargeable batteries for future applications, the all-solid-state configuration using inorganic solid electrolytes (SE) has become a promising option. Research in this field is mainly motivated by the promise to further increase the energy density as well as the safety characteristics compared to today’s battery technology. However, all-solid-state batteries still fall short of expectation largely because of limited interface kinetics and interface stability. Moreover, processing of the materials and preparation of the cells needs to be significantly improved to reach higher energy densities and/or lower price compared to conventional cells with liquid electrolytes. In particular, sulfide-based SEs are strongly investigated due to their high ionic conductivity and ductility. The SE Li3PS4 (LPS) exhibits an acceptable ionic conductivity of 10⁻³ to 10⁻⁴ mS cm⁻¹ at room temperature as well as low grain boundary resistance even under cold pressing conditions. In our study, we combine LPS with different transition metal sulfides as cathode active materials. The attractiveness of such materials lies in their high specific capacity of their reaction with lithium. The transition metal sulfides react with lithium in a conversion reaction described by the general formula MₙSₓ + (n) Li ↔ aM + LiₓS (M = transition metal, e.g. Mn, Fe, Cu, Ni, Co, Zn, Mo). The performance of the all-solid-state batteries is evaluated with respect to capacity, cycle life and rate capability and reversible capacities of several hundred mAh g⁻¹ are demonstrated. Additionally, the impact of the electrode composition and cathode loading on the cell performance is evaluated. At last, we discuss analogue cells with sodium as charge carrier ion.

Atomically-Precise Interfacial Engineering of Solid-State Batteries Neil P. Dasgupta; Department of Mechanical Engineering, University of Michigan, Ann Arbor, Michigan, United States.

Solid-state batteries have experienced a recent explosion in R&D, owing to their potential to improve safety and energy density. However, the requirements on an all-solid-state battery are stringent, as cells must simultaneously incorporate a high ionic conductivity electrolyte, form high performance interfaces against both anode and cathode materials, and exhibit stability against chemical, electrochemical, morphological, and mechanical evolution under a wide range of cycling conditions. In particular, it has been widely recognized that solid-state interfaces present unique challenges compared to traditional liquid electrolytes, including high interfacial impedances, evolution mechanical stresses due to solid-solid interfacial contact with active materials, and (electro)chemical instabilities that can arise from localized gradients in ionic and electronic concentrations.

To address this challenge, our group focuses on gaining new fundamental insights into the coupled phenomena occurring at interfaces, and applied this knowledge to rationally design interfacial chemistry to address the root cause of performance limitations. This is accomplished through a combination of experimental techniques, including in situ/operando analysis using optical and x-ray techniques, precise surface/interfacial energy measurements, and design of model interfaces to decouple factors that contribute to electrochemical behavior. Equipped with this knowledge, we employ atomically-precise interfacial modifications to rationally design interfacial chemistry.

In this talk, examples will be presented in both bulk solid-state battery interfaces [1], and thin film electrolytes deposited by Atomic Layer Deposition (ALD) [3,4]. By studying interfacial chemistry across length scales ranging from atoms to millimeters, we have been able to systematically identify the mechanisms of interfacial degradation. At bulk length scales, the coupled chemical/electrochemical/morphological evolution of a range of solid electrolytes will be discussed, including oxides, sulfides, and polymers. The link between surface chemistry, Li wettability, and interfacial impedance are quantitatively evaluated [1]. Trends and tradeoffs are observed in these systems, which represents a systems engineering problem to optimize overall battery performance. To modify these surfaces, ALD of solid electrolytes is demonstrated [2,3], which enables tunability of surface chemistry, morphology, and stability. These ALD electrolytes are demonstrated in both thin-film battery architectures and as interfacial layers against bulk solid electrolytes. Through this interdisciplinary approach of fundamental chemistry and applied engineering, strategies to address future interfacial challenges will be addressed, which will accelerate the pathway from laboratory science to scalable manufacturing.

Highly Lithium-Ion-Conducting Halide Electrolytes for 4 V Class All-Solid-State Batteries and Their Conduction Path Akihiro Sakai, Tetsuya Asano, Satoru Ouchai, Masashi Sakaida, Akinobu Miyazaki and Shinya Hasegawa, Technology Innovation Division, Panasonic, Kadoma, Japan.

We recently reported that the solid halide electrolytes consisting of rightly-selected cations satisfy the high lithium ion conductivity, electrochemical stability, material stability, and deformability: all of which are simultaneously required properties for solid electrolytes for application in all-solid-state batteries (ASSBs) [1] Theionic conductivity of the halide electrolytes surpassed 1 mS/cm. The bulk-type ASSBs fabricated with cold-pressed method exhibited excellent performances: higher than 94 % coulombic efficiency with 4-V class cathode active materials as well as discharge capacity retention higher than 98 % for 100 cycles. These superior material properties as well as excellent battery performance indicate that the halide electrolytes are another good candidate for the solid-state electrolyte for ASSB application other than sulfides and oxides. Here, we will report the identified crystal structures of these halide electrolytes and the ionic conduction pathway to elaborate the relationship of lithium ionic conductivity and the crystal structure of these halide electrolytes. Interestingly, the crystal structures of these highly lithium-ion-conducting halide materials do not satisfy the “criteria for high ionic conductivity” of sulfide electrolytes which is BCC-like arrangement of anion sublattice. [2] On the other hand, these halide electrolytes consist of nearly close-packed anion sublattice, and yet, still show as high lithium ionic conductivity as 0.1 - 1 mS/cm. The simulated ionic conduction paths understoodly indicate that cation-cation coulombic repulsion reduces the available conduction paths and alters the crystallinity-conductivity relationship. These results indicate that the design principles of the halide electrolytes for high ionic conductivity differ from previously reported sulfide or oxide electrolytes.

Transition Metal Sulfide Nanostructures (CuS, MoS2) as Conversion Electrodes for Rechargeable All-Solid-State Batteries Agunda Lingamurthy Suthusha, Raimund Koeverd, Kilian Pollok, Falko Langenhorst, Juergen Janeck and Philipp Adelhelm; 1Institute of Geoeciences, Friedrich Schiller University Jena, Jena, Germany; 2Institute of Physical Chemistry, Justus-Liebig-University Giessen, Giessen, Germany; 3Institute for Technical Chemistry and Environmental Chemistry, Friedrich-Schiller-University Jena, Jena, Germany.

Solid-state batteries have experienced a recent explosion in R&D, owing to their potential to improve safety and energy density. However, the requirements on an all-solid-state battery are stringent, as cells must simultaneously incorporate a high ionic conductivity electrolyte, form high performance interfaces against both anode and cathode materials, and exhibit stability against chemical, electrochemical, morphological, and mechanical evolution under a wide range of cycling conditions. In particular, it has been widely recognized that solid-state interfaces present unique challenges compared to traditional liquid electrolytes, including high interfacial impedances, evolution mechanical stresses due to solid-solid interfacial contact with active materials, and (electro)chemical instabilities that can arise from localized gradients in ionic and electronic concentrations.

To address this challenge, our group focuses on gaining new fundamental insights into the coupled phenomena occurring at interfaces, and applied this knowledge to rationally design interfacial chemistry to address the root cause of performance limitations. This is accomplished through a combination of experimental techniques, including in situ/operando analysis using optical and x-ray techniques, precise surface/interfacial energy measurements, and design of model interfaces to decouple factors that contribute to electrochemical behavior. Equipped with this knowledge, we employ atomically-precise interfacial modifications to rationally design interfacial chemistry.

In this talk, examples will be presented in both bulk solid-state battery interfaces [1], and thin film electrolytes deposited by Atomic Layer Deposition (ALD) [3,4]. By studying interfacial chemistry across length scales ranging from atoms to millimeters, we have been able to systematically identify the mechanisms of interfacial degradation. At bulk length scales, the coupled chemical/electrochemical/morphological evolution of a range of solid electrolytes will be discussed, including oxides, sulfides, and polymers. The link between surface chemistry, Li wettability, and interfacial impedance are quantitatively evaluated [1]. Trends and tradeoffs are observed in these systems, which represents a systems engineering problem to optimize overall battery performance. To modify these surfaces, ALD of solid electrolytes is demonstrated [2,3], which enables tunability of surface chemistry, morphology, and stability. These ALD electrolytes are demonstrated in both thin-film battery architectures and as interfacial layers against bulk solid electrolytes. Through this interdisciplinary approach of fundamental chemistry and applied engineering, strategies to address future interfacial challenges will be addressed, which will accelerate the pathway from laboratory science to scalable manufacturing.

Beyond state-of-the-art lithium-ion battery (LIB) technology with metallic lithium anodes to replace conventional ion intercalation anode materials is highly desirable because of lithium’s highest specific capacity (3,860 mA/g) and lowest negative electrochemical potential (∼3.040 V vs. the standard hydrogen electrode). In this work, we report for the first time, to our knowledge, a 3D lithium-ion-conducting ceramic network based on garnet-type Llu3Fe3Al2SiO12 (LLZO) lithium-ion conductor to provide continuous Li+ transfer channels in a polyethylene oxide (PEO)-based composite. This composite structure further provides structural reinforcement to enhance the mechanical properties of the polymer matrix. The flexible solid-state electrolyte composite membrane exhibited an ionic conductivity of $2.5 \times 10^{-6}$ S/cm at room temperature. The membrane can effectively block dendrites in a symmetric Li+ electrolyte | Li cell during repeated lithium stripping/plating at room temperature, with a current density of 0.2 mA/cm² for around 500 h and a current density of 0.5 mA/cm² for over 300 h. The presentation will focus on our recent development of 3D garnet nano structured solid-state electrolyte membrane for Li metal batteries.

**PEO/Perovskite Composite Electrolyte with Enhanced Li+ Conductivity**

Henghui Xu, Yutao Li, Nan Wu and John Goodenough; The University of Texas at Austin, Austin, Texas, United States.

Rapid developments in electric road vehicles and grid energy storage are boosting the development of long-life, high-energy-density lithium-ion batteries (LIBs) with high safety. Replacing the liquid electrolyte in conventional LIBs with solid electrolytes can not only address the limitation of leakage and flammability but also guarantee a long cycle life because of the stable structure of the all-solid-state components. Moreover, LIBs built with solid electrolytes may achieve high energy density by using a Li-metal anode and commercially available cathodes. However, there are no ideal solid electrolytes so far that possess high Li+ conductivity and small interfacial resistance. Composite polymer electrolytes (CPE) prepared by incorporating ceramic nanoparticles into polymer matrix have been deemed an effective way to simultaneously enhance ionic conductivity, improve the electrochemical stability, and reduce the critical interfacial resistance between electrodes and electrolytes. Unfortunately, most reported Li+ conductivities of composite polymer electrolytes are still lower than $1 \times 10^{-5}$ S/cm at room temperature. We reported a flexible composite polymer electrolyte with an enhanced conductivity of $4 \times 10^{-5}$ S/cm at room temperature by blending a perovskite solid electrolyte with a PEO polymer electrolyte. The addition of perovskite not only helps to reduce the polymer crystallinity and increase the mechanical strength but also constructs a strong bond with the anions in Li salts. As a result, many more lithium ions are released from the Li salts to render a much higher ion conductivity. Surface-sensitive techniques are carried out to directly visualize and probe the stable interphase formed between the CPE and electrodes, which improves the Li+ transfer across the interface. A symmetric Li/Li cell and an all-solid-state LiFePO4 cell with the CPE show small overpotentials, high Coulombic efficiencies, and stable cycling performance at 40 °C.

**Garnet Electrolyte Coated with a Single-Li+-Conducting Polymer for All-Solid-State Lithium Batteries**

Weidong Zhou; Beijing University of Chemical Technology, Beijing, China.

To meet the requirements of high energy density, safety and long cycle life, it is necessary to replace the organic flammable electrolyte and graphite anode of the Li-ion battery by a solid electrolyte and metallic-lithium anode that can be plated/striped reversibly without lithium-dendrite formation. Garnet electrolyte with a high room-temperature Li-ion conductivity and a good stability against lithium metal suffers from the huge interfacial resistance and fast lithium-dendrite growth. A Li+ conducting polymer with a high Li+ transport number of 0.9, which was coated on the surface of garnet electrolyte as an artificial SEI layer, not only reduced the Li metal anode/garnet interfacial impedance but also suppressed the formation and growth of lithium dendrites along the garnet grain boundaries. In all-solid-state Li/LiFePO4 cells, a high Coulombic efficiency near 100% was achieved for long cycling. These tests show the feasibility of a safe Li-metal rechargeable battery having an appropriate single Li+ conducting polymer SEI between a ceramic electrolyte and the metallic lithium anode.

**The Structure and Conductivity of 3D Superionic Na3SbS4 Conductor at Extremely Low Temperatures**

Hui Wang1, Yan Chen1, Zachary D. Hood1,3,4, Jong K. Keum1, Amaresh Pandian1, Miaoafang Chi2, Ke An3, Chengdu Liang3 and Mahendra Sunkara2; 1University of Louisville, Louisville, Kentucky, United States; 2Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 3Georgia Institute of Technology, Atlanta, Georgia, United States; 4Electrochemical Materials Laboratory, Massachusetts Institute of Technology, Boston, Massachusetts, United States; 5College of Chemical and Biological Engineering, Zhejiang University, Hangzhou, China.

Overcoming the solid-liquid state transition of the lithium electrolyte in state-of-the-art batteries represent a grand challenge for the next-generation energy storage. All-solid-state batteries that employ superionic solid conductor potentially enable the broadening of battery operation in harsh environments, such as under sub-zero temperatures and even lower. The solid electrolyte as the key component requires structural stability, high-efficiency of ion transportation channels, and low activation energy to maintain the fast-ion conduction against temperature drop. Compared to one-dimensional (1D) conductive chain, a three-dimensional (3D) framework of ion-conduction tunnel is more favorable structure for solid conductors to work at subzero temperature range. The tetragonal Na3SbS4 is such a superionic conductor that holds 3D tunnel network for Na-ion transportation and exceptionally low activation energy of 0.205 eV. In this work, we use Na3SbS4 as a model system to investigate the structure stability and Na-ion conduction paths of 3D superionic conductor at extreme low temperature (20 K) via cryogenic neutron and X-ray diffractions. Cryogenic in-situ neutron and X-ray diffractions reveal that Na3SbS4 maintains a stable tetragonal crystal structure and the anisotropic lattice contraction upon cooling. The evolution of S-gate, where Na ions hop through in the 3D transportation network, is found to maintain open sizes in the xy-plane, contributing to the low activation energy and impressive
The holy grail of battery research is the coupling of a metal negative electrode with a high capacity positive electrode to produce a cell with higher energy density than lithium-ion cells. Sulfur cathode has a high theoretical capacity of 1672 mAh g⁻¹ and a theoretical energy density of 2500 Wh kg⁻¹ in a lithium sulfur (Li-S) battery. Li-S batteries are tormented by several challenges, most notably the dissolution of polysulfide in the electrolyte during the reduction of sulfur and the growth of lithium dendrite during charging. [1,2,3] A paradigm shift is required to completely block or avoid polysulfide dissolution. One option is to use inorganic solid electrolyte such as lithium thio phosphate in place of the liquid electrolyte. [4,5] Lithium thio phosphate solid electrolyte has a narrow potential window which make thermodynamically incompatible with lithium metal anode. [6] We will discuss how the lithium/solid electrolyte interface and electrolyte structure can dramatically affect the stripping/plating of lithium metal. The challenges associated with using the lithium thio phosphate electrolyte in Li-S battery will also be examined.

Li⁺ Ion Conduction Mechanisms of Li⁺-Doped NaI and Its Electrochemical Properties Reona Miyazaki¹, Isao Sakaguchi² and Takehiko Hihara², ¹Nagoya Institute of Technology, Nagoya, Japan; ²National Institute for Materials Science, Tsukuba, Japan.

From the early stage of the research, solid electrolytes for the all-solid-state lithium ion batteries have been developed mainly based on the Li compounds. On the other hand, we have been evidenced that the solid electrolytes can also be fabricated by the doping of Li compounds to “Li-free” compounds like the liquid electrolytes prepared by the dissolution of a given ionic salt into the carrier-free liquid solvents. These types of solid electrolytes are so-called “Co-ionic conductor”, where the small doped guest ions play a major role for the ion conduction in the host materials [1]. From our previous research, it has been shown that both NaI and KI become pure Li⁺ ion conductors via doping 6 mol% of LiBH₄, whose conductivity value exceeds that of LiI [1, 2]. However, the details of the ion conduction mechanisms in NaI-LiBH₄ system, especially for the host Na⁺ ions are not well understood. The purpose of the present work is the investigation of the ion conduction mechanisms in NaI-LiBH₄ systems. The electrochemical stability will be also investigated as a function of the concentration of LiBH₄.

NaI-LiBH₄ systems were fabricated by ball-milling. The given molar ratio of NaI and LiBH₄ (Aldrich Co) were mechanically milled at 400 rpm with 10 pieces of balls in a chrome still pot (45 ml). The total milling time was 5 hours. In order to investigate the conduction mechanism of Li⁺ and Na⁺ ions separately, all-solid-state half-cell was fabricated using the sputtered amorphous Si (a-Si) film and 15NaI_LiBH₄ as an anode material and a solid electrolyte, respectively. Li foil was used as a counter electrode. After charging, the half-cell was disassembled and the Si film was collected in a glove box. Subsequently, the depth profile inside the charged Si film was investigated by SIMS measurement. Cyclic voltammetry was performed using Mo and Li foils as a working and counter electrode, respectively.

During the charging of a-Si film, two kinds of plateau regions were observed at around 0.2 and 0.1 V vs. Li⁺/Li, which are the typical lithiation curves for a-Si film [4]. From the SIMS measurement inside the charged Si film, it was confirmed that Li⁺ ions are mainly detected. The steady state charging of Li⁺ ions can be attained by the constant transport of the Li⁺ ions in NaI. Hence, the main conduction carrier in the NaI doped with 6 mol% of LiBH₄ was shown to be the small doped Li⁺ ions. On the other hands, 23Na⁺ ions were also detected inside the Si film although the signal intensity was three orders of magnitude smaller than that of Li⁺ ions. The detailed conduction mechanism and electrochemical stability of NaI-LiBH₄ systems will be shown in the presentation.

Electrochemomechanical Failure in Active Materials and Solid Electrolytes Yet-Ming Chiang; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

The pursuit of high energy density and long life in rechargeable lithium batteries has exposed several modes of failure due to electrochemical-mechanical coupling. This talk will discuss specific examples in intercalation cathode and inorganic solid electrolytes, and potential failure-mitigation approaches.

It is now recognized that even active materials with much lower chemical expansion coefficients than the well-known extreme cases (e.g., Si or Sn and their alloys) undergo cycling induced fracture at the secondary particle level. The possible failure modes have been previously classified [1] and studied using macroscopic measurements such as acoustic emission [1,2]. Recently a methodology has been developed for measuring the electrochemical response of single electrode particles and directly observing the electrochemomechanical damage [3]. Applied to NMC333 and NCA particles, it is shown that the resulting single-particle kinetics are a trade-off between surface area increase, and loss of electrical continuity, both due to microscopic fracture at the secondary particle level.

Inorganic solid electrolytes undergo lithium metal penetration via an entirely different failure mode than classical dendrite formation in liquid electrolytes [3]. Although it has been argued that grain boundaries are a weak link along which Li metal preferentially penetrates, we show that even single crystals are highly susceptible to metal penetration from surface defects. Failure criteria such as the existence of a critical overpotential that are related to flaw size and the physical properties of the solid electrolyte can be tested using deliberately introduced surface flaws of controlled size. A new result to be discussed is the impact of field concentration effects at current collector discontinuities.

Degradation Mechanisms of All-Solid-State Li-S Battery with LiPSsCl Saneyuki Ohno, Georg Dewald, Juergen Janek and Wolfgang G. Zeier, Institute of Physical Chemistry, Justus-Liebig-Universität Gießen, Gießen, Germany.

While the demand for batteries with a high energy density is rapidly growing, the current commercially available Li-ion battery chemistry is approaching a theoretical limit.1 To overcome this issue, Li-S batteries exploiting the conversion reaction between sulfur and Li2S have been attracting significant attention as a promising candidate of the next generation batteries.2 “The history of the conventional Li-S battery development has been a fight against the notorious shuttle effect caused by polysulfides dissolved into the liquid electrolyte. However, a concept of all solid state batteries can physically hinder the polysulfide shuttle. Indeed the exhibit no evidence of the shuttle effect the all-solid-state Li-S battery cells, composed of Li-ion conducting thiophosphate (e.g. LiPSsCl), exhibit no evidence of the shuttle effect.

Nevertheless, there are still multiple challenges to achieve a high capacity and its good retention. One of the critical issues is a large capacity loss in the first battery cycle. A poor capacity retention over the long term cycling is another issue. In this study, we elucidated the degradation mechanisms of an all-solid-state Li-S battery employing LiPSsCl as an electrolyte and achieved a significant improvement of the battery performance based on it. The deeper understanding of the underlying chemistry of the degradation mechanisms will lead to further enhancement of the capacity and cyclability of the all-solid-state Li-S batteries.

Interface Engineering of the Garnet-Based Solid-State Batteries and In Situ Neutron Depth Profiling Diagnose Chengwei Wang, Yunhui Gong, Hua Xie, Lei Zhang, Hao Wang, Eric D. Wachsman and Liangbing Hu; University of Maryland, College Park, Maryland, United States.

Garnet-based solid state electrolytes (SSEs) have attracted much attention for their high ionic conductivities and stability with lithium metal anodes. However, the high interfacial resistances between electrodes and garnet SSEs are one of the main challenges to develop all solid state lithium (Li) metal batteries. Herein, we develop several effective techniques to significantly improve Li-garnet interface and lead to an interface resistance as low as ~ 7 Ω●cm2. We also develop an effective cathode-garnet interface using a mixed ionic electronic (MIE) conductor, which enables cycling of all solid state batteries without a liquid or polymer electrolyte interface. The solution-processed two dimensional (2D) layered TiS2 shows MIE conductivity after slow pre-lithiation, resulting in more than 20 times lower interfacial resistance. The all solid state batteries can work at high temperatures from 100 °C to 150 °C for 400 cycles at current densities up to 1 mA/cm2. To reveal the interfacial behaviors of garnet SSE in contact of metallic Li, neutron depth profiling (NDP), a nondestructive and unique Li-sensitive technique, is used to in situ monitor Li plating-stripping processes. The NDP measurement has demonstrated the predictive capabilities for diagnosing short-circuits in garnet-based solid state batteries.

Dendrite-Free Lithium Metal Batteries Capable of Stable Operation at Elevated Temperature Based on Liquid Organic Electrolytes Hong Li; Chinese Academy of Sciences, Beijing, China.

Rechargeable lithium metal batteries have attracted wide attention due to high theoretical energy density. For practical applications, high-temperature performance of lithium batteries is essential due to complex application environments, in terms of safety and cycle life. However, it’s difficult for normal operation of lithium metal batteries at high temperature using current electrolyte systems. Herein, a kind of new electrolyte system is designed by adding two thermal-stable lithium salts together (i.e. LiTFSI and LiDFOB) into carbonate solvents with high boiling/flashing point (i.e. EC and PC). Low ratio of LiPF6 is also added to prevent the corrosion of Al current collector. The results indicate that the new electrolyte system possesses good high-temperature performance, meanwhile, it is beneficial to effectively suppress the formation of lithium dendrite. At a current density of 1.2 mA/cm2, LiCoO2 cathode with 2.4 mAh/cm2 shows the capacity retention of 90% after 100 cycles at 80 oC in a lithium metal cell. Such performance is achieved for the first time for rechargeable lithium metal battery using liquid organic electrolyte. The enhanced cycling performance at elevated temperature is ascribed to effective protection of lithium metal by the generation of organic-inorganic composite solid-electrolyte interphase (SEI) on surface of lithium anode, formation of cathode electrolyte interphase (CEI) with high content of LiF on LiCoO2 cathode and good stability of electrolyte itself. Its the first demonstration of dendrite-free Li metal battery capable of stable operation above 60 oC using liquid organic electrolyte. The improved cycling performance at elevated temperature based on the new electrolyte system is ascribed to effective protection of Li metal by the generation of organic-inorganic composite SEI on surface of Li anode, formation of CEI with high content of LiF on LiCoO2 cathode and good stability of electrolyte itself. In addition, in situ solidification is also introduced to this system to form a solid electrolyte, which can improve the interfacial solid/solid contact significantly during cycling.
Very High Lithium Diffusion in LiTi2(PS4)3 Through Energy Landscape Frustration

Geoffroy Hautier1, Davide Di Stefano1, Anna Miglio1, Koen Robeyns1, Yaroslav Filinchuk1, Marine Lechartier1, Anatoliy Sensyn1, Hiroyuki Ishida1, Stefan Spannenberger1, Bernhard Roling1, Denis Prutsch2, Daniel Rettenwander1, Martin Wilkening1, and Yuki Kato1; 1Materials Science and Engineering, University of California, Berkeley, Berkeley, California, United States; 2Materials Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 3Argonne National Laboratory, Argonne, Illinois, United States.

Recent years have witnessed the increasing demand for high-quality, safe, and low-cost rechargeable batteries. Metal-based solid-state batteries are particularly promising in this regard, where extremely high energy densities can be attained by utilizing metallic Li/Na anodes, and the use of a ceramic solid-state electrolyte membrane greatly enhances battery safety. However, most solid-state electrolytes react with lithium and sodium metals, causing a continuous increase of the cell impedance and thus battery degradation. Therefore, passivation reaction with Li/Na metal is required for the electrolyte to achieve a relatively stable interface. Herein, we present a ‘reverse design’ strategy to improve the stability of the interface between solid-state electrolytes and metal anodes. Using the advanced first-principles computational tools developed in our previous work, we identify a protective hydrate coating for solid electrolytes that would lead to the generation of passivating decomposition products upon contact of the electrolyte with metal electrodes. A significantly improved interface stability with the metal electrode of a hydrate coated solid-state electrolyte is observed, compared with that of its non-hydrated counterpart. The buried interface between the surface-treated solid-state electrolyte and the metal electrode was characterized using post-operando synchrotron X-ray depth-profiling, providing spatially resolved evidence of the multilayered phase distribution in the metal-based symmetric solid-state cell. The experimental results are consistent with our theoretical predictions. In addition, we propose a general strategy of interface reverse design and discuss the possible pretreatment of the solid-state electrolyte using other chemicals.

Investigating the Effects of Lanthanum Concentration in Ta-Doped Li0.5La2+xZr1.5Ta0.5O12 Solid Electrolyte

Joseph M. Valle and Jeff Sakamoto; University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States.

Solid electrolytes based on the garnet crystal structure have shown promise in the push to develop electrochemical cells utilizing lithium metal anodes due to their high lithium conductivity and stability against metallic lithium. One of these solid electrolytes is cubic phase lithium lanthanum zirconium oxide (LLZO). The critical doping of LLZO with tantalum at the zirconium site has been shown to stabilize the highly conductive cubic LLZO phase at room temperature $Li_xLa_{2-y}Zr_1Ta_{y}O_{12}$. This critical doping has been shown to provide an optimal amount of lithium vacancies to stabilize the cubic phase without transitioning to the less conductive tetragonal phase of LLZO. While much work has been done to investigate the doping and charge balancing on the zirconium site, comparatively little focus has been paid to the lanthanum site. The effects of the stoichiometric use of lanthanum on the crystal structure of LLZO have yet to be characterized.

In this work, lanthanum content is varied in the LLZO structure $Li_xLa_{2+y}Zr_1Ta_{y}O_{12}$ from $x = 0$ to $x = 1.2$. X-ray diffraction and electrochemical impedance measurements were performed in order to correlate the effect of lanthanum deficiency on crystal structure and electrochemical properties of LLZO. A linear increase in lattice parameter is observed until the stoichiometric composition ($x = 1.0$) is achieved. An increase in conductivity is also observed ranging from $0.41mS/cm^2$ at $x = 0.2$ to $0.72mS/cm^2$ at $x = 1.2$.

11:30 AM ET01.03.10

Garnet and Anti-Perovskite Solid Electrolytes—Atomic-Scale Studies on Li-Ion Conduction, Surface Structures and Grain Boundaries

Saiful Islam; University of Bath, Bath, United Kingdom.

Major advances in solid-state lithium batteries require the discovery and characterization of solid electrolyte materials. It is clear that a complete understanding of such materials requires greater fundamental knowledge of their underlying structural, ion transport and interface properties on the atomic- and nano-scales. For example, grain boundary effects on Li-ion transport are not fully understood. This talk will highlight recent studies [1-3] in two related areas: the influence of grain boundaries on Li-ion conduction in the Li-rich anti-perovskite Li3OCl and the particle morphologies and lithium segregation to surfaces of the garnet Li7La3Zr2O12. A combination of advanced materials modelling techniques has helped us gain new insights into these complex materials, which are valuable in developing strategies to optimize their electrolyte properties.

11:45 AM ET01.03.11

Very High Lithium Diffusion in LiTi2(PS4)3 Through Energy Landscape Frustration

Geoffroy Hautier1, Davide Di Stefano1, Anna Miglio1, Koen Robeyns1, Yaroslav Filinchuk1, Marine Lechartier1, Anatoliy Sensyn1, Hiroyuki Ishida1, Stefan Spannenberger1, Bernhard Roling1, Denis Prutsch2, Daniel Rettenwander1, Martin Wilkening1, and Yuki Kato1; 1Materials Science and Engineering, University of California, Berkeley, Berkeley, California, United States; 2Materials Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 3Argonne National Laboratory, Argonne, Illinois, United States.

Solid-state materials with fast high ionic diffusion are necessary to many technologies including all-solid-state Li-ion batteries. In this work, we demonstrate that LiTi2(PS4)3 (LTPS) exhibits the largest Li-ion diffusion coefficient ever measured in a solid. We use extensive characterisation (neutron, X-ray diffraction, impedance and NMR) as well as theoretical studies to study the lithium diffusion in LTPS. We show for instance with recent X-ray data that the Li mobility is so high that low temperature is needed to freeze and observe the lithium ions positions. We rationalise the exceptional performances of this new superionic conductor through the concept of frustrated energy landscape. The absence of regular and undistorted lithium site to occupy leads to low energy barrier for diffusion as well as an exceptional pre-factor. We discuss how this frustration could be present in previously known ion conductors and be used to search and design new structural families of superionic conductors.
Fast solid ionic conductor electrolytes are key enablers of all-solid-state batteries, which potentially possess high energy density and diminish safety concerns during battery operation in large scale energy storage system. Compared to liquid electrolytes, low ionic conductivity is one of the critical issues in solid electrolyte development. Understanding its origin of potential high ionic conductivities provides insight of designing better electrolytes. The ionic transportation efficiency in solid crystals depends on the accessible tunnels in the structure as well as the active vacancy for ion hopping. Via neutron and X-ray diffraction, the ionic transport tunnels, from one-dimension to three-dimension, can be revealed in typical oxide- and sulfide-base light ionic (Li\(^+\), Na\(^+\)) conductors. The directions of the ionic transport have strong correlation with the lattice symmetry and the atomic arrangement in those solid conductors. The effective ion tunnel and the active vacancy quantity can be altered by neighboring aliovalent dopants, which is manipulated for optimal ionic conductivity in the solid electrolyte. The tunnel accessibility is also influenced upon temperature change, due to the tuned framework structure. The evolutions of the tunnel size and the anisotropic oscillation of charge carrier ions indicate the possible dimensional change of the transport pathway network. Moreover, the directional conduction is found to correlate with the anisotropic physical properties, demonstrated by the uneven coefficients of the thermal expansion along different crystallographic axes. These correlations of conduction tunnel provide valuable guidance in materials searching for solid conductors with superior performance in varied environments. The results of the anisotropic thermal-strain response correlated with ionic transport also provide consideration of the physical compatibility in the design of all-solid-state batteries.

Incorporating Two-Dimensional Materials in Semi-Solid Electrolytes for Fast Charge Li-Ion Batteries

Ramin Rojaee\(^1\), Salvatore Cavallo\(^1,2\), Santosh Mogurumppelly\(^1\), Bill Wheelie\(^3\), Venkat Ganesan\(^1\) and Reza Shabahanzadeh-Yasours\(^1\); Mechanical and Industrial Engineering Department, University of Illinois at Chicago, Chicago, Illinois, United States; \(^2\)Department of Energy-DENERG, Politecnico di Torino, Torino, Italy; \(^3\)Institute for Computational Molecular Science (ICMS) and Temple Materials Institute (TMI), Philadelphia, Pennsylvania, United States; \(^4\)Department of Chemical Engineering, The University of Texas at Austin, Austin, Texas, United States.

Poor electrochemical stability and low ionic conductivity trigger of prime importance for the development of new-generation of lithium-ion batteries. Solid electrolytes have been attracted significant attention owing to their superior safety and potential for boosting specific energy density. Here, we report a new type of semi-solid electrolytes with two-dimensional materials embedded in ternary polymer electrolyte. The developed electrolyte has a high electrochemical stability of 5.5 V vs. Li/Li\(^+\). We report a high ionic conductivity of 4×10\(^{-4}\) S cm\(^{-1}\) at ambient temperature and significantly low interfacial resistance over the long period of time of 600 h overpotential cycling tests. The developed electrolyte is capable of fast charging with great capacity retention benefiting due to unique atomic arrangement of 2D material additive: FTIR, Raman, and NMR characterizations revealed the higher concentration of the free cations will be present in the electrolyte by about 30\% upon addition of designated 2D material nanosheets. The layered 2D material lowers the binding energy for hopping the ions through the electrolyte to allow improved storage capacity and power density. We hypothesize that 2D materials introduce unique properties to the electrochemical behavior of the electrolyte and boost the ionic conduction through the electrolyte by providing efficient pathways for local ion transport through the structure and can be a great candidate for novel lithium polymer batteries. MD simulation studies confirmed our experimental achievements and suggested that the f-BP nanosheets facilitate Li\(^+\) ion movement by lowering the required energy to dissociate cations and move along the electrolyte.

Advanced Sulfide Solid Electrolyte by Core-Shell Structural Design—Theory and Experiment

Xin Li; Harvard University, Cambridge, Massachusetts, United States.

Ceramic sulfide solid electrolyte can show high lithium conductivity, while the voltage stability was reported as an issue in many previous literatures. We show in this talk a new way to improve the voltage stability of sulfide solid electrolyte materials by microstructure modification of the electrolyte materials. The improved battery performance and voltage stability are shown by electrochemical test. A combination of first principle simulation and transmission electron microscopy imaging techniques are used to understand the principle behind the phenomenon. Specifically, sulfide Li-Si-P-S has been synthesized, characterized, and tested to show an improved voltage stability window up to 3.1 V and quasi-stable voltage window up to 3.5 V due to the microstructure modification. This is far beyond the limited voltage stability of these sulfides around 1.7 – 2.1 V as predicted by DFT simulation. We further from a combined thermodynamic modeling and DFT simulation understand the principle behind this promising result. A new design principle and theory is proposed and discussed systematically for tuning the voltage stability of solid electrolyte, giving the guidelines for the design of advanced sulfide electrolytes.

Electrochemical Characterization of All-Solid-State Battery with Li\(_7\)La\(_3\)Zr\(_2\)O\(_{12}\) Solid Electrolyte

Kiyoshi Kanamura; Tokyo Metropolitan University, Tokyo, Japan.

Li\(_7\)La\(_3\)Zr\(_2\)O\(_{12}\) (LLZO) is promising electrolyte due to its high chemical stability against Li metal and high ionic conductivity. All solid state battery has been fabricated by using LLZO. However, the cell performance is not so good. This is due to a high impedance of the prepared cell. The resistance of solid electrolyte is the largest among resistances in the cell. In addition, the interfacial impedance between cathode and anode and solid electrolyte is not easily decreased. The interface between Li metal anode and LLZO solid electrolyte pellet is large due to poor contact. The contact has been improved by using an interlayer between Li metal and LLZO. A thin gold layer prepared by sputtering method has been employed as the interlayer. The thickness was about 50 nm. The gold layer reacted with Li to form alloy. During this alloying process, the good connection was formed. A cathode material is usually powder sample. The interfaces between cathode material and LLZO sheet and LCO powder and solid electrolyte powder in the cathode layer exist in all solid state battery. In this study, the cathode layer was fabricated by aero-sol deposition process (AD). The aero-sol of LCO was deposited on the LLZO sheet. Li\(_3\)BO\(_3\) is fabricated on the LLZO. The discharge and charge behavior of the fabricated cathode layer was investigated at constant current of 0.1 C rate. The discharge capacity was decreased. The cell impedance was evaluated with electrochemical AC impedance measurement at various temperatures. Before the heat...
Solid-state batteries (SSBs), one of the most promising energy storage devices for next generation, have now been extensively developed due to their high safety and long cycle life. Here, the interfacial layers between solid electrode and solid electrolyte is one of most important features for the design of solid-state lithium batteries. Normally, the interfacial layer should be stable, highly conductive for Li ions, and flexible to tolerate the big volume changes during charging/discharging process. In this presentation, I will present some examples we have used in this lab to build up such thin but important interfacial layer, making the highly efficient Li dissolution/deposition possible. For example, we proposed an ultra-simple and effective strategy to enhance the interfacial connection between garnet SSEs and Li metal just by drawing a graphite-based soft interface with a pencil. Both experimental analysis and theoretical calculations confirm that the reaction between graphite-based interfacial layer and metallic lithium forms a lithiated connection interface with good lithium-ionic and electronic conductivity. Compared to the reported interfacial materials, the graphite material provides a soft interface with better ductility and compressibility. With the improvement by this soft interface, the impedance of symmetric Li cells significantly decreases from 1350 to 105Ωcm² and the cell can cycle for over 1000 hours at a current density of 300 mA/cm² at room temperature. In addition, some examples to construct an intimate solid electrolyte interface(SEI) in sulfide-based electrolyte by using ionic liquids will be also presented.

Simulations of Varying Li-Ion Vacancy Concentrations in Lithium-Oxyhalide Anti-Perovskites Reveal the Effects of Correlated Motion on Diffusion
Zerina Mehmedovic, Vanessa Wei, Andrew Grieder and Nicole Adelstein; San Francisco State Univ, San Francisco, California, United States.

Introduction: Our simulations are designed to answer the long-standing question in solid-state batteries: how to increase Li-ion conductivity in solid electrolytes through engineering the structure and chemistry of the anion sub-lattice. Understanding the mechanism behind lithium ion diffusion in promising solid electrolytes, such as lithium-oxyhalide anti-perovskites, can provide design principles for new battery materials. Our ab-initio molecular dynamics (AIMD) simulations of Li3OCl with Li vacancy concentrations between 0.5 and 2% reveal the origin of complex interactions between vacancies and new insights into the effect of correlated motion on the diffusion mechanism. Previous simulations of Li3OCl compute conductivities that are much lower than measured experimentally [1] and our simulations show that finite size effects are part of the problem.

Methods: ab-initio molecular dynamics were performed on a 4x4x4 supercells using VASP. The size of the supercell (320 atoms) allows for realistic vacancy concentrations and reducing finite size effects. The supercells had at least one and up to four Li vacancies. Maximally Localized Wannier Functions were used to calculate the dynamic polarization of anions and their effect on Li diffusion, which is a novel technique that we developed for analyzing solid electrolytes [2]. As is standard, the diffusion coefficient for each compound was determined using the mean squared displacement. The ‘binding energy’ of Li vacancies is calculated and lattice screening is separated into the strain and electronic effects.

Results: We discovered new collective diffusion mechanisms in Li3OCl and that finite size effects plague most AIMD simulations. For example, simulating two Li vacancies (0.5% concentration) increases diffusion because the negatively charged vacancies push other each other along. The largest vacancy concentration we simulated was 2%, which gave the highest diffusion due to disordering of the Li-sublattice, rather than a “push” mechanism. Vacancies can interact up to 7 Å from each other, with strain effects dominating 5 Å or closer. Vacancies communicate through the lattice, especially through polarization of anions. The dynamics of the anion polarization can be quantified easily in a nudged-elastic-band calculation and is still important even in AIMD. Thus, diffusion may be controlled by changing the polarizability of the anions, such as creating Br and F alloys with Li3OCl.

Tuning Charge Diffusion in Polyethylene Oxide-Based Electrolytes Using Secondary Sites—Insights from Molecular Dynamics Simulations
Arthur France-Lanord, Yanning Wang, Tian Xie and Jeffrey C. Grossman; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Solid-state polymer electrolytes (SPEs) constitute a promising technology for energy storage applications. In addition to a more flexible form factor, batteries using such electrolytes have the potential to be safer, less expensive, and greener than the current liquid-based standard technology. However, hindered by their low ionic conductivity, SPEs can only operate under limited conditions. The improvement of SPEs requires a deeper understanding of ion transport in polymer networks, where modeling and computation can play an important role. Here, through classical molecular dynamics simulations, we investigate charge diffusion in SPEs consisting of a mixture of polyethylene oxide (PEO) based polymers and lithium bis(trifluoromethane)sulfonimide (LiTFSI) salt. By varying the chemical structure of the polymer, we alter the ion-polymer binding strength, which allows us to explore various ionic transport mode. Importantly, this study reveals the delicate balance between ionic association on one hand, and ionic crosslinking on the other hand.

Two-Dimensional Boron Nitride-Protected Solid Electrolyte for Rechargeable Lithium Metal Batteries
Qian Cheng; 1 Aijun Li; 2 and Yuan Yang; 1 1Program of Materials Science and Engineering, Department of Applied Physics and Applied Mathematics, Columbia University, New York, New York, United States; 2School of Earth and Space Sciences, Peking University, Beijing, China.

Solid-state lithium batteries can improve the battery safety and energy density compared with conventional Li-ion batteries. However, a lot of solid electrolytes with low cost and high ionic conductivities can be reduced by the anode in lithium battery systems (e.g. lithium, graphite). Here, we introduce a novel strategy, in which chemically and mechanically robust two-dimensional boron nitride (BN) film was deposited onto the surface of solid electrolyte (e.g. Li1.2Al0.8Ti0.3(PO4)3, LATP) to prevent reduction of solid electrolyte from lithium. The lithium symmetric cells with BN protected LATP/liquid hybrid electrolyte can cycle up to 700 hours with a current density up to 0.5 mA/cm², and full cell utilizing LiNi0.5Mn1.5O4/LATP/Li can cycle 100 times without apparent decay at a current density of 0.3 mA/cm². In contrast, LATP/liquid hybrid electrolyte can only be cycled for 40 cycles with fast capacity fading. Meanwhile, with PEO coated on both sides of LATP/BN, all-solid-state Li/LiFePO4 cells show a good cycling ability, further demonstrating excellent protection on solid electrolytes. This research provides a universal strategy to protect solid electrolytes of small electrochemical windows against...
lithium metal, leading to notable improvement of stability and cycling ability.

Fabrication of Ultrathin Films of Li$_{3-x}$Al$_x$La$_3$Zr$_2$O$_{12}$ with Tunable Surface Morphology by Spray Pyrolysis
Zachary D. Hood$^1$, Yuntong Zhu$^1$, Lincoln Miara$^2$ and Jennifer L. Rupp$^{1,2}$; $^1$Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; $^2$Samsung Research America, Advanced Materials Lab, Burlington, Massachusetts, United States; $^3$Department of Electrical Engineering and Computer Science, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Garnet-based lithium solid electrolytes are expected to improve next-generation energy storage technology in electric vehicles and portable electronics on the basis of energy density, safety, cost, amongst other parameters. Yet many of these solid electrolytes, such as Li$_{3,8}$Al$_x$La$_3$Zr$_2$O$_{12}$ (LLZO), were previously difficult to process into thin films between 200 nm and 5 μm in thickness using solution-based techniques. Several vacuum-based$^{3,4}$ and sol-gel-derived$^{5,6}$ methods shown success in making thin garnet-based solid electrolyte films with relatively high ionic conductivity ($\sim 10^{-4}$ - $10^{-5}$ S/cm at room temperature), yet better methods are desired to improve the bulk resistance of the electrolyte and overall cost of production. Therefore, the exploration of scalable fabrication techniques is of special importance to develop thin films of garnet-based solid electrolytes that hold high ionic conductivity and compatibility with high-capacity cathodes. In this work, we developed a novel method of fabricating thin films with controllable thicknesses of garnet-based LLZO solid electrolytes using spray pyrolysis. We show that the crystallization and the phase transformation can be modulated to lower temperatures ($\sim$750 °C) by tuning the concentration of cations and the boiling point of the solvents used in the spray solution. Also, by altering the chemistry of the spray solution and the post-annealing conditions, we show that the surface roughness can be modulated while still maintaining dense and continuous membranes of LLZO. Our results highlight a new opportunity for manufacturing garnet-based solid electrolytes with tunable electrochemical surface areas, and the insights from this work are expected to serve as fundamental guidelines for future optimization of thin film superionic garnet-based materials for next-generation lithium metal batteries.

Solid Polymer Electrolyte from Polytetrahydrofuran-Epoxy Copolymers for Lithium-Ion Conduction

Francielli S. Genieri1, James Barna2, Jiayue Wang1, Saeid Biria1 and Ian Hosein1; 1Syracuse University, Syracuse, New York, United States; 2Cazenovia High School, Cazenovia, New York, United States.

High performance batteries are central components to the development of safe, clean and affordable energy storage systems. For this reason, the replacement of the liquid or gel electrolyte with a solid polymer material, namely a solid polymer electrolyte (SPE), has been a research area of intense interest. Solid electrolytes have the potential to enable higher energy densities and address concerns over the volatility and flammability of currently used organic solvents. Of the numerous polymer systems under investigation, SPEs produced through crosslinking are quite attractive owing to their high conductivity and excellent mechanical stability. Commonly, crosslinking is achieved through free-radical initiated reactions involving end-functionalize monomers or oligomers. This approach is limited by the available polymer precursors, often necessitating deliberate end-functionalization of the molecules to carry out the reaction. Hence, the formation of crosslinks from molecules in their native form would be more cost-effective and straightforward. In this work, a novel crosslinked solid polymer electrolyte was developed through the copolymerization of polytetrahydrofuran (PTHF) and a cycloaliphatic epoxide (referred as Epoxy) under visible light, without previous functionalization. In particular, these chemicals were employed due to PTHF’s potential to achieve high conductivity and the thermal and mechanical stability associated with cycloaliphatic epoxides, creating a stable, solid crosslinked material. The crosslinked samples were evaluated for their ionic conductivity, thermal stability, crystallinity and mechanical stiffness. They presented conductivity to order of 10-5 to 10-3 S/cm, similar to previously reported electrolytes, now with the manufacturing benefits from the photocuring process, which is energy-efficient and less thermally stressful to the substrate materials. Thermogravimetric analysis of the electrolytes indicated stability at battery operating temperatures, and differential scanning calorimetry demonstrated the material’s amorphous behavior over a wide temperature range. The electrolytes also showed excellent mechanical stiffness. Further studies on 2032 coin cell batteries will be presented and discussed. This work represents a new route for cleaner and safer energy storage devices with potential for a broad variety of applications.

Synthesis and Characterization of a New Lithium Chloro-Thiophosphat as a Solid State Ionic Conductor

Zhan Tao Liu1, Yue Liu2, Sylvia Indris3, Wenqian Xu2, Shan Xiong1, Xuetian Ma4, Lu Feng Yang5 and Hailong Chen2; 1Georgia Institute of Technology, Atlanta, Georgia, United States; 2Neutron Scattering Division, Oak Ridge National Laboratory (ORNL), Oak Ridge, Tennessee, United States; 3Karlsruhe Institute of Technology-Institute for Applied Materials, Karlsruhe, Germany; 4X-ray Science Division, Argonne National Laboratory, Argonne, Illinois, United States.

Solid state Li+ and Na+ conductors have attracted great interest as the electrolyte for all-solid-state batteries. Compared with conventional batteries using liquid organic electrolytes, all-solid-state batteries with non-flammable solid electrolyte have significant advantages in safety. Among known solid-state Li+ conductors, sulfide-based electrolytes are superior in ionic conductivity than oxide conductors and a number of sulfides with different chemical compositions and crystal structures have demonstrated conductivities comparable to liquid electrolytes [1].

Here we report the synthesis, structural characterization and ionic transport study of a novel lithium chloro-thiophosphate compound, Li4+P2S5Cl. Li4+P2S5Cl can be synthesized in pure phase with facile solid state reaction method under relatively low temperature. The crystal structure of Li4+P2S5Cl is characterized with using neutron and synchrotron x-ray powder diffraction techniques, indicating it has an I-4d3 cubic space group. The ionic conductivity was measured by electrochemical impedance spectroscopy at different temperatures. At 30 °C, Li4+P2S5Cl exhibited an ionic conductivity of 4-2 x 10-5 S/cm. The lithium ion transport in Li4+P2S5Cl was also studied by multiple solid-state NMR methods, including pulsed field gradient and variable temperature NMR. The discovery of this new compound provide a new crystal structure that can served as a foundation for the design of more sulfide ionic conductors with high conductivities.

growth of lithium through the bulk of the garnet-type Li$_2$La$_3$Zr$_2$O$_12$ (LLZO) electrolyte, despite its thermodinamic stability and high shear modulus. An alternative to LLZO is the NASICON family of solid electrolytes, which offers comparable conductivities and mechanical properties. The disadvantage of these materials is that they are chemically unstable against lithium metal, and they typically react upon contact to form a high-impedance interface. While the chemical reaction between NASICON material Li$_{x}$La$_{y}$Al$_{z}$Ge$_{1-x}$ (PO$_4$)$_2$ (LAGP) and lithium was recently shown to cause mechanical and thermal failure, comprehensive understanding of the electrochemical reaction mechanism and phase transformation process at the Li/LAGP interface has not been attained. This knowledge is key for stabilizing NASICON-based batteries for long lifetimes. Here, we investigate the reactions between LAGP and lithium using various electrochemical and ex situ/in situ analytical techniques. In symmetric electrochemical cells, the extent of reaction and distribution of the reacted region throughout the solid electrolyte is found to be strongly dependent on the applied current density. Cell failure is ultimately governed by a dramatic increase in impedance due to mechanical fracture of the solid electrolyte. Multiple characterization techniques reveal that the reacted phase is amorphous, in contrast to the crystalline reaction products predicted to exist by prior density functional theory calculations. Both ex situ and in situ electron microscopy demonstrate that LAGP experiences a volume expansion during reaction, which likely drives fracture of the ceramic. These results demonstrate that the thermodynamic instability of LAGP against lithium alters the failure mechanism when compared to a stable material such as LLZO, and they suggest that NASICON-type materials could be used within viable solid-state devices with additional engineering to stabilize interfaces.

ET01.05.06 Diffusion Mechanism in the Superionic Conductor Li$_3$PS$_4$1 Studied by First-Principles Calculations Karsten Albe, Sabrina Sicolo and Constanze Kalcher, TU Darmstadt, Darmstadt, Germany.

Li$_3$PS$_4$1 was recently discovered as a novel crystalline lithium ion conductor by applying a soft chemistry approach. It adopts a tetragonal structure type suggesting a three-dimensional migration pathway favorable for a high conductivity [S.J. Sedlmaier, Chem. Mater. 29 (2017) 1830]. In order to shed light on the full potential of this material, we performed a theoretical study of Li$_3$PS$_4$1 in the framework of density functional theory. After creating a structural model that accurately accounts for the partial occupancies determined by diffraction experiments, we performed molecular dynamics simulations, unraveled the diffusion mechanisms and calculated diffusion coefficients and the activation barrier for diffusion. The results of the theoretical study on both a crystalline and a glassy supercell imply that Li$_3$PS$_4$1 is in fact a superionic conductor with a much higher conductivity than reported so far.

ET01.05.07 Effect of Cell Volume on Li$^+$ Diffusion in Ordered and Disordered LLZO Systems Andrew Grieder1, Tae Wook Heo2, Nicole Adelstein1, Brandon Wood2 and Prateek Mehta1; 1San Francisco State University, San Francisco, California, United States; 2Lawrence Livermore National Laboratory, Livermore, California, United States; 3University of Notre Dame, Notre Dame, Indiana, United States.

The garnet Li$_3$La$_2$Zr$_2$O$_7$ (LLZO) was identified as a promising candidate for solid electrolyte due to its stability and fast lithium diffusion. A lithium deficient system Li$_{1-x}$La$_3$Zr$_2$O$_7$ (LLZO) was studied using classical molecular dynamics simulations to investigate the effect of cell size on ordered and disordered LLZO systems. The disordered systems serve as a proxy for grain boundaries, which are thought to impede Li$^+$ conductivity in polycrystalline materials. We find that the disordered system has regions with more free volume where Li$^+$ gets trapped. Results from the simulations with ordered cell volumes confirm that more free volume in the system decreases the rate of diffusion. Activation energies and diffusion pre-factors were extracted from Arrhenius plots of diffusion at temperatures ranging from 500 K to 2000 K for systems with volumes ranging from 92% to 108% of the experimental cell volume. The activation energies were found to decrease for smaller cell sizes even though there is less space for Li$^+$ to jump. The activation energies for the disordered systems were found to be higher than the ordered systems. The pre-factor and activation energy of the ordered system increase stepwise when cell volume is 106% of the experimental cell volume indicating a change in diffusion mechanism at this volume. The results from different cell volumes of ordered and disordered systems provides insight into diffusion around and through grain boundaries for the LLZO system.

ET01.05.08 Kinetics and Chemical Analysis of the Crystallization Process of Li$_{3-x}$Al$_x$La$_3$Zr$_2$O$_7$ Thin Films Deposited by a Sol-Gel-Derived Wet Chemistry Method Yuntong Zhu1, Zachary D. Hood1, Lincoln Miara2, Kunjoong Kim1, Juan Carlos Gonzalez-Rosillo1 and Jennifer L. Rupp1-3; 1Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Advanced Materials Lab, Samsung Research America, Burlington, Massachusetts, United States; 3Department of Electrical Engineering and Computer Science, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Garnet-based solid-state batteries exhibit several exceptional properties, including its wide electrochemical stability window, high room temperature Li-ion conductivity, and good thermal stability, rendering it as one of the most promising candidates for next-generation electrochemical energy storage devices. While many studies have detailed bulk garnet-based electrolytes such as Li$_{3-x}$Al$_x$La$_3$Zr$_2$O$_7$ (LLZO), the preferred choice for future electric vehicles is thin films as it can effectively reduce the bulk resistance of the electrolyte layer, and therefore, improve the energy density of the battery. Several studies have demonstrated a promising room temperature ionic conductivity of LLZO thin films using vacuum-based deposition techniques, such as pulsed laser deposition (PLD) and sputtering. Only a few groups have demonstrated the possibility to synthesize LLZO thin films using scalable wet chemical methods such as sol-gel-derived spin coating and dip coating which are of essence for mass-manufacturing. Amongst these techniques, there is still a lack of understanding in the kinetics of the LLZO phase formation via wet chemistry routes. In this study, LLZO thin films are prepared via a sol-gel-derived wet chemistry method. The crystallization and phase transitions of the LLZO thin films during annealing processes were studied by in situ Raman spectroscopy and differential scanning calorimetry (DSC). Furthermore, X-ray photoelectron spectroscopy (XPS) was used to study the surface chemistry of the films during the phase transformation processes. Our results reveal that the as-deposited films undergo several phase transformation processes and the pure garnet phases can be obtained in an attractive low-temperature range. Additionally, we investigated the effect of precursor composition on the phase transformation. This work provides a better understanding of the LLZO phase formation through wet chemistry synthetic methods and offers valuable insight for the design and synthesis of electrolytes for all-solid-state lithium batteries.

We investigated nucleation and growth of Li in a commercial all solid-state thin film Li free battery with a LiPON solid electrolyte. We conducted Incorporation and Anion Dynamics as Synergistic Drivers for Ultrafast Diffusion in Superionic LiCB\textsubscript{11}H\textsubscript{12} and NaCB\textsubscript{11}H\textsubscript{12}.

The disordered phases of solid lithium and sodium polyborate-based salts, such as closo-borate (B\textsubscript{12}H\textsubscript{12}\textsuperscript{2-}, B\textsubscript{6}H\textsubscript{10}\textsuperscript{3-}, CB\textsubscript{11}H\textsubscript{12}\textsuperscript{-}, and CB\textsubscript{9}H\textsubscript{10}\textsuperscript{-}) and nido-borate (B\textsubscript{11}H\textsubscript{14}\textsuperscript{-}, 7-CB\textsubscript{7}B\textsubscript{12}H\textsubscript{12}\textsuperscript{2-}, and 7-9-C\textsubscript{5}B\textsubscript{7}H\textsubscript{12}\textsuperscript{-}), possess superb superionic conductivities making them intriguing molecules for use in organometallic catalysis and as electrolyte anions in metal-ion battery technologies. This dramatically high conductivity (e.g., ~0.03 S cm\textsuperscript{-1} for NaCB\textsubscript{11}H\textsubscript{12} at 297 K) is enabled by the emergence of a vacancy-rich cation sublattice and possibly further aided by the concomitant onset of high reorientational mobility (typically >10\textsuperscript{10}-10\textsuperscript{11} reorientational jumps s\textsuperscript{-1}) of the quasi-spherical anions. Furthermore, these superionic-conducting phases can be better stabilized at device-relevant temperatures via additional strategies such as ball-milling and anion-mixing.

Neutron scattering techniques are invaluable for elucidating the dynamical nature of the reorienting anions with these hydrogenous materials. Obtaining any detailed fundamental understanding of the reorientational dynamics of these complex anions requires appropriate experimental probes, such as neutron scattering fixed window scan analysis (FWS) and incoherent quasielastic neutron scattering (QENS).

In this work, FWS, QENS, and ab initio molecular dynamics calculations are combined to probe anion reorientations and their mechanistic connection to cation mobility over a broad range of timescales and temperatures.\textsuperscript{1,2} The relationship among the reorientational behaviors and mobilities of the different divalent and monovalent polyhedral anions within the various disordered salt structures obtained from these techniques and the unusually rapid cation translational diffusion properties will be discussed. It is found that anions do not rotate freely, but rather transition rapidly between orientations defined by the cation sublattice symmetry. Furthermore, there appears to be a correlation between reorientational mobility of the anions and the diffusion rates of the cations. The results suggest that synergy between the anion reorientational dynamics and the cation-anion interaction significantly accounts for the high cationic conductivity observed in these salts.

8:15 AM ET01.06.02 Understanding the Effect of Interlayers at the Thiophosphate Solid Electrolyte/Lithium Interface for All-Solid-State Li Batteries Lingzi Sang\textsuperscript{1}, Ralph G. Nuzzo\textsuperscript{2} and Andrew Gewirth\textsuperscript{2}; \textsuperscript{1}University of Alberta, Edmonton, Alberta, Canada; \textsuperscript{2}University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

All-solid-state Li-ion batteries afford possibilities to enhance battery safety while improving their energy and power densities. Current challenges to achieving high performance all-solid-state batteries with long cycle life include shorting resulting predominantly from Li dendrite formation and infiltration through the solid electrolyte (SE), and increases in cell impedance induced by SE decomposition at the SE/electrode interface. In this work, we evaluate the electrochemical properties of two interlayer materials, Si and Li\textsubscript{x}Al\textsubscript{2-x/3}O\textsubscript{3} (LiAlO), at the Li\textsubscript{7}P\textsubscript{3}S\textsubscript{11} (LPS)/Li interface. Compared to the Li/LPS/Li symmetric cells in absence of interlayers, the presence of Si and LiAlO both significantly enhance the cycle number and total charge passing through the interface before failures resulting from cell shorting. In both cases, the noted improvements were accompanied by cell impedances that had increased substantially. The data reveal that both interlayers prevent the direct exposure of LPS to the metallic Li, and therefore eliminate the intrinsic LPS decomposition that occurs at Li surfaces before electrochemical cycling. After cycling, a reduction of LPS to Li\textsubscript{2}S at the interface when a Si interlayer is present; LiAlO, which functions to drop the potential between Li and LPS, suppresses LPS decomposition processes. The relative propensities towards SE decomposition follows from the electrochemical potentials at the interface which are dictated by the identities of the interlayer materials. This work provides new insights into the phase dynamics associated with specific choices for SE/electrode interlayer materials and the requirements they impose for realizing high efficiency, long lasting all-solid batteries.

8:30 AM ET01.06.03 Mechanical Properties and Nucleation of Nano-Sized Li Electrodeposited in a Solid-State Battery Michael Citrin\textsuperscript{1}, Heng Yang\textsuperscript{2}, Wenpei Gao\textsuperscript{3}, Simon Nieh\textsuperscript{1}, Xiaoping Pan\textsuperscript{4}, Joel Berry\textsuperscript{4}, David J. Srolovitz\textsuperscript{4} and Julia R. Greer\textsuperscript{1}; \textsuperscript{1}California Institute of Technology, Pasadena, California, United States; \textsuperscript{2}Front Edge Technology, Baldwin Park, California, United States; \textsuperscript{3}University of California, Irvine, Irvine, California, United States; \textsuperscript{4}University of Pennsylvania, Philadelphia, Pennsylvania, United States.

Li metal is the most energy dense anode material for Li-based rechargeable batteries, with a theoretical specific capacity of 3860 mAh\textsuperscript{g\textsuperscript{-1}}. Its use in commercial batteries has been largely limited by the formation of dendrites during cycling in liquid electrolytes, leading to early cell death. It has been theorized that a sufficiently strong and stiff solid electrolyte can mechanically suppress dendrite formation and growth.\textsuperscript{1} Gaining a fundamental understanding of the mechanics of Li dendrite nucleation, strength, and stiffness as a function of microstructure and crystallographic orientation is essential to successfully implement solid electrolytes in Li metal batteries.

We investigated nucleation and growth of Li in a commercial all solid-state thin film Li free battery with a LiPON solid electrolyte. We conducted electrochemical cycling experiments \textit{in-situ} inside a scanning electron microscope (SEM). We observed that during charging, Li preferentially nucleated from the LiPON-Cu interface by rupturing through the Cu film along the topological landscape that reflects the domain boundaries of the underlying...
LiCoO₂ cathode. Continuum electrochemical simulations of Li ion transport suggest that Li is driven to these preferential nucleation sites by the local electrostatic potential that concentrates at the domain boundaries.

We observed Li nuclei with varying morphologies: micron-sized spheres, ~200 nm diameter fibers, and ~300 nm to 1 micron-diameter pillars. We conducted in-situ uniaxial compression experiments in an SEM on electroplated pillars with diameters between 350 nm and 1 μm and aspect ratios of about 3:1, which revealed an average elastic modulus of 6.56 ± 3.03 GPa and an average yield strength of 15.4 ± 8.57 MPa, over an order of magnitude higher than the material’s bulk polycrystalline strength. No size effect was observed, in contrast to the ubiquitous “smaller is stronger” size effect present in single crystalline metallic pillars created by Ga+ focused ion beam (FIB) milling. The results of this work enables laying out a parameter space for stiffness and strength of Li as a function of its deposition process, electrolyte, microstructure and orientation. The results have significant implications for lithium dendrite suppression using robust solid electrolytes for the next generation of lithium metal secondary batteries.

Composite solid electrolyte is attractive as it combines high ionic conductivity of ceramic electrolyte and excellent mechanical properties of polymer electrolyte. For maximizing the ionic conductivity of composite electrolyte, one ideal structure is vertically aligned ceramic particles in the polymer matrix. Here, by using the ice-templating method, we report a vertically arranged wall structure of high ionic conductivity Li₇La₃Zr₂O₁₂ (LLZO) ceramic particles combined with polyethylene oxide (PEO) polymer. The vertical LAGP walls with the shortest lithium-ion transporting path were gathered by the force of the ice crystal growth. Filling PEO in the space between LAGP walls could achieve flexible composite electrolyte and lower interfacial resistance with electrode surfaces. This as-synthesized solid-state composite electrolyte had a conductivity as high as 1.5×10⁻⁴ S cm⁻¹ at room temperature, which was even more significant at high temperature with excellent stability. LiFePO₄/LAGP-PEO/Li full cell was also assembled to test its electrochemical performance; the capacity only decayed ~8% after more than 130 cycles. This research successfully utilizes the ice-templated vertically aligned structure in ceramic/polymer composite electrolyte for solid-state batteries, with comprehensively enhanced battery performance. It could provide new design and application strategy for further composite electrolyte study.

The mechanism could be governed by quantum mechanical aspects; an explanation that has not been considered before. The results of this work could help better understand Li-solid electrolyte interface and how to increase the rate at which solid-state batteries are cycled.

Ice-Templated Ceramic/Polymer Composite Electrolyte for Solid-State Batteries Xue Wang1, 2, Huawei Zhai3 and Yuan Yang1; 1 Columbia University, New York, New York, United States; 2 Harbin Institute of Technology, Harbin, China.

Solid polymer electrolytes (SPEs) are considered as promising building blocks for the next-generation lithium-ion batteries. However, current SPEs have yet to be incorporated into real-world applications, due to their low ionic conductivity. This motivates the development of advanced computational models, for better understanding the ionic transport mechanisms and fast exploring the high-dimensional material parameter space, towards designing highly conductive SPE materials. Here we develop a coarse-grained molecular dynamics (CGMD) model with parameters calibrated by full atomistic simulations. For maximizing the ionic conductivity of composite electrolyte, one ideal structure is vertically aligned ceramic particles in the polymer matrix. Here we develop a coarse-grained molecular dynamics (CGMD) model with parameters calibrated by full atomistic simulations. The model captures both the ion motion and the polymer conformational evolution during the transport process, from which the conductivity and transference number are extracted. Adopting the Bayesian optimization (BO) algorithm, conductivity optimization is conducted by automated CGMD simulations in iterations, for screening influential factors, such as the size of molecules and the strength of intermolecular interactions, on the conduction of the polymer-salt system. This research sheds light on the mechanisms of ionic transport in polymers, and provides useful guidance for designing innovative SPE materials.

Examining the Low Voltage Stability of Li₇La₃Zr₂O₁₂ (LLZO) Regina Garcia-Mendez and Jeff Sakamoto; Materials Science and Engineering, University of Michigan, Ann Arbor, Michigan, United States.

The band gap of bulk Li₇La₃Zr₂O₁₂ (LLZO) was reported to be 5.87 eV with its band edges positioned above and below the electrochemical potential of Li metal and high voltage cathodes (~5 V), respectively. From a quantum mechanical perspective, this unprecedented wide stability window could enable a paradigm shift in secondary Li batteries whereby the electrolyte does not decompose against the anode and cathode. However, it has been observed that the Li-LLZO interface is destabilized at high Li plating current densities resulting in Li metal penetration. In this study, we hypothesize for the first time that Li metal penetration could result from a quantum mechanical instability rather than an electrochemical or mechanical instability. To analyze this phenomenon, all-solid-state cells consisting of separate working and reference electrodes were used to measure the stability of the Li-LLZO interface at and below 0 V vs Li/Li⁺. Unlike typical tests that vary the current and measure the resulting potential, this study controls the potential and measures the current. At low underpotentials, the Li-LLZO interface exhibits Ohmic behavior. However, at greater underpotentials, deviation from Ohmic behavior is observed, which we believe it is an indicator of a threshold voltage; above which the Li Fermi level is above the conduction band minimum and below which the Li Fermi level is pushed into the conduction band. This study will analyze and interpret the consequences of the latter. Furthermore, galvanostatic tests were conducted in three electrode Li-Li symmetric cells, in which current densities were increased from 0.1 to 2 mA cm⁻² on the Li plating side. It was found that the current density of 0.5±0.1 mA cm⁻² at which the drop in voltage was observed in galvanostatic conditions is comparable to the 0.6±0.1 mA cm⁻² current density at which the threshold voltage occurs in the voltage sweep tests. At this macroscopic scale, no electric field dependence was observed. In this study, we propose a hypothesis to explain why relative soft Li metal can penetrate a relatively hard ceramic electrolyte. The mechanism could be governed by quantum mechanical aspects; an explanation that has not been considered before. The results of this work could help better understand Li-solid electrolyte interface and how to increase the rate at which solid-state batteries are cycled.

9:30 AM ET01.06.06

Solid polymer electrolytes (SPEs) are considered as promising building blocks for the next-generation lithium-ion batteries. However, current SPEs have yet to be incorporated into real-world applications, due to their low ionic conductivity. This motivates the development of advanced computational models, for better understanding the ionic transport mechanisms and fast exploring the high-dimensional material parameter space, towards designing highly conductive SPE materials. Here we develop a coarse-grained molecular dynamics (CGMD) model with parameters calibrated by full atomistic simulations. The model captures both the ion motion and the polymer conformational evolution during the transport process, from which the conductivity and transference number are extracted. Adopting the Bayesian optimization (BO) algorithm, conductivity optimization is conducted by automated CGMD simulations in iterations, for screening influential factors, such as the size of molecules and the strength of intermolecular interactions, on the conduction of the polymer-salt system. This research sheds light on the mechanisms of ionic transport in polymers, and provides useful guidance for designing innovative SPE materials.

9:45 AM ET01.06.07
Amorphous Li₅₋ₓLaₓTiO₃ (LLTO) has been proved to be a promising candidate for electrolyte in All-Solid-State-Battery (SSB), amorphous LLTO thin films were also synthesized by sol-gel process in our previous work. The ionic conductivities of amorphous LLTO thin films were 4.5*10⁻⁸, 6.9*10⁻⁸, 1.3*10⁻⁷, and 3.8*10⁻⁷ S/cm at 30°C, 50°C, 70°C, and 90°C, respectively. However, the inner relationship among the ionic conductivity, structure and mechanism of Li ion transfer is still unexplored. In this study, we successfully prepared amorphous LLTO thin film and amorphous LLTO powder via similar sol-gel procedure, moreover, differences were introduced during the sintering process. XRD and SEM were applied to demonstrate the morphology change with different annealing conditions. In addition, the ionic conductivities of the thin film prepared were measured sequentially. With the accumulation of annealing time, the ionic conductivity of LLTO thin film raised from 2.3*10⁻⁸ S/cm to 9.0*10⁻⁸ S/cm, then dropped back to 1.65*10⁻⁹ S/cm at 30°C. Whereas the activation energy of lithium ion transferring is approximately constant, from which proved the lithium ion transfer in LLTO is dynamic-controlled. It gave us an optimized synthesis condition of LLTO thin film in the meantime for future investigation.

10:30 AM ET01.06.08

All-solid state Li-ion batteries (SSBs) have emerged as very attractive alternatives to conventional liquid electrolyte cells for automotive transportation, owing to their enhanced safety and higher energy densities. Similarly, low-cost solid state Na-ion batteries may prove an excellent alternative for grid storage. SSBs are founded on high-performance fast-ion conducting electrolytes, and in the important search for new materials, alkali thio phosphates are a particularly promising class of materials owing to their ductility and good mechanical properties. This presentation will focus on several new alkali fast ion conductors within this class recently developed in our laboratory, and the understanding of superionic conductivity in these materials using a combination of structural elucidation via single crystal X-ray/powder neutron diffraction, ion conductivity via impedance studies, and ab initio molecular dynamics simulations. We correlate crystal structure with ionic conductivity in a range of our newly developed fast ion Li and Na conductors to understand how changes in composition and vacancy population affect the conductivity and activation energy. These considerations lead to an overarching understanding of the relative importance of interstitial alkali ion site occupation for ion migration, and the factors that govern thermodynamic (meta)stability.

11:00 AM ET01.06.09
Li Transport Induced Phase Transitions in Epitaxial LiCoO2 Thin Films Yingge Du, Zhenzhong Yang, Phuong-Vu Ong, Le Wang and Peter V. Sushko; Pacific Northwest National Laboratory, Richland, Washington, United States.

Structurally ordered materials exhibit a broad range of structural, physical, and ion transport properties, which can be further tuned or even drastically transformed by means of judicious elemental doping, strain, and defect engineering. This talk will highlight our most recent effort aiming to modify LiCoO₂ through heteroepitaxy for tunable Li transport, which have profound implications in energy conversion and storage devices. We will present the epitaxial growth and in situ TEM studies of LiCoO₂ with or without overlayers to understand the Li transport processes across the epitaxial interfaces, and device failure mechanisms. We show that while orienting Li containing planes of LiCoO₂ can effectively tune the Li ion transport characteristics, allowing Li incorporation into the overlayers across the interface, it does not modify its stability against Li metal (mimicking a Li dendrite), which preferentially attack the LiCoO₂ crystal structure along the [001] direction, enabling to Li propagation across Li-containing planes.

11:15 AM ET01.06.10
Lithium-Metal Anode Protection—From Liquid to Solid-State Batteries Chunjpeng Yang and Liangbing Hu; University of Maryland at College Park, College Park, Maryland, United States.

High-energy lithium metal batteries are among the most promising candidates for next-generation energy storage systems. With a high specific capacity and a low reduction potential, the Li metal anode has attracted extensive interest for decades. Dendritic Li formation, uncontrolled interfacial reactions, and huge volume effect are major hurdles to the commercial application of the Li metal anodes. In this talk, I will introduce our approaches to protect Li metal anodes from liquid batteries to solid-state batteries. We designed advanced host structures with nanoseconded nucleation sites for Li anode, ion-conductive protecting layers for Li metal anode, and so on. The strategies in liquid batteries improve the performance and safety of Li metal anodes in liquid electrolytes significantly. Superior to the liquid electrolytes, solid-state electrolytes are considered able to inhibit problematic Li dendrites and build safe solid Li metal batteries, but their utilization is mainly hindered by the poor interface between the solid electrolyte and electrodes. We introduce a solid-state Li anode hosted in a 3D garnet-type ion-conductive framework with bottom-deposited Cu. The Li anode is plated within the solid garnet framework from the bottom Cu layer and shows a dendrite-free deposition behavior, effectively averting the dendrite penetration issue. Owing to the 3D ion-conductive host, the volume change and interface contact problem of the Li anode have been significantly mitigated, realizing a high-capacity and safe Li metal anode for solid-state high-energy-density batteries.

11:30 AM ET01.06.11
Dominating Factors Controlling The Ion Conductivity of Na-β''-Alumina Ceramic Electrolytes Marie-Claude Bay¹,², Meike V. Heinz², Nicola Zanon³, Ulrich F. Vogl² and Corsin Battaglia¹; ¹Empa-Swiss Federal Laboratories for Materials Science and Technology, Dübendorf, Switzerland; ²Albert-Ludwigs-Universität Freiburg, Freiburg i. Breisgau, Germany; ³FZJ/Nick SA, Stabio, Switzerland.

Ceramic Na-β''-alumina is a fast solid-state sodium-ion conductor at elevated temperature (0.2 S/cm at 300 °C) and thus favored as electrolyte in high-temperature batteries (Na/NiCl₂, Na/S) [1]. Furthermore it is gaining attention as interesting candidate for all-solid-state batteries (1 mS/cm at room temperature) [2]. Although known since the 1970s, processing of Na-β''-alumina into a dense material with high ion conductivity is challenging, in particular due to significant Na loss during sintering. Ion conductivity values reported in the literature vary by a factor of 100 [3]. While these variations are largely accounted for by Archie’s law and results in lower conductivity down to 0.04 S/cm at 68 % density. The overall Na content remains constant within experimental uncertainties. However, we observe evidence in X-ray diffraction that the local sodium concentration inside the grains increases with increasing sintering temperature. We present a model to predict the influence of grain size on the ionic conductivity and effective activation energies of grain and grain-boundary phases. Our insights into microstructural factors controlling ionic conductivity such as grain size and density are instrumental for the
successful integration of Na-b' alumina ceramic electrolytes into next-generation batteries.

Kinetische Monte Carlo Simulations of Solid State Battery Materials
Steffen P. Grieshammer1,2; Helmholtz-Institut Muenster, Forschungszentrum Juelich GmbH, Muenster, Germany; 2Institute of Physical Chemistry, RWTH Aachen University, Aachen, Germany.

Ionic conductivities of solid state battery materials are of crucial importance for the efficiency of solid state batteries. Quantum chemical methods, such as density functional theory (DFT), have become a useful tool to predict structural and electronic properties of solid state materials as well as the migration paths of the ionic charge carriers. In ideal materials with dilute concentration of defects the macroscopic ionic conductivity can be derived analytically from the microscopic energy barrier of ion motion. However, at non-dilute concentration of defects, the motion of ions is correlated and depends on the local environment due to the interactions of the defects. In this case the ionic conductivity is determined by the inhomogeneous energy landscape of ion migration and can be simulated by the Kinetic Monte Carlo (KMC) method.

In this talk, the simulation of the ionic conductivity of solid state materials for battery applications is presented. DFT calculations are performed to derive migration energies and defect interaction energies, which are used to model the energy landscape for the migrating ions. The energy models are applied in an in-house KMC code to simulate the ionic conductivity depending on composition and temperature.

Simulations are performed for oxygen ion conductors like doped ceria and melilitic structured oxides, which are potential electrolytes in rechargeable oxide batteries. In doped ceria, the conductivity is influenced by the interaction of oxygen vacancies with dopant ions leading to a ‘trapping’ next to the dopant ions and ‘blocking’ of the migration paths. In melilitic structured oxides, different migration paths with different energies exist for oxygen interstitials and migration energies are additionally shifted depending on the local arrangement of cations. The effects of these local environments on the conductivity are investigated here.

Simulations are extended to lithium ion conducting materials for application in solid state Li-ion batteries including both electrolytes and electrodes. In particular, the ionic conductivity of Li-intercalation electrodes changes with the charge state of the battery and the advantages and challenges of the KMC method to predict these changes are discussed with regard to selected examples.

The Structural and Compositional Factors that Control the Li-Ion Conductivity in LiPON Electrolytes
Valentina Lacivita1, Nongnuch Artrith1 and Gerbrand Ceder1,2; 1Materials Science and Engineering, University of California, Berkeley, Berkeley, California, United States; 2Materials Science Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Amorphous or glassy materials are ubiquitous in rechargeable battery devices. Therefore, understanding the structural and chemical factors affecting the ionic transport in such materials is key for battery technology. However, the complexity of amorphous systems makes this task very challenging. We addressed this question using ab initio computational methods. Specifically, in this presentation we report atomistic-level insight into the mechanisms underlying the mobility of Li+ in amorphous LiPON (lithium phosphorus oxynitride) thin-film electrolytes. These materials have been known for more than twenty years for their outstanding electrochemical performance which combines good ionic conductivity at room-temperature (around 2-3 μS/cm) and compatibility with Li metal anode. Despite the importance of LiPON electrolytes, no conclusive explanation has yet been given for their electrochemical behavior. Our work fits in this context revealing for the first time how structure and chemistry interplay to influence the Li-ion mobility in amorphous LiPON. We show that the conductivity benefits from both amorphization of the phosphate framework and nitrogen doping. In particular, the N doping involves 1(N):1(O) substitutions (apical N) as well as 1(N):2(O) substitutions promoting the condensation between phosphate units (bridging N). We find that the ratio between apical and bridging N changes with the Li:P content, correlating with the conductivity trends experimentally observed and also well reproduced by our models. This detailed understanding of the structural mechanisms that affect Li+ mobility should be useful in optimizing the conductivity of LiPON and other amorphous Li-ion conductors. This work was supported by the ARPA-E IONICS program, U.S. Department of Energy, award DE-AR0000775.

Fabrication of All-Solid-State Lithium-Ion Battery Using Inorganic-Organic Hybrid Solid Electrolyte
Jong Heon Kim and Hyun-suk Kim; Chungnam National University, Daejeon, Korea (the Republic of).

Lithium ion battery is considered to be the most promising battery technology currently available because it exhibits relatively high energy density compared to other chemical batteries. Normally, conventional lithium ion battery using organic liquid electrolyte exhibits relatively high ionic conductivity, but has some disadvantages such as safety problem, short lifetime, high cost and low power density. All-solid-state thin film battery is one of the ways to solve these problems, and safety is improved by using non-flammable solid electrolyte. It also has long lifetime, high energy density and less requirements on packaging. However, in spite of these many advantages, the low ionic conductivity of the material itself and the interfacial resistance between the electrode and the solid electrolyte are major problems to overcome for commercial application.

In this work, we studied inorganic-organic hybrid electrolyte with polyethylene oxide (PEO) based polymer and lithium phosphorous oxynitride (LiPON) of oxide based ceramics to reduce the interfacial resistance between the solid electrolyte and the electrodes. LiNi0.5Mn1.5O4 and Li4Ti5O12 were used for cathode and anode, respectively, and all the layers were fabricated on a stainless steel substrate as a thin film. Polymer electrolytes were fabricated by
electrospinning system and all other thin films were fabricated by sputtering system. The thickness, microstructure and surface morphology were examined using transmission electron microscopy and scanning electron microscopy. The crystal structure was identified by X-ray diffraction. The ion-conductivity was measured by an AC impedance method. The electrochemical properties were studied with charge-discharge cycling test and cyclic voltammetry.

On Applications of Li-Garnets in Energy Storage and Sensing Devices
Michal Struzik1, 2, Reto Pfenninger1, 2 and Jennifer L. Rupp3, 4; 1Warsaw University of Technology, Warszawa, Poland; 2DMSE, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 3Department of Materials, ETH Zürich, Zurich, Switzerland; 4ECSS, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Technological and social advancement stimulates a need for clean and sustainable production of energy, its storage and efficient utilization, that will ensure energetic safety of the society of tomorrow. Most popular, nowadays, energy storage technology, based on components consist of lithium conducting polymers and liquids, suffer from limited power densities available, limited miniaturization potential and safety, due to dendrites growth of Li pathways in the electrolyte. New possibilities for safe energy storage devices arise with a development of new generation of highly conducting Li⁺ electrolytes, such as Li-La-Zr-O system, showing pure ionic conductivity of ca. 10⁻³ S/cm² at room temperature, good structural, thermal and chemical stability and compatibility with many of high capacity electrode materials. Li⁺ conducting ceramics can be employed not only as the electrolytes for batteries, but also can be utilized as electrolytes for potentiometric gas sensors for i.e. CO₂ detection and monitoring. The flexibility of applications and perspectives of functionalization of one electrolyte material with different sets of electrodes to define multiple functionalities is in focus of this work.

We discuss on the ceramic processing of Li-La-Zr-O; based solid electrolytes and their structural and electrical properties by the means of X-ray Diffraction, Raman Spectroscopy and Impedance Spectroscopy. Further, we employ Li-garnet electrolytes in all-solid-state battery cells and discuss their performance with emphasis on the interfacial effects. Further we turn on to gas sensing of Li-garnets. We report on the fabrication of potentiometric gas sensor for CO₂ levels monitoring and we perform an experimental evaluation of its performance in a simulated environment. We discover quick response times of ca. 60 s at working temperatures of ca. 300°C, which is faster than similar systems based on NASICON electrolytes.

Grain Boundary and Dopant Engineered Ultra-Dense Garnet Towards Stable High Current Cycling
Lei Zhang, Chengwei Wang, Dennis McOwen, Jack Gritton, Liangbing Hu and Eric D. Wachsmann; University of Maryland, College Park, Maryland, United States.

High capacity and high rate are the two major requirements for the next generation Li ion batteries. Among all candidates, solid state Li metal battery utilizing solid electrolyte is promising. Garnet type Li ion conductor has been the most widely studied material system due to its high conductivity and stability with Li metal. Aside from high capacity, the high rate cycling with Li garnet solid electrolyte is hard to achieve. Previous reports on cycling failure pointed out Li dendrite growth at grain boundaries. However, a close examination at those reports reveals that the microstructure in their ceramics is not satisfactory. Small grain, clean grain boundary and high relative density are the three key factors that guarantee ceramics to have good mechanical properties. Herein, an ultra-dense garnet pellet was fabricated by controlling grain size and grain boundary phase. The high relative density (>99%) grants the pellet to be translucent. Nano indentation results show the improved mechanical property of ultra-dense garnet to conventional pressed-sintered garnet. Besides good mechanical property, electrochemical stability of dopants in Li garnet is another requirement. Nb, Ta and Al doped garnet were compared. It is found that Ta doped garnet has the best electrochemical stability. Nb doped garnet can be reduced upon Li metal coating. Al doped garnet is venerable to Li dendrite formation. Together with the grain boundary engineering and dopant engineering, stable long-term high-current cycling was proved to be achievable.

3:45 PM ET01.07.05
New Insights into the Most Promising Solid Electrolytes
Daniel Rotterwander1, 2, Gänther Redhammer1 and Martin Wilkening1, 2; 1Institute for Chemistry and Technology of Materials, Technical University of Graz, Graz, Austria; 2Christian Doppler Laboratory for Lithium Batteries, Technical University of Graz, Graz, Austria; 3Department of Chemistry and Physics of Materials, University of Salzburg, Salzburg, Austria.

Much scientific attention is devoted to the development of all-solid state batteries (ASSB) as important and superior alternative to electrochemical cells relying on aprotic liquid electrolytes. Among promising solid electrolytes Li-garnets, NASICON (Na-ion Super Ionic CONductor), and LiRAP (Li-Rich Anti-Peroxides) attracted most attention having the potential to realize those future energy storage technologies, due to there extremely high ionic conductivities and exceptional high stability versus low or high voltage electrode material. Despite all the research already performed, however, many questions remain unanswered. In particular, these include the fundamental ones concerning structure, stability, Li ionic conductivity and diffusivity. Herein, we will show, e.g., that (i) the acentric cubic garnet structure is the thermodynamically favored modification of Ga-stabilized LLZO at room temperature with improved chemical and electrochemical properties, (ii) the variation in the phase behavior and ionic transport reported for “NASICON”-based solid electrolytes is related to the preparation history, and (iii) that Liₓ(OH)Cl and variants of Liₓ₋₀.1(OH)⁺Cl⁻ with x > 0, are so far the only thermodynamically stable LiRAPs having experimental proof.

4:00 PM ET01.07.06
Discovery of New Oxide and Sulfide Compounds as Electrolytes for All-Solid-State Li-Ion Batteries
Shan Xiong1, Xingfeng He2, Zhantao Liu1, Zhenhong Ren1, Shuo Chen1, Yifei Mo3 and Hailong Chen1; 1Mechanical Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States; 2Materials Science and Engineering, University of Maryland, College Park, Maryland, United States; 3Physics, University of Houston, Houston, Texas, United States.

All-solid-state batteries (ASSBs) are considered as a promising alternative to conventional Li-ion batteries owing to their good safety properties and potentially higher volumetric energy density. Multiple challenges now exist in the development of ASSBs, including the lack of good solid electrolytes with high conductivity, good electrochemical stability and mechanical compatibility. Here we report recent progresses in our research group in the design and discovery of new oxide and sulfide based lithium ion conductors. Lithium tantalum oxosilicate was identified through a computation assisted search and screening with using ab initio molecular dynamics (AIMD). While the stoichiometric compound is expected to be an ionic insulator, a number of different ion doped compounds were predicted to have very high Li⁺ conductivities. A group of zirconia doped lithium tantalum oxosilicate were successfully synthesized and tested. The 12.5% Zr doped 3 samples showed encouraging ionic conductivity of 5×10⁻⁵ mS/cm at room temperature. Meanwhile, a group of lithium chloro-thiophosphate compounds were also experimentally identified assisted by in situ X-ray diffraction investigations. The new compounds have a novel crystal structure that have never been reported previously. The structure of both sulfides and oxides new compounds were characterized with using synchrotron X-ray diffraction and neutron diffraction. The conduction mechanisms were investigated combing AIMD computation, electrochemical impedance spectroscopy and solid state NMR experiments.

4:15 PM ET01.07.07
Resolving the Amorphous Structure of Lithium Phosphorus Oxynitride (Lipon) Andrew S. Westover1, Valentina Lacivita2, Andrew Kercher1, Nathan Phillips1, Guang Yang1, Gabriel Veith1, Gerbrand Ceder1, 2 and Nancy J. Dudney1; 1Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2Lawrence Berkeley National Laboratory, Berkeley, California, United States; 3Material Science, University of California, Berkeley, California, United States.

Lithium phosphorus oxynitride or Lipon solid-state electrolytes are at the center of the search for solid-state Li metal batteries. Key to the performance of Lipon is a combination of high Li content, amorphous structure, and the incorporation of N into the structure. Despite the material’s importance, our work presents the first study to fully resolve the structure of Lipon. In order to resolve the structure structural models were first developed using a combination of ab initio molecular dynamics. In this presentation we compare simulated neutron pair distribution functions (PDF), and infrared spectroscopy (IR) of the Lipon with the experimental PDF and IR data. For both techniques we see exceptional agreement between the simulated and experimental results.

Although details of the modeling efforts will be presented in a separate talk, some of the key findings show that N forms both bridges between two phosphate units and non-bridging or apical N. The model further shows that as the Li content is increased the ratio of bridging to apical N shifts from being predominantly bridging at Li contents around 2.5:1 Li:P to only apical N at higher Li contents of 3.38:1 Li:P. Furthermore, the simulations show that Li hopping events are faster in the vicinity of bridging N. This crossover from bridging to apical N appears to directly correlate and explain both the increase in ionic conductivity with the incorporation of N and the ionic conductivity trends found in our own experimental results and across the literature.

This work was supported by the ARPA-E IONICS program, U.S. Department of Energy, award DE-AR0000775.

4:30 PM ET01.07.08
Vertically-Aligned and Continuous Ceramic-Polymer Interfaces in Composite Solid Polymer Electrolytes for Enhanced Ionic Conductivity Xiaokun Zhang1, Yong Xiang1 and Yi Cui2; 1University of Electronic Science and Technology, Chengdu, China; 2Stanford University, Stanford, California, United States.

Among all solid electrolytes, composite solid polymer electrolytes, comprised of polymer matrix and ceramic fillers, garner great interest due to the enhancement of ionic conductivity and mechanical properties derived from ceramic-polymer interactions. Here, we report a composite electrolyte with densely-packed, vertically-aligned, and continuous ceramic-polymer interfaces, using surface-modified anodized aluminum oxide as the ceramic scaffold and polyethylene oxide as the polymer matrix. The fast Li transport along the ceramic-polymer interfaces was proven experimentally for the first time, and an interfacial ionic conductivity higher than 10^-3 S/cm at 0 °C was predicted. The presented composite solid electrolyte achieved an ionic conductivity as high as 5.82×10^-4 S/cm at the electrode level. The vertically-aligned interfacial structure in the composite electrolytes enables the viable application of the composite solid electrolyte with superior ionic conductivity and high hardness, allowing Li-Li cells to be cycled at a small polarization without Li dendrite penetration.

SESSION ET01.08: Poster Session II

Role of Lattice Polarization and Rotation on Lithium Diffusion in Li10GeP2S12 (LGPS), β-Li3PS4 (LPS), and Li10GeP2O12 (LGPO) Solid Electrolytes from Ab Initio Molecular Dynamics Alex T. Hall1, Nicole Adelstein1, Nima Leclerc2, Joel B. Varley3 and Leonid Kahl4; 1San Francisco State University, San Francisco, California, United States; 2Cornell University, Ithaca, New York, United States; 3Lawrence Livermore National Laboratory, Livermore, California, United States; 4Ecole Polytechnique Federale de Lausanne, Lausanne, Switzerland.

The search for a solid electrolyte in order to create a safe, long-lasting, all-solid battery has been extensive, but the fundamentals of lithium diffusion are still not completely understood. One of the fastest conducting electrolytes that has been identified is Li10GeP2S12 (LGPS), though this electrolyte faces challenges to incorporation in batteries due to instability with the electrode interface. While significant computational research has been done on LGPS, nuances of the mechanisms governing ion diffusion are still unknown. Insight into the extraordinary conductivity of LGPS will enable the engineering and search for new electrolyte materials. Polarization of anions and (P/Ge)S4 tetrahedra as well as rotation of tetrahedra were studied in order to elucidate the difference in conductivity between the LGPS, β-Li3PS4 (LPS), and Li10GeP2O12 (LGPO) solid electrolytes. Experimentally, LGPS has orders of magnitude lower ionic conductivity than LGPS, but a very similar composition and structure. These analyses allow quantification of the effects of electronic structure (polarization) and rotation on lithium diffusion. Polarization and rotation events were extracted from Density Functional Theory Molecular Dynamics (DFT-MD) simulations. Detailed analysis of the DFT-MD simulations revealed correlation of both tetrahedral rotation and polarization with lithium ion diffusion. Expansion of the unit cell in LGPS was found to facilitate the rotation of PS4 tetrahedra in addition to increasing lithium ion diffusion. In constrast, expansion of the LPS unit cell did not affect tetrahedral rotation in a meaningful way. Anion polarization was found to correlate with lower lithium ion diffusion in LPS. The polarization of oxygen in LGPO, a structural isomer of LGPS, is calculated to study the effect of anion polarizability.

ET01.08.02
Microstructural Characterization of Cathodes in Sulfide-Based All-Solid-State Batteries via Tomographic Techniques Sungjun Choi, Wo Dumn Jung, Ji-Su Kim, Hyoungeul Kim, Byeung-Kook Kim and Hae-Weon Lee; Korea Institute of Science and Technology, Seoul, Korea (the Republic of).

The all-solid-state lithium-ion batteries (LIBs) have drawn increasing interests and demands as the next-generation rechargeable batteries for electric vehicles and energy storage devices since they have much more potentials (e.g., higher safety, reliability, power density, and design flexibility) than conventional LIBs. However, we all know that any further advances in all-solid-state LIBs are not possible without solving the current raising issues of all-solid-state LIBs, such as low lithium-ion conductivity, structural instability, and high resistance of electrode/electrolyte interface. Recently, sulfide-based all-solid-state LIBs are exhibiting the best performance approaching to the commercialization stage with various material advantages (e.g., excellent lithium-ion conductivity, room-temperature formability, and so on). Despite the comprehensive studies to develop high-performance sulfide-based all-solid-state LIBs, the fundamental understanding of crystallographic structure and elemental distribution for materials used in sulfide-based all-solid-state LIBs has been lacking.

Here we present the recent advances of structural and elemental analysis in sulfide-based all-solid-state LIBs using vacuum-transferred transmission electron microscopy (TEM) and 3-D tomography techniques. According to the high-speed energy dispersive X-ray spectroscopy and selected area penetration.
Lithium ion batteries have shown great promise in electrical energy storage with enhanced energy density, capacity, and cycling lifetimes. However commercial liquid electrolytes consisting of lithium salts dissolved in organic solvents are toxic, corrosive or flammable. Solid electrolytes with superionic conductivity can avoid those shortcomings, so that for safe application. Meanwhile, the mechanical property of solid electrolyte enable it to prevent the risk of lithium dendrites, thereby to achieve high energy density. Here we present a novel class of solid electrolyte materials with three-dimensional conducting pathways based on lithium-rich anti-perovskites (LiRAP). Our previous work shows its high ionic conductivity, low activation energy, and high stability with lithium metal. LiRAP also serves as solid electrolyte functionally in a half battery with LTO and lithium metal, running at elevated temperature. The new LiRAP materials can be readily manipulated via chemical, electronic, and structural means to boost ionic conductivity and serve as high-performance solid electrolytes. Furthermore, by transition metal doping, as TM-LiRAP, this material can serve as cathode in lithium battery. This creative idea is promoted by the fact that the solid-solid interface is a critical issue in solid batteries. Therefore a seamless interface with bi-layered LiRAP electrolyte and TM-LiRAP cathode is designed, and preliminary test evidenced this concept. The enhanced compatibility between LiRAP based electrolyte and cathode, in the aspects of crystal lattices, chemical compositions, thermal evaporation coefficient and volume change during cycling, could improve the solid state interface and hence the battery performance. These results could be quite helpful for the R&D of solid state lithium batteries.

Enhanced Performance of Dopamine Modified Li₆.4La₃Zr₁.4Ta₀.6O₁₂/PEO Composite Electrolyte for Solid-State Battery Huang Zeya and Chang-An Wang; Tsinghua University, Beijing, China. Solid state electrolyte with high ionic conductivity and low interfacial resistance as well good stability is essential for the application of solid state battery. The Ta doped garnet-type solid state electrolyte - Li₆.4La₃Zr₁.4Ta₀.6O₁₂ (LLZTO) has high ionic conductivity and wide electrical window. However, it is not easy to be assembled into batteries due to lack of flexibility. Polymer electrolytes such as poly(oxycetylene) (PEO) have good flexibility, but the room temperature conductivity is low. The PEO has relative narrow electrochemical window and poor thermal stability. The composite electrolyte where the LLZTO particles are dispersed in the PEO has enhanced electronic conductivity, electrochemical stability, thermal stability, and good processability. The addition amount of LLZTO is an important factor affecting the performance of the composite electrolyte. A high ceramic/polymer ratio will significantly increase the proportion of high-speed channel for ion transport in the composite electrolyte and thus achieve better electrical performance. However, the increase in the proportion of ceramics will bring about problems of particle agglomeration, uneven dispersion, and deterioration of mechanical properties. These problems are caused by the incompatible of polymer and ceramic due to their difference in surface energy. In this paper, LLZTO was modified by dopamine to improve the wettability of LLZTO and PEO, so that more than 80wt% of LLZTO can be uniformly dispersed in 20% of PEO/LiTFSI polymer electrolyte. Because of the wetting nature of dopamine, the composite electrolyte has good adhesion with both positive and negative electrodes, which will improve the interfacial contact and thus decrease the resistance. The composite electrolyte with 80wt% LLZTO coated with dopamine in PEO was synthesized by solvent casting method. Electrochemical performance tests showed that after dopamine modification, the conductivity at room temperature (20 °C) increased from 2x10⁻⁸ S/cm to 4x10⁻⁵ S/cm, and the interface resistance between the composite electrolyte and metallic lithium decreased from 490 Ω·cm² to 191 Ω·cm². The thermal stability and electrochemical stability of the composite electrolyte have also been improved. These results showed that the performance of PEO-LLZTO composite electrolyte can be improved by dopamine modification.

Combined DFT and Semi-Continuum Modelling of Space-Charge Regions in Li₃OCl Solid Electrolytes Georgina Wellock, James A. Dawson, Pieremannue Canepa, Saiful Islam and Benjamin J. Morgan; University of Bath, Bath, United Kingdom. Over recent decades, lithium-ion batteries have become the dominant power source for portable devices due to their high energy densities and low self-discharge rates. However, this success, there are safety concerns regarding the use of lithium ion batteries in applications such as electric vehicles and grid scale storage, due to their use of flammable organic liquid electrolytes. Lithium rich anti-perovskites, such as Li₃Oₓ, where X is a halide ion, are a promising family of solid electrolytes with the potential for improved safety in commercial lithium-ion batteries. In polycrystalline Li₃Oₓ, the presence of grain boundaries can strongly affect the transport of lithium ions, due to local changes in atomic structure and associated electrostatic potentials, and therefore affect measured ionic conductivities. Although there has been recent work investigating the effect of grain boundaries on lithium transport in Li₃Oₓ anti-perovskites, this is still not fully understood. A key mechanism by which grain boundaries affect ionic transport is through the formation of space-charge regions. Charged defects, such as lithium vacancies, are expected to segregate to, or from, grain boundaries, which produces a net local charge. This charge interacts with the surrounding crystal regions, where the bulk defects are depleted or accumulated in so-called “space-charge” regions to restore equilibrium. Because these space-charge regions can have defect concentrations that strongly differ from the bulk crystal, they can strongly enhance or decrease the ionic conductivity of the sample. Grain boundary effects on space charge formation and ionic conductivity in Li₃Oₓ and many other lithium-ion solid electrolytes, are not fully understood, especially on the atomic scale. Considering Li₃OCl as a model polycrystalline electrolyte, we have calculated explicit defect segregation and conduction using density functional theory. We have then used these positions and segregation energies to perform self-consistent semi-continuum 1D Poisson-Boltzmann calculations, to predict equilibrium defect concentrations, electrostatic potentials, and resistivities at grain boundaries and their adjacent space-charge regions.

Compared to current commercial available lithium ion batteries, solid-state batteries are emerging as an attractive energy storage device because of their high safety, reliability and high energy density when paired with lithium metal anode. Rigid ceramic electrolytes have a high ion conductivity, but exhibit a very high interfacial resistance due to the discrete contact with electrodes. Soft polymer electrolytes enable a good contact with electrodes with a low interfacial resistance, but their conductivity is too low. Incorporating rigid ceramic electrolytes into soft polymer electrolytes matrix simultaneously enhances ionic conductivity and reduces the interfacial resistance between electrodes and electrolytes. Here we demonstrated a PEO/NASICON composite electrolyte with a high conductivity of $10^{-3}$ S cm$^{-1}$ at 60 °C. When used as a solid electrolyte in Li symmetric cell, the as-prepared PEO/NASICON composite membrane exhibits a very low interfacial resistance. Surface analyses were carried out to prove the mechanism of the low interfacial resistance. Our results show that an interphase was formed between the lithium metal anode and the composite electrolyte, which may account for symmetric cells with low resistance and high stability. Furthermore, a LFP/PEO-NASICON/Li cell was assembled to demonstrate its feasibility for practical applications.

TEM Single-Particle Analysis of Solid-State Electrolyte with Mobile Biasing Probe
Nikhilendra Singh$^1$, Timothy S. Arthur$^2$, Julio A. Rodriguez Manzo$^1$, Daan H. Alsøn$^1$ and Norman Salmon$^1$; $^1$Hummingbird Scientific, Lacey, Washington, United States; $^2$Toyota Research Institute of North America, Ann Arbor, Michigan, United States.

Solid-state electrolytes are an alternative to liquid-based electrolytes, when it comes to improving the safety of batteries and their energy density. However, large impedances at solid-state electrolyte-electrode interfaces remain a challenge.

Obtaining reliable electrochemical information from individual solid-state particles is difficult; particles can have nanoscale dimensions and ionic current paths cannot be confined to a single particle unless the electrodes are touching only the particle of interest. However, understanding single-particle effects is paramount to optimize the functionality of assemblies—ion insertion rates can vary at subparticle length scales [1]. This challenging characterization need, however, can be addressed with a purpose-designed in-situ transmission electron microscope (TEM) sample holder with biasing capabilities and a mobile electrode probe. With this TEM platform, a static sample can be approached with a biasing sharpened probe—usually a few tens of nanometers in diameter—to create an electrical circuit, where the contact point can be chosen with high spatial resolution. With the right control electronics, ionic currents in the order of picoamps can be measured while, simultaneously, all TEM-related characterization techniques (high-resolution imaging, electron-based spectroscopy, electron diffraction, etc.) can be applied to study the particle and its interfaces. This approach has been used to investigate, for example, the switching of oxide resistive memories [2], anode materials for batteries [3,4], and the conductance through rows of atoms [5,6].

Here, we present an in-situ TEM study of solid-state electrolyte particles under load. Micron-sized particles were contacted with a mobile probe and cyclic voltammograms were obtained. Ionic currents in the order of picoamps were measured and, simultaneously, electrochemical induced structural changes—within particles and at interfaces—were imaged. Our results show clear correlations between gathered electrochemical data and structural transformations. This approach can be used to study any solid-state electrolyte-electrode configuration, provided that the electron irradiation-induced effects are taken into consideration.

Analyzing the Role of Li Transport in Achieving High Critical Current Densities in Li$_7$La$_3$Zr$_2$O$_{12}$: Michael Wang and Jeff Sakamoto; University of Michigan, Ann Arbor, Michigan, United States.

The development of cubic Li$_7$La$_3$Zr$_2$O$_{12}$ (LLZO) for physically stabilizing the Li-electrolyte interface has shown potential for safe, high energy-density Li-ion batteries in recent years. Despite its high elastic modulus and hardness, it has been observed that Li metal filaments can propagate through LLZO above a certain critical current density (CCD). Currently, reported values for CCD are still well below the current density regimes relevant to electric vehicles, and therefore, there is a need to increase the CCD and understand the mechanisms of Li propagation in LLZO. This study utilizes a combination of recently developed processing methods from the literature in order to achieve low Li-LLZO interface resistance and consistently high CCDs close to 1mA/cm$^2$ at room temperature in Al-stabilized LLZO. The relationship between CCD and temperature is examined. By analyzing the flux of Li$^+$ at the Li-electrolyte symmetric cell, the as-prepared Li$_7$La$_3$Zr$_2$O$_{12}$ symmetric cell exhibits a very low interfacial resistance. Surface analyses were carried out to prove the mechanism of the low interfacial resistance. Our results show that an interphase was formed between the lithium metal anode and the composite electrolyte, which may account for symmetric cells with low resistance and high stability. Furthermore, a LFP/PEO-NASICON/Li cell was assembled to demonstrate its feasibility for practical applications.

Mechanochemical Assembly of 3D Mesoporous Conducting-Polymer Aerogels for High Performance Hybrid Electrochemical Energy Storage: Luhua Cheng$^1$, Xiaosong Du$^1$, Yadong Jiang$^1$ and Alexandru Vlad$^1$; $^1$State Key Laboratory of Electronic Thin Films and Integrated Devices, University of Electronic Science and Technology of China (UESTC), Chengdu, China; $^2$Institute of Condensed Matter and Nanosciences, Université Catholique de Louvain, Louvain-la-Neuve, Belgium.

Functional and structural tailoring of three-dimensional (3D) conducting polymer nanoarchitectures is a promising route but remains challenging to develop high-performance electrodes for electrochemical energy storage. Herein, we design poly(3, 4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) 3D mesoporous aerogel electrodes through a simple and original one-pot mechanochemical processing route. The hierarchical structure of neat PEDOT:PSS aerogel displays a highly interpenetrated porous conductive network with a record high active surface area of 470$^2$ g$^{-1}$ amongst the class of conducting polymer architectures. Robust structural and electrochemical performances are achieved with high gravimetric, areal and volumetric capacitance metrics of 120 F/g, 2.5 F cm$^{-2}$, and 124 F cm$^{-3}$, respectively, as the result of a mixed hybrid faradic - capacitive charge storage mechanism. Moreover, these performances are attained in organic based electrolytes, reported so far to be incompatible or hinder the electrochemical activity of PEDOT:PSS. We undermine the fundamentals of the electrochemical operation in these electrodes and show that the electrolyte chemistry and the aerogel morphology particularly impact the charge storage performances demonstrating the superiority of the mesoporous architecture for charge transfer and ion exchange. Asymmetric cells are built having a specific capacitance of 40 F/g based on the total mass of electrodes and a good cyclic stability with 90%
A new memory device that can be switched between high and low open-circuit voltages, Vol-RAM, has recently been proposed [1]. Vol-RAM has a laminated structure of Li, amorphous solid electrolyte Li3PO4 and Au, and may be able to achieve higher performance than other memory devices in terms of power consumption and integration. Elucidation of microscopic elementary processes during its operation is strongly desired for practical application. Since it has already been found that the Li ion distribution in Li3PO4 and Li3PO4/Au interface differs between the two voltage states, the next important issue that should be clarified is the behavior of Li ions in Li3PO4 under applied voltages, in other words, under electric fields. First-principles molecular dynamics (MD) simulations would be powerful to study this, but are computationally expensive. On the other hand, the computational cost of MD simulations using empirical potentials is cheap, but determination of their functional forms and parameters to achieve sufficient reliability is extremely difficult. Considering this situation, we have been trying to tackle with this issue using the high-dimensional Neural Network (NN) potential [2], which is expected to achieve high reliability and low computational cost simultaneously. Since the NN potential of Li3PO4 has already been constructed in our previous study [3], we focus on the inclusion of the effects of voltage application in the NN potential in the present study. Using simulations within the density functional theory with VASP package, we examined the dependence of the forces acting on atoms on the structure and applied electric field, and found the followings. First, the change in the force acting on the atom is proportional to the electric field. Second, the proportional coefficient shows a strong correlation with Born effective charge. Third, the Born effective charge correlates with the features of the local atomic structure. These results suggest that NN to predict the Born effective charge from the atomic arrangement information can be constructed, and the NN potential taking account of the effect of applied electric fields can be constructed using the NN for the Born effective charge. We have already constructed a preliminary NN for the Born effective charge, though its accuracy is insufficient. Its improvement is in progress.

8:00 AM ET01.09.01 Microstructural Exploration of Solid-State Electrolytes for Dendrite Suppression—Towards a Reliable Mechanical and Electrochemical Performance Xiaomei Zeng1, Andrew J. Martinolich2, Kimberly A. See2 and Katherine T. Faber1, 1Applied Physics and Materials Science, California Institute of Technology, Pasadena, California, United States; 2Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, California, United States.

The garnet-type oxide Li$_2$La$_{2/3}$Zr$_2$O$_7$ (LLZO) is one of the most promising candidates as a solid-state electrolyte in lithium ion batteries, due to its unique combination of high ionic conductivity (up to ~1.8 mS/cm), and good chemical and electrochemical stability with lithium metal or lithium-containing compounds. The high mechanical strength and shear modulus of LLZO were believed to be adequate for suppressing the formation of lithium dendrites, which is a major challenge in lithium ion battery design. However, recent research reported that the flaws in the polycrystalline microstructure, such as the grain boundaries and interconnected pores, still serve as pathways for lithium dendrite formation and lead to short-circuit in the battery. These boundaries and pores produce dendrite nucleation sites at the electrode/electrolyte interface and their propagation within the electrolyte. Though numerous studies have been conducted to modify the electrode/electrolyte interface to achieve uniform current distribution and suppress the nucleation of dendrites, limited effort has been devoted to optimizing the LLZO microstructure to obtain a robust electrolyte. In this work, we systematically explored the parameters controlling densification and grain growth of LLZO during synthesis. It was discovered that particle agglomeration is responsible for the formation of large cavities and interconnected pores along grain boundaries. The grain size was found to be limited by powder size and moisture content on the powder surface. Through high energy ball milling and freeze drying, nanoscale powders without agglomeration were successfully obtained, which sinter into dense LLZO electrolyte with a relative density > 97% and a grain size > 200 μm. This combination of large grain size and strong grain boundary without interconnected pores significantly enhances the mechanical and electrochemical reliability of the electrolyte. As a result, lithium dendrites were effectively suppressed under high current density > 0.5 mA/cm$^2$. This type of robust electrolyte is critical for the development of all-solid-state batteries to have reliable cyclic performance.

8:15 AM ET01.09.02 Probing the H$^+$ and Li$^+$ Ion Mobility in (Li$_{2/3}$H$_{0.25}$Al$_{0.25}$)La$_{2}$Zr$_2$O$_7$: Through Comprehensive Neutron Scattering and Advanced Electron Microscopy Xiaoming Liu1, Yan Chen1, Cheng Ma1, Zachary D. Hood1, Bui Wang1, Ke An2, Jeff Sakamoto2, Yongjiang Cheng1, Niina Jalarvo1 and Miaofang Chi1; 1Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2University of Science and Technology of China, Heifei, China; 3University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States.

Though liquid-based lithium-ion batteries are ubiquitous to our daily life, they are reaching their theoretical limits in terms of their energy and power densities. New battery configurations are urgently needed to meet the requirements for large-scale applications, especially in applications where the power densities are relatively high (e.g. electric vehicles, grid energy storage systems, etc.). Aqueous lithium batteries are considered to be one of the most promising solutions due to their low cost, high rate capability, and their prospect in utilizing metallic lithium, the solid-state anode with highest theoretical capacity and lowest electrochemical potential. Recently, it was reported that the garnet-based Li$_{0.25}$Al$_{0.25}$La$_{2}$Zr$_2$O$_7$ (LLZO) shows excellent structural stability towards exposure to aqueous solutions with a large range of pH value, with Li$^+$ ions being partially substituted by H$^+$, demonstrating its promise to be used as a separator to stabilizing Li metal in aqueous lithium batteries. However, the mobility of Li$^+$ and H$^+$ ions in protonated LLZO (H$_x$-LLZO), that critically determines the performance of LLZO, has yet to be investigated. This work is largely due to the challenges in differentiating the diffusion of
the two ions. In this work, we successfully reveal not only the structural evolution after ion exchange in Hx-LLZO, but also the mobility of H+ and Li+ ions by combining high-resolution scanning transmission electron microscopy (STEM), neutron diffraction, and electron energy loss spectroscopy. Our results show that the H+ ions in Hx-LLZO are largely immobile at temperatures less than 200 °C while the Li+ ions remains mobile in the structure. The activation energy of Li+ ions in protonated LLZO is about 20.08 kJ/mol at room temperature, which is ~1.5× that of pristine LLZO, indicating a reasonable Li+ ion conductivity in Hx-LLZO. Our results highlight the potential of LLZO as a separation layer to protect metallic lithium anode in aqueous lithium batteries.

8:30 AM ET01.09.03
Direct Growth of 3D Host on Cu Foil for Stable Lithium Metal Anode Xiaogang Han¹, Fei Shen¹ and Xuchun Gui²; ¹Xi'an Jiaotong University, Xi'an, China; ²Sun Yat-sen University, Guangzhou, China.

Due to light-weight and high specific capacity, lithium (Li) metal anode has been regarded as the “Holy Graal” for lithium-ion based batteries. However, the issues of mossy and dendritic Li formation and infinite volume expansion, leading to low Coulombic efficiency and poor cycling performance, retards Li metal anode application in practice. Effort should be done to address the issues in order to the application of Li metal anode. In this study, we report a novel design to stabilize Li metal anode by growing porous carbon nanotube (CNT) sponge directly on Cu foil, (C-host@Cu), where CNT sponge as host and Cu foil as current collector. The intrinsic porous feature of CNT sponge meets the requirements for an outstanding Li host: 1) high porosity to accommodate infinite volume change of Li; 2) low local current density to suppress Li dendrite formation; 3) stable and electrically conductive framework for Li deposition during long-term cycles; 4) strong seamless attachment to the current collector. The as-designed 3D host Li metal anode exhibits stable cycling performance with high Coulombic efficiency ~99% at a current density of 1 mA/cm² over 250 cycles. In contrast, the bare Cu electrode presents a mossy-like morphology with a low Coulombic efficiency ~60% after 150 cycles. The results reveal that the effective confinement of Li deposition in this unique 3D host successfully suppresses the growth of Li dendrites.

Simulations of Ionic Transport in Disordered and Correlated Solid Polymer and Amorphous Ceramic Electrolytes Boris Kozinsky¹, ², Chris Ablitt¹, ², Mordechai Kornbluth¹, Jonathan Mailoa¹ and Nicola Molinari²; ¹Harvard University, Cambridge, Massachusetts, United States; ²Imperial College London, London, United Kingdom; ³Bosch Research, Cambridge, Massachusetts, United States.

Materials design for next-generation solid-state Li-ion batteries require atomistic-level understanding of ionic transport mechanisms and the required ingredients and design principles for enabling high ionic conductivity in solid-state materials at room temperature. Strong ion-ion interaction, geometric frustration, disorder and collective motion are emerging as common themes in recent investigations of super-ionic materials. In this talk, we present recent efforts to gain mechanistic understanding of the influence of correlation, disorder and frustration on ionic transport in solid polymer and ceramic materials. We find that ionic dynamics in polymer electrolytes is strongly influenced by the host polymer dynamics and the strong coupling between mobile component species and the host polymer. In the domain of inorganic electrolytes, the success of LiPON thin films indicates promise of amorphous materials, which are known to have different transport properties than their crystalline counterparts. Using atomistic simulations of ion dynamics, we analyze ionic transport mechanisms in the presence of disorder, using insights to develop design rules for optimizing structure and composition of glassy electrolytes.

9:30 AM ET01.09.05
Electrochemical Characterization of Ionic Liquid Electrolytes for Printed Secondary Zinc-Manganese Dioxide Batteries Bernard Kim¹, James W. Evans² and Paul K. Wright³; ¹Mechanical Engineering, University of California, Berkeley, Berkeley, California, United States; ²Materials Science and Engineering, University of California, Berkeley, Berkeley, California, United States.

Ionic liquids are room temperature solutions of cations and anions that have emerged as possible electrolyte materials for batteries due to their wide thermal and electrical potential stability windows relative to conventional electrolytes [1]. In the case of zinc-based batteries, their use has been shown to enable reversible cycling with traditional electrode materials, unlike cycling in aqueous electrolytes [2]. Furthermore, their extremely low vapor pressure allows for integration with a polymer to form a printable, monolithic gel polymer electrolyte which can function both as a mechanical separator as well as an ion conductor [3]. However, the vast array of possible cation and anion pairs making up each ionic liquid as well as each pair’s compatibility with supporting metal salts reveals a significant challenge in characterizing all possible combinations for optimal performance in full cells. Specifically, this work seeks to identify optimal ratios of ionic liquid, supporting metal salt, and gel polymer in order to maximize redox currents as well as mitigate losses associated with repeated cycling.

This work is conducted in two parts. The first part determines the diffusion coefficient of Zn²+ and the peak currents, solution resistance, and redox potentials of Zn/Zn²⁺ in solutions of only ionic liquid and zinc salt. The second part determines the solution resistance and characterizes the reversibility of gel polymer electrolytes with varying compositions of ionic liquid, zinc salt, and polymer binder. Cyclic voltammetry and electrochemical impedance spectroscopy are used to determine constant values and characterize material compositions.

Ionic liquids with smaller cations demonstrate higher peak currents in cyclic voltammograms, but they also exhibit narrower potential stability windows with higher rates of unwanted reactions within the Zn/Zn²⁺ redox window. Gel polymer electrolytes demonstrate good reversibility for at least 50 cycles and solution resistances comparable with the pure ionic liquids.

A Mechanism for Lithium Metal Penetration Through Solid Electrolytes—Atomic Simulations for Grain Boundary Softening Seungho Yu and Donald Siegel; University of Michigan--Ann Arbor, Ann Arbor, Michigan, United States.

Models based on linear elasticity suggest that a solid electrolyte with a high shear modulus will suppress ‘dendrite’ formation in batteries that use metallic...
We present a quantitative analysis of mechanical reliability of composite electrodes. We quantify the mechanical stress caused by chemical expansion and accommodate intercalation-induced deformations. Consequently, the effective ionic conductivity is expected to reduce. Second, interfacial delamination reduces internal contact and may become the kinetic link to the battery power-density. Low porosity solid-state composite electrodes are generally more prone to mechanical degradation if not designed to accommodate inhomogeneities in elastic properties arising from microstructural features.

This talk will review the concept and fabrication of all-solid-state Li-ion microbatteries using TiO$_2$nts as negative electrode [1-7]. Effects of material selection and processing on the performance and reliability are presented as a means to develop conceptual guidelines to understand and improve microbattery designs. Fundamentals such as electrode reactions, lithium ion diffusion and the conformal electrodeposition mechanism of polymer electrolytes onto the nanostructured electrodes will be presented. The fabrication of a full 3D microwell showing high electrochemical performance will be presented and the development of the next generation of 3D microbatteries will be discussed.

Li$_3$SnZr(PO$_4$)$_3$: NASICON-Type Solid Electrolyte for Lithium Batteries Sunil Kumar, Tanvi Pareek and Sushmita Dwivedi; Metallurgy Engineering and Materials Science, Indian Institute of Technology Indore, Indore, India.

Safety issues associated with the high flammability and volatility of organic electrolytes used in commercial rechargeable lithium-ion batteries has led to significant attention to ceramic-based solid electrolytes. In this work, Li$_3$SnZr(PO$_4$)$_3$ (LSZP) ceramics were fabricated via a sol-gel route and were characterized for their properties using the X-ray diffraction, Raman spectroscopy, X-ray photoelectron spectroscopy, and electrochemical chemical impedance spectroscopy. Rietveld refinement of synchrotron X-ray diffraction data confirmed the room temperature crystal structure of Li$_3$SnZr(PO$_4$)$_3$ as rhombohedral (R-3c space group). The Zr 3d, Sn 3d, P 2p, Li 1s and O 1s, core level X-ray photoelectron spectra associated with different valence states on the LSZP sample were deconvoluted. Surface morphology, densification, and the ionic conductivity of ceramics sintered at various temperatures were investigated. LSZP ceramics sintered at 1273 K exhibited an excellent room temperature bulk ionic conductivity of about $10^{-3}$ S cm$^{-1}$ and associated activation energy ~ 0.36 eV in the temperature range of 300 – 500 K. DC polarization study confirmed the conductivity of LSZP ceramics as predominantly ionic. Distinct relaxations observed in dielectric and modulus formalisms and the temperature dependence thereof are also discussed.

11:15 AM ET01.09.09
Fluorinated Solid Electrolyte Interphase Enables Highly Reversible Solid-State Li Metal Battery Xiulin Fan, Xiao Ji, Fudong Han, Jie Yue, Ji Chen and Chunsheng Wang; University of Maryland, College Park, College Park, Maryland, United States.

Solid-state electrolytes (SSEs) have received great interest in recent years due to the escalating demands for the next-generation high energy battery technologies. However, the facile formation of the Li dendrite in the SSEs with much lower critical current density of only 1/10 of the conventional non-aqueous electrolytes hindered the possible commercialization of the high energy SSE Li metal batteries. Herein, we describe a simple and efficient strategy to stabilize the Li metal anode in the SSE batteries by in situ forming an efficient LiF-rich solid electrolyte interphase (SEI) layer between the SSE and the Li metal. This LiF-rich SEI layer not only effectively blocks electron leakage but also efficiently facilitates Li transport along the interface and suppresses the penetration of Li dendrite into the SSE.

11:30 AM ET01.09.10
Electro-Chemo-Mechanical Stability of Solid-State Battery Interfaces Giovanna Bassì$^{1,2}$, Peter K. Hart$^{1}$, Yet-Ming Chiang$^{3}$ and Craig Carter$^{1}$; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; $^{2}$Energy Storage, Bosch, Sunnyvale, California, United States; $^{3}$Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Despite the progress in achieving high solid-electrolyte bulk conductivity, the rate capability of many all-solid-state batteries (ASSBs) remains poor. This is typically ascribed to various interfacial phenomena, including chemo-mechanical instability of composite electrodes and unstable metallic lithium interfaces. Such mechanisms are difficult to ascertain and characterize experimentally.

Fracture in solid Li-ion conductors represents a barrier for Li transport, and accelerates the decay of rate performance. Therefore, mechanical degradation is linked to the battery power density. Low porosity solid-state composite electrodes are generally more prone to mechanical degradation if not designed to accommodate intercalation-induced deformations.

We present a quantitative analysis of mechanical reliability of composite electrodes. We quantify the mechanical stress caused by chemical expansion and contraction of electrode particles and identify two main degradation mechanisms. First, the formation of micro-cracks within the solid electrolyte (SE) is expected to reduce the SE effective ionic conductivity [1, 2, 4]. Second, interfacial delamination reduces internal contact and may become the kinetic resistance.
Our analyses lead to guidelines for the engineering of particle size, volume ratio of active material, interfacial cohesion and the electrolyte mechanical properties [2-5]. The impact of mechanical degradation on an electrode's transport properties will also be discussed. In particular, we illustrate, via random-walk analysis, how micro-cracking of solid-Li-ion conductors increases the cell tortuosity, especially in densely packed microstructures [4, 5].

Finally, we explore the interplay of surface geometry and interfacial resistance in the Li-metal cells. Electric field magnification at the tip of surface defects and grain boundaries may lead to a largely non-uniform current density and localized Li-plating. Strategies for current density regularization are investigated. For instance, mechanical confinement causes pressure to rise within the Li metal filling a crack. Exploiting stress-potential coupling, such pressure can prevent further plating and divert deposition away from the crack tip. The model predicts the limiting conditions that hinder Li plating at the crack tip and prevent further electrolyte’s fracturing.

Intrinsic Improvement of LLZO Solid-State Electrolyte to Suppress Li Dendrite Formation
Yulia Arinicheva1, Juliane F. Nonemacher2, Fadli Rohman2, Maria Meledina1, Chih-Long Tsai1, Alexander Schwedt1, Joachim Mayer1, Jürgen Malzbender2, Dina Fattakhova-Rohlfing1, Olivier Guillou1 and Martin Finistenрубucher1; 1Forschungszentrum Jülich GmbH, Institute of Energy and Climate Research Materials Synthesis and Processing (IEK-1), Jülich, Germany; 2Forschungszentrum Jülich GmbH, Institute of Energy and Climate Research: Microstructure and Properties of Materials (IEK-2), Jülich, Germany; 3Central Facility for Electron Microscopy, RWTH Aachen University, Aachen, Germany.

After the unexpected discovery of similar metal dendrite issues in dense ceramic electrolytes as in conventional liquid ones, the key factors governing the Li dendrite formation e.g. in LLZO are still not fully understood. Possible factors include lithium ion diffusion kinetics at grain boundaries, influenced by microstructure [1, 2] and density [3], as well as inhomogeneous contact between LLZO solid electrolyte and Li electrodes, leading to high contact resistance. Multiple strategies can be employed to reduce the contact resistance: first, the surface can be treated in order to remove LiOH/Li2CO3-contamination [4], second, the effective contact area can be increased [5] and third, surface defects can be reduced [6], and finally, the surface can be coated to increase the wettability [7-9].

To elucidate the interdependence of the various possibilities, the present work focuses on the effect of doping, microstructure, surface properties and density of the Li0.66La3Zr1.6Ta0.4O12 solid state electrolyte on its electrochemical performance, especially the resistance to dendrite penetration. Al-doped and Al-free LLZO:Ta precursor powders with larger (~5 μm) and nano-sized particles were synthesized via solid-state synthesis and solution-assisted solid-state synthesis, respectively. LLZO:Ta pellets with high density (~99% of the theoretical density), high conductivity (~10⁻⁴ S/cm ) and various grain sizes were obtained for both precursor powders by hot pressing. The grain size dependence of mechanical properties (fracture toughness, micro hardness, Young modulus), ionic conductivity, cycling stability, stability in contact with humid air on microstructure was investigated. The conductivity was separated into grain and grain boundary contributions. Activation energies of polycrystalline conductivity for the samples with larger and smaller grains were determined. Lower interfacial resistances and better cycling behaviour was found and attributed to surface quality and mechanical properties of the material.

Structure and Ion Transport at Polymer-Ceramic Electrolyte Interface
Xi C. Chen, Amaresh Samuthira Pandian, Xiaoming Liu, Robert Sacci, Gabriel Verith and Nancy J. Dudney; Oak Ridge National Lab, Oak Ridge, Tennessee, United States.

Composite solid electrolytes consisting of a polymer electrolyte and a ceramic electrolyte are promising in meeting the challenging requirements to stabilize lithium metal anode to achieve high energy density. The requirements include high ionic conductivity, high shear modulus, good chemical stability and adhesion with metallic lithium. When the components act synergistically, composite electrolytes may overcome the intrinsic weaknesses of single component electrolytes such as brittleness of ceramic electrolytes and low shear modulus of polymer electrolytes. However, composite electrolytes with high ceramic loadings suffer from low ionic conductivity due to a large interfacial resistance for ion transport [1, 2] The origin of this interfacial resistance is not well-understood.

This work focuses on understanding ion transport at the interface between polymer electrolyte and ceramic electrolyte. Polymer-ceramic-polymer electrolyte (trilayer) cell is constructed to study the interfacial resistance between the polymer and ceramic electrolyte. Sintered ceramic plate from Ohara corporation is sandwiched between two thin layers of polymer electrolyte (poly(ethylene oxide) + lithium triflate salt) obtained by spray coating. The interfacial resistance is determined by analyzing the impedance spectra of single layer ceramic plate, single layer polymer electrolyte and the trilayer sample. We discovered that at 30 °C, the interfacial resistance is as high as 10000 Ohm. As an effort to decrease the interfacial resistance, plasticizers such
as tetraethylene glycol dimethyl ether (TEGDME) and dimethyl carbonate (DMC) are infused into the polymer electrolyte of the trilayer cell. Both plasticizers enhance the ionic conductivity of the polymer electrolyte but have limited effects on facilitating ion transport across the polymer-ceramic interface. The structure of polymer electrolyte at the polymer-ceramic interface is examined with depth-profiling infrared spectroscopy and neutron reflectometry in order to shed light on the origin of this large interfacial resistance.

Structure, Chemistry and Charge Transfer Resistance of the Interface Between Garnet Solid Electrolyte and Oxide Cathodes Bilge Yildiz, Gulin Vardar, Younggyu Kim and Yet-Ming Chiang, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

All-solid-state batteries promise significant safety and energy density advantages over liquid-electrolyte batteries. The interface between the cathode and the solid electrolyte is an important contributor to charge transfer resistance. Strong bonding of solid oxide electrolytes and cathodes requires sintering at elevated temperatures. Knowledge of the temperature dependence of the composition and charge transfer properties of this interface is important for determining the ideal sintering conditions. To understand the interfacial decomposition processes and their onset temperatures, model systems of LiCoO2 (LCO) thin films deposited on cubic Al-doped Li3La2Zr2O7 (LLZO) pellets were studied as a function of temperature using interface-sensitive techniques. X-ray photoelectron spectroscopy (XPS), secondary ion mass spectroscopy (SIMS), and energy-dispersive X-ray spectroscopy (EDS) data indicated significant cation interdiffusion and structural changes starting at temperatures as low as 300°C. La2Zr2O7 and Li2CO3 were identified as decomposition products after annealing at 500°C by synchrotron X-ray diffraction (XRD). X-ray absorption spectroscopy (XAS) results indicate the presence of also LaCoO3, in addition to La2Zr2O7 and Li2CO3. Based on electrochemical impedance spectroscopy, and depth profiling of the Li distribution decomposition products after annealing at 500°C, the interfaces exhibited significantly increased impedance, up to 8 times that of the as-deposited samples after annealing at 500°C. This work was primarily supported by the U. S. Department of Energy (DOE-EERE), Vehicle Technologies Office (Advanced Battery Materials Research, Tien Du-Duong). We thank Brion Hoffman, Ohara Corporation, for supplying ceramic electrolyte powders.

Fracture Toughness Improvements and Lithium Metal Penetration in Nanocomposite Ceramic Electrolytes Maria C. Ramirez, Mok Yun Jin and Brian W. Sheldon; Brown University, Providence, Rhode Island, United States.

The relatively low fracture toughness of ceramic solid oxide electrolytes can significantly limit battery performance and reliability. While small dimensions are generally needed for faster ion transport, these length scales also restrict the approaches that can be used to improve fracture resistance. Nanoscale reinforcements are thus a logical option for improving the fracture resistance of ceramic electrolytes. Graphene oxide and reduced graphene oxide have been successfully used to reinforce a variety of polymer and engineering ceramics, where significant changes in the elastic modulus and toughness have been obtained with relatively low volume fractions. In the present work, we explore the reinforcement capability of small amounts of graphene oxide added to oxide-based lithium ion conductors. Standard electrochemical measurements were used to measure ionic and electrical conductivities. Fracture toughness measurements on both large and small scale specimens were then employed, to provide detailed information about the mechanical properties of these materials.

Effects of Electrochemical Cycling on the Mechanical Behavior of High Purity Lithium Erik G. Herbert1, Stephen A. Hackney1, Nancy J. Dudney2 and Fereshette Mallakpour3; 1Michigan Technological University, Houghton, Michigan, United States; 2Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Nanindentation experiments have been performed in high purity vapor deposited and electrochemically cycled lithium. At a homologous temperature of 0.66, the measured hardness is found to depend significantly on the indentation depth and strain rate, and is studied as a function of cycling conditions. The experimental observations are rationalized in terms of lithium’s evolving dislocation density, Nabarro-Herring and Harper-Dorn creep and dislocation mediated flow. In well-annealed, low dislocation density lithium, it is surmised that dislocation motion is initiated by the activation of a Frank-Read source. Prior to dislocation motion, the plastic deformation is taken to be controlled by self-diffusion to the free surface and/or preexisting dislocations. Collectively, the proposed rationalizations provide a novel framework to better understand the complex relationship between electrochemical cycling, the dislocation density and the mechanisms that control pressure within submicron scale defects at the lithium/solid electrolyte interface. Moreover, the experimental observations and mechanistic rationalizations provide new insight into the mechanisms capable of causing mechanical failure of a solid electrolyte.

Beyond Dendrites, Cycling Li-Metal Across Garnet at High Current Densities Eric D. Wachsman; Maryland Energy Innovation Institute, University of Maryland, College Park, Maryland, United States.

Solid-state Li-batteries (SSLiBs) have the potential to be a transformational and intrinsically safe energy storage solution. However, their progress has been limited by high solid-solid interfacial impedance and numerous reports of Li-dendrites and a corresponding “critical current density”. By first modifying the garnet surface to enable Li-metal to wet it and then fabricating garnet-electrolytes into tailored tri-layer microstructures to form electrode supported dense thin-film (~10μm) solid-state electrolytes we have been able to overcome these limitations. The microstructurally tailored porous garnet scaffold support improves electrode/electrolyte interfacial area, overcoming the high impedance typical of planar geometry SSLiBs resulting in an area specific resistance (ASR) of only ~2 to 7 Ωcm² at room temperature. The unique garnet scaffold/electrolyte/scaffold structure further allows for charge/discharge of the Li-metal anode and cathode scaffolds by pore-filling, thus providing high depth of discharge ability without mechanical cycling fatigue seen with typical electrodes. Moreover, the scalable multilayer ceramic fabrication techniques, without need for dry rooms or vacuum equipment, provide for dramatically reduced manufacturing cost.

The fabrication of supported dense thin-film garnet electrolytes, their ability to cycle Li-metal at high current densities with no dendrite formation, and results for Li-metal anode/garnet-electrolyte based batteries with a number of different cathode chemistries will be presented.
Enhancing Stability Between Garnet Electrolyte and Li Metal Electrode with a Metal Carbide Coating

Fengyu Shen, Mamid Dixit, Wahid Zaman and Kelsey B. Hatzell, Vanderbilt University, Nashville, Tennessee, United States.

Overcoming large interfacial resistances at electrode/electrolyte interfaces is a major challenge facing all-solid-state batteries. To alleviate this challenge, there has been a significant push toward manufacturing and processing monolayer thin films and coatings at solid electrolyte interfaces [1, 2]. Typically, atomic layer deposition has been the manufacturing approach used within the solid electrolyte community. While effective, this process increases the cost of processing solid electrolytes [1, 3]. Herein, we explore a facile coating process where colloidal low-dimensional metal carbide materials are deposited on the solid electrolyte with a spray coater. The effects of spray coating sub-micron scale metal carbide coatings directly on Li10YS2La203-δZrO2 (LLZO) electrolytes to decrease the interfacial resistance are investigated. Electrochemical characterization reveals that the growth rate of interface resistance for the coated LLZO is almost one order of magnitude smaller than that of the bare LLZO. The wettability of Li on LLZO electrolyte is enhanced and a greater electrochemical window is obtained. The critical current density is improved 2x with the metal carbide coating at room temperature and the capacity of LiTi4S2/LLZO/Li cell is stabilized. This work demonstrates a facile and scalable way of coating ceramic electrolytes for low interfacial resistances.

Intercalation Induced Mechanical Failure of Olivine Compounds

Ananya Renuka Balakrishna1, Christian Henrikss2, Kai Xiang1, Dothe B. Ravnsbaek2, Ming Tang1, Craig Carter1 and Yet-Ming Chiang1; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2University of Southern Denmark, Odense M, Denmark; 3Rice University, Houston, Texas, United States.

When electrodes fail mechanically, it affects a battery's capacity, rate capability and lifetime. In ion storage compounds, mechanical failure typically occurs after ion intercalation changes the electrode's volume. These volume changes increase the elastic energy stored in electrodes. Sometimes, electrodes crack to relieve this stored elastic energy. Electrode cracking can be mitigated by reducing the electrode particle size [1], by doping electrode compounds [2] and by operating at low overpotentials [3]. Our recent experiments show that when crack propagation is suppressed, olivine compounds such as NaFePO4 and NaMnFe203-P2O7 release their stored elastic energy by forming a disordered phase [4].

Here, we identify the critical particle size at which electrode cracking and amorization are suppressed. To that end, we use olivine compounds, such as LiFePO4, NaFePO4, LiMnFe203-P2O7, and NaMnFe203-P2O7, as model systems. We compute the elastic energy stored in electrodes analytically as a function of particle size and lattice constant. Furthermore, we compare the electrodes' stored energy with the energy required to form new surfaces (fracture) or a disordered phase (amorization). This analysis results in a narrow range of particle sizes at which olivine compounds neither crack nor amorize. The present research provides insight into the effects of scaling, lattice strains, and glass-former conditions on the mechanical stability of intercalation electrodes.

Rational Design of Nanostructures in Solid Polymer Electrolyte

Snehashis Choudhury and Lynden Archer; Cornell University, Ithaca, New York, United States.

Metal based batteries that comprise of a reactive metal anode like lithium, sodium or potassium are the future of energy storage devices because of their high volumetric and gravimetric energy density. However, these batteries fail by three distinct modes – chemical instability due to internal reactions, morphological instability due to uneven electrodeposition and hydrodynamic instability due to convective flows at the vicinity of electrode-electrolyte interface. Both liquid based, and solid-state electrolytes have their individual advantages and disadvantages in mitigating these issues. In this work, we show that solid-polymer interphases based on crosslinked polymer networks can essentially possess qualities from both of these worlds. We find that by tuning the thermodynamic interactions between the polymer network and oligomer diluents, one can control the bulk properties like ion transport and mass transfer rate. Thus, it is possible to design solid-like electrolyte-phases where the electroconvective flows can be inhibited, while maintaining high ionic conductivity. We further show that these polymer networks act as excellent interfacial layer for lithium metal electrode to inhibit dendrite growth and side reactions. On pairing with high voltage cathodes, the lithium metal battery exhibit over 250 cycles of stable operation even at high current densities.

Organic Radical Thin-Film Batteries with Solid-State Electrode

Roland Roese1, 2, Philip Zimmer1, 2, Raik Zacharias1, 2, Tina Mede1, 2, Ulrich S. Schubert1, 2 and Harald Hoppe1, 2; 1Center for Energy and Environmental Chemistry Jena (CEEC Jena), FSU Jena, Jena, Germany; 2Laboratory of Organic and Macromolecular Chemistry (IOMC), FSU Jena, Jena, Germany.

All-solid state thin film batteries with organic radical polymer electrodes, such as TEMPO (2,2,6,6-tetramethyl-4-piperidinyl-N-oxyl radical) [1] and TCAQ (tetraacyano-9,10-anthraquinonedimethane) [2] are demonstrated. These electrodes as well as the solid-state electrolyte were cast from solution respectively liquid-phase, which was enabled by use of orthogonal solvent systems. The thickness of all functional films within this device as well as the...
solid-state electrolyte were systematically varied in order to understand performance limiting factors, such as limited charge or ionic conductivity. For analysis of the same, impedance spectroscopy was applied. Finally, charging and discharging kinetics are presented and linked with an optimized device layout.

SYMPOSIUM ET02

TUTORIAL: High-Efficiency Crystalline Silicon Photovoltaics—Fabrication, Devices, and Testing
November 25 - November 25, 2018

* Invited Paper

Silicon and related thin films are applied widely in solar cells and other electronic devices. This tutorial will introduce the preparation methods, materials properties, fundamental Si surface chemistry, and device engineering. This will be followed by a review of the device physics of solar cells and the device output characteristics during testing. We shall also survey different monocrystalline Si solar cell architectures, with special emphasis on interdigitated back contact cells and the use of carrier-selective passivating contacts in advanced cell designs. Finally, we will discuss the physics of carrier lifetime and efficiency measurements in silicon solar cells and modules.

1:30 PM
Crystalline Si Growth, Surface Chemistry, and Passivation Sumit Agarwal; Colorado School of Mines

Overview of c-Si growth, converting SiO2 to c-Si wafers; single and multi-crystalline Si; effect of oxygen in p-type Si solar cells; passivated of c-Si; H-terminated silicon surfaces; and structure and properties of the c-Si/SiO2 and c-Si/Al2O3 interfaces.

2:15 PM
Device Physics of Solar Cells Ron Sinton; Sinton Instruments

Silicon solar cells are converging on high efficiency devices. For these the device physics is tremendously simplified, well described by a formalism first developed for high-efficiency n-type concentrator solar cells. This description, based on balancing photogeneration with recombination, gives simple insight into the operation of all modern solar cells, with extensions relevant to the interpretation of test data as well.

3:00 PM BREAK

3:30 PM
High-Efficiency Approaches for Monocrystalline Si Solar Cells Sumit Agarwal; Colorado School of Mines

Standard Al back surface field silicon solar cells; p-type PERC cells, light induced degradation and regeneration; methods for creating passivated contacts; interdigitated back contact Si solar cells; and HIT cells.

4:15 PM
Test and Measurement of Silicon Ingots, Wafers, Cells, and Modules Ron Sinton; Sinton Instruments

This section will focus on minority-carrier lifetime measurements as a tool for monitoring and optimizing device design and process optimization at each step in the production process. The difficulties in measuring the new generations of high-efficiency solar cells and modules will be discussed in detail.
Invited Paper

Interactions with the main R&D actors in the SHJ community, through collaborative projects. Three contributions of our group to this interesting research field will be reported: First, theoretical investigations of the current transport mechanism. Passivating contacts based on a stack of polycrystalline (poly-) Si on a thin interfacial oxide (POLO) are attracting enormous research interest in crystalline Solid State Physics, Leibniz Universität Hannover, Hannover, Germany. Moreover, intense R&D activities are focusing on new paths to further boost the efficiency, in the field of materials, integration, processes and new architectures thanks to the know-how developed at CEA in the field of organic, perovskite, microelectronics and materials and thanks to efficient interactions with the main R&D actors in the SHJ community, through collaborative projects.

SESSION ET02.01: Poly-Silicon Contacts I

8:30 AM *ET02.01.01
In-Depth Study of poly-Si / Oxide / c-Si Junctions and p+ poly-Si / n+ poly-Si Tunneling Junctions for Applications in Si Single Junction and Si-Based Tandem Cells
Robby Peibst1, 2, Nils Folchert1, Felix Haase1, Christina Klamt1, 3, Yevgeniya Larionova1, Jan Krügener2, Agnes Merkle1, Byungsul Min1, Michael Rienäcker1, Udo Römer1, Sören Schäfer1, Dominic Tetzlaff2, Tobias Wietler1, 2 and Rolf Brendel1, 3; 1Institute for Solar Energy Research INES as one of the main European actors in the SHJ development.

In this work, an overview of the amorphous/crystalline (SHJ) activity performed at CEA-INES during the last 15 years will be presented. First, the ramping-up of R&D developments allowed us to unlock the path to > 21% efficiencies in 2011. These results were obtained through a core understanding of the technology to overcome its main limitations and drawbacks, from the silicon material up to metallization. Back then, this placed CEA-INER as one of the main European actors in the SHJ development.

Then (2012-2016), these developments were taken to the next level through the startup of the first pilot-line (1200 wph) that brought the devices to a mature technology. This second step got us familiar with production constraints and associated issues such as defectivity, silicon material impact, and reproducibility or tack-time constraints. A milestone was an R&D record bifacial cell >23% with median efficiencies around 21% in production, along with >300W on 60-cells modules thanks to associated module development.

The third phase (2016-present) based on the new generation of MeyerBurger tools (2400wph) is ongoing, demonstrating the potential of the technology in a ready-to-market approach. Median efficiencies >21.5% in a 4-busbar and >22.5% in a busbarless technology on bifacial devices are demonstrated. R&D record cells surpassing 23.5% efficiency are also systematically obtained (up to 23.8%) using R&D processes on top quality Cz wafers. Bifacial GG modules over 380W on a 72-cells are demonstrated and transfer is ongoing towards ENEL and others. A record-breaking 410W module was also recently achieved on a GBS configuration coupling the SwartWire technology and top efficiency SHJ cells form the production line (>23.4%). Bankability studies demonstrate also the economic potential of the technology.

Moreover, intense R&D activities are focusing on new paths to further boost the efficiency, in the field of materials, integration, processes and new architectures thanks to the know-how developed at CEA in the field of organic, perovskite, microelectronics and materials and thanks to efficient interactions with the main R&D actors in the SHJ community, through collaborative projects.

Carrier selective tunnel oxide passivated contact (TOPCon) c-Si solar cell has attracted a great attention as one of potential technologies for high efficiency c-Si module production beyond the passivated emitter rear contact solar cell (PERC) structure. Currently, the highest TOPCon solar cell efficiencies have reached 25.7% and 24.4% with N-type and P-type c-Si wafers, respectively [1,2], demonstrating the potential in efficiency improvement of solar panels. In this contribution, we will report out recent progresses in the research and development of high efficiency TOPCon solar cells, including the fabrication and optimization of SiOx passivation layer, P-doped poly-Si contact layer, Al(OH)/SiNx:H emitter passivation, and metallization, with the focus on the post-crystallization treatment effect on the passivation quality and improvement of TOPCon solar cell efficiency. The ultrathin SiOx (~1.5 nm) passivation layers were grown in 68% HNO₃ acid at 60-110°C or in a mixed/concentrated acid of 68% HNO₃+H₂SO₄ at 60°C for 15 minutes on solar grade N-type c-Si wafers, following a 40-nm thick phosphorus doped hydrogenated amorphous silicon (n-a-Si:H) deposition on both sides. The double-side passivated samples were subjected to a high temperature annealing at 820°C for crystallizing the n-a-Si:H layer to form n- poly-Si layer as the electron selective contact layer. Furthermore, various post-crystallization treatments were carried out to study the hydrogen passivation effect on the TOPCon structures by measurement the minority carrier lifetime and the implied open-circuit voltage (Voc), including forming gas annealing, hydrogenated silicon nitride (a-SiNₓ:H) coating and annealing, and atomic layer deposited Al₂O₃ coating and annealing. We found that the mixed/concentrated acid at 60°C has much stronger oxidation capability and produces more fully oxidized chemical structures with better passivation quality than the 68% HNO₃ process at 90-110°C. The relatively lower temperature oxidation process in the mixed/concentrated acid is suitable for mass production. For the hydrogenation of the TOPCon structure, the most effective method is the Al₂O₃ coating with an annealing at 450°C for 30 minutes, which results in a minority carrier lifetime of 1.5 ms at 5¹⁰¹³ cm⁻³ carrier injection, saturated reverse recombination current density J₀=1.3 pA/cm², and Voc=743 mV. Using the improved hydrogenation procedure, we attained an energy conversion efficiency of 21.2% with the 4 cm² small area and 21.0% with 243 cm² large area n-TOPCon solar cells.

Amorphous silicon / crystalline silicon heterojunction (SHJ) solar cells have historically suffered from high series resistance that stems from transport across the heterojunction. We present a systematic analysis of the contributions from each layer of an a-Si:H(i)/a-Si:H(p/n)/ITO/Ag contact stacks and show that we can reproduce the measured series resistance of SHJ cells by summing the independently measured contributions. We find that contact resistance accounts for 50-80% of the series resistance and is most sensitive to the a-Si:H(i) layer thickness and ITO doping density. For example, a 2 nm increase in the a-Si:H(i) layer thickness above its baseline value will cause a 1.5% drop in fill factor, and this in turn narrows the processing windows of silicon heterojunction cell manufacturing. As one method to reduce contact resistance, we introduce a-Si:H(i)/a-Si:H(p/n)/Al contacts in which the Al begins to alloy with the doped a-Si:H but does not spike through the passivation layer. These contacts have resistances that are two orders of magnitude lower than conventional SHJ contacts, enabling partial-area contacts without appreciable fill factor loss.

Reducing the Resistance of Heterojunction Contact Stacks in Silicon Solar Cells
Zachary Holman; Arizona State University, Tempe, Arizona, United States.

Amorphous silicon / crystalline silicon heterojunction (SHJ) solar cells are one of the most promising photovoltaic technologies owing to the outstanding passivation quality ensured by the material that will be used in real production environment. Furthermore, it was demonstrated experimentally on the CEA-INES line that screen-printing layout changes could enable efficiency improvements up to 1% abs., going from four to six busbars. Finally, we will show recent progress on the fabrication and characterization of full bifacial SHJ modules.

Reducing the Resistance of Heterojunction Contact Stacks in Silicon Solar Cells
Zachary Holman; Arizona State University, Tempe, Arizona, United States.

Reducing the Resistance of Heterojunction Contact Stacks in Silicon Solar Cells
Zachary Holman; Arizona State University, Tempe, Arizona, United States.
Our research on front-back-contacted (FBC) cells reveals that the effective minority carrier collection is essential to minimize the drop from SunsVoc to Voc. Thick doped nc-SiOx:H layers can effectively shield the device precursor from the influence of ITO’s field effect and keep its overall passivation quality after ITO sputtering. Accordingly, the best FBC device performs promising SunsVoc with 727 mV and 734 mV, pseudo-Fill Factor (pFF) of 0.862 and 0.841, measured before and after metallization, respectively. Besides, we found that adding few nanometers of doped non-oxidic nc-Si:H between the nc-SiOx:H and ITO leads to critical improvement in FF from 0.56 to 0.73. Currently, our best FBC cell exhibits η of 20.4% with JSC measured from EQE, with the potential of large step improvement in short term by enhancing the FF via minimizing the cell series resistance. Finally, we developed a novel one-step patterning process for fabricating tunneling IBC-SHJ solar cells. Since the non-HF resistant behavior of the doped nc-SiOx:H layers and the excellent HF etching selectivity to intrinsic a-Si:H material, the process enables superior chemical passivation and no patterning step for emitter due to the tunneling IBC concept. With the optimized SHJ passivating contacts, the preliminary tunneling IBC device, exhibits an η of 18.2% with a Voc of 659 mV, Jsc of 41.3 mA/cm², FF of 0.67. Further optimization of the layer thicknesses and patterning process in the second run enables much higher Voc of 715 mV over 7 cells. By addressing the low η of the non-optimized (n)nc-SiOx:H, which limits the cell FF (~ 60%), a cell η over 22% is expected in short term.

In a second part of this work, the recombination parameters (capture cross sections and position in the gap) of the LID defect are studied using transient-PCD. The defect SRH signature is shown to be the same over the 36% of the ingot affected by the defect. We found that the experimental data cannot be reproduced by SRH parameters from either BO-, Copper- or FZ-related LID. We conjecture that either several SRH centers are simultaneously at play, or that the defect here is singular and specific. Eventually, we report its “effective” SRH parameters to lie within: $0.2 \, \text{eV} < E_c - E_T < 0.84 \, \text{eV}$ and $10^{-2} < k < 4 \times 10^{-1}$.

Stability of Na Atoms at Stacking Faults in Si Depending on the Fermi Level

Yutaka Ohno1, Haruhiko Morito1, Kentaro Kutsukake1, Ichiro Yonenaga1, Tatsuya Yokoi2, Atsutoshi Nakamura2 and Katsuyuki Matsunaga2; 1Tohoku University, Sendai, Japan; 2Nagoya University, Nagoya, Japan.

In megawatt-scale solar power plants, high-voltage stresses are inevitably applied between each cell and its module frame, and the stresses sometimes cause a power drop in the module (a so called potential induced degradation (PID)). The key factor of the PID in p-type Si solar cells is sodium (Na) impurities in solar module encapsulation. During operation, they agglomerate at stacking faults (SFs) in Si cells [1]. Na atoms would spontaneously diffuse into SFs and create an electrically conductive layers [2], resulting in a reduction of the shunt resistance [1]. Those SFs would nucleate from microscopic defects on Si cells such as dislocations, during the PID stress under the influence of Na penetration [3]. Also, the Na penetration process would be modified depending on the doping level [4]. These results suggest that the formation energy of SFs varies depending on the Fermi level, as well as on the existence of Na atoms. In this work, we examine the stability of Na atoms at SFs in Si crystals with different Fermi levels, which determines the PID phenomena in p-type solar cells.

SF ribbons bound by pairs of partial dislocations were intentionally introduced into B-doped p-type Si ($c = 8 \times 10^{18} \, \text{cm}^{-3}$), P-doped n-type Si ($3 \times 10^{19} \, \text{cm}^{-3}$), and nominally undoped n-type Si ($3 \times 10^{17} \, \text{cm}^{-3}$), by applying a compressive stress at an elevated temperature. Each crystal and a Na sample were sealed within a stainless steel tube with Ar gas, and the crystal was doped with Na atoms by heating the tube in a furnace at 973 K for 5 h. The width of each SF ribbon $w_{SF}$ was estimated by TEM, as a function of the line orientation $u$ defined by the angle of $b$ to $u$ in which $b$ is the sum of the Burgers vectors of the dislocations and $u$ is a vector along the dislocations, and the formation energy of SFs $E_{SF}$ was calculated with $w_{SF}(u)$. In all the examined crystals, $w_{SF}(u)$ increased by Na doping, and the ratio between the $w_{SF}(u)$ before Na doping and that before doping was almost independent of $u$. Therefore, Na atoms would agglomerate at the SFs due to an attractive electronic interaction, and the interaction results in the reduction of $E_{SF}$. The degree of the energy reduction would decrease with rising the Fermi level; $E_{SF}$ was reduced by more than 10 mJ/m$^2$ in p-Si while it was barely reduced in n-Si [5]. These results indicate that Na agglomerates at SFs in p-Si are stable in comparison with in n-type one, and this is consistent with the PID phenomena in p-type solar cells. The SF formation energy depending on the Fermi level can be explained by using ab-initio calculations [5]. For comparison, the stability of Na atoms at $E_3$ [111] GBs will be discussed.

Annealing Effects on the Layer Structure in BaSi2 Thin Films Studied by DB-PAS

Ana B. Montes1, 2, Yilei Tian1, Daan Schopmeijer1, Stephan Eijt1, Hendrik Schut1, Takashi Suemasu2, Noritaka Usami3, Joao Serra2, Olindo Isabella1 and Miro Zeman1; 1TU Delft, Delft, Netherlands; 2Universidade de Lisboa, Lisboa, Portugal; 3Nagoya University, Nagoya, Japan; 4University of Tsukuba, Tsukuba, Japan.

BaSi2 is a promising material for solar cell applications due to its elemental abundance, non-toxicity and electrical and optical properties [1,2]. Presently, heterojunction BaSi2/c-Si solar cells with efficiency reaching 9.9% have been reported [3]. As an industrially applicable technique, radio frequency (RF) sputtering was employed in this research. Doppler-Broadening Positron Annihilation Spectroscopy (DB-PAS) is applied to study the layer structure, material composition and the open volume deficiencies therein.

BaSi2 films were deposited by sputtering and subsequently crystallized by annealing treatment. Samples were analysed by DB-PAS depth profiling and Raman spectroscopy. Thus, $S$ and $W$ parameter curves vs positron implantation energy (roughly reflecting thickness of layers) were acquired. $S$ and $W$ physically represent annihilation events with low- and high-momentum electrons, respectively. $S$ and $W$ are fitted by VEPFIT software [4] with a five-layer model (oxide/oxide-BaSi2 interface/BaSi2/BaSi2-substrate interface/substrate) based on our previous research [5]. In the $S$ profiles, three regions are recognized as function of positron energy: surface, bulk and substrate. Once $S$ and $W$ are sensitive to the composition of the layer, such variations can be caused by changes either in composition or formation/presence of vacancies. According to our previous research, surface and bulk material hold different compositions. In the surface region, an increase of $S$ is observed by increasing annealing temperature ($T_a$) from 650 to 700°C. This can be caused by the oxidation enhancement with $T_a$. For $T_a = 700°C$, increasing the annealing time ($t_a$) from 1 to 5 min induces a shift to higher positron implantation energies of the oxide/BaSi2 interface, suggesting that the surface oxidation mainly occurs within the first 5 min, and subsequently saturates.

In the bulk, either a higher $T_a$ or a longer $t_a$ decreases the $S$. Higher $T_a$ enhances crystallization, which can decrease the defect concentrations. This may cause a lower $S$. A decrease in $S$ is observed within the first 5 min. This can be caused by the crystallization of BaSi2, as supported by Raman analysis. Longer $t_a$ cause a decrease in $S$ which is attributed to Ba diffusion. Further characterizations, e.g., positron lifetime studies, are needed to determine the presence/formation of vacancies. Films produced by molecular beam epitaxy and thermal evaporation as potential references are being studied, in order to benchmark the quality of sputtered BaSi2 films by normalizing of $S$ and $W$ to those of reference films. This contribution serves as a platform for material development and solar cell devices based on BaSi2.

Metal Oxide and Fluoride Heterocontacts for High Efficiency Silicon Solar Cells

James Bullock; University of California, Berkeley, Berkeley, California, United States.

The fast-growing terrestrial solar cell industry is currently dominated by crystalline silicon cell architectures which employ doping and direct metallization for electron/hole separation. Despite being commonplace, the use of doping and direct metallization is known to incur a range of fundamental and practical performance limitations. A new strategy to address these shortcomings is to replace such regions with surface passivating heterocontacts. One burgeoning stream of research utilizes low-temperature materials like metal oxides, fluorides, sulphones and organic molecules to form such heterocontacts. I will discuss recent breakthroughs in this research area, which demonstrate the potential of this concept to simultaneously reduce fabrication costs and remove efficiency limitations.

Post-annealing Temperature Effect on Electrical Properties of Al2O3 Films on Silicon by Atomic Layer Deposition for Solar Cell Applications

Ergi Dönerçark, Bilge Imer and Rasit Turan; The Center for Solar Energy Research and Applications (GUNAM), Middle East Technical University, Ankara, Turkey.

Silicon wafers, being the most dominant and almost inevitable material for solar cell production, require surface passivation to increase the solar cell efficiency by decreasing recombination losses. For this reason, several research groups are currently focused on the usage of thin alumina (Al2O3) as a passivation layer. The success of Tunnel Oxide Passivating CONFerence (TOPConf) solar cell, Passivated Emitter Rear Totally diffused (PERT) solar cell and Passivated Emitter Rear cell (PERC) structures demonstrate enhanced passivation quality of crystalline silicon (c-Si) solar cells with Al2O3 films.

The determining parameters for the passivation quality of Al2O3 can be summarized as interface trap states (Dit), fixed charge density (Qf) and flat band voltage (VFB). Due to enhanced field effect passivation quality of thin Al2O3 layer, high ratio Qf can be accomplished. Qf has been reported as high as 1-4x10^13 cm^-2eV^-1 in literature by several research groups and this charge density is sensitive to both deposition conditions and post-thermal treatments.

In addition to field effect passivation, Al2O3 layer also provides chemical passivation with relatively low density of Df. This context, the effect of different deposition conditions and post-annealing temperatures on Al2O3 films formed by atomic layer deposition (ALD) were investigated using conductance method to identify and clarify relation between interface properties and fixed charge densities under initial deposition conditions varying in between 160 - 200°C in combined with various post-annealing conditions (400°C to 600°C for 30 minutes). C-V and G-V measurements were done for each sample with various frequencies from 1kHz to 5MHz. From C-V measurements, the oxide capacitance and VFB values were calculated and conductance method was applied to determine Dit values. It was shown that Dit decreased when the post-thermal annealing was applied. The highest Dit was 5.13x10^13 cm^-2eV^-1 and the lowest one was 2.43x10^11 cm^-2eV^-1. Dit decreased at 400°C post-annealing temperature for different deposition temperatures. The highest Dit was 2.79x10^13 cm^-2eV^-1 and the lowest one was 2.39x10^12 cm^-2eV^-1. The lowest Dit was found at 400°C post-thermal annealing temperature under N2 ambient with 165°C prior deposition temperature. It was concluded that when Qf values increase, Dit values also increase. High variation on VFB was found where it changed in between 1.09V to 4.19V.

Band Alignment at the Heterojunction Between Plasma Enhanced Atomic Layer Deposited SnO2 and N-Doped Hydrogenated Amorphous Silicon

Ganna Chistiakova, Mathias Mews and Lars Korte; Helmholtz-Zentrum Berlin für Materialien und Energie, Berlin, Germany.

Tin oxide, SnO2, is a “classical” transparent conductive oxide (TCO) material used for a variety of optoelectronic devices, including thin film solar silicon cells. Its alloy with indium, ITO, is widely used for silicon heterojunction solar cells. Furthermore, the pure tin oxide material has recently been demonstrated to perform well as electron transport layer in perovskite solar cells. Thus, it can be surmised that SnO2 on silicon might also be used as part of the recombination contact in silicon/perovskite tandem solar cells.

Motivated by these applications, we study atomic layer deposition (ALD) of SnO2 on hydrogenated amorphous silicon. We use TDMASn as precursor, which is a prominent choice for SnO2 ALD due to its low temperature requirements and high uniformity. For this work plasma enhanced atomic layer deposition (PEALD) of TDMASn with an oxygen plasma as oxidizer was used. With the ALD process it is possible to monitor changes at the interface of the recombination contact in silicon-perovskite tandem solar cells.

During the ALD process no growth delay was observed, and the Sn 3d core level signal was already detectable after the first growth cycle. We find that during the first cycles an oxide interlayer is formed, which influences the valence band position, work function and the total band bending. The main cause is assumed to be the formation of a dipole at the interface, due to the oxygen rich conditions during the initial growth stages. Upon continued deposition, the dipole vanishes, and we observe a reversal of the Sn 3d band bending and the formation of a chemically clean SnO2 layer. The conduction band offset from (n)-a-Si:H to SnO2 was determined to be ~270 meV. Therefore, SnO2 could be applied as an electron contact to (n)-a-Si:H, if the formation of the strong interface dipole can be suppressed.

In the past eight years, perovskite solar cells (PSCs) have quickly evolved into a high-efficiency technology due to the excellent electronic and optical properties of perovskite absorbers. Among the two \( \text{p-i-n} \) and \( \text{n-i-p} \) configurations, the \( \text{n-i-p} \) has now reached record conversion efficiencies (PCE) close to 23\%, followed at some distance by its \( \text{p-i-n} \)-counterpart. The choice of solvent-compatible HTLs and the lack of efficient \( \text{p-type} \) metal oxides restricts the main causes hampering the rise of \( \text{p-i-n} \) PSCs, whose options were limited to hole transport polymers for several years. In this regard, nickel oxide (NiO\(_x\)) offers promising characteristics to replace the polymers, such as chemical stability, high broadband optical transparency, intrinsic \( \text{p-type} \) semiconducting nature, higher open circuit voltage (\( V_{oc} \)) and its deeper work function. Thanks to these unique properties, NiO\(_x\) has been studied widely and several successful reports have been published for solution processing such as sol-gel and combustion methods. However, these techniques require high-temperature annealing which increases the processing time and hinders its use on low-temperature stable substrates; low-temperature processing is crucial for monolithic perovskite/silicon tandem solar applications which promises very high efficiency beyond the single junction limit. The most promising silicon bottom cell for perovskite tandems is silicon heterojunction technology (SHJ) which has the highest \( V_{oc} \) and PCE for perovskite/silicon tandem applications. However, SHJ solar cells are only compatible with top cell processes up to ≈200 °C. Above this temperature, \( V_{oc} \) of the devices sharply drop because of hydrogen effusion from the amorphous silicon layers, hampering the passivation effect. Based on this limitation, we took advantage of RF sputtering deposition to fabricate amorphous NiO\(_x\) layers. RF sputtering offers room temperature processing, flexibility to control composition by simply changing the deposition parameters, and fast deposition. Moreover, RF sputtering enables conformal deposition on complex surfaces such as random-pyramid textured silicon solar cells. Besides, owing to its high transparency NiO\(_x\) is well fit as a scalable HTL for tandem applications. In this work, we employ various characterization methods and DFT analysis how the electrical and optical properties of optimized films correlate strongly with the specific defect chemistry of NiO\(_x\). For planar, \( \text{p-i-n} \) configured MAPbI\(_3\) based PSCs, RF-sputtered NiO\(_x\) at room-temperature enables PCE values of 17.6\%, which is highest achieved among the PSCs adopting sputtered NiO\(_x\) as HTL without heteroatom doping. These results pave the road for the development of the perovskite/silicon tandem solar cells on pyramidal textured surfaces.

Towards CIGS Perovskite Tandem Cells

Jesper Jacobsen, Adam Hultqvist, Häkan Rensmo and Gerrit Boschloo;
Chemistry, Uppsala University, Uppsala, Sweden; 2Uppsala University, Uppsala, Sweden.

Perovskite solar cells will have a hard time to reach competitiveness with respect to conventional PV-technologies; unless they are integrated in tandem-architectures that possibly could outperform single junction silicon cells. One interesting potential perovskite tandem companion is CIGS, CuIn_xGa_{1-x}Se_2, which is a commercial thin film technology with record efficiencies above 22 % and a variable band gap. In this project, we strive for constructing efficient 2-terminal CIGS-perovskite tandem cells. We will here discuss progress and challenges connected to recombination layers, perovskite engineering, and transparent top contacts in CIGS-perovskite tandem architectures.

Thermal, Oxidative, and Operational Stability in Low Band Gap Tin-Lead Perovskite Solar Cells for Robust All-Perovskite Tandems

8:30 AM

Rohit Prasanna, Tomas Leijtens, Arevé Gold-Parker, Eli Wolf, James A. Raiford, Stacey F. Bent, Michael F. Toney and Michael McGehee;
Stanford University, Stanford, California, United States; 2Chemical Engineering, University of Colorado Boulder, Boulder, Colorado, United States.

Low band gap ABX_3 perovskites tin and lead at the B-site are a breakthrough that have enabled fabrication of efficient all-perovskite tandem solar cells. However, tin is susceptible to oxidation to the +4 state, a degradation pathway unique to tin-containing perovskites. Suppressing this oxidation reaction is essential to ensure that highly efficient all-perovskite tandem solar cells are also stable against long term environmental stressors.

We identify the specific chemical mechanism by which pure tin-based perovskites undergo oxidation using a combination of chemical methods including thermogravimetric analysis and solvent extraction of degradation products. We find that the oxidation reaction depends on a cooperative mechanism that involves simultaneous oxidation of multiple adjacent tin iodide octahedra. Critically, the most favorable oxidation pathway is blocked by substitution of 50% or more of the B-site with lead because this significantly lowers the chances of there being multiple adjacent tin octahedra that can facilitate the cooperative mechanism. As a result, the stability of tin perovskites toward oxidation is improved by orders of magnitude upon alloying with lead. The resulting guideline is that low band gap perovskites can be designed to have significantly enhanced oxidative stability by keeping the tin fraction at 50% or below.

We proceed to design solar cells to withstand aging under elevated temperatures in air. We probe the thermal stability of high-performing low band gap solar cells by aging at 85 C in air. Encouragingly, there is no measurable change in the bulk absorption of the perovskite absorber under thermal aging in air, indicating that the strategy of suppressing oxidation by using a mixed tin-lead perovskite successively avoids oxidative breakdown. However, the fill factor drops due to the formation of an S-kink after 100 hours of aging. We develop a treatment of the tin-lead perovskite film by exposure to methylammonium chloride vapour that results in significant grain growth and healing of cracks between grains. This post-treatment drastically improves the thermal stability of the full solar cells. Using an MACI-vapour-treated low gap perovskite with 50% tin, capped with a sputtered Indium Tin Oxide (ITO) top electrode, we successfully demonstrate a solar cell that maintains its full power conversion efficiency for 150 hours in air at 85 C, and remains above 85% of initial PCE for over 300 hours. In addition, we demonstrate stable operation of a tin-lead solar cell at maximum power point under 1-sun illumination for over 100 hours with no drop in performance. These measurements are a huge improvement upon any thermal stability results reported for tin-containing perovskites. The fact that good thermal stability in air is achieved with no encapsulation represents a major step toward proving the long-term stability of tin-low band gap perovskite solar cells, and of efficient all-perovskite tandem solar cells.

Two conflicting characteristics compete where the commercial viability of one-sun tandem solar cell is concerned: On the one hand, tandem solar cells have fundamentally higher efficiencies than single junction solar cells. On the other hand, tandem solar cells are intrinsically more complex than single junction solar cells and require more fabrication steps, which makes them more expensive. Only if the benefit from the additionally generated energy outweighs the higher fabrication cost can tandem solar cells be successful.

The question under which conditions the last sentence is true is a multilayered one. The value of efficiency is highest when considering the integrated PV system, which makes it necessary to explore system level aspects. These aspects include, among others, economic considerations as well as topics from material science; for example degradation.

In this work we attempt to provide an overview of what is needed to make tandem solar cells economically successful. Central to our findings is the concept of “marriage of equals”, which states that the sub cells in a tandem should be similar, as well as enable high efficiencies. We will take a look at different material pairings, including perovskite on silicon, III-V on silicon and thin-film on thin-film tandems and investigate how these tandems compare to single junction solar cells in various types of systems and various locations.

We find that under the right circumstances one-sun tandem solar cells can outperform single junction solar cells economically. Yet more than techno-economic considerations are needed to make these types of solar cell a wide-spread reality. As an outlook we hope to offer a perspective of future opportunities for this technology.

Designing Metal Halide Perovskites Solar Cells to be Stable for High Efficiency Tandems

Michael D. McGehee;
Department of Chemical Engineering, University of Colorado Boulder, Boulder, Colorado, United States.

The talk will begin by showing what we have done to make perovskite on silicon tandem solar cells with 25 % efficiency and how 30 % efficiency can probably be obtained in the coming years. Then the challenge of making solar panels with metal halide perovskite semiconductors that will last for more than 25 years will be addressed. We will show that packaged solar cells can survive industry standard reliability tests such as 1000 hrs at 85°C and 85% humidity, 200 temperature cycles between -40°C and 85°C, and ultraviolet exposure. The strategies for making stable perovskite cells include choosing perovskite compositions that have higher thermal and oxidative stability, managing stress during the formation of the film to prevent buckling that makes perovskite compositions that have higher thermal and oxidative stability, managing stress during the formation of the film to prevent buckling that makes subsequent processing difficult, minimizing tensile stress in the final film since it appears to make bonds weaker, using solution processing of the top contact layer to fill in gaps at grain boundaries so that a sputtered transparent conducting oxide layer can form a super barrier layer, using polyolefin as the encapsulant since it does not chemically react with the perovskite and has an ideal elastic modulus, using butyl rubber edge seals and using glass on glass packaging.

High Efficiency Perovskite/Silicon Tandem Solar Cells

Kylie Catchpole; Australian National University, Acton, Australian Capital Territory, Australia.
Combining perovskites with well-established photovoltaic materials such as silicon or CIGS is an attractive option for producing cheap, high efficiency and high voltage solar cells. Perovskite-based tandem solar cells can potentially achieve over 30% tandem efficiency. We demonstrate a 4-terminal tandem perovskite-silicon configuration in which the efficiency is as high as 26%. We also demonstrate a two-terminal monolithic tandem device with a perovskite top subcell and a high-temperature tolerant homojunction c-Si bottom subcell, with an efficiency of over 22%, and a perovskite/CIGS tandem with an efficiency of over 23%, which is the highest efficiency that has been reported for this configuration. We describe the optical and electronic factors that have been instrumental in reaching these efficiencies. We also show that interface passivation can lead to open circuit voltages over 1.2V for a 1.6 eV bandgap perovskite, and that semi-transparent cells can achieve high stability under combined heat and light. These results show the clear potential of perovskitk in practical high efficiency tandem devices.

With open circuit voltages (Voc) above 730 mV, silicon heterojunction (SHJ) solar cells are promising candidates for the bottom cells in organic-inorganic lead halide perovskite/silicon tandem solar cells. Using simulation studies, we have shown that under realistic assumptions, power conversion efficiencies up to 30% should be achievable with such devices [1]. To attain this goal, starting from first devices with moderate stabilized efficiencies of 18.1% [2] we carefully optimized the optical and electrical properties of the device in order to achieve low parasitic absorption and reflection, photocurrent matching between the two sub-cells and lowly resistive current transport across the internal tunnel-recombination junction.

In this presentation, I will discuss how we were recently able to demonstrate certified 25% efficient perovskite/SHJ tandem cells [3] by addressing these issues. I will focus on the silicon bottom cell and contact stack optimization: Starting from a rear junction SHJ cell design on double side textured wafers with 22.6% power conversion efficiency (Jsc = 38.3 mA/cm², Voc= 731 mV, FF = 80.6 %) [4], we developed a rear side only-textured SHJ cell, which allows to process the perovskite top cell using conventional spin-coating methods. Optimizing film thicknesses at the perovskite/SHJ interface and tuning the refractive index of the nc-SiO₂:H film used as front surface field in the SHJ to an intermediate value of ~2.6 (at 800 nm) were instrumental in achieving 25% efficient cells with photocurrents above 17.8 mA/cm². On this basis, I will briefly discuss the potential to further enhance device performance using alternative deposition methods, such as plasma-enhanced ALD for tin oxide interlayers, and alternative materials such as tungsten oxide alloys for carrier selective contacts.

Progress on Si Tandems

Antia Ho-Baillie1, Hamid Mehrvarz2, Jianghui Zheng1, Fajun Ma1, Chuq Yi1, Stephen Brenner2, Shujuan Huang1, Hidenori Mizuno2 and Tyler. Grassman1,2 "Australian Centre for Advanced Photovoltaics, The University of New South Wales, Sydney, New South Wales, Australia; 2Fukushima Renewable Energy Institute, National Institute of Advanced Industrial Science and Technology, Fukushima, Japan; 3The Ohio State University, Columbus, Ohio, United States.

Tandem solar cell is a promising approach for achieving high efficiencies for photovoltaics [1]. The challenge is to find an efficient, economical and stable technology for each cell stack to realize true savings in the system’s levelised cost of energy. Nevertheless, substantial progress has been made in the demonstrations of two-terminal Si tandem cells. The advantage of 2-terminal over 4-terminal configuration is the reduced complexity in wiring and packaging [2]. The challenge lies in the integration of the cell stacks without electrical and optical losses.

Recently, a simple perovskite/Si tandem cell structure has been reported [3]. It does not require additional interface layer for the integration of perovskite and Si cells. Instead, the electron transport layer in the perovskite top cell serves as the recombination layer between the top and bottom sub cells. The lack of lateral conductivity in this recombination layer means undesirable shunts are effectively localized. Another advantage of this structure is its compatibility with homo-junction Si cells – the most common choice for incumbent commercial Si photovoltaic technology. Recent optimizations have improved cells’ performance from 20.5% to 22.7% on 4cm².

Great progress has been made on 2-terminal III-V/Si and III-V/Si tandems via wafer bonding and direct growth. Many of these tandem cell structures require smooth interface negating the use of textured Si bottom cell. This means external measures are required for anti-reflection and light trapping. Strategies for improving the optical performances of InGaP/GaAs//Si tandem by SmartStack [4] and monolithic epitaxial GaAs/Si tandem [5] will be presented in this talk.

that such effect is influenced by the a-Si:H thickness. In fact, increasing the thickness of a-Si:H layer to 50 nm, sample annealed at 650 °C presents similar optical properties to the bare BaSi2 film annealed at 650 °C rather than 700 °C. Thinner a-Si:H layers may suppress the formation of defective structures with >20 mA/cm2 in both the perovskite and silicon subcells (excluding metallization-induced shadow losses). Parasitic absorption was minimized thanks to the bottom cells for maximal optical performance given the reduced reflection losses and enhanced light trapping. This enabled current-matching conditions - Reaching maximal performance:

Overall, these results suggest a path in the development of monolithic perovskite/silicon tandem solar cells with realistic efficiency potential >30% on large area with enhanced stability.

We will review our recent attempt to integrate data science with experimental science, theory, and computation in order to enable a paradigm shift in development of complicated multicrystalline materials. This multidisciplinary scientific approach, “multicrystalline informatics”, is shown to be useful to realize ideal multicrystalline silicon (mc-Si) ingot for solar cells by various aspects. Photoluminescence (PL) images of mc-Si wafers with intentional partial introduction of the reflected incident laser contains information of crystal defects and microstructures. We captured PL images from mc-Si wafers produced from the same ingot, and attempted to clarify the distribution of crystal defects inside the ingot. Although the surface of mc-Si wafers sliced by diamond wires is mirror-like with one directional saw marks, image processing could successfully visualize crystal defects as dark regions and microstructures with different average luminance. By sequentially stacking PL images of mc-Si wafers from the bottom to top of the ingot, the structural variation in the ingot could be visualized. Furthermore, by extracting crystal defects with thresholding, three-dimensional distribution of crystal defects could be visualized. These revealed that crystal defects, which are most likely assigned as dislocation clusters, are generated at grain boundaries followed by propagation and annihilation. This permits to extract a hundreds of generation points of crystal defects for further analysis of underlying physics. To obtain information on orientation distribution in mc-Si, optical images of mc-Si wafers with white light illumination would be useful. We captured a series of optical images with different illumination angles, and investigated the relationship between angular variation of average luminance and crystal orientation. Machine learning would be utilized for fast prediction of orientation distribution in mc-Si.

By combining these information, physics of crystal defects in complicated mc-Si will be manifested to show the guide to realize high-quality mc-Si ingot for solar cells.

Effects of Amorphous Si Capping Layer on Sputtered BaSi2 Film Properties Yilei Tian1, Ana B. Montes1, 2, Olindo Isabella1 and Miro Zeman1; 1Delft University of Technology, Delft, Netherlands; 2Universidade de Lisboa, Lisbon, Portugal.

BaSi2 has gained interest as a promising light-absorbing material for thin-film solar cells. BaSi2 is stable in ambient condition and possesses a suitable band gap ~1.3 eV for solar energy conversion [1]. Its potential also stems from attractive optical and electrical properties, i.e., a high absorption coefficient reaching 10^5 cm^-1 for hv > 1.5 eV [1], a long minority carrier lifetime ~27 μs [2], and essentially elemental abundance and non-toxicity. Theoretically, the attainable conversion efficiency of the BaSi2 solar cell is up to 25% [3]. However, BaSi2 is confronted with the issue of surface oxidation due to its reactivity with oxygen. The oxidation-induced structure transformation, altering the stoichiometry and degrading the film quality, has been uncovered by our previous research [4]. Hence, it is essential to develop anti-oxidation capping layer to improve BaSi2 film quality.

In this contribution, hydrogenated amorphous silicon (a-Si:H) is studied as capping layer. Effects of a-Si:H on film properties are investigated by Raman, atomic force microscopy, and spectrophotometry. BaSi2 films were deposited by RF magnetron sputtering and then capped by PECVD a-Si:H. Samples were subsequently annealed at temperatures ranging from 650 to 750 °C. Raman spectra confirm the formation of crystalline BaSi2 in annealed a-Si (10 nm)/BaSi2 films. Aside from the BaSi2 peaks, the crystalline Si peak is noticeable for films annealed at 650 °C, resulting from Si crystallization in both a-Si:H and BaSi2 layers. Only a Si peak is displayed instead in spectra of a-Si (10 nm)/BaSi2 film annealed at 700 °C. Besides, a-Si:H (10 nm)/BaSi2 annealed at 650 °C exhibits similar optical properties to those of an uncapped BaSi2 film annealed at 700 °C. The existence of a-Si:H capping can, therefore, decrease the thermal budget for crystallizing BaSi2 but we found that such effect is influenced by the a-Si:H thickness. In fact, increasing the thickness of a-Si:H layer to 50 nm, sample annealed at 650 °C presents similar optical properties to the bare BaSi2 film annealed at 650 °C rather than 700 °C. Thinner a-Si:H layers may suppress the formation of defective structures and/or metallic phases, thus altering positively the optical properties of the fabricated a-Si:H (10 nm)/BaSi2. Furthermore, a 10-nm thick capping a-Si:H layer increases sample surface roughness from 20 nm (bare BaSi2) to 47 nm.

The mechanism of tailoring BaSi2 properties via a-Si:H capping layer is being investigated by further composition and electrical characterizations.
Additionally, the in-situ fabrication of a-Si/BaSi₂ films by a multi-targets sputtering method is being investigated. These results lay the groundwork for the development of BaSi₂-based thin-film solar cells.

Status of and Pathways to Achieve Wafer Equivalent Crystalline Silicon Solar Cells on Glass by Liquid Phase Crystallization Daniel Amkreutz¹, Chamin Thi, Mártina Trahns, Klaus Jäger, Christiane Becker and Rutger Schlattmann; ¹Silicon Photovoltaics, Helmholtz Zentrum Berlin, Berlin, Germany; ²Young Investigator Group Nano-SIPPE, Helmholtz-Zentrum Berlin für Materialien und Energie, Berlin, Germany; ³IPh-comB, Helmholtz-Zentrum Berlin für Materialien und Energie, Berlin, Germany.

Laser- or electron-beam induced zone-melting crystallization of silicon films is a fast and scalable technology to fabricate polysilicon layers on glass with customizable thicknesses and grain sizes up to several centimeters. Liquid-phase crystallized (LPC) silicon is thus a very interesting material for large area applications. Especially for PV, but also for microelectronics, MEMS or microfluidic applications. In the past, most effort was put on the development of a suitable layer stack between glass substrate and silicon absorber. This interlayer is mandatory for surface passivation, provides an antireflective coating and prevents impurity diffusion into the silicon absorber during the LPC process. Based on the progress in interlayer development, we demonstrated open circuit voltages up to 660 mV using n-type silicon. Nevertheless, fabricating a suitable contact system is challenging, because the carrier lifetime amounts to a few microseconds resulting in bulk diffusion lengths in the range of 30 to 60 micrometers. An interdigitated-back-contact system (IBC) was developed which is compatible with the crystallization process on glass and which is well suited for these diffusion lengths. With this contact system we were able to show conversion efficiencies up to 14.2% with current densities up to 31 mA/cm² for an IBC cell, which exhibits a planar silicon-glass interface and a pyramidically textured silicon rear side. In this contribution we summarize the current status of liquid-phase crystallized silicon on glass with emphasis on the interlayer and contact system development. Future steps towards wafer-equivalent conversion efficiencies for silicon (thin-) film solar cells on glass are discussed. It is shown that the device performance is no longer governed by surface recombination at the interlayer so that the focus for further development shifts to the reduction of losses related to imperfect contact system and light trapping scheme. Aside from losses due to grain boundary recombination, the short circuit current mainly suffers from insufficiently passivated contacts. Together with optical losses, these effects result in a reduction of the theoretical short circuit current density by approximately 30%. While alternative ways to passivate the absorber contact are currently under investigation, optical losses have to be reduced using improved light trapping schemes. The main challenge is to texture the interlayer-silicon and silicon-air interfaces without sacrificing the electronic quality by disturbing the crystal growth process. It is shown that the SMART (smooth anti-reflective texture) scheme is well suited to enhance the optical absorption while enabling theoretical short circuit current densities exceeding 37 mA/cm². Based on this estimation, first IBC cells with front- and rear-side texture are evaluated.

Fabrication of SiGe Layer on Si Substrate by Screen-Printing Masahiro Nakahara¹,², Moeko Matsubara¹, Shota Suzuki¹, Shogo Fukami², Marwan Dhamrin² and Noritaka Usami¹; ¹Toyo Aluminum K.K., Shiga, Japan; ²Engineering, Nagoya University, Nagoya, Japan.

During the past few years, the photovoltaics market has grown rapidly and the total cumulative installations amounted to 400GW at the end of 2017, capable of producing roughly 2% of the world wide electricity demand. And crystalline silicon has continued to dominate the solar industry with over 90% of the market share. However the energy conversion efficiency of crystalline silicon solar cell is approaching its theoretical limit, Shockley-Queisser limit, of around 29%, giving the industry no choice but to search for new alternatives of solar cell structures that exceed this limit [1]. Meanwhile multi-junction solar cells, which combine multiple pn-junctions of different band gap energies to absorb the spectrum of the sun, are the state-of-the-art approach for achieving high efficiencies. However, compared with single junction silicon solar cells, the cost is still very high because it utilize Ge wafer as a bottom cell, which substrate for its best lattice match to grow Three Five films on it. Therefore substitution of Ge with low cost material, such as silicon, has a great interest to expand the Three Five solar cell market for terrestrial applications. The lattice mismatch between the epitaxially grown Three Five materials like a GaAsP and Si will result in a low open circuit voltage because of a high threading dislocation density when growing it directly on Si. There are few solutions to address this issue including wafer bonding, lift-off, sample recycling and growing sacrificial thick buffer layers of SiGe/Ge which increase the time and fabrication cost [2].

In this work, single-crystalline SixGe₁₋ₓ thick layers grown by screen-printing technique on Si substrate is investigated. Pastes with different Ge, Al, and Si contents were screen-printed on Si (100) substrate and annealed at different temperature in air and Inert gas to investigate the impact of different Ge paste deposition on the Si substrate. After annealing, the residue pastes on the surface were selectively removed by wet etching with a phosphoric acid solution (HFPO₄: CH₃COOH: HNO₃: H₂O = 16:1:1:2) at 60 degree. Then, the morphology, atomic composition, crystal orientation and crystal quality were characterized by scanning electron microscopy (SEM), energy dispersive X-ray spectroscopy (EDX) and X-ray diffraction (XRD). The SEM-EDX analysis indicated that SixGe₁₋ₓ layers with good uniformity and thickness up to 30µm were obtained. Also Ge content of more than 20% is achieved. The formed SixGe₁₋ₓ / Si wafer can be used with Ge buffer layer to fabricate high efficiency Three Five solar cells on cheap silicon substrates.

Minority Carrier Lifetime Characterization from Silicon Bricks to Modules—Current Status and Future Opportunities Harrison Wiltsendeink, Adrienne Blum, Cassidy Sainsbury, Wes Dobson, Justin Dinger and Ronald Sinton; Sinton Instruments, Boulder, Colorado, United States.

Minority carrier lifetime characterization is integral to the design and production of silicon PV devices in both laboratory and industry settings. Since development of the quasi-steady-state photoconductance (QSSPC) technique for silicon wafers in 1994, comparable lifetime characterization methods have been extended to span the entire solar PV production chain—it is now possible to track relevant lifetime parameters from bulk material (ingots/bricks) all the way to finished solar cells and modules. Already this has enabled implementation of sophisticated quality control systems in production settings, for example: screening incoming material lifetime prior to processing, and monitoring/optimizing changes in lifetime for critical production processes—e.g., diffusion, passivation, laser ablation, nitride deposition, metallization, etc.
Applications of lifetime characterization at the finished cell and module stages have so far been largely untapped, but may prove especially insightful for high-efficiency cell designs featuring passivated emitters (PERC, PERL), rear contacts (IBC), or heterojunction interfaces (HTJ). For cell production lines, lifetime characterization allows power losses to be quantified and sorted by specific loss mechanisms—bulk recombination, emitter recombination (J_{ee}), shunt resistance, and series resistance. This advanced characterization is possible at line-speed, which then enables continuous data feedback to inform material screening criteria and process optimizations for the entire production line. For finished modules, lifetime characterization can enhance understanding of power degradation observed in the field. For degradation modes with distinct lifetime signatures, such characterization enables development of device-physics-based degradation models, which can inform accelerated degradation protocols and highlight potential cell-level solutions to degradation issues.

This presentation will present an overview of the applications of lifetime characterization across the whole silicon production chain mentioned above, with an emphasis on potential future applications.

Improvement of Electrical Properties of Laser-Induced Liquid-Phase-Crystallized Silicon Thin Films for Photovoltaic Application

Hiroshi Umishio, Takuya Matsui, Hitoshi Sai and Koji Matsubara; National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan.

In crystalline silicon (c-Si) solar cells, decreasing wafer thickness is expected to be a way for reducing material cost. However, using thinner wafers has two major technical problems. First, wafer slicing creates extensive kerf loss that cannot be reduced easily when thinning the wafer. Second, manufacturing solar cells with thin wafers (<100 µm) is still technically challenging because of the high probability of wafer breakage. If the high quality c-Si thin films can be formed on cheap and strong glass substrates, one could avoid the kerf loss and the breakage risk of thin wafers. In addition, the long process chain for making wafers can be shortcut and that makes the wafer fabrication cost cheaper. Liquid-phase-crystallization (LPC) has emerged as a new technique to make high-quality poly-Si thin films with high crystallinity and large grains (several mm to a few cm in size) on glass. In LPC process, an amorphous silicon (a-Si) precursor film deposited on glass is melted and crystallized rapidly with a line-shaped laser or an electron beam. To achieve sufficient conversion efficiency using LPC-Si absorbers, the deeper understanding of the electrical properties of LPC-Si and their impact on photovoltaic performance are of importance. A factor that has a large impact on the electrical properties of LPC-Si is the grain quality such as grain size and defects present in the intra-grain and/or grain boundaries. In the fabrication process of multicrystalline silicon wafer, cooling rate of molten silicon is an important factor that determines grain size and dislocation densities. In case of LPC-Si, laser scan speed might play an important role in controlling the cooling rate of Si during crystal growth. Another important factor is the doping concentration that affects the carrier mobility and the carrier lifetime. In this study, to gain insight into the electrical properties of LPC-Si, we studied the majority carrier mobility and the minority carrier lifetime of the LPC-Si films prepared in a wide range of doping concentration and laser scan speed. In addition, test solar cells were made and their open-circuit voltage (V_{OC}) and internal quantum efficiency (IQE) were evaluated.

Impact of Undoped Substrates on High Performance Silicon Solar Cells

André Augusto, Apoorva Srinivasa, Richard King and Stuart G. Bowden; Arizona State University, Tempe, Arizona, United States.

We investigate the potential advantages of using undoped silicon wafers, including high resistivity n- and p-type, to manufacture high performance solar cells. As the quality of Czochralski material improves and carrier selective contact architectures deliver superior surface passivation (J_{0} < 5 fAcm^{-2}), the cell injection regime increases by a factor of 10 and Auger recombination becomes more predominant. This is particular true for substrates with Shockley-Read-Hall minority carrier lifetime over 1ms. For silicon heterojunction solar cells, high-resistivity base shows potential to increase both the V_{OC} and FF.

We experimentally investigate silicon heterojunction solar cells on substrates in a wide range of dopant concentrations (8-20000 ohm.cm), observing closely the transition from low-level to high-level injection. The idea is to understand the device physics in this regime where neither limiting case of injection is an accurate approximation. In field conditions modules experience different illumination conditions and as a result we also included in this study simulation and experimental measurements of the performance of these cells under light intensities from 0.2-1 suns. Preliminary results on solar cells using 8-20000 Ohm.cm n-type wafers shows excellent surface passivation (J_{0} < 2 fAcm^{-2}) regardless the base doping, impacting positively the pFF, FF and V_{OC}. These cells show similar performance behavior for different light intensities regardless their base resistivity. These studies have important implications for the yield fabrication of c-Si grown wafers for which dopant concentration varies along the length of the ingot, and for the effect of Fermi level position on cell and ingot manufacturing yield, silicon cell power output, and module reliability.

Liquid Phase Crystallized Silicon for Application in All-in-Thin-Film Perovskite/Silicon Tandem Cell

Martina Trahmel, Cham T. Trinh, Maurice Nuyts, Uwe Breuer, Uwe Zastrow, Natalie Preissler, Marko Jost, Steve Albrecht, Rutger Schlatmann and Daniel Amkreutz; 1Institute for Silicon Photovoltaics, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Berlin, Germany; 2Institute of Energy and Climate Research - Photovoltaics-(IEK), Forschungszentrum Jülich GmbH, Jülich, Germany; 3Central Institute for Engineering, Electronics and Analytics (ZEA), Forschungszentrum Jülich GmbH, Jülich, Germany; 4PVcomB, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Berlin, Germany; 5Young Investigator Group Perovskite Tandem Solar Cells, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Berlin, Germany.

Liquid phase crystallization (LPC) of silicon is an emerging photovoltaic technology that is based on laser-induced melting and subsequent crystallization of an amorphous or nano-crystalline Si-absorber. This technique avoids kerf loss which is typically associated with wafer processing. The absorber is deposited on glass with a thickness between 5 µm and 40 µm. During the crystallization process, a poly-crystalline Si-absorber with grain sizes in the order of cm in length and mm in width is formed. With an interdigitated back contact (IBC) system, conversion efficiencies of up to 14.2% were achieved. Another important factor that affects the carrier mobility and the carrier lifetime is the doping concentration. In this study, to gain insight into the electrical properties of LPC-Si, we studied the majority carrier mobility and the minority carrier lifetime of the LPC-Si films prepared in a wide range of doping concentration and laser scan speed. In addition, test solar cells were made and their open-circuit voltage (V_{OC}) and internal quantum efficiency (IQE) were evaluated.
within the absorber and are likely to segregate at grain boundaries. Impurities at the LPC-Si/a-Si heterojunction interface can also be responsible for a strong reduction of Voc. The SIMS results suggest that defects at the heterojunction, decorated grain boundaries as well as intra-grain defects might be responsible for the observed losses. To develop a suitable strategy for further device improvement, it is crucial to investigate which of these loss mechanisms are limiting the cell performance.

4:30 PM ET02.06.03
Watching Nanodefects Grow in Si Crystals Andreas Magerl, University of Erlangen-Nuremberg, Erlangen, Germany.

Nucleation and growth of oxygen precipitates in moderately p- ([B] ≈ 10^{15} 1/cm^3) and highly p+ ([B] ≈ 10^{18} 1/cm^3) boron doped Czochralski Si crystals has been investigated in-situ up to 1000°C to monitor continuously the evolution of the defect properties from their very early stages to the long time behavior. Thickness-dependent Pendellösung oscillations as described by the dynamical theory of X-ray diffraction are extremely sensitive to strain fields from defects in a host crystal. Based on this, we initiated a novel approach to study the precipitation kinetics of oxygen in Si. The data is interpreted within a diffusion-limited model of growing spherical precipitates, where two growth regimes are identified. An initial diffusion driven growth is followed by a long time precipitation behavior, which is interpreted as Ostwald ripening.

In addition, synchrotron-based rocking curves (ID15, ESRF, Grenoble) provide information about the size distribution and morphology of the precipitates. A quantitative analysis of the in-situ experiments during annealing at 1000 °C shows two growing particle populations differing in polydispersity and particle density.

4:45 PM ET02.06.10
Improving Sub-Bandgap Photoresponsivity in Silicon Photodiodes via Pulsed Laser Melting-Tailored Hyperdoping Philippe K. Chow1, Qi Lim2, Jim S. Williams3 and Jeffrey M. Warrrender4; 1Benet Laboratories - ARDEC, Watervliet, New York, United States; 2The Australian National University, Canberra, Australian Capital Territory, Australia.

Extending the absorption edge of silicon to harvest below-bandgap-energy photons is one route towards improving/extending the short-wave infrared (SWIR) performance capability of optoelectronic silicon devices including intermediate-band photovoltaics and photodetectors. Non-equilibrium pulsed-laser melting (PLM) and resolidification of silicon containing highly-substitutional chalcogen (e.g. sulfur) and transition metal (e.g. gold) impurities at above-solubility limit concentrations is known to enhance the room-temperature sub-bandgap absorption coefficient dramatically, to the order of ~10^4 cm^{-1} in the 1-2 micron range. However, the best demonstrated external quantum efficiencies (EQE) of photodiodes formed by a junction between the laser-doped layer and the Si substrate have been rather low, on the order of 10^{-1} - 10^{-2} %. It remains to be investigated how PLM condition-dependent material characteristics including impurity lattice location, concentration profile, microstructural homogeneity and chemistry influence photodiode EQE.

In a general effort to boost EQE, we investigate the PLM-dependent structure-property relationships as is relevant to optoelectronic material development. We report our findings from complementary material and photodiode characterization using the most well-studied hyperdoping impurities, gold and sulfur. To explain the observed photoresponsivity results, we employ Rutherford backscattering spectrometry, secondary ion-mass spectrometry, optical absorption spectroscopy and scanning electron microscopy. Among the results, we report order-of-magnitude sub-bandgap EQE enhancement in gold-doped photodiodes, which were fabricated using a recently developed physical vapor deposition-based doping technique. This work aims to unify the state-of-the-art understanding of PLM-induced material properties and of the resulting optoelectronic device performance. Our results showcase the flexibility of PLM-based methods towards their tailoring the structural and electronic properties of silicon for real device applications.

SESSION ET02.07: Poly-Silicon Contacts II
Session Chair: Robby Peibst

8:30 AM *ET02.07.01
Material Limitations for High-Efficiency Silicon Solar Cells Jan Benick; Fraunhofer ISE, Freiburg, Germany.

Passivating and carrier-selective contacts such as amorphous Si heterojunctions or TOPCon have led the way to further push the efficiency of silicon solar cells to the theoretical material limit. The replacement of partial rear contacts (PRC) by passivating contacts as a full-area rear contact for both sides contacted solar cells so far resulted in efficiencies records up to 25.8% for mono- and 22.3% for multi-crystalline silicon (20x20 mm²). Achieving highest efficiencies requires both, a technology and cell architecture as well as a silicon base material which allows such high conversion efficiencies.

In this paper we discuss the technology of our mono- and multi-crystalline n-type solar cells featuring a front side boron emitter and a rear side passivating electron contact. We further address material aspects and limitations in the cell efficiency associated with the silicon base material (e.g. resistivity and impurity contamination). Whereas the efficiency limitation caused by base material is more obvious in the case of multi-crystalline silicon, we show that even for mono-crystalline n-type silicon, which is less sensitive to common impurities than p-type silicon, even quite low impurity concentrations can be sufficient to limit the cell efficiency potential below 25%.

9:00 AM *ET02.07.02
Upscaling Passivating and Carrier Selective Contacts for Industrial Applications Ingrid Romijn, Maciej Stodolny, Paula Bronsveld, Agnes Mewe, Piero Spinelli and Kees Tool; ECN part of TNO, Petten, Netherlands.

The performance of current industrial solar cells is for a large part limited by recombination at metallic contacts. A solution to overcome this is to screen minority carriers from the metal by using so-called passivating carrier selective contacts. Using carrier selective contacts based on doped polysilicon layers combined with tunnel oxides, efficiencies well above 25% have already been reached on front and back contacted cells on laboratory scale.

In this contribution, we will first focus on upscaling of these polysilicon passivating contacts to 6" bifacial cells using industrial screen printed and fired metallization. The main challenge for such solar cells lies in keeping the contact recombination low, while applying a cost effective, industrial metallization approach. The contact mechanism of commercial silver and silver/aluminum pastes on both n+ and p+ doped polysilicon layers has been extensively studied using scanning and tunneling electron microscopy (SEM, TEM), X-ray and contact resistance (TLM) characterization and a comprehensive model has been built. Contact recombination on n+ poly-Si surfaces has been reduced down to 80 fa/cm² while keeping the contact resistance low enough to enable FFs above 79.5%. V_{oc} up to 685 mV have been obtained enabling initial cell efficiencies of 21.5%. Further optimization of the passivating polysilicon layers itself has yielded record low values for J_{sh} on textured surfaces: we present J_{sh} and implied V_{oc} measurements with best values of <1
Furthermore, results of an even more innovative type of carrier selective contacts based on transparent metal-oxides will be presented. Electron beam (E-beam) deposited molybdenum oxide (MoOx) has been investigated for its potential as a hole selective contact. The high work function of MoOx induces strong band bending in the silicon absorber, which diminishes the electron density at the e-Si surface, while allowing band-to-band transport for holes. Additionally, its high transparency, due to the wide bandgap and dopant-free hole selectivity, makes it a good candidate to replace other high-quality carrier-selective contacts based on doped layers (e.g. a-Si and polysilicon) at the sunny side of the cell or in bifacial solar cells.

By making large-area "moly-poly" cells, with a front side MoOx/aSi:H(i) passivating contact and a rear-side poly-Si/SiOx stack, we have demonstrated that MoOx based e-Si solar cell technology can be scaled to industrial 6" wafer size. Excellent surface passivation was achieved using MoOx and poly-Si, leading to implied Voc values > 725 mV, and a final cell Voc of 687 mV. Using thin PECVD poly-Si layers to avoid too high FCA losses, a 18.1% efficient 9.2×9.2 cm² moly-poly cell was made, which is to our knowledge the highest reported efficiency so far for moly-poly cells.

9:30 AM ET02.07.03
Carrier-Selective Passivating Contacts Based on polySiC for High Efficiency Si Solar Cells Luana Mazzarella1, Guangtao Yang2, Gianluca Limodio3, Paul Procel1, Arthur Weeber4,1, Olindo Isabella1 and Miro Zeman1; 1PVMD group, Delft University of Technology, Delft, Netherlands; 2Solar Energy, ECN part of TNO, Petten, Netherlands.

Carrier-selective passivating contacts (CSCPs) based on an ultra-thin SiO2 capped with doped thin Si based layers exhibit excellent surface passivation of the Si wafers by the SiO2 and selective carrier extraction thanks to the poly-SiC layers. Poly-Si material exhibits generally poor transparency, owing to high parasitic and free carrier absorption, enabling the use of those materials in an interdigitated back contacted (IBC) cell configuration1 with efficiency up to 26.1%. On the other hand, such materials can improve the passivation of the front side of the device induces current losses. Therefore some efforts have been carried out to reduce the layer’s thickness and to incorporate carbon or oxygen to improve their transparency. Recently, CSCP based on poly-Si alloyed with C4 and O1.4 demonstrated their potential on device level resulting in conversion efficiency up to 25.7% in front back contacted (FBC) cell configuration2.

In this study, we develop polyisolocarbide (poly-SiC) CSCPs with both doping polarities grown by plasma enhanced chemical vapor deposition in an initial amorphous arrangement (a-Si:C:H) on top of a chemically-grown SiO2 (<1.5 nm). We thus monitor the passivation quality during the fabrication process to obtain poly-SiC material. Firstly, we investigate the effect of C alloying, doping and layer thickness on the final material properties and passivation performances.

Furthermore, we optimize the annealing treatment varying both the temperature and time in a wide range (800-950 °C, 5-60 min) to identify the optimal conditions to crystallize the layer stack and drive-in the dopants beneath the passivating SiO2 thin film into the e-Si absorber. Contextually, we enhance the passivation quality of the CSPS stacks by using sacrificial layer schemes that act as source of hydrogen. In this respect, we test SiNx, Al2O3 and Al2O3/SiNx, in forming gas annealing atmosphere at 400 °C. Preliminary results were obtained on symmetric test samples capped with 75-nm thick SiN layer feature promising passivation quality for potential application in both FBC and IBC solar cells. We found that n-type poly-SiC ensures much higher temperature stability than the p-type counterpart with implied open circuit voltage (i-Voc) above 700 mV for the range of annealing temperature / time investigated. For the p-type, the value is limited to 653 mV, with much more margin of improvement. For a stack initially consisting of (a-SiC:H)2/a-Si:H (5 nm) 30 nm, we measure i-Voc above 710 mV, carrier lifetime of 7.5 ms and recombination current densities of 12 fA/cm².

9:45 AM ET02.07.04
Inkjet Printing as a New Method for the Preparation of POLO Contacts Fabian Kiefer1, Nadine Wehmeier1, Till Brendemühl1, Larysa Mettner1, Felix Haase1, Michael Holthausen2, Christian Daeschlein2, Christoph Mader2, Odo Wunnicke2 and Sarah Kajari-Schroder1; 1Institut für Solarenergieforschung GmbH, Emmerthal, Germany; 2Evonik Creavis GmbH, Marl, Germany.

The increase of Si solar cell efficiencies in the last years have been mainly driven by passivating contacts, either with amorphous Si (heterostructure with intrinsic thin layer, HIT) or silicon oxide (poly-Si on oxide, POLO; tunnel oxide passivating contact, TopCon) as an interface layer3-5. Intersubband contact (IBC) solar cells have demonstrated the highest efficiencies of more than 26 % at, as they combine a high voltage resulting from the passivating contacts and a higher current compared to front-contacted solar cells due to the absence of metal shading. A drawback shared by all presented techniques for the deposition of POLO contacts so far is that they cover the full area of one or both sides of the wafer6. During the process of an IBC Si solar cell, a structuring of the deposited poly-Si layer is necessary.

To overcome these hurdles, Evonik developed an inkjet printable, doped precursor (Evonik’s liquid silicon) which can be used for the direct generation of structured amorphous and polycrystalline Si layers7. As direct printing on silicon oxide layers used for POLO junctions is possible, this is a novel, unique possibility to prepare in-situ doped and in-situ structured poly-Si layers with only three process steps: Printing of the liquid Si ink onto the wafer under inert atmosphere with an inkjet printer – conversion of the liquid Si into amorphous Si on a hotplate – annealing of the layer stack in a tube furnace with break-up of the silicon oxide and conversion of the amorphous Si into poly-Si. The shape of the printed Si layer can be designed freely, the minimum structure size of the printed POLO contact is limited only by the drop size of the inkjet process.

In this work, we present the preparation and properties of phosphorous-doped inkjet-printed POLO layers. The electrical characterization of the layers includes measurements of the recombination current densities J0 via photoconductance decay and the contact resistances between aluminum and the printed Si layer and between poly-Si and substrate via transfer length method. We print the ink on one side of the wafer in quadratic fields with an area of 4×4 cm², which is a suitable size for the measurements. The rear side of the wafer is passivated with a silicon nitride passivation layer. We investigate the influence of two process parameters on the electrical properties of the POLO contacts: the thickness of the printed liquid Si layer and the thermal budget of the annealing process. For several poly-Si layer thicknesses and annealing temperatures between 900°C and 1000°C, we achieve J0 of the first P-doped inkjet-printed POLO contacts of < 20 fA/cm² with a minimum value of 14 fA/cm².

Recent progress in development of silicon heterojunction (SHJ) solar cells promotes this technology for mass production of future PV modules. In view of technology upscaling use of abundant materials for cell production is highly desirable. Particularly the tin-doped Indium oxide (ITO) - the transparent conductive oxide contact applied in high efficiency SHJ cells may be challenging in mass production due to indium-related supply/economic and environmental issues. One viable alternative for ITO in SHJ solar cells is more environmentally friendly, abundant and low-cost Al-doped Zinc Oxide (AZO). In our work we develop rear emitter SHJ solar cells with AZO contacts prepared at room temperature to explore the potential for reduction of thermal budget of SHJ cell preparation.

From the long lasting experience in the field of thin film silicon solar cells it is widely accepted that AZO as a window TCO forms better contact with microcrystalline or nanocrystalline Si (nc-Si:H) p-layer compared to the amorphous Si (a-Si:H) p-layer. Formation of the barrier for hole transport has been evident thermal activation of fill factor confirming presence of the carrier transport barrier in the cells with a combination of nc-Si:H p-layer and AZO contact. As for the n-type layers, both amorphous and nanocrystalline Si n-layers form proper contacts with room temperature AZO. In the rear emitter cells with n-type back the n-layer is at the front and nc Si:H is more beneficial than a-Si:H concerning transmission in short wavelength region of the solar spectrum. With combination of the a-Si:H p-layer, nc-Si:H n-layer, and room temperature AZO cell efficiency of 20.2% has been achieved.
Reducing thickness of crystalline silicon (c-Si) <100 µm is one of the keys to low-cost solar cells. On such thin c-Si, small textures are necessary to reduce c-Si losses by texturing process and to keep the robust property in fabrication processes. To obtain small textures with a size <2 µm, we already established “Microparticle-Assisted Texturizing” (MPAT) process and reported elsewhere. However, cleaning of such small texture surface is always challenging. Therefore, in this work, we aimed to develop a suitable cleaning procedure for the small texture surface. After attempted many cleaning procedures, finally we found a novel cleaning method to obtain large effective minority carrier lifetime ($\tau_{\text{eff}}$) of 7.8 ms corresponding to an extremely low surface recombination velocity (SRV) of 0.6 cm/s. In this cleaning method, we noticed an importance role of solution surface tension, hence methanol (CH$_3$OH) was mixed with the solutions to control the surface tension. It should be noted that without using methanol in the cleaning, only SRV$\approx$3.5 cm/s was obtained. We named this finding “Methanol-Assisted Cleaning (MAC)” process. We also verified that mixing methanol reduces contact angles or surface tensions of the solutions on the flat c-Si (100), flat c-Si (111), and textured c-Si (100). Owing to the low surface tension, the solution can reach even the bottom of the complicated small texture surface, leading to uniform chemical cleaning and better passivation quality. Features of the MAC process is also presented in this work, which are expected to be useful for cleaning of any kinds of Si wafers other than solar cell ones.

**Fabrication of Silicon Heterojunction Solar Cells Using PECVD-Grown 40 µm-Thick Epitaxial Silicon Wafers**

Ji-Eun Hong$^1$, Ka-Hyun Kim$^2$, Dong Suk Kim$^3$ and Soon-Ho Oh$^4$, KIER-UNIST Advanced Center for Energy, Korea Institute of Energy Research, Ulsan, Korea (the Republic of); $^1$Department of Integrated Energy and Photon Technology, Cheongju University, Cheongju, Korea (the Republic of).

Wafer cost occupies about 40 % of module cost in the crystalline silicon solar cells. Current wafering technology relies on wire sawing that produces wasteful kerf-loss and high mechanical stress, resulting in additional production cost and limited production yield. Various kerf-less wafering technologies, such as exfoliation or spalling of silicon wafer from an ingot, growth of wafers directly from a silicon melt, and chemical vapor deposition of silicon on release layer or sacrificial substrate, enables to reduce kerf-loss as reported by D. M. Powell et al. Among these, epitaxy silicon growth on mono- or multi-crystalline silicon seems to be the most promising candidate for the next generation wafering technology due to the fact that epitaxy growth also enables to fabricate built-in junction structure simultaneously during growth. In other word, epitaxy growth process can significantly reduce solar cell fabrication steps (i.e. gas-to-wafer) compared to the conventional solar cells using wire sawn wafers, as also reported by R. Hao et al. Recently, many research results were reported mentioning that epitaxial growth of Si films on c-Si substrates was achieved by Atmospheric Pressure Chemical Vapor Deposition (APCVD). However, this technology usually disassociates the gas precursors at substrate temperatures higher than $1000 \, ^\circ\text{C}$. As Kambara et al. reported in a recent paper that high temperature process is one of the most cost generating factors in mass production, necessity of such high temperature for APCVD makes the commercialization of the silicon epitaxy technology using APCVD less attractive. Compared to APCVD, Plasma Enhanced CVD(PECVD)-based epitaxy can be performed at a low substrate temperature of $\approx-200 \, ^\circ\text{C}$, leading it to the far more cost-effective alternative. Thus, in this presentation, we studied on epitaxy silicon growth at $200 \, ^\circ\text{C}$ using PECVD, and also demonstrated kerfless wafering using direct exfoliation. We succeeded in depositing 40 µm-thick silicon epitaxy layer at $200 \, ^\circ\text{C}$. Measurements showed that there were porous and H-rich interface layers, which can be utilized as a separation layer. Growth mechanism of epitaxy layer was further confirmed by ellipsometry using Bruggeman effective medium approximation (BEMA). And, cross-sectional transmission electron microscopy (TEM) images showed that there were hydrogen rich interface layers, and atomic arrangement at the interface was not disturbed. In addition, we investigated the exfoliation of epitaxy layer using metallic stress layer. Finally, we used the exfoliated 40 µm-thick free-standing epitaxial wafers to fabricate silicon heterojunction solar cells. The fabricated cell exhibited an efficiency of 11.42 % ($J_{\text{sc}} : 32.28 \, \text{mA/cm}^2$, $V_{\text{oc}} : 610 \, \text{mV}$, $\text{FF} : 58 \%$).

**Organic-Silicon Heterojunction Solar Cell**

Baoquan Sun; Institute of Functional Nano and Soft Materials Laboratory (FUNSOM), Soochow University, Suzhou, China.

Numerous new materials and device structures have been widely explored in order to cut the cost of photovoltaic (PV) manufacture. Organic-inorganic hybrid solar cells based on nanostructured semiconductor have built up in few years ago, which may promise the low cost and high performance. However, the device performances are relatively lower than its pristine all-inorganic PV devices, resulting from the numerous surface defect and improper organic-inorganic phase segregation. Here, we demonstrate that hybrid PVs based on organic conjugated molecular and nanostructured silicon nanowire arrays can achieve a high PCE by controlling the phase separation as well as surface passivation. An advantage of hybrid devices presents the excellent light harvest capability of nanostructured as well as simple fabrication process. Especially, hybrid composites of conjugated organic materials and nanostructured inorganic materials are potential candidates for cost-effective and efficient solar-energy harvesting devices. This device can be worked by a light-modulated field effect solar cell, which can be potentially integrated with halide perovskite. In addition, this type device can be easily integrated with other type energy device, for example, an energy harvesting structure that integrates an organic-Si heterojunction solar cell and a triboelectric nanogenerator (TENG) device is built to realize power generation from both sunlight and raindrop. In addition, a self-charging power unit based on an organic-Si heterojunction solar cell and a polypyrrole supercapacitor, which simultaneously achieved both photoelectric conversion and energy storage.

**Effect of Permanent Dipole Layers in the Electrical Characteristics of Electronic Devices and Solar Cells**

Elia Rosi¹, Zaira Barquera², Isidro Martin³, Pablo Ortega³, Cristobal Voz³, ⁴, Joaquim Puigdollers³ and Ramon Alcubilla³; ¹University of Politecnica-Catalunya, Barcelona, Spain; ²Cinvestav, Querétaro, Mexico.
In the last years, there has been a generalized tendency towards the use of novel materials for the formation of electron-selective contacts on n-type crystalline silicon (c-Si) heterojunction solar cells. Until recently transition metal oxides (TiO$_2$-open style=tint=accent color=010332@2×640px) or alkali and alkaline earth metal salt interlayers (LiF, MgF$_2$) have been mainly used. However new organic molecules with a permanent dipole moment are on the rise as promising candidates to improve the electric contact with the metallic electrode. Conceptually speaking, the dipole of the molecule induces a build-in tension on the layer that can move the effective work function of the metallic electrode at the interface with the semiconductor.

This effect is strongly dependent on the dipole package and orientation, but also the on the individual molecular dipole moment. Amino acids, are known for strong spatial charge splitting as amino group protonation yields a net positive charge and Carboxylate ionization yields a net negative charge. This accounts for many amino acids strong dipole moment. In this group we can find Glycine, as a stable and easy processable material. Amino acids, are known for strong spatial charge splitting as amino group protonation yields a net positive charge and Carboxylate ionization yields a net negative charge. This accounts for many amino acids strong dipole moment. In this group we can find Glycine, as a stable and easy processable material.

In a first approximation, we have studied the electric contact using Transfer Length Method (TLM) of n-type crystalline silicon with an Atomic Layer Deposited Al$_2$O$_3$/TiO$_2$ stack, reaching a maximum contact resistance of 0.75 Ohms cm$^2$. Furthermore, the effect of the dipole layer has been confirmed on Thin-Film Transistors (TFTs) by depositing a glycine thin-film layer (20 and 5 nm thick) between the silicon dioxide and the semiconductor. The incorporation of the glycine interlayer results in a significant increase of the threshold voltage. Variation of the threshold voltage allows to estimate the dipole moment of the interlayer. Finally, the influence of the incorporation of the glycine dipole was studied on final solar devices. In particular, low temperature dopant-free c-Si solar cells were fabricated using Glycine as a new ETL with the following structures ITO/V$_2$O$_5$/n-cSi:H/Glycine/Al and ITO/V$_2$O$_5$/n-cSi:Al$_2$O$_3$/TiO$_2$/Glycine/Al.

Effect of Slow-Speed Evaporation of BaSi$_2$ on the Performance of P-Type BaSi$_2$/n-Type Crystalline Si Solar Cells

Michinobu Fujiwara, Kazuma Takahashi, Yoshihiko Nakagawa, Kazuhiro Gotoh, Yasuyoshi Kurokawa and Noritaka Usami; Nagoya University, Nagoya-shi, Japan.

Alternatives to p-type amorphous Si (a-Si) for hole selective contacts in Si heterojunction (SHJ) solar cells have attracted significant attention. We have recently proposed p-type BaSi$_2$ (p-BaSi$_2$) as a promising candidate for a hole selective material, since device simulation (Afor-Het ver. 2.5) showed that p-type BaSi$_2$ improves open-circuit voltage ($V_{oc}$) of SHJ solar cells [1]. To deposit p-BaSi$_2$ on a large-area substrate, we developed a simple method to perform thermal evaporation of BaSi$_2$ on B-doped hydrogenated a-Si:H (a-Si:H) deposited by plasma enhanced chemical vapor deposition (PECVD). To realize high-quality p-BaSi$_2$/n-type crystalline Si (c-Si) heterostructures, control of the deposition rate during the evaporation is of crucial importance. In fact, we have shown that employment of a slow deposition rate at the initial stage of the evaporation improves $V_{oc}$ presumably due to the enhanced diffusion of Ba into the Si substrate [2]. In this study, we changed the time to hold slow-speed deposition of BaSi$_2$ and investigated the effect on film properties and solar cell characteristics.

B-doped a-Si:H thin film with a thickness of about 10 nm was deposited on a c-Si(111) substrate (resistivity: 3-6 Ωcm) by PECVD. The flow rates of SiH$_4$, H$_2$ and 1% B$_2$H$_6$ were 40, 40 and 40 sccm, respectively. Substrates were heated at 600°C for 3 h in the evaporation chamber. BaSi$_2$ granules with the weight of 0.008 and 0.1 g were evaporated by resistive heating. The heating current was initially held at 90 A for 0, 30, 180 and 600 s and then raised to 140 A. Rapid thermal annealing (RTA) was performed for some samples to diffuse B into the evaporated BaSi$_2$ thin films. After that, the solar cell structure (Ag/TO thickness (t): 80 nm/p-BaSi$_2$/30 nm/n-c-Si r. 280 mm/Au-Sb) was fabricated, and their J-V characteristics were measured under AM1.5G illumination. BaSi$_2$ single films were characterized by Raman spectroscopy and X-ray diffraction (XRD).

As a result of J-V characteristics, we achieved conversion efficiency of 8.37% by holding slow-speed deposition for 180 s. Changing the holding time of slow deposition from 0 to 180 s improved $V_{oc}$ as well as fill factor (F.F.) from 402 to 464 mV and from 24.1 to 60.1%, respectively. At the holding time of 600 s, the highest $V_{oc}$ of 554 mV was obtained although F.F. was degraded to 28.0%. Raman spectroscopy showed that the a-Si layer, which was found at the surface after evaporation, disappeared after RTA. XRD patterns showed that the holding time of 180 s a-axis-oriented BaSi$_2$ was the most predominant after evaporation. After RTA for the sample at the holding time of 180 and 600 s, a-axis orientation was enhanced and FWHM was reduced. These results show that the slow-speed evaporation improved the homogeneity and film quality, and led to the improvement of solar cell performance.

Effects of Surface Doping of Si Absorbers on the Performance of Carrier-Selective Contacts

Hyunju Lee¹, Takefumi Kamioka¹, Noritaka Usami¹ and Yoshio Ohshita¹; ¹Toyota Technological Institute, Nagoya, Japan; ²Graduate School of Engineering, Nagoya University, Nagoya-shi, Japan.

Recently, a new alternative to the conventional silicon heterojunction (SHJ) solar cell concept has been suggested and intensively studied. In this new concept, a set of dopant-free carrier-selective contacts (CSCs) is employed to separate and collect photo-generated free carriers in a single cell structure [1]. One of the most promising materials for dopant-free CSCs is transition metal oxides (TMOs). TMOs were first used in organic solar cells. So far, as dopant-free n- and p-type CSC materials, amorphous titanium dioxide (TiO$_2$) and sub-stoichiometric molybdenum oxide (MoO$_x$) is the most promising material in TMO-based CSC Si solar cells, respectively [2-3]. Meanwhile, TMO-based CSCs have demonstrated significant progress in Si solar cell performance. However, the performance of TMO-based CSC Si solar cells is still inferior to that of thin tunnel SiO$_x$/phosphorus-doped hydrogenated poly silicon (n‘-poly-Si:H) stack-based CSC Si solar cells (also referred as TOPCon structured solar cells) owing to the higher level of surface recombination and contact resistance of TMO-based CSCs [2]. In particular, the higher performance of the TOPCon seems to be partially due to shielding of the tunnel oxide/Si interface recombination without appreciably introducing Auger recombination by shallow phosphorus diffusion from an n‘-poly-Si:H layer into an n-type Si absorber through an ultra-thin tunnel oxide layer during polysilicon annealing [4].

In this study, we have investigated:

- The performance of TiO$_2$ and MoO$_x$-based CSCs on shallowly doped n‘- and p‘- Si surfaces.
- The effects of various ultra-thin tunnel layers on the performance of TiO$_2$ and MoO$_x$-based CSCs.
- The stability of the fabricated TiO$_2$ and MoO$_x$-based CSCs on shallowly doped n‘- and p‘- Si surfaces under light illumination, for developing cost-effective, high-performance and stable CSC Si solar cells and elucidating the effects of the surface doping of Si absorbers and the ultra-thin tunnel layers on the performance of TiO$_2$ and MoO$_x$-based CSCs. During our presentation, we will discuss the experimental results and suggest ways to enhance the performance and stability of CSCs.

References

In the current study, a novel three-dimensional multiple-slip crystal plasticity based model and specialized finite-element formulations are used to analyze the reliability and lifetime of PV devices. Embedded Void Approach (EVA) to reduce defects at heterogeneous interfaces of thin-films by overcoming the thermal mismatches of multi-junction photovoltaic, e.g. Indium Gallium Nitride (InGaN) and deep reactive ion etching (DRIE) processes. To achieve the high efficiency of MW radial junction solar cells, we developed the high conductive and transparent top electrode to replace the conventional bus-finger electrode which has a significant shading loss. We devised a novel micro-grid top electrode which shows superior transparency (over 97%) and low sheet resistance (less than 30 Ω/□). By applying the micro-grid electrode on the top surface, the MWs solar cells showed outstanding fill factor (81.2%) and improved efficiency (16.5%).

As an efficient way to decrease the flat-top-surface reflection of the MWs and increase the light absorption property of the radial junction solar cells, a tapered-MW structure was employed using a simple wet-etching process. When a c-Si wafer with MWs is dipped in a silicon etchant (RSE-100, transene), the top part of the MWs that has a shorter diffusion path compared to the bottom part is etched more quickly. Since the diameter of the tapered MWs gradually increased from the top to the bottom, the tapered MWs can act as a buffer layer to compensate for the mismatch between the refractive indexes of air (1) and the silicon substrate (4). Thus, the surface reflection of the tapered MWs was observed to be less than 2% at a wavelength of 550 nm. The tapered MW based radial junction solar cells exhibit improved efficiency up to 18.9% thanks to the enhanced light absorption property.

As the last step for optimizing the device structure of the MWs solar cells, we used high purity doping process using acid dopant sources that showed improved minority carrier lifetime (from 79.29 µs to 272.24 µs). Accordingly, we achieved high efficiency (20.2%) MWs radial junction solar cell by applying all of the developed technologies such as the micro-grid electrode, tapered MWs, and high purity doping process. At present, we are aiming at developing an ideal passivation layer to achieve the more than 25% efficiency of the radial junction solar cells. Therefore, we believe the MW structures with the suggested technologies become a foundational technology for the highly efficient radial junction solar cells.

Saw damage removal and different pyramidal texture size on passivation characteristics of the SHJ solar cells. Furthermore, making abrupt pyramidal textured c-Si/i-a-Si:H interface is of significant importance. For example, Stefaan De Wolf et al. (J. Appl. Phys. (2007)) reported that for a-Si:H films with no crystalline component the passivation properties enhances by annealing most likely by film relaxation, which is not the case when an epitaxial layer was grown at the interface. However, there are few reports regarding combined effects of surface texturing and abruptness of c-Si/i-a-Si:H interfaces on the passivation properties and subsequent performance of SHJ solar cells.

Thus, in this presentation, we report on the combined effects of saw damage removal and different pyramidal texture size on passivation characteristics of i-a-Si:H/e-c-Si/a-Si:H structures. Transmission electron microscopy (TEM) observations showed that the peaks of the pyramids are not sharp but somewhat flat, and flat and side-wall area of pyramids exhibited different crystalline orientations ((100) and (111), respectively). Cross-sectional TEM measurements also showed that the c-Si/i-a-Si:H interface was abrupt when i-a-Si:H was deposited on the side walls (i.e. (111) side) of the pyramids whilst the sidewalls were textured in chemical solutions to make pyramidal textures at the both surfaces. Then, i-a-Si:H thin films (~10 nm thick) are deposited on top of pyramidal and thermal expansion coefficients mismatch during the growth of i-a-Si:H thin-film on c-Si substrate, both with/without embedded micro-voids. Further, a parametric study of voids aspect and volume ratios impact on dislocation evolution is studied.

Thus, in this study, we report on the combined effects of saw damage removal and different pyramidal texture size on passivation characteristics of i-a-Si:H/e-c-Si/a-Si:H structures. Transmission electron microscopy (TEM) observations showed that the peaks of the pyramids are not sharp but somewhat flat, and flat and side-wall area of pyramids exhibited different crystalline orientations ((100) and (111), respectively). Cross-sectional TEM measurements also showed that the c-Si/i-a-Si:H interface was abrupt when i-a-Si:H was deposited on the side walls (i.e. (111) side) of the pyramids whilst the sidewalls were textured in chemical solutions to make pyramidal textures at the both surfaces. Then, i-a-Si:H thin films (~10 nm thick) are deposited on top of pyramidal and thermal expansion coefficients mismatch during the growth of i-a-Si:H thin-film on c-Si substrate, both with/without embedded micro-voids. Further, a parametric study of voids aspect and volume ratios impact on dislocation evolution is studied.

Effects of Different Pyramidal Texture Size and Interfacial Abruptness on the Performance of Silicon Heterojunction Solar Cells

Joon-Ho Oh1, Ji-Eun Hong2, Hee-Eun Song3, Ka-Hyun Kim2 and Dong Suk Kim1; 1Department of Electrical and Computer Engineering, North Carolina State University, Raleigh, North Carolina, United States; 2Centre for Simulation Innovation and Advanced Manufacturing, The British University in Egypt, Cairo, Egypt.

The present study focuses on suppressing/sinking dislocations generated at the interface during the fabrication of single-junctions with high lattice and thermal mismatches of multi-junction photovoltaic, e.g. Indium Gallium Nitride (InGaN) thin-film on Silicon (Si) substrate. Such defects act as scattering centers that impact the minority carrier lifetime, reduce thermal conductivity, and form easy pathways for impurity diffusion. Thus, limit the performance, reliability, and lifetime of PV devices. Embedded Void Approach (EVA) to reduce defects at heterogeneous interfaces of thin-films by overcoming the thermal expansion coefficient mismatch and lattice mismatch between different layers is studied.

In the current study, a novel three-dimensional multiple-slip crystal plasticity based model and specialized finite-element formulations are used to address InGaN growth on Si substrates. The new formulations account for threading dislocations generation, mobility and interaction to account for lattice and thermal expansion coefficients mismatch during the growth of InGaN thin-film on Si substrate, both with/without embedded micro-voids. Further, a parametric study of voids aspect and volume ratios impact on dislocation evolution is studied.

Enhancement of Light Trapping for Thin-Film Silicon Solar Cells

Y. Sha Yi, M. Ye and D. Wu
University of Michigan, Dearborn, Michigan, United States

Next generation thin film solar cells (inorganic or organic) are generating wide interests recently as it promises to reduce the materials usage and significantly lower the cost of electricity generated by solar cells. One of the main types of thin film solar cells, with Si as the absorbing layer, presents two main challenges for further development: (1) how to achieve broadband antireflection at the front surface; (2) how to achieve broadband light trapping at the bottom surface (especially at longer wavelength) within the AM1.5 solar spectrum. With the rapid progress of nanotechnology, many nano scale photonic devices as small as 30 nm have been realized, which is very promising for achieving manipulation of photons at chip scale and having broad applications in renewable energy (photovoltaic cells, solid state lighting), telecommunications and the bio medical field. Accordingly, there are many routes to enhance the light absorption for thin film. Various methods of enhancing optical absorption have been proposed, including the use of dielectric photonic structures or plasmonic metallic nanoparticles; most of which are mainly focused on either front side antireflection film, or light trapping structures on the back side. Few works have been proposed that take into account the two challenges stated above; broadband antireflection photonic structures on the front side and light trapping photonic structures at the bottom side, as well as their correlation for enhancing the light absorption for thin film solar cells.

In this work, we have studied light trapping effects utilizing both top and bottom nanophotonic structures. We propose broadband nano scale pyramid light trapping top photonic structures to increase the absorption of thin film solar cells, especially at short wavelength; and broadband light trapping bottom omni directional photonic crystal structures to optimize the optical path length for longer wavelength, especially to increase the near bandgap wavelength absorption of thin film solar cells. The correlation between the front side and bottom side nano photonic structures suggests the importance of light trapping from both aspects.

ET02.10.04
Investigation of Metal Oxide/Amorphous Silicon Interfacial Conductivity Towards Solar Cells Based on Ultra-Sparse Metal Mesh

Qingyu Cui and L. Jay Guo
University of Michigan, Ann Arbor, Michigan, United States

In large-area optoelectronic and display industries, Indium Tin Oxide (ITO) is the most widely used transparent electrodes, because of its excellent transparency and conductivity. However, the storage of indium is becoming more and more limited, which will give rise to the increasing cost and concerns. In recent decades, researchers showed wide interests to the alternative candidates of ITO, including other cost-efficient conductive oxides, ultra-thin metal films, carbon-based electrodes, metal mesh and so on. Among them, the metal mesh is drawing extensive attentions, due to its easy fabrication, including nano-imprinting, electroplating, photo-lithography, even solution-coating of nanowires. However, it is not that desirable for solar cell or light emitting devices because of the large non-conductive holes in the metal mesh. As a result, people usually use conductive polymer to enhance the local conductivity.

Here we report on the device structure of amorphous silicon (a-Si) solar cells without such a conductive layer for metal mesh, which incorporates the dramatically increased interfacial conductivity for tungsten oxide (WOx) and a-Si.

Based on the inter-digitated Tungsten (W) electrodes, we found the film lateral conductance of 60nm a-Si deposited on 30nm WOX is at least 4 orders higher than individual a-Si or WOX films, where the obtained resistances are 677 ohm, 6.67E+6 ohm and over 1E+10 ohm for WOX / a-Si, WOX and a-Si, respectively. Probably this is due to the quantum confinement and reduced recombination site density for carriers along the WOX / a-Si interface, then resulting in the enhanced lateral carrier transportations.

Utilizing the WOX / a-Si interface, we fabricated solar cells (ITO / WOX / a-Si / Cathode) based on ITO-mesh with different size. The ITO mesh period is 420 um x 420 um, and the edge length of non-ITO window increases from 0 um to 410 um (the window ratio from 0% to 95.3%). We found that the WOX / a-Si interface is still sufficiently conductive to collect the photo-generated holes even under ultra-sparse mesh (window ratio 95.3%), without sacrificing the Photo-Conversion Efficiency (PCE), which remains around 3.5% for 60nm a-Si. Moreover, Jsc increased from 11.2 mA/cm2 to 13.2 mA/cm2, which is partly because of the increased overall transparency of ITO. Then Voc decreases from 0.60 V to 0.51 V, probably due to the reduced overall work-function of anode. The serial resistance decreased from 43 to 26 ohm*cm2 and the ambipolar diffusion length increased from 55.3 nm to 99.8 nm, possibly resulting from the increased lateral electric field, faster carrier transportation and reduced recombination site density along the WOX / a-Si interface.

The results reported here verified the lateral carrier transportation along the interfaces between different active interlayers can be well utilized to achieve simpler device designs, especially based on the metal mesh with a much higher overall transparency than ITO.

Figure-of-Merit Evaluation of Gold-Hyperdoped Silicon for Photovoltaic Applications

Senali Dissanayake1, Matthew Wilkins2, Philippe K. Chow3, Wenjie Yang4, Quentin Hudspeth1, Shao Qi Lim3, Jimmy Williams4, Jeffrey M. Warrender3, Jacob J. Krich2 and Meng-Ju Sher1

1Physics Department, Wesleyan University, Middletown, Connecticut, United States; 2Department of Physics, University of Ottawa, Ottawa, Ontario, Canada; 3U.S. Army ARDEC - Benet Labs, Watervliet, New York, United States; 4Research School of Physics and Engineering, The Australian National University, Canberra, Australian Capital Territory, Australia.

Laser hyperdoping offers a viable method to introduce large concentrations of impurities into silicon, introducing states deep in the silicon band gap that could enable an intermediate band solar cell architecture. A previously reported quantitative figure of merit has been advanced as a heuristic for assessing the promise of a candidate silicon-hyperdopant system. The figure of merit is proportional to the product of the electron mobility, the recombination lifetime, and the square of the average sub-gap absorption coefficient.[1] For the first extensively-studied dopant, sulfur, the figure of merit was found to be fairly low at all S concentrations due to extremely short (~130 ps) carrier lifetimes.[2] Recent work has shown evidence of sub-band gap photocurrent response resulting from the introduction of transition metals in hyperdoping concentrations.[3] Ion implantation followed by melting is a well-established hyperdoping method for heavy chalcogen dopants (S, Se and Te), but incorporating transition metals at supersaturated concentrations with high crystalline quality has been challenging. One complication of working with transition metals as impurities is the incidence of cellular breakdown – a microstructure that results from instability during solidification – under some solidification conditions. In this work we optimize maximum concentrations that can be
practically synthesized for the prospect for PV device. We use time-resolved THz spectroscopy measurements to study carrier lifetime, and we compare these to the previously reported results for S. This work reports on a systematic study to experimentally determine the mobility, lifetime, and absorption coefficient for gold-hyderdoped silicon at several concentrations, and use these to compute a figure of merit for each dopant and dose.

ET02.10.06
Tunnel Oxide Passivated Contact for Crystalline Silicon Solar Cells Using Hot-Wire Chemical Vapor Deposition
Kaining Ding1, Manuel Pomaska1, Shenghao Li1, Jan Lossen1, Jan Hoss1, Maurice Nuyts1, Friedhelm Finger1 and Uwe Rau1; 1Research Center Juelich, Julich, Germany; 2ISC Konstanz, Konstanz, Germany.

In this work, hot-wire chemical vapor deposition (HWCVD) was utilized to fabricate amorphous silicon(a-Si) thin films for tunnel oxide passivated contacts of crystalline silicon n solar cells. So far low pressure chemical vapor deposition or plasma enhanced chemical vapor deposition are usually used to deposit thea-Si:H thin films on crystalline silicon covered by a thin tunnel oxide(SiO2/c-Si) to form the passivated contact, giving rise to excellent solar cell performances of up to 26.1% energy conversion efficiency. As the fabrication process of the solar cells includes several high temperature process steps of up to 900 °C, the a-Si precursor layer needs to have the property of remaining blister-free after all process steps. At the same time, the c-Si surface should be very well passivated by the a-Si/SiO2 layers at the end of all process steps. Last, the deposition rate should be high, in order to be attractive for photovoltaic mass production. We developed ex-situ as well as in-situ n-doped a-Si films for the electron selective passivated contacts. The films remain blister-free after all process steps, give rise to promising passivation qualities with implied open circuit voltages of more than 720 mV, and were deposited with rates of more than 1 mm/s. To correlate the passivation quality to the material properties of the n-doped layer, X-ray diffraction was measured before and after and every high temperature process step. Additionally, the investigation was completed by measuring the hydrogen and phosphorus concentration profiles using secondary ion mass spectrometry and by measuring the doping profiles using the electrochemical capacitance-voltage profiling technique.

Recombination Activity of Inclined Σ3{111} Grain Boundaries in High-Performance Si Ingots
Yutaka Ohno1, Kentaro Kutsukake1, Takehiro Tamaoka2, Seiji Takeda2, Yasuo Shimizu2, Naoki Ebisawa2, Koji Inoue2, Yasuoyoshi Nagai3 and Noritaka Usami4; 1MR, Tohoku University, Sendai, Japan; 2ISIR, Osaka University, Osaka, Japan; 3The Oarai Center, IMR, Tohoku University, Oarai, Japan; 4GSE, Nagoya University, Nagoya, Japan.

Grain boundaries (GBs) are inevitably introduced in polycrystalline silicon (Si) ingots for solar cells, and they have substantial influences on electronic properties such as minority carrier lifetime, via the segregation of impurity atoms. Especially, asymmetric GBs with higher-Σ value of the associated coincident site lattice (CSL) are frequently introduced in Si ingots, and they severely affect the overall material properties even when their density is very low. Therefore, a comprehensive knowledge of the recombination activity of the GBs, as well as their structural properties, is indispensable to produce cost-effective high-efficiency solar cells by controlling the formation of those detrimental GBs.

In the present study, we discuss the recombination activity of asymmetric Σ3 {111} GBs with the <110> tilt axis, whose GB planes are slightly inclined from [111], introduced frequently in high-performance Si ingots. The activity of those asymmetric GBs was high even when their inclination angle was small, while the activity of the symmetric Σ3{111} GBs was negligible. High-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM) revealed that, most of the parastas of the asymmetric GBs were composed of arrays of GB dislocations lying on symmetric Σ3{111} GB segments. Those dislocations were edge-type with the Burgers vector of 1/3<111> 1. Atom probe tomography (APT) revealed that oxygen atoms segregated at the atomic sites under tensile stress above about 2 GPa, which were presumably introduced along the GB plane due to the GB dislocations [1, 2]. Carbon atoms also segregated, while they would locate only nerby the dislocation cores. Small amount of metal precipitates such as iron silicides were occasionally observed on the asymmetric GBs, presumably along the GB dislocations [3, 4]. The correlation between the segregation ability of impurity atoms and the recombination activity will be discussed.

Acknowledgments: This work is partly supported by “Multicrystalline informatics toward establishment of general grain boundary physics & realization of high-quality silicon ingot with ideal microstructures” project in JST/CREST, Grant No. JMPJCR17J1 (2017-2023).

P-Type Molecular Monolayer Doping of Silicon for Photovoltaic and Semiconductor Devices
Megan E. Detwiler, Scott Humski, Jenna Doran, Scott Williams and Santosh Kurinec; Rochester Institute of Technology, Rochester, New York, United States.

P-type doping of silicon wafers using molecular monolayer deposition (MLD) will be presented. Our method minimizes additional lattice defects, allows the formation of ultra-shallow junctions, and enables doping of non-planar surfaces. This is an attractive alternative to the industry standards as the process does not induce crystalline damage, unlike ion implantation, and utilizes materials less hazardous than those involved in spin-on diffusion. Monolayers are formed with allylboronic acid pinacol ester (ABAPE) as well as other selected boron-containing molecules. The wafer was then photonicly or thermally treated to create the ultra-shallow junction with optimized sheet resistivities. The doping concentrations and profiles are evaluated using sheet resistance measurements, SIMS, DLTS, and TXRF. MLD temperature and time optimization will be discussed.

Effects of Oxidants of Atomic-Layer-Deposited Al2O3/TiO2 Films on Silicon Surface Passivation
Dongchul Suh; Division of Chemical Engineering, Hoseo University, Asan, Korea (the Republic of).

Al2O3 thin films have attracted substantial interest for their use as alternative passivation films of crystalline silicon (c-Si) solar cells because of their improved field-effect and chemical passivation. Among several methods that have been employed for the growth of Al2O3 films, atomic layer deposition (ALD) is very suitable in the sense that it is a self-limiting film growth process based on sequential surface reactions that offers excellent thickness uniformity. The most common ALD process is the deposition of Al2O3 by alternating exposures of trimethyl aluminium (TMA) and H2O, due to the broad ALD process window, but less extensively for passivation. In typical ALD of Al2O3 thin film for surface passivation, O2 plasma has been widely used as an oxygen source due to higher negative charge density, in particular for low deposition temperature. Thermal ALD using reactive O3 has also been introduced because it is easy to purge as well as reactive, enabling batch ALD process for high throughput.
In the formation of Al₂O₃ film, chemical exchange reaction is dominant between TMA and H₂O. However, growth mechanism of ALD Al₂O₃ using O₂ plasma and O₃ is not clearly established but believed that film growth is accompanied by covalent Si-OH group. Different growth mechanisms and high reactivity of the O₂ plasma and O₃ would cause different physical structures, electrical properties, and surface passivation qualities of Al₂O₃. The minimal Al₂O₃ thickness without compromising the passivation properties is 5 nm for plasma ALD Al₂O₃, whereas for thermal ALD, films >10 nm are required. In addition, even though low interface defect density of 10¹⁳ eV⁻¹ cm⁻² is obtained after annealing of Al₂O₃ made from all oxidants, field-effect passivation is dominant for O₂ plasma and O₃-based Al₂O₃ after annealing, but less prominent for H₂O-based Al₂O₃ before and after annealing. The oxidant has a significant influence on the surface passivation mechanism during atomic layer deposition. In this work, we studied the influence of different oxidants and thermal post-deposition treatments for the passivating ALD Al₂O₃ single layers and Al₂O₃/TiO₂ stacks. Al₂O₃ thin films have been deposited on crystalline silicon by atomic layer deposition using various oxygen precursors, such as H₂O and O₃. The electrical characterization of the stack layers has shown that in as-deposited states on Al₂O₃, H₂O-TiO₂ has lower saturation current density (J₀e) than H₂O/O₃-TiO₂ in which both H₂O and O₃ are used as oxidants. Annealing is beneficial for H₂O/O₃-TiO₂ to decrease J₀e, which is analogous to H₂O-Al₂O₃ vs. O₃-Al₂O₃.

The Effect of H in the Atomic and Electronic Structure of Amorphous Si and Hydrogenated Amorphous Si Reza Vatan Meidanishahi, Stuart G. Bowden and Stephen M. Goodnick; School of Electrical, Computer and Energy Engineering, Arizona State University, Tempe, Arizona, United States.

Hydrogen incorporation in the fabrication of amorphous Si (a-Si) plays an important role in improving its electronic and optical properties. An important question is how H interacts with the a-Si atomic network, and consequently affects the electronic properties of a-Si. The common assumption is that the role of H is to passivate the dangling bonds (DBs) of the a-Si structure, which subsequently leads to a reduction in the density of midgap states and localized states within the mobility gap. In the present work, we first employ a combined molecular dynamic (MD) and density functional theory (DFT) method to create stable configurations of a-Si:H, and then analyze the atomic and electronic structure to investigate which structural defects interact with H, and how the electronic structure changes with H addition. We show that in contrast with the simple dangling bond picture, atoms bonded by highly strained bonds (SBs) are most significantly affected by the addition of H, in terms of the lowest energy configuration, with similar if not greater importance to that of dangling bonds in passivating a-Si. We find that H atoms decrease the density of mid-gap states of a-Si by bonding to the Si atoms with SBs. Our results also indicate that Si atoms with SBs creates highly localized orbitals in the mobility gap of a-Si and a-Si:H, and the bonding of H atoms to them can significantly decrease the degree of orbital localization. The results demonstrate the beneficial effects of hydrogenation of a-Si in terms of reducing the overall strain energy of the a-Si network, with commensurate reduction of mid-gap states and orbital localization.

ET02.10.11
Estimation of Voltage-Dependent Photocurrent Factor in Metal-Oxide Based Carrier-Selective Contact Silicon Solar Cell Suren Patwardhan1,2, Sandeep Maurya1 and Balasubramaniam Kavarijetti1; 1Indian Institute of Technology Bombay, Mumbai, India; 2K J Somaiya College of Engineering, Mumbai, India.

Typical heterojunction carrier-selective contact silicon (CSC-Si) solar cell has hole and electron selective layers on same or opposite faces of crystalline Si (c-Si) wafer. This is done by depositing thin films of either doped amorphous silicon (a-Si) or transition metal oxides/alkali metal fluorides. In our work, we fabricated heterojunction CSC-Si cells using molybdenum trioxide (MoO₃) as hole selective layer and titanium dioxide (TiO₂) as electron selective layer – to be called as “Test Cell”. It was made on a 280 μm thick n-type Si wafer (n-Si) of 1-5 Ω cm resistivity. MoO₃ was thermally evaporated and TiO₂ was deposited by atomic layer deposition (ALD). The control cell structure consisted of phosphorous diffused back surface field on n-Si (n/n+ BSF) and then analyzed in place of TiO₂ film. Dark and light current-voltage (I-V) measurements were taken at 1 sun simulated radiation with class AAA solar simulator. We tried to estimate the voltage-dependent photocurrent factor (n) due to TiO₂/Si interface based on our experimental data and available literature on heterojunction solar cells. All of our control cells (25) followed current superposition. On the other hand, all the test cells did not follow current superposition as their dark and light current densities crossed-over each other. They also possessed lower fill factor. The CSC-Si cell has many non-idealities such as voltage dependent photocurrent due to which, the current superposition is generally not obeyed. In our test cells, the light-generated current density (Iₗ) was higher by nearly 40% than the control cells. The average fill factor different (AFF) observed between them was 0.14. By using the equation AFF = (1 - n)ⁿVm max, where Vm max is the ideal voltage that a solar cell can deliver under one sun conditions, and Vm is the maximum power point (MPP), Here, Vm = 0 and Vm = V in voltage at maximum power and open circuit conditions respectively, (n is unity for conventional Si solar cell), n for our control cells is taken to be unity and voltage-independent as they showed current superposition. Average Jₗ for these cells at MPP was 15.95 mA/cm² while for the test cell, it reached 20.45 mA/cm². This ratio comes out to be 0.78, matching with that obtained from the equation above by assuming Jₗ for the control cell to be Jₗc (as n = 1). The cell parameters obtained from I-V measurements showed consistency over different sets of samples prepared. This voltage dependence results in loss of fill factor as it is mainly effective for voltages below Vm. Hence estimation of n is a key factor while designing heterojunction carrier selective contact types of cells.

Impurity Distribution at Si/GaAs Heterointerfaces Fabricated by Surface-Activated Bonding Analyzed by Atom Probe Tomography Yasuo Shimizu1, Naoki Ebisawa1, Yutaka Ohno1, Jianbo Liang1, Naotero Shigekawa1, Koji Inoue1 and Yasuyoshi Nagai1; 1Tohoku University, Ibaraki, Japan; 2Tohoku University, Sendai, Japan; 3Osaka City University, Osaka, Japan.

Tandem solar cells composed of Si and III-V materials have attracted considerable attention for next generation photovoltaic system towards 30% efficiency. Surface-activated bonding (SAB) is reported as a method to fabricate tough Si/III-V heterointerfaces, by creating dangling bonds under ion irradiation prior to bonding at room temperature in a high vacuum environment [1]. More recently, intrinsic microstructure of Si/GaAs heterointerface fabricated by SAB was examined by plane-view TEM and cross-sectional STEM [2]. Although the thin foils for TEM specimens were carefully prepared by mechnochanical etching, the TEM inspections revealed that Si/GaAs heterointerface fabricated at room temperature suggests a defective crystalline GaAs layer with less than 1 nm-thick and amorphous Si layer with around 3 nm-thick. For a comprehensive understanding of the electrical property at the SAB interfaces towards complete fabrication processes, distribution analysis of impurities at the SAB interface is required. Here we employ laser-assisted atom probe tomography (APT) for three-dimensional mapping of the impurity distribution, which has been proven useful to examine a specific grain boundary [3]. Quantitative analysis of the impurity concentration at the SAB interfaces by TEM is insufficient due to its lower detection limit than that by APT. In this meeting, we report on the impurity concentration at the SAB interfaces.

In this work, p-Si/n-GaAs heterointerfaces fabricated by SAB method at room temperature were utilized [1]. For comparison, p-Si/n-GaAs heterointerfaces were fabricated under the same SAB condition. For APT specimen preparation, Ga-FIB apparatus equipped with SEM (Helios APT). In this meeting, we report on the impurity concentration at the SAB interfaces.
Nanolab600i, FEI) was used. A local electrode atom probe (LEAP4000XR, CAMECA) equipped with a 355 nm wavelength pulsed laser was employed for APT analysis. Our APT reveals the existence of impurities such as Fe, Ni, and Cu at the Si/GaAs interfaces. These impurities, which may affect the electrical property, were introduced prior to bonding, even though the surface of both Si and GaAs substrates are activated by creating dangling bonds via the removal of native oxide under Ar bombardment in high vacuum. It should be noted that needle-shaped specimens for APT measurements were processed by Ga-FIB. The intermediate layer around SAB interfaces bonded at room temperatures seems to be unstable in an atomistic level under the Ga bombardment. One should take the FIB condition into account for precisely analyzing the impurity distributions. Their distributions found at the homo-interfaces will be also shown in the meeting.

Material Removal Simulation in Sawing Processes of Photovoltaic Silicon
Florian Wallburg1, 2, 3 and Stephan Schoenfelder1, 2; 1Faculty of Mechanical and Energy Engineering, Leipzig University of Applied Sciences, Leipzig, Germany; 2Fraunhofer Center for Silicon Photovoltaics CSP, Halle (Saale), Germany; 3Institute of Mechanics and Fluid Dynamics, TU Bergakademie Freiberg, Freiberg, Germany.

The mass production of wafers, the basic substrates of solar cells, is realised with the multi-wire sawing technology in which silicon wafers are sawn from high-purity silicon bricks. In crystalline photovoltaics the wafering processes and the material costs represent a considerable cost share of about 40% of the complete photovoltaic module. During wire sawing material removal mechanisms resulting from the interaction between hard cutting particles and the silicon surface play an important role regarding the reliability of the processes and products. However, it has not been possible so far to numerically model the mechanically complex process of material removal and subsurface damage as a function of the process parameters. Thus, it is absolutely essential to investigate the direct relationship between removal processes and sawing parameters concerning a reliable production of wafers that are continually getting thinner and thinner.

The investigations made here are focused on the diamond wire sawing process as it has become the major technique to slice bricks into wafers. Due to fixed abrasives the material removal mechanism is significantly defined by grinding processes. In order to analyse the cutting behaviour in fixed diamond wafering single grain scratch experiments were carried out since they can provide better insights into the complex material removal mechanism of grinding processes. By means of several scratch grooves at defined distances, interaction effects and their influence on the fracture process can furthermore be observed. Within this research work this relationship is investigated numerically as well as experimentally.

The basis of the numerical modelling is a pressure-sensitive Drucker-Prager material law with modified caps in the tensile and compressive zone. With the aid of that model phase transformation processes and thus, closely related volumetric changes of the silicon crystal can be predicted which is necessary for crack development. Considering the anisotropic mechanical properties in conjunction with a cleavage-plane illustrating cohesive network it can be shown that different crack systems can be described fundamentally and in interaction with each other – which ultimately leads to the material removal processes. Surface and subsurface damage processes, that are also experimentally investigated, can be examined consequently in more detail. From this, it is feasible in future to derive possibilities for a microstructure-based control of the wire process design, for example, via the cutting geometry shape and arrangement as well as the feed speed. It is well understood that changes to these parameters have a strong impact on the substrate strength and, as a consequence, on the breakage rate. The necessary further developments in substrate production are therefore directly connected to an increase in product quality.

Improved Al/n-Si Electron Selective Contact by Intermediate PFN Dipole Layer
Zaira Barquera1, 2, Eloi Ros1, Cristobal Voze, Pablo Ortega1, Isidro Martin1, Ramon Alcubilla1 and Joaquin Pugdollers1; 1University of Politcnica-Catalunya, Barcelona, Spain; 2-CNINVESTAV-I.P.N. Unidad Queretaro, Queretaro, Mexico.

Selective contacts used in crystalline silicon solar cells require both good surface passivation and very good carrier conductivity, i.e. low ohmic contact resistances, to reach high-efficiency solar cells. Traditionally selective contacts are made using high doped regions by thermal or laser process diffusion stages, which are expensive and high-cost energy. Alternatively a cost-effective approach to obtain good selective contacts relies on the use of electron or hole transport layers (ETL and HTL) processed at low temperatures. Carrier selectivity of these transport layers can be beneficial from the incorporation of dipole interlayer between the metal electrode and the ETL (HTL) layers. By using dipole interlayers a better energy band alignment can be achieved by reducing the work function of the electrode. In this work, we report on the use of a polymer dipole (PFN) to improve ohmic contact with n-type crystalline silicon. In particular, the following solar cell configuration Al/PFN/ETL/n-Si/V2O5/ITO/Ag were studied. Poly (9,9-bis(3’-(N,N-dimethylamino) propyl)-2,7-fluorene-alt-2,7-(9,9-dioctyfluorene)(PFN) was used as intermediate dipole. The influence of PFN interlayer dipole was studied on two different electron selective contacts: AlO3/TiO2 deposited by ALD and a-Si:H/a-Si:H deposited by PECVD. Best results were obtained by using a-a-Si:H/a-Si:H configuration, with Voc=0.67 V, Jsc=33.3 mA/cm2, FF=76.6% and a efficiency of 17.2%.

However, using dopant-free electron transport layer (TiO2-based), fabricated solar cells provided a Voc= 0.61 V, Jsc=30.5 mA/cm2, FF=76% and a efficiency of 14% conversion efficiency.

ET02.10.15
High Performance Transparent Electrodes in the Red/Infrared Range Made by Colloidal-Structured Metallic Micro-Grids
Antonio Terrasi1, 2, Giacomo Torrisi1, 2, Olalla Sanchez-Sobrado1, 2, Manuel Joao Mendes3, Hugo Aguas3, Elvira Fortunato3 and Rodrigo Martins3; 1IMM-CNR, Catania, Italy; 2Faculty of Physics and Astronomy, University of Catania, Catania, Italy; 3Cenimat-i3n, Faculdade de Ciencia e tecnologia, Caparica, Portugal.

One of the most promising approaches to produce industrial compatible Transparent Conducting Materials (TCMs) with excellent characteristics is the fabrication of TCO/metal/TCO multilayers. In this work, we report on the electro-optical properties of a particular type of TCO/metal/TCO, in which the intra-layer is a metallic grid instead of a uniform thin film. The grid is obtained by evaporation of Ag through a mask of polystyrene colloidal micro-spheres deposited by the Langmuir-Blodgett method and partially dry-etched in plasma. IZO/Ag grid/IZO with different thicknesses and size of the mesh have been fabricated, exhibiting excellent electrical characteristics and a particularly high optical transmittance in the red and infrared (IR) spectral region, as compared to planar (unstructured) TCM multilayers. This optical behaviour is of primary importance for the new generation of four-terminal mechanically-stacked tandem solar cells, such as the Perovskite-on-Si double junctions or the bi-facial Si solar cells. In the former case the red-IR light must pass through the junctions entering into the Si bottom cell, while in the latter case a consistent amount of red-IR light can be reflected by the ground and collected from the back side of the cell. Numerical simulations were also used to highlight and understand the role of the Ag mesh structure on the electrical properties of the material.
Enhancement at discrete wavelengths: (i) a guided resonance due to the Bragg attenuation length of the photonic crystal and (ii) confinement due to the presence of the a-Si:H layers incorporated into a-Si:H/c-Si and MoOx/a-Si:H/c-Si devices are dead layers that allow no carrier extraction and Jsc of the solar cells is limited by the minority carrier diffusion length and surface recombination velocity from the EQE analysis. Based on the EQE analysis results, the current loss mechanisms in various types of c-Si solar cells will be discussed.

We have developed a quite general device analysis method that allows the direct evaluation of optical and recombination losses in crystalline silicon (c-Si)-based solar cells. By applying this technique, the optical and physical limiting factors of the state-of-the-art solar cells with ~20% efficiencies have been revealed. In the established method, the current loss mechanisms are characterized from the external quantum efficiency (EQE) analysis with very low computational cost. We find that the developed method provides almost perfect fitting to EQE spectra reported for various textured c-Si solar cells, including c-Si heterojunction solar cells, a dopant-free c-Si solar cell with a MoOx layer, and a PERL solar cell. Detailed analyses show that a-Si:H layers behave as a perfect reflector exhibiting nearly 100% reflectivity in the stop bands, and by (ii) generating guided resonant modes at many discrete wavelengths.

We observe that a 3D inverse woodpile photonic crystal enhances the absorption of a thin silicon film by (i) behaving as a perfect reflector exhibiting increased by using a highly efficient back reflector that sends unabsorbed light back into the solar cell. As an interesting candidate for a back reflector, we study here a thin 3D photonic band gap crystal that forbids light within the band gap for all directions and for all polarizations. We consider a dispersive complex refractive index obtained from experiments. We find by extensive finite-element computations of the 3D time-harmonic Maxwell equations that even a very thin silicon 3D photonic band gap crystal slab reflects broadband visible light omnidirectionally for all polarizations. Our results show a nearly 2.6 times enhanced angle- and polarization-averaged absorption between 680 nm and 890 nm compared to a 2400 nm thin silicon film.

We find that the absorption is enhanced by positioning an inverse woodpile back reflector at the back side of a thin silicon film, which will keep the length of the solar cell unchanged and also reduce the mass of the thin film solar cell. For a very thin sub-wavelength absorbing layer with a photonic crystal back reflector, we identify two physical mechanisms that cause the large enhancement at discrete wavelengths: (i) a guided resonance due to the Bragg attenuation length of the photonic crystal and (ii) confinement due to the effective surface defect on the photonic crystal.

Field Effect Passivation of High Aspect Ratio Silicon Surfaces 

A high efficiency silicon solar cell combines high electrical performance with high optical performance. A common method to improve the optical performance is to utilize subwavelength, high aspect ratio structures, resulting in a surface with a graded refractive index and low reflectance throughout the wavelength spectrum. Although such high aspect ratio structures are relatively harder to passivate than conventional structures, reasonably high surface passivation quality have also been achieved by several research groups. However, surface recombination losses remain to be one of the major loss mechanisms for high efficiency silicon solar cells. One of the widespread methods to achieve high passivation performance on undiffused silicon surfaces is to use passivating dielectric layers with high density of fixed dielectric charges. The combination high aspect ratio structures and dielectric charges is commonly expected to result in an enhanced field effect passivation, resulting in less recombination losses in the textured region than what would be expected from the high surface area enhancement. Yet, despite the comprehensive experimental studies, quantitative analyses of the field effect passivation are mostly based on one-dimensional theory utilizing semi-ininitely thick structures. A detailed numerical analysis of the field effect passivation in multi-dimensional structures is still missing.

In this work, we provide numerical and analytical analyses of field effect passivation for two-dimensional and undiffused surface textures coated with dielectrics. We show that when the dielectric charge density is very large, an enhancement in field effect passivation is only very minor at surfaces upon texturing. Then, the local surface recombination rate is very similar for textured and planar surfaces with similar interfaces and surface recombination losses increase in proportion with surface area. For moderately-large dielectric charge densities, on the other hand, we show the effect of the enhanced field effect is much more significant at the surfaces and surface recombination losses increase sub-linearly with surface area. Thus, through proper material and process choice enabling moderate dielectric charge densities and high interface quality, surface recombination losses are expected to decrease further by taking full advantage the field effect.

Modeling of Effective Secondary Electron Emission Yield from Black Silicon

Black Silicon, a material with a small reflection over a broad wavelength range and large fraction of absorbed photons, introduces a complex surface architecture based on structured absorbers which can also significantly reduce the total effective emission of photogenerated charges. Although overall reflection of incident photons are reduced, the increased surface area from the sub-micron relief vertical formation introduces inherent losses in the collection of photogenerated charges and from the interference by low-energy, secondary charges emitted from the sides and lowermost region of the structures. An analytical model was developed to calculate both the cumulative secondary charge emission from the vertical surface of the black silicon and the resulting parasitic net loss in photogenerated charges based on parameters including height (above base), lateral size and packing density.

In the numerical simulations performed, a set of conditions were identified, which must be adhered to in order to suppress the effect of secondary charge emissions, and that these conditions are highly dependent on incident angle of photons to the surface coupled with the aspect ratio. In one case, a nearly 90% reduction in the parasitic secondary charge emission was observed for shallow angles, while almost 40% was achieved for normal incidence, compared to the flat surface. Our analysis assumes that secondary charge emission occurs only at the material surface, with no bulk effects. Although the formation of black silicon is becoming increasingly standard, analysis of a limited experimental sample set has shown while some low secondary charge emission yields were achieved from the material surface, many samples demonstrated significantly higher secondary charge emission yields either across the full sample size, or in regions. In this work we present the optimal aspect ratio (including packing density, lateral and vertical size) of the black silicon architecture which demonstrated the greatest suppression of secondary charge emission. This work may offer design improvements to the large scale development of black silicon to photovoltaics with optimised opto-electronic properties based on relatively controllable structural morphology features.

Multiscale Design of Disordered Porous Silicon Heterostructures for Infrared Light Control Alessio Palavicini Cruz and Chumin Wang; Instituto de Investigaciones en Materiales, Mexico City, Mexico.

Disordered multilayer heterostructures based on porous silicon are designed using a hybrid quantum-classical approach consisting of a Density Functional Theory calculation of the dielectric function of semiconductor layers. Each layer is modelled with a supercell of silicon atoms forming a crystalline structure where missing atoms characterize the porosity and these periodic pores are saturated with hydrogen and oxygen atoms. The ab-initio calculations are followed by the application of the transfer matrix method to compute the electromagnetic wave propagation along the heterostructure. Optical transmittance of the multilayer designs is verified by synthesizing freestanding samples of porous silicon multilayered films, obtained by means of electrochemical anodization of crystalline silicon wafers which allows us to etch each layer with specific porosities by varying current density, thus producing films with arbitrary dielectric function profiles. These samples are characterized through scanning electron microscope images and its transmittance is measured with a Fourier transform infrared spectrophotometer to compare theoretical and experimental results. Layer sequences with distinct types of disorder are assessed and compared with periodic ones for their performance as photonic structures such as mirrors and filters which could potentially be integrated into electronic circuits or used as elements of all-silicon photonic devices.

Materials for Solar Fuels—Coupling Efficient Water Splitting Catalysts and High-Performance Photovoltaics by Atomic Layer Deposition Paul C. McIntyre; Department of Materials Science and Engineering, Stanford University, Stanford, California, United States.

Atomic layer deposition (ALD), a cyclic form of chemical vapor deposition that occurs via a series of self-limiting chemisorption reactions, is an increasingly important enabler of nanotechnology and advanced energy technologies. Exciting energy-related applications of ALD that have emerged in recent years include surface passivation of photovoltaics, electrode coating for advanced batteries, and catalyst synthesis. In this presentation, I will summarize recent research in which ALD has been used to promote stable photoelectrolysis of water for solar fuel synthesis. ALD-grown TiO_x layers are found to be particularly effective in inhibiting oxidative corrosion of high-quality semiconductor absorbers and in electronically coupling these semiconductors to efficient catalysts for oxygen evolution, the kinetically-limiting step in water splitting. In addition, ALD is used to alloy TiO_x with transition metal oxides that are themselves good catalysts for water oxidation and that exhibit a high work function. These layers produce high photovoltages in excess of 600 mV in n-Si Schottky MIS junction water splitting photoanodes. Such ALD-grown metal oxide alloys have the potential to become "all-in-one" catalyst/protection/hole-selective contact layers for photoelectrochemical devices. Finally, results obtained from a novel multijunction silicon photoelectrochemical cell incorporating ALD-TiO_2 protection and exhibiting > 10% solar-to-hydrogen efficiency will be described.

11:00 AM ET02.12.02
On the Passivating Contact Performance of Atomic-Layer-Deposited TiO_x for Silicon Solar Cells Jimmy Melskens1, Willem-Jan Berghuis1, Bas van de Loo2, 1, Bart Macco1, Lachlan Black1 and Wilhelmus (Erwin) Kessels1; 1Department of Applied Physics, Eindhoven University of Technology, Eindhoven, Netherlands; 2Temprex, Vaassen, Netherlands.

Transition metal oxides are attractive as full-area passivating contact materials for silicon solar cells due to their transparency which can be combined with good surface passivation and low contact resistivity [Melskens et al., IEEE JPV 2018]. A promising example is titanium oxide (TiO_x) fabricated by atomic layer deposition (ALD), which can form an electron-selective contact to silicon and has enabled solar cell efficiencies above 22% using a full-area rear contact involving a TiO_x/Al stack [Yang et al., SOLMAT 2016; Adv. Mater. 2016; PiP 2017]. However, there are still many open questions with respect to the passivating contact performance of TiO_x that need to be addressed. For example, when trying to exploit the TiO_x transparency by combining it with a transparent conductive oxide (TCO) in a front contact, a high open-circuit voltage has so far not been achieved [Boccard et al., IEEE PVSC 2016], contradicting simulations which indicate that this should be achievable.

We have investigated the TiO_x contact performance in terms of passivation quality and contact resistivity by conducting a systematic study and by making a careful comparison with the existing literature. We found that there are several ways to achieve state-of-the-art passivation performance with typical optimum lifetimes of 1-2 ms. First of all, good passivation results can be obtained using titanium(IV)isopropoxide (TTIP) or tetrakis(dimethylamido)titanium (TDMAT) as ALD Ti precursor, while good results have also been reported for titanium(IV)chloride (TiCl_4) [Cui et al., SOLMAT 2016]. Other experimental parameters, such as the substrate treatment prior to the TiO_x deposition, TiO_x deposition temperature, post-deposition annealing temperature, and film thickness have a much stronger impact on the contact performance. We found that ideally, the film is prepared at low temperature (50-200 °C) on HF-dipped Si such that crystallization is also avoided. The film thickness is particularly critical and we found that approximately 3 nm yields an optimal contact performance (S_{eff,max} = 11.6 cm/s, \rho_c = 10^2 Ωcm^2). This is similar to state-of-the-art results reported in the literature [Titova et al, Energy Proc. 2017].
It appears that there is a large field-effect contribution to the passivation that is induced by a net negative fixed charge, which is surprising for a material that can function as an electron-selective contact. The associated upward band bending in the silicon yields a rectifying contact, in particular when increasing the growth temperature or film thickness too much, although contacting the TiOx layer by either a TCO or Al might play an important role here. An Ohmic contact that provides excellent surface passivation is achievable after annealing when keeping the TiOx film sufficiently thin. This underlines that carefully engineering a thin TiOx layer is key both in improving the passivating contact performance and the understanding of the underlying working principles.

Recent developments have enabled experimental results and suggest ways to enhance the performance and stability of electron-selective TiOx contacts. For developing cost-effective, high-performance and stable electron-selective TiOx contacts and elucidating the effects of the level and polarity of fixed charges for developing cost-effective, high-performance and stable electron-selective TiOx contacts, the level and polarity of fixed charges and the electronic structure of tunnel layers on the performance of TiOx electron-selective contacts has not been evaluated under light illumination [2]. Meanwhile, the performance of electron-selective TiOx contacts strongly depends the thickness and electrical property of a SiOx tunnel layer between a TiOx thin layer and a Si substrate according to previous research [3].

In this study, we have investigated:
1. The performance of electron-selective TiOx contacts fabricated by ALD and e-beam evaporation and oxidation of Ti thin layers.
2. The effects of various metal oxide or nitride tunnel layers on the performance of electron-selective TiOx contacts.
3. The stability of the fabricated electron-selective TiOx contacts under light illumination.

for developing cost-effective, high-performance and stable electron-selective TiOx contacts and elucidating the effects of the level and polarity of fixed charges and the electronic structure of tunnel layers on the performance of TiOx electron-selective contacts. During our presentation, we will discuss the experimental results and suggest ways to enhance the performance and stability of electron-selective TiOx contacts.

Local Evaluation of Non-Uniform Charge Distribution in Al2O3 Passivation Layers for Silicon Solar Cells Using Super-Higher-Order Scanning Nonlinear Dielectric Microscopy Kento Kakikawa1, Yuji Yamagishi1, Katsuto Tanahashi2, Hidetaka Takato1 and Yassuo Cho1; 1Tohoku University,
One of the factors that lower the efficiency of monocrystalline silicon solar cells is the recombination of carriers at the surface of bulk Si layers [1]. Aluminum oxide (Al₂O₃) is a promising candidate for the passivation of the bulk Si layers of monocrystalline silicon solar cells. It has been reported that the deposition of atomic-layer-deposited (ALD) Al₂O₃ passivation layers on the bulk Si layers effectively reduce the recombination losses. In the case of the passivation of the rear side of p-type passivated-emitter-and-rear-cell (PERC) solar cells, Al₂O₃ is reported to be as effective as thermally-grown SiO₂, which is also regarded as one of the best candidates for the passivation layers. It is widely accepted that the suppression of the carrier recombination by the Al₂O₃ passivation layers is attributed to the reduction of the density of recombination centers and consequently directly reduces the carrier recombination velocity.

The increase of the negative fixed charges is also effective to reduce the carrier recombination velocity because the fixed charges produce a local electric field at the surface and suppresses the diffusion of minority carriers to the recombination centers near the surface. While a number of studies investigate the passivation mechanism by Al₂O₃ from a macroscopic view, a microscopic knowledge on the passivation mechanism, which is also expected to be useful information on the properties of Al₂O₃/Si interfaces, is still missing.

In this study, we investigated the Al₂O₃/Si interfaces using scanning nonlinear dielectric microscopy (SNDM) [2] and super-high-order SNDM (SHO-SNDM) [3]. SNDM is a kind of capacitance microscopy with a sensitivity of as high as 2×10⁻²² F Hz⁻¹/₂ and has been used in the evaluation of a number of dielectric and semiconductor materials. SHO-SNDM is an extended technique of SNDM and is capable of obtaining local C⁻V curves over the sample surface. This ability enables to investigate distribution of local charges at oxide/semiconductor interfaces by analyzing the shift of the change of local C⁻V curves. We demonstrate that these techniques are applicable in the evaluation of non-uniform distribution of charges at Al₂O₃/Si interfaces. We also show that the scale of patterns observed in SNDM and SHO-SNDM images are changed by a post deposition annealing of the Al₂O₃/Si samples. Moreover, the increase of the areal density of negative fixed charges by the post deposition annealing was estimated by analyzing the local C⁻V curves obtained by SHO-SNDM.

For the sustained growth of the silicon PV market, a continued increase in cell efficiency, traditionally characterized at 25 °C, is noted as a prerequisite. However, the energy yield under field conditions, in which the cell temperature can deviate considerably from standard test conditions, is of primary importance. In this work, we analyze the thermal effects that contribute to cell heating, and so energy yield loss, in a variety of silicon solar cell designs. This knowledge will be of consequence for cells and modules deployed in high insolation, high temperature environments which are suitable for PV generation.

To demonstrate the significance of heat generation in silicon solar cells, we first analyze the energy loss in the ideal Shockley-Queisser limit of a single junction solar cell with a bandgap of 1.12 eV operating under the AM1.5 spectrum. Here, only ~34% energy from the solar spectrum is converted to electricity. The remaining energy is lost, either via transmission (19%), re-emission (15%), or thermalization (32%). It is the latter process which is the main source of heating, accounting for an increase in cell temperature above the ambient. In real devices, additional energy losses that decrease the cell efficiency from the theoretical limit contribute further to cell heating, e.g. resistive losses, extrinsic recombination and parasitic absorption.

In the above calculation, sub-gap photons are transmitted through the device. However, recent emissivity measurements on an aluminum back surface field (Al-BSF) cell by Riverola et al. demonstrate that over 80% of this energy is actually absorbed, further contributing to the thermal load of the cell. In this study we assess the absorption of sub-gap photons in the most prominent cell architectures – Al-BSF, passivated emitter and rear cell (PERC), mono- and bi-facial silicon heterojunction (SHJ) – via spectrophotometry measurements over the entire AM1.5 spectral range. We complement these measurements with quantum efficiency, and temperature dependent current-voltage (TD-IV), to assess both the current losses and the cell’s temperature coefficients.

While it is known that the SHJ cell’s temperature coefficient out-performs the Al-BSF and PERC devices, little is known of the relative difference in heat generation between these architectures. Our investigation extends this work by analyzing the thermal contribution from each material in the SHJ device. Spectroscopic ellipsometry is used to characterize each layer over the whole AM1.5 spectrum and optical modeling is utilized to estimate the contribution of each layer to cell heating. To this end, various TCOs, dopant-free contact layers, as well as the conventional a-Si layers are analyzed. These results enable accurate thermal simulation and optimization for minimizing heat generation and maximizing energy yield. Both the mono-facial and bi-facial cases are considered in our analysis.

Dorothee Menzel,
High work function materials such as molybdenum oxide (MoOx) [1] and tungsten oxide (WOx) [2] have recently been investigated as carrier-selective hole contacts for silicon heterojunction solar cells, where they could replace the p-type amorphous silicon layer. They provide a higher optical transparency, and due to their high work function it is expected that they can improve the cell’s fill factor due to a more efficient carrier separation [3]. However, we have found in previous studies [3] that tungsten oxide suffers from a tradeoff of rather poor conductivity for high work function films close stoichiometry, or a strongly reduced work function for more conductive, substoichiometric films. Therefore, we investigate possibilities to improve the electrical properties by combining the high work function and wide band gap of WOx with the good conductivity of indium oxide (InOx) in InWOx alloys. Recently, we have presented investigations of InWOx deposited with different ratios of indium-to-tungsten oxide by thermal evaporation, spanning the full range from pure tungsten oxide to pure indium oxide. Using in-situ (X-ray and UV) photoelectron spectroscopy, optical spectroscopy and surface photo voltage measurements, we found a pronounced decrease of the work function from $\Phi \approx 6.3$ eV for pure WOx down to $\Phi \approx 4.5$ eV for 40% of indium content in the alloy. Within the same tungsten oxide range, this was accompanied by a decrease of the band bending in the crystalline silicon substrate by 200 meV [4].

In the present study, we provide further insight into InWOx materials properties upon annealing of the layers up to 600 °C: We investigate the crystalline structure using X-Ray diffraction and find that InOx is fully crystallized at 250 °C, whereas WOx only starts to crystalize at 550 °C. For an indium content of more than 40 % the mixture remains in the indium oxide structure (also above 550 °C), while the tungsten rich layers show two different structures after crystallization, one at about 25 % InOx content (InOx2W1) and another one for even lower InOx content, which resembles the one of pure tungsten oxide. Concomitantly, optical transmission and reflection measurements show an increase in transmission for indium rich layers with increasing annealing temperature up to 400 °C, while tungsten rich layers showed a lower or even no change in transmission. We explore, whether such high-temperature annealed films yield improved performance when incorporated into devices.

**Passivating contacts as drop-in replacement of partial rear contacts**: for a “lean” process integration, we developed passivating contacts that are manufactured with the thermal processes employed in the PV-industry such as P-diffusion or firing. Boron-doped micro-crystalline silicon oxide layers (µc-SiOx(p)) enabled to withstand long annealing at high temperature (>800°C; >30min) typical of diffusion processes. For a firing-compatible passivating contact, the incorporation of C in nano-crystalline-SiCx(p) ensures a resilience to blistering, that may otherwise occur due to the fast firing (>800°C, >10s). The cell integration of the nc-SiCx(p) in a co-fired process with a Ag-paste contacting a front P-diffused emitter resulted in a conversion efficiency of 22.5% on 2x2 cm².

**Passivating contacts for front and rear contacted c-Si solar cells**: P and B doped silicon carbide layers were developed as electron and hole selective contacts, respectively. Very high degree of surface passivation on p-type planar c-Si is evidenced by $V_{oc}$ values of 735mV and 746mV for the hole and electron contacts, respectively. The performance of the SiCx layers is demonstrated at device level with a simple patterning-free and co-annealed process flow enabling high-level of current extraction and surface passivation with FF=84%, $V_{oc}=727$mV on planar cells, and efficiencies up to 22.6% with front-textured-cells. Highly-transparent P-doped microcrystalline silicon (µc-Si(n)) were developed as alternative to front SiCx(n) layer. High surface passivation with $V_{oc}$ of 729mV and 707mV were reached on planar and textured samples without post-hydrogenation, respectively. In a first attempt, solar cell characteristic include a promising $J_{sc}$ of 39.92mA/cm².

**Monolithic textured perovskite/e-Si tandem solar cells**: the SiCx-based cell architecture with passivating contacts deposited on both sides was used as bottom cell. This bottom cell had a textured front side, on which a fully conformal perovskite top cell was deposited to achieve a steady-state efficiency >24.5% (area ≥1 cm²).

Fuel produced from the electrochemical splitting of water can be used to power a wide variety of technologies including information communication technologies infrastructure. The slow kinetics of the oxygen evolution reaction (OER) is one of the performance-limiting factors for hydrogen production through electrolysis. OER catalysts are often unstable in alkaline environments exhibiting deactivation and structural transformation causing a significant challenge for use in photoelectrochemical cells and water electrolyzers. Moreover, in nanoscopically thin catalyst layers, OER activity also decreases due to inefficient charge transfer to the electrolyte-catalyst interface. Epitaxial heterostructures are promising to solve these issues, though recent attempts yielded improved stability only at the expense of greatly reduced OER activity. In this presentation, we elucidate the competing factors for deactivation of LaₙSr₁₋ₙCoO₃ (LSCO) in nanoscopically thin layers supported on conducting perovskite substrates, and demonstrate heterostructured anodes with simultaneously high activity and stability during electrochemical water splitting in alkaline environments (pH = 13).

Epitaxial thin films of Laₙ₋₂SrₓCoO₃, Ba₄₋₃La₃SnO₇, and SrₓLa₄TiO₇ were grown by pulsed laser epitaxy. Interface energetics were characterized using in situ X-ray and ultraviolet photoelectron spectroscopies. Scanning transmission electron microscopy and electron energy loss spectroscopy were used to resolve the atomic structures, and scanning nonlinear dielectric microscopy used to probe the nature of the charge carrier character on the heterostructured catalyst surface. Density functional theory calculations were used to assess the impact of the electronic structure of the heterostructured catalyst layers on the overpotential and OER catalytic activity.

While the LSCO undergoes dramatic structural and electronic changes during electrolysis, including leaching of La and Sr from the film to yield a layer of cobalt oxyhydroxide, the thickness dependence of the OER activity will be revealed to be due to inefficiency of charge carrier transport to active sites. We demonstrate engineering of depletion layers widths and chemical stability using heterostructures comprised of nanoscopically thin epitaxial layers of degenerately doped stannate and titanate perovskite structure oxides to yield low overpotentials ~300 mV at current densities (~10 mA/cm²) relevant for hydrogen production in electrolyzers and photo-electrochemical cells, at hundreds of hours operations in nanoscopically thin active layers. Implications of the results for applications of nanoscopically thin oxide heterostructures for designs of high activity and stable anodes for carbon neutral energy production via the electrochemical splitting of water will be discussed.

OER Catalyst Stability Investigation Using RDE Technique—A Stability Measure or an Artifact? Hanu El-Sayed, Alexandra Weiß, Lorenz Olbrich, Garin Pratomo and Hubert A. Gasteiger; Chair of Technical Electrochemistry, Technical University of Munich, Garching, Germany.

The development of OER catalysts for PEM water electrolysis requires both activity and stability testing methods. The OER catalyst activity can be estimated by using rotating disk electrode (RDE), flow-channel methods, or in an electrolyzer. The evaluation of catalyst stability is realized using accelerated tests as testing over the whole lifetime (5-10 years) under realistic conditions is not practical. 1, 2 A protocol for the OER catalyst stability using RDE was proposed by the ICP group and is now used by other researchers. In this protocol, a constant current is applied in a half-cell configuration and the change in potential is monitored until a sudden increase in potential indicates complete catalyst degradation. It was shown recently that the measured catalyst stability depends on the nature of the electrode substrate onto which the catalyst powder is being supported. Based on this, it was recommended that Au and boron-doped diamond be used as they show better stability of the catalyst under investigation, while glassy carbon and fluorine doped tin oxide electrodes were deemed unsuitable in such stability test. 2

Here we present a careful examination of the use of RDE for investigating OER catalyst stability. Although the increase in potential in an RDE St. T. is thought to be due to catalyst degradation (dissolution), our findings provide a clear evidence that the change in potential is rather due to an experimental artifact. The source of this artifact are nano- and micro-bubbles formed within the pores of the catalyst layer during the OER that cannot be removed by electrode rotation. These bubbles accumulate and block the OER active sites, resulting in a potential increase, which is mistakenly interpreted as catalyst degradation. Our findings indicate that almost no catalyst degradation takes place at the first phase of the St. T., which can last for several hours. In this phase, the bubbles accumulate and block the active sites, resulting in an artificial increase in the potential. The second phase of the St. T. starts once a threshold potential is realized, where a rapid potential increase is observed, due to catalyst dissolution at high potentials. Gas bubbles accumulation is responsible for the increase in potential, and ultimately resulting in the full degradation of the catalyst layer. A proper St. T. using RDE technique should avoid the accumulation of oxygen bubbles, which is currently under investigation and preliminary results will be also presented.

8:30 AM ET03.01.03

Modern societies face the challenge of supplying a continuously increasing energy demand. Intensive research is being conducted all around the globe to ensure that these needs can be satisfied while minimizing carbon emissions and other environmental threats. Electrochemistry holds promise to satisfy this requirement, either by using renewable energy to obtain fuels or store electricity or by converting fuels into electricity. Here catalysis research is pivotal, providing key advances in electrolyzers, fuel cells, and metal-air batteries.

Nature Catalysis, a new journal from the Nature Research group launched in January 2018, provides coverage of top research from the area of electrocatalysis, as well as all other areas of catalysis. Our broad scope, drawing from the work of scientists, engineers and researchers in industry and academia, ensures that published work reaches the widest possible audience. Nature Catalysis brings together researchers from all chemistry and related fields, publishing work on homogeneous, heterogeneous, and biocatalysis, incorporating both fundamental and applied studies that advance our knowledge and inform the development of sustainable industries and processes.

9:00 AM ET03.01.04

The need for a sustainable source of hydrogen has been widely recognized, not just as a potential transportation fueling vehicles, but to limit CO₂ production and fossil fuel consumption from existing industrial processes such as ammonia generation. Currently over 95% of hydrogen is made from fossil fuels through natural gas reforming or coal gasification. However, significant growth has occurred in recent years in water electrolysis research, especially in catalyst research for the hydrogen (HER) and oxygen (OER) evolution reactions. Proton exchange membrane (PEM)-based systems are relatively mature in that the technology has been commercialized, but further research and development can achieve significant impact; for example, order of magnitude reductions in catalyst loading. Anion exchange membranes based systems are still under development, with membrane and ionomer stability in the operating environment being a critical issue. In both the AEM and PEM case, there are complex interactions at the electrode level which need to be considered in catalyst and membrane development. First, the liquid electrolyte environment used for catalyst activity screening, where all of the catalyst surface is accessible to the reactant is often not comparable to a complex, 3-dimensional, ionomer-based electrode. Also, similar to automotive fuel cells, the operating environment is highly important and should be considered when claiming improvements over state of the art. For example, catalyst performance at very low current densities may indicate inherent activity but may not represent capability at typical device operating currents. Similarly, a membrane which cannot operate at differential pressure may be highly limited in utility even if more efficient than current commercial solutions. This talk will describe some of the complex interactions that need to be considered, typical operating requirements, and stages of development where relevant conditions should be introduced.

9:30 AM ET03.01.05

The catalytic oxygen evolution reaction (OER) to extract electrons from water molecules is important for the artificial photosynthesis to generate useful chemicals such as hydrogen and organic compounds [1, 2]. In terms of elements strategy, utilization of abundant element for OER catalysts is remarkably advantageous for future low-cost artificial photosynthetic system. Fe-based OER catalysts, based on the fourth most earth-abundant element, are attractive, but are known to suffer from low OER activity due to limited electrical conductivity and non-ideal electronic structures near the surfaces of these catalysts.
Here, we report a highly crystalline, 10 nm-sized red rust OER catalyst composed of pure β-phase FeOOH(Cl) nanorods (ca. 3 × 13 nm) doped with Ni ions (β-FeOOH(Cl):Ni) [3] and surface-modified with amorphous Ni(OH)2 (a-Ni(OH)2) at a Ni to Fe ratio of 22 at.%, which shows the highest level of performance among Fe-rich oxides and oxyhydroxides. This catalyst can be synthesized by a facile one-pot process at room temperature, and colloidal aqueous solutions of the β-FeOOH(Cl):Ni/a-Ni(OH)2 nanorods are very stable, with no apparent precipitation over a time span of at least one month. Electrochemical measurements for β-FeOOH(Cl):Ni/a-Ni(OH)2 stacked nanorod anodes deposited on carbon paper (CP) were performed in a 3-electrode configuration using a Ag/AgCl reference electrode and a Pt wire counter electrode. The overpotential during the electrochemical OER over the anodes was 170 mV, and an OER current of 10 mA/cm² was obtained at an overpotential of 430 mV(+1.66 V vs. RHE) in 0.1 M KOH (without subtracting the IR drop). It is suggested that the surface modification with the a-Ni(OH)2 lowered the OER overpotential of β-FeOOH(Cl):Ni, resulting in the very high current density at low potential compared with Fe-rich oxide and oxyhydroxide electrodes reported previously. Mössbauer spectroscopy also suggested electronic interaction between Fe and Ni species, which may be crucial evidence for the enhanced activity in the Fe-rich OER system [4]. The present cost-effective Fe-based OER catalysts can be widely applied to construct artificial photosynthetic systems for solar fuel generation by combination with CO2 reduction catalysts.

Hydroxide Exchange Membrane Electrolyzers (HEMELs) for Hydrogen Production Yushan Yan; University of Delaware, Newark, Delaware, United States.

One of the grand challenges facing humanity today is the development of an alternative energy system that is safe, clean, and sustainable and where combustion of fossil fuels no longer dominates. A distributed renewable electrochemical energy and mobility system (DREEMS) based on cheap renewable electricity could meet this challenge. At the foundation of this new energy system, we have chosen to study a number of electrochemical devices including fuel cells, electrolyzers, and flow batteries. We have been working on the development of hydroxide exchange membrane fuel cell (HEMFCS) and electrolyzers (HEMELs) which can work with nonprecious metal catalysts and inexpensive hydrocarbon polymer membranes. We have developed roadmaps for HEMFCs and HEMELs, the most chemically stable membranes, and the most active nonprecious metal catalysts. We have also studied why hydrogen oxidation and evolution reactions (HOR/HER) are slower in base than in acid for precious metal catalysts. For flow batteries we have developed novel designs, chemistries and cost models e.g., double-membrane aqueous flow batteries with high voltages (i.e., 3 V), single-element-mimic redox pairs, and user friendly physics-based analytical cost models. In this presentation, I will focus on our HEMEL work highlighting a new class of membranes, nonprecious metal catalysts and base/salt-free HEMEL cells for hydrogen production.

Water Oxidation Mechanism of Assembled MnO Nanoparticles Ki Tae Nam; Department of Materials Science and Engineering, Seoul National University, Seoul, Korea (the Republic of).

Water splitting is regarded as a promising step towards environmentally sustainable energy schemes. The oxygen evolution reaction (OER) requires extremely high overpotential due to its slow reaction kinetics. The water oxidizing cluster in photosystem II, in the form of cubical Mn4CaO5 cluster, efficiently catalyzes water oxidation. Inspired by Mn4CaO5 cluster, we previously identified a new crystal structure, Mn3(PO4)2·3H2O, and demonstrated its novel designs, chemistries and cost models e.g., double-membrane aqueous flow batteries with high voltages (i.e., 3 V), single-element-mimic redox pairs, and user friendly physics-based analytical cost models. In this presentation, I will focus on our HEMEL work highlighting a new class of membranes, nonprecious metal catalysts and base/salt-free HEMEL cells for hydrogen production.

Ultrathin Pinhole-Free Molecular Wires-Embedded SiO2 Membrane Connecting Incompatible Redox Reactions for Scalable Artificial Photosynthesis Ween Jun Joo, Georgios Katsoukis and Heinz Frei; Lawrence Berkeley National Laboratory, Berkeley, California, United States.
Replacing fossil fuels with renewable resources to meet the global need requires a technology that is scalable to the unprecedented level of several terawatts. Natural photosynthesis is the sole existing technology that produces energy dense chemicals on the terawatt scale (~100 TW). Its key design feature is the closed cycle of H₂O oxidation and formation of the primary reduction products on the shortest possible length scale, the nanometer scale, while separating the incompatible redox environments by an ultrathin membrane. This offers the advantage of minimizing efficiency-degrading mass transport processes and unwanted side reactions.

To incorporate the key feature into artificial photosystems, we assembled ultrathin (2 nm), pinhole-free, molecular wires-embedded SiO₂ membrane on planar and nanotube constructs. This membrane system spatially separates the H₂O oxidation CO₂ reduction, but enables (photo-)electrochemical communication between the incompatible redox reactions by transmitting protons and electrons in a precisely controlled manner, while preventing O₂ transport causing unwanted reverse reactions. This unique mass-transport behavior on planar and nanotube configurations was systematically studied via cyclic voltammetry, electrochemical impedance spectroscopy, and visible light-sensitized short circuit current experiments. The embedded molecular wires’ integrity before and after the mass-transport process was confirmed by time-resolved optical spectroscopy and grazing angle ATR-FT-IR or IRRAS characterization.

Interesting Proton Conduction Environment within Thin Films of Fluorocarbon based Ionomers with Single or Multi-Acid Side Chains Shadipoto K. Dinhara. University of Nebraska--Lincoln, Lincoln, Nebraska, United States.

Polymer-catalyst interfaces control the energy efficiency of many energy conversion and storage devices. The interfacial polymer layers are very thin (typically less than one micron thick). Many interesting structural, mechanical and transport properties in such thin ion containing polymer (ionomer) layers evolve as a result of complex multimodal interfacial interactions, unusual hydration behavior and confinement. Especially ion conductivity at the interface can be drastically different from that in the bulk membranes and the route to this poor ion conduction behavior is not well-understood. It is thus highly needed to systematically study how the ion conduction environment and water uptake change with the change in ionomer structure and film thickness. In this work, three potential fluorocarbon based hydrogen fuel cell ionomers (Nafion, 3M PFIA, 3M PFSA) having single/multiple acids at side chain were studied in sub-micron thick films. All three ionomers have fluorocarbon (PTFE) backbones. The difference between Nafion and 3M PFSA is in the side chain structure, but both has single acid at the side chains. On the other hand, 3M PFIA has bis(sulfonfyl)imide group in addition to perfluorosulfonic acid which makes the polymer more acidic. By tracking the fluorescence response of photoacid dye HPTS incorporated within hydrated ionomer thin films, very interesting trends were obtained regarding the extent of proton transfer. The results, when combined with the information on nanoscale structure and water sorption, clearly indicated that there are many factors controlling the proton conduction behavior in thin ionomer films, in addition to water uptake.

SESSION ET03.02: Battery Fundamentals, Characterization and Modeling
Session Chairs: Weiyang Li and Nian Liu
Monday Afternoon, November 26, 2018
Hyne, Level 3, Room 302

2:00 PM ET03.02.02

Nanoscale transport and materials are critical to electrochemical energy storage, such as power density, cycling life and safety. In this talk, I will present two examples on advanced tools and fabrication to understand nanoscale transport phenomena and designing of nanoscale materials. The first one is based on an emerging Stimulated Raman Scattering Microscopy, which is three orders of magnitude faster than traditional Raman microscopy. Therefore it can clearly track ion transport in electrolyte together with lithium dendrite, to illustrate their correlations. A positive feedback mechanism has been visualized, which guide methods to suppress lithium dendrite. The second example is through designing nanoscale modification of interfaces between battery electrodes and solid electrolyte. Therefore, the stability between electrodes and electrolyte and the cycling life of corresponding full cells are significantly improved.

2:30 PM ET03.02.03

The design/discovery of layered materials for applicability in next-generation battery technologies requires a fundamental understanding of the links between the atomic-scale structure, chemistry and the mechanisms and energetics of intercalation and de-intercalation reactions, and a consideration of other solid-state reactions that might compete. The goal of our research is to design/discover layered material microstructures as alternatives to graphite using an innovative combination of atomic-scale modeling, experimental in-situ characterization of the microstructural evolution during (de)intercalation reactions. Density functional theory (DFT) simulations are carried out to investigate the structural accommodation of the layered material during insertion and exertion of the intercalating species (energy barriers, volumetric expansion, and phase transformations). The structural stability of the 2H and 1T phases of MoS₂ during lithiation suggests that a phase transformation of the 2H phase of MoS₂ to the 1T phase may occur when MoS₂ is reacted with Li; the computational study allows different dosages of Lithium ion to be assessed with the aim of testing these the validity of these models using in-situ characterization of the solid-state reactions between Li and MoS₂ in the transmission electron microscope (TEM). The mechanisms of strain relaxation and the energetics of Li intercalation-induced phase transformations in MoS₂ at the atomic scales will be presented. This work is supported by NSF grant No. 1820565.

2:45 PM ET03.02.04
Mechanistic Understanding of Lithiation in MoS₂ by Atomic Scale Characterization Shalini Tripathi2, Matthew T. Janish2, William Moyer Mook1, Katherine L. Jungjohann1, Avinash M. Dongare3, Arthur Dobley3 and C B. Carter1, 4; 1Center for Integrated Nanotechnologies (CINT), Sandia National
Understanding the structure and phase changes associated with two-dimensional (2D) layered transition metal dichalcogenides (TMDs) is critical in optimizing performance in lithium-ion batteries. The large interlayer spacing in MoS$_2$ (≈ 0.65 nm) accommodates species such as alkali metal ions (Li$^+$, Na$^+$, K$^+$) during intercalation. Intercalation is reported to change the electronic structure of the host molecule, resulting in variations in their electrical and optical properties. In this work, we examine the solid-state reactions between Li and MoS$_2$. Li$^+$ ions can be inserted into the vdW gap; the reaction is still unclear. Plan-view imaging has been extensively used, however, it is essential to visualize the process with the electron beam being parallel to the basal planes of the layer material to understand the reaction process. Lattice-fringe images have been discussed for several systems but relying on microtoming or simply using curved thin layers, the orientation of the specimen was less than ideally controlled. Here, TEM specimens are made using FIB, and oriented for detailed study of the intercalation process. This study of TMDs uses a Tecnai F30 and a Cs-image-corrected Titan equipped with a direct electron detector camera, K2. This camera has two major advantages: the electron dose can be minimized and quick changes during reactions are recorded; both instruments have EELS and XEDS capabilities. DFT calculations are used to probe the structure and bonding changes during these reactions.

Volumetric expansion, energy barriers, phase transformations and the role of doping, defects and interfaces can be modeled. The dynamics of the structural response are modeled using ab initio MD simulations. Electrochemical aspects can be monitored in situ in real-time and at atomic scale to provide understanding of lithium-ion storage mechanisms in these solid-state reactions and thus to test the modeling-based results.

In plan-view specimen, variations normal to the basal plane are not seen. Defects associated with the reactions were monitored real-time. As the reaction between MoS$_2$ and Li proceeds, white-line defects were observed under high-resolution imaging by TEM. Lower-magnification images show that the understanding of lithium-ion storage mechanisms in these solid-state reactions can be substantially improved by using nanoscale characterization techniques to elucidate the structural and chemical changes occurring in Li ion battery cathodes containing LiV$_3$O$_8$ thin film with high density of states and electronic occupation) at the electrode/electrolyte interface. We have developed a back-gated electrode structure that utilizes electrostatic charging (induced by a gate bias) to control electrochemical kinetics on ultrathin or 2D materials (5-nm-thick ZnO, monolayer MoS$_2$, and graphene). Such back-gated electrodes are fabricated with nanometer-thick semiconductors on SiO$_2$-degenerated Si substrates, analogous to the metal–oxide–semiconductor stack in the CMOS technology. Due to the extreme thinness of the electrode materials, the alignment of electronic bands as well as the electronic occupation, at the electrode/electrolyte interface, can be dramatically altered by the gate-induced charge carriers. Thus, real-time, continuous and efficient modulation of reaction kinetics can be achieved on 2D materials by varying the gate bias.

In this presentation, we will use back-gated monolayer MoS$_2$ as an example to demonstrate how the applied gate bias affects the kinetics of heterogeneous charge transfer and surface binding processes. Specifically, the standard charge transfer rate constant between MoS$_2$ and ferrocene/ferrocnium redox couple can be tuned by over two orders of magnitude and the catalytic overpotential of hydrogen evolution reaction on 2H-MoS$_2$ can be reduced by more than 150 mV. Overall, the approach introduced here is generally applicable to investigation and optimization of interfacial electrochemical phenomena in a wide range of electrochemical systems. With the ability to control the band alignment and electronic occupation independent of the electrode potential, the back-gated 2D electrodes will provide new insights to rational design of electrode materials.

4:00 PM ET03.02.07 Simulation of Charge Transfer Reactions at Graphite and Electrolyte Solution Interfaces with Density Functional and Implicit Solvation Theory Jun Haruyama and Minoru Otani; National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan.

Development of a stable energy-storage device is a fundamental approach to solve energy-related issues. Lithium-ion batteries (LIBs) are one of the most promising candidates because of their high energy density and long cycle life. From electrochemical impedance spectroscopic measurements, the cell resistance of conventional LIB is dominated by charge transfer resistance at electrode/electrolyte interfaces. [1,2] Therefore, we investigate the charge transfer process, i.e. Li insertion/desorption process, at the interface between a graphite anode and 1 M LiPF6 EC electrolyte. The density functional theory (DFT) with effective medium screening (ESM) method [3] combined with the reference interaction site model (RISM), called ESM-RISM, is employed to simulate the Li insertion/desorption process. [4] In this method, the graphite surface (LiC6slab and additional Li+) and liquid solution (1 M LiPF6 EC) are represented as quantum mechanical and implicit classical solution, respectively. The energy landscapes of reaction are revealed under constant electron chemical potential conditions at the interface. Across the transition state where the Li forms a half-solution shell, the reacting Li inside the electrode changes to a full solution structure in the solution accompanied by electron transfer. The activation energies at the equilibrium potentials of the charge transfer reaction are approximately 0.6 eV, [5] which is consistent with the electrochemical impedance spectroscopy measurements. In the presentation, we explain the details of the ESM-RISM simulation and introduce the energy profiles of the Li insertion/desorption path at the LiC6/EC LiPF6 interface.

4:15 PM ET03.02.08 Measurement of Mechanical Properties and Assessment of Mechanical Degradation of Solid Electrolyte Interphase (SEI) Formed with Carbonate-Based Electrolytes Insun Yoon; Brown University, Providence, Rhode Island, United States.

Rapidly increasing demand for low-cost, high energy density energy storage motivates researchers to develop advanced and reliable anode materials. Lithium alloying anodes such as Si, Sn, or Ge has three to ten times of charge capacity compared to the traditional graphite electrodes, and thus gathered enormous research interest. One of the major challenges associated with the lithium alloying anodes originates from de/lithiation-induced large volume change (~300%). Such volume change applies excessive cyclic strain on solid electrolyte interphase (SEI) to cause its mechanical failure and continued breakdown of SEI, and thus affects the reversibility of the Li alloying/demallloying reactions. Therefore, we investigate the mechanical properties of SEI and correlate them with the cycling performance of Si electrodes. Several electrolyte additives such as fluoroethylene carbonate (FEC) or vinylene carbonate (VC) have been investigated and demonstrated to improve cyclic performance of Si electrodes. Furthermore, we use molecular dynamics (AIMD) simulations to understand the deformation mechanism of SEI. With this background, we have developed an experimental approach to characterize elastic modulus, yield stress, inelastic deformation behavior, and crack density evolution of SEI formed with carbonate-based electrolytes. An SEI (~100nm) is prepared by lithium thin film - electrolyte (1.2M LiPF6 in ethylene carbonate) reactions on a rectangular free-standing polydimethylsiloxane (PDMS) membrane (~300 - 400nm in thickness). The prepared sample is subjected to bulge testing in an inert environment; various level of controlled pressure is applied to the SE/PDMS membrane and the corresponding deflection is measured by the atomic force microscopy (AFM). The plane strain elastic modulus and the yield stress of SEI are evaluated from the pressure-deflection relationship from the bulge testing. Moreover, a careful observation of SEI surface topography yields the evolution of crack density as a function of applied strain. The experiment is repeated using FEC added electrolytes to investigate the influence of the FEC additive on mechanical stability of SEI.

4:30 PM ET03.02.09 Developing an Understanding of Solid-Electrolyte Interphase Formation in Multivalent Ion Batteries Using First Principles Calculations Joshua Young and Manuel Smeu; Physics, Binghamton University, Binghamton, New York, United States.

Multivalent ion batteries (MIVB), or those utilizing Mg, Ca, Zn, and Al, are garnering increasing attention as alternatives to Li-ion batteries in applications where portability is not an issue owing to their high energy density, cost efficiency, and abundance. However, the lack of suitable electrolytes allowing for the reversible plating of metallic anodes has limited the development of MIVBs, especially those involving Ca. This is primarily due to the fact that the solid-electrolyte interphase (SEI), a passivating layer which forms between the electrolyte and anode, often does not allow for the migration of ions in the reversible plating of metallic anodes. [1,2] In this work, we develop an understanding of the SEI in MIVB systems using a computational approach combining density functional theory (DFT) and ab initio molecular dynamics (AIMD) simulations. [3] We first identify the principle components of the SEI by studying the decomposition of the solvents and salts comprising various electrolytes on Li, Ca, and Al surfaces using AIMD. Following this, we identify electrolytes which can be used with a Ca metal anode by investigating the diffusion of Ca ions through the likely inorganic compounds produced using DFT. Finally, we investigate the decomposition of these electrolytes in the presence of external electric fields to more fully understand these reactions in electrochemical systems. We anticipate the promising new electrolytes proposed in this work will help guide experimentalists in the development of rechargeable MIVBs.

J.Y. and M.S. were supported by funds from Binghamton University. DFT calculations were performed on the Spiedie cluster at Binghamton University, as well as the Extreme Science and Engineering Discovery Environment (XSEDE), which is supported by NSF Grant No. ACI-1053575, under allocations TG-DMR170127 and TG-DMR180009.

Room temperature ionic liquids (ILs) have recently emerged as highly promising electrolytes for a wide range of emerging energy technologies, including next-generation supercapacitors and ion-batteries, due to their high thermal stability, ionic conductivity and wide electrochemical windows. The chemical and structural diversity of ILs creates a vast design space that could be exploited to optimize the device performance and stability. However, many mechanistic details remain enigmatic, including the fundamental nature of the cation-anion interactions and their relevance in determining structural and electronic properties of the liquids. Having this information for the bulk liquid is a prerequisite for eventually deciphering the complexity the arises at nanostructured electrode interfaces, which are ubiquitous among energy storage devices. In this presentation, we combine high-level first-principles simulations and synchrotron X-ray characterization experiments to unravel the key structural, chemical and electronic properties of several archetypal ILs comprised of imidazolium-based ILs. In particular, we utilize extensive ab initio molecular dynamics simulations to probe the local density distribution and medium-range order of the ILs, which can be directly compared and validated by X-ray scattering measurements. Soft and tender X-ray absorption spectroscopy at the K-edge of fluorine, phosphorus, and sulfur contained on the anion also complements the chemical and electronic picture from the simulations. Our integrated theoretical and experimental approach relates these structural and chemical signatures with the intrinsic cation-anion interactions, by considering ILs with anions having significant differences in the molecular geometry, chemical composition, and charge distribution.

This work was supported by the U.S. Department of Energy at the Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.
maximize the productive use of electric vehicles, it is very essential to meet up with the intermittent energy needs and variable power demands. Following the intermittent nature of energy from solar and wind, energy storage devices became the need of the hour. Therefore, the excellent catalytic activity and durability of N,P-HCNTs make them potential materials for replacing noble catalysts in both ORR and OER.

**Ionic Transports in Liquid Under Confinement**

**Yuqings Guan** and Jin Suntivich; Materials Science and Engineering, Cornell University, Ithaca, New York, United States.

This presentation presents an ionic-transport measurement in aqueous electrolytes that are confined within the cavities of nanomeshes. Ionic transport plays an important role in electrochemical energy storage devices. Many studies have reported high ionic transport in nanomeshes, for example, in porous carbon and in metal-organic framework materials. However, very little is understood how the confinements affect ionic transport. In this presentation, we present our measurement of the ionic transport through different nanomeshes with controllable pore sizes and surface charges. We use these experimental measurements to establish the ionic transport ability and the role of electrical-double layer on ionic diffusions. These results provide insights into the elusive role of the electrical-double layer on confined ionic diffusions and a design strategy of future nanomeshes for energy storage devices.

**Graphene Oxide Enhanced Performance and Durability of Proton Exchange Membrane Fuel Cells (PEMFCs)**

**Likun Wang**, Yuchen Zhou, Stoyan Bliznakov, Miriam Raffalovich, Danielle Kelly, Audrey Shin and Guan Hao Chen; Stony Brook University, Stony Brook, New York, United States; 2Friends Academy, Locust Valley, New York, United States; 3Plainview Old-Bethpage JFK High School, Plainview, New York, United States; 4St. Georges High School, New York, New York, United States.

Proton exchange membrane fuel cells (PEMFCs) has attracted tremendous attentions as energy conversion device due to its high energy density, low operating temperature and environmentally friendly emission. Numerous efforts have been made to explore efficient catalysts for the reaction when GO is deposited on the Nafion membrane or into the catalysts layer. The maximum power output of the cell under H2/air atmosphere showed an enhancement over 20%. More importantly, the durability of PEMFCs was significantly improved by the GO introduction. 26.1% of maximum power degradation was observed for the cell without GO while only half amount decrease obtained for the cell with GO after 30K cycles of accelerated stress test based on DOE2020 protocol. Nearly 100% enhancement for the durability of PEMFCs can be attributed to the prohibition of H2O2 production. The promising durability promotion effect induced from low-cost GO involvement will help to accelerate the large-scale commercialization of PEMFCs.

**ET03.03.06**

**Effect of the Oxygen Vacancies and Concentration of Ce3+ Valence State on Enhanced Electrochemical Performance of One Step Solvothermally Synthesized CeO2 Nanoparticles**

**Hyeyeong-Heo Park**, Manjeet Kumar, Joondong Kim and Ju-Hyung Yun; 1Incheon National University, Incheon, Korea (the Republic of); 2Korea Advanced Nano Fab Center (KANC), Suwon, Korea (the Republic of).

Environment friendly, low-cost and high performance energy storage systems have been progressively required because of the global warming which has become an imperative and unavoidable factor. The increasing environmental setbacks along with the depletion of fossil fuels necessitate the transition of solar photovoltaic and wind power as a source of electrical energy in practice[1, 2]. But, the unavailability of power from photovoltaic systems during night time and fluctuation in wind speed of the deliverable power have directed the researchers towards the usage of energy storage devices. Moreover, to maximize the productive use of electric vehicles, it is very essential to meet up with the intermittent energy needs and variable power demands. Correspondingly, high power delivery and long cycling stability is some of the most important criterion to be fulfilled by an energy storage device.[3]. To accomplish these demands, devices which could entail huge initial power to start up and show capability of charging with quicker rate are prerequisite. Therefore, supercapacitors have been explored as an upgraded energy storage devices to replace batteries and conventional capacitors with superior features[4].

In this work, different sized CeO2 nanoparticles were synthesized using one step low-cost solvothermal method with various reaction time. Defect states were induced due to the reduction of Ce4+ into Ce3+ valence state. X-ray photoelectron spectroscopy results recommend that Ce3+ valence states and defects in the form of oxygen vacancies be present on the surface of CeO2 nanoparticles. Such availability of oxygen vacancies provided high specific capacitance up to 142.5 Fg-1 at a current density of 0.25 Ag-1 in three electrode system using 1 M Na2SO4 electrolyte. There is an increase in faradaic reactions taken place on the surface which is attributed to the high surface area, more oxygen vacancies, and increased diffusion rate. The highest energy density is obtained to be ~12.68 Wh/kg, and the stability result confirmed that the capacitance retention is ~75 % after 1000 cycles of operation indicating that well optimized CeO2 is a potential candidate as electrode materials for supercapacitor applications due to their fast mutation between Ce4+ to Ce3+ oxidation state.

**Heteroepitaxially Activated Durable [111]_{fcc}–Faceted Nickel Nanocrystals by Suppressing NiOOH Exfoliation during the Oxygen Evolution Reaction in an Alkaline Electrolyte**

**Byeongyoon Kim**, Aram Oh, Minral K. Kabirazz, Sang-II Choi and Kwangyeeol Lee; 1Korea University, Seoul, Korea (the Republic of); 2Kyungpook National University, Seoul, Korea (the Republic of).

One of the best catalyst for alkaline OER anode, nickel exist in various form of nickel oxide, hydroxide and oxyhydroxide in alkaline aqueous solution. Particularly facet-controlled surface of β-NiOOH is expected to have the best heterocatalytic performance. However, due to the great stability of layered structure of hcp crystal, Ni(OH)2 or NiOOH naturally prefer sheet-shape which is fully coordinated but difficult to form uncoordinated facet enclosure. Moreover, β-NiOOH inevitably oxidize to γ-NiOOH in alkaline OER condition. Herein, we demonstrate [111]_{fcc} facet controlled Ni nanoparticles and characteristic heteroepitaxy between [111]_{hcp} facet of rock salt NiO and layered Ni(OH)2/NiOOH during the sequential oxidation in alkaline OER. As the result, (100)_{hcp} faceted β-NiOOH surface formed on Ni octahedral nanoparticles that have resistance further oxidation. β-NiOOH/Ni octahedral
nanoparticles showed excellent electrocatalytic activity and stability for OER in an alkaline electrolyte, requiring an overpotential of 0.32 V at 10 mA cm\(^{-2}\) after 2 h of chronopotentiometric stability test. The facet-dependent heteroepitaxy of ionic crystals is responsible for the excellent electrocatalytic activity and stability.

ET03.03.08
Size-Controllable Synthesis of \(\text{Pd}_4\text{Ru}_4\) Solid-Solution NPs for Catalytic Applications

Dongshuang Wu, Kohei Kusada and Hiroshi Kitagawa; Graduate School of Science, Kyoto University, Kyoto-shi, Japan.

Pd and Ru, which are two neighbouring elements of Rh, are highly attractive for their wide applications in catalysis and energy area. However, the two metals are immiscible at the atomic level in bulk state even at the melting point of Pd. Very recently, our group synthesized PdRu non-equilibrium solid-solution nanoalloys over the whole composition range and demonstrated their applications in CO oxidation, formic acid electrooxidation and Suzuki–Miyaura cross-coupling reaction.[1-3] In view of both fundamental research and practical application, the influence of particle size on catalytic performance should be an interesting and significant subject. The surface area, electronic state and adsorption/desorption energy, which are important factors in catalysis, will change with size, especially in the sub-10 nm size range. Since Pd and Ru are immiscible metals in their bulk form, it is difficult to simultaneously control the metal composition and size of the PdRu solid-solution nanoparticles. To date, there is no report on the size effect in PdRu solid-solution system. Herein, fixing the Pd/Ru molar ratio at 1:1, we successfully synthesized \(\text{Pd}_4\text{Ru}_4\) solid-solution nanoparticles from 2 to 15 nm with narrow size distribution via a simple one-pot reaction. The relationship between size and catalytic properties is discussed.

ET03.03.09
Construction of Ternary Transition Metal Selenides Nanosheets for High-Performance Bifunctional Water Splitting

Jing Yu; Harbin Engineering University, Harbin, China.

Water electrolysis by splitting \(\text{H}_2\text{O}\) into hydrogen and oxygen is currently recognized as an attractive approach for developing regenerative hydrogen energy, which could in turn help to resolve the energy crisis and environmental pollution caused by overreliance on fossil fuels. The exploration of efficient electrocatalysts is highly desirable for reducing the energy barrier and accelerating the reaction kinetic. Transition metal selenides have drawn intense attention because of their outstanding electrocatalytic activity. However, the performance is not comparable favorably with costly noble-metal-based catalysts. Adding another metal element to binary selenides provides the opportunity to tune their crystalline and electronic structures and thus their electrocatalytic properties. In this work, we developed ternary NiCoSe\(_2\) nanosheets configuration via an electrodeposition technique. The loose accumulation of crimped nanosheets on carbon cloth creates a porous structure with large surface area, which could provide abundant active sites for electrocatalysis and good diffusion of charge and electrolyte. The interaction between bimetallic atoms leads to significant enhancement of the catalytic performance. Density functional theory (DFT) calculation reveals the intrinsically metallic behaviour of NiCoSe\(_2\), confirming good electronic conductivity. The prepared NiCoSe\(_2\) exhibited superior and durable activities toward hydrogen evolution reaction (HER) and oxygen evolution reaction (OER), as well as full water splitting. The ternary metal selenides with tunable compositions provide a novel platform to develop low-cost and high-active catalysts for clean energy strategy.

ET03.03.10
Modifying Commercial Carbon with Trace Amounts of ZIF to Prepare Derivatives with Superior ORR Activities

Bing Ni, Chen Ouyang and Xun Wang; Tsinghua University, Beijing, China.

Efficient electro-catalysts are highly demanded in many energy conversion devices, such as proton exchange membrane fuel cell, rechargeable batteries, water splitting devices, etc. Electrocatalytic process can be seen in this way: electrons are transported to (or removed from) the catalysts under external voltage, then catalysts deliver electrons to (or attract from) the surface active sites and then to the reactants, the reactants receive (or donate) electrons and proceed the catalytic reactions. Thus the methods to enhance electrochemical activities mainly rely on four aspects: (1) enhancing the conductivity of catalysts; (2) increasing the intrinsic activities of active centers; (3) augmenting the amount or concentration of active centers; (4) optimizing the mass transfer during the reaction. Tuning one or multiple factors in these four could help to enhance the electrocatalytic activities. On the other hand, reducing costs while maintaining high activity and stability of the catalysts is also vital to applications. Guiding by the aforementioned aspects, we combined the virtue of zeolitic imidazolate frameworks (ZIFs, potential active centers) and commercial carbon black (CB, good conductor) to realize efficient and cheap oxygen reduction reaction (ORR) catalysts in alkaline solution.[1-3]. The modified CB (MBC) was prepared by sequentially soaking the CB in cations (Co\(^{2+}\) and/or Zn\(^{2+}\)) and ligand (2-methylimidazole) solutions, which was followed by a pyrolysis process. The sequential soaking process enabled a thin-layer coating of ZIF on the CB, and the amounts of ZIF were trace which could contribute to the great reduction of the costs (the total costs of the catalysts were less than 70RMB/kg). After the pyrolysis process, the obtained MBC showed large diffusion-limited current density (6.18mA/cm\(^2\)), half-wave potential (0.858V vs RHE), and no obvious decay after 20000 cyclic voltammetry cycles. The MBC also displayed high resistance to methanol poison. The combined experimental and theoretical studies illustrated that the C-O bond formed on the CB surface by the modification process was the main reason for the high activity, but not single-atom implanted carbon structures or metal oxides. The pristine CB surface had a large content of C=C double bonds or sp\(^2\) carbon, while the MBC had a larger content of C-O bonds which are more active in ORR, and the activity increased with the increasing content of C-O bonds. On the other hand, when this kind of materials is in acidic conditions, the C-O active sites would be protonated and lose activity.

ET03.03.11
Zr-Doped TiO\(_2\) Nanotubes with Rich Ti\(^{4+}\) Species for Electrochemical N\(_2\) Fixation

Na Cao and Gengfeng Zheng; Fudan University, Shanghai, China.

The production of ammonia (NH\(_3\)) by the well-known Haber-Bosch process from \(\text{N}_2\) and \(\text{H}_2\) has marked over a century success for providing > 80% nitrogen source for fertilizer and an alternative energy carrier with large energy density. In spite of the natural abundance of \(\text{N}_2\), the high bond energy of N\(_2\) (940.95 kJ mol\(^{-1}\)) prevents it as a reactive form and thus requires a significant amount of the global energy cost annually. In addition, the use of fossil fuels to produce \(\text{H}_2\) reactant also leads to a significant level of \(\text{CO}_2\) release. The electrochemical \(\text{N}_2\) reduction reaction (NRR) can be processed in ambient conditions and use inexpensive aqueous electrolytes as proton source, and thus is regarded as a promising approach. However, the development of high
selective electrocatalysts for simultaneously producing NH₃, rather than the competing hydrogen evolution reaction (HER), is still challenging. Herein, combined with activity of Ti³⁺ species of titanium oxides, and more strong N-adsatoms binding strength than H-adsatoms on the surface of Ti and Zr, we developed a type of hybrid oxide Zr-doped TiO₂ nanotubes via a facile wet-chemical process towards a NRR catalyst. N₂ and water were used as nitrogen and protons sources, respectively. The replacement of Ti⁴⁺ with larger diameter of Zr⁴⁺ leads to the formation of adjacent oxygen vacancies and the increase of Ti³⁺ concentration. In contrast, further increase of the dopant size (such as Ce⁴⁺) is not capable of incorporating dopants into the original TiO₂ lattice structure. As a result, the Zr-doped TiO₂ NTs exhibited excellent catalytic ammonia synthesis performances (NH₃ yield: 9.07 µg h⁻¹ cm⁻² cat., Faradaic efficiency: 4.83%) at -0.45 V vs. reversible hydrogen electrode (RHE) in 0.1 M KOH electrolyte at ambient conditions. This size-dependent doping strategy suggests an attractive way to tune the active catalytic centers of electrocatalysts.

ET03.03.12
The Gate-Opening Behavior of Water Insertion Toward Heterogeneous Catalysis
Chia-Shuo Hsu; Chemistry, National Taiwan University, Taipei, Taiwan.

For heterogeneous catalyst, the behavior of interphase between liquid and solid is the key for the activity of catalysis. The phase-transition step have been reported as the necessary one to improve the reaction. However, this behavior happened represent the catalyst have the interaction not only on the surface. The water should insert several layers of the structure. For the insertion undergoing, the structure need to open first and let the space enough to have water inside. But this gate-open behavior might not only happen toward the phase-transition. It would occur when the voltage applied. Therefore, We used three different kind of samples, Fe₃O₄, CoFe₂O₄, and NiFe₂O₄.In previous work, it have realized that the phase-transition occur in CoFe₂O₄ and NiFe₂O₄, Fe₃O₄ kept the original phase. By in-situ XRD, the gate-open can be observe and relate to the applied voltage. And three samples showed the same behavior. Furthermore, in-situ partial fluoresce yield can describe the change of structure during the gate-open. And by in-situ TEM, the amount of water capacity can be calculated. According to these in-situ technologies, this detail of this behavior can be seen. And this behavior should be considered to every heterogeneous catalysis between liquid and solid.

ET03.03.13
Open Hollow Co-Pt Clusters Embedded in Carbon Nanoflake Arrays for Highly Efficient Alkaline Water Splitting
Hong Zhang1, Yanyu Liu2, Haijun Wu1, Zongkui Kou1, Wei Zhou1, Wenjie Zang1, Stephen John Pennycook1, Jianping Xie1, Cao Guan1 and John Wang1; National University of Singapore, Singapore, Singapore; Beijing Institute of Technology, Beijing, China; Tianjin University, Tianjin, China.

Water splitting provides a clean and renewable way to produce high-purity hydrogen, but the slow kinetics and poor stability of electrocatalysts limit its practical application. Here we report a class of open hollow Co-Pt nanoclusters embedded in N-doped carbon nanoflake arrays aligned on carbon cloth (Co-Pt/C NAs, 2.5 wt% Pt), which display low overpotentials (50mV for hydrogen evolution, 320 mV for oxygen evolution, vs RHE) in alkaline media. The high performance arises from the unique nanostructure and the synergy of Co-Pt promoting water dissociation demonstrated by density functional theory (DFT) calculation results. It can be directly utilized as a highly efficient bifunctional electrocatalyst for overall alkaline water splitting and outperform noble-metal-based materials in terms of much lower operation voltage (1.54 V at 10 mA cm⁻²) and higher stability (no degradation at constant current or voltage up to 120 hrs.), representing a highly promising electrode for electrochemical energy conversion.

ET03.03.14
Gas-Phase Etched Platinum-Nickel Nanoframes and Their Extraordinary Activity Towards Methanol Electro-Oxidation
Yiliang Luan1, Can Li1, Shaohui Yan1, Bo Zhao2, Amar Kumbhar3, Chenyu Wang1 and Jiye Fang1; SUNY Binghamton, Binghamton, New York, United States; Texas Tech University, Lubbock, Texas, United States; University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States.

Highly open nanoframes are a class of promising catalysts in many application fields due to their ultra large surface area and quasi-one-dimensional structure. However, the fabrications of such nanoframes is still a challenge. To date, they are usually produced by de-etching one active component from a bimetallic precursor with an inert counterpart in a solution system, using an acidic medium such as acetic acid or even nitric acid. The drawback of this de-etching method is that it could generate ill-defined structures with defect-rich surfaces, leading to severely deformed morphologies in the subsequent step of processing such as a substrate carbon loading process. Our recent achievement in the preparation of platinum(Pt)-nickel(Ni) tetrahexahedral nanoframes demonstrates that etching with carbon monoxide (CO), i.e. the Mond Process, is an efficient way to produce Pt-Ni nanoframes, in which a segregation of the Ni-component in the precursors is preferred. Here, we have synthesized a cationic Pt-Ni nanoparticles via this CO etching approach, which has never been reported. The nanoframe precursors presented via a colloidal synthesis presented a conventional concave cuboid profile. Our characterization indicated that there was a considerable segregation of the Ni-component on the solid concave cuboid precursors. The segregated Ni atoms could be easily removed through the Mond Process in CO atmosphere at an elevated temperature. According to TEM characterization, the resultant Pt-Ni nanoframes showed an apparent open frame structure with a solid metallic core. Further evaluation of these Pt-Ni nanoframes towards methanol electro-oxidation indicated that their surface specific activity is ~6.5-fold higher than that of the commercial Pt/C catalysts, suggesting an extraordinary performance.

ET03.03.15
Coupling Polyoxometalates and Carbon Dots for Photoelectrocatalysis
Antonino Madonna1, Fabrizio Messina1, Delphine Schaming1 and Souad Ammar1; 1ITODYS Laboratory, Université Paris Diderot, Paris, France; 2IDFC, Università degli Studi di Palermo, Palermo, Italy.

Nowadays the need for new energy sources required to let us overcome the intensive use of fossil fuels is more actual than ever. Some efforts have been focused on the development of a system to produce and store hydrogen in an affordable way; right now, though, this gaseous fuel is still produced by the decomposition of biomass. A strategy then been adopted by scientists is to develop new materials capable of producing hydrogen directly from the catalytic reduction of water, a process commonly known as water splitting. Being hydrogen a very powerful combustible that only produces water when burned, giving rise to a so-called hydrogen cycle, it could be the green fuel of the future.

In the field of nanotechnologies, among some of the most interesting materials studied for this very purpose are Polyoxometalates (POM), a class of polyatomic clusters with rich redox and photochemical properties that can be opportunely tuned modifying their structure and composition [1]; despite several reports confirming their ability to catalyze water decomposition, their main drawback lies in their sensitivity to light, limited only to the UV part of the spectrum. In order to make use of their appealing properties via the employment of the full solar radiation, several strategies have thus been approached. In this regard, many efforts have been made to obtain an effective coupling with different photosensitizers [2]; with this in mind, the recent discovery of Carbon Dots (CDs) opens completely new perspectives. CDs are a novel class of carbon-based nanostructures, very cheap to synthesize, often non-toxic and that usually show an intense and tunable fluorescence when excited by both UV and visible light. Also, it has been reported they possess a remarkable tendency to transfer their excitation state when coupled to other species [3]. Making use of the broad distribution of molecular moieties found on CDs outer shell which allows an electrostatic interaction, we have been able to obtain a static coupling between these two species, as shown both by steady state and time resolved spectroscopy. This nanohybrid has thus been used to prepare photoelectrodes that, studied in a common photoelectrocatalytic cell, show activity when irradiated by UV-
Two-dimensional (2D) layered transition-metal dichalcogenides has been regarded as highly promising electrode materials for fast-rate Li-ion and Na-ion batteries. Monolayer or multilayer MoS₂ nanoflakes have been employed for metal ion batteries, but the material suffers from poor cyclic stability due to damage of the layered structure in a decomposition reaction. Herein, we judiciously synthesize ultrathin MoS₂-xSex nanoflakes quasi-vertically aligned on 2D graphene-like carbon foam backbone (the obtained material is referred to as MoS₂-xSex/GF). The MoS₂-xSex/GF electrode with a Se concentration (x=0.9) exhibits enhanced rate performance with a higher reversible capacity and capacity retention compared to pure nanoflake MoS₂/GF electrodes. Quantitative analysis reveals that the improved pseudocapacitive contribution, derived from enlarged interlayer spacing by selenium substitution, is the origin of good rate performance. We also investigate the decomposition reaction of MoS₂-xSex with in-situ Raman and ex-situ XRD measurements in different potential ranges (0.01-3.0 V and 0.5-3.0 V vs. Na+/Na), which reveals that the 2D structure in MoS₂-xSex can be preserved due to Na-ion intercalation process in the potential range above 0.5 V. Discharge to 0.01 V leads to damage of the 2D structure and aggregation. So we can maintain the 2D layered structure and thus significantly improve the capacity retention by choosing appropriate potential ranges. This study sheds new light on better understanding of the metal ion storage mechanism of 2D transition metal chalcogenides that are being widely investigated.

ET03.03.18

Intercalation Na-Ion Storage in Two-Dimensional MoS₂-xSex and Capacity Enhancement by Selenium Substitution Guichong jia and Hongjun Fan; Nanyang technological University, Singapore, Singapore.

Carbon dioxide (CO₂) is one of the main greenhouse gases accumulating from fossil fuel consumption has been caused urgent energy crisis and serious global warming problem, which represent two major challenges of the world. The electrochemical reduction of CO₂ into value-added chemicals and fuels provides both an attractive strategy for industrial-scale means and a candidate for energy storage. Copper (Cu) has been known as an unique metal catalyst in its ability of directly converting CO₂ into a high quantity of fuels from the electrochemical reduction of CO₂. However, poor selectivity and activity degradation are two remaining restraints for practical application. Upon most occasions, the CO₂ molecules obtain an electron to form CO₂⁻ intermediate has been regarded as a rate-determining step. However, the CO₂⁻ intermediate is the key role to obtain deep reduction products. For instance, to formation of C₂H₄, the selectivity-determining step is the generation of the COH intermediate by protonation of CO₂⁻ and the subsequent to generate ethanol. To investigate the absorbed CO on the copper surface and discuss different reaction pathway through the CO₂⁻ intermediate. We designed facile electrochemical deposition strategy to synthesize Cu nanodendrites by carbonyl coordination to expose the adsorbed CO site. Meanwhile, the adsorbed CO severely restricts hydrogen formation and the CO₂⁻ intermediate adsorption strength can tailored by adjusting the applied potential.

ET03.03.19

Surface Tailoring Induced by Pt Modification on Mixed-Phase Manganese-Cerium Oxides—A Promising Cathode Catalyst for Direct Methanol Fuel Cells Ammar B. Younaf and Peter Kasak; Qatar University, Doha, Qatar.

Developing substituent of monometallic platinum (Pt) precious metal as promising cathode catalysts in direct methanol fuel cells (DMFCs) have attracted great interests underlying sustainable energy applications. Numerous strategies have been adopted to produce active Pt-based binary and ternary alloys to overcome the faced challenges in oxygen reduction reactions (ORR). To this end, we have introduced a facile strategy to develop an efficient electrocatalyst with enhanced ORR performance and negligible methanol crossover effect to maintain the overall cell voltage as a stable in DMFCs. Surface tailoring of mixed-phase manganese-cerium oxides were induced by fabrication of ultra-low and smaller sized Pt nanoparticles by capping agent free dry-chemistry reduction process. The geometry and structural analysis of as-obtained electrocatalyst were characterized by scanning electron microscopy (SEM), transmission electron microscopy (TEM), high-resolution transmission electron microscopy (HRTEM), X-ray diffraction (XRD) and X-ray photoelectron spectroscopy (XPS). In addition, the precise surface tailoring was screened out by HAADF-STEM element mapping and atomic force microscopy (AFM). The cathode catalyst performance of Pt/Manganese-cerium oxides nanocomposite was analyzed by electro-reduction of oxygen with and without presence of methanol in alkaline medium to evaluate the negligence of methanol crossover from anode to cathode. The higher ORR performance with excellent methanol tolerance behavior compared with commercial Pt/C catalyst proved the promising nature and applications of present material in DMFCs.

ET03.03.20

Cobalt Phospide—A Stable, Non-Precious Metal Hydrogen Evolution Reaction Catalyst in a Commercial Proton Exchange Membrane Electroclyzer McKenzie A. Hubert1, Laurie King1, Chris Capuano2, Judith Manco1, Nemanja Danilovic1, Eduardo Valle1, Thomas R. Hellstern2, Katherine Ayers2 and Thomas F. Jaramillo1; 1Stanford University, Stanford, California, United States; 2Proton Onsite, Wallingford, Connecticut, United States.

Proton exchange membrane (PEM) electrolyzers are a promising route to large-scale energy storage. Platinum is the state-of-the-art hydrogen evolution reaction (HER) catalyst used in commercial PEM electrolyzers today owing to its excellent activity and stability. However, the cost and scarcity of Pt motivate research into non-platinum group (NPG) electrocatalysts. For decades, electrocatalysis research has focused on developing cheaper, efficient HER catalysts to reduce the capital cost of PEM electrolyzers1. However, a gap in this research has been demonstrating the stability of a non-platinum group (NPG) HER catalyst in a commercial-grade electrolyzer operating under conditions much different than lab-based tests.
Cobalt phospide is among the most active NPG catalysts for HER and has been well-studied and characterized in the literature. In this work, we develop a synthesis technique to prepare large batches of nanoparticulate CoP on a high surface area carbon support. In this form, we were able to directly integrate the nanomaterial into an 86 cm² commercial PEM membrane electrode assembly (MEA) electrolyzer without making significant changes to the fabrication process. This CoP PEM MEA demonstrated excellent stability by maintaining a nearly constant voltage for > 1500 hours of continuous operation at a current density of 1.86 A.cm⁻² and elevated temperature and pressure. To the best of our knowledge, this is the first demonstration of a stable NPG HER catalyst in a commercial PEM MEA electrolyzer.

For the purpose of energy storage, PEM electrolyzers will likely operate intermittently, following the flux in renewable power generation. We therefore also investigate lab-based accelerated stress tests (ASTs) to probe degradation of CoP to better understand failure mechanisms and predict catalyst performance when translated from the lab to a commercial device. Pre- and post-test characterization techniques such as x-ray photoelectron spectroscopy (XPS), transmission electron microscopy (TEM), and inductively coupled plasma mass spectrometry (ICP-MS) were used to observe and quantify degradation. Establishing standard lab-scale ASTs for HER catalysts is essential for benchmarking stability across a wide range of materials.

Vertically Aligned Nanoplatelets of Sputtered Iridium Oxide for the Oxygen Evolution Reaction David Baker, Milena B. Graziano and Brendan Hanranan; Sensors and Electron Devices Directorate, U.S. Army Research Laboratory, Adelphi, Maryland, United States.

The key to efficient water electrolysis is finding a durable oxidation catalyst with a low overpotential for the four-electron oxygen evolution reaction (OER). Among known catalysts, iridium oxide (IrO₂) is often recognized as having one of the lowest overpotentials for the OER, and is found to be stable in a wide range of aqueous media. IrO₂ electrodes are readily deposited by reactive sputtering, a method that can reproducibly control the resulting thickness, chemistry, and morphology of the IrO₂ films by changing the sputtering growth parameters. Under low deposition temperatures and high O₂ flowrates, IrO₂ grains become vertically aligned nanoplatelets with a rutile crystal structure. Due to their vertical orientation the IrO₂ nanoplatelets exhibit exceptional antireflective properties not seen with other sputtered IrO₂ morphologies, and can be electrochemically probed for their performance as OER catalysts when deposited onto electrodes. The nanoplatelet IrO₂ electrodes demonstrate high activity and good durability compared with sputtered IrO₂ exhibiting planar surface morphologies. Tafel analysis shows that the structure of the nanoplatelets is also found to have a large impact on the OER kinetics beyond simply increasing the surface area. These electrodes also exhibit comparable performance in a wide range of media, ranging in pH values from 1 to 12. Anti-reflective, nanoplatelet IrO₂ coatings are high performance catalysts for solar water splitting, without the need for damaging treatments to make antireflective patterns out of highly specialized semiconductor light absorbers.

ET03.03.22

Currently considerable efforts are made to develop renewable ways to replace the fossil-based route for producing hydrogen. As a well-studied option, water photoelectrolysis is restricted by its low energy efficiency and low output. Water electrolyser are promising for producing renewable hydrogen based on acidic proton-exchange membranes (PEMs) or alkaline water electrolyser. However, the electrode materials of the PEM electrolyzers contain platinum group metals (PGMs), which are relatively scarce and expensive thus hindering mass commercialization. By contrast, both cathode and anode materials for alkaline water electrolyser can be produced from non-noble transition metal compounds, suitable for large scale production. However, the oxygen evolution reaction (OER) in alkaline solution is still sluggish and needs a high overpotential (>350 mV) to reach a current density of 10 mA.cm⁻². Developing the right materials with favorable structures and properties can help improve the OER performance of catalysts in alkaline solutions.

As reported by Chatenet group, magnetic nanoparticles generate magnetic heating under high-frequency alternating magnetic fields. The localized heating to the catalysts in an electrolyser can considerably reduce the overpotential for OER. Besides, introducing Fe into Ni-based materials may improve its conductivity and lead to an activation effect on Ni, resulting in a dramatically enhancement of the OER performance. In addition, hierarchical structures could facilitate the electrochemical catalysis process, with active sites locating at the micro- and mesopores (nanopores) and the macropores promoting facile diffusion of species towards these active sites.

Here we report a synthesis method that Fe was introduced into the oxide precursor (NiMoO₄) by an ion exchange method to form Russian blue analogues (PBA, KNiFe(CN)₆) which was further transformed into hierarchical hollow sub-microwires composed of NiFe metal nanoparticles without the need for hydrog post-treatment. The obtained hierarchical NiFe hollow sub-microwires, with a diameter of ~200 nm, had a high specific surface area (53 m²g⁻¹) which provided lots of active sites. These sub-units—NiFe nanoparticles, with a size of 3-5 nm, acted as precursors and experienced activation to form NiFe oxide in situ on the surface, favorable to OER.

This work introduces a facile and versatile way to introduce Fe into the precursor by an ion exchange method from different transition metal oxides, and also opened up new routes for synthesizing magnetic hierarchical hollow sub-microwires based on metal nanoparticles by directly annealing from their corresponding PBA precursors without introducing explosive hydrogen for heat-treatment.

Computational Design of Core/shell Nanostructured Materials for Energy Conversion and Storage Liang Zhang, Abhinav S. Raman and Aleksandra Hanrahan; Sensors and Electron Devices Directorate, U.S. Army Research Laboratory, Adelphi, Maryland, United States.
Given the crucial role of catalysis science in our society, understanding how to design catalyst structures for desired catalytic activity and selectivity becomes a grand challenge. Core-shell nanostructured materials hold the promise of being active, cost-effective, and stable catalysts. I will demonstrate how we understand the structure-performance correlation at the atomic-scale level through a set of computational approaches and apply it to address the catalyst challenge in the fields of energy conversion and storages. Computationally, we designed heterostructured perovskites for electrochemical water splitting, which were experimentally synthesized, characterized and validated. This sets the stage for the future design of core-shell oxide nanoparticles and their use for chemical reactions under harsh chemical environments. I will provide an understanding of the activation mechanism of the heterostructures based on first principle simulations. Finally, I will bridge core-shell architecture oxide and transition metal systems and discuss our vision of potential design strategies.

Highly Stable Sodium Metal Anodes Enabled by Tuning the Thickness of Ultrathin Graphene Films Huan Wang, Chuanlong Wang and Weiyang Li; Dartmouth College, Hanover, New Hampshire, United States.

Effective surface protection of lithium metal anode is the enabling factor for next-generation high-energy batteries. However, the exacting requirements on the stability, mechanical properties and homogeneities of the protection layer hinder the realization of an ideal artificial interface. Among all the material choices, diamond with its renowned mechanical strength and exceptional electrochemical inertness is a prime candidate for lithium metal stabilization. Herein, by special synthetic techniques and rational design, we successfully rendered this desirable material compatible as lithium metal interface, which could strictly satisfy all the critical requirements. By fabricating high-quality nanodiamond film with long-range homogeneity but weak adhesion to the current collector, lithium can be electroplated solely underneath the film and effectively protected from parasitic reactions with liquid electrolyte. Notably, the nanodiamond interface possessed the highest modulus of all the lithium metal interfaces reported so far (>200 GPa), which can effectively arrest dendrite propagation to afford a dense deposition morphology. And the good flexibility of the thin film can accommodate the volume change of electrode during cycling. Importantly, since pinholes and mechanical damages during cycling are the main failure mechanisms of the artificial coatings developed so far, a unique double-layer nanodiamond design was proposed for the first time to enhance the defect tolerance of the nanodiamond interface, which enabled more uniform ion flux and mechanical properties as confirmed by both simulation and experimental results. Thanks to the multifold advantages of the double-layer nanodiamond interface, high Coulombic efficiency of over 99.4% can be obtained at a current density of 1 mA cm−2 and an areal capacity of 2 mAh cm−2. Moreover, with ~250% excess Li, more than 400 stable cycles can be realized in prototypical lithium-sulfur cells at a current density of 1.25 mA cm−2, corresponding to an average anode Coulombic efficiency of above 99%.

Nanostructured materials have been found to be critical in promoting the performance of energy storage and conversion devices, such as batteries. Here, Si anodes for Li-ion batteries (LIBs) and high capacity alloy anodes for Na-ion batteries (SIBs) are discussed as examples for the importance of design electrode materials at nanoscale.

For LIBs, we designed porous structured Si-C composite materials as high performance anodes. In one effort, the large mesoporous silicon sponge of tens of microns prepared have controlled porosity and pore size, which can limit the particle volume expansion at full lithiation to ~30% and prevent pulverization of bulk particles. The electrodes with the loading of 1.5 mAh per cm2 demonstrated ~92% capacity retention over 300 cycles. The composite electrodes of porous Si and graphite (~3 mAh per cm2 loading) with a specific capacity of ~650 mAh per gram demonstrate ~82% capacity retention over 450 cycles. In another effort, hierarchical structured Si-MWNT microspheres developed not only have good porous structure to accommodate the volume expansion and achieve ~30% apparent particle swell at full lithiation, but also demonstrate good mechanical integrity with the structure sustained up to ~220 MPa pressure. The anodes deliver a high specific capacity of ~1500 mAh per gram and 85% capacity retention over 200 cycles at the areal loading of ~3 mAh per cm2.
For SIBs, yolk-shell structured Sb@C particles and pomegranate microspheres have been prepared as high capacity anodes. With well-controlled nanostructure, these materials render stable cycling performance. The Sb@C yolk-shell structures prepared by controlled reduction and selective removal of Sb2O3 from carbon coated Sb2O3 nanoparticles can accommodate the Sb swelling upon sodiation and improve the structural/electrical integrity against pulverization. It delivers a high specific capacity of ~554 mAh per gram and long cyclability with 92% capacity retention over 200 cycles. Sb@C yolk-shell microspheres by the emulsion method further improved the packing density and the cycling stability with ~99% capacity retention over 200 cycles.

9:00 AM ET03.04.04
Towards Better Electrochemical Devices—Building Effective Transport Networks for Electrons and Ions Yunfeng Lu; Department of Chemical and Biomolecular Engineering, University of California, Los Angeles, Los Angeles, California, United States.

Electrochemical devices, such as batteries and fuel cells, are commonly used for energy storage and conversion. Generally, such devices are operated through the separation, translocation, and recombination of electrons and ions (e.g., protons and lithium ions) between the electrodes. Building devices with rapid and effective transport mechanisms towards improved performance and long cycling life. In this context, this presentation will discuss the design and synthesis of materials, as well as the engineering of electrode structure, towards electrochemical devices with improved performance. Three main topics will be covered, including 1) the design and synthesis of anode and cathode materials, 2) novel solid electrolytes and functional separators, and 3) novel hydrogen fuel cells with multifunctional anodes for enhanced transient power and prolonged lifetime.

9:30 AM ET03.04.05
Multi-Functional Few Layered Black Phosphorus Composite Qinyu Yan; Nanyang Technological University, Singapore, Singapore.

Delamination of black phosphorus (BP) into monolayer or few-layer, dubbed phosphorene, and manipulation of its newly discovered properties that are unattainable by its bulk structure have been a recent scientific breakthrough. As an elemental analogue of graphene, researchers intended to exploit its structural similarity to substitute graphene as anode for lithium ion batteries (LIBs) as one of the dominant power sources for portable electronic devices. In addition, for thermoelectric applications, theoretical studies have revealed that very high ZT values can be possibly achieved in BP with controlled charge carrier concentration.

We will present our recent activities on synthesis of few layered black phosphorus nanosheets through different methods and study their properties in Li/Na storage applications. We try to improve the chemical stability of phosphorene based composite by forming composite structures with the aid of spark plasma sintering (SPS) process. It shows that excellent air stability of SPS-processed black phosphorus can be achieved over the 60 days observation in maintaining its high storage properties. We also developed 0D-1D hybrid phosphorene-Ni3P structures to show enhanced Li storage properties.

10:30 AM ET03.04.06
The Design of Nanomaterials for Pseudocapacitive Energy Storage Bruce S. Dunn; University of California, Los Angeles, Los Angeles, California, United States.

Battery materials exhibit high energy density by utilizing reversible redox reactions, but their slow ionic diffusion leads to long charging times. Electrochemical double layer capacitors (ELDCs) offer some advantages over batteries, including fast charging times (<1 minute) and long lifetimes (~500,000 cycles). However, ELDCs do not involve redox reactions and as a result they have lower energy densities compared to batteries. For this reason, there is widespread interest in pseudocapacitance, a faradaic process involving surface or near-surface redox reactions, that can lead to high energy density at high charge-discharge rates. In recent work, we have suggested that pseudocapacitive materials can be classified as extrinsic or intrinsic; in the latter case, pseudocapacitive behavior is dependent on particle size, as fundamental changes in redox reactions may occur in finite sized systems. This paper will review our work on identifying Li+ conducting nanoscale materials which exhibit pseudocapacitive behavior. One key feature associated with pseudocapacitance is that the rate of charge storage is determined by surface-like kinetics rather than semi-infinite diffusion as occurs with battery materials. In this regard, the presence of two-dimensional pathways in the structure of the oxide or sulfide material seems to be favorable for obtaining a pseudocapacitive response. In addition, when materials are reduced to nanoscale dimensions, they may begin to exhibit pseudocapacitive characteristics because of the large number of surface sites or because phase transitions which occur in the corresponding bulk materials are suppressed. MoO3 is a good example of this behavior as micron-sized particles exhibit battery-like properties while nanosized materials exhibit pseudocapacitive responses and operate at high charge/discharge rates without decreasing the level of charge storage. Morphology is another parameter that has been used to develop pseudocapacitive responses in a variety of systems. Mesoporous materials, which possess an interconnected pore network that provides electrolyte access to thin (<15 nm) redox-active walls, lead to a pseudocapacitive response while two-dimensional nanosheets of transition metal oxides exhibit surface-controlled kinetics indicative of pseudocapacitive behavior. The ensemble of these results suggests that we can expect an increasing number of nanoscale materials to be developed that retain high energy density at charge/discharge rates which are well above those of battery materials.

11:00 AM ET03.04.07
In Situ Formation of Sulfide Solid-State Electrolyte Protection Layer on the Surface of Metallic Li for High Performance Li Batteries Jianwen Liang, Xiaona Li and Xueliang A. Sun; University of Western Ontario, London, Ontario, Canada.

Metallic lithium (Li) has attracted extensive attentions for Li-S, Li-air and solid-state Li batteries, due to its high theoretical capacity and low redox potential [1-3]. However, several challenges substantially hinder the real application of Li anodes, such as dendrite formation and unfavorable reaction between Li and electrolyte. In fact, the real problem is originated from the unavoidably react of Li with electrolyte and the non-uniform distribution of electrochemical active sites for Li plating/stripping during cycling.

Formation of a thin and stable protection layer with uniform and high Li ion flux on the surface of Li metal may address all of the main problems of Li anode. Sulfide-based solid-state electrolyte possesses reasonably high ionic conductivity (especially for nanostructured layer, which can achieve ionic conductivities higher than 10 mS cm⁻¹ at room temperature), which is a good choice for the materials of Li metal protection layer. While, the formation of a thin sulfide-based solid-state electrolyte layer, especially for in-situ or adjustable layer with nanosize and different thickness, on the surface of Li metal is still a challenge due to the high chemical active of metallic Li and the difficult synthesized conditions of sulfide-based solid-state electrolyte. Here, we show an in-situ dispositional strategy to form a sulfide solid-state electrolyte protection layer on the surface of metallic Li to address the dynamic Li plating/stripping process. Taking adjustable Li2PS4 solid-state electrolyte layer as an example, due to the high ionic conductivity and low electrochemical activity of Li2PS4, the intimate protection layer of Li2PS4 between Li metal and liquid organic electrolyte can not only restrain the formation of Li dendrite, but also reduce the SEI formation and prevent further corrosion of Li metal during battery cycling. Thus, excellent electrochemical performance has been achieved: (1) Symmetric cells with the Li2PS4 protection layer can deliver stable Li plating/stripping for 2000 h with voltage hysteresis as low as ~10 mV; (2) Full cells assembled with the Li2PS4-protected Li exhibit two times higher capacity retention in Li-S batteries (~800 mAh g⁻¹) at 5 A g⁻¹ for over 400 cycles compared to their bare Li counterparts; (3) High rate performances can be achieved with Li-
In essence, nanocrystalline metals are promising building units to realize high-capacity anodes are enabling ever-increasing gravimetric and volumetric energy densities in lithium-ion batteries (LIBs), but their fading capacities upon both pulverization and electrical disconnection caused by large volume changes during repetitive lithiation/delithiation reactions must be remedied. Another challenge is the lack of a fast and scalable process to fabricate nanocrystalline metals into real electrodes. Herein, we report graphene pliable pockets (GPPs) remedying the limitations of nanocrystalline metals for high-performance LIBs, and Metal_encapsulated GPPs (M_GPPs) can be fabricated via the ultrafast dynamic polymerization and evaporation of specific polymers on nanocrystalline metals. This process is also shown to enable scalable mass production upon increasing the batch size.

We applied the GPP structure to silicon, a most promising but also difficult to handle electrode material. Utilizing Si GPPs with high tap densities exhibits excellent rate capability and robust cycle life. We discover that the inner graphene pliable layers allow electrical conductance to Si and the outer GPP controls formation of solid-electrolyte interface (SEI) layers, while both of them provide pliable compartments to prevent volume expansion and pulverization of Si nanocrystals during repeated lithiation/delithiation cycles. Full-cell LIBs of the Si GPP electrodes assembled with representative cathodes of LiCoO2 (LCO), LiMnO2 (LMO), and LiFePO4 (LFP) demonstrate remarkably high gravimetric and volumetric energy densities. Moreover, Si GPPs can be used as the battery-type electrodes for lithium-ion capacitors (LIC), such an attempt lead to a result in much faster charging/discharging and strikingly longer life performance while maintaining high energy densities. GPP structures are superior and feasible than other promising anode structures, thereby applicable to industries and attainable shortly.

In situ sodiation experiments were performed on the Na-Sn system to evaluate the rate capability and cycle stability of the anode material. Experiments showed that the sodiation rate of crystalline Sn (c-Sn) is 2-3 orders of magnitude faster than the lithiation rate of c-Si with the same diameters. Furthermore, the observed rates were nearly the same regardless of the orientation of c-Sn, causing the Sn anode to swell in an isotropic manner and thus mitigating pulverization. Here, using atomic simulations and advanced analysis techniques, we elucidated the mechanistic origins responsible for the ultrafast sodiation and isotropic swelling observed from for the Sn anode by clarifying the diffusion kinetics at the Na-Sn diffusion couple. It was found that both the crystalline-to-amorphous phase transformation at thin layers of c-Sn near the propagating interface and pipe diffusion through sodiation-induced dislocations are the two dominant structural features occurring during sodiation. These sodiation behaviors observed from the Na/Sn interface alleviate the rate-limiting behavior of the propagating interface, while nullifying the orientation effect of diffusion in c-Sn. This promotes the Na diffusion to c-Sn at unprecedented rates and enables isotropic swelling of c-Sn. The observed phenomena provide insight into the design of anode materials for realizing batteries with high rate performance and cycle stability.

1:30 PM ET03.05.01
Recent Developments in the Design and Synthesis of Platinum-Based Catalysts for Fuel Cell Application Younan Xia; Georgia Institute of Technology, Atlanta, Georgia, United States.

Platinum (Pt) is by far the best catalyst for the oxygen reduction reaction (ORR) occurring on the cathode of a proton exchange membrane fuel cell (PEMFC). Its low abundance, limited supply, and ever-increasing price have kept motivating researchers to minimize the loading of this precious metal in the catalyst. In this talk, I will discuss a number of strategies for greatly increasing the mass activity and durability of Pt-based ORR catalysts, including...
facet-controlled synthesis, increase of dispersion by forming a core-shell or hollow structure, manipulation of surface strain, electronic coupling through the incorporation of a second metal, and use of particles with an uniform, optimal size. These strategies have resulted in the development of advanced ORR catalysts, enabling the society to achieve a sustainable use of precious metals such as Pt in energy conversion, industrial catalysis, and related applications.

2:00 PM ET03.05.02
Extending the Limits of Pt/C Catalysts with Passivation-Gas-Incorporated Atomic Layer Deposition
Shicheng (John) Xu1, Yongmin Kim1, Joonsuk Park2, Drew Higgins3, Peter Schindler4, Dickson Thian5, J. Provine6, Jan Torgersen1, 7, Tanja Graf8, Thomas D. Schladt8, Marat Orazov3, 7
1Civil and Environmental Engineering, Stanford University, Stanford, California, United States; 2Department of Mechanical Engineering, Stanford University, Stanford, California, United States; 3Department of Chemical Engineering, Stanford University, Stanford, California, United States; 4Chemical Engineering, Stanford University, Stanford, California, United States; 5Department of Materials Science and Engineering, Stanford University, Stanford, California, United States; 6Department of Chemical Engineering, Stanford University, Stanford, California, United States; 7Department of Mechanical and Industrial Engineering, Norwegian University of Science and Technology, Trondheim, Norway; 8Volkswagen Group Research, Wolfsburg, Germany.

Cost and life-time are key factors in limiting the broad adoption of polymer electrolyte fuel cells for cars. In response, we have been investigating the morphology of noble metal nanoparticles during surface deposition. In particular, we explored the influence of precursor-substrate and precursor-deposit interactions. Depositions can be improved through a variety of means, including tailoring the surface energy of a substrate to improve precursor wettability, or by modifying the surface energy of the deposits themselves. Here, we show that carbon monoxide can be used as a passivation gas during atomic layer deposition to modify the surface energy of already deposited Pt nanoparticles to assist direct deposition onto a carbon catalyst support. The passivation process promotes two-dimensional growth leading to Pt nanoparticles with suppressed thicknesses and a more than 40% improvement in Pt surface-to-volume ratio. This approach to synthesizing nanoparticulate Pt/C catalysts achieved high Pt mass activities for the oxygen reduction reaction (ORR), along with excellent stability likely facilitated by strong catalyst-support interactions afforded by this synthetic technique.

2:30 PM ET03.05.03
High-Productivity Electrochemistry with Flow-Through Nanowire Electrodes
Myung Jun Kim, Feichen Yang and Benjamin Wiley; Duke University, Durham, North Carolina, United States.

The high surface area per unit volume and large mass-transfer rates offered by porous, flow-through electrodes have resulted in their use in a wide variety of electrochemical processes, including organic electroosynthesis, water electrolysis, water treatment, fuel cells, and redox flow batteries. Many types of porous electrodes are commercially available, including carbon paper, graphite felt, reticulated vitreous carbon (RVC), metal mesh, and metal foam. Metal foam offers relatively high conductivity but a low surface area, whereas carbon paper has one of the highest surface areas but lower conductivity.

This presentation will describe the characteristics of a Cu nanowire flow-through electrode that has 15 times more surface area and is 32 times more conductive than carbon paper. The improvement in surface area is due to the small diameter of the nanowires relative to carbon fibers. The higher conductivity is due to the intrinsically higher conductivity of Cu, and the fact that the metal nanowires can be sintered together. The nanowire electrode has a porosity of 94%, but its hydraulic permeability was 89 times lower than carbon paper. For Cu ion reduction, the Cu nanowire electrode can achieve the same single-pass conversion as carbon paper at flow rates 300 times greater under mass transport-limited conditions, and 10 times greater under kinetically limited conditions. We will also report the performance of the flow-through nanowire electrodes for organic electroosynthesis and for water splitting. The high-conductivity, high surface area, and high porosity that can be achieved with metal nanowire electrodes create new opportunities for improving the performance of electrochemical systems for energy storage, hydrogen production, water treatment and the production of fine chemicals.

2:45 PM ET03.05.04
Quasi-2D PdPt Alloy Nanoclams for CO2 Reduction and Proposed Application in Tandem with Microbial Communities
Andrew B. Wong1, Joseph A. Gauthier1, Frauke Kracke2, Antaeres Antoniuk-Pablant1, Christopher Hahn1, 3, Karen Chan1, 3, Alfred Spormann2, 4 and Thomas F. Jaramillo2, 4, 5, 6
1Department of Mechanical Engineering, Stanford University, Stanford, California, United States; 2Civil and Environmental Engineering, Stanford University, Stanford, California, United States; 3Department of Materials Science and Engineering, Stanford University, Stanford, California, United States; 4SUNCAT Center for Interface Science and Catalysis, Department of Chemical Engineering, Stanford University, Stanford, California, United States; 5SUNCAT Center for Interface Science and Catalysis, SLAC National Accelerator Laboratory, Menlo Park, California, United States; 6Chemical Engineering, Stanford University, Stanford, California, United States.

Improving the performance of cathodes for the electrochemical CO2 reduction reaction (CO2RR) will benefit from the discovery of new materials as well as the introduction of new paradigms. This presentation focuses on the synthesis and systematic study of the CO2 reduction activity of a novel quasi-2D PdPt bimetallic ‘nanoclam’ catalyst synthesized on carbon cloth electrodes via a pulsed electrodeposition technique. These results highlight the importance of nanostructuring to improve selectivity and geometric activity for CO2 reduction in this system through the comparison of the bulk and nanostructured PdPt. In addition, we also propose that the high activity of this catalyst at low overpotential is ideal for paring with biological systems to realize a hybrid system for CO2 reduction.

The PdPt nanoclams catalysts that combine high surface area with exposure of numerous undercoordinated sites for CO2 reduction with activity exceeding that of either Pd or Pt for CO2 reduction to formate at 0.2 V vs RHE, which is a provocative result. In comparison with bulk Pd, PdPt, and Pt systems, we find that the interplay of multiple trends affects selectivity and activity:

1. Increasing Pt content shifts selectivity from formation of formate to hydrogen evolution in the bulk
2. Increasing Pt content increases overall activity and prevents catalyst deactivation by changing the energetics of hydride intercalation into PdPt
3. Nanostructured morphology of PdPt nanoclams increases selectivity to formate in PdPt nanoclams vs in bulk, planar PdPt.

In addition to this understanding, we report our initial results on the creation of a hybrid electrochemical-biological CO2 reduction system in which formate and hydrogen are produced through electrochemical CO2 reduction by PdPt nanoclams. These products are metabolized by methanogens in combination with CO2 to yield ~100% faradaic efficiency to methane. Going forward, the integration of microbial communities with these nanostructured PdPt catalysts has the potential to combine the best-of-both-worlds from electrochemical and biological systems to achieve a regenerative catalytic system with high-selectivity, high activity, and low overpotential.

Rational Design of Electrode-Electrolyte System for Highly Efficient Electrochemical Nitrogen Reduction Reaction
Bryan H. Suryanto2, Colin S.
Ammonia is one of the most important chemicals used in the modern society. As an essential precursor used in the fertilizer production, the supply of ammonia is strongly associated to food furnishing. Without ammonia, it is predicted that more than half of the world population would starve. However, the synthesis of ammonia is extremely challenging due to the great thermodynamic stability of the nitrogen triple bond. Currently, more than 90% of the global ammonia commodity is produced by the Haber-Bosch process which is responsible for the release of ~12 Gt (1.5% of global total greenhouse gas emissions) of CO₂ into the atmosphere, annually. Therefore, the synthesis of ammonia from atmospheric N₂ utilizing renewable energy sources with zero carbon footprint will become an important process in moving forward.

Electrochemistry provides a direct pathway for N₂ conversion into NH₃ utilizing renewable electricity. Historically, the NH₃ electro-synthesis suffers from the drawbacks of low yield rate and selectivity (<10%), mainly due to the predominating hydrogen evolution reaction (HER). In this work, an electrochemical nitrogen reduction reaction (NRR) with a significantly enhanced selectivity and yield rate of NH₃ have been obtained via both electrode and electrolyte engineering. Surface area enhanced α-Fe₃O₄ nanorods were employed as the NRR cathode in an apricot solvent – ionic liquid mixed electrolyte. Remarkably, a NH₃ yield rate of ~2.35 × 10⁻¹¹ mol s⁻¹ cm⁻² with a high selectivity of ~32% was achieved. This work reveals that the abilities to both regulate the proton availability and enhance the N₂ solubility in the engineered electrolyte are imperative in achieving highly efficient NRR at room temperature and pressure.

Nitrogen Fixation via Electrochemical Biosynthesis Under Ambient Atmospheric Environment Shengtao Lu, Xin Guan and Chong Liu; Division of Chemistry, University of California, Los Angeles, Los Angeles, California, United States.

The hybridization of electrochemical interface and microbiological synthesis combines the high efficiency of electrochemical reactions and the catalytic capability of microbes to produce valuable chemicals. Such hybrid can be used for nitrogen fixation, which consumes renewable energy such as solar electricity, and can also drive distributed production of environmental-friendly fixed nitrogen species. However, a fundamental contradiction occurs as the crucial nitrogen fixing enzyme, nitrogenase, is incompatible with oxygen. This prevents nitrogen fixation via nitrogenase in air, the most abundant nitrogen source. Here we report a micro-structured electrochemical interface that solves this problem. Our design enables successful nitrogen fixation under ambient atmospheric conditions. We also prove that such interface is scalable, which enables potential applications.

4:15 PM ET03.05.08
The INCA (Ionomer Nc Analysis) Method, a New Approach to Study Perfluorinated Ionomers Riccardo Narducci1, 2 and Maria Luisa Di Vona1, 2; 1University of Rome Tor Vergata, Roma, Italy; 2LIA, Roma, Italy.

Both the impelling need for a constant reduction of pollution in large cities and carbon dioxide in the atmosphere, as well as the continuous increase in petrol cost, have reinforced the interest in more efficient, clean, and sustainable systems such as fuel cells (FCs) for the conversion of electrical energy.

However, the present FC technology does not give till now the wished performances and the complete assurance for a long durability in all climatic conditions. The proton conducting separators preferred by cars producers are perfluorosulfonic acid (PFSA) membranes at temperatures of about 80 °C. The main target of the use of the INCA Method (Ionomer Nc Analysis) is the study and the understanding of ionomers in the conditions of use and the improvement of ionomeric membranes under operating conditions. In this presentation we will illustrate the results obtained comparing pristine Nafion 1100, oriented Nafion 1100 prepared in our laboratory, and stabilized (crystalline) Nafion 1100 membranes treated with special annealing agents. We will propose the best taylor made annealing in order to avoid critical degradations of mechanical properties and ionic conductivity due to the formation of layered morphologies, prevalently oriented in the direction parallel to the membrane surface. Hence commercial Nafion 1100 membranes were treated with dimethylsulfoxide (DMSO) for 7 days at 140 °C, to increase the thermal stability because of the formation of semi-crystalline phase (physical crosslinking), followed by hydrothermal annealing in liquid water to obtain a suitable water Uptake (WU). The results obtained with the INCA Method will be compared with the Dynamic Mechanical Analysis (DMA) and tensile stress measurements. The INCA analysis was also used to study the effect of the presence of H-bond and/or crystallinity in un-crystallized Nafion 1100 prepared from the solution. This material, prevalently amorphous, has a melting temperature (Tm) lower of about 50 °C respect to commercial Nafion 1100, but presents a high WU in the same condition of temperature and relative humidity. At the same time we will present the effect of the variation of the equivalent weight (EW) on the Tm: the lowering of EW causes a decrease in Tm of 10 °C. The knowledge of this effect on Tm is fundamental for Aquivion membranes, which have a wide range of EW. The INCA method allowed us to evaluate the behavior of Aquivion membranes in fuel cell conditions and compare them with Nafion membranes. The results permit to suggest the most appropriate thermal/hydrothermal treatments to stabilized these ionomers, where the mechanical stability play a fundamental role.

4:30 PM ET03.05.09
Unveiling the Effect of Pt-Based L1₁ FCT Core in Core/Shell Nanoparticles for Oxygen Reduction Reaction Mingjie Liu, Huolin L. Xin and Qin Wu; Brookhaven National Laboratory, Upton, New York, United States.

Rational design of active, durable and low-cost catalysts for oxygen reduction reaction (ORR) is highly desirable in fuel cell research. Nanoparticles with a core (Pt-based alloy)/shell (few layers of Pt skin) structure have attracted much attention due to their lower cost than pure Pt and potential benefits of activity tuning afforded by careful configuration of the core alloys. Previous theoretical work studying the enhancement effects has primarily focused on core alloys with cubic structures, i.e. disordered alloy or L1₁ ordered structure. In this work, using ab initio calculations, we have systematically investigated the structure-activity relationship of a new class of PtₓMₓ₂ (M=V, Cr, Fe, Co, Ni, and Cu) core alloy that has a low-temperature tetragonal L1₁ intermetallic structure. We have calculated the adsorption energies of O₂, OH, and OOH on various Pt skins and the underlying tetragonal structured alloys. We comprehensively explore the interaction between Pt layers and host materials to acquire the best Pt thickness associated with certain host material, tuning the ORR activity toward the peak of the ORR volcano plot. We further decompose the enhancement factor into ligand, normal and shear strain effects in these systems and clarify the origin of the improved activity of this class of catalysts. Our results could facilitate future design of ordered intermetallic FCT structure in ORR applications.

Oxide Nanoparticles as High Performance Bifunctional Catalyst Hongmei Luo, Meng Zhou and Litao Yan; New Mexico State University, Las Cruces,
New Mexico, United States.

Developing efficient electrocatalysts for oxygen evolution reaction (OER) and oxygen reduction reaction (ORR) are vital to the new generation of electrochemical storage and conversion devices such as electrolyzer, metal-air batteries, and fuel cells. For the demand of reversible fuel cells and rechargeable metal-air batteries, the bifunctional catalyst that can be used for both ORR and OER is gathering attention. In order to address the longstanding problems with high cost and poor stability of noble metal electrocatalysts, perovskite (ABO₃) formula, where A is rare-earth or alkaline metal and B is transition metal) with low cost, high versatility in structure and potential as bifunctional catalyst is of special interest. Applying our successful and novel polymer-assisted chemical solution (PACS) method, we will present the controlled synthesis of \((La_{0.8}Sr_{0.2})_3(Mn_{1-y}B_y)O_3\) (B: Ir and Co, x=0-0.1, y=0-0.2) nanoparticles with different particle sizes, A-site nonstoichiometry, B-site doping, and oxygen vacancy, and epitaxial thin films with different crystal orientations. Structural characterizations and electrochemical analysis are utilized to investigate the correlation between their compositions, structures, and electrochemical properties.

ET03.06.01 Nono Scale Three-Dimensional Resistivity Mapping of the Lithium-Ion Battery Solid Electrolyte Interphase on Silicon Anodes Caleb Stetson¹,², Taeho Yoon³, Yanli Yin³, Steve Harvey³, Andrew Norman³, Chunmei Ban³, Chunsheng Jiang³, Steven DeCaluwe¹ and Mowafak Al-Jassim²; ¹Colorado School of Mines, Golden, Colorado, United States; ²National Renewable Energy Laboratory, Golden, Colorado, United States.

In lithium-ion batteries, the solid electrolyte interphase (SEI) is an important passivating layer formed on the anode from electrolyte decomposition products. On silicon anodes, the SEI is believed to be critical to battery reliability and performance. SEI must be both electronically insulating to prevent further electrolyte decomposition and ionically conductive to permit the flow of lithium ions. While electronic resistivity is a critical intrinsic property of SEI, characterization tools to investigate the electronic properties of this thin, reactive layer have been limited.

To advance understanding of the electronic properties of SEI, our group has developed an instrumental approach utilizing scanning spreading resistance microscopy (SSRM) to characterize electronic properties in three dimensions in the nanoscale. Resistivity vs. depth profiling results originating from this technique have shown that electronic resistivity decreases from the surface of SEI moving towards the SEI/Si interface. Moreover, total SEI thickness is readily calculated by the identification of electronically conductive silicon beneath the insulating SEI. Thickness of SEI is highly variable based on the electrolyte and the cycling conditions utilized. Additionally, two-dimensional mapping of electronic resistivity at varied depths within the SEI gives quantitative and qualitative data regarding the heterogeneity of SEI structures in the nanometer regime.

Investigation of reference materials with known electronic properties has allowed for determination of instrumental resolution. Characterization of model SEI systems with SSRM alongside transmission electron microscopy (TEM), X-ray photoelectron microscopy (XPS), and time-of-flight secondary ion mass spectrometry (ToF-SIMS) permits the association of electronic properties with specific SEI chemical components.

ET03.06.02 Muon Spin Spectroscopy as a Nanoscale Probe for Studying Ionic Diffusion in Electrode Materials Beth L. Johnston¹, Peter Baker² and Serena Corr¹; ¹University of Glasgow, Glasgow, United Kingdom; ²ISIS Pulsed Neutron and Muon Source, Didcot, United Kingdom.

Lithium ion batteries are ubiquitous in today’s technology: they power our phones, laptops and are finding greater use for larger scale applications such as electric vehicles. Developments in sodium ion batteries are also of great current interest for use in stationary energy storage technologies such as grid storage for renewable energy sources. The movement of Li⁺ or Na⁺ ions through the active electrode material in a battery is crucial for its electrochemical performance, yet quantifying this behaviour can be very technique dependant. For example, macroscopic ionic diffusion measurements can indicate greater activation energies for ion diffusion due to the extra impedance imparted by macroscopic grain boundaries. Here, we demonstrate the use of muon spin relaxation spectroscopy (µ⁺-SR) as a valuable local tool to probe the Li⁺ and Na⁺ diffusion dynamics in battery electrode materials. The µ⁺-SR method allows one to probe the nanoscale distribution of ions via the muon spin perturbation due to diffusing ions nearby. Developing a clearer understanding of these diffusion processes at a local scale can provide us insights into electrochemical behaviour and the opportunity to optimise and tailor performance.

We present the investigation of local ion diffusion in the polyamionic positive insertion electrode materials LiFeSO₄F and Na₂FePO₄F using µ⁺-SR for the first time. It is predicted that these structures possess multi-dimensional ionic diffusion pathways, suggesting facile ion diffusion. In addition to enhanced ionic diffusion, these compounds display high energy densities driven by the inductive effect where the presence of electronegative species such as fluoride changes the ionic-covalent nature of bonds. The results obtained from these µ⁺-SR studies indicate lower activation energies and larger diffusion coefficients at room temperature compared to values obtained by computational and bulk characterisation means. This indicates intrinsically favourable diffusion dynamics which could be accessed by improvements in, for example, engineering of materials to reduce impedance effects from grain boundaries.

ET03.06.03 In Situ Electrochemical Dilatometry Study of Capacity Fading in Nanoporous Ge-Based Na-Ion Battery Anode During Sodiation-Desodication Cycles Manni Li¹,² and Eric Detsi¹; ¹Materials Science & Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States; ²Materials Science & Engineering, Harbin Institute of Technology, Harbin, China.

Although the rechargeable battery industry is currently dominated by lithium-ion battery technology, sodium-ion batteries are expected to play a key role in the near future, owing to the high abundance of raw sodium resources. Achieving high energy densities in sodium-ion batteries equal to, or exceeding...
lithium-ion batteries requires alloy-type high-capacity anode materials such as Sn, Sn. P. Ge [1]. However, alloying reaction of sodium with these materials result in significant phase transformation-induced stresses and volume changes, which ultimately cause a rapid capacity fading. In this work, nanoporous germanium was made by selective alloy corrosion and used to prepare sodium-ion battery composite slurry anodes. The performance of this composite electrode for reversible sodium storage was investigated by in situ electrochemical dilatometry, during which the (de)sodiation-induced macroscopic dimensional changes were recorded simultaneously during (dis)charging cycles, and for the first 200 cycles. (De)sodiation-induced dimensional changes and capacity fading were found to be proportional [2].

Theoretical Investigations on the Structural and Electrochemical Properties of Silicon Nano-Particle Anode Material for Lithium-Ion Batteries
Seung Eun S. Lee1, Hyung Kyu Lim2 and Sangheon Lee3; 1Chemical Engineering and Materials Science, Ewha Womans University, Seoul, Korea (the Republic of); 2Chemical Engineering, Kangwon National University, Seoul, Korea (the Republic of).

Lithium-Ion batteries (LIBs) are one of the most predominant energy storage systems for portable to stationary electronic devices. The LIBs are indispensable to laptops, mobile phones, and electric vehicles due to their high energy/power density and long cycle life. Accordingly, there is a continuing increase in the technical demand for developing higher capacity/power LIBs. Especially, silicon (Si) has been intensively pursued as the most promising anode material for its high specific capacity (> 3500 mAh/g) and abundance. Despite its high capacity, Si suffers from fast capacity loss caused by its large volume change (> 300%), unstable solid electrolyte interphase (SEI) and physical disintegration (cracking and crumbling) of the electrode structure during lithiation/delithiation processes. Therefore, there are various research activities to control the physico-chemical stabilities of Si anode material. Currently, Si nanostructures such as nanowires and nanoparticle carbon composites are proved to be effective methods for improving capacity and cycling stability, since nano-sized Si can alleviate mechanical stresses during volume changes. In this work, we conducted a series of computational simulations to understand how the physico-chemical stabilities of nanostructured Si anodes are associated with the high surface ratio of Si nanostructures. Using Monte Carlo simulations within the first-principles based reactive force-field (ReaxFF) framework, we determined atomic structures of Si nanoparticles in terms of particle size and lithiation ratio. Then, we elucidated a unique relationship between the structure of Si nanoparticle anodes and their physico-chemical properties such as theoretical charge/discharge potentials, by using the density-functional theory (DFT) calculations. Our theoretical findings will provide future guidance for developing next-generation Si nanomaterials, which can be successfully applied to commercialization of Si anode materials.

ET03.06.05
Yongkwon Song, Seunghui Woo, Junsang Yun and Jinhan Cho; Department of Chemical and Biological Engineering, Korea University, Seoul, Korea (the Republic of).

The development of flexible and conductive electrodes is crucial for rapidly evolving flexible/wearable electronic applications. For this purpose, various Ag nanomaterials with high electrical conductivity, such as nanoparticles and nanowires, have been physically deposited onto flexible substrates, but the electrical conductivity and mechanical stability of these electrodes are still restricted. Including Ag nanomaterials, commercially available cellulose papers have received great attention as promising substrates for next-generation flexible electrodes due to their high flexibility, large specific surface area, lightweight and low cost. Herein, we introduce a highly porous paper electrode with bulk metal-like electrical conductivity using room-temperature metallic fusion-assisted layer-by-layer (LbL) assembly. The newly synthesized tetraethylammonium thiosulfate (TOAS) stabilized Ag NPs were LbL-assembled with tris(2-aminoethyl) amine (TAA), allowing the almost perfect ligand exchange reaction between bulky/insulating TOAS ligands and small TAA molecules. The introduced small TAA molecules connect between neighboring Ag NPs, significantly decreasing the interparticle distance of Ag-Ag NPs. In addition to the minimized interparticle distance of Ag-Ag NPs, the low cohesive energy of Ag NPs strongly induces metallic fusion between closely packed Ag NPs at room temperature without any additional treatments. The resultant multilayers of (TOAS-Ag NP/TAA), exhibits the bulk metal-like electrical conductivity of ~ 1.60 x 10^5 S cm^-1. When depositing the Ag NPs onto cellulose papers through our approach, the insulating papers can be converted to flexible and bulk metal-like conductive papers that can be used as 3D current collectors for high-performance energy storage devices.

ET03.06.06
Electron-Dense Ligands and Their Optoelectronic Effects on PbS Quantum Dot Photovoltaics
Daniel Gregory, Hazel Assender and Andrew Watt; University of Oxford, Oxford, United Kingdom.

Quantum dot solar cells offer a low-cost route to flexible photovoltaics, with additional effects such as the relative ease of multiple exciton generation (MEG) offering tantalising possibilities of breaking the Shockley Queisser limit in the future. However, bottlenecks in device design and fabrication currently limit this technology's record efficiencies. Chief among those problems are the mobility of charges within the quantum dot layers of the device – causing a reduction in fill factor - and the need for stronger n-doping to improve open circuit voltages. One method of suppressing these problems is through ligand passivation, or combinations thereof. Current research has focused on ever-smaller ligands, down to individual halide ion passivation with dissociating organic salts, while research into the effects of substitution groups residing beyond the coordinating groups of small molecules has waned. This research begins with the introduction of novel ligand systems using electron-dense substituents outside the coordinating functional group, and follows with an exploration of the optoelectronic properties this class of ligands can provide to PbS quantum dot films, finishing with an overview of the photovoltaic performance of these systems.

ET03.06.07
Two-Dimensional Hexagonal Indium Selenide Nanosheets for Li-Ion Battery Applications
Valeria Nicolosi, Chuanfang Zhang and Meiying Liang; Trinity College Dublin, Dublin, Ireland.

Metal chalcogenides (MCs), including metal sulfides, metal selenides and metal tellurides, have attracted tremendous attention for energy storage applications and development of rechargeable lithium-ion batteries due to their unique physicochemical properties (e.g. high electrical conductivity, good thermal stability, earth abundance, etc.). Especially, MCs possess higher theoretical specific capacities for rechargeable lithium-ion batteries compared to traditional intercalation electrode materials. In addition, metal chalcogenides tend to be more electrochemically reversible as compared to metal oxide counterparts due to their faster charge transfer kinetics.

Recently, as an alternative anode material for replacing currently commercialized graphite or carbon-based anode materials, various two dimensional (2D) MCs materials, such as 2D gallium sulfide nanosheets, are investigated because of their large theoretical capacity. However, there is still a plenty of room for the development of new efficient anode materials from 2D MCs since only a few studies are carried out for this type of materials.
In this work, hexagonal shape indium selenide (InSe) was prepared via phase-controlled synthesis method and 2D InSe nanosheets were obtained via liquid phase exfoliation approach. Then, single-wall carbon nanotube (SWCNT) was added to improve the conductivity and flexibility of the hexagonal shape 2D InSe nanosheets electrodes for lithium-ion batteries’ anodes. Compared to commercially available InSe and bulk layered InSe, the hexagonal shape 2D InSe nanosheets displays the most excellent rate capability and high specific capacity (926 mAh g⁻¹ and 595 mAh g⁻¹ at 50 mA g⁻¹ and 2 A g⁻¹, respectively). In addition, it shows exotic cycling stability. The capacity of it has increased with the increase of cycling numbers (the capacity of the battery dramatically increased in the first 100 cycles and it continuously increased until 900 cycles), which means the quality of a battery will be improved when the battery is used. This work opens up vast opportunities for InSe to be scalable processed into flexible conductive composite films with a broad range of applications such as wearable electronics, optoelectronics, and other energy storage systems.

ET03.06.08
Nickel Vanadium Layered Double Hydroxides Nanosstructures for High-Performance Flexible Supercapacitor Applications Ankita Tyagi and Raju Kumar Gupta; Department of Chemical Engineering, Indian Institute of Technology Kanpur, Kanpur, India.

In recent times, demand for portable electronic devices like mobile phones, cameras, and laptops, etc. is increasing day by day. Energy storage devices such as batteries and supercapacitors have significant importance because of their high energy density and high power density, respectively.¹ The supercapacitor is gaining a considerable amount of attention because it uses the less toxic material, offers high power density, excellent electrochemical stability, a wide range of operating temperatures and durability. Facile fabrication of low cost, efficient, stable, eco-friendly and earth-abundant electrode materials for supercapacitors is critical.² Layered double hydroxide (LDH) is a new class of material having positively charged hydroxylate-like layers, weakly bound, intercalating charge compensating anions and water molecules, has shown tremendous supercapacitive performance.³ In this work, an ionic lamellar, two-dimensional (2D) nickel-vanadium layered double hydroxide (NV LDH) nanosheets have been synthesized via facile, cost-effective and potentially scalable hydrothermal method. The as-prepared 2D NV LDH nanosheets over carbon cloth (NVL@CC) was used as the supercapacitor electrode. The electrochemical characterization techniques such as cyclic voltammetry (CV), galvanostatic charge-discharge (GCD) and electrochemical impedance spectroscopy (EIS) were used to characterize the material for its electrochemical properties, while SEM, TEM, XRD, BET, and XPS, etc. techniques have been used for their morphological, structural and physical characterization. The high specific capacitance of ~2600 F g⁻¹ at the current density of 1 A g⁻¹ was observed in a three-electrode system using KOH as an electrolyte, which remained quite high at an increased current density of 10 A g⁻¹. This work demonstrates excellent potential for NV LDH nanosheets as an electrode material for supercapacitor applications.

Improvement of LiCoO2 High Voltage Cycling Stability by Nanoscale Polymer Surface Engineering via Chemical Vapor Deposition Polymerization Laisuo Su and B. Reeja Jayan; Mechanical Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania, United States.

The interface between an electrode and electrolyte is crucial to the overall performance of lithium ion batteries (LIBs). Here we demonstrate chemical vapor deposition polymerization as a novel method to improve the performance of LiCoO2 cathode electrode for LIBs, including both rate capability and high voltage (4.5 V) cycling stability. Three polymers are utilized to engineer the surface and CR2016 coin cells are fabricated to study the effect of these polymers on LIBs electrochemical performance. The three polymers are poly(3,4-ethylenedioxythiophene) (PEDOT), poly(divinylbenzene) (PDVB) and poly(divinylbenzene-co-1H,1H,2H,2H-perfluorocyclyl acrylate (PDVB-co-PFDA)). Our results show that the PEDOT improves both the rate and the high voltage cycling performance of LiCoO2 electrodes, the PDVB has little effect on the both performances, while the PDVB-co-PFDA inhibits the performances. The PEDOT coating increases 100% rate capacity by 62% (from 34 to 55 mAh/g). The high voltage cycling number is increased by 250% (from 40 to 100 times) when the capacity decreases to 50% of its initial capacity. X-ray photoelectron spectroscopy is applied to understand the improvement of cycling stability. The results suggest that chemical or coordination bonds form between Co in LiCoO2 and O and S in the PEDOT film, while there is no bonds formation from the PDVB or the PDVB-co-PFDA coatings. The bonds stabilize the surface of LiCoO2 and thus improve the high voltage cycling performance. This work introduces chemical vapor deposition polymerization as a new research tool for surface modification and interface engineering of lithium ion battery electrodes.

ET03.06.10
Mutually Embedded MOF-Derived Uniformly Dispersed CoS2 within Porous Graphitic Carbon Polyhedrons and Carbon Nanotube Sponge for Ultralong Life Lithium-Sulfur Batteries Hui Zhang; Peking University, Beijing, China.

Lithium sulfur battery represents an advanced energy storage system because of its environmental benignity, high theoretical energy density (2600 Wh kg⁻¹) and natural abundance of sulfur. However, the low conductivity of sulfur, polysulfides dissolution, and sulfur volumetric expansion during lithiation/delithiation process will decrease the reaction kinetics of polysulfides and sulfur utilization, leading to low capacity, limited rate capability and inferior cycling stability. To solve these problems, there have been intensive efforts in choosing highly conductive carbon materials to design porous or hollow structures for secure sulfur hosts. Although these materials can effectively alleviate polysulfides dissolution during short-time cycling, the weak interaction with polar polysulfides will inevitably results in increase of charge transfer and dissolution of polysulfides over long-time electrochemical reaction. Here, we first grew ZIF-67 nanoparticles (~350 nm) uniformly within a three-dimensional carbon nanotube sponge, and then carbonization and sulfuration, we finally fabricated a hybrid network with numerous carbon nanotubes penetrating hierarchically porous graphitic carbon polyhedrons uniformly dispersing CoS2 nanoparticles (from ZIF-67) to host sulfur. Co,S,has been reported to have strong affinity to polysulfides, and can act as a catalyst to accelerate the conversion of polysulfides to Li2S/LiS (insoluble discharged products), which are beneficial for improving battery cycling stability (polysulfide stabilization) and rate capability (increased reaction kinetics). In our system, highly dispersed CoS2 nanoparticles can provide sufficient sites to trap polysulfides and catalyze the conversion reaction smoothly, additionally the outer wrapping porous graphitic carbons (physical barriers) can further protect polysulfides from dissolving into the electrolyte. Moreover, the highly three-dimensional conductive CNT and graphitic carbon hybrid network acting as a self-standing electrode can not only facilitate electrolyte infiltration and charge transport, but also improve sulfur loading and utilization. As a result, our novel 3D hybrid electrodes exhibit a much superior ultralong Li-S battery performance than previously reported MOF-based electrodes in recent literature.

ET03.06.11
Photo- and Redox-Active Eumelanin on Carbon Quantum Dot Current Collectors as Sustainable Electrode Material for Solar Batteries Abdelaziz
Monika Biener1; 1Lawrence Livermore National Laboratory, Livermore, California, United States; 2University of California, Riverside, Riverside, California, United States.

Melanin is a bio-pigment found in various classes of mammals, fishes, and different species of plants. This organic bio-pigment features unique physiochemical properties such as UV-Vis near IR absorption, redox activity (hydroquinone-semiquinone-couple bonds), metal chelation and ion-electronic hybrid electrical conduction [2]. The photoredox properties of melanin combined to its capability to reversibly bind cations opens the door to explore this intriguing quinone-based material as electrode for solar batteries [3].

We here report on the use of melanin on carbon quantum dots (CQD)-based current collectors. CQDs offer high surface area to the redox active melanin and facilitate the electron transport to the back contact. Cyclic voltammetry and galvanostatic charge/discharge cycles were employed to evaluate the storage performance of the melanin-electrode materials at different pH conditions and chemical composition of the electrolyte (e.g. including cations such as H+, Na+, K+, Mg2+), under simulated solar light. We observed that the redox state of the melanin-based electrodes affects its photoreponse. Our work constitutes a relevant contribution towards (photo)electrodes for sustainable, aqueous, rechargeable solar batteries.

Comparison of Stress Evolution in Silicon and Silicon Oxide Composite Electrodes
Mok Yun Jin1, Ravi Kumar2 and Brian W. Sheldon1; 1Brown University, Providence, Rhode Island, United States; 2Ram Research Corporation, Tualatin, Oregon, United States.

Silicon has received much attention as a promising negative electrode material, owing to its greater theoretical capacity than state-of-the-art graphite negative electrodes. Silicon, however, undergoes internal microstructural changes and large volume changes that induce substantial compressive stresses inside of particle-based electrodes. These are believed to contribute to poor cycling performance.

In the present work, in-situ stress and electrochemical measurements are monitored directly to capture stress evolution in silicon and silicon oxide composite electrodes with various particle sizes. Silicon nanoparticle electrodes reveal a stress response with notable hysteresis characterized as plastic flow. When silicon oxide(SiOx) is incorporated, the cycling performance improves and the amount of stress decreases. The stress response of electrodes based on SiOx composite particles also shows more reversible and elastic behavior compared to electrodes with silicon nano particles.

High Tap-Density and Layer-by-Layer Assembled LiFePO4 Nanosheets as Advanced Cathode Materials used in High Power Li-Ion Batteries
Hajian Zhang1, 2, Ben Pei1, Lu Zhang1, Wenwu Qin2, Jun Zhang1 and Jiye Fang1; 1SUNY Binghamton, Binghamton, New York, United States; 2Lanzhou University, Lanzhou, China; 3China University of Petroleum, East China, Qingdao, China.

As a class of outstanding cathode material for lithium-ion (Li-ion) batteries, LiFePO4 has an obstacle of low rate capability due to its slow Li ionic diffusion and poor electronic conductivity as well as power density issue. To improve this, one should shorten the channels of Li-ion travelling (i.e. reduce the dimension of LiFePO4 in <010>), and enhance the particle impact on the same crystallographic orientation. According to this hypothesis, one of the proposals is to produce 2D LiFePO4 as the building block materials by exposing their {010} facets as the termination planes, and to further pack these 2D LiFePO4 along the <010> direction efficiently. Herein, we report a novel synthesis of ultrathin 2D LiFePO4 nanosheets using a modified hot organic solvent approach. The structure of the resultant LiFePO4 is precisely controlled with some unique features: the nanosheets exhibit in shape of rectangle with a thickness of as small as ~10 nm. Importantly, the exposed planes are {010}, which can maximize the channels for the travel of Li-ions. Calcination of the oleylamine/oleic acid capped LiFePO4 nanosheets resulted in densely hierarchical structures containing Layer-by-Layer stacked assemblies with a tap density as high as 1.3 g cm⁻³. In contrast, the tap density of freestanding LiFePO4 nanomaterials is usually less than 1.0 g cm⁻³. The in-situ generated carbon blacks from the pyrolysis of the capping ligands act as not only a medium conductor for the electrons but also a baffle to possibly prevent the nanosheets from fusing into larger particles during the calcination. With such an in-situ carbon coating evenly on every single nanosheet, the 2D LiFePO4/C composite nanosheets self-assembled into superstructures. The electrochemical evaluations on these LiFePO4/C assemblies show a reversible specific capacity of as high as 105 mAh g⁻¹ at 10 C, as well as an excellent rate capability and cycling performance. Both the high tap density and high-rate capability are promising for the increase of volumetric power and energy density as Li-ion cathodes. Such layer-by-layer compacted patterns, rather than an accumulation of disordered building blocks, could also effectively increase both gravimetric and volumetric power densities of LiFePO4 electrodes, paving the way for promoting high-rate capacity and minimizing the ionic diffusion issue by shortening the length of Li-ion travelling channels.

Capacitive Performance of C60-Functionalized Graphene Supercapacitors—Atomistic Origins and Implications
Tuan Anh Pham1, Cheng Zhan1, 2, Maira Raquel Ceron Hernandez1, Patrick G. Campbell1, Vedasri Vedharathinam1, Minora Otani1, De-en Jiang2, Juergen Biener1, Brandon C. Wood1 and Monika Biener1; 1Lawrence Livermore National Laboratory, Livermore, California, United States; 2University of California, Riverside, Riverside, California, United States; 3National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan.

Controlling the electrical response at the electrode-electrolyte interface is key to the development of next-generation supercapacitors and other electrochemical storage systems. In this work, we utilize first-principles calculations to elucidate the key factors that determine the performance of C60-functionalized graphene as a promising carbon-based supercapacitor material. We show that, for the hybrid electrode, the surface morphology influences the electric double-layer (EDL) formation by affecting the charge localization character, which in turn significantly enhances the EDL contribution to the capacitance, in sharp contrast to pristine graphene. In addition, the electronic structure was found to govern not only the quantum capacitance but also the double-layer response. Our study highlights a complex interplay among surface morphology, electronic structure and functionality of the hybrid electrode, suggesting general improvement strategies for optimizing EDL and total capacitance in carbon-based supercapacitor materials.
Lithium-ion battery (LIB) is widely utilized in many modern applications as energy sources. Numerous efforts have been dedicated to increasing electrochemical performances, but improvement on battery safety remains a visible challenge. While new electrode materials have been developed, advancement in new separators for LIBs has remained relatively slow. A separator is the polymeric porous material that physically separates electrodes and allows free flow of ions through its structure. It is electrochemically inactive but essential for avoiding thermal runaway conditions. Besides its crucial functions, the separator has been known as the mechanically weakest component. Structural battery is a new approach that employs a multifunctional material concept to use LIB as a load-bearing material to minimize the weight of the complete system and maximize the efficiency. Separator materials are required to have good thermal stability, battery chemistry, and mechanical performance. This work aims at creating electrospun membranes with improved thermal resistance and structural integrity as the next generation LIB separators. The electrospinning (ES) is known as a versatile and straightforward technique to fabricate continuous fibers at nano- and micro-scale. Solution and process parameters including, type of polymer and solvent system, concentration of polymer solution, acceleration voltage, and solution feed rate have been studied to achieve the desirable membrane properties. Adding various ceramic materials to the polymers have been studied for improving the thermal shrinkage, increasing ionic conductivity and, decreasing interfacial resistance of the composite separators. In this study, nanofibrous membranes are created by the electrospinning process. Graphene oxide is used due to its high storage modulus. Synthesized, non-conductive graphene oxide and titanium dioxide nanoparticles (for comparisons) are incorporated into the polymer solutions for the electrospinning. In this presentation, we will discuss the control of electrospinning process, graphene oxide synthesis and properties of composite membranes for structural battery applications.

ET03.06.16
Facile and Cost effective Synthesis of Ultradense and Porous Nitrogen Enriched Carbon Hollow Shells for Energy Storage Application
Gihwan Kim1 and Jeung Ku Kang2, 1; 1Department of Materials Science and Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea
(Republic of); 2Graduate School of EEWS, Korea Advanced Institute of Science and Technology, Daejeon, Korea (Republic of).

Mesoporous carbon materials have received intensive attention due to their wide applications including energy storage/conversion, catalysis and adsorption applications. Herein, ultradense and porous nitrogen enriched carbon hollow shells have been synthesized by a facile and cost effective sol-gel coating method using different ratio of carbon precursor and nitrogen precursor. As-synthesized hollow shells possessed uniform size of ~120nm in diameter and ~4.5nm significantly thin, porous shells obtained from silica template that size controlled by solvent ratio. As the ratio of nitrogen precursor increased, thinner and smaller shells were synthesized. In lithium ion hybrid capacitor system, cathode electrode material is storing electrical energy through electrical double-layer capacitance mechanism of electrode surface. Based on these mechanisms, as-synthesized ultradense and porous nitrogen enriched carbon hollow shells used as a cathode material of lithium ion hybrid capacitor. It is shown remarkable electrochemical performance, delivering a high reversible capacity (~48mAh/g in 3.0V~4.5V (Li/Li+) potential range) as well as superior rate performance for long cycles in an organic solvent system. These excellent results can be attributed to two major reasons. First, hollow and porous structures could improve the properties of surface adsorption for lithium ion capacitor by facilitating the accessibility of ions. Sites from both inside and outside of carbon shell can be accessed by PF6- ions, whereas the closed window of the pore for solid sphere can offer the sites for electrostatic adsorption only on the outside surface. Second, nitrogen contents could significantly change the interaction sites and enhance the adsorption of ion towards a carbon shell framework. These effects are also shown in capacity analysis of various synthesized samples with different amounts of nitrogen precursor. As the nitrogen content increased, the capacity tended to increase. Even in the case of carbon precursor only, the capacity is less than half of that of nitrogen contained hollow shells. This simple and cost effective strategy could be extended to synthesize tunable interior architecture mesoporous carbon composites like yolk-shell structure and core-shell structure with metal, metal oxide. Also, due to the characteristic of the nitrogen-containing material, it can be applied to various ions adsorption. By applying this phenomenon, it can be utilized not only for commercial carbon material like an electric double layer capacitor (EDLC) but also for various electrochemical energy storage and conversion applications.

ET03.06.17
Electrochemical Behaviors of Room Temperature Ionic Liquids—Carbon Electrodes Interfaces
Kirti Bhardwaj and Greg Swain; Michigan State University, East Lansing, Michigan, United States.

Room temperature ionic liquids (RTILs) have great potential to replace conventional organic solvent/electrolyte systems in energy storage devices because of their remarkable properties like wide electrochemical potential window (>4V), environmentally-benign characteristics (non-volatility, non-toxicity) and excellent thermal and electrochemical stability. To optimally harness these properties and engineer RTIL-based devices, a comprehensive fundamental understanding of their electrochemical behavior is critical. Understanding the structure, distal extent, and dynamics of interfacial organization at RTIL-carbon electrodes interfaces has been the subject of both fundamental and applied research, particularly in the field of supercapacitors. Research is needed to better understand how electrode properties, like its material, microstructure, surface chemistry, affect the electrochemical behavior of RTILs. Traditional models of the electrochemical double layer based on the dilute-solution approximation may not be applicable to RTILs because of the absence of solvent, high concentration of ions (3–5 M), asymmetric charge distribution and strong interionic interactions. In this presentation, potential dependent capacitance of carbon electrodes as a function of the RTIL type, carbon electrode type and surface wettability will be reported on. 1-alkyl-3-methylimidazolium-based RTILs were studied at hydrogen- and oxygen-terminated boron-doped diamond and nitrogen-incorporated tetrahedral amorphous carbon thin-film electrodes. Comparison measurements were made in aqueous electrolytes. Cyclic voltammetry and electrochemical impedance spectroscopy were used to measure the interfacial capacitance. Our findings suggest that interfacial capacitance depends on the length of alkyl chain in the cationic component of RTIL. Capacitance-potential (C-E) trends on carbon electrodes are in stark contrast with theoretical models predicted for metallic electrodes. It is intriguing that heavily-doped diamond behaves as a metal with respect to faradic processes have characteristic interfacial behavior. This work highlights the unique C-E trends shown by carbon electrodes in RTILs and serves to progress the current understanding of interfacial organizations and the role of electrode-electrolyte interactions.

ET03.06.18
Freestanding 2D MXene/Polyaniline Pseudocapacitive Electrodes with High Mass loading and Ultrahigh Gravimetric and Volumetric Capacitances
Armin VahidMohammadi and Majid Beidaghi; Auburn University, Auburn, Alabama, United States.

Two-dimensional (2D) MXenes (i.e. Ti3C2Tx) have shown fascinating performances as electrode materials for electrochemical capacitors (ECs). However, conventional methods for fabrication of freestanding MXene films results in their self-restacking, decreasing ionic accessibility to their redox-active sites and limiting their rate-capability. These problems are more significant for thicker electrodes and, as a result, fabrication of MXene electrodes with thicknesses and mass loadings close to commercial EC electrodes is not feasible. Here, we demonstrate a strategy to fabricate hybrid electrodes of MXene and conductive polyaniline (PANI) with highly accessible surfaces and excellent electrochemical performance event at high mass-loadings and thicknesses. The freestanding and flexible films of Ti3C2Tx/PANI were fabricated through an oxidant-free in situ polymerization of aniline monomer on the surface of MXenes sheets. The fabricated hybrid electrodes delivered outstanding gravimetric and volumetric capacitances of 503 F g⁻¹ and 1682 F cm⁻³, respectively, at a scan rate of 2 mV s⁻¹. Even at electrode thicknesses close to commercial ECs, these hybrid electrodes could maintain their high specific capacitance. For instance, a 90-µm-thick electrode with a mass loading of 23.82 mg cm⁻² could deliver a specific capacitance of about 336 F g⁻¹ and 888 F cm⁻².
The best agreement is achieved by constructing a novel cluster expansion for alloy nanoparticles of varying shape and size that explicitly includes experimentally relevant sizes can be prohibitively expensive. It has been demonstrated that this problem can be addressed through the generation of cluster Density functional theory (DFT) is widely used to predict the structures and properties of materials, but its direct applications to nanomaterials of reaction (CO2RR) on Au nanowires. Nanowires with the 4H structure have shown enhanced activity relative to fcc nanowires and nanoparticles. Cluster expansion models trained by DFT. In this talk, two examples of using cluster expansions to better understand structure-property relationships in Biomolecular Engineering, Johns Hopkins University, Baltimore, Maryland, United States.

In recent years, alloy anion exchange membrane fuel cells (AAEMFCs) have a rapid development due to their advantages including high electrode reaction activity, free from precious metal catalysts, low fuel permeation and so on. However, anion exchange membrane (AEM), which is a crucial component in AEMFCs, continue to perform unfavorably owing to its low conductivity and poor alkaline stability. Thus, constructing novel hydroxide-conducting materials with both high ionic conductivity and good alkaline stability for AEM has attracted wide interest. Herein, we have designed and synthesized a new hybrid membrane with high alkaline and thermal stability via combining quaternary ammonium (QA) functionalized covalent organic framework and brominated poly(2,6-dimethyl-1,4-phenylene oxide) (BPPO). Covalent organic framework was quaternized via in situ assembly of N,N,N’,N’-tetramethyl-1,6-hexanediamine (TMHDA) and allyl bromide within the highly ordered pores of two-dimensional imine-linked COF-LZU1, to fabricate long-range ordered one dimensional ion channels. The obtained QA@COF-LZU1 as a novel filler was then incorporated into QAPPO to fabricate hybrid anion exchange membrane for the application in AAEMFCs. Hybrid membranes were evaluated by hydroxide conductivity, alkaline stability, thermal stability, and so forth. Remarkably, the QA@COF-LZU1/PPO hybrid membranes showed high hydroxide conductivity, and alkaline and thermal stability of QA@COF-LZU1/PPO hybrid membranes were significantly enhanced.

8:15 AM ET03.07.02
Understanding Structure-Property Relationships in Nanocatalysts by Using Cluster Expansions Chenyang Li1, David Raciti2, Yuxuan Wang3, Liang Cao4, Chao Wang4 and Tim Mueller5; 1Materials Science and Engineering, Johns Hopkins University, Baltimore, Maryland, United States; 2Chemical and Biomolecular Engineering, Johns Hopkins University, Baltimore, Maryland, United States.

Density functional theory (DFT) is widely used to predict the structures and properties of materials, but its direct applications to nanomaterials of experimentally relevant sizes can be prohibitively expensive. It has been demonstrated that this problem can be addressed through the generation of cluster expansion models trained by DFT. In this talk, two examples of using cluster expansions to better understand structure-property relationships in nanocatalysts are given. In the first example, we compare predicted Pt-Cu nanoparticle structures with experimental characterization. We demonstrate that the best agreement is achieved by constructing a novel cluster expansion for alloy nanoparticles of varying shape and size that explicitly includes adsorbates, enabling the prediction of nanoparticle structure in an oxidizing environment. In the second example we present a study of the CO2 reduction reaction (CO2RR) on Au nanowires. Nanowires with the 4H structure have shown enhanced activity relative to fcc nanowires and nanoparticles. Cluster expansions are used to predict the equilibrium surface structures of fcc, 4H, and twinned nanowires. DFT calculations are then performed on the extended surfaces identified from cluster expansions to construct a free energy diagram for CO2 reduction. The enhanced CO2RR activity on 4H-Au nanowires is ascribed to the unique surface structure of the 4H phase, which could provide design principles for experimental research.

Nanoparticle Catalysts for Electrochemical Transformation of Carbon Dioxide to Value-Added Products Peidong Yang1, 2 and Dohyung Kim3, 4. 1University of California, Berkeley, Berkeley, California, United States; 2Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Electrochemical conversion of CO2 to valuable products has gained much interest recently, as a part of the many efforts to develop sustainable practices that can support our society. Among a variety of approaches, utilizing nanoparticles as CO2 electrocatalysts have brought significant advances to the field. Here, various structural aspects of nanoparticles used as electrocatalysts, that range from the atomic scale all the way to the macroscopic length scales, are correlated with their CO2 electrocatalytic performances. Furthermore, the catalytic role of the dynamics of nanoparticles has been explored which can be utilized to promote their CO2 reduction activity. The complexity originating from the larger number of structural variables associated with nanoparticles requires a deepened understanding of their combined effects to the catalytic behavior of nanoparticles. Acknowledging this complexity and a thorough consideration of its impact will lead to further improvements of nanoparticles used as CO2 electrocatalysts.

9:00 AM ET03.07.04
Electrochemical Synthesis of Highly Concentrated C2 Product Streams Matt Kanan; Chemistry, Stanford University, Stanford, California, United States.

Electrochemical CO2 and CO conversions provide direct pathways to harness renewable electricity for chemical and fuel synthesis. This talk will describe our recent work to develop catalyst- and cell-design principles for electrochemical systems that generate concentrated C2 product streams. For the catalyst, a key issue is to identify structural features that favor CO2/CO reduction over H2O reduction at low overpotentials. We have previously shown that grain boundaries are correlated with electrocatalytic activity for CO2 reduction on Au and CO reduction on Cu electrodes, but not with H2O reduction on these materials. We will describe our recent work to uncover the structural origin of grain boundary effects. Experimental studies combining electron diffraction and spatially resolved (<1 µm) electrocatalytic measurements have revealed that grain boundary surface terminations are “hot spots” for electrocatalytic CO2 reduction on coarse-grained Au electrodes. This phenomenon may result from the accumulation of line defects in the grain boundary vicinity, which perturb the surface structure. I will discuss our efforts to test this model with nanograined materials and extend these studies to electrochemical CO2 reduction on Cu. For the cell design, electrocatalytic synthesis must simultaneously achieve high synthesis rates and high single-pass conversions of CO2/CO at low potentials to maximize the energy efficiency and minimize the separation costs. To this end, we have developed a gas-diffusion CO electrolysis cells that reach >100 mA cm–2 with >70% single-pass conversion at moderate cell potentials. With optimized electrode/membrane interfaces, the cells can simultaneously produce concentrated ethylene in the gas phase and a liquid product stream that is nearly 1 M in acetate. I will discuss the design features that are critical for generating concentrated products and efforts to optimize nanostructured catalysts for high synthesis rates.
Utilization of CO₂ as a feedstock for the production of intermediates for chemical or fuel production such is one of several approaches being explored to help reduce anthropogenic CO₂ emissions, while also reducing society’s dependence on fossil fuel reserves. A range of active electrocatalysts for the selective reduction of CO₂ to products such as formic acid, CO, ethylene, and ethanol have been reported. We have explored both Ag- and Au-based catalysts as well as micro-structured CuAg alloy films, respectively for the selective and energy efficient reduction of CO₂ to CO [1,2] and to ethylene and ethanol [3]. Partial current densities for CO exceeding 150 mA/cm² at cell overpotentials less than 1V now can be achieved readily at energetic efficiencies of 50-60%. Similarly, high surface area CuAg alloy films exhibit Faradaic efficiency for C₂H₄ and C₂H₅OH production of 60% and 25%, respectively, at a cathode potential of just ~0.7 V vs RHE and a total current density of ~300 mA/cm², the highest levels of selectivity at high activity and low applied potential reported to date. This talk will report mechanistic insights regarding CO₂ electroreduction on these different catalysts in alkaline electrolyte. E.g., the onset cathode potentials, the kinetic isotope effect, and Tafel slopes indicate that the production of CO at low overpotentials in alkaline media is the result of a pH-independent rate-determining step (i.e., electron transfer) in contrast to a pH-dependent overall process. Also, in situ Raman and electroanalysis studies suggest that the origin of the high selectivity toward C₂ products observed with CuAg alloy films results from both the enhanced stabilization of the Cu₂O overlayer and the optimal availability of the CO intermediate due to the Ag incorporated in the alloy. The talk will also provide a summary of techno-economic feasibility of CO₂ electrolysis for the production of these different intermediates.

Gold Nanoparticles on Polymer-Wrapped Carbon Nanotubes: An Efficient and Selective Catalyst for the Electroreduction of CO₂ to Ethylene and Ethanol, T.T.H. Hoang, S. Verma, M. Graetzel, and Y. Surendranath; 1Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Chemistry and Chemical Engineering, Ecole Polytechnique Federale de Lausanne, Lausanne, Switzerland.

CO₂-derived fuels, electrochemically synthesized using renewable energy, present an attractive route towards fuel formation from sustainable energy. However, insufficient understanding of the factors controlling catalytic activity and selectivity, as well as the limited availability of selective, active and inexpensive catalyst materials remain key challenges on the way to the production of renewable carbon fuels. Copper is a particularly interesting electrocatalyst for this reaction since it can reduce CO₂ to a variety of products including carbon monoxide and hydrocarbons but rational modification of its selectivity towards a single product remains challenging. In this context, we here demonstrate the successful tuning of copper electrocatalysts towards the selective production of CO from CO₂ and we present unprecedented insight into the mechanistic pathways governing the electrochemical reduction of CO₂ to hydrocarbons on copper surfaces. Atomic Layer Deposition (ALD) is introduced as a versatile tool for the modification of electrocatalyst selectivity. By ALD modification with thin layers of SnO₂, the wide product distribution observed from CuO-derived nanowires could be narrowed to yield predominantly CO at low overpotentials, a feat which normally requires gold catalysts. The origin of this performance modification is investigated on the basis of kinetic studies, HR-STEM and gas chemisorption analysis. Operation of the SnO₂-CuO catalyst is subsequently demonstrated in an all Earth-abundant electrolysis cell using a bipolar membrane, allowing for the separation of product gases while maintaining a sustained pH gradient. Driven by a 3-junction solar cell, this device achieved long-term solar splitting of CO₂ into CO and O₂ at an efficiency of 13.4 %, constituting the current record.

10:45 AM ET03.07.07
Metal Ion Cycling of Cu Foil for Selective C–C Coupling in Electrochemical CO₂ Reduction Huotian Wang, Harvard University, Cambridge, Massachusetts, United States.

Electrocatalytic CO₂ reduction to higher-value hydrocarbons beyond C₁-products is desirable for applications in energy storage, transportation and the chemical industry. Cu catalysts have shown the potential to catalyse C–C coupling for C₂+, products, but still suffer from low selectivity in water. Here, we use density functional theory to determine the energetics of the initial C–C coupling steps on different Cu facets in CO₂ reduction, and suggest that the Cu(100) and stepped (211) facets favour C₂+ product formation over Cu(111). To demonstrate this, we report the tuning of facet exposure on Cu foil through the metal ion battery cycling method. Compared with the polished Cu foil, our 100-cycled Cu nanocube catalyst with exposed (100) facets presents a sixfold improvement in C₂+/C₁ product ratio, with a highest C₂-Faradaic efficiency of over 60% and H₂ below 20%, and a corresponding C₂+ current of more than 40 mA/cm².
Electrocatalytic reduction of carbon dioxide (CO₂) to value-added carbon-based chemical feedstocks addresses the need for long-term storage of renewable electricity and decarbonization of the transportation sector. Liquid multi-carbon alcohols such as ethanol and n-propanol are desired as renewable transportation fuels. They offer high energy densities, ease of long-range transport, and direct drop-in usage in existing internal combustion engines.

Engineering copper-based catalysts that favor high-value alcohols is desired. In the design of catalysts, much progress has been made to target deliberately the C–C coupling step; while comparatively little effort has been expended to target post-C–C coupling reaction intermediates.

Among electrocatalysts for CO₂ reduction, Cu-based materials are the most prone to reduce CO₂ to C₂ and above products, with alkenes traditionally dominating multi-carbon product formation. To develop more efficient electrocatalysts for alcohol production, it is crucial to modify the catalyst structure to promote the desired alcohol and suppress alkene electrosynthesis. Additionally, it is vital to understand the mechanisms that underlie selectivity to enable further catalyst refinement. We reasoned that—since ethylene and ethanol share a penultimate reaction intermediate (\(\text{C}_2\text{H}_3\text{O}\))—we could potentially modify a catalyst’s surface structure to target the hydrogenation of this intermediate, and thereby promote \(\text{C}_2\) liquid production. Suppressing off-produced ethylene would enhance production and selectivity towards alcohols.

Here we report a class of core/shell vacancy engineering catalysts that utilize sulfur atoms in the nanoparticle core and copper vacancies in the shell to achieve efficient electrochemical CO₂ reduction to propanol and ethanol. These catalysts shift selectivity away from the competing ethylene reaction and toward liquid alcohols. We increase the ratio of alcohol-to-ethylene by over 6x compared to bare-copper nanoparticles, highlighting an alternative approach to electroproduce alcohols instead of alkenes. We achieve a C₂+ alcohol production rate of \(126 \pm 5\) mA cm⁻² with a selectivity of \(32 \pm 1\%\) Faradaic efficiency.

11:15 AM ET03.07.09
Photoelectrochemical CO₂ Reduction with Nanoporous Au Electrodes

Mya Norman, Peter J. Reed and Robert H. Coridan; University of Arkansas, Fayetteville, Arkansas, United States.

Here we report a large-area, catalytically-active and highly stable nanoporous gold (np-Au) electrode for (photo)electrocatalytic CO₂ reduction in aqueous electrolytes. A one μm thick np-Au electrode has a 27x larger electrochemical activity than a comparable planar Au film, owing to increased surface area. The np-Au structure is fabricated via electron beam co-deposition of a gold/silver (Au/Ag) alloy of tunable elemental composition (10/90 to 30/70) and variable thickness (0.1 μm to 2 μm), followed by a chemical etch of silver with nitric acid to yield a monolithic, np-Au structure. Depending on the etching temperature, we can alter the Au feature size from 10 nm to 25 nm. The np-Au also possesses near-unity absorption throughout a broad portion of the visible spectrum from 400 nm to 600 nm. Gas chromatography indicates H₂ and CO as the main CO₂ reduction products from np-Au electrodes in a 50 mM K₂CO₃ buffer. Although produced in a similar CO₂:H₂ product ratio vs applied potential as that obtained for planar Au electrodes, the increased surface area results in significantly higher partial current densities for CO than planar Au. Chronoamperometry measurements indicate stable np-Au electrode operation over periods exceeding 24 h at a potential of ~0.5 V vs. RHE and a cathode current of ~6 mA/cm². The faradaic efficiency remains similar across different thickness and etch temperatures, although the current does increase as the surface area of the np-Au layer increases. These np-Au electrodes show a photocatalytic response marked by an increase in current density of ~1mA/cm² upon irradiation with white light at an incident power of 1.5 W/cm². Changes in the product selectivity observed from np-Au photocathodes as a function of electrolyte temperature, illumination wavelength, and incident light power will be discussed. In summary, np-Au electrodes exhibit both high electrocatalytic activity and sustained electrochemical stability, making them interesting candidates as cathodes for (photo)electrochemical CO₂ reduction.

11:30 AM ET03.07.10
Influence of Graded Mesoporosity on CO₂ Reduction Reaction on Copper

Mya Norman, Peter J. Reed and Robert H. Coridan; University of Arkansas, Fayetteville, Arkansas, United States.

Carbon dioxide reduction reaction (CO₂-RR) provides an environmental friendly way to convert readily available resources such as carbon dioxide and water to produce high-valued chemicals and energy-dense fuels to address the energy storage challenge. In this work, we compare the CO₂-RR on the planar copper electrode vs. mesoporous copper as a function of microstructure and pore sizes. The hypothesis is that mesoporous copper can recapature the intermediate(s) such as carbon monoxide for further reduction. We prepare the model graded mesoporous copper electrodes using electroless plating on the template formed by self-assembled trilobal terpolymer and control the pore sizes by tuning the phase separation. On these copper electrodes, we quantify the CO₂-RR products over a fixed potential range and compare the results to that of planar polycrystalline copper. We will discuss the product distribution as a function of pore sizes and new insights from this analysis in the context of the intermediate confinement and how they can be applied to the future design of CO₂-RR catalyst.

11:45 AM ET03.07.11
Photoelectrodes Fabricated by Selective Atomic Layer Deposition in Self-Assembled, Composite Colloidal Films

Mya Norman, Peter J. Reed and Robert H. Coridan; University of Arkansas, Fayetteville, Arkansas, United States.

Hierarchically structured materials are employed for applications that depend on the coordination of chemical and physical processes that function on disparate length scales. An example is photoelectrochemical energy conversion, where the electrode structure must optimize the balance of light absorption, carrier collection at a semiconductor-liquid junction, electron transfer, and mass transport of reactants in order to maximize the energy conversion efficiency of the system. Strategies for designing electrodes generally depend on techniques borrowed from semiconductor fabrication, which allow precise control for prototyping, but are not readily transferrable to the development of scalable materials. Here we describe the fabrication of hierarchically structured electrodes based on selective atomic layer deposition of ZnO in composite colloidal films. The distinct chemical susceptibilities of SiO₂ and polystyrene nanospheres can be used to generate hierarchically porous materials. By choice of the initial colloidal components, the characteristic length scales for light absorption, carrier collection, and mass transport can be independently engineered into a thin film electrode for photoelectrochemical applications. Optimized nanostructured conductive scaffolds can be prepared with a facile, continuously tunable, solution-phase synthesis. This approach offers a scalable route for synthesizing nanostructured photoelectrodes based on strategies developed from more complex fabrication techniques.
SESSION ET03.08: Interface and Beyond-Li Batteries
Session Chairs: Wei Li and Nian Liu
Wednesday Afternoon, November 28, 2018
Hynes, Level 3, Room 302

1:30 PM *ET03.08.01
Safe Li-Ion Battery Electrolytes—From Aqueous, Nonflammable Organic to Solid State Chuansheng Wang; University of Maryland, College Park, Maryland, United States.

Li-ion batteries are the critical enabling technology for the portable devices, electric vehicles (EV), and renewable energy. However, the safety of current battery still need to be improved to satisfy these requirements. We systematically investigated the electrochemical stability window of the electrolytes, interface/interphase stability and resistance between electrodes and electrolytes, reversibility and robustness of the cells using these electrolytes. The critical issues limiting these safe electrolytes will be discussed.

2:00 PM *ET03.08.02
Interface Design and Materials in Batteries—From Liquid to Solid-State Xueliang A. Sun; University of Western Ontario, London, Ontario, Canada.

The control and understanding of reactions at the electrode/electrolyte interface (EEI) is essential to develop strategies to enhance cycle life and safety of lithium batteries. The poor cell lifetimes of Li/Na batteries are rooted mainly in side reactions occurring at the electrode-electrolyte interface. The use of surface coatings to control the electrode-electrolyte interface is an important strategy to design new electrodes. Atomic layer deposition (ALD) and molecular layer deposition (MLD) are ideal techniques to synthesize ultrathin and conformal coatings due to the self-limiting nature [1,2,3]. This talk will include three parts related to interface control:

In the first part, we will report our work on the applications of atomic layer deposition (ALD) in Li ion batteries including coating materials on NMC cathode in Li ion batteries[4,5] and MLD coating on Li-S batteries operating at 55C [6].

In the second part, we will discuss our recent results on ALD and MLD coatings on Li metal protection and interface control between solid-state electrolyte and cathode/anode materials for solid-state batteries [7-10].

Ionic Liquids and Dilute Electrolytes—The Surprising Connection Matthew A. Gebbie1 and Jacob N. Israelachvili; 1Stanford University, Stanford, California, United States; 2University of California, Santa Barbara, Santa Barbara, California, United States.

Solid-electrolyte interfaces are critical elements of many electrochemical devices. Nevertheless, key questions surround the nature of solid-electrolyte interfaces in highly concentrated electrolytes, particularly in nanoconfined environments. I will discuss using a novel technique that combines molecular force measurements with in situ electrochemical spectroscopy to characterize nanoscale ionic liquid-electrode interfaces. As single component liquids composed entirely of ions, it was thought that ionic liquids contain extremely high free ion densities. Yet, the conductivities of most ionic liquids are orders of magnitude lower than aqueous electrolytes. I will present our discovery that the electric double layers formed by ionic liquids can extend more than 20 ion diameters away from charged surfaces, indicating that greater than 99.99% of the ions actually behave as neutral pairs, in equilibrium with a small population of thermally-dissociated charges. This picture provides insight into the low conductivities of typical ionic liquids, and I will also highlight a molecular framework for designing high performance ionic liquids. More broadly, our findings suggest new ways of envisioning concentrated electrolytes in nanoconfined interfaces, with implications for understanding diverse electrochemical processes in nanoscale materials.

3:45 PM ET03.08.04
Interfacial Interaction between Chemically-Engineered Copper Host and Metallic Sodium for Facilitating Highly Stable Sodium Metal Anode Chuanlong Wang, Huan Wang, Edward Matios, Xiaofei Hu and Weiyang Li; Dartmouth College, Hanover, New Hampshire, United States.

Sodium (Na) metal is the most promising alternative for lithium metal as an anode material for the next-generation energy storage systems due to its high theoretical capacity, low cost and high natural abundance. However, huge volume change and severe dendrite growth of Na metal anode during repeated electrochemical stripping/plating cycles result in rapid electrode degradation, low Coulombic efficiency, and even the risk of explosion caused by short circuit of the batteries. The volume and morphology change of the “hostless” Na severely aggravates the growth of Na dendrites. Thus, it is essential to seek an ideal host to support Na metal so as to maintain the high integrity of the electrode. Despite the most recent research in using porous carbon or aluminum substrate as Na host, current research in Na metal is still in its infancy, and the exploration on promising matrices for Na metal anode is highly desirable. More important, a systematic and thorough understanding on the interfacial interaction between metallic Na and the host materials as well as its impact on the stability of Na metal anode is critical, but missing.

Through a facile and cost-effective surface treatment on commercially available Cu foam, a chemically engineered 3D porous copper (Cu) matrix with a cylindrical core-shell skeleton structure as a highly stable host for metallic Na anode was manufactured as a composite anode for Na-based batteries. It is noted that the unique surface characteristics of the as-obtained matrix can not only facilitate uniform impregnation and confinement of Na within the matrix pores promoted by the chemical interaction between Na and the matrix, but also can divert the Na plating from the matrix skeleton towards the Na reservoirs within the pores upon cycling. These special features significantly suppress the volume change and dendrite Na growth over repeated Na stripping-plating process. Benefiting from the delicately surface-engineered matrix as a host for Na, an excellent Na anode cycling stability in carbonate
electrolyte without any additives over 100 cycles (300 hours) at a current density up to 2 mA cm$^{-2}$ with a high cycling capacity up to 3 mAh cm$^{-2}$. A full cell made of Na$_3$V$_2$(PO$_4$)$_3$ as cathode and the as-prepared surface-treated Na composite as anode is further tested, showing superior cycling performance and high rate capability (at 5C) compared with that using bare Na metal as anode.

To fundamentally understand performance improvement, we systematically investigated the interfacial interactions between treated/un-treated Cu matrices and metallic Na to reveal how the surface property of the matrix skeleton greatly influences the electrochemical stability of Na anode. We believe that our approach provides a facile and low-cost route to the fabrication of stable Na metal anode for high-energy Na-based batteries, and could be a viable strategy for other metallic anode systems.

All-solid-state Li batteries using inorganic solid electrolytes are attracting intensive research interests due to the highest safe system and high energy densities. However, these systems are still confronted with major challenges in terms of rechargeability, cycling stability, Coulombic efficiency and rate performance, which are far from commercialization.[1]

The fatal weaknesses of all-solid-state Li batteries are poor Li$^+$ and electron transports between the electrode and the electrolyte. Unlike batteries with liquid electrolytes that can easily wet the electrodes and ensure smooth Li$^+$ transport, the Li$^+$ transport in solid-state batteries is highly limited at the electrode-electrolyte interface. Although many of sulfide-based solid-state electrolytes exhibit high Li$^+$ conductivities (10$^{-4}$ to 10$^{-3}$ S cm$^{-1}$ at room temperature),[2] the Li$^+$ transport through the interface can be lagged by several orders of magnitude. For instance, the Li$^+$ conductivity of Li-argyrodite phase Li$_2$PS$_3$Cl electrolyte is reported as high as 1.3×10$^{-3}$ S cm$^{-1}$ as a bulk, but the conductivity is dramatically reduced to 10$^{-11}$ S cm$^{-1}$ at the interface with the Li$_2$S cathode.[3]

Therefore, developing new cathode materials with compatible interface between electrode and electrolyte to achieve high Li$^+$ transport in the interface and high electronic conductivity in the electrochemical active electrode particles is one of the main point to realize the high performance all-solid-state Li batteries. Herein, all-solid-state Li-Se battery chemistry with the commercial Li$_2$PS$_3$Cl electrolyte was achieved. Apart from the high electron conductivity (1×10$^{-3}$ S cm$^{-1}$) of Se, a high Li$^+$ conductivity of 1.4×10$^{-3}$ S cm$^{-1}$ across the Se-Li$_2$PS$_3$ interface can be achieved. Such high Li$^+$ conductivity within the interface should be due to the formation of interfacial species of PS$_4$-Se$_3$ proved by in-situ Raman test. The Se cathode exhibited significantly high electrochemical kinetics process with high utilization and low polarization during cycling. All-solid-state Li-Se cell showed a high reversible capacity of 652 mAh g$^{-1}$ (96% of theoretical capacity) and good cycling stability with 585 mAh g$^{-1}$ remained after 100 cycles at room temperature. This work demonstrates all-solid-state Li-Se batteries as promising high-energy storage system and provides new insights of the solid-state electrode/electrolyte interfacial chemistry.[4]

Reference

Next-generation air-breathing cathodes in alkaline fuel cells and metal–air batteries will require discovering and formulating catalysts with higher activity for the reduction of molecular oxygen (ORR catalysis) and for the oxidation of water/hydroxide back to O$_2$ (OER catalysis). Strategies to enhance electrocatalytic activity. A single variable does not serve as a definitive predictor of catalytic performance, whether that variable is surface area, crystallite size, porosity, or some other factor. For example, the activity of catalysts can be enhanced by increasing the surface area, which can be achieved by increasing the particle size or by introducing defects into the crystal lattice. However, increasing the particle size can also lead to decreased activity due to the decreased contact area between the electrode and the electrolyte. Therefore, a balance must be achieved between the two factors.

As an energy storage system, Li-ion batteries are not safe because they use flammable organic electrolytes. A safer alternative is rechargeable Zn-based batteries with aqueous electrolytes. Among them, Zn-air batteries have high theoretical volumetric energy density (4400 Wh L$^{-1}$), which can even compete with lithium-sulfur batteries. Alkaline electrolyte is preferable for Zn-air batteries. However, the performance of Zn anodes in alkaline electrolyte is limited by passivation, dissolution and hydrogen evolution. Through SEM investigation, critical passivation size was found to be ~2 μm. Sub-micron-sized Zn anodes will not have passivation problem. As a result, we focus our research on nanoscale. However, Zn dissolution of nanosized anodes will be accelerated because of large electrode-electrolyte surface area.

Thus, anode modification and protection are needed to alleviate the dissolution. We designed a (1) Zn mesh@GO anode: GO layers on the Zn mesh surface deliver electrons across insulating ZnO and can slow down the Zn dissolution; (2) lasagna-inspired ZnO@GO anode: ZnO nanoparticles encapsulated by GO can solve simultaneously the passivation and dissolution problems; (3) core-shell ZnO@TiN nanorod anode: thin and conformal TiN coating mitigates Zn dissolution, mechanically maintains the nanostucture, and delivers electron to nanorods.

Hydrogen evolution is a competitive side reaction on the zinc anodes, which causes low efficiency of Zn based batteries. Two approaches are investigated.
to suppress hydrogen evolution, including (1) modify the anode with a hydrogen suppressive material: core-shell ZnO@TiO2 nanorod anode was made with hydrogen suppressive TiO2 coating, which solves hydrogen evolution, passivation and dissolution problems at the same time; (2) design a hydrogen evolution suppressive nanostuctured alloy anode: Zn-Ag alloy with increased standard reduction potential was used, which is more competitive compared with hydrogen evolution and more stable in aqueous electrolyte.

All of these anodes show superior performance compared with unmodified anodes. These anodes can be paired with air cathodes to make high energy Zn-air batteries. The nanoscale design principles here can potentially be applied to overcome intrinsic limitations of other battery materials.

4:45 PM ET03.08.08
Spontaneous Corrosion of Mg2Sn in APC Electrolyte Zeyu Wang1,2, Hemant Kumar1, Vivek Shenoy1 and Eric Detsi1; 1Materials Science & Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States; 2Materials Science & Engineering, State Key Laboratory of Advanced Welding and Joining, Harbin Institute of Technology, Harbin, China.

Although the rechargeable battery industry is currently dominated by lithium-ion battery (LIB), there is a growing concern for the limited availability of raw lithium and cobalt resources used in commercial LIBs. The desire to keep pace with a growing market has led to intensive research of alternative rechargeable battery technologies that are safer and utilize earth-abundant elements such as magnesium-ion batteries (MIBs). Progress toward practical MIBs has been halted partly by the absence of suitable electrolytes that are compatible with magnesium (Mg) metal. In particular, most of the simple salts and/or organic solvents containing unsaturated carbon atoms yield a Mg-blocking passive film on metallic Mg. As a result, only a handful of electrolytes including all-phenyl-complex (APC) are compatible with Mg metal as the negative electrode [1]. Despite the huge success of APC for reversible Mg plating, this electrolyte has been reported to corrode current collectors and stainless support in battery cells at operating voltages above 2.2 V vs. Mg, limiting in that way the operating voltage window below 2.2 V vs. Mg. Chloride ion has been pointed out as the corroding agent in APC electrolyte, and this corrosion phenomenon has been investigated only electrochemically when the cell is under a bias voltage. On the contrary, the spontaneous corrosion (i.e. without any applied voltage) in APC of Mg metal and Mg alloys used as anodes in MIBs has been barely reported. In this talk, I will demonstrate that APC electrolyte has adverse effect on MIB anodes even in the absence of applied bias voltage. In particular, we have found experimentally that Mg spontaneously dissolves from Mg2Sn—a very promising MIB anode with in the presence of APC. We attribute this spontaneous corrosion to galvanic replacement, during which at least one of the following anions: Ph4Al-, Ph2AlCl2-, PhAlCl3 and AlCl4− present in APC electrolytes extract electrons from the Mg in Mg2Sn, resulting in Mg dissolution and aluminum metal deposition, as confirmed by X-ray photoelectron spectroscopy in our work. In addition, density functional theory (DFT) was used to determine the redox potentials of Ph4Al, Ph2AlCl2, PhAlCl3 and AlCl4−, in order to confirm that these anions are susceptible to dissolve Mg. This work raises fundamental questions regarding the origin of the relatively poor cycling longevity of alloy-type anodes in MIBs operating in APC electrolytes [2].

Enhanced Photoelectrochemical Properties of ZnO/Cu2O Heterostructures by Built-in Potential From p-n Cu2O Homojunction
Photovoltaics Joon-Soo Yoon, Joo-Won Lee and Yun-Mo Sung; Korea University, Seoul, Korea (the Republic of).

There have been suggestions integrating a photoelectrochemical (PEC) cell and a photovoltaic (PV) cell, known as PV-PEC cell, to further utilize the sunlight more efficiently. In this system, additional photovoltaic can be obtained from the photovoltaic cell, which makes the maximum of theoretical efficiency much higher than that of single or tandem PEC cell. Herein, we report the fabrication method for n-type Cu2O thin films using the electrodeposition of p-type Cu2O layers and the successive conductivity type transition to n-type by a simple solution treatment. The p-n homojunction was constructed by additional electrodeposition of p-type Cu2O on the n-type Cu2O layers. This approach could allow the fabrication of high-quality p-n Cu2O thin films. Au thin film was sputtered onto p-n Cu2O and ZnO NRs were hydrothermally grown on the Au thin film to complete PV-PEC cells. XRD, SEM, UV-vis spectroscopy analysis were performed to identify each components. The Mott-Schottky analysis, photoresponse measurement and linear sweep voltammetry support the enhancement of ZnO NRs/Au/p-n Cu2O compared to ZnO NRs/Au/n-Cu2O with respect to photovoltage and photocurrent. Finally, band structures are suggested to visualize the working mechanism. The built-in potential occurred spontaneously because of p-n homojunction. The built-in potential offered additional potential so that the photocurrent onset was shifted to the cathodic direction and the photocurrent was increased under illumination. Based upon the band diagram, it was clarified that z-type scheme and the buried p-n junction work effectively for our PV-PEC system. As a result, the enhancement of photocurrent density by 237% was achieved for ZnO-n-pn via the photocurrent-time measurements under 0.2 V vs. SCE.

Mesoporous Co/N-Amorphous N-Doped Carbon Nanocubes via Co[Co(CN)6]2 Nanocubes as an Efficient Electrocatalysts for the Oxygen Evolution Reaction Bonkuk Kang1, Sung Hoon Kwag2, Dong H Jeong2, Hyung Wook Cho1, Dae ho Yoon1 and Woo Seok Yang2; Sungkyunkwan University, Suwon, Korea (the Republic of); 1Korea Electronics Technology Institute, Seongnam-si, Korea (the Republic of).

In recent years, the water splitting process with electrocatalytic and photocatalytic, as one of the next generation energy conversion technology for producing hydrogen and oxygen molecules has been widely considered in solving energy and environmental problems. However, half reaction of oxygen evolution reaction (OER) plays a critical role in improving overall conversion efficiency of the water splitting process because the OER system encounters the bottleneck of a kinetically sluggish reaction with multistep proton-coupled electron transfer and considerable overpotential value (> thermodynamic value: 1.23 V). Precious metal and oxide materials (Pt, RuO2, and IrO2) as the superior active catalyst for OER have been used, however, high cost, poor stability, and scarcity of these metals hinder widespread practical use and technique. Hence, extensive research activities have focused on inexpensive earth-abundant metal based materials such as multi-composite transition metal (Ni, Fe, Mn, and Co etc.) compounds (nitride, oxide, and hydroxide), as well as hybrid structures with carbon-based materials (graphite, graphene, and carbon nanotubes (CNT)) as candidate catalysts for alternative developed OER electrocatalyst. Surprisingly, the suitable materials, metal nitrides, are a promising class of electrocatalysts for highly efficient oxygen evolution reaction (OER) because they exhibit superior intrinsic conductivity and have higher sustainability than oxide based materials. Herein, we report successful design and fabrication of unique mesoporous CoNi/amorphous N-doped carbon (AN-C) nanocubes (NCs) based on in-situ nitridation and calcination via Prussian blue analogue (PBA) of Co[Co(CN)6]2 NC precursors. Unique architectures (mesoporous and AN-C hybrid) could assign well dispersed pore, highly active sites, and good durability of Co3N NCs for OER. Mesoporous Co3N@AN-C NCs electrode exhibits outstanding performance of low overpotential of 280 mV at 10 mA cm-2 as well as excellent stability at 20 mA cm-2 in alkaline (1.0 KOH) solution for 24 hours.

ET03.09.04
2 Dimensional Structured Iron Nickel Nitride/Reduced Graphene Oxide Hybrid Composite as Oxygen Evolution Reaction Electrocataysts for Efficient Water Splitting Sung Hoon Kwag1, 2Bongkuk Kang and Woo Seok Yang1; Nano Materials & Components Research Center, Korea Electronics Technology Institute, Gyeonggi-do, Korea (the Republic of).

In water splitting, oxygen evolution reaction (OER) is important process because high overpotential is required to achieve the current density for the reaction. Transition-metal nitrides (TMN) used as electrocatalyst materials for OER are being recently studied because of high yield, easy operation, and excellent catalytic activity by high electrical conductivity. In particular, iron-nickel nitride has very high catalytic activity due to owing to high electro-catalytic and high stability. Reduced graphene oxide (rGO) known as 2 Dimensional (2 D) carbon materials is extensively used as supporting material owing to high conductivity, large theoretical specific surface area, and excellent stability. In this study, we successfully synthesized Fe2Ni2N/rGO hybrid composite for OER electrocatalyst material through two-step process with hydrothermal method and annealing. The morphology of precursor and Fe2Ni2N/rGO hybrid composite was analyzed by FE-SEM. The crystallinity of sample was confirmed by XRD. GO was confirmed by Raman spectroscopy. And the components of as-prepared precursor were measured by FT-IR spectra. Furthermore, we analyzed electrochemical properties of synthesized sample.

ET03.09.05
La0.6Sr0.4Co0.2Fe0.8O3-δ Decoration With CoO Nanoparticles and the Effect on Its Performance as SOFC Cathode Julian Ascolani Yael1, 2, Alejandro Montenegro-Hernandez1, Laura Baque1, Alberto Caneiro1 and Liliana Mogni2; 1CNEA - CAB, Bariloche, Argentina; 2Instituto Balseiro, Bariloche, Argentina.

Reducing fuel cells degradation and cathode polarization losses are currently two of the most important challenges in order to achieve more efficient and cost competitive SOFCs. One strategy has been to reduce operation temperatures to the range between 600 °C and 800 °C (IT-SOFC), which reduces degradation rates but increases activation over potentials as a consequence (mainly the cathode reaction overpotential, due to the high activation energy of oxygen reduction reaction –ORR–). Several approaches have been taken to counteract this problem and recently, promising results [1] have been obtained by modifying the electrodes surface using the impregnation technique. This technique consists of synthesizing catalyst nanoparticles on the electrode surface through a liquid solution-based process [2, 3]. The mechanisms through which the impregnated catalysts reduce the polarization resistance and even enhance durability are not completely well understood yet, especially when non conventional catalysts are impregnated, as the performance improvement relies upon the microstructure and coupled interactions between the materials.

In this work, a SOFC cathode surface modification by nanoparticle decoration was carried out. La0.6Sr0.4Co0.2Fe0.8O3-δ –LSCF– ceramic cathodes impregnated with cobalt oxide (Co3O4) nanoparticles were characterized by Scanning and Transmission Electron Microscopy –SEM and TEM-, X-ray diffraction –XRD– and Raman Spectroscopy. The electrochemical response as a function of temperature and oxygen partial pressure pO2 (10^-4 < pO2 < 1 atm) was evaluated by electrochemical impedance spectroscopy -EIS-. The impregnation was found to reduce the cathode polarization resistance –Rc– around 50% in the temperature range between 400°C and 700°C.
Electrodeposited Ni or Ni-Fe alloy was shown to effectively stabilize and catalyze the Si photoanode continuously for 24 h of water splitting. However, electrolytes but also poor catalytic property for the photo-drive electrolysis. Bandgap (1.12 eV) and high carrier mobility. However, the Si has not only low stability for the PEC cell due to the photo-induced corrosion in contact with metal oxides for water splitting via tailoring their optical and electronic properties. The need to extend the absorption spectrum to NIR and Visible regions of the light spectrum is crucial to enhance their characteristics as efficient photoelectrodes in photoelectrochemical water splitting. Bandgap tuning of semiconductors via induced defects is vital to control their optical and electrical properties. The EIS spectra show at least two arcs, where the pO2 dependence of each one allows to model the electrochemical response by a complex mechanism where the oxygen reduction reaction is co-limited by oxygen ion diffusion and oxygen surface exchange.

First-Principles Study of Bi-Functional Electrocatalytic Activity on Bi$_2$RuO$_4$ Pyrochlore Oxide Gwan Yeong Jung1, Joohyuk Park1-2, Sung O Park1, Jaephil Cho1 and Sang-Kyu Kwak1; 1School of Energy and Chemical Engineering, UNIST, Ulsan, Korea (the Republic of); 2Department of Materials, University of Oxford, Oxford, United Kingdom.

Searching for an effective catalyst to reduce CO$_2$ to value-added hydrocarbons has been a key challenge for CO$_2$ utilization. Here we design the Cu@Cu$_2$O catalyst by taking advantage of copper featuring a thin oxide layer on the surface under ambient conditions. Our results demonstrated that Cu(I) oxide species on Cu@Cu$_2$O surface can remain relatively stable against reduction under CO$_2$ electrode-reduction condition, and the synergism between surface Cu$^+$ and Cu$^{2+}$ in Cu@Cu$_2$O composites contributes to boosting its efficiency and selectivity towards to C$_2$ products. This Cu@Cu$_2$O catalyst achieved low onset potential (~0.8V vs RHE) as well as excellent selectivity (up to 50% at ~1.0V vs RHE) for C$_2$ (C$_2$H$_4$ and C$_2$H$_5$OH) production.

Cu@Cu$_2$O for Selective Reduction of CO$_2$ to C$_2$ Products Longmei Shang and Gengfeng Zheng; Laboratory of Advanced Materials, Fudan University, Shanghai, China.

Bandgap tuning of semiconductors via induced defects is vital to control their optical and electrical properties. The need to extend the absorption spectrum to NIR and Visible regions of the light spectrum is crucial to enhance their characteristics as efficient photoelectrodes in photoelectrochemical water splitting. However, the nature of defects, whether deep or shallow and how they influence the photoelectrochemical performance of TiO$_2$ is yet to be understood. Herein, four factors were utilized to increase the defect density, and eventually decrease the bandgap: alloying with Nb and Zr, nanostructuring in the form of multipodal nanotubes, annealing in a reducing atmosphere (H$_2$), and deposition of solvothermally prepared narrow bandgap CZTS nanoparticles on the nanotubes. Air-annealed samples were used as a reference to study the effect of reducing atmosphere. TEM images verified the formation of uniformly distributed MPNTs. XRD, XPS, and Raman Spectroscopy for the Hydrogen-annealed samples confirmed the presence of ZrTiO$_3$ in addition to Ti-Nb-Zr-O as single mixed oxide possessing an anatase crystal structure. XPS core spectra fitting verified the presence of Ti$^{4+}$. The presence of a large number of Ti$^{4+}$ defects/Oxygen vacancies justified the 4-orders of magnitude increase in the donor density exhibited when Mott-Schotky analysis was performed. These results were further confirmed by XPS valence band spectra showing the presence of valence band tail states. These tail states resulted in a decrease in the bandgap, besides forming a tail in the absorption spectra reaching NIR/Vis. region. Bare MPNTS showed a 25 times enhancement in the photocurrent compared to Air-annealed samples. Decorating the MPNTS with CZTS lead to further 6 times enhancement. However, on testing several cycles, CZTS showed a lack of stability in the alkaline electrolyte. This large current was attributed to the formation of a p-n junction with the desirable band alignment; enhancing charge separation and leading to charge carriers’ injection on the NTs/particles interface. Hence, annealing in a reducing atmosphere is capable of producing disordered and defective structures. This would stimulate an intriguing route for activating other promising metal oxides for water splitting via tailoring their optical and electronic properties.
Oxygen reduction reaction (ORR) is a sluggish process that causes significant cell voltage losses in low- and intermediate-temperature solid oxide fuel cells (SOFCs). Surface engineering of electrocatalysts and thin-film interfaces introduced between the cathode and electrolyte can mitigate the voltage losses associated with ORR on the cathode. In this presentation, we study the role of the metal oxide-based nanoscale interlayer inserted between the cathode and electrolyte in the kinetics and rate-limiting steps of ORR process through a series of electrochemical analyses and imaging techniques. Ultrathin yttria-doped ceria (YDC), yttria-stabilized zirconia (YSZ) and ceria (CeO$_2$) layers with different stoichiometry and thickness were inserted as the interlayer by atomic layer deposition (ALD) technique on a gadolinia doped ceria (GDC) layer that was screen printed on YSZ electrolyte supported cells. A series of electrochemical tests have been performed with two different cathode materials – lanthanum nickel ferrite (LNF) and lanthanum strontium cobalt ferrite (LSCF) cathodes – with different electronic and ionic conductivities to examine the interface engineering impact on ORR. $\text{pO}_2$-dependent ORR kinetics tested under different oxygen partial pressures ($\text{pO}_2$) ranging from 0.04 to 1.0 atm. The reaction order $m$, defined as the relation $R_p$ cathodic polarization resistance; $\text{pO}_2$, O$_2$, partial pressure) is a widely used indicator of the rate-limiting step in ORR. In addition to the dependency on $\text{pO}_2$, the wide variation in the dependency on temperature and overpotential suggests that the interface treatment not only changed the overall ORR kinetics but also shifted the bottleneck process of ORR. However, it was found that most of the samples are largely rate-limited by the charge transfer processes, but mostly in conjunction with chemical processes such as diffusion of electroactive species and/or dissociation processes.

**Mesoporous CuO$_x$-Derived Nanostructured Copper Catalysts for CO$_2$ Reduction**

Giorgio Giuffredi$^{1, 2}$ and Fabio Di Fonzo$^2$

$^1$Istituto Italiano di Tecnologia, Milano, Italy; $^2$Department of Energy, Politecnico di Milano, Milano, Italy.

The electrochemical reduction of anthropogenic CO$_2$ to fuels and complex hydrocarbons represents a promising solution to reduce global CO$_2$ emissions and, at the same time, to efficiently store intermittent, renewable energies-generated electricity in the form of chemical energy of carbon-based fuels. The progress of the technology is still hindered by the unsatisfactory efficiency and stability of currently employed electrocatalysts. The thermodynamic stability of CO$_2$ requires a large overpotential to be applied for the reaction to take place at a satisfying rate. Moreover, electrocatalysts often undergo degradation after a limited operation time because of poisoning due to incorrect reduction of CO$_2$.

Copper, among the many metals tested as CO$_2$ reduction electrocatalysts, is interesting because, due to its ability to reduce CO$_2$ to complex hydrocarbons with good efficiency. However, even copper catalysts, when their structural and morphology are not nano-engineered, require high overpotentials and have limited selectivity and stability.

To overcome these problems, oxide-derived copper catalysts are being studied: they show improved CO$_2$ reduction efficiency, higher selectivity towards complex hydrocarbons and have longer stability. Morphology also plays a critical role in determining activity and selectivity of oxide-derived copper nanostructures: a controlled morphology in fact allows to maximize the exposed active sites and to increase the surface area, resulting in higher Faradaic efficiency towards CO$_2$ products and lower overpotentials.

In this contribution, we propose Copper Oxide (CuO$_x$) mesoporous nanostructures synthesized through Pulsed Laser Deposition (PLD) as oxide-derived Cu catalysts for CO$_2$ reduction. We evaluate the influence of both morphology and composition of the nanostructures on the final electrochemical performance, by carefully tuning the process gas kinetics and process gas type during the synthesis. We are thus able to fine-tune the deposit morphology and composition up to the nanoscale: we obtain films with different degrees of nanostructuractation, from compact films to porous nanostructures, and compositions ranging from Cu$_2$O to CuO. The PLD-synthesized nanostructures are composed of an amorphous matrix with embedded crystalline CuO$_x$ seeds, differently from other reported, purely crystalline oxide-derived Cu catalysts. This morphological feature allows for a higher availability of undercoordinated surface active sites which, coupled with the high surface area, can enhance the activity of the catalysts.

The nanostructures are characterized electrochemically, showing good current densities even at low overpotentials. The influence of both composition and morphology of the nanostructures on Faradaic efficiency and selectivity are evaluated.

This contribution shows the potential of a PLD-based technique for the synthesis of efficient oxide-derived Cu nanostructured catalysts with controlled morphology and composition.

**Investigation on the Nano Size Effect of Ultra-Small Manganese Oxide Nanoparticles**

Kang Hee Cho, Sunghak Park, Hongmin Seo, Kang Gyu Lee, Yoon Ho Lee and Ki Tae Nam; Department of Materials Science and Engineering, Seoul National University, Seoul, Korea (the Republic of).

Nowadays, nanotechnology is really close to our daily lives and its applications are diverse such as energy, biomedical, sensors and foods. Especially in energy fields, rational design and synthesis of highly efficient nanocatalysts for various reactions are an important issue. And because of some characteristics such as large exposed surface area, morphology tuning at nano scale and electronic confinement effects within NPs, they show specific nano size effects.

Recently, our group newly synthesized partially oxidized sub-10 nm MnO NPs which show superior catalytic performance compared to the bulk manganese oxides. And in further study which was reported in JACS last year, we implemented various in-situ electrochemical analysis and in-situ spectroscopic tools such as XAS, UV-VIS and Raman and we found completely different mechanistic behavior of our NPs compared to the conventional Mn-based catalyst. Herein, we extend our understanding on nano-size effect to our manganese oxide NPs. For synthesis of ultra small NPs, various size-control parameters and synthesis methods were pre-screened. And very recently, we successfully synthesized average size of 4.1 nm NPs which show superior OER activity compared to sub-10 nm NPs. Using these as-synthesized NPs, applicability for chirality manganese oxide NPs formation will be explored and also we expect enhanced surface focused spectroscopic analysis for the capture of reaction intermediates. Additional studies on the relation between OER performance and the size of NPs will also proceed.

**Nitrogen Doped Carbon Nanonions for Oxygen Reduction Reaction (ORR) Electrocatalysis in Fuel Cells for Microgravity Conditions**

Armando Pena-Duarte$^2$, S.H. Vijapur$^2$, T.D. Hall$^2$, E. Jennings Taylor$^2$ and Carlos R. Cabrera$^2$; $^2$Department of Chemistry, University of Puerto Rico at Rio Piedras, San Juan, Puerto Rico, United States; $^3$Department of Mechanical Engineering, University of California Merced, Merced, California, United States; $^4$Faraday
Nitrogen doped carbon nanostructures have been previously used as catalyst support in ORR [1,2]. A metal-free mesoporous nitrogen-doped carbon catalyst showed a high electrocatalytic activity, durability and selectivity toward peroxide by electrocatalysis of O$_2$ in a non-corrosive neutral as well as in acidic reaction medium [3,4]. Human space travel requires several technological developments that support the energy-efficient preservation of closed systems in microgravity spaceship environments. Especially, a technique for the in-situ generation of cleaning/sanitizing solutions such as H$_2$O$_2$ is needed to meet personal hygiene necessities during space missions. Accordingly, we developed an alternative post-synthesis nitrogen doping of CNOs by Chemical Vapor Deposition Method (CVD) in atmospheric pressure, using dicyandiamide as nitrogen precursor. The operational parameter conditions of the CVD reactor were a reaction temperature 700 °C, 2 mL/min of total argon gas flow, and a composition of precursors 2:1 DCDA:CNOs. The structural properties of the NCNOS were investigated using X-ray diffraction, Raman spectroscopy, scanning electron microscopy, and X-ray photoelectron spectroscopy. Our research involves increase surface area of carbon pristine source and improve its electronic structure and understanding of the nitrogen intercalation process by possible pyrolytic–nucleophilic mechanism of N–C doping reaction. NCNOS electrochemical characterization revealed higher performance than CNOs due to N doping. Nitrogen doping in the CNOs enhances the electronic conductivity and specific capacitance. An analysis of the rotating disk electrode (RDE) technique data was done to evaluate the ORR kinetics, including n-values which are related to the mechanism of oxidation, at the NCNOS, using the Koutechy-Levich (K-L) equation. The pH Effect on Oxygen Reduction Reaction over N-Doped CNOs in O$_2$ saturated 0.2 M Na$_2$SO$_4$ was evaluated by a scan rate of 10 mV/s at different rotation rates: 300, 700 1100, 1500, and 1900 rpm. Our results could be evidence that the H$_2$O$_2$ or H$_2$O selectivity, two-electrons and four-electrons transfer pathway, respectively, depend on the supporting electrolyte, i.e., pH value and nature of electrolyte, and increases to 0.2M Na$_2$SO$_4$ according to neutral (2.5 electrons) > acidic (1.4 electrons) > alkaline (3.4 electrons). Therefore, our approach would be promising to control of two-electrons route kinetics of ORR by the supporting electrolyte, through nitrogen carbon nanonion electrocatalyst systems for fuel cells in aerospace technologies.

ET03.09.15
First-Principles Studies of B-Site Doped PrCoO$_3$-d Perovskite
Jianguo Yu; Idaho National Laboratory, Idaho Falls, Idaho, United States.

Solid-oxide fuel cells (SOFC) based on proton-conducting (PC) ceramics are gaining wide interest as promising green technologies for H$_2$ production and conversion. However, its large-scale deployment has been hindered by severe limitations at electrodes, which must ensure catalytic activity, electronic conduction, and high proton diffusion rates. Perovskite oxides are highly desirable as the promising electrode candidates for SOFC. In this work, we present results of a density-functional theory (DFT+U) study of B-site doped PrCoO$_3$(PCO) perovskite. The investigation was focused on the key processes that determine proton transport, i.e., oxygen vacancy formation, water dissociative incorporation into the defective lattice, and proton transfer along the oxide sublattice. The materials are PCO and B-substituted derivatives with Ni. The effects of the crystal structural from cubic, tetragonal to orthorhombic and surface will also be discussed.

ET03.09.16
Promoting Surface Charge Utilization by Incorporating Novel Ternary ZnCoMn Layered Double Hydroxide Nanowall with Bismuth Vanadate for Efficient Photocatalytic Water Oxidation
Truong-Giang Vo, Yian Tai and Chia-Ying Chiang; National Taiwan University of Science and Technology, Taipei, Taiwan.

Strategically integrating a highly efficient oxygen evolution reaction electrocatalysts with a semiconductor film to reduce surface recombination and enhanced photocurrent is known as the bottleneck in solar-driven water splitting [1]. Herein, a novel integrated ZnCoMn layered double hydroxides (LDHs) photoanode with the high-quality interface was directly and conveniently deposited on a BiVO$_4$ to enhance photocatalytic photochemical water oxidation performance via fast and facile preoxidation coupled electrochemical method. Uniform two-dimensional LDH nanowalls with controlled composition anchoring onto the surface can be accomplished at room temperature within tens of seconds. Benefiting from efficient exposure of active sites, favorable charge transport and enhanced surface reaction kinetics, surface modification with ZnCoMn-LDH exhibits about 170% increment in photocurrent density at 1.23 V vs. RHE and a 280 mV shift in onset potential compared to bare bismuth vanadate. More interestingly, charge injection efficiency at the BiVO$_4$/electrolyte interface, which is well-known as one of the critical limiting factors in achieving efficient photocatalytic water splitting [2], reaches almost 100%. The results obtained here suggest the possibility of using ternary LDH as low-cost earth-abundant co-catalysts for solar water splitting. This work also provides a facile and cost-effective synthesis route that holds great promise for large-scale industrial manufacture and can be potentially used in energy conversion devices.

ET03.09.17
Stable GaAs Photoanode with Manganese Modified TiO$_2$ Protective Coatings for Water Oxidation
Xin Shen and Shu Hu; Chemical Engineering, Yale University, New Haven, Connecticut, United States.

Artificial photosynthesis, commonly used to refer to any scheme for capturing and storing the energy from sunlight in the chemical bonds of a fuel (a solar fuel), has long been considered as option to mitigate energy crisis and global climate change. Photoelectrochemical (PEC) water splitting converts water into hydrogen and oxygen, and is a major research topic of artificial photosynthesis. However, there are still lots of challenges in designing an efficient PEC cell to split water. Except for efficiency and cost, stability problem of efficient semiconductor/liquid interfaces like Si and GaAs has greatly hindered the development of many potential excellent photoanode materials as these material undergoes positive photo-corrosion during PEC operation. So, it is imperative that through this project we: 1 Understand typical photoanode corrosion process with a detailed description for the different corrosion stages with the help of our in-situ laser set-up; 2 Find the main factors influencing anode of our PEC water oxidation; 3 Determine an optimized condition for stable and efficient GaAs water oxidation, as our preliminary results showed the relative neutral PH condition (PH 5 to 9) is beneficial for PEC water oxidation by greatly lower electrode overpotential. Particularly, in this project we would also compare GaAs/TiMnOx/In to traditional GaAs/TiO$_2$/Ni to show the superiority of acid stable TiMnOx/In as a novel protective coating/co-catalyst system.

ET03.09.18
Preparation of Vertically Oriented Carbon-Coated Titanium Dioxide Nanorods as Alternative Catalyst Support to Carbon for Fuel Cells
Applications Naser Mohammadi and Mohamed Mohamedi; *Énergie Matériaux Télécommunications, INRS, Montreal, Quebec, Canada.

At present, catalyst supports in fuel cells are often made of carbon-based materials, such as graphite fiber brush, carbon paper, reticulated vitreous carbon, carbon nanofibers, etc. TiO₂ is one of the most attractive metal oxides used in many areas concerning solar cells, photocatalysis, sensors, supercapacitor, etc. TiO₂ has very good chemical stability, biocompatibility, and also is abundant as well as environment-friendly. These advantages are very attractive for practical fuel cell electrodes. Because of their special application in fuel cells, the growth of one-dimensional single-crystalline TiO₂ nanostructures on a flexible substrate is receiving intensive attention [1].

In this study, TiO₂ nanorods are hydrothermally grown on carbon paper (CP) and Titanium foil. Then Platinum layer deposited onto TiO₂ nanorods by pulsed laser deposition (PLD) at room temperature. Scanning electron microscopy (SEM), X-ray diffraction (XRD) and X-ray photoelectron spectroscopy (XPS) were employed to characterize the synthesized nanorods, According to the SEM study, the synthesized particles have 200 nm in diameter. The catalyst showed the highly dense TiO₂ nanorods were directly grown on the Titanium foil and carbon Paper substrates, also the Pt-coated onto the surface of TiO₂ nanorods were uniform. Cyclic voltammotry (CV) and chronoaamperometry were employed to study the electrocatalytic properties and durability of thus synthesized TiO₂-Pt and CP/TiO₂-Pt samples towards ethanol electro-oxidation, the reaction that is of fundamental significance to direct ethanol fuel cells (DEFCs). The Ti/TiO₂-Pt and CP/TiO₂-Pt electrocatalysts have a larger active surface area as compared to the Ti/Pt and CP/Pt electrocatalysts. Meanwhile, the Ti/TiO₂-Pt and CP/TiO₂-Pt electrocatalysts display much better catalytic activity and higher stability for the ethanol electrooxidation in acidic than the Pt/C and Pr/Ti electrocatalysts as a result of the synergistic effect of Pt and the TiO₂ support. Thus, the prepared electrode with low platinum loading and high stability is a promising material for fuel cells and TiO₂ nanorods substrate is a potential alternative to carbon paper substrate for fuel cell technology.

8:00 AM  ET03.10.01 Directional Flow-Aided Sonochemistry Yields Graphene with Tunable Defects to Provide Fundamental Insight on Sodium Metal Plating Behavior David Miltin1 and Wei Liu; 1Chemical and Biomolecular Engineering and Mechanical Engineering, Clarkson University, Potsdam, New York, United States; 2Institute of New-Energy and Low-Carbon Technology, Sichuan University, Sichuan, China.

This is the first report of a novel directional flow-aided sonochemistry (FAS) exfoliation method to synthesize graphene with nearly ideal structure. The FAS treatment allows for control of graphene structural order and chemical uniformity not possible through prior top-down wet methods. Graphite is exfoliated into single-nm scale thickness graphene that is nearly defect free (at-edge sonication graphene "AES-G") or is highly defective (in-plane sonication graphene "IPS-G"). The AES-G has a Raman G/D band intensity ratio of 14.3 and an XPS derived oxygen content of 1.3 at.%, while the IPS-G has IₓOᵧ of 1.6 and oxygen content of 6.2 at.%. Graphene and related carbons are widely employed as templates and protection layers to improve metal plating behavior in sodium and lithium metal battery (SMBs, LMBs) anodes. We then use AES-G and IPS-G to examine the role of structure and chemistry of graphene supports in promoting efficient Na metal cycling. The graphene serves a dual role in stabilizing the Na metal anode, being a nucleation template and serving as a protective layer to keep the metal from severely reacting with the electrolyte. We are the first to demonstrate that graphene defects are actually quite deleterious for efficient Na plating and stripping. AES-G yields state-of-the-art Na performance, with stable cycling at 2 mA/cm² at 100% Coulombic efficiency (CE), and an areal capacity of 1 mAh/cm². Meanwhile IPS-G performs on-par with the baseline Cu support in terms of severe charging instability. The explanation is that the defective graphene demonstrates much more copious SEI formation due to its defects and oxygen groups being catalytic. A thicker SEI results in a larger overpotential and worse CE loss during subsequent Na plating/stripping, manifesting in severe mossy metal dendrite growth and periodic electrical shorts. We therefore propose the following design rule for next-generation supports for Na metal: An ideal architecture will not only possess a large surface area for copious preferred heterogenous nucleation, but itself will be non-catalytic for SEI formation.

8:30 AM  ET03.10.02 Nanostructured Graphene-Coated Cathodes for High-Performance Lithium-Ion Batteries Mark C. Hersam; Northwestern University, Evanston, Illinois, United States.

Efficient energy storage systems based on lithium-ion batteries represent a critical technology across many sectors including consumer electronics, electrified transportation, and a smart grid accommodating intermittent renewable energy sources. Nanostructured electrode materials present compelling opportunities for high-performance lithium-ion batteries, but inherent problems related to the high surface area to volume ratios at the nanometer-scale have impeded their adoption for commercial applications. Here, we demonstrate a scalable materials and processing platform that realizes high-performance nanostructured lithium manganese oxide (nano-LMO) spinel cathodes with conformal graphene coatings as a conductive additive. Graphene coatings provide a chemically stable interface between the electrode and electrolyte, which minimizes the formation of the solid-electrolyte interphase and mitigates electrode chemical instabilities such as manganese dissolution [1]. The resulting nanostructured composite cathodes concurrently resolve multiple problems that have plagued nanoparticle-based lithium-ion battery electrodes including low packing density, high additive content, and poor cycling stability [2]. Moreover, this strategy enhances the intrinsic advantages of nano-LMO, resulting in extraordinary rate capability and low temperature performance. With 75% capacity retention at a 20C cycling rate at room temperature and nearly full capacity retention at temperatures as low as -20 °C, this work advances lithium-ion battery technology into unprecedented regimes of operation.

Electrochemical capacitors (ECs) with high-power capabilities and stable cycling can effectively improve the state of the art in power delivery and energy storage. In this study, we investigate reactively sputtered titanium nitride (TiN) electrodes on three-dimensional (3D) substrates with various electrolytes and high-rate cycling conditions. These electrodes exhibit cycling stability with negligible capacitance fading after thousands of cycles and a great rate capability, allowing the (dis)charge rate to extend from 0.1 to 10 V s⁻¹ and retaining nearly 50% of the capacitance in a three-electrode system. Symmetric devices made with TiN/Ti electrodes are capable of working at scan rates up to 100 V s⁻¹, yielding a remarkable power density. To further maximize the energy density, the aqueous electrolyte can be replaced with an organic one. Despite not having energy density of carbon-based supercapacitors, other aspects of TiN-based systems are very attractive for future applications. Strategies for further maximizing the performance of this system will be discussed, as well as synthesis and device processing options suggest that 3D TiN structures can enable a new class of high-power ECs with enhanced stability compared to their carbon- and pseudo- counterparts.

Energy Storage Mechanisms in Niobium Oxides with Different Electrolytes Jiahe Zhang and Haitao Zhang; Chinese Academy of Sciences, Beijing, China.

Electrical energy storage and conversion devices, electrochemical capacitors and batteries, are attracting broad interests due to their advantageous features of high round-trip efficiency, long cycle life. Among of different compounds, niobium oxides are pursued drastically owing to their high specific capacitance. Numerous nanocarbons are being utilized to modify these electron insulating niobium oxides to fully manifest their high specific capacitance. In addition, these compounds are also excellent candidate anodes for solid state devices. Therefore, the energy storage processes become more complicated once solid state and formulated electrolytes are employed. Generally, there are two storage behaviors involved, surface behavior and bulk charge behavior. Here we are going to present our recent results related to the energy storage mechanisms in niobium based oxides with ionic liquids based electrolytes. (1) Qualitative analysis, the contribution of the capacitive and diffusion-limited elements are separated in different environments by using the b value. The ionic liquid system that has the highest b value can deliver the biggest capacitive contribution than organic and gel systems. (2) Quantitative analysis, we calculated the capacitive contributions at various scan rates in three systems. The highest capacitative ration exists in inorganic liquid system at all scan rates. The ionic liquid system’s capacitive contribution increased gradually with increasing scan rate. (3) Effect of temperature on the mechanisms was evaluated to optimize the formula. We found that the capacitive ratio increased gradually and ionic liquid system could achieve maximum ratio with increasing temperatures. Our finding suggests that the liquid systems could offer more capacitive contribution and regulate the storage mechanism.

Solvent-Driven Morphology Controls of Nanomaterials for High Performance Supercapacitors Jae-Jin Shim, Debananda Mohapatra, Marjorie Baynosa, Van Quang Nguyen and Ganesh Dhakal; Yeungnam University, Gyeongsan, Korea (the Republic of).

Energy storage is essential for steady supply of renewable energy such as solar energy and wind energy. A supercapacitor is an important energy storage device together with rechargeable battery. Numerous researchers have been developing novel materials for electrochemical energy storage. Graphene and carbon nanotubes have been used to enhance conductivity of active electrode materials such as metal oxides, sulfides, or hydroxides. In addition, 3-D nanostructures have been used to increase the surface area and pore sizes for a better charge collection and transfer. In this study, the morphology of nanomaterials has been successfully controlled by using different reaction medium and by use of microwave and ultrasound. Several different morphologies will be shown and their synthesis processes will be discussed. Some of them show excellent energy storage performances. The materials synthesized by these new methods may be used for energy storage devices, sensors, and photocatalysts in the near future.

Titanium Nitride Films as Electrodes for High Power Electrochemical Capacitors Tianye Zheng, Mohammad H. Tahmasebi and Steven T. Boley; Hong Kong Polytechnic University, Kowloon, Hong Kong.

As electronic technology advances, the need in safe and long-lasting energy storage devices that occupy minimum volume arises. Short charging times of several seconds to minutes, with energy densities comparable to those of batteries, can be achieved in electrochemical capacitors (supercapacitors), in particular pseudocapacitors, which utilize fast redox reactions to store charge and, thus, feature high energy densities. However, metal oxides that are currently used in energy storage technologies have certain limitations. Due to low intrinsic electrical conductivity they might suffer from poor cyclability and deterioration of electrochemical performance for thick electrodes. As an alternative, conductive materials with build-in redox centers pose particular interest. Herein, we report on the new family of the conductive 2D porous metal organic frameworks and we investigated their potential for electrochemical capacitors. A perspective of usage of the metal organic frameworks for the energy storage is particularly appealing since it can enable energy-efficient way of the room temperature synthesis of the electrode materials. Our evaluation demonstrated impressive gravimetric capacitance up to 500 F/g coupled with high volumetric capacitances up to 760 F/cm³. Moreover, we demonstrate excellent scalability of the electrochemical performance for this system: upon increase in electrode thickness up to 350 um, the areal capacitance did not plateau and reached a value over 20 F/cm². This demonstrates that redox-active conductive MOFs can potentially outperform other traditional materials in energy storage applications. We also discuss charge storage mechanism and factors affecting electrochemical performance of the conductive MOFs.

Nanoscale Ostwald Ripening—Characterizations and Effects on Realizing Fast Charging Capability of Electrochemical Capacitors with Abundant Manganese Dioxide Tianyu Lui, Yu Song, Xiaoxia Liu and Yat Li; 1Department of Chemistry and Biochemistry, University of California, Santa Cruz, Santa Cruz, California, United States; 2Department of Chemistry, Northeastern University, Shenyang, China.

We recently discovered that, nanoscale Ostwald ripening of a thick layer of manganese dioxide (MnO₂) nanosheets could be induced by a facile hydrothermal treatment. This nanoscale process coalesced the surface nanosheets into a highly crystalline and porous coating layer, forming a well-resolved core-shell structure. The presence of this crystalline coating was capable of substantially facilitating both ion diffusion and electron transport throughout the thick MnO₂ film, which was desirable for practical electrochemical capacitors with high mass loading of active materials. The core-shell structure, when deployed as a pseudocapacitive electrode with 9 mg cm⁻² of MnO₂, achieved a geometric areal capacitance of 618 mF cm⁻² at a fast scan rate of 200 mV s⁻¹. The MnO₂ mass loading could further be promoted to as remarkably high as 23.5 mg cm⁻² without greatly compromising its fast charge-
Nano-Sized Structurally Disordered Metal Oxide Composite Aerogels as High-Power Anodes in Hybrid Supercapacitors

Huijian Huang, Xing Wang \textsuperscript{1,3}, Elena Tervoort, Guebo Zeng \textsuperscript{1}, Tian Liu, Xi Chen \textsuperscript{1}, Alla Sologubenko \textsuperscript{1} and Markus Niederberger \textsuperscript{2}; \textsuperscript{1}ETH Zurich, Zurich, Switzerland; \textsuperscript{2}University of California, Berkeley, Berkeley, California, United States; \textsuperscript{3}Paul Scherrer Institute, Zurich, Switzerland.

With rechargeable battery technology moving to an era of medium/large-scale applications, the development of next-generation energy storage devices offering not only high-energy density but also high-power density becomes more and more imperative. Rechargeable lithium-ion batteries usually have high energy density, whereas their power density and cycle life are far from satisfactory. Alternatively, supercapacitors exhibit rapid power delivery, but are limited by low charge storage capacity. To integrate both high-power delivery, lithium-ion hybrid supercapacitors (Li-HSCs) have been explored in recent years. One of the main challenges on the way to fabricating high-performance Li-HSCs is the development of high-power Faradaic anodes to solve the kinetic imbalance between the sluggish Faradaic anode and the capacitive cathode.

In this work, we developed a general method for synthesizing nano-sized metal oxide nanoparticles with highly disordered crystal structure and their processing into stable aqueous dispersions.\textsuperscript{1} With these structurally disordered nanoparticles as building blocks, a series of nanoparticles @ reduced graphene oxide (rGO) composite aerogels are fabricated and used as binder-free high-power anodes for lithium-ion hybrid supercapacitors (Li-HSCs). To clarify the effect of the degree of disorder, control samples of crystalline nanomaterials with similar particle size are prepared. The results indicate that the structurally disordered samples show a significantly enhanced electrochemical performance compared to the crystalline counterparts. In particular, structurally disordered Ni\textsubscript{1,4}Fe\textsubscript{0,6}O\textsubscript{4}@rGO delivers a capacity of 388 mAh g\textsuperscript{-1} at 5 A g\textsuperscript{-1}, which is 6 times that of the crystalline sample. The volumetric capacitances of more than 1200 F cm\textsuperscript{-3}, maintain gravimetric capacitances in excess of 200 F g\textsuperscript{-1} at extremely high charging rates of over 100 A g\textsuperscript{-1}, and provide life cycle and capacitance retention that excel those of Ti\textsubscript{3}C\textsubscript{2}Tx. The research findings summarized in this presentation will provide a path toward high-power Faradaic anodes for Li-HSCs.

developed to potentially serve as the electrode platform component in a novel textile capacitor. This research will advance the fundamental understanding of the relationship between high surface area and the use of redox reactive nanoparticles on electrochemical charge storage mechanisms.

Electrochemical Intercalation of MoS2 Composites for Supercapacitor Electrodes Using Non-Hydrated Cations Pawin Iamprasertkum1,2, Wisit Hirunpinyopad1,2, Mark A. Bissett3 and Robert A. Dryfe1,2; 1School of Chemistry, University of Manchester, Manchester, United Kingdom; 2National Graphene Institute, University of Manchester, Manchester, United Kingdom; 3School of Materials, University of Manchester, Manchester, United Kingdom.

Nanochannels can be spontaneously fabricated by forming "membranes" of two-dimensional materials. MoS2 has attracted attention in this respect for fundamental studies and due to its superior properties in energy storage applications [1]. However, the charge storage mechanism, including surface ion adsorption and intercalation, are not yet fully understood. In this work, free-standing MoS2 composite electrodes are prepared and studied via the intercalation of non-hydrated cations (without hydration shell). It is found that tetramethylammonium chloride (TMACl) provides double the capacitance compared to tetraethylammonium chloride (TEACl) and tetratetrapropylammonium chloride (TPACl). This is because MoS2 provides an interlayer spacing of 0.615 nm, which is greater than the crystallographic diameter of TMA+ (0.558 nm). In contrast, the crystallographic diameter of TEA+ (0.674 nm) and TPA+ (0.758 nm) are greater than that of MoS2. This can lead to storage of the charge only on the surface of the materials, through ion adsorption. Moreover, we have found that using the TPA+ ion that is larger than that interlayer spacing of MoS2 leads to the partial re-exfoliation of the as-prepared materials, which can enhance the capacitance retention during cycling. These results improve the understanding of charge storage mechanism of layered 2D materials.

Carbon-Based Metal-Free Electrocatalysis for Efficient Energy Conversion and Storage Liming Dai; Case Western Reserve University, Cleveland, Ohio, United States.

Green and renewable energy technologies, such as fuel cells, batteries, and water-splitting systems, hold great promise to solve current energy and environmental challenges. However, noble metal catalysts (e.g., Pt, Pd, RuO2, IrO2) are generally needed to promote the hydrogen evolution reaction (HER) for hydrogen fuel generation from photo-electrochemical water-splitting, oxygen reduction reaction (ORR) in fuel cells for energy conversion, and oxygen evolution reaction (OER) in metal-air batteries for energy storage. The high cost of precious metal-based catalysts and their limited reserve have precluded these renewable energy technologies from large-scale applications. Along with the recent intensive research efforts in non-noble metal based ORR catalysts, we have previously demonstrated that vertically-aligned nitrogen-doped carbon nanotubes could actively catalyze ORR via a four-electron process free from the CO poisoning effects with a 3-time higher electrocatalytic activity and better long-term durability than that of commercial Pt/C catalysts. The improved catalytic performance was attributed to the doping-induced charge transfer from carbon atoms adjacent to the nitrogen atoms to change the chemisorption mode of O2 and to readily attract electrons from the anode for facilitating the ORR.

Subsequently, it was demonstrated that various graphitic carbon materials, doped with heteroatoms of different electronegativities from that of carbon atom, physically adsorbed with certain polyelectrolytes, and even without any apparent dopant or physically adsorbed polyelectrolyte, could also exhibit good ORR performance. More recent studies have further demonstrated that certain heteroatom-doped carbon nanomaterials could act as metal-free bifunctional catalysts for O2/R on metal-air batteries for energy storage, and even O2/R/ORR/HER trifunctional catalysts for self-powered water-splitting to generate hydrogen fuel and oxygen gas from water.

In this talk, I will summarize some of our work on the metal-free catalysts based on carbon nanomaterials for various energy-related reactions, along with an overview on the recent advances and perspectives in this exciting field.

Electrochemically Driven High Hydrogen Concentrations into Palladium via Aqueous and Solid Electrolytes Yet-Ming Chiang1, Jesse D. Benck1, Ariel Jackson1, David Young1 and Daniel Rettenwander2; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2TU Graz, Graz, Austria.

Metal hydrides are critical materials in numerous energy technologies including hydrogen storage, gas separation, and electrocatalysis. Here, using Pd-H as a model metal hydride, we perform electrochemical insertion studies of hydrogen via liquid and solid state electrolytes at 1 atm ambient pressure, and achieve H2/Pd ratios near unity, the theoretical solubility limit, in nanometer-scale films. We show that the compositions achieved result from a dynamic balance between the rate of hydrogen insertion and evolution from the Pd lattice, the combined kinetics of which are sufficiently rapid to enable accurate quantification of the composition of electrochemically synthesized PdHx. Furthermore, we show that the achievable hydrogen concentration is severely limited by electrochomechanical damage to the palladium and/or substrate. The understanding embodied in these results helps to establish new design rules for achieving high hydrogen concentrations in metal hydrides.

2:30 PM ET03.11.03
Computational Study of Nanoscale Active Sites in PGM-Free Electrocatalysts for Proton Exchange Membrane Fuel Cells Kexi Liu, Boyang Li, Zhenyu Liu and Guofeng Wang; University of Pittsburgh, Pittsburgh, Pennsylvania, United States.

Proton exchange membrane fuel cells (PEMFCs) can covert chemical energy stored in hydrogen fuels to electricity and produce environmentally benign product water. However, the commercialization of PEMFCs is hindered by the present requirement of expensive Pt group metals (PGM) as their electrocatalysts. To advance PEMFC technology, it is of great interest to develop earth-abundant, non-precious metal based catalysts in replacement of Pt,
especially for oxygen reduction reaction (ORR) occurring at the cathode of PEMFCs. Recently, non-precious transition metal/nitrogen doped carbon (TM-N-C) catalysts have been shown much attention as a promising PGM-free ORR electrocatalyst due to its ORR activity approaching to Pt. However, the chemical structure of the active sites in these TM-N-C catalysts and their catalytic mechanism for ORR have not been fully understood. To gain insight into the nature of the nanoscale active sites in the TM-N-C catalysts, we have performed density functional theory (DFT) calculations to investigate the progression of ORR on various types of TM-Nx (TM = Fe, Co) moiety substituted embeddingly into a graphene plane. On each possible TM-Nx active site, we calculated the adsorption energies of all the relevant chemical species, namely, O2, O, OH, OHOO, and H2O, and the activation energies for O-O dissociation reactions involved in ORR using the DFT method. On FeNx and/or CoNx embedded in an intact graphene plane, our DFT calculations predicted that the ORR could happen through 4e- associative pathway on the FeNx site, whereas follow a 2e- pathway on the CoNx site due to high activation energy for O-O bond splitting and extremely weak adsorption of H2O on the CoNx site. These theoretical results are in agreement with experimental observations. In addition, we studied the ORR on a FeNx moiety bridging two adjacent armchair like graphene edges as well as a FeNx moiety bridging two adjacent zigzag graphene edges with a porphyric architectural. Among the three FeNx moieties, the porphyric-like FeNx moiety was predicted to catalyze ORR with the highest onset potential. Moreover, we found that the O-O bond scission had lower activation energy on the FeNx moieties bridging graphene edges than on the FeNx moiety embedded in an intact graphene layer. Consequently, our computation results suggest that introduction of micropores in the TM-Nx catalysts would enhance their catalytic activity for ORR through improving not only the specific area but also the intrinsic activity of the active sites.

2:45 PM ET03.11.04
Design of Cathode Materials for Solid Oxide Fuel Cells—A Mechanistic Approach
M. Ali Haider and Uzma Anjum; IIT Delhi, New Delhi, India.

Molecular Dynamics (MD) simulations were utilized to calculate the oxygen anion diffusivity (D) in the lattice of the LnBa2SrCo2Fe2O8 (LnBSCF, Ln = Gd, Pr) double perovskite structure. Oxygen anion diffusion coefficient for the PrBaCoO3.4 (PBCO) material was calculated to be 3 x 10^-2 cm^2 s^-1 at 873 K in the a-b (Pr-O and Co-O) direction, which was observed to be higher than in the Ba-O plane (D = 8x10^-7 cm^2 s^-1 at 873 K). On doping, the A-site of PBCO with Sr and B-site with Fe, the resultant PrBa1.8Sr0.2CoFe2O8 (PBCF) structure was calculated to show an order of magnitude higher diffusivity (D = 1.1x10^-2 cm^2 s^-1 at 873 K) as compared to PBCO. Calculated diffusivity coefficients compared well with the measured electrocatalytic activity of the material. The electrochemical measurements were performed on a geometrically well-defined nanostructured thin-film electrode, fabricated as a symmetric cell using a spray pyrolysis deposition method. In combination with density functional theory (DFT) and MD simulations, experiments provided an insight into the operating mechanism. Following the hypothesis of a characteristic thickness (Lc) below which the performance is expected to be predominately controlled by surface reactivity, the Lc for layered perovskite LnBSCF at 973 K was calculated to be well above 1000 nm. Interestingly, a dense thin-film electrode of PBCSF (1 to 3 μm thick) deposited using the spray pyrolysis method showed a thickness dependent electrochemical performance suggesting bulk diffusion limitation. To understand the origin of this diffusion limited electrochemical performance, DFT calculations were utilized to calculate the surface energy (γ) and oxygen vacancy (Eov) formation energies. For example, the Eov in the Gd plane (98.4 kJ/mol) of GdBaCoO3.4 (GBCO) was calculated to be lower than that of Ba plane (Eov = 266.3 kJ/mol). However, the surface energy of the Ba plane was calculated to be minimum (γ = 7.2 kJ/mol), which makes it the most exposed surface, while it is least diffusive. GBCO nanoparticles of reduced size were expected to expose higher energetic Gd plane, which may enhance diffusivity at the surface. The particle size of GBCO was reduced to 20 nm using a bio-milling approach, wherein the chemically synthesized particles were subjected to fungus Saccharomyces Cerevisiae, for 72 hours. The measured impedance of the electrode made up of bio-milled nanoparticles was improved by 20% as compared to the chemically synthesized material. MD simulation on the GBCO nanoparticles indicated two distinct regimes of diffusion; one corresponding to the surface and other to the bulk region of the nanoparticle. The diffusivity of the shell regime (D = 6.8x10^-11 cm^2 s^-1 at 1073 K) was calculated similar to that of core (D = 5.7x10^-11 cm^2 s^-1 at 1073 K). Thus, nanoparticles showed improved electrochemical performance as compared to the bulk electrode, likely due to the disruption of the Ba-plane at the surface.

How Strain Affects Reactivity at the Nanoscale
Andrew A. Peterson, Shubham Sharma, Cheng Zeng and Alireza Khorsheid; Brown University, Providence, Rhode Island, United States.

The reactivity of nanoscale surfaces drives the functional nature of materials such as catalysts, electrocatalysts, sensors, and batteries. This reactivity is known to be a function of the strain applied to the material. Here, we present a new way to rationalize such strain effects via an eigenstress model, which at the nanoscale manifests itself in simple force-displacement terms. We show how this can quantitatively rationalize such effects, and can lead to new designs at the nanoscale, such as anistropic strain, which can break conventional constrains of amterials design (such as the adsorbate scaling relations).

3:45 PM ET03.11.05
Theoretical Insights into the Effects of Transition Metal Doping on the Structure and Enhanced Stability of Pt-Ni Nanoparticles
Liang Cao and Tim Mueller; Department of Materials Science and Engineering, Johns Hopkins University, Baltimore, Maryland, United States.

We present the use of ab-initio calculations and the kinetic Monte Carlo method to develop atomic-scale structure-stability relationships for Pt-Ni nanoparticles, promising catalysts for the oxygen reduction reaction (ORR). Although the practical use of Pt-Ni catalysts is limited by Ni dissolution under cell operating conditions, it has recently been shown that it is possible to stabilize octahedral Pt-Ni nanoparticles by alloying them with transition metals (e.g. Mo, Cu, and Rh). We discuss two examples of alloyed Pt-Ni nanoparticles: Mo-Pt-Ni and Cu-Pt-Ni. Using a newly developed kinetic Monte Carlo (KMC) model based on cluster expansions, we demonstrate that Mo atoms are preferentially located on the vertex and edge sites of Mo-Pt-Ni in the form of oxides which are stable within the wide potential window of the electrochemical cycle. These surface Mo oxides help protect Ni in sub-surface layers against acid dissolution. KMC simulations reveal that the enhanced stability of Cu-Pt-Ni is likely due to the reduction of the number of Ni and Cu atoms on the surface during synthesis, reducing the opportunity for Ni and Cu atoms in sub-surface layers to move to the surface and dissolve.

4:00 PM ET03.11.06
Ionomer Distribution Control in Fuel Cell Catalyst Layer via Pt Surface Modification
Gisu Doo, Seongmin Yuk, Sungyu Choi, Dong-Hyun Lee, Dong Wook Lee and Hee-Tak Kim; KAIST, Daejeon, Korea (the Republic of).

An universal structure of catalyst layer for polymer electrolyte membrane fuel cell is a mixture of proton conducting ionomer and carbon supported Pt nanoparticle catalyst. Such structure is commonly used because of its large catalyst surface area with abundant multiscale pores for gas diffusion. But, since the membrane is fabricated just by a vigorous mixing process, it has a limitation on the uncontrollabe distribution of ionomer on catalyst particles. And because of the high polar-polar attraction between Pt and ionomer, the ionomer generally tends to distribute to Pt surface, forming few nanometer film. The ionomer films on Pt surface retard the oxygen transfer for the oxygen reduction reaction and adversely affect the power performance especially at a low Pt content in cathode. In this sense, nano-scale ionomer distribution modification toward the ionomer film reduction is needed for the enhancement of
Anion-Exchange Membrane Fuel Cells with Improved CO₂-Tolerance—Impact of Chemically Induced Bicarbonate Ion Consumption

Yu Katayama1,2,3, Kosuke Yamazaki1, Kohei Hayashi1, Takeou Okamishi1, Hiroki Muroya1, Toshiaki Matsui1, Yuuki Kikkawa1, Takayuki Negishi1, Shin Watanabe1, Takenori Isomura1 and Koichi Eguchi1, 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Yamaguchi University, Ube, Japan; 3Kyoto University, Kyoto, Japan; 4Tokuyama Corporation, Tsukuba, Japan.

Over the last few decades, owing to the significant development of anion exchange membranes, increasing efforts have been devoted to the realization of anion exchange membrane fuel cells (AEMFCs) that operate with the supply of hydrogen generated on-site. In this work, ammonia was selected as a hydrogen source, following which the effect of conceivable impurities, unreacted NH₃ and atmospheric CO₂, on the performance of AEMFCs was established. In situ surface enhanced infrared absorption spectroscopy (SEIRAS) revealed that the degradation of the cell performance was primarily due to the inhibition of the hydrogen oxidation reaction (HOR). This is attributed to the active site occupation by CO-related adsorbates derived from bicarbonate adsorbates. The degradation in the HOR activity is suppressed in the presence of both NH₃ and HCO₃⁻ due to the bicarbonate ion consumption reaction induced by the existence of NH₃. A fuel cell test was conducted by using the practical AEMFC with the supply of NH₃-contained H₂ gas to the anode and ambient air to the cathode. The coexistence of NH₃ and HCO₃⁻ improved CO₂-tolerance of AEMFCs, the cell performance was nearly 95% of that without any impurity in the fuels. These results clearly show the impact of the chemically induced bicarbonate ion consumption reaction on the realization of highly CO₂-tolerant AEMFCs.

Mapping Lattice Distortions with Sub-Nanometer Resolution in Strained Core-Shell Nanoparticle Fuel Cell Catalysts

Elliot Padgett1, Megan E. Holtz1, Paul Cueva1, Anusorn Kongkanand2, Venkata Yarlagadda2 and David Muller1,3, 1Applied and Engineering Physics, Cornell University, Ithaca, New York, United States; 2Global Fuel Cell Business, General Motors, Pontiac, Michigan, United States; 3Kavli Institute at Cornell for Nanoscale Science, Cornell University, Ithaca, New York, United States.

Strain and lattice distortions play an important role in a variety of electrochemical energy materials, such as enhancing activity in catalytic nanoparticles and driving fracturing in lithium ion battery materials. However, detailed understanding of strain in many real nanoscale systems has remained elusive because of challenges for effective strain characterization. Localizing strain in nanomaterials requires spatial resolution unavailable in conventional diffraction, while sample instabilities and random crystallite orientations frequently hinder strain characterization by conventional high-resolution direct imaging techniques. With a new generation of fast, high-dynamic range electron cameras, scanning nanobeam diffraction provides a powerful approach to mapping lattice structure and distortions across a variety of length scales, from multi-micrometer battery particles to nanometer-sized core-shell nanoparticles.

Here we apply this approach to Pt-Co nanoparticle fuel cell catalysts, where a Pt-Co alloy core exerts a compressive strain on the surrounding Pt shell. This compressive strain is believed to enhance the oxygen reduction activity by modifying the electronic structure and oxygen binding strength at the catalyst surface. However, the relationship between activity and the structure of the nanoparticle and shell, as well as mechanisms by which strain may be relaxed, remain poorly understood. Using scanning nanobeam diffraction with new algorithms, we map lattice distortions with pico-meter precision and sub-nanometer spatial resolution. In combination with composition mapping by electron energy loss spectroscopy, this allows us to establish the connection between the nanoparticle structure, composition, and strain distribution. We examine the impact of variable Pt shell thickness on the surface strain, including unique strain relaxation effects due to the geometry of core-shell nanoparticles, and investigate the implications for catalyst activity. We also explore the mechanisms of strain loss after electrochemical aging in fuel cell membrane electrode assemblies leading to catalyst activity losses.

Scale up of Advanced Fuel Cell Catalysts

A recently discovered Pt₃Ni(111) catalyst exhibits 90-fold improvement of catalytic activity compared to commercial Pt/C catalyst toward oxygen reduction reaction (ORR). Following this exciting development a variety of Pt alloy nanostructures with controlled size, morphology, composition, and surface arrangements have been synthesized using wet chemistry methods. Significant performance improvement has been observed in rotating disk electrode (RDE) measurements for many of the new materials. However, their performance in membrane electrode assembly (MEA) have been rarely tested because of the difficulty of producing larger quantity of uniform, high quality nanoparticles. One of Argonne’s Materials Engineering Research Facility (MERF) programs is devoted to investigate the chemistry and processes that govern the reproducibility and scalability of nanomaterials synthesis. The aim of this program is to develop scalable processes for making large quantity of materials without sacrificing performance and to eliminate batch-to-batch variation in order to accelerate the transition of new discoveries from lab to industrial applications. In this presentation, I will talk about our recent efforts in scaling up advanced fuel cell catalysts. A multi-layer Pt-skinned PtNi nanoparticles have been successfully scaled up from tens of milligrams to several grams per batch with improved ORR activity in RDE measurement which is a 10-fold improvement over commercial Pt/C catalyst. The material was synthesized in a sufficient amount to enable MEA tests to be carried out. The results revealed significant performance improvements compared to commercial Pt/C catalyst. Our recent effort to remove restraints associated with batch processes lead us to develop a continuous flow synthesis platform. Our approach to gain fundamental understanding of the particle formation mechanism in microfluidic reactors will also be discussed.
Light-Weight 3D Co-N-Doping Hollow Carbon Spheres as Efficient Electrocatalyst for Rechargeable Zinc-Air Battery  Shengmei Chen; City University of Hong Kong, Hong Kong, Hong Kong.

Rational design of cost-effective, nonprecious metal-based catalysts with desirable oxygen reduction reaction (ORR) performance by simple and economic synthesis route is a great challenge for future fuel cell and metal air batteries commercialization. Herein, the light-weight 3D Co-N-doped hollow carbon spheres (Co-NHCSs) has been fabricated via a facile emulsion approach followed by carbonization. The prepared 0.1-Co-NHCS catalyst with suitable Co doping content exhibits favorable ORR catalytic activity (onset potential of 0.99 V and half-wave potential of 0.81 V vs. RHE), comparable to that of the commercial Pt-C (onset potential of 1.02 V and half-wave potential of 0.83 V vs. RHE) and rivals that of Pt-C with better cycling stability. The excellent performance of the catalyst is attributed to the synergetic effect of Co and N doping with high total ratio of active sites, high surface area and good conductivity of the material. More impressively, the assembled rechargeable zinc-air batteries based on the 0.1-Co-NHCS catalyst outperforms those afforded by commercial Pt-C. The progress represented by this reported work is of great importance in the development of outstanding non-noble metal based electrocatalyst for the fuel cell and metal air battery industry.

ET03.12.02 Hierarchical SbMoO6 Hollow Microspheres with Distinctive Capability of Self-Constructing Conductive Buffer Matrix for Sodium-Ion Batteries Xuan Lu1, 2; Hongkang Wang1 and Weiyang Li2; 1Electrical Engineering, Xian Jiaotong University, Xi'an, China; 2Thayer School of Engineering, Dartmouth College, Hanover, New Hampshire, United States.

In order to solve the capacity degradation problem caused by the severe volume expansion in alloy-type Sb anode materials, we report a simple and efficient microwave-assisted hydrothermal method of hierarchical Sb\textsubscript{6}Mo\textsubscript{2}O\textsubscript{6} hollow microspheres (denoted as h-SMO-hms) assembled by one-dimensional (1D) nanobelts without use of any surfactants, as well as a special conductive Na\textsubscript{10}Mo\textsubscript{5}O\textsubscript{26}, NaMoO\textsubscript{4} buffer matrix is firstly proposed. When used as an anode material for sodium-ion batteries (SIBs), it delivers large reversible discharge capacities of ~637.3~/~498.7 mA h/g at current densities of 200/1000 mA/g after 100 cycles, respectively, and an exceptional rate capability with ~429.1 mA h/g retained at 5A/g. By means of ex-situ XRD, XPS, (HR)TEM, STEM-EDS mappings and results of the first-principles calculations, such superior electrochemical performances can be attributed to their distinctive capability of self-constructing conductive Na\textsubscript{10}Mo\textsubscript{5}O\textsubscript{26}, NaMoO\textsubscript{4} buffer matrix during the discharge/charge process, which not only efficiently buffer the volume expansion of the Na-Sb alloying-dealloying upon cycling, but also provide good electronic conductivity to facilitate electron transfer. More importantly, the novel Sb\textsubscript{6}MoO\textsubscript{26} anode materials can achieve excellent electrochemical behaviors without the need to hybridize with any carbonaceous materials (ex. carbon nanotubes, graphene and carbon nanofibers) in contrast to those of Sb-C composites. This kind of materials may offer new strategies for researchers to design high-performance energy storage devices.

ET03.12.03 Single-Site Active Iron-Based Bi-Functional Oxygen Catalyst for a Compressible and Rechargeable Zinc-Air Battery Longtao Ma; Department of Materials Science and Engineering, City University of Hong Kong, Hong Kong, Hong Kong.

With the ever-increasing energy demands for portable electronic equipment, numerous researches have been done to develop related functional (e.g., stretchable, compressible, bendable/flexible, self-healing) electrochemical energy storage and conversion devices. Zinc-air battery, which is typically comprised of air electrode containing a catalyst painted on gas diffusion layer, alkaline electrolyte and metallic zinc electrode to provide a high theoretical energy density (1370 Wh/Kg), is a promising energy storage appliance for next-generation portable electronics. For rechargeable zinc-air battery, a high-efficient, low-cost and stable non-noble metal-based catalyst with oxygen reduction reaction (ORR) and oxygen evolution reaction (OER) simultaneously, as air electrode material is significantly crucial. Moreover, the compressible flexibility of a battery is the prerequisite of wearable or/and portable electronics.

Herein, we present a strategy via single-site dispersing Fe-N\textsubscript{x} species on a two dimensional (2D) highly-graphitic porous nitrogen-doped carbon layer to implement superior catalytic activity toward ORR/OER (with a half-wave potential of 0.86 V for ORR and an over-potential of 390 mV at 10 mA/cm\textsuperscript{2}} for OER) in alkaline medium. Furthermore, an elastic polyacrylamide (PAM) hydrogel based electrolyte with the capability to retain great elasticity even under highly corrosive alkaline environment, is utilized to develop a solid-state compressible and rechargeable zinc-air battery. The creatively developed battery performs a low charge-discharge voltage gap (0.78 V at 5 mA/cm\textsuperscript{2}) and large power density (118 mW/cm\textsuperscript{2}) largely and bended up to 90° without charge/discharge performance and output power degradation. Our results reveal that single-site dispersing catalytic active sites on porous support for bi-functional oxygen catalyst as cathode integrating specially designed elastic electrolyte are feasible strategies for fabricating efficient compressible and rechargeable zinc-air batteries, which could enlighten the design and development of other functional electronic devices.

ET03.12.04 Silicon Nanoparticles in Lithium-Ion Batteries—Influence of Size and Morphology Samson Y. Lai1, Thomas J. Prestor2, Hallgeir Klette2, Trygve T. Mongstad2, Jan Petter Mehlen2 and Alexey Y. Koposov2; 1Neutron Materials Characterization Department, Institut For Energiteknikk, Kjeller, Norway; 2Battery Technology Department, Institutt For Energiteknikk, Kjeller, Norway.

Silicon as a negative electrode material attracts significant research and development attention for next-generation lithium-ion batteries (LIBs). To counteract the high volume expansion associated with lithiation, silicon nanoparticles are materials designed to extend cycle life. However, silicon nanoparticles can be synthesized using different routes that result in variations in particle size, size distribution, and morphology, which then influence the overall electrochemical performance. The optimal size of the particles is still disputed in the literature. Correlating morphology and size with battery properties is needed to apply the diverse knowledge of these different approaches toward understandable behavior of silicon nanoparticles in LIBs.

In the present work, we examine silicon nanoparticles synthesized by pyrolysis of silane gas and correlate morphological characteristics with battery performance. We demonstrate that temperature and silane concentration during synthesis influence the size and morphology of the silicon nanoparticles. For example, relatively low temperatures typically produce a mixture of small and large round particles with smooth surfaces while relatively high temperatures produce particles with rougher surfaces with a narrower size distribution. These differences are correlated to crack formation and propagation in the electrode during formation cycles, as evidenced by post-mortem analysis. Furthermore, although charge-discharge capacities and Coulombic efficiencies of half cells made with these particles are initially high, the degradation rate of particles with rougher surfaces is noticeably worse, suggesting a synergistic mechanism in action. Thus, although nanoparticle smaller than a widely cited 200 nm size may resist cracking individually, the size and morphology of the nanoparticles appears to influence macro-scale crack formation in the electrode and consequently, electrochemical performance. As silicon nanostructures become more defined and controlled through synthesis, understanding the relationship between structure and properties of silicon nanoparticles is important in order to take full advantage of this promising approach in LIBs.

ET03.12.05 LiNi0.5Mn0.3Co0.2O2/Au Nanocomposite Thin-Film Cathode with Enhanced Electrochemical Properties Zhimin Qi1, Jie Jian1, Jijie Huang1, Jialiang

University of Hong Kong, Hong Kong, Hong Kong.

Efficient microwave-assisted hydrothermal method of hierarchical Sb\textsubscript{6}Mo\textsubscript{2}O\textsubscript{6} hollow microspheres (denoted as h-SMO-hms) assembled by one-dimensional (1D) nanobelts without use of any surfactants, as well as a special conductive Na\textsubscript{10}Mo\textsubscript{5}O\textsubscript{26}, NaMoO\textsubscript{4} buffer matrix is firstly proposed. When used as an anode material for sodium-ion batteries (SIBs), it delivers large reversible discharge capacities of ~637.3~/~498.7 mA h/g at current densities of 200/1000 mA/g after 100 cycles, respectively, and an exceptional rate capability with ~429.1 mA h/g retained at 5A/g. By means of ex-situ XRD, XPS, (HR)TEM, STEM-EDS mappings and results of the first-principles calculations, such superior electrochemical performances can be attributed to their distinctive capability of self-constructing conductive Na\textsubscript{10}Mo\textsubscript{5}O\textsubscript{26}, NaMoO\textsubscript{4} buffer matrix during the discharge/charge process, which not only efficiently buffer the volume expansion of the Na-Sb alloying-dealloying upon cycling, but also provide good electronic conductivity to facilitate electron transfer. More importantly, the novel Sb\textsubscript{6}MoO\textsubscript{26} anode materials can achieve excellent electrochemical behaviors without the need to hybridize with any carbonaceous materials (ex. carbon nanotubes, graphene and carbon nanofibers) in contrast to those of Sb-C composites. This kind of materials may offer new strategies for researchers to design high-performance energy storage devices.
Silicon (Si) is regarded as a most promising anode material because of its high energy density, the earth-abundant, and low toxic nature. However, the electrochemical reversibility of Si degrades upon cycling; mainly due to huge volume changes and crack formation during lithiation and delithiation.

Recent work has investigated the cracking formation mechanism and the impact of capping layer on the mechanical deformation behavior. Here, we will demonstrate the agreement between experiments and simulation.

Li(Ni0.5Mn0.3Co0.2)O2 (NMC) is considered as one of the most promising cathode materials for Li-ion batteries. Highly textured LiNi0.5Mn0.3Co0.2O2 (NMC532) thin films with well dispersed Au nanoparticles (~5 nm in average diameter) were deposited by pulsed laser deposition. Microstructure studies reveal the epitaxial nature of the Au nanoparticles and NMC matrix, and their lattice matching relationships. The Au nanoparticles are uniformly distributed and form faceted interfaces with NMC matrix. NMC with 2 at.% Au shows the highest volumetric capacity, best initial columbic efficiency, highest cycling performance, best rate capability and highest capacity retention among all the samples, due to alteration of chemical environment of transition metal while keeping high crystallinity. Moreover, the electrochemical impedance spectroscopy shows that the incorporation of the Au nanoparticles also reduces charge transfer resistance compared to the pure NMC. The results suggest that appropriate Au nanoparticle incorporation enhances the volumetric capacity and promotes the charge transfer process, and thus could lead to enhanced battery performance.[1]

ET03.12.06
The Initial Stages of Polaron Formation in Energy Materials Shuaishuai Yuan, Zi Wang and Kirk H. Bevan; McGill University, Montreal, Quebec, Canada.

Polaron transport severely limits the conduction properties of most transition metal oxides utilized electrochemical energy storage and conversion applications. Thus, to improve the charge performance of such energy devices, it is essential to delve more deeply and understand the fundamental stages of polaron formation. To this end, we have conducted extensive first-principles studies of polaron evolution in the peroxide family of materials: lithium peroxide (Li2O2), sodium peroxide (Na2O2) and potassium peroxide (K2O2). Our analysis points to competing lattice and electronic realization phenomena driving the rapid localization of polarons very early on in the relaxation process. They also indicate that the formation of polarons may be mitigated by suitably engineering the electronic structure response to lattice distortions, through a delayed electronic relaxation mechanism. Overall, these results point towards a systematic bottom-up approach for engineering the conductivity and overall electrochemical rate performance of metal oxide energy materials.

ET03.12.07
Novel Application of Magnetite Nanospheres as Supercapacitors—Synthesis, Magnetic, and Electrocapactive Study Dipesh Neupane, Deepa Guragain, Sanjay R Mishra and Ram Gupta; Pittsburg State University, Pittsburg, Kansas, United States.

Among various morphologies of nanomaterials, hollow spheres are of great interest because of their high ratio of surface to volume, large pore volume and low density, which could be exploited for applications in controlled encapsulation-release of drugs and medical diagnostic, energy storage and conversion, photocatalysis, chemical sensors, and photonic crystals. In the context of magnetism, magnetic hollow spheres can show unique physical properties compared to those of flat thin films and their solid counterparts of the same sizes, due to their confined hollow geometry and curved surfaces. It is known, that coercivity is dependent on domain-wall motion and the barrier to domain-wall propagation along a curved surface is larger than that of a flat surface. Due to growing application of nanoscale magnetic hollow spheres in biomedical and energy fields it remains important to understand the influence of growth parameters to prepare Fe3O4 with highly homogeneous features in terms of size and shape.

In this work, effect of hydrolyzing agents such as urea, ammonium bicarbonate (ABC), dodecylamine (DDA) on morphology, size and electrochemical activity of Fe3O4 nanospheres was investigated. For comparison, Fe3O4 nanospheres were also synthesized without hydrolyzing agent. The structural and morphological assessment of the synthesized Fe3O4 nanopowder was performed using x-ray diffraction, scanning electron microscopy and surface area analysis. The room temperature magnetic properties were studied via vibrating sample magnetometer. The scanning electron microscopy images showed nanospheres of Fe3O4 with a range of sizes (150-330 nm) which depend on hydrolyzing agents used. All the synthesized samples were crystalline in structure with distinct signature of maghemite phase. The surface area analysis indicated that these particles were mesoporous in nature. VSM measurement show that Fe3O4 prepared via hydrolyzing agent display high magnetization ~85 emu/g with average coercivity in the range of 150 Oe. Different hydrolyzing agents were observed to have minimum influence on the magnetic property of Fe3O4 hollow spheres. Electrochemical characteristics were investigated using cyclic voltammetry and galvanostatic measurements. Cyclic voltammetry measurements were performed in three different electrolytes viz. KOH, NaOH, and LiOH and observed that specific capacitance of the synthesized Fe3O4 depend on electrolyte used. Relatively high specific capacitance of 173.8 F/g was observed for Fe3O4 prepared using DDA in 3M KOH electrolyte. Fe3O4-DDA also showed excellent cyclic stability as well, retaining 107% of specific capacitance value at up to 5,000 cycles measured. The study clearly elucidates the effect of hydrolyzing agent on physical and morphological properties of Fe3O4. In addition, through electrochemical testing the study illustrates the choice of aqueous electrolyte in optimizing the electrocapactive performance of Fe3O4 nanospheres.

ET03.12.08
Population Dynamics of Driven Reactive Mixtures Applied to Li-Ion Battery Electrodes Hongbo Zhao and Martin Bazant; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Li-ion batteries manifest intriguing asymmetric autocatalytic or autoinhibitory reaction kinetics during charge or discharge through experimental techniques such as X-ray imaging or diffraction performed on lithium iron phosphate and LiNi0.5Mn0.3Co0.2O2 (NMC). We use a population-dynamics approach to model such asymmetry, as the phenomenon arises from an assemble of particles that consist of the electrode. We study the collective dynamics of such systems with thermodynamically consistent nonequilibrium kinetics. When chemical driven, autocatalytic or autoinhibitory reactions lead to broadening or narrowing of the population distribution in terms of the state of subsystems compared to the intrinsic variance due to thermodynamic fluctuations and system noises. As an application, we obtain the inherent reaction kinetics from XRD and electrochemical experiments performed on NMC and demonstrate the agreement between experiments and simulation.

ET03.12.09
Current Density Dependency of Crack Formation in Si Wafer Electrode Taeho Yoon, Chuanshiao Xiao, Jun Liu, Seoung-Bum Son and Chunmei Ban; National Renewal Energy Laboratory, Lakewood, Colorado, United States.

Silicon (Si) is regarded as a most promising anode material because of its high energy density, the earth-abundant, and low toxic nature. However, the electrochemical reversibility of Si degrades upon cycling; mainly due to huge volume changes and crack formation during lithiation and delithiation.

Recent work has investigated the cracking formation mechanism and the impact of capping layer on the mechanical deformation behavior. Here, we will...
focus on the effects of current density on crack formations and propagation. The information from this research is essential to develop high-capacity and high-power Si electrode materials for high-performance lithium-ion batteries. Si (0.1 μm wafer) has been used as a model electrode to establish a systematic understanding of cracking behavior as a function of lithiation/delithiation rate. Moreover, the internal strain energy developed at the high current density and the strategies to mitigate cracking formation and propagation will be discussed in this work.

ET03.12.10 Effect of Graphene Oxide on Electrochemical Behavior of MnO2 Super capacitor Rahul Singhal1, Justin Fagnoni2, David Thorne1 and Mani Maniannthanavan2; 1Central Connecticut State University, New Britain, Connecticut, United States; 2Global Pragmatic Materials, Morgantown, Virginia, United States.

Super-capacitors have received a lot of attention due to their high-power performance, long cycle life, and low maintenance, for applications in hybrid electric vehicles, portable electronic devices, and power back-up devices [1-3]. Various researchers studied MnO2 cathode materials for application in electrochemical capacitors, because of its low cost and natural abundance [2, 3]. However, MnO2 has limited electrochemical performance because of its poor conductivity and low surface area. To improve the electrochemical performances of MnO2, we have synthesized MnO2/graphene oxide (GO) nanocomposite with varying concentration of GO (0.4 mg/ml and 0.8 mg/ml).

GO/MnO2 nanocomposite was synthesized by adding KMnO4 in a solution of water and ethanol (3:1), containing desired amount of GO. The brown precipitates were obtained after a continuous stirring for 1 hr. The precipitate was washed and dried to obtain the GO/MnO2 nanocomposites. The electrodes were prepared by spreading a slurry of GO/MnO2 powder, carbon black, PTFE binder (80:15:5 weight ratio) onto Ni mesh. The electrochemical characterizations were carried out in an aqueous solution of 1M Na2SO4. The charge discharge studies were carried out between 100 mA/g to 5A/g current range. The discharge capacities were found to be 227 F/g and 90 F/g at a current of 100 mA/g and 5A/g, respectively for 0.4 mg/ml GO. These results will be presented and discussed at the meeting.

ET03.12.11 Sub-5 nm Graphene Oxide Nanofilm with Exceptionally High H+/V Selectivity for Vanadium Redox Flow Battery Seul Chan Park, Moon G. Hyoen, ByungSu Kim and Yong Soo Kang; Energy Engineering, Hanyang University, Seoul, Korea (the Republic of).

Highly H+/V selective membranes are desirable in high-performance vanadium redox flow batteries (VRFBs) to overcome the cross-over phenomena of vanadium species. Herein, we first demonstrated that the molecular-sieving nanochannels (~0.84 nm) formed inside a graphene oxide (GO) laminate (~5 μm) efficiently blocked the transport of vanadium ions, while allowing the transport of H+. Furthermore, a ultrathin (sub-5 nm) and highly-selective GO nanofilm was successfully coated on a porous substrate to increase the H+ flux using a facile spin-coating method. The GO-coated thin-film composite (TFC) membrane showed much higher H+ flux, along with an exceptionally high H+/V selectivity (up to 850), due to the molecular-sieving nanochannels inside the GO nanofilm, leading to a much more enhanced VRFB performance in terms of the energy efficiency (EE: ~84%), compared to the benchmark Nafion membrane (EE: 69.2%). The GO-coated thin-film composite membrane was successfully coated on a porous substrate to increase the H+ flux using a facile spin-coating method. The GO-coated thin-film composite (TFC) membrane showed much higher H+ flux, along with an exceptionally high H+/V selectivity (up to 850), due to the molecular-sieving nanochannels inside the GO nanofilm, leading to a much more enhanced VRFB performance in terms of the energy efficiency (EE: ~84%), compared to the benchmark Nafion membrane (EE: 69.2%).

ET03.12.12 Lattice Strain and Phase Transition Induced by Li Migration in Cyclic NCM111 (LiNi0.5Co0.2Mn0.3O2) Young-Woon Byeon1, 2, Jun-Dong Kim1 and Jaeyoung Ahn1; 1Advanced Analysis Center, Korea Institute of Science and Technology, Seoul, Korea (the Republic of); 2Matier Science and Engineering, Korea University, Seoul, Korea, (the Republic of).

The phase transformation of LiNi0.5Co0.2Mn0.3O2 (NMC) cathode materials during charging and discharging Li-ion batteries was evaluated by lattice strain measured by nano-beam diffraction (NBD) equipped in transmission electron microscopy (TEM). Here we propose a relationship between lattice strain determined by Li contents and phase transition. When Li site in NCM lattice was emptied below 1% by the delithiation during charging, the surface of NCM particles has high strain over 3% and the correlated phase transition also occurred from rhombohedral to spinel structure. The continued Li release in NCM led to the expansion of the spinel region from surface. Most of the strain and phase transition occurred near the side planes of NCM, not prism planes. On the Li insertion during discharging, on the other hand, the lattice strain of NCM recovered up to the level, below 0.8%, of pristine NCM due to the reverse phase transition from spinel to rhombohedral structure. However, NCM that had cycled under the harsh condition of 60 cycles at 60°C showed irreversible phase transition to rhombohedral phase, which acted as a reason of a direct degradation. We propose a design rule that can prevent the capacity decrease of batteries by clarifying the relationship between the lattice strain and phase transition, which act as a direct cause of the deterioration phenomenon of NCM.

ET03.12.13 Fabrication and Characterization of the Microporous Foam Thick Electrodes Based on LiFePO4/Carbon Nanotube Composites Tawaddod S. Alkindi, 1Rahmat Susantyoko1, Saif Al Mheiri1, Daniel Choi1, Sultan N. Al Dahmani1 and Hamed Fadad1, 1Khalifa University of Science, Technology and Research, Abu Dhabi, United Arab Emirates; 2United Arab Emirates Space Agency, Abu Dhabi, United Arab Emirates.

Although Li-ion batteries are very promising, their areal capacity is quite low (2.09 mAh cm-2 for conventional LiFePO4 on aluminum foil). The aim of this work is to create CNT/LiFePO4 composite thick cathode via Freeze-casting method to enhance the areal capacity of LiFePO4 cathode. The CNTs form electrically conductive networks that also result in enhancing the charge transport of Li-ions. Conventional Li-ion batteries consist of multiple stacks of electrodes with aluminum and copper separator between them. This cell configuration increases the size of the battery, which increases battery weight, waste of the material, thus, yields to high cost. Using thick electrodes that will provide a favorable electrode to current collector ratio per stack volume, will increase the interface area between electrode and electrolyte, and fewer cutting and stapling steps. However, mechanical stability is a main challenge in thick electrodes that are synthesized by this method. Various amount of polyvinylidene difluoride (PVDF) additives is added to the CNT/LiFePO4 mixture to study their effect on the mechanical stability along with the battery performance. After determining the optimum thickness and composition, batteries with thick electrodes will be assembled and characterized (CV, charge-discharge, EIS) using battery tester and potentialstat/galvanostat. Investigation of the multi-layered CNT/LiFePO4 sheets by scanning electron microscopy, Raman scattering spectroscopy and X-ray diffraction is also in progress. Preliminary result shows 125 mAh g-1 for 3.14 mm thickness cathode of CNT/LiFePO4/PVDF (3% PVDF) which is very close to that from the conventional 2.03 mm thick conventional CNT/LiFePO4 electrode (0% PVDF). Mechanical compression results show that we can sacrifice the small decrease in specific capacity for the enhancement in the mechanical stability where CNT/LiFePO4/PVDF (3% PVDF) exhibited stress values of 0.83752
MPa, while CNT/LiFePO4 electrode (0% PVDF) exhibited a value of 0.05685036 MPa. Further increased thicknesses of electrodes with improved mechanical and thermal properties are to be pursued in future work. Such thick CNT/LiFePO4 electrodes are very promising candidate for applications which is very sensitive to weight but not sensitive to size, such as space applications and electrical truck/bus.

ET03.12.14

The electrochemical reduction of oxygen is a critical process for many energy storage and conversion technologies including metal-air batteries and fuel cells. For these technologies, the energy output is proportional to the oxygen reduction reaction (ORR) potential. Although the theoretical potential of the ORR reaction in alkaline media is 0.3 volts vs. Hg/HgO, most electrodes are far below 0.3 volts vs. Hg/HgO due to the slow ORR kinetics. In this abstract, we use surfactant-modified dealloying to synthesize (100) rich nanoporous gold (100-np-Au) electrodes which increased the ORR potential from -0.01 to 0.18 V vs. Hg/HgO when compared to nanoporous Au (np-Au) synthesized without surfactant. The 100-np-Au had a higher reduction potential than conventional np-Au because Au (100) is the most active ORR facet of gold in alkaline solution. Density functional theory simulations show that Au (100) activity exceeds platinum in alkaline solution.1 We observe a similar trend experimentally as the 100-np-Au electrodes (2.1 mg/cm2) had a 2.8% improved ORR potential vs. Hg/HgO when compared to nanoporous gold Au (np-Au) synthesized without surfactant. The 100-np-Au had a higher reduction potential than conventional np-Au because Au (100) is the most active ORR facet of gold in alkaline solution.1

The ORR potential vs. Hg/HgO compared to high performance commercial platinum coated electrodes with double the mass loading density (4 mg/cm²). When integrated into aluminum-air batteries, the 2.1 mg/cm² 100-np-Au increased the cell energy density to 4256 mWh/g-AI compared to 3575 mWh/g-AI for 2.1 mg/cm² np-Au and 4060 mWh/g-AI for 4mg/cm² Pt/C cathodes by improving both the extracted capacity, through improved activity, and output voltage. The 100-np-Au Al-air battery achieved a 2800 mAh/g capacity at 50 mA/cm² and a peak power density of 176 mW/cm². We synthesized 100-np-Au by adding sodium citrate to a nitric acid dealloying bath. The stronger binding energy between the citrate ligand and Au (100) surface reduced the (100) facets. This technique could be extended to the design and synthesis of various nanoporous catalysts with specific facets for energy storage and conversion.

Vertically Integrated Method For The Development of Nano-Structured Electrodes for Flow Battery Application Eugenio Rovera1,2, Francesco Funagalli1, Matteo Zago1, Andrea Casalegno1 and Fabio Di Fonzo1,2; CNST@Polimi, Milano, Italy; 2Energy, Politecnico di Milano, Milan, Italy.

Hollow particles are regarded as a class of promising anode materials for lithium-ion batteries since they benefit from their shorter Li-ion and electron diffusion paths, an increased amount of electrochemically active sites created by more electrode/electrolyte interfaces, and the ability to better accommodate the strain induced by volume changes during cycling. In this work, we developed a facile and low-cost process for fabricating hierarchical hollow and dense submicrospheres assembled from SnS nanosheets and protected with a uniform layer of nitrogen-doped carbon. In the synthesis, oleic acid is utilized to form micro-droplets in ethylene glycol as soft templates. We found that by manipulating the precursor concentration and the number of template droplets, the nuclei process is confined to take place either inside the droplet or merely on the surface, leading either to dense or hollow particles. High-resolution transmission electron microscopy showed that the particles are built up by nanosheets with 4-6 atomic layers, wrapped in a uniform carbon shell of 4-5 nm. By using focus ion beam technique, we cut the particles and observe the cross-section by scanning electron microscopy, confirming that the desired morphologies are obtained. The fact that the two hierarchical particles with the same composition and building block dimension only differ in the internal morphology, we got a good opportunity to show the electrochemical merits from the hollow structure. The lithium-ion storage capacities of the hollow and dense spheres were tested and compared as anodes in lithium-ion battery half cells. The hollow microspheres showed low internal charge transfer resistance, good buffering of volume changes during lithiation and delithiation and good rate and cycling performance. After 1000 cycles, the hollow SnS composite still delivered a capacity of 420 mAh g⁻¹ at 1.0 A/g, which is 2.5 times higher than that of the dense spheres. The capacity retention from the second cycle on was 84% and 75%, respectively. Due to the enhanced overall electrical conductivity from the carbon shell and the hierarchical hollow structure, 40% to 70% capacities are contributed from pseudocapacitive behaviors at different cyclic voltammetry scan rates, explaining the good

ET03.12.17  Enhanced Cycling Stability of Macroporous Bulk Antimony-Based Sodium-Ion Battery Anodes Enabled through Active/Inactive Composites

Olivia Ruiz, Mark Cochrane, Yan Yan, Ke Ma, Jintao Fu, Sarah Tolbert, Vivek Shenoy and Eric Detsi

Engineering approaches based on ‘nanostructuring’ and ‘active/inactive composites’ have been used to improve the performance of alkali-ion battery electrodes. In this talk it will be shown that a combination of both approaches yields an anode material with high cycle life. Specifically, we show that the use of a macroporous Sb/MgF2 active/inactive composite material creates a high-performance Na-ion battery anode. This composite consists of a porous Sb phase as the electrochemically active component, with pore size in the sub-micrometer range, and a dense MgF2 phase as the electrochemically inactive component. This high performance is attributed to the "porous active/inactive" configuration. In such a configuration the dense inactive phase absorbs a part of the phase transformation-induced stresses, while porosity in the active phase helps to accommodate part of the phase transformation-induced volume expansions generated in this active phase. Porosity is also expected to help facilitate the electrolyte transfer into the bulk of this composite. This new strategy could be used to improve the performance of high-capacity materials for next generation alkali-ion battery anodes [1, 2].

ET03.12.18  Influence of the Carbon Material Structure on the MoS2 Charge Storage Mechanism

Basant A. Ali, Ossama I. Metwali, Asmaa M. Omar, Ahmed S. Khalil and Nagham K. Alamm

Developing materials for energy storage that can maintain both high energy density and high power density is becoming a mandatory demand in our modern society. Supercapacitors can store energy in the electrical double layer (EDL), especially when carbon-based materials are used that store energy in the form of accumulated ions at their surfaces. The other mechanism of charge storage is the pseudocapacitors “faradic materials” in which the material undergoes redox reaction. In order to benefit from both the faradic materials and the carbon materials, hybrid materials are usually used. However, the charge storage and delivery mechanisms are not very well understood for those hybrid materials. MoS2 has proved to be a good material that undergoes both redox and EDL capacitance mechanisms. Unfortunately, the 2H semiconductor phase of the MoS2 has a low capacitance but much more stable than the 1T conductor phase.

In this study, flower-shaped MoS2 was mixed with two different structures of carbon materials in different ratios in order to investigate the effect of the shape of the carbon material and its amount on the charge storage mechanism and the energy density, power density and capacitance. Our results showed that mixing MoS2 with graphene nanoflakes (GNF) or 8 nm-diameter carbon nanotubes (CNT) increased the capacitance linearly with increasing their amount. However, CNT showed higher capacitance than the GNF mixtures. A mixture of equal weights of MoS2, CNT and GNF (MCG) showed the highest capacitance among all mixtures and increased the capacitance of the MoS2 by 111%. The small diameter of the CNT allowed to interfere with the flower shaped MoS2 and surround it from outside and inside. On the other hand, the GNF sandwiched the MoS2 flowers between its layers. These different shapes of the carbon material affected the mechanism of charge storage and the origin of capacitance. From Tafel plots, all the materials studied originate current due to electric faradic mechanism. The contribution of current to the faradic mechanism was larger for the MoS2 alone and with increasing the ratio of carbon materials, the contribution of current towards the EDL mechanism increased. The contribution of current towards the EDL changed from 11.2 % to 28 % in the MoS2 and the MCG mixture, respectively. For the capacitance value origin, it was found that more than 98% of the capacitance of the studied materials was diffusion controlled and the carbon materials enhanced the diffusion capacitance of the MoS2 up to 97.8%.

8:15 AM ET03.13.01  Metallic Carbon and Its Applications in Lithium-Ion Batteries

Qian Wang; Peking University, Beijing, China.

Due to the special electronic configuration, small atomic size and flexible bonding features, carbon exhibits many phases with very different physical and chemical properties. In this talk, I will focus my discussion on our recently identified metallic carbon phases, including 3D metallic T6-C4, Hex-C182 and a 2D metallic ψ-graphene2, and their applications as potential anode materials in lithium-ion batteries (LIBs). These new carbon allotropes are not only dynamically, thermally and mechanically stable, but also metallic. Due to their unique atomic configurations and metallicity, they provide the basis for the storage and transportation of Li ions with good conductivity. For instance, Hex-C18 exhibits exceptional properties such as a large heat capacity, high Debye stiffness, and anisotropic elasticity, while ψ-graphene shows robust metallicity against external strain during the adsorption of Li-ions. We demonstrated that both Hex-C18 and ψ-graphene have promising applications as effective anode materials in LIBs.

Novel Design of Hollow \(g\)-C\(_3\)N\(_4\) Nanofibers Decorated with MoS\(_2\) and S, N-Doped Graphene for Stable Electrochemical Hydrogen Evolution Reaction
Suhee Kang, Joonyoung Jang and Caroline S. Lee; Hanyang University, Ansan, Korea (the Republic of).

Recently, depletion of fossil fuels and contamination of environmental issues leading to the energy crisis is making renewable energy productions extremely important. Among the sustainable energy, hydrogen is considered as one of the most important alternative fuel and the ways to obtain this gas have been widely studied during the past few years. Many catalysts have been developed for hydrogen production but still, its activity is limited owing to wide band gap energy and long-term stability problems. Therefore, electrocatalysts should be proposed to design innovative structures with superior performance.

Graphitic carbon nitride (g-C\(_3\)N\(_4\)), a non-metallic semiconductor having a bandgap of 2.6 eV, has been attracting much attention due to its easiness to manufacture as well as its environmentally benign and high thermal stability. However, g-C\(_3\)N\(_4\) suffers from high recombination rate of charge carriers and low surface area. To overcome these drawbacks, one-dimensional (1-D) structured nanofiber can be considered to be an effective accelerator of the electrons as well as separators of the electron-hole pairs. Moreover, decorated MoS\(_2\) onto g-C\(_3\)N\(_4\) nanofibers can be properly matched to band levels and accelerate the electron pathways. Sulfur/nitrogen-doped graphene (SNG) is again applied onto g-C\(_3\)N\(_4\)/MoS\(_2\) nanostuctures to improve charge transportation by increasing its entire surface area. In the present work, hollow g-C\(_3\)N\(_4\) nanofibers (HGCNF) were prepared by electrospinning followed by thermal condensation methods. The prepared hollow g-C\(_3\)N\(_4\) nanofibers decorated with MoS\(_2\)/SNG are synthesized in-situ by a hydrothermal process at relatively low temperature. The morphologies by SEM and TEM analysis were used to characterize this fabricated sample. XPS analysis was measured to distinguish its chemical compositions according to their properties. Finally, HGCNF/SNG/MoS\(_2\) showed the lowest Tafel slope of 83 mV/dec as well as the lowest impedance value among those of all prepared samples. This structures also showed the lowest overpotential of 282 mV at 10 mA/cm\(^2\) from hydrogen evolution reaction among all prepared samples with stable current density at applied potential under 48 hours. Therefore, the optimized heterostructures were proven to be efficient electrocatalytic materials which can be applied to various fields including CO\(_2\) reduction, artificial photosynthesis, solar cell, bio-application and Li-ion battery cell.

Nanostructured Conjugated Polymers as Promising Electrodes for Li-Ion Batteries
Qichun Zhang; Nanyang Tech University, Singapore, Singapore.

Electrode materials play a critical role in approaching high energy density and long cycle life lithium-ion batteries (LIBs). The increasing concern about the traditional inorganic electrode materials on resources and environmental issues has strongly inspired scientists to switch on searching green energy electrodes. Organic compounds are potentially sustainable and renewable materials as many of them can be obtained from natural products and biomass. Additionally, the properties of organic compounds can be tuned through the modification of the structures as well as the introduction of functional groups. In this talk, I will present our recent progress on the preparation of novel conjugated polymers and their application in Li-ion batteries.

9:15 AM ET03.13.04
Measuring Surface Phonon Vibrations on the (010) Surface of LiFePO\(_4\) Platelet Particles
Peter Benedek¹, Nuri Yazdani¹, Hungru Chen², Nils Wenzler¹, Fanni Juranyi³, Martin Månsson⁴, Saiful Islam⁴ and Vanessa Wood⁴; ¹ETH Zürich, Zürich, Switzerland, ²University of Bath, Bath, United Kingdom; ³Paul Scherrer Institut, Villigen, Switzerland; ⁴Royal Institute of Technology, Stockholm, Sweden.

LiFePO\(_4\) (LFP) is a commercial cathode material often used for high power applications. Typically, nanoparticles of LFP are used due to the shorter path-length for lithium ions in the [010] transport direction. However, since nanoparticles have a large surface area to volume ratio compared to larger micron-sized particles, the question of how the surface influences ion diffusion and transfer becomes relevant. Here, we report on how surface vibrational modes at the surface of LFP differ from those in the bulk of the LFP particle and how different surface treatments change the vibrational structure at the surface of LFP. To systematically measure the influence of surface, we prepare platelet-shaped LFP particles of different sizes, where the number of atoms at the (010) surface changes from less than 1% of the total number of atoms in the particle to more than 10%. On these different samples, we measure the phonon density of states via inelastic neutron scattering (INS) and find that Li-O bond changes at the (010) surface. Combining our technique with other analytical techniques such as FTIR and XRD as well as density functional theory (DFT) simulations, we find that carbon coating, for example, can be used to influence the Li-O bonding at the LFP surface.

Mesoscopic Phase Transition Kinetics in Secondary Particles of Battery Electrode Materials
Kai Xiang², Kaiqi Yang¹, Craig Carter², Ming Tang¹ and Yet-Ming Chiang²; ¹Rice University, Houston, Texas, United States; ²Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Many battery compounds undergo first-order phase transformations upon composition swing during charge and discharge. While such phase transformations are often studied using single crystalline particles as model systems, real battery electrodes are typically composed of mesoscopic assemblies of nanocrystallites, of which the phase transformation behavior is still not well understood. Here we report systematic measurements of the phase transition kinetics under potentiostatic conditions in secondary particles of several representative intercalation compounds including LiFePO\(_4\), LiMn\(_2\)O\(_4\), FePO\(_4\) and Li\(_2\)Ti\(_2\)O\(_7\). We find that the measurement results, which are obtained over a wide range of overpotential, composition, primary particle size and temperature, can be self-consistently interpreted in the framework of the Johnson-Mehl-Avrami-Kolmogorov (JMAK) model for nucleation and growth kinetics. This finding suggests that the interfaces between primary particles do not impede the propagation of phase transformation in a secondary particle. Interestingly, the JMAK analysis suggests that the phase growth appears to be predominantly one-dimensional in nature in the systems studied regardless of the lithium diffusion anisotropy, which can be explained by a hybrid growth model in which rapid surface propagation is followed by slower growth into particles.

Size-Dependence of Li-Mediated Phase Transformation in Roxhyte Nano-Disks
Yuan Yao and Richard D. Robinson; Materials Science and Engineering, Cornell University, Ithaca, New York, United States.

Nanostructuring is one of the best strategies to improve the existing electrode materials due to the decrease in diffusion length and the higher surface area for accessibility of reactions. However, there are many outstanding questions fundamental mechanism behind the size-dependent electrochemical behavior. The Cu\(_{2-x}\)S system have been studied extensively as a cathode material for lithium ion batteries due to its high theoretical capacity and ionic conductivity, and low material costs. However, the exact mechanism for the first discharge plateau is still under debate (lithium intercalation versus lithium-induced phase transformation). Within the nanoscience community Cu\(_{2-x}\)S nanosynthethic chemistry has progressed to the degree that a high level of size control and
size dispersion has been achieved. This makes Cu2−xS a good system for studying the relationship between nanoparticle size and electrochemical properties. Using high concentration synthesis methods, we synthesize a series of roxbyte (Cu2S) hexagonal nanodisks ranging from 10 nm to 27 nm. A size-dependent discharge plateau behavior is found on the first discharge plateau: as the size of the particle decreases, the discharge plateau decreases, resulting in lower capacities. As a result, the discharge curve for smallest nanoparticles resemble a supercapacitor, meaning the capacity has a linear relationship with the potential. To understand the reaction mechanism on the first plateau, we use XRD and UV-Vis spectroscopy to study the phase evolution and plasmonic peak change before and after discharge. The reaction mechanism is confirmed to be a lithium-induced phase transformation from Cu2S to CuS. Through XRD and HRTEM we find that lithium ions react laterally, through the side (16 0 0) of the nanodisk, and, the extent of the phase transformation reaction is limited for smaller size particle. We find the surface of the nanoparticle is dominated by Cu2+, and the core is mainly composed of Cu1+. As a result, the surface of the particle has a lower reaction potential, and, smaller size particles contain more Cu2+. This leads to the size-dependent electrochemical behavior. Based on these information, we build a model to simulate the discharge curve. The model successfully captures the size-dependent capacity and plateau length.

Controlled Nanoscale Morphology of Sodium Rhodizonate Ionic Crystal Realizing Reversible Four-Sodium Ion Storage Minah Lee1, Yi Cui2 and Zhenan Bao1; 1Chemical Engineering, Stanford University, Stanford, California, United States; 2Materials Science & Engineering, Stanford University, Stanford, California, United States.

Sodium ion batteries (SIB) for grid-scale applications need active materials that combine a high energy density with sustainability. Organic compounds which can be obtained from natural biomass with minimum energy consumption are an attractive low-cost and sustainable choice for battery electrode materials, provided a high energy density and long cycling stability can be obtained. Given the earth abundance and high theoretical specific capacity of 501 mAh g−1, disodium rhodizonate (Na2C6O6) is one of the most promising cathodes for SIB. However, substantially lower reversible capacities have been obtained compared to the theoretical value while the origin of such discrepancy remains unanswered. Here, we reveal the origin of the limited electrochemical performance of Na2C6O6 and provide an effective path to achieve reversible four-sodium storage. By controlling of nanoscale morphology, we reveal that phase transformation of Na2C6O6 is kinetically limited during the desodiation process, being the origin of deteriorating redox activity of Na2C6O6. The reversible phase transformation of Na2C6O6 accompanied with spontaneous nanostructuring of active particles is achieved by decreasing active particle sizes and selecting proper electrolytes, which provides a mechanism to realize efficient four-sodium ion storage with a specific capacity of 484 mAh g−1. Our work highlights the importance of understanding redox mechanisms at nanoscale, which opens up new opportunities to build a high performance and sustainable energy storage system.

Study of Anisotropic Charge Storage Behaviour of LiNi0.5Mn0.3Co0.2O2 Using Pulse Laser Deposited Epitaxial Thin Films Rohit Satish, Yang Zhou, Rodney Chua Yong Sheng and Madhavi Srinivasan; Nanyang Technological University, Singapore, Singapore.

To realise future demands of energy storage, enhancements in terms of performance need to be made across the table in all the components of a battery including the Cathode, anode, separator and the electrolyte. A cursory examination of literature would indicate that anode chemistries are already able to store much more energy when compared to their cathode counterparts. This is largely due to the formation of an anode/electrolyte interface which passivates the anode and allow s for facile Li migration through it. Unlike its anodic counterpart the cathode/electrolyte interface is one of the least investigated and one of the least understood aspects of Li-ion battery design. It is thus of high impact to develop an understanding of the charge storage process at the surface of the cathode. In this study we observe the surface of epitaxially grown layered LiNi0.5Mn0.3Co0.2O2 with an aim to understand the dependence of the cathode/electrolyte interface, material stability and charge storage mechanism, on the direction of Lithium diffusion. Epitaxial LiNi0.5Mn0.3Co0.2O2 with restricted lattice parameters are grown on single crystal SrTiO3 substrates oriented along 110,111 and 100 directions with SRO as conductive buffer layer. The samples oriented along 100, 110 and 111 were probed using Cyclic Voltammetry, Impedance Spectroscopy coupled with X-ray Diffraction and ex-situ X-ray reflectivity measurements and ex-situ STEM measurements. Initial testing indicated we have been able to grow perfectly epitaxial films with negligible amount of lattice mismatch. Electrochemical studies surprisingly indicate different storage and failure mechanism for each of the samples. Reversible intercalation was observed only along the 110 direction with indication of a stable Ni2+ to Ni3+ transition coupled with an Co3+/4+ transition. A combination of X-ray reflectometry measurements carried at specific potentials coupled with ex-situ STEM micrographs indicate that for samples grown along the 111 and 100 directions there is a greater tendency towards cation disorder, and loss of the overall layered structure during cycling but in the case of the samples grown along the 110 direction stable structure accompanied with the formation of a thin organic layer on the surface is observed. The SEI layer formed is expected to passivate the electrode at higher potentials and prevent any capacity decay. The results of the study can potentially open the doors for the widespread application of high energy density Ni rich layered structures as cathodes of the future.

Towards Three-Dimensionally Interdigitated Energy Storage Nanoarchitectures—A Bottom-Up Battery Synthesis Joerg Werner1, Gabriel G. Rodriguez-Calero2, Héctor D. Abruña2 and Ulrich Wiesner2; 1Harvard University, Cambridge, Massachusetts, United States; 2Cornell University, Ithaca, New York, United States.

The traditional design of two-dimensionally layered anode-electrolyte/separator-cathode assemblies has persisted over centuries as the dominating battery architecture for its advantage of separated manufacturing of each component and ease of subsequent assembly. In common batteries these layers 100s of microns thick, soaked with liquid electrolyte for ion transport. The need for energy storage systems that exhibit high energy storage capacity coupled with fast accessibility of the energy manifested by high power output, demands architectures that increase the kinetics of batteries. A major hurdle for fast battery kinetics are ionic transport and solid-state reactions in nanodimensions are fast, porous nanostructured electrode materials have enabled much higher power densities of batteries over the past decades. However, the high porosity of nanostructured electrode materials comes at the price of reduced energy density due to a lower volumetric loading of the energy storing material. To overcome these limitations, intriguing 3-D architectures for batteries have been proposed over 15 years ago. In such 3-D designs, the porosity of one nano- or micro-structured electrode is coated and filled with the electrolyte and second electrode materials, respectively. The design principle of 3-D batteries conceptually enables fast diffusion and reaction kinetics due to small electrode dimensions and distances without sacrificing space for porosity. To obtain such intricate architectures with nanoscale dimensions, the battery components have to be synthesized within each other from the bottom up. The difficulties of compatibility and spatial
precision in such nanoconfined synthesis of functional materials have significantly held back the development of nano-interdigitated 3-D batteries. Here we present a step-wise bottom-up strategy to such nanoarchitectures with all functional phases synthesized and integrated within a triblock terpolymer derived core-shell double gyroid morphology. Our 3-D interdigitated design comprises a gyroidal carbon anode network that is electrochemically coated with an ultrathin polymer electrolyte in a self-limiting and self-correcting process. The 3-D continuously nanoporous anode-electrolyte monolith is in turn filled with an inorganic-polymer hybrid cathode that is synthesized in the confinement of the nanoporous network. All three-dimensionally networked phases are less than 20 nm in their layer dimensions and integrated throughout a macroscopic monolith. Despite the small separation distances, the solid-state nano-3-D energy storage system exhibits battery-like characteristics and can be cycled numerous times.

11:15 AM ET03.13.10
Hybrid Aqueous Electrochemical System of Lithium Manganese Oxide and Prussian Blue Analogue for Low-Grade Thermal Energy Harvesting Yezhou Liu, Caitian Gao, Soojin Sim, Moobum Kim and Seok Woo Lee; Nanyang Technological University, Singapore, Singapore.

Low-cost and high-efficiency systems are in urgent demand to harvest abundant but mostly wasted low-grade heat sources (<100°C). Existing technologies like thermoelectric for heat-to-electricity conversion shows limited efficiency due to relatively low figure of merit at low temperature differential. Thermally regenerative electrochemical cycle (TREC) is a promising candidate to harvest heat by using dependence of electrode potential on temperature. By varying the temperature in a TREC cycle, the electrochemical cell is charged at a lower voltage and discharged at higher voltage, therefore, converting heat to electricity. Most previous TREC studies focused on materials with negative temperature coefficient (α), such as Prussian Blue Analogs (PBAs). Combining negative-α material with positive-α material without ion-exchange membrane could improve the efficient and reduce the cost. Exploring suitable positive-α material is necessary and urgent for further development of TREC low-grade heat harvesting system. Here we report lithium manganese oxide, a widely-used lithium-ion battery cathode material, showing positive-α of 0.617 mV K⁻¹ and stable performance in aqueous electrolyte. An electrochemical cell consists of lithium manganese oxide (LMO) cathode and copper hexacyanoferrate (CuHCF) anode. The electrochemical system is operated in Li⁺ and K⁺ hybrid aqueous electrolyte without ion exchange membrane. The temperature coefficient of the full cell is 1.161 mV K⁻¹ and the relative conversion efficiency of heat-to-electricity convert can reach 3.8% in TREC cycling between 10 and 50 °C without heat recuperation. This new application of LMO may open the opportunities for positive α material and lead to an affordable and simple-structure low-grade heat harvesting electrochemical system.

11:30 AM ET03.13.11
From Thermopower Waves to Asymmetric Chemical Doping—New Concepts in Energy Storage and Generation Using Molecular Interactions with Single-Walled Carbon Nanotubes Albert T. Liu, Yuichiro Kunai and Michael Strano; Chemical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

There is a pressing need to find alternatives to conventional energy generation techniques, specifically those that rely on elements in finite global supply. Thermopower wave (TPW) devices, which convert chemical to electrical energy by means of self-propagating reaction waves guided along nanostructured thermal conduits, have the potential to address this demand. We show that conversion efficiency can be increased significantly by selecting molecules such as sodium azide or sucrose with potassium nitrate to offset the inherent penalty in chemical potential imposed by strongly p-doping chemicals, a validation of the predictions of Excess Thermopower theory. Such chemical-potential-gradient-induced-electricity can be further exploited in a more direct manner, decoupled completely from the combustion reactions, affording another novel energy generation scheme using only molecular interactions, and subsequent charge transfers, with single-walled carbon nanotubes. Specifically, we demonstrate that chemically-modified carbon nanotube fibers enable unique power sources driven entirely by a chemical potential gradient. Short circuit electrical current (11.9 μA mg⁻¹) and open circuit potential (525 mV) are reversibly produced by localized acetoniitride doping under ambient conditions. An inverse length-scaling of the maximum power as L⁻¹.⁰ three to four orders of magnitude larger than previously reported, this work could open new avenues for the exploitation of nanoscale energy harvesting.

11:45 AM ET03.13.12
Thermal Transport Crossover from Crystalline to Partial-Crystalline Partial-Liquid State in Li-S Batteries Ming Hu1 and Yanguang Zhou; 1University of South Carolina, Columbia, South Carolina, United States; 2University of California Los Angeles, Los Angeles, California, United States.

Phase change materials (crystalline at low temperature and partial-crystalline partial-liquid state at high temperature) are widely used as thermoelectrics (Cu2Se [Phys. Rev. Lett. 118, 145901 (2017), Proc. Natl. Acad. Sci. 111, 15031 (2014) and Nature Mater. 11, 422 (2012)] and Ag2Te [Nanotech. 26, 25702 (2014)]) and battery electrodes (Li2S [Sci. Rep. 7, 5873 (2017)] and LiSi [Nano Energy 18, 89 (2015)]) due to their low thermal conductivity and high ionic conductivity, respectively. Both thermoelectrics and Li batteries are energy related subjects and the relevant researches are hot topics in physics, chemistry and materials fields today. The scientific challenge resides in that, the well-developed computational methods such as anharmonic lattice dynamics coupled with Boltzmann transport equation (ALD/BTE) cannot be straightforwardly used to study such partial-crystalline partial-liquid systems. By performing systematic first-principles and reaxFF molecular dynamics simulations, for the first time we give a robust and detailed explanation of the thermal transport behavior in phase change material (i. e., Li2S). At the temperature range in which the system can be regarded as a solid, the large hopping of Li is found to be the reason for phonon thermal conductivity’s deviation from the traditional 1/T relationship. At the high temperature range (T > 1000 K), the contribution of convection and across increase significantly due to the fluidization of Li ions. The effective mean free path of the crystalline part shows that, at high temperature (e. g., 1300 K), the diffusions, which transport heat via overlap of ions’ trajectories, can contribute as much as 44% of the total thermal conductivity, which leads to the unusual increase of k waived at temperature above 1200 K. These results offer useful guidance for the development of phase change material based thermoelectrics (such as Cu2Se and Ag2Te based thermoelectrics), where low thermal conductivity is required to maximize the efficiency, and also suggest a strategy to solve the overheating problem in LIBs. This work will not only be of interest to the thermoelectrics and Li battery community, and the revealed thermal transport mechanism will also have large impact in the nanoscale thermal transport community.

SYMPOSIUM ET04
While perovskite solar cells (PVSCs) have drawn intense attention due to their high solar-to-power conversion efficiency (PCE), their practical application is hampered by the poor long-term stability against moisture. Although strategies have been reported to solve this issue, they are introduced during core-device fabrication processes which will increase the risk of introducing unexpected impurities during the fabrication.

In this work, we propose a new scheme of ligand-induced post-device (LPD) modification of perovskite on completely fabricated devices at room temperature to simultaneously improve the performance and stability of PVSCs [1]. The ligand vapors will induce chemical modification in the selected lateral regions particularly that of perovskite layer which prevent the diffusion of water molecules into the protected active perovskite region for enhancing PVSC stability. This post-device treatment could also passivate the surface defects of perovskites in active region for improving the PVSC performance. Interestingly, this LPD modification strategy shows a special ‘stitching effect’, namely repairing the as-fabricated ‘poor devices’ by healing the defects of perovskite in the operation region and significantly improve PCE by over 900%. The work greatly improves the production yield of PVSCs and their performance of perovskite solar cells via off-the-shelf post-device ligand treatment”, Energy & Environmental Science, 2018, DOI: 10.1039/C8EE00580J.

conversion efficiency, particularly for large-area cells, is the tradeoff between the optical and electrical performance of the top contact. Because perovskite absorbers are not used in traditional electrode materials, they provide a little lateral conductivity for current collection; a transparent conduction oxide (TCO) such as indium tin oxide (ITO) must be used for the front contact. However, TCOs offer a tradeoff between transparency and conductivity, resulting in cells that slightly compromise both their short-circuit current density due to optical losses, and their fill factor due to resistive losses. A solution is to increase the density of the grid fingers such that thicker TCOs can be used; however, this increases the shading losses.

Recently, a method to produce effectively transparent front contact grids has been described (Adv. Optical Mater. 4 (10), 1470-1474 (2016); Photovoltaic Specialists Conference (PVSC) IEEE 43rd, 3612-3615, (2016); Sustainable Energy and Fuels, 1 (3), 593-598, (2017)). This approach yields a relatively dense array of high-aspect-ratio, triangular-shaped front contact fingers, in which light striking the metal is reflected towards the cell. We previously described the application of this technique to produce effectively transparent superstrates for perovskite solar cells, which based on optical absorption measurements, is expected to increase the short-circuit current density of perovskite solar cells by ~1 mA/cm² (R. Saive, et al., PVSC 2018).

In the present work, we describe our efforts to integrate the effectively transparent superstrates with functional perovskite solar cells to realize the benefits of effectively transparent contacts (ETCs). We have investigated various combinations of perovskite absorbers and selective contact materials, and will report the results of our fabrication efforts. We are also investigating other approaches to integrate ETC technology with perovskite solar cells, including directly printing or transferring ETCs onto substrate-based perovskite cells topped with optimally thickned ITO layers.

Highly Efficient Thermally-Stable Perovskite Solar Cells via Cs-NiOx/CuSCN Double Inorganic Hole Extraction Layer Interface Engineering
Sawanta S. Mali and Chang Kook Hong; Chonnam National Univ, Gwangju, Korea (the Republic of).

Obtaining long-term thermally stable via low-cost inorganic-hole extraction layer (i-HEL) is the best choice towards the commercialization of thermally stable, low-cost perovskite solar cells (PSCs). In the present investigation we have developed a simple method for p-type cesium doped NiOx (CsNiOx) an active interfacial layer between perovskite and CuSCN i-HEL towards thermally stable low-cost PSCs. CsNiOx nanoparticles were synthesized by simple solution method followed by spin-coating between perovskite and CuSCN interface for mesoscopic regular (n-i-p) type PSCs. The developed method is not only protecting perovskite layer from poor diethyl sulfide solvent but also extract holes efficiently. The best efficiency based on CsNiOxCuSCN double i-HEL devices exhibited 18.42% with >95% thermal stability over 1000 hours at 60 degree Celsius. Interestingly, NiOx/CuSCN and CsNiOxCuSCN double i-HEL based devices are much stable either conventional spiro-MeOTAD or single i-HEL based PSCs due to perfect isolation of the perovskite layer from polar solvent.

9:15 AM ET04.01.05
Progress on Device Stability Enhancement of Perovskite Solar Cells via High Mobility P-Type Buffer Layer or Phthalocyanine Derivative with Long Carrier Lifetime
Xiaoli Zheng1, Yulong Wang2, Hongwei Lei1, Guang Yang1, Zongxiang Xu2 and Guojia Fang1; 1School of Physics and Technology, Wuhan University, Wuhan, China; 2Department of Chemistry, South University of Science and Technology of China, Shenzhen, China.

Organo-lead halide perovskite solar cells (PSCs) have attracted tremendous attention owing to their superior photovoltaic properties. However, despite the excellent power conversion efficiencies (PCEs) that have recently been achieved, the device stabilities are still a challenge for the commercialization of PSCs. Spiro-OMeTAD is a widely used hole transport layer (HTL) in conventional n-i-p type PSCs, which has been reported to suffer degradation from the permeate of moisture due to the hydrophobic additive and the presence of pinholes. To fix the relatively low device stability of PSCs based on spiro-OMeTAD, numerous strategies have been developed and used in PSCs. One approach to diminishing these adverse effects introduced by the moisture permeate and ion migration is to insert a buffer layer. To avoid decreasing the device performance while improving the stability, this p-type semiconductor needs possess high conductivity and superior hole mobility besides hydrophobicity. Lead sulphide (PbS) is a traditional direct bandgap semiconductor with high hole mobility. We found that when inserting a thin layer of PbS between the metal electrode and spiro-OMeTAD, the PSCs with PbS buffer layer exhibited a better photovoltaic performance and significantly enhanced stability with respect to the reference cells. The superior hole mobility of spiro-OMeTAD/PbS bilayer was considered to be the dominant origin of the device performance improvement. And the hydrophobic nature and dense morphology of PbS enable it to provide an efficient permeation barrier against moisture and metal migration. The champion cell with PbS buffer layer displayed a PCE of 19.58% and maintained almost 100% of its initial PCE after 1000 h stored in ambient air. While in this structure the spiro-OMeTAD is still requisite. Metallophthalocyanine (MPC) compounds that consist of an 18-electron conjugated macrocycle skeletal structure are potential candidates for stable HTLs in PSCs. We reported a novel heavy metal Pb derivative, octamethyl-substituted palladium(II) phthalocyanine(PPm2Pc), which shows promise as an HTL in PSCs. The introduction of the heavy Pd atom endows the material with a long carrier lifetime and without dramatically reducing its mobility. This PdMPC exhibited a long carrier diffusion length (LD) which is benefit to reducing the charge recombination. As a result, the devices based on PdMPC displayed a relatively high PCE of 16.28% and good long-term stability.

9:30 AM ET04.01.06
Environmental-Induced Luminescence Hysteresis in Cs-FA Perovskites
John M. Howard1,2, Elizabeth Tennyson1,2, Sabayasachi Barik2,3, Rodrigo Szostak1, Edo Waks4, Michael F. Toney5, Ana F. Nogueira5, 3, Bernardo Neves2, 6 and Marina S. Leite1, 2; 1Department of Materials Science and Engineering, University of Maryland, College Park, Maryland, United States; 2Institute of Chemistry, University of Campinas, Campinas, Brazil; 3Department of Electrical and Computer Engineering, University of Maryland, College Park, Maryland, United States; 3Stanford Synchrotron Radiation Lightsource, SLAC National Accelerator Laboratory, Menlo Park, California, United States; 4Department of Physics, Federal University of Minas Gerais, Belo Horizonte, Brazil; 5Department of Physics, University of Maryland, College Park, Maryland, United States.

Metal halide perovskites show great potential for a wide variety of optoelectronic devices, ranging from light-emitting diodes to photocatalysts. While the prototypical MAPbI3 has relatively poor stability under ambient conditions, the addition of small amounts of Cs (10-20%) to FAPbI3 has been shown to enhance thermal, optical, and structural stability across the entire range of possible IBr ratios. However, the influence of moisture, oxygen, and temperature on the optoelectronic properties of these Cs-FA perovskites remains unknown. To explore the individual and combined contributions of each of these parameters onto perovskites' optical behavior, we use micro-photoluminescence (micro-PL) with in situ environmental control on four relevant Cs,FAPbI3,(1-x)PbBrx compositions [1,2]. We subject each sample to temporally identical humidity loops (< 5%, 15%, 35%, 55%, and < 5%RH) and identify that humidity levels up to 55%RH increase the PL emission of all compositions considered by removing surface trap states. By contrast, we find that 55%RH reduces the overall PL emission for 38%-Br films, but sustains the PL enhancement from the prior 35%RH soak for the 17%-Br perovskites. The same 38%-Br films also show an appreciable and partially reversible red shift in their PL peak, correlated with the relative humidity level. Finally, upon completion of the humidity loop, all compositions except Cs-17%-Br-38% exhibit luminescence hysteresis; the extent of hysteresis is predominantly influenced by the Cs-Br ratio. We attribute this PL hysteresis to surface-limited degradation occurring throughout the 55%-RH condition, where sufficient intercalation of the water into the perovskite lattice leads to the formation of FAI,FABr,PbI and PbBr. This degradation process leads to the
formation of new sites for nonradiative recombination. Our environmental micro-PL method can be expanded to a range of emerging perovskite compositions and extended to include additional degradation factors. Finally, we will discuss how the control of each environmental parameter on perovskites degradation and recovery can be tackled by a machine-learning paradigm [3].

Charge Injection from Excited CsPbBr3 Nanocrystals into TiO2 in Perovskite and Its Role in the Degradation of Perovskite Layer in Visible Light Prashant Kamat, Rebecca A. Scheidt and Elisabeth Kerns; University of Notre Dame, Notre Dame, Indiana, United States.

The role of TiO2 as an electron transport layer (ETL) that captures electrons from excited CsPbBr3 seems to play an important role in delivering superior device performance. However, its role in perovskite solar cell is yet to be understood fully. By anchoring CsPbBr3 nanocrystals onto mesoscopic TiO2 film, we have probed the charge injection from excited perovskite into mesoscopic TiO2 and other semiconductor oxides. The electron transfer rate constant in all these case was found to be >10^11 s^-1. When subjected to steady state irradiation with visible light in air, the injected electrons are scavenged away from the TiO2, thus inducing oxidation of CsPbBr3 nanocrystals. No such degradation is seen when CsPbBr3 nanocrystals are coated on an inert support such as ZrO2. We have also probed the charge recombination process in CsPbBr3 deposited on FTO/TiO2 films at different applied electrochemical bias and investigate the influence of electron charging effect in TiO2 layer. Steady state and luminescence measurements that elucidate the role of TiO2 in the solar cell operation will be discussed.

10:30 AM ET04.01.08
Exploring Bulk and Interfacial Degradation Effects in Perovskite and Perovskite-Inspired Absorbers for Solar Cells Azat Akbulatov2, Lyubov Frolova1,2, Olga Yamilova1, Sergey Luchkin1, Moneim Elshobaki1, Sergey Tsarev1, Alexandra Sveshnikova1, Keith Stevenson1 and Pavel Troshin1,2; Skoltech, Moscow, Russian Federation; 1IPCP RAS, Moscow, Russian Federation.

The emerging perovskite solar cells have demonstrated impressive power conversion efficiencies exceeding 22%, while their practical application is restricted mainly by poor operation stability. We have reported recently that hybrid MAPbX3 (X=I, Br, I+Br, I+Cl) perovskites undergo facile thermal and photochemical degradation even under anoxic conditions without exposure to oxygen and moisture, while their all-inorganic counterparts CsPbX3 proved to be significantly more stable [1]. Here we will discuss our most recent results coming from a systematic study of the intrinsic stability of a broad range of materials represented by various lead-based perovskites as well as lead-free complex halides of tin, germanium, bismuth and antimony. The revealed pathways of thermal, photochemical and electrochemical degradation processes will be presented and a conclusion on the potential of different groups of materials for practical application in PV technology will be drawn.

We will also analyze the interface degradation effects occurring between the electrodes, charge transport layer materials and the photactive layer induced by electric field, elevated temperatures, solar light or a combination of these stress factors [2-3]. Finally, it will be shown that any commercially interesting operation lifetimes for perovskite solar cells requires a considerable shift from the currently used device design paradigms as well as a comprehensive multiparametric optimization of all used materials and functional components.

10:45 AM ET04.01.09
Transport Layers Limit the Efficiency of Perovskite Solar Cells—An Experimental and Theoretical Study Vincent Le corre1, Lorena Perdigón Toro1, Markus Feuerstein1, Martin Stolterfoht2, Dieter Neher2 and Lambert Jan Anton Koster1; 1Zernike Institute for Advanced Materials, University of Groningen, Groningen, Netherlands; 2Institute of Physics and Astronomy, Universität Potsdam, Potsdam, Germany.

Perovskite solar cells (PSCs) are the current rockstar of photovoltaic research attracting more and more attention. With efficiency now reaching up to 23% PSCs are on the way of catching up with classical inorganic solar cells. However, PSCs have not reached their full potential yet. In fact, their efficiency is limited, on the one hand, by non-radiative recombination, mainly via trap states located either at the grain boundaries or at the interface between the perovskite and the transport layers. On the other hand, it is limited by losses due to the poor transport properties of the commonly used transport layers. Indeed, state-of-the-art transport layers (e.g. TiO2, PCBM and Spiro-OMeTAD…) suffer from rather low mobilities, typically within 10^-4 – 10^-2 cm^2 V^-1 s^-1, measured when compared to the high mobilities, 1 – 10 cm^2 V^-1 s^-1, measured for perovskite using field-effect transistors or space-charge-limited-current measurement.

In this work, the effect of the mobility, thickness and doping density of the transport layers was investigated by means of a combined experimental and modeling analysis. For the experiment, two sets of devices made of a triple-cation perovskite were studied, including n-i-p and p-i-n structures demonstrating efficiencies of up to 20%. For the two structures, the thickness and doping density of one of the transport layers were varied in order to understand their effect on the performance and especially on the FF. In addition, we performed a transient extraction experiment to look at the influence of the transport layers properties on the rate of extraction. The experimental results were then reproduced using drift-diffusion simulations to explain how and by how much every single parameter influences the extraction and the performance. A new and simple formula was also introduced to easily calculate the amount of doping necessary to counterbalance the low mobility of the transport layer.

In conclusion, this work presents a comprehensive analysis of the effects of the different properties of a transport layer on the efficiency of PSCs. We also present general guidelines on how to optimize a transport layer to avoid losses.

11:00 AM ET04.01.10
Strategically Construct Bilayer SnO2 as Electron Transport Layer in Perovskite Solar Cells Liuangyou Lin1,2, Jacob Tse-Wei Wang1, Timothy Jones1 and Gregory J. Wilson1; 1CSIRO Energy, Newcastle, New South Wales, Australia; 2Huazhong University of Science and Technology, Wuhan, China.

The highly diverse and adaptable architectures of the PSCs is also one of the key steps that leading PSCs to the forefront of the emerging PV technologies.
Among various device configurations, the “n-i-p” planar structure without secondary mesoporous layers has attracted lots of attention due to its simple device fabrication process where n-type metal oxides have been widely applied as the first layer on top of the FTO or ITO. TiO2 is the most commonly used electron transport material in the PSCs due to its mature development in the field of DSSCs, however, several studies have pointed out that TiO2 may not be the best candidate to carry PSCs toward commercialization due to its unfavorable properties, including UV instability, high-temperature sintering process, large energy level offset, etc. On the contrary, SrTiO3 emerged as an ideal n-type layer for PSCs recently, with advantages of higher electron mobility, low-temperature process, and UV-stabilized properties. However, SrTiO3 behaves quite differently while prepared by different methods. In this work we devised a facile strategy to combine the strength of two different SrTiO3. Interestingly, we found the bilayer displays better energy level alignment with perovskite, faster charge extraction, and lower trap-density. As a result, the photovoltaic devices based on this electron transport layers demonstrate a superior power conversion efficiency up to 20.5% with Voc close to 1.2 V and negligible J-V hysteresis in the device.

ARGON PLASMA TREATMENT TO TUNE PEROVSKITE SURFACE COMPOSITION FOR HIGH EFFICIENCY SOLAR CELLS AND FAST PHOTODETECTORS

Xun Xiao1, Chunxiong Bao, Yannian Fang, Jun Dai, Benjamin R. Ecker, Yue Li1, Shi Tang, Ye Li2, Yehao Deng1, Xiaopeng Zheng1, Yongli Gao1, Xiao Cheng Zeng1 and Jinsong Huang1,2

1University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States; 2Mechanical and Materials Engineering, University of Nebraska-Lincoln, Lincoln, Nebraska, United States. 1Department of Chemistry, University of Nebraska–Lincoln, Lincoln, Nebraska, United States; 2Department of Physics and Astronomy, University of Rochester, Rochester, New York, United States.

The surface composition of perovskite films is very flexible in film process and can deviate from optimal, which generates unfavorable defects and results in efficiency loss in solar cells and slow response speed in photodetectors. An argon plasma treatment is introduced to modify the surface composition by tuning the ratio of organic and inorganic component ratio as well as defects type before deposition of passivating layer and form an ultra-thin n-type self-doping layer. It efficiently enhanced the charge collection over the perovskite-electrode interface by suppressing charge recombination. Therefore, perovskite solar cells with argon plasma treatment yield enhanced efficiency to 20.4% and perovskite photodetectors can reach their fastest respond speed which is solely limited by the carrier mobility.

FROM THIN-FILM TO SINGLE CRYSTALS—PROBING THE INTRINSIC ANISOTROPY AND INSTABILITY IN CUBIC LEAD PEROVSKITES

Qing Sun1, Federico Brivio1, Fengxia Wei1, Yue Wu2, Zeyu Deng1, Gregor Kieslich2, Paul D. Bristowe1, Pietro Buonassisi1 and Anthony K. Cheetham2,3

The commercialization of perovskite solar cells (PSCs) have been hindered by their chemical, structural and thermal instability. There is an increasing interest in compositional tuning of perovskites to improve their intrinsic stability. In this study, extrinsic and intrinsic strain in cubic perovskites, methylammonium lead iodide (MAPbI3) and formamidinium (FA) lead bromide were examined in thin-film, powder and single crystal forms to investigate the role of A-site cations on the structural-property relationships. Based on laboratory and synchrotron X-ray diffraction and density functional theory (DFT), our quantitative analysis reveal the presence of anisotropic strain in the cubic perovskites, where the lattice strain is the highest on {111} and lowest on {100}. Comparative studies on FA(PbI3)2 and MAPbBr3 showed that the cation dynamics and hydrogen bonding of FA contributes to the higher strain as well as more compliant bulk properties. Our results shed light on the rational perovskite compositional design to minimize strain induced decomposition.

THERMALLY DRIVEN EVOLUTION OF FERROELECTRIC DOMAINS IN PEROVSKITE SOLAR CELLS

Holger Röhm, Tobias Leonhard, Alexander Schulz, Michael J. Hoffmann and Alexander Comlmann, Karlsruhe Institute of Technology, Karlsruhe, Germany.

Every perovskite solar cell undergoes changes in temperature during operation and most fabrication routes include one or more thermal annealing steps. For methylammonium lead iodide (MAPbI3), the archetype of metal halide perovskite solar cells, both the formation and growth of the crystals are strongly interlinked with the phase transition temperature at 328 K. At this temperature, the crystal changes from a polar tetragonal to a non-polar centrosymmetric cubic structure. To date, the majority of research related to the thermal treatment of perovskite solar cells focuses on the growth of crystals from precursor chemicals during layer formation or the thermal decomposition at elevated temperatures. So far, the influence of temperature on the formation of the microstructure within perovskite grains such as formation and evolution of polar domains remains unclear. Here, we study the effects of annealing temperature and duration on the formation and transformation of ferroelectric domains and show the influence of domain patterns on the optoelectronic microstructure and macroscopic device performance of solar cells. Annealing of MAPbI3 layers at 100°C yields flat grains with an average diameter of > 1 μm. After fast grain growth in the first few minutes, further annealing does not change the layer morphology anymore. However, ferroelectric domains as revealed by piezoresponse force microscopy (PFM) show vastly different orientations and domain shapes during this thermal treatment. The investigation of the corresponding solar cells elucidates the influence of changes in the sub-grain microstructure on the JV-characteristics, power conversion efficiencies and the hysteretic behavior of solar cells.
charge carriers largely contributes to the outstanding optoelectronic properties of lead-halide perovskites.

Perovskite Material and Solar Cell Research by Surface Science and Advanced Characterization Yabing Qi; Okinawa Institute of Science and Technology, Okinawa, Japan.

Perovskite solar cell research has been continuously advancing in various fronts. To fabricate high performance stable perovskite solar cells, it is of paramount importance to obtain a better understanding of fundamental aspects with the help of surface science and advanced characterization. My group at OIST is making concerted efforts to investigate these materials and devices and to develop innovative strategies to improve their performance. In this talk, I will present our research progress on the improvement of perovskite solar cell stability and development of upscalable processes to fabricate perovskite solar cells and modules.

Perovskite Solar Cells—The Role of Ions, Density of States and Device Structure Nir Tessler1 and Yana Vaynzof; 1Technion-Israel Institute of Technology, Haifa, Israel; 2Universität Heidelberg, Heidelberg, Germany.

Preventing hysteresis and enhancing stability remain key challenges that could be resolved with the aid of judicious device design. We report numerical study of a solar cell model system that is based on a mixed electron-ion conducting perovskite active layer having various device configurations. In the full picture we allow for both mobile ions and the polarizability due to the easy-rotational methylammonium (MA). We then compare with cells where the MA rotation is frozen and/or the ions are non-existing. Several insights, resulting from these detailed simulations, will be presented.

For example: Even when there is no indication of hysteresis and the device’s characteristics can be modelled using ionic free model, the actual electron and hole distributions may be vastly different to the predictions by ionic free model. The low effective DOS promotes higher Voc but makes it more difficult to overcome energy level mismatch. These are related to the fact that the ionic motion is not only causing the hysteresis, it also allows for large deviations between electron and hole densities. Also, when a large energy mismatch exists between the BL and the perovskite the charge density distribution self-adapt to create an effective dipole at the interface. Such self-induced dipole can compensate for 0.4eV mismatch and thus prevent any loss in Voc. In this context formamidinium is preferred to MA.

We also found that while the use of doped BLs is effective to reduce serial resistance and potential S shapes it also results in a relatively pronounced ionic motion. We note that even in hysteresis-free cells the ions still redistribute as a function of bias. We show that by keeping a certain level of resistivity, as in undoped BL, the ionic motion is significantly reduced. We expect this to have significant impact on device long term stability.

Structural Origins of Light-Induced Phase Segregation in Organic-Inorganic Halide Perovskite Photovoltaic Materials Rachel E. Beal1, 2, Hans Steinrueck2, Nanna Zhou Hangström2, Michael F. Toney2 and Ana F. Nogueira1; 1Stanford University, Stanford, California, United States; 2Materials Sciences Division, Stanford Synchrotron Radiation Lightsource, Stanford, California, United States; 3Institute of Chemistry, University of Campinas, Campinas, Brazil; 4Stockholm University, Stockholm, Sweden.

Organic-inorganic perovskite materials offer a promising route to reducing the dollars-per-watt cost of solar energy due to their ease of deposition and favorable optoelectronic properties. A wide range of perovskite compositions can be solution processed with relative ease where changing the stoichiometry of the material allows for the preparation of materials with bandgaps tailor-made for specific tandem and single-junction applications. Early work showed that varying the Br:I ratio in (CH3NH3)Pb(Br1-xIx)3 tunes the bandgap between 2.3 and 1.6 eV, but photo-induced phase segregation leads to the formation and I-enriched regions in materials with x ≥ 0.2 that trap carriers and pin the voltage of photovoltaic devices. Materials with a combination of formamidinium (FA) and cesium of the A-site in the general ABX3 stoichiometric formyla have demonstrated improved stability to this phenomenon, but the fundamental and mechanistic underpinnings of photo-induced phase segregation are not well understood. We have studied the structural origins of photo-induced phase segregation by coupling synchrotron X-ray diffraction with photoluminescence experiments. We examine materials with a range of FA:Cs and Br:I ratios and show that optical stability is observed at the phase boundary between Br-poor cubic and Br-rich tetragonal compositions, with material compositions farther from the boundary demonstrating a greater extent of segregation. Ours is the first study to examine materials in the FA:Cs phase space with bandgaps relevant for high-efficiency device applications. By mapping out the phase boundary, we provide a roadmap for compositional selection for photostable devices.

'The Life' of Halide Perovskite—Evolution From the Solution and Degradation in the Environment Yuanyuan Zhou; Brown University, Providence, Rhode Island, United States.

Halide perovskites have recently emerged as a new family of semiconducting materials that are revolutionizing the field of photovoltaics. The rapid development of perovskite-based solar cells is being led by advances in microstructural/compositional engineering of perovskite thin films. In this context, understanding the 'life' of halide perovskite: evolution/crystallization from the solution and degradation in the environment, and developing new strategies for the 'life-lengthening' (stabilization) of perovskites are becoming the most significant research directions.

In this talk, first, I will look at fundamental phenomena pertaining to nucleation & grain growth and grain-boundary evolution involved in the thin-film crystallization of perovskitites from a materials-science perspective. Established scientific principles that govern these phenomena will be invoked in the context of specific examples of perovskite thin films. Based on these fundamentals, I will present a set of new synthetic strategies that have been recently developed in our group for scalable processing of high-performance large-area perovskite thin films and devices. Second, I will discuss the key role of
grain boundaries in the degradation processes of perovskites, and show our recent progress in the grain-boundary tailoring of perovskite thin films that enable perovskites with new functionalities and enhances the perovskite stability. Finally, I will discuss the challenges and opportunities in the advanced characterization (high-resolution and in-situ/operando TEM, etc.) of perovskites for not only gaining a deep understanding of defects/microstructures, but also elucidating classical and non-classical phenomena pertaining to the crystalization, degradation, and stabilization of perovskites. The overall goal is to gain a deterministic control over the perovskite thin films with engineered microstructures/compositions for efficient PSCs that are also highly durable under environmental (heat/moisture/light) stresses.

How Does the Chemical Reactivity of Mobile Ions Trigger Reversible Performance Losses at Reverse Bias in Lead Halide Perovskite Solar Cells? Luca Bertolazzi, 1 Kevin A. Bush, 1 Rohit Prasanna, 1 Brian O'Regan, 1 and Michael D. McGehee; 2 Stanford University, Stanford, California, United States; 3Sunlight Scientific, Berkeley, California, United States; 4Department of Chemical Engineering, University of Colorado Boulder, Boulder, Colorado, United States.

Enhancing the stability of perovskite solar cells is currently one of the main preoccupations of the perovskite research community. Environmental degradation triggered by moisture, oxygen, UV light and termal stress, is being efficiently tackled by the concomitant engineering of the device architecture and encapsulation. 1 However, multiple groups have pointed out that different conditions of light and applied voltage can also lead to partially reversible efficiency losses. We recently reported partially reversible performance losses caused by reverse bias. 2 Other groups remarked that devices placed outdoor loose part of their efficiency during the day and partially recover during the night. 3 Finally, since these processes are not fully reversible, it is important to understand and stop them for reliability reasons.

Mobile ions within the active material have been suspected to trigger these processes. We have recently proposed a drift-diffusion model to examine the role of such ions at reverse bias. 2 We concluded that while ion migration can explain the reverse bias leakage current, ionic transport alone cannot explain the reversible performance losses we measured. Instead, we suggested that a reversible electrochemical reaction involving these ions is likely to take place. In a different study, Maier and coworkers showed that iodide vacancies can be created under prolonged illumination due to the oxidation of iodide into iodine, which subsequently migrate to interstitial sites. 4 While growing evidence suggests that ionic chemistry is triggering partially reversible losses, it is crucial to understand and stop ionic reactivity. In this talk, we will discuss the nature of the ionic reaction triggered by prolonged reverse bias by resorting to different electrochemical techniques for strategically chosen perovskite compositions and contacts. In addition, we use a drift-diffusion model to explain a mechanism for how such a reaction can lead to partially reversible performance losses.

Deposition of Halide Perovskite Thin Films and Solar Cells Using the RIR-MAPLE Technique

Wiley A. Dunlap-Shohl, 1 E. T. Barraza, 2 Andrew Barrette, 3 David J. Dirkes, 4 Wei You, 1 Kenan Gundogdu, 1 Adrienne D. Stiff-Roberts 2 and David Mitzi 1, 5

Although many techniques have been developed for the deposition of high-quality halide perovskite thin films, the dominant solution- and vapor-deposition methods often possess some undesirable attributes, such as the challenges associated with drenching potentially sensitive substrates in solvents, or with controlling fluxes of volatile and thermally unstable organic salts. These obstacles constrain the range of possible device architectures used in halide perovskite optoelectronics. Thus, it is desirable to explore novel perovskite thin film deposition methods that might help to circumvent these challenges. In this work, we use the resonant infrared matrix-assisted pulsed laser evaporation (RIR-MAPLE) technique, wherein a frozen solution of the precursors is evaporated by a laser whose energy is resonant with chemical bonds in the solvent, to deposit various hybrid halide perovskite thin films and explore their morphological, compositional, and optoelectronic characteristics. 1 We demonstrate, for the first time, perovskite solar cells with absorber deposited by RIR-MAPLE, which reach stabilized power conversion efficiency of over 12%. 2 The technique is also extended to consider layered or two-dimensional perovskites with more complex organic structure.

The state-of-the-art PSCs use mixed-cation and mixed-halide perovskite compositions due to the superior qualities over the archetypal MAPbI3. Adding Cs+ to perovskites has been shown to improve qualities including thermal stability, reproducibility; and suppression of phase segregation. In general, controlling the precise stoichiometry in a perovskite is critical for meeting its desired properties. However, it has been found purposely introduced excess PbI2 in the perovskite causes significant influence on the intrinsic perovskite qualities. The few percent excess PbI2 predominantly resides at grain boundaries, providing benefits of prolonged carrier lifetime, enhanced charge carrier injection, suppressed ion migrations and hysteresis, leading to improved overall device performance. Theories have been proposed to explain these beneficial effects, including the better energy level alignments, grain boundary passivation, and superior crystal quality and crystallinity. Nevertheless, there are also reports showing the residual PbI2 can lead to degradation and fragile film structure with long-term device stability concerns. Nonetheless, with most of the best performing cells still incorporating slight excess PbI2, it is important to investigate this indefinite property function for further improving device performance and stability.

In this study, we use the Cs0.05(FA0.85MA0.15)0.95Pb(Br0.15I0.85)3 stoichiometric perovskite structure as a platform to demonstrate a simple yet effective recrystallization method for PbI2-rich perovskite crystals with a series of recrystallization agents. Surprisingly, for the first time, through the Grazing Incidence X-ray Diffraction (GIXRD), we found not only the excess PbI2 in the film can be successfully removed, the perovskite had a profound recrystallization throughout the bulk, showing enhanced PL emission/lifetime, charge collection efficiency, reduced defects at grain boundaries (GBs) as well as superior device performance over 20% PCE.

High crystallinity and compactness of the active layer is essential for metal-halide perovskite solar cells. Here, a simple pseudohalide (NH4SCN)-induced film retreatment technology is developed as the passivation for preformed perovskite film. It is found that the retreatment process yields a controllable decomposition-to-recrystallization evolution of the perovskite film. Correspondingly, it remarkably enlarges the grain size of the film in all directions, as well as improving the crystallinity and hindering the trap density. Meanwhile, owing to an intermediate catalytic effect of the pseudohalide compound (NH4SCN), no crystal orientation changing and no impurity introduction in the modified film. By integrating the modified perovskite film into the planar heterojunction solar cells, a champion power conversion efficiency of 19.44% with a stabilized output efficiency of 19.02% under 1 sun illumination is obtained, exhibiting a negligible current density–voltage hysteresis. Moreover, such a facile and low-temperature film retreatment approach guarantees the application in flexible devices, showing a best power conversion efficiency of 17.04%.

In our work, an inorganic-organic bilayer hole transport layer (B-HTL) was designed and utilized in planer perovskite solar cells. Here the B-HTL consist of the inorganic V2O5 matrix and copper phthalocyanine (CuPc) buffer layer, providing the excellent resistance of moisture as well as the alignment of the interfacial energy level. Benefiting from this typical HTL, enlarged built-in potential and charge extraction can be achieved in PSCs simultaneously. Correspondingly a champion device with B-HTL shows a 16.85% efficiency with negligible hysteresis, which is superior to the PSC based on PEDOT:PSS HTL. Meanwhile, significantly prolonged stability of the PSCs with B-HTL can be observed, exhibiting an only 10% efficiency loss after 350 hours in the ambient air. Moreover, such an entire low-temperature (~560C) fabrication process of this typical PSCs exhibits its successful application in flexible devices.

Inorganic-organic bilayer hole transport layer: the B-HTL is consist of the inorganic V2O5 matrix and copper phthalocyanine (CuPc) buffer layer, with excellent resistance of moisture as well as the alignment of the interfacial energy level.

Considerable improvement of the PCE: nearly 20% PCE enhancement of the PSCs based on B-HTL compared with the device with PEDOT:PSS HTL. Meanwhile, significantly prolonged stability of the PSCs with B-HTL can be observed, exhibiting an only 10% efficiency loss after 350 hours in the ambient air. Moreover, such an entire low-temperature (~560C) fabrication process of this typical PSCs exhibits its successful application in flexible devices.

Organic-inorganic hybrid lead-based perovskite solar cells have shown tremendous growth in power conversion efficiency (PCE) over recent years. Despite remarkable strides in performance, one of the biggest barriers to commercialization is the toxicity of lead. Therefore, there has been a growing interest in implementing high performance solar cells based on lead-free perovskites with lower toxicity and outstanding optoelectronic properties. In this regard, tin-based perovskite solar cells have been spotlighted because they show suitable optical band gap, high absorption coefficient and high charge carrier mobility. However, self-p-doping by the oxidation of Sn2+ to Sn4+ in tin-based perovskite solar cells has been a critical issue for achieving high performance tin-based perovskite solar cells. Therefore, essential strategies that take into account tin chemistry are required to mitigate the intrinsic instability and improve the performance of tin-based perovskite solar cells. Based on the chemical nature of tin, N-, S-, O-based electron donors can coordinate with tin halides (SnX3, X = halide anions) by donating a lone pair electron to the empty orbital in the valence shell of divalent tin. Accordingly, it is expected that coordination between Sn2+ ions and appropriate ligands could block the reaction of Sn2+ ions with oxygen, resulting in effective suppression of the oxidation of Sn2+ to Sn4+. Taking this into account, herein we fabricated quasi-two-dimensional (quasi-2D) tin-based perovskite solar cells with greatly enhanced performance and stability compared to conventional three-dimensional (3D) formamidinium tin iodide (FASnI3) perovskite solar cells, by employing an additional formamidinium thiocyanate (FASCN) additive into the quasi-2D tin-based perovskites. The incorporation of the FASCN additive greatly prevented quasi-2D tin-based perovskites from oxidation during film formation, through the strong chemical interactions with tin component (Sn2+). Moreover, it resulted in a coarser perovskite grain and a higher degree of crystallinity in the out-of-plane direction, leading to enhanced optoelectronic performance of the quasi-2D tin-based perovskites. As a result, we achieved reproducible high-performance tin-based perovskite solar cells with improved stability, reaching the highest PCE up to 8.17% compared to that of 3D FASnI3 device (1.84%), and retaining over 90% of its initial efficiency after 1000 hours aging in a nitrogen-filled glove box. These results demonstrate a versatile, yet simple methodology that can be applied to other lead-free perovskites suffering from poor oxidative stability.

Plasmonic Enhancement for High Efficient and Stable Perovskite Solar Cells by Employing ”Hot Spots” Au Nanobipyramids
Feifei Wei, Hua Dong, Jie Xu, Ting Lei and Zhaoxin Wu; Xi’an Jiaotong University, Xi’an, China.

Metal plasmonic effect is one promising way for improving the performance and stability of the perovskite solar cells via optical-electrical behalves, and the ability is in proportion to the enhanced local electromagnetic fields induced by metal nanostructures. In our work, unique gold nanobipyramids (Au NBs) structures were explored and incorporated in the hole transport layer of planar heterojunction PSCs. This typical “bipyramid-like” metal nanostructure with sharp tips has the multiple and strong plasmonic absorption properties from visible to the NIR, exhibiting high plasmonic-induced probability. In addition, generated “hot spots” around Au NBs provided much stronger EM fields enhancements than conventional Au nanoparticles, hence enhanced light harvesting and improved interfacial charge dynamic process can be achieved simultaneously. As for the further investigation of the electrical property, hot holes injection induced by Au NBs effectively filled in the interfacial traps under operation condition, contributing to the improvement of the open circuit voltage, the elimination of the hysteresis effect and the long-term stability. Accordingly, the best PSC incorporated with Au NBs showed the PCE of 18.84% whereas the reference device just showed the PCE of 16.02%. Our work demonstrated that plasmonic metal nanostructures possessing the feature of “hot spots” offered a great potential to further expand the performance limitation and operation tolerance of the PSCs.

ET04.03.05
Theoretical Investigation of Water-Resistant Halide Perovskites
Hiromitsu Takaba, Tatsuya Hongo and Junna Takahashi; Kogakuin Univ, Tokyo, Japan.

Organic / inorganic perovskite compound is capable of highly efficient energy conversion and halide perovskites are important issue for its practical application in a solar cells. However most perovskite of APbI3 has a problem that the structure is distorted and degraded by invasion or diffusion of water molecules or the existence of defect in the crystal. Therefore, it is necessary to search for structures having energetically stable and high water resistance. In this study, energetically stable and water resistance for various virtual halide perovskites containing fluoride in A-ion site were investigated by density functional theory and molecular dynamics. Dynamics of bond dissociation or water adsorption as well as the electronic structure, e.g. band gas and light adsorption spectrum, of various compounds were systematically investigated and then the novel composition for durable halide perovskite was theoretically suggested. Our simulation results indicate that fluoride halide perovskite is stable and a little bit wide band gap compared to CH3NH3PbI3 (MAPbI3) perovskite. The calculated adsorption energy of water molecule on the surface of fluoride halide perovskite is smaller than that on MAPbI3. The reaction barrier for 2(Pb-I) + H2O = PbO + 2HI was estimated and it is confirmed the presence of fluoride molecule at A-ion site prevent from the reaction showing higer reaction barrier than that for MAPbI3. This would be due to the interaction with negatively charged atoms of F. We also investigated the combination of fluoride and other A-ion to tune the band gap suitable for the application to solar cell.

ET04.03.06
Highly Efficient and Stable Tandem Solar Cells Based on Halide Perovskites
Ik Jae Park, Jaey Hoon Park, Su Geun Ji, Min Ah Park and Jin Young Kim; Seoul National University, Seoul, Korea (the Republic of).

The tandem configuration consisting of two or more solar cells is practically the only approach to overcome the Shockley-Queisser limit. From theoretical calculation shows that the combination of a top cell with a large bandgap energy (1.5~1.7 eV) and a bottom cell with a low bandgap energy (1.0~1.1 eV) can lead to a conversion efficiency higher than 30%. Given that the bandgap energy of most commercial single junction solar cells is around 1.1 eV, the perovskite solar cell with a bandgap energy around 1.6 eV must be a very promising candidate for the top cell of tandem solar cells. In this presentation, I will discuss the essential requirements for preparing highly performing perovskite top cells of tandem solar cells. Firstly, the strategies for improving the performance of the p-i-n type planar perovskite solar cell will be introduced. After a series of interfacial engineering procedures to the charge extraction layers, a conversion efficiency as high as 19% could be achieved. Secondly, strategies for fabricating transparent perovskite solar cells with a TCO top electrode layer will be discussed. Finally, some of the recent results on the highly efficient (> 23%) tandem solar cells incorporating the transparent perovskite top cell will be introduced.
Enhancing Stability for Organic-Inorganic Perovskite Solar Cells by Atomic Layer Deposited Al2O3 Encapsulation Eun Young Choi1, Jinhook Kim1, Seun Lim1, Ekyu Han1, Anita Ho-Bailie1 and Nochang Park1; 1University of New South Wales, Sydney, New South Wales, Australia; 2Korea Electronics Technology Institute, Seongnam-si, Korea (the Republic of).

In this work, we employed atomic layer deposition (ALD) to form Al2O3 layer as an encapsulant for perovskite solar cells (PSCs). Al2O3 layer deposited at temperature as low as 95°C achieved excellent water vapour transmission rate (WVTR) of 1.84 x 10⁻² g/m²/day at 45°C-100 %RH when thermal ALD (Th-ALD) was used. In order to test the moisture barrier capability of Al2O3 layer for PSCs, mesoporous perovskite devices, with spiro-OMeTAD or PTAA as hole transport layer (HTM) encapsulated by 50 nm Al2O3 film, were exposed to 65°C-85 %RH for 350 hours and their stabilities were monitored. We found that the colour of perovskite did not change after 350 hours of exposure regardless of the type of HTM used. With regards to Th-ALD encapsulated devices, PTAA based PSCs experienced a smaller power conversion efficiency (PCE) drop than spiro-OMeTAD based PSCs after thermal stress at 65°C. This is due to the presence of pinholes within spiro-OMeTAD layer after thermal stress which were not observed in PTAA. Finally, we have successfully achieved excellent durability test results for mesoporous (HC(NH2)2PbI3)x(CH3NH3PbBr3)1-x/PTAA devices encapsulated by 50nm Al2O3 with less than 4% drop in PCE after 7500 hours (>10 months) of exposure to 50 %RH under room temperature.

Planar Perovskite Solar Cells with High Open-Circuit Voltage Containing a Supramolecular Iron Complex as Hole Transport Material Dopant Yasemin Saygili1, Silver-Hamill Turren-Cruz1, 2, Selina Olthof1, Iknar Bayrak Pehlivan1, Michael Saliba1, Klaus Meierholz2, Tomas Edvinsson4, Shaik Mohammed Zakeeruddin1, Silver-Hamill Turren-Cruz1, 2, Juan-Pablo Correa-Baena1, Anders Hagfeldt1, Marina Freitag2 and Wolfgang Tress1; 1Institute of Chemical Sciences and Engineering, Ecole Polytechnique Federale de Lausanne, Lausanne, Switzerland; 2Benemerita Universidad Autonoma de Puebla, Puebla, Mexico; 3Department of Chemistry, University of Cologne, Cologne, Germany; 4Department of Engineering Sciences, Solid State Physics, Uppsala University, Uppsala, Sweden; 5Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 6Department of Chemistry Angstrom Laboratory, Uppsala University, Uppsala, Sweden; 7Adolphe Merkle Institute, Fribourg, Switzerland.

In perovskite solar cells (PSCs), the most commonly used hole transport material (HTM) is spiro-OMeTAD, which is typically doped by metalorganic complexes, for example, based on Co, to improve charge transport properties and thereby enhance the photovoltaic performance of the device. In this study, we report a new hemicage-structured iron complex, 1,3,5-tris(5'-methyl-2,2'-bipyridin-5-yl)ethylbenzene Fe(III)-tris(bis(trifluoromethylsulfonyl)imide), as a p-type dopant for spiro-OMeTAD. The formal redox potential of this compound was measured as 1.29 V vs. the standard hydrogen electrode, which is slightly (20 mV) more positive than that of the commercial cobalt dopant FK209. Photoelectron spectroscopy measurements confirm that the iron complex acts as an efficient p-dopant, as evidenced in an increase of the spiro-OMeTAD work function. When fabricating planar PSCs with the HTM spiro-OMeTAD doped by 5 mol % of the iron complex, a power conversion efficiency of 19.5 % (AM 1.5G, 100 mW cm⁻²) is achieved, compared to 19.3 % for reference devices with spiro-OMeTAD with 20% Co dopant.

Two-Dimensional Perovskites with Short Interlayer Distance for High Performance Solar Cell Chunqing Ma, Dong Shen, Yuhui Ma and Sai-Wing Tsang; City University of Hong Kong, Hong Kong, Hong Kong.

Two-dimensional (2D) perovskites have emerged as one of the most promising photovoltaic materials owing to their excellent stability compared to their three-dimensional (3D) counterparts. However, in typical 2D perovskites, the highly conductive inorganic layers are isolated by large organic cations leading to quantum confinement and thus inferior electrical conductivity across layers. To address this issue, the large organic cations are replaced with small propane-1,3-diammonium (PDA) cations to reduce distance between the inorganic perovskite layers. As shown by optical characterizations, quantum confinement is no longer dominating in the PDA-based 2D perovskites. This leads to considerable enhancement of charge transport as confirmed with electrochemical impedance spectroscopy, time-resolved photoluminescence and mobility measurements. The improved electric properties of the interlayer-engineered 2D perovskites yield a power conversion efficiency (PCE) of 13.0%. Furthermore, environmental stabilities of the PDA-based 2D perovskites are improved. PDA-based 2D perovskite solar cells (PSCs) encapsulated can retain over 90% of their efficiency upon storage for over 1,000 h and PSCs without encapsulation can maintain their initial efficiency at 70°C for over 100 h, which exhibit promising stabilities. These results reveal excellent optoelectronic properties and intrinsic stabilities of the layered perovskites with reduced interlayer distance.

Direct Observation of Cation-Exchange in Liquid-to-Solid Phase Transformation in FAx-MAxPbI3 Based Perovskite Solar Cells Yue Min Xie, Xiwen Xu, Menglin Li, Yuhui Ma and Sai-Wing Tsang; City University of Hong Kong, Hong Kong, Hong Kong.

As one of the emerging photovoltaic technologies, the high performance and ease of fabrication of organometal halide perovskite based solar cells (PVSCs) draw tremendous attention in the photovoltaic community. Recently, formamidinium (FA) dominating mixed-organic-cation FAx-MAxPbI3 perovskites are attracting intensive attention for their extended optical absorption range (reduced optical bandgap) and high photovoltaic performance. However, FAx-MAxPbI3 based perovskite usually has undesired yellow colour non-perovskite phase (δ-phase) leading to a compromised efficiency, and a facile strategy to achieve pure-phase FAx-MAxPbI3 is rarely reported. Here, we demonstrate a facile approach to form δ-phase free FAx-MAxPbI3 using non-stoichiometric precursor solution. It is found that even a small amount of excessive methylammonium iodide (MAI) added in the precursor solution has a profound effect on perovskite crystallization during the liquid-to-solid phase transformation. In contrast to previous reports, using an in-situ photoluminescence spectroscopy measurement, it is directly observed that the organic-cation-exchange process is in fact occurred in the early stage of film formation during the liquid-to-solid phase transition, which can promote the formation of FAx-MAxPbI3 and pure-phase perovskite film can be achieved. By controlling the amount of cation ratio in the precursor solution optimized pure-phase FAx-MAxPbI3 is achieved. The champion perovskite solar cell exhibits an encouraging power conversion efficiency (PCE) of 17.40%. This study demonstrates a facile method to achieve high performance FAx-MAxPbI3 dominating mixed-organic-cation perovskite devices while providing insight into the ion-exchange process during perovskite crystallization.

Publication: Direct observation of cation-exchange in liquid-to-solid phase transformation in FA1-xMAxPbI3 based perovskite solar cells, Yue-Min Xie et al., J. Mater. Chem. A, 2018, 6, 9081-9088.
Organolead halide perovskite devices are reported to be susceptible to thermal degradation, which is resulted from heat-induced fast ion diffusion and structural decomposition. In this work, it is found that perovskite solar cells fabricated in humid air (RH: 70%) can achieve a power conversion efficiency (PCE) of 19.1% when the controlled devices have a VOC of 1.07 V and a PCE of 18.0%. To the best of our knowledge, up to now, this is the highest VOC obtained by using an inorganic electron transport layer for pure CH3NH3PbI3-based P-PSCs. Moreover, a higher EFF and ECBM of ETL are believed to drive a larger VOC and a better PCE. These indicate that it is a very significant method to achieve a higher VOC for P-PSCs by matching ETLS with a higher EFF and ECBM.

High-Performance MA0.96FA0.04PbI3 Perovskite Solar Cells Made in a Humid Air with a Relative Humidity of 70% Xiuwen Xu, Yuenin Xie, Menglin Li, Yuhui Ma and Sai-Wing Tsang; City University of Hong Kong, Hong Kong, Hong Kong.

Understanding air-processing limitations and developing facile strategies to fabricate high-performance air-processed perovskite solar cell (PSC) is appealing yet challenging for the low-cost industrial deployment. Here, we demonstrate that besides the general wisdom of the moisture effect, oxygen induces a de-wetting behavior during the spin-coating of PbI2 precursor solution, both of which leads to the failure of desirable PbI2 deposition in air. Interestingly, by simply preheating the substrate and PbI2 solution, uniform PbI2 films can be deposited in air with a relative humidity (RH) of 70%. This is probably due to the rapid solvent evaporation at high temperature, reducing the ingress of oxygen and moisture. With the preheating approach, PSCs based on MA0.96FA0.04PbI3 achieves an encouraging power conversion efficiency (PCE) of 18.11%. More importantly, it is found that the combination of preheating and a PbI2(Cs)0.15(FAPbI3)0.85 intermediate complex can unlock the processing limitation and facilitate the growth of high-quality FA based perovskite films in humid air (RH: 70%). With the coupled method, a low-temperature air-processed planar Cs0.15FA0.85PbI3 PSCs achieves a high PCE of 15.56% with superior thermal-stability and photo-durability. Our work not only reveals the origin of the detrimental effects on perovskite formation in humid air, but also provides practical strategies for high-efficiency air-processed MA or FA based PSCs for future commercialization.

ZnO/SnO2 Double Electron Transport Layer Guides Improved Open Circuit Voltage for Highly Efficient CH3NH3PbI3-Based Planar Perovskite Solar Cells Duo Wang; School of Physics, Peking University, Beijing, China.

The electron transport layer (ETL) is a very important component of planar perovskite solar cells (P-PSCs), and it can effectively extract photon-generated electron from perovskites and convey them to the cathode. By this token, its properties directly determine the photovoltaic performances of P-PSCs. Herein, we developed ZnO/SnO2 as a double electron transport layer for CH3NH3PbI3-based P-PSCs, achieving a high open circuit voltage (VOC) of 1.15 V with the power conversion efficiency (PCE) of 19.1% when the controlled devices have a VOC of 1.07 V and a PCE of 18.0%. To the best of our knowledge, up to now, this is the highest VOC obtained by using an inorganic electron transport layer for pure CH3NH3PbI3-based P-PSCs. Moreover, a higher EFF and ECBM of ETL are believed to drive a larger VOC and a better PCE. These indicate that it is a very significant method to achieve a higher VOC for P-PSCs by matching ETLS with a higher EFF and ECBM.

High Crystallization of Perovskite Film by a Fast Electric Current Annealing Process Wei Luo; School of Physics, Peking University, Beijing, China.

High efficiency organic–inorganic hybrid perovskite solar cells have experienced rapid development and attracted significant attention in recent years. Crystal growth as an important factor would significantly influence the quality of perovskite films and ultimately the device performance, which usually requires thermal annealing for 10 min or more. We demonstrate a new method to get high crystallization of perovskite film by electric current annealing for just 5 s. Two strip electrodes were clipped onto the opposite sides of the FTO/SnO2 coated perovskite film, and subsequently applied with a direct voltage of 30 V for 5 s. The coated perovskite film was annealed quickly by the joule heat current flowing through the FTO layer. In contrast to conventional thermal annealing, a homogeneous perovskite film was grown on large grains and fewer pinholes, leading to a better performance of the device with higher open-circuit voltage and fill factor. The average PCE consequently improved to 17.02% from 16.05% with the conventional thermal annealing (100 °C for 10 min). In addition, the annealing time is significantly shortened to a few seconds and the heating area is relatively concentrated to the only film. This facile electric current annealing process with less energy loss and time consumption shows great potential in the industrial mass production of photovoltaic devices.

Solution-Processed Cu9Sn5 as Hole Transport Doping Layer for Efficient and Stable Perovskite Solar Cells Dong Han; School of Physics, Peking University, Beijing, China.

In recent years, perovskite solar cells have drawn widespread attention. We believe that investigation of long-term stability of perovskite solar cells is a critical issue and necessary to solve for its commercialization. As a hole transport material (HTM), Cu9Sn5 is widely used in n-i-p perovskite solar cells (PVSs). However, it suffers from a severe degradation from the penetration of moisture due to the doping of lithium bis(trifluoromethyl)sulfonyl)amide (Li-TFSI), which has strong hygroscopicity. In this paper, we propose a method which offers a new way to reduce the hysteresis and improve the stability of n-i-p perovskite solar cells by employing nitrogen-doped SnO2 (N:SnO2) electron transport layer (ETL) and Spiro-OMeTAD/Cu9Sn5 hole transport layer (HTL) without Li-TFSI doping. Cu9Sn5 is a p-type transport material with favorable energy level matching with Spiro-OMeTAD. Furthermore, since there is no Li-TFSI doping in HTL, it can avoid devices suffering a severe degradation from the permeation of moisture. In the meantime, the LUMO of SnO2 can be tuned from -4.33 eV to -3.91 eV by implanting nitrogen ions into the SnO2, which exactly match the LUMO of CH3NH3PbI3 (-3.90 eV) and thus help to reduce the hysteresis. The modified n-i-p perovskite solar cells achieve maximum PCE of 17.10% and remain about 96 % of PCE after 1200 hours stability test in air environment with no encapsulation.

thin-film and wafer-based solar cell technologies. Nevertheless, the toxicity of Pb remains as a major issue for the commercialization of perovskite photovoltaics. So far, Sn-based perovskites showed the most promising results in Pb-free perovskite solar cells with efficiencies up to 9.0 %. However, Sn-based perovskite layers typically suffer from poor layer quality (coverage and homogeneity issues) and fast degradation caused by the instability of the Sn2+ ion which easily oxidizes to Sn4+.

In this work, we present formamidinium tin iodide (FASnI3) perovskite solar cells which are processed by spin-coating under inert nitrogen atmosphere, employing a standard non-inverted stack composed of compact and mesoporous TiO2, the perovskite layer and Spiro-MeOTAD sandwiched between fluorine-doped tin oxide (FTO) and evaporated gold contacts. Morphological and structural characterization of processed layers and devices is carried out by scanning electron microscopy. Photovoltaic measurements are performed in nitrogen atmosphere under simulated AM1.5 sunlight of 100 mW/cm² illumination. Absorption spectra measurements are conducted in the wavelength range of 300 - 1000 nm. To increase the area covered with the perovskite film, we examine the influence of using different amounts of toluene as anti-solvent initiating a rapid crystallization. It was determined that 1 ml of toluene is sufficient for 80 µl perovskite solution to produce closed films. To suppress Sn2+ oxidation and to obtain smooth perovskite films, pyrazine and SnF2 were added into the perovskite precursor solution. By varying the ratio of additives in this solution, their impact on layer morphology and on cell performance are investigated. A pyrazine/SnF2 ratio of 0.2 M / 0.1 M has proven to be the optimum leading to smooth layers and a maximum PCE of 2.1 %. We highlight that layers with higher concentrations of additives suffer from delayed crystallization and therefore reduced coverage. However, we found that these layers exhibit additional light absorption for wavelengths above 650 nm and still provide reasonable photocurrents.

High Efficiency Perovskite Solar Cells with Molecular Passivated NiOx Charge Extraction Layer
Menglin Li; Materials Science and Engineering, City University of Hong Kong, Hong Kong, Hong Kong.

Developing low cost and stable metal oxide charge extraction layer is attractive yet challenging for fabricating long-term stable high-performance perovskite solar cells (PSCs). Here, it is found that the solution processed NiOx based PSCs surface suffers from strong recombination with interfacial defects. We have found that continuous light soaking is required in the NiOx based PSCs to recover the built-in potential and consequently open-circuit voltage ( VOC ). Interestingly, we have found that n-butylamine molecular monolayer can effectively passivate those defects in the NiOx layer. The device power conversion efficiency (PCE) with molecular passivated NiOx as the hole transport layer is increased from 13.5% to 18.0%. Further molecular dynamic simulation reveals auto-decomposition process at as-prepared NiOx/MAPbI3 interface, which can be eliminated by surface passivation.

Understanding the Crucial Design of Amorphous Hole Transport Materials in Perovskite Solar Cell
Kun-Han Lin, Antonio Prlj and Clémence Corminboeuf; Institute of Chemical Sciences and Engineering, Ecole polytechnique fédérale de Lausanne (EPFL), Lausanne, Switzerland.

Within the last nine years, the power conversion efficiency of perovskite solar cell (PSC) has soared to 22.7% [1]. Among recently proposed high-performance PSCs, hole transport layers have proved to be essential components for these devices [2]. A promising HTM should possess a suitable ionization potential (IP) to enlarge the open-circuit voltage (Voc); meanwhile, it should transport charge carriers efficiently from the perovskite/HTM interface to the electrode [3]. In contrast to this well-known design principle, a comprehensive understanding of the structure-property relationship remains lacking, especially for the challenging relationship between molecular structure and mobility. The discrepancy of knowledge in these two aspects hampers the discovery pace of promising HTMs. As a result, investigating the non-trivial structure-mobility relation with the aid of computer simulations at a molecular level would be beneficial. Our recent work on a prototype HTM, TPAC-3M [4], demonstrated that increasing the number of “carbazole side arms” (mono- to tri- arm) attached to a triphenylamine (TPA) core enhances the mobility by approximately 5 times by lowering the reorganization energy and the energetic disorder. Further optimization of the IP of the high-mobility tri-arm HTM by substituting methoxy groups with various other electron-withdrawing groups results in HTMs with desirable energy alignments with the perovskite materials. Care should be taken, however, as an enormous molecular dipole moment can result from IP-tuning, which magnifies the energetic disorder and leads to a mobility loss of more than one order of magnitude. After a thorough investigation, we propose a new tri-arm molecule containing pyridine substitutions, that possesses enhanced hole mobility and a suitable IP. Moreover, the pyridine moiety can also serve as a Lewis base that passivates the surface defects of perovskite, which reduces charge recombination at the perovskite/HTM interface [5].

ET04.03.21
Thermal Stability of Polycrystalline Hybrid Perovskite Thin Films Demonstrated by Grain Boundary Ruihan Yang, Yaefe Wang and Shibin Li; University Of Electronic Science And Technology Of China, Chengdu, China.

Perovskite solar cells (PSCs) have been developed rapidly with power conversion efficiencies (PCE) rushing from 3.8% to a certified 22.1%. Accompanied with the improvement of PCE, the stability of perovskite has become a focus recently. Thermal instability of hybrid perovskite thin films is one of the important issues that must be overcome on the way to commercialization of PSCs, and then its essence to deeply understand the degradation mechanism of perovskite thin films caused by thermal instability. In this work, we studied the dependence of thermal stability of CH$_3$NH$_3$PbI$_3$ (MAPbI$_3$) crystals on grain size. We fabricated MAPbI$_3$ films by anti-solvent one-step deposition method and increased the grain size by IPA solvent annealing. According to the SEM, XRD and UV-Vis absorption measurements, it was demonstrated the thermal stability of polycrystalline hybrid perovskite thin films dominated by grain boundaries (GBs). The grain size plays a key role in the thermal degradation of the MAPbI$_3$. It was found that degradation rates of MAPbI$_3$ films in thermal environment are sensitive to the grain size and temperature. MAPbI$_3$ films with larger grain sizes and less GBs have a better resistance to heat-transfer. To further understand the thermal degradation mechanism of perovskite crystals, a molecular model was put forward. The dangling bonds in GBs were considered to promote the process of thermal decomposition. Thus MAPbI$_3$ films with less GBs exhibit higher thermal stability. Meanwhile, solar cell devices with a structure of FTO/TiO$_2$/meso-TiO$_2$/MAPbI$_3$/PTAA/Au were fabricated and J-V curves of PSCs were measured to compare the photovoltaic performance of PSCs. The highest efficiency of PSCs increased from 16.87% to 18.56% with the increase of grain size. The results indicate that the reduction of GBs of perovskite is a feasible way to improve the thermal stability of PSCs.

ET04.03.22
Multi-Layered Thin Film Encapsulation for Perovskite Solar Cells via Low-Temperature Plasma-Enhanced Atomic Layer Deposition Seong Hyun Lee1, Jung Wook Lim1,2, Gayoung Kim1,2 and Man Gu Kang1,2; 1ICT Material Research Group, Electronics and Telecommunications Research Institute, Daejeon, Korea (the Republic of); 2Department of Advanced Device Engineering, University of Science and Technology (UST), Daejeon, Korea (the Republic of).

The performance of perovskite solar cells (PSCs) has dramatically improved over half a decade, and a record efficiency of 22.7% for a cell with an active area of less than 0.1 cm$^2$ has been achieved. However, the stability against moisture is essential for viability in the commercial market. Many efforts have been devoted to modifying the stability of either the perovskite material itself or the electron and hole transport layers but the fundamental solutions have not been found to date. Therefore, the encapsulation technologies have received a considerable amount of attention for the long-term stability of PSCs. In this study, we investigated the thermal stability of perovskite thin films deposited by low-temperature plasma-enhanced atomic layer deposition (PEALD). The multi-layered encapsulation films consist of Al$_2$O$_3$ and SiO$_2$ layer which have high moisture barrier properties. We optimized the thickness of each layers and the number of layer interfaces of the encapsulation layers to reduce the water vapor transmission rate (WVTR). Through the MOCON test, it was demonstrated that the WVTR of Al$_2$O$_3$/SiO$_2$ multi-layered encapsulation film with a 100 nm-thick is lower than that of Al$_2$O$_3$ and SiO$_2$ single-layered encapsulation film with the 100 nm-thick. And, in the case of multi-layered encapsulation, it was indicated that the number of Al$_2$O$_3$/SiO$_2$ interfaces strongly affects the values of WVTR. Based on above results, we applied the multi-layered encapsulation to PSCs and investigated the moisture stability of the PSCs with respect to the process temperature, film thickness and process sequences of the multi-layered encapsulation thin films. And we explored the effect of plasma damage on the performance and moisture stability of the PSCs during the PEALD process. Furthermore, we will discuss the performance degradation of large-scale PSC modules with the Al$_2$O$_3$/SiO$_2$ multi-layered encapsulation under damp heat conditions consisting in 85 °C and 85% relative humidity, during a period of 1000 hours. This work would pave the way for the commercialization of the practical PSC modules in the near future.

ET04.03.23
Interconnection Optimizations for Efficient Perovskite Solar Modules Zhen Li1,2, Mengjin Yang1, Donghoo Kim1, Talsya Klein2, Maikel van Hest1 and Kai Zhu1; 1Chemistry and Nanoscience Center, National Renewable Energy Laboratory, Golden, Colorado, United States; 2State Key Laboratory of Solidification Processing, Center for Nano Energy Materials, School of Materials Science and Engineering, Northwestern Polytechnical University and Shannxi Joint Laboratory of Graphene (NPU), Xi’an, China; 3Materials Science Center, National Renewable Energy Laboratory, Golden, Colorado, United States.

Small area perovskite solar cells (PSCs) have achieved power conversion efficiency (PCE) comparable to other thin film solar cells. Pushing PSC technology toward commercialization requires developing large-area perovskite solar modules with fully scalable deposition approaches. A fully scalable deposition scheme for perovskite module fabrication was demonstrated using spray coating for TiO$_2$ electron transport layer (ETL) and blade coating for both perovskite absorber layer and spiro-OMeTAD hole transport layer (HTL). It is found that the interconnections between sub-cells in the PSC modules are important for achieving high performance and reliability. Due to the difficulty of removing TiO$_2$ layer by scribing, the interconnection between sub-cells contains a TiO$_2$/metal junction. The TiO$_2$/metal junction shows a schottky diode or ohmic contact behavior, depending on the thickness of the TiO$_2$ layer. Optimization of the interconnection contact achieves better module performance, mainly contributed from improved fill factor. Finally, we demonstrated a highly efficient 4-cell MA$_0.7$FA$_{0.3}$PbI$_3$ perovskite module with a stabilized PCE of 15.6% measured from an aperture area of ~10.36 cm$^2$, corresponding to an active-area PCE of 17.9% with a geometric fill factor of ~87.3%.

ET04.03.24
The Abnormal Synergetic Effect of Organic and Halide Ions on the Stability and Optoelectronic Properties of Mixed Perovskite via In Situ Characterizations Minzhu Long, Tiankai Zhang and Jianbin Xu; Chinese University of Hong Kong, Hong Kong, China.

The mixed cation lead mixed halide perovskite (MLMP) Cs$_x$FA$_{1-x}$PbI$_3$Br$_y$ is one of the most promising candidates for both single-junction and tandem solar cells applications due to its high efficiency and remarkable stability. However, the composition effect on thermal stability and photovoltaic performances has not yet been comprehensively investigated. Therefore, the interplay between composition, crystal structure, morphology and optoelectronic properties under heat stress, were systematically elucidated here through a series of in situ characterizations. It is revealed for the first time that the FA and Br-spin span style="font-size:10.8333px">-would release synchronously at first even under mild annealing. This release leads to serious
Methylammonium lead halide perovskites suffer from a high degradation rate of \(<0.1\% \text{ h}^{-1}\). Some of this degradation is extrinsic, e.g. exposure to humidity, which can be minimized via device encapsulation. However, perovskite is also intrinsically unstable, even in completely encapsulated conditions hybrid perovskite degrade at the temperatures \(>80\, ^\circ\text{C}\), mainly due to the organic component i.e., methyl ammonium ion (MA). In this work, we report a novel mixed-cation perovskite with 40% acetamidinium (AA) cation in the MAPbI\(_3\) matrix. Unlike MA cation, the AA cation has a restricted C-N bond rotation due to delocalized n-electron cloud over N-C-N bond. This results in stronger hydrogen bonding that enhances the intrinsic stability of the lattice. MA\(_x\)AA\(_{1-x}\)PbI\(_3\) thin-films with 5%, 10%, 20% and 40% AA are synthesized in the same manner as MAPbI\(_3\), with AAI precursor added to the precursor solution in the stoichiometric ratio. Spin-coated films are annealed at 100°C to obtain black coloured MA\(_x\)AA\(_{1-x}\)PbI\(_3\) films. The XRD pattern shows a monotonic shift in 29 peak from 14.24 to 14.02 when we increase the AA% in perovskite matrix from 0 to 20%, however, we see the presence of some other secondary phases like AAAPbI\(_3\) when AA% is \(>10\%\). Further, post-treatment of the as deposited film with methylamine vapor suppresses the secondary phases. In addition, it also improves the grain sizes from about 200 nm needles to 1-2 \(\mu\text{m}\) grains with complete surface coverage in accordance with a literature. The improvement in the film quality also reflects in the increase in the carrier lifetimes to 37 \(\mu\text{s}\) for 10% AA substituted films compared to 25 \(\mu\text{s}\) for the standard MAPbI\(_3\) films. Further, 12 devices with FTO/c-TiO\(_2\)/m-TiO\(_2\)/MA\(_x\)AA\(_{1-x}\)PbI\(_3\)/Spiro-OMeTAD structure were fabricated. An increase in the open-circuit voltage was observed for the AA substituted devices having \(V_{oc}\) in the range of 1.04–1.08 V against 0.96–1.01 V of the standard MAPbI\(_3\) devices. Also, the fill-factors of the AA cells increased to 0.73–0.75 against 0.67–0.69 of the MAPbI\(_3\) devices. But the short-circuit currents of the AA devices fell to 15–19 mA/cm\(^2\) from 21–22.5 mA/cm\(^2\) of the standard devices. The thicknesses and absorption spectra of the films are currently under investigation to account for the decrease in the \(J_{sc}\). The overall PCE of the AA devices came out to be 13.2% against 14.53% of the standard devices. Increasing the thickness of the AA substituted films will increase the \(J_{sc}\) of the devices possibly without affecting the \(V_{oc}\) owing to their higher carrier lifetimes, thus providing scope for higher PCE’s. Also, thermal degradation measurement shows that as expected, AA substituted films are more stable than pure MAPbI\(_3\) films. While pure films lose their color and luster in just 32 hours at 120 °C, MA\(_x\)AA\(_{1-x}\)PbI\(_3\) films retain the black phase. The thermal stability measurements of the fabricated devices are underway.

**Towards CIGS Perovskite Tandem Cells**

**Jesper Jacobsen**, Adam Hultqvist, Håkan Rensmo and Gerrit Boschloo; 1Chemistry, Uppsala University, Uppsala, Sweden; 2Uppsala University, Uppsala, Sweden.

Perovskite solar cells will have a hard time to reach competitiveness with respect to conventional PV-technologies; unless they are integrated in tandem-architectures that possibly could outperform single junction silicon cells. One interesting potential perovskite tandem companion is CIGS, CuIn\(_x\)Ga\(_{1-x}\)Se\(_2\), which is a commercial thin film technology with record efficiencies above 22 % and a variable band gap. In this project, we strive for constructing efficient 2-terminal CIGS-perovskite tandem cells. We will here discuss progress and challenges connected to recombination layers, perovskite engineering, and transparent top contacts in CIGS-perovskite tandem architectures.
Low gap ABX₃ perovskites tin and lead at the B-site are a breakthrough that has enabled fabrication of efficient all-perovskite tandem solar cells. However, tin is susceptible to oxidation to the 4⁺ state, a degradation pathway unique to tin-containing perovskites. Suppressing this oxidation reaction is essential to ensure that highly efficient all-perovskite tandem solar cells are also stable against long term environmental stressors.

We identify the specific chemical mechanism by which pure tin-based perovskites undergo oxidation using a combination of chemical methods including thermogravimetric analysis and solvent extraction of degradation products. We find that the oxidation reaction depends on a cooperative mechanism that involves simultaneous oxidation of multiple adjacent tin iodide octahedra. Critically, the most favorable oxidation pathway is blocked by substitution of 50% or more of the B-site with lead because this significantly lowers the chances of there being multiple adjacent tin octahedra that can facilitate the cooperative mechanism. As a result, the stability of tin perovskites toward oxidation is improved by orders of magnitude upon alloying with lead. The resulting guideline is that low band gap perovskites can be designed to have significantly enhanced oxidative stability by keeping the tin fraction at 50% or below.

We proceed to design solar cells to withstand aging under elevated temperatures in air. We probe the thermal stability of high-performing low band gap solar cells by aging at 85°C in air. Encouragingly, there is no measurable change in the bulk absorption of the perovskite absorber under thermal aging in air, indicating that the strategy of suppressing oxidation by using a mixed tin-lead perovskite successively avoids oxidative breakdown. However, the fill factor drops due to the formation of an S-kink after 100 hours of aging. We develop a treatment of the tin-lead perovskite film by exposure to methylammonium chloride vapour that results in significant grain growth and healing of cracks between grains. This post-treatment dramatically improves the thermal stability of the full solar cells. Using an MAC1-vapour-treated low gap perovskite with 50% tin, capped with a sputtered Indium Tin Oxide (ITO) top electrode, we successfully demonstrate a solar cell that maintains its full power conversion efficiency for 150 hours in air at 85°C, and remains above 85% of initial PCE for over 300 hours. In addition, we demonstrate stable operation of a tin-lead solar cell at maximum power point under 1-sun illumination for over 100 hours with no drop in performance. These measurements are a huge improvement upon any thermal stability results reported for tin-containing perovskites. The fact that good thermal stability in air is achieved with no encapsulation represents a major step toward proving the long-term stability of tin-lead low band gap perovskite solar cells, and of efficient all-perovskite tandem solar cells.

Two conflicting characteristics compete where the commercial viability of one-sun tandem solar cell is concerned: On the one hand, tandem solar cells have fundamentally higher efficiencies than single junction solar cells. On the other hand, tandem solar cells are intrinsically more complex than single junction solar cells and require more fabrication steps, which makes them more expensive. Only if the benefit from the additionally generated energy outweighs the higher fabrication cost can tandem solar cells be successful.

The question under which conditions the last sentence is true is a multilayered one. The value of efficiency is highest when considering the integrated PV system, which makes it necessary to explore system level aspects. These aspects include, among others, economic considerations as well as topics from material science; for example degradation.

In this work we attempt to provide an overview of what is needed to make tandem solar cells economically successful. Central to our findings is the material science; for example degradation.

The talk will begin by showing what we have done to make perovskite on silicon tandem solar cells with 25% efficiency and how 30% efficiency can probably be obtained in the coming years. Then the challenge of making solar panels with metal halide perovskite semiconductors that will last for more than 25 years will be addressed. We will show that packaged solar cells can survive industry standard reliability tests such as 1000 hrs at 85°C and 85% humidity, 200 temperature cycles between -40°C and 85°C, and ultraviolet exposure. The strategies for making stable perovskite cells include choosing perovskite compositions that have higher thermal and oxidative stability, managing stress during the formation of the film to prevent buckling that makes subsequent processing difficult, minimizing tensile stress in the final film since it appears to make bonds weaker, using solution processing of the top contact layer to fill in gaps at grain boundaries so that a sputtered transparent conducting oxide layer can form a superb barrier layer, using polyolefin as the encapsulant since it does not chemically react with the perovskite and has an ideal elastic modulus, using butyl rubber edge seals and using glass on glass packaging.

Combining perovskites with well-established photovoltaic materials such as silicon or CIGS is an attractive option for producing cheap, high efficiency and high voltage solar cells. Perovskite-based tandem solar cells can potentially achieve over 30% tandem efficiency. We demonstrate a 4-terminal tandem perovskite-silicon configuration in which the efficiency is as high as 26%. We also demonstrate a two-terminal monolithic tandem device with a perovskite top subcell and a high-temperature tolerant homojunction c-Si bottom subcell, with an efficiency of over 22%, and a perovskite/CIGS tandem with an efficiency of over 23%, which is the highest efficiency that has been reported for this configuration. We describe the optical and electronic factors that have been instrumental in reaching these efficiencies. We also show that interface passivation can lead to open circuit voltages over 1.2V for a 1.6eV bandgap perovskite, and that semi-transparent cells can achieve high stability under combined heat and light. These results show the clear potential of perovskites in practical high efficiency tandem devices.

With open circuit voltages (V_{oc}) above 730 mV, silicon heterojunction (SHJ) solar cells are promising candidates for the bottom cells in organic-inorganic lead halide perovskite/silicon tandem solar cells. Using simulation studies, we have shown that under realistic assumptions, power conversion efficiencies up to 30% should be achievable with such devices [1]. To attain this goal, starting from first devices with moderate stabilized efficiencies of 18.1% [2] we carefully optimized the optical and electrical properties of the device in order to achieve low parasitic absorption and reflection, photorecurrent matching between the two sub-cells and lowly resistive current transport across the internal tunnel-recombination junction. In this presentation, I will discuss how we were recently able to demonstrate certified 25% efficient perovskite/SHJ tandem cells [3] by addressing these issues. I will focus on the silicon bottom cell and contact stack optimization: Starting from a rear junction SHJ cell design on double side textured wafers with 22.6% power conversion efficiency (J_{sc} = 38.3 mA/cm², V_{oc} = 731 mV, FF = 80.6 %) [4], we developed a rear side only-textured SHJ cell, which allows to process the perovskite top cell using conventional spin-coating methods. Optimizing film thicknesses at the perovskite/SHJ interface and tuning the refractive index of the nc-SiO_{x}:H film used as front surface field in the SHJ to an intermediate value of ~2.6 (at 800 nm) were instrumental in achieving 25% efficient cells with photocurrents above 17.8 mA/cm². On this basis, I will briefly discuss the potential to further enhance device performance using alternative deposition methods, such as plasma-enhanced ALD for tin oxide interlayers, and alternative materials such as tungsten oxide alloys for carrier selective contacts.

Progress on Si Tandems [Anita Ho-Baillie1, Hamid Mehrvarz1, Jianghui Zheng1, Faqun Ma2, Chuo Y1, Stephen Brenner1, Shujuan Huang2, Hidenori Mizuno2 and Tyler J. Grassman3;1Australian Centre for Advanced Photovoltaics, The University of New South Wales, Sydney, New South Wales, Australia; 2Fukushima Renewable Energy Institute, National Institute of Advanced Industrial Science and Technology, Fukushima, Japan; 3The Ohio State University, Columbus, Ohio, United States.

Tandem solar cell is a promising approach for achieving high efficiencies for photovoltaics [1]. The challenge is to find an efficient, economical and stable technology for each cell stack to realize true savings in the system’s levelised cost of energy. Nevertheless, substantial progress has been made in the demonstrations of two-terminal Si tandem cells. The advantage of 2-terminal over 4-terminal configuration is the reduced complexity in wiring and packaging [2]. The challenge lies in the integration of the cell stacks without electrical and optical losses. Recently, a simple perovskite/Si tandem cell structure has been reported [3]. It does not require additional interface layer for the integration of perovskite and Si cells. Instead, the electron transport layer in the perovskite top cell serves as the recombination layer between the top and bottom sub cells. The lack of lateral conductivity in this recombination layer means undesirable shunts are effectively localized. Another advantage of this structure is its compatibility with homo-junction Si cells – the most common choice for incumbent commercial Si photovoltaic technology. Recent optimizations have improved cells’ performance from 20.5% to 22.7% on 4cm². Great progress has been made on 2-terminal III-V/Si and III-V/Si tandems via wafer bonding and direct growth. Many of these tandem cell structures require smooth interface negating the use of textured Si bottom cell. This means external measures are required for anti-reflection and light trapping. Strategies for improving the optical performances of InGaP/GaAs/InP tandem by SmartStack [4] and monolithic epitaxial GaAsP/Si tandem [5] will be presented in this talk.

Textured Monolithic Perovskite/Crystalline Silicon Tandem Solar Cells with >25% Power Conversion Efficiency [Jeremie Werner1, Florent Sahli1, Brett Kamino2, Matthias Brüning2, Raphael Mond1, Giszem Nogy1, Philippe Wyss1, Andrea Ingenito1, Bertrand Paviot-Salomon2, Loris Barnaud1, Laura Ding2, Juan Diaz Leon2, Gianluca Cattaneo1, Arnaud Walter1, Soo-Jin Moon2, Terry Chien-Jen Yang1, Peter Fiala1, Fan Fu1, Mathieu Boccard1, Matthias Despeisse1, Bjorn Niesen2, Sylvain Nicoloy2, Quentin Jeangros1 and Christophe Ballif1;1PV-Lab, Ecole Polytechnique Fédérale de Lausanne (EPFL), Neuchâtel, Switzerland; 2PV-Centre, CSEM, Neuchâtel, Switzerland.

As crystalline silicon (c-Si) solar cells are approaching their efficiency limit of 29%, novel solutions must be found to increase the competitiveness of Si photovoltaics compared to conventional energy sources. One of the most promising approaches lies in combining c-Si solar cells with a low-cost wide-bandgap top cell to form a tandem device. Organic-inorganic halide perovskite solar cells are particularly attractive candidates for top cells, showing high efficiencies with simple and potentially cost-effective device fabrication. Calculations have shown that the practical efficiency potential of perovskite/c-Si tandem solar cells is beyond 30%.

Here, we present perovskite/silicon tandem devices featuring fully textured bottom cells, through a careful control of the top cell deposition conditions and hence of the optoelectronic properties and interfaces of the different materials. These cells were employed as a platform to address the most crucial questions for tandem development: - Reaching maximal performance: fully conformal perovskite top cells were developed and optimized, enabling the usage of industrially viable textured bottom cells for maximal optical performance given the reduced reflection losses and enhanced light trapping. This enabled current-matching conditions with >20 mA/cm² in both the perovskite and silicon subcells (excluding metallization-induced shadow losses). Parasitic absorption was minimized thanks to the development of highly transparent charge transport layers and electrodes. This optical optimization of the tandems led to a certified steady-state
efficiency of 25.2% for an aperture area of >1 cm².
- **Up-scaling:** A nanocrystalline silicon intermediate recombination layer was developed to increase the shunt resistance and enable large-area tandem devices, achieving 13-cm² cells with a steady-state efficiency above 20%.
- **Silicon bottom cell technology:** We tested our process with different bottom-cell technologies (silicon heterojunction or tunnel oxide passivated contact) and reached >25% efficiencies on both cell types for an aperture area of >1 cm².
- **Industrially viable metallization:** A screen-printed silver (Ag) metallization method was developed for the front grid. It employs a low-temperature Ag paste that can be cured without affecting the perovskite properties.
- **Encapsulation and cell reliability:** An encapsulation process involving a glass/glass configuration with a butyl rubber edge sealant was developed. Encapsulated tandems were subjected to standard reliability testing conditions, including damp heat at 85 °C/85%RH and light soaking for 1000 hours. Overall, these results suggest a path in the development of monolithic perovskite/silicon tandem solar cells with realistic efficiency potential >30% on large area with enhanced stability.

SESSION ET04.05/ET05.05: Joint Session: The Past, Present and Future of Halide Perovskites
Tuesday Afternoon, November 27, 2018
Hynes, Level 3, Room Ballroom B

1:30 PM *ET04.05.01/ET05.05.01
**Hybrid Halide Perovskite Semiconductors—An Historical Perspective**

David B. Mitzi
Duke University, Durham, North Carolina, United States.

Organic-inorganic perovskites enable a combination of useful organic and inorganic properties within a single molecular-scale composite and have attracted substantial interest for use within organic-inorganic electronic devices [1], in part due to the high carrier mobilities, long minority carrier lifetimes, tunable structures/band gaps, relatively benign defects and grain boundaries, and facile processing for systems based on Group 14 metals (e.g., Ge, Sn, and Pb). Most recently, these materials have enabled unprecedented rapid improvement in performance within single junction photovoltaic (PV) devices, from an initial demonstration in 2009 [2] to levels with >20% power conversion efficiency and open circuit voltages >1V [3]. This talk will provide an historical perspective on foundational work related to the organic-inorganic perovskite semiconductors, including discussion of crystal structure flexibility, semiconducting properties, film deposition approaches and electronic device applications of the three-dimensional and lower-dimensional perovskite structures [4,5]. Recent trends in the field, as they relate to application in photovoltaics and related devices, will also be coupled into this discussion.

2:00 PM *ET04.05.02/ET05.05.02
**Photovoltaics of Halide Perovskites and Perspectives of Extensive Applications from the Ground to the Universe**

Tsutomu Miyasaka; Toin University of Yokohama, Yokohama, Japan.

Lead halide perovskite absorbers have achieved high photovoltaic performance exceeding the efficiency of CIGS and CdTe and their long term stability against heat, moisture, and light are being improved by compositional engineering of perovskite and surrounding carrier transport materials. For industrial applications, thermal stability of perovskites and carrier transport materials is a critical issue in comparison with thermally highly strong inorganic solar cell (Si, CdTe, etc.). Metal oxide electron transport layers (ETLs) generally have advantage in higher thermal stability than organic ETLs. We have been working with TiO₂ ETL-based cation perovskite cells, which yielded efficiency over 21% by ambient air solution processes. Light intensity dependence of Voc shows ideality factor low enough (n<1.4) for the perovskite solar cell to work as a high voltage power source even under weak light. Such merit meets a requirement in solar cell application to space satellite missions, which needs high photovoltaic performance even under very weak sunlight (Mars and Jupiter). We have examined the durability of perovskite solar cells which have thermally stable compositions comprising FA-based perovskites, TiO₂ ETL, and P3HT as hole transport layer (HTL). These cells exhibit good stability against thermal impact between temperature range between ~80°C and +100°C. We also confirmed very poor thermal stability of spiro-OmeTAD as a reference HTL. On exposure to high energy electron and proton radiations as accelerated conditions simulating long term space irradiations, the perovskite cells demonstrated high stability and tolerance, which are superior to those of Si and GaAs solar cells. Space applications also require fabrication of lightweight flexible devices. Thin film substrate-based perovskite solar cells were fabricated by low-temperature multilayer coating methods using amorphous TiO₂ as ETL, which yield efficiency up to 18%. Future perspectives of industrialization of perovskite photovoltaic devices will be discussed focusing on the durable composition of perovskite devices and advantage of lightweight thin film device.

**Perovskite Photovoltaics—History, Progress and Perspective**

Nam-Gyu Park; Sungkyunkwan University, Suwon, Korea (the Republic of).

Since the first report on the high efficiency, stable solid-state perovskite solar cell (PSC) in 2012 by our group, following two seed works on perovskite-sensitized liquid junction solar cells in 2009 and 2011, PSC demonstrated its power conversion efficiency (PCE) of 22.7% in 2017. According to Web of Science, publications on PSC increase exponentially since 2012 and total number of publications reaches about 9,000 as of May, 2018, which is indicative of a paradigm shift in photovoltaics. Although high photovoltaic performance was achieved, current-voltage hysteresis has been issued because it is related
to stability of PSC. In this talk, methodologies to remove hysteresis are described. Interlayers at heterojunction are found to play important role in reducing hysteresis and improving stability. Manipulation of Frenkel defect is a universal approach toward hysteresis-free PSC. We have discovered novel methods for large-area perovskite coating and phase transformation in perovskite, which will be discussed in detail. In addition to photovoltaics, perovskite can be used to other applications. Long charge diffusion length and high energy stability of organic-inorganic halide perovskite are suitable for low-dose, high resolution X-ray imaging. We demonstrated X-ray image using millimeter thick perovskite film based on multicrystalline perovskite crystal with single-crystal-like optoelectronic properties. For heading toward Shockley–Queisser limit, research direction in PSC is proposed in this talk.

3:30 PM  *ET04.05.04/ET05.05.04*  
Compositional Engineering for Efficient and Durable Perovskite Solar Cells  
Anders Haasefeldt, Laboratory of Photomolecular Science, Swiss Federal Institute of Technology Lausanne (EPFL), Lausanne, Switzerland.

In our work on perovskite solar cells (PSC) we have achieved efficiencies above 20% with a mixed composition of iodide/bromide and methyl ammonium/formamidinium [1]. For cells larger than 1 cm\(^2\) we have obtained 19.6% [2], replacing the anti-solvent step in the perovskite film formation with a vacuum flash treatment. With the use of SnO\(_2\) compact underlayers as electron acceptor contacts we have constructed planar perovskite solar cells with a hysteresis free efficiency above 20% [3]. The cation mixing strategy has been developed further by including the Cs in a so-called ‘triple cation’ composition, i.e. Cs/FA/Ma as well as Rb in a quadruple cation mixture. Larger grains grown in a monolithic manner are observed and for example with a hysteresis free efficiency above 20% [3]. The cation mixing strategy has been developed further by including the Cs in a so-called ‘triple cation’ composition, i.e. Cs/FA/Ma as well as Rb in a quadruple cation mixture. Larger grains grown in a monolithic manner are observed and for example with a hysteresis free efficiency above 20% [3]. At the meeting we will discuss our follow up works [3] and present our champion data; up to 22% efficiency with an external electroluminescence of 4%, and an outstanding open-circuit voltage of 1.24 V at a band gap of 1.63 eV entailing one of the smallest loss-in-potential of 0.39 V ever measured for any solar cell material. Furthermore, we will report promising stability at 85 °C for 500 h under full solar illumination and maximum power point tracking (during which 95% of the initial performance was retained). Recently, we have also commented on the standardization of PSC aging tests [6].

Perovskite Solar Cells—The Path to a Printable Terawatt-Scale Technology  
Kai Zhu; National Renewable Energy Laboratory, Golden, Colorado, United States.

Perovskite solar cells (PSCs) have become a competitive photovoltaic (PV) technology with rapid progress of efficiencies reaching to about 23%. Uniquely, PSCs have the highest efficiencies when they are solution processed, so one can envision solar cells printed in a similar manner and scale as newspapers. In addition, the bandgap tunability through perovskite composition engineering can enable high-efficiency multijunction devices, including perovskite/perovskite, perovskite/silicon, or perovskite/thin-film absorber (e.g., CIGS). Thus, PSCs are suited to helping address the challenge of terawatt-scale, PV-based electricity production that can power the future world. In this talk, I will discuss our recent progress in two areas: (1) scalable fabrication of high-efficiency, large-area perovskite solar cells and modules; (2) development of perovskite-based tandem devices. I will discuss our recent studies toward better control of film formation across the device stack at large scales by improving the precursor chemistry to better match the processing methods. The precursor chemistry and growth conditions affect significantly the physical and optoelectronic properties of perovskites. The challenges associated with perovskite solar module fabrication will be discussed. I will show the impact of interconnections on the performance of perovskite solar modules fabricated by scalable depositions. Toward perovskite-based tandem device development, I will discuss our recent effort on improving the optoelectronic properties of wide-bandgap as well as low-bandgap perovskite absorbers through solution chemistry engineering. Challenges and progress on perovskite-based tandem devices will also be discussed. These results demonstrate a promising path towards commercialization of the perovskite photovoltaic technology.

Understanding the Doping Effect on NiO—Toward High-Performance Inverted Perovskite Solar Cells  
Wei Chen\(^1\), Yinghui Wu\(^1\), Aleksandra B. Djurišić\(^1\) and Zhubing He\(^1\); \(^1\)Southern University of Science and Technology, Shenzhen, China; \(^2\)Physics, The University of Hong Kong, Hong Kong, Hong Kong.

Metal organic halide perovskite solar cells (PSCs) are emerging photovoltaic technology of significant interest due to their high power conversion efficiency (PCE), with record efficiency exceeding 22%. The use of inorganic hole transport layers (HTLs) in PSCs has been attracting increasing attention to improve the stability of the devices. Among various inorganic hole extraction/hole transport materials, NiO is of particular interest for PSC application. However, low intrinsic conductivity of NiO is a significant drawback, since it can result in hole accumulation near the perovskite interface, increasing the chance of recombination and reducing the charge collection. Therefore, considerable efforts have been made to improve the charge collection by improving the quality of deposited NiO and/or doping the NiO to improve conductivity and charge collection.

In this abstract, we synthesized high-quality copper doped nickel oxide (Cu: NiO) nanoparticle as hole transport layers in inverted perovskite solar cells at room temperature without further processing. In agreement with theoretical calculations predicting that Cu doping results in acceptor energy levels closer to the valence band maximum compared to gap states of nickel vacancies in undoped NiO, an increase in the conductivity in Cu: NiO films compared to
high performance of hybrid perovskite solar cells via organic fullerene doping and interfacial modification

High Performance of Hybrid Perovskite Solar Cells via Organic Fullerene Doping and Interfacial Modification

Yuchen Zhou1, Likun Wang1, Yifan Yin1, Zhenhua Yang1, Chang-Yong Nam2, and Miriam Rafailovich3; 1Stony Brook University, Stony Brook, New York, United States; 2Center for Functional Nanomaterials, Brookhaven National Laboratory, Upton, New York, United States.

The metal halide perovskite solar cells (PSCs) with remarkable power conversion efficiency (PCE) have been unprecedentedly popular in the research community in past several years. The state-of-art PSCs require a smooth and pinhole-free perovskite layer. It has been proved that key characters of high-quality perovskites can be obtained through optimizing the kinetics of nucleation and growth of perovskite crystals. Despite of several successful practices of modifying the crystal formation process, the lack of precise controls over the structure makes these methods less repeatable. In this study, we utilized a simple but effective doping method by firstly introducing a small amount of insulating polymer of poly (lactic acid) (PLA) into the perovskite layer as a dopant. The benefits of doping PLA polymer comes in 2-folds: 1) the PLA additive can serve as heterogenous nucleus for preferential formation and growth of perovskite crystals. 2) PLA can also introduce PbI2 passivation via the bonding of electron donor-acceptor pairs between C=O and Pbl6− ions. The bonds induced precipitation of PbI2 would preferentially assemble at grain boundaries of perovskites during the process. It is believed that the passivation of PbI2 by PLA at the boundaries can largely reduce the defects and trap states and benefit the overall cell efficiency. Characterizations based on x-rays diffraction and scattering (XRD and GIWAXS), microscopies (scanning electron microscopy and atomic force microscopy) and spectrometers (photoluminescence emission and lifetime decay spectrometer) were carried out to prove the morphology, structure and optical variation of the doped/passivated perovskites. Do so, we were able to confirm the increase of crystal grain size, the presence of PbI2 passivations and the extended carrier lifetime, etc. of our passivated perovskites. Finally, as compared with the original counterparts, the non-encapsulated devices of passivated perovskites were able to maintain 20% power conversion efficiency under the ambient condition, with the best PCE exceeding 18%.

Improving Uniformity and Reproducibility of Hybrid Perovskite Solar Cells via a Low-Temperature, Vacuum Deposition Process for NiOx Hole Transport Layers

Seong Ryal Paek, Segi Byun, Jekyung Kim, Min Kyu Kim, and Byungha Shin; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).  

Recently, the trend in inverted hybrid perovskite solar cells (PVSCs) has been to utilize NiOx as hole transport layers. However, the majority of reported solution-processed NiOx films require a high-temperature thermal annealing process which is unfavorable for large-scale manufacturing and suffers from lack of uniformity. We report, for the first time, e-beam evaporation as a low-temperature, vacuum process for the deposition of NiOx, hole transport layers for PVSCs. Device characterization shows that efficiency is on par with solution-processed methods; the highest efficiency exceeding 15.4% with no obvious hysteresis. Differences are found to be due to the presence of more Ni3+ in e-beam evaporated NiOx which are responsible for a lower transmittance but higher conductivity. Most importantly, e-beam evaporated NiOx-based PVSCs show greater uniformity and reproducibility compared to those of spin-coated NiOx-based PVSCs. Finally, e-beam evaporated NiOx has the additional advantage of being a low-temperature deposition process and being applicable over large areas. This work, therefore, represents a significant step towards large-area PVSCs where e-beam evaporation can be used for the low-temperature, uniform deposition of charge transport layers such as NiOx.
Perovskite solar cells are especially promising when considering the technology lifespan. The advantages of using perovskite for the active layer include but are not limited to broad a light absorption spectrum, tunable band gaps, long charge carrier diffusion, and low fabrication cost. The current project involves the design and simulation of different configurations of Methyl Ammonium Bismuth Iodide active layer based lead-free perovskite solar cell. The goal of the project is to develop a configuration that is non-toxic as well as stable in natural open air environments with a specific resistance to moisture. This design incorporates the use of organic and inorganic materials, as well as the efficient use of the perovskite crystalline structure that is produced by using the properties of Bismuth (III). The project also includes opto-electronic simulations of a variety of different configurations using two software packages. The configurations include perovskite layers using low toxicity alternatives of Pb: Bi and Mn. Different halide species has also been explored to evaluate the impacts on opto-electronics, and photon-to-current conversion efficiencies. The stacking structure is further modulated within the cell by progressively including a recombination-inhibiting thin TiO2 of a ZnO layer with the FTO, followed by an electron-transport layer (various oxides). The aim of these studies is to delineate the sources and quantify the impacts of efficiency-limiting process such as recombination. This work is intended to build up to a broader project of selecting the most optimal low-toxicity perovskite cell to stack onto a Si or FTO bottom cell for tandem configurations.

ET04.06.06

Owing to their remarkable photovoltaic performance, hybrid organic-inorganic perovskite solar cells have attracted tremendous research interest. The high efficiencies are enabled by the outstanding electronic properties of the hybrid perovskite materials. On the other hand, the design of the device structure, including the selection of electron- and hole- transport materials, determines how efficiently the photo-excited charge carriers can be selectively extracted from the perovskite absorber, ultimately influencing the energy conversion efficiency. The use of alternative metal oxide charge-transport layers is a strategy to improving device reliability for large-scale fabrication and long-term applications.

Here we demonstrate solution-processed perovskite solar cells employing nickel oxide hole-extraction layers produced in situ using an atmospheric pressure spatial atomic layer deposition (AP-SALD) system, which is compatible with high-throughput processing of electronic devices from solution. Our sub-nanometer-thick (average roughness < 0.6 nm) oxide films enable efficient collection of holes and the formation of perovskite absorbers with high electronic quality. Highly uniform, sub-nm smooth AP-SALD NiOx films also improve the reproducibility of perovskite optoelectronic devices. Initial solar cell experiments show a power-conversion efficiency of 17%, near-unity ideality factor, and a fill factor of >80% with negligible hysteresis. Transient measurements reveal that a key contributor to this performance is the reduced luminescence quenching trap density in the perovskite/nickel oxide structure. We also present perovskite green light-emitting diodes(LEDs) adopting AP-SALD NiOx with an EQE > 8% and luminance over 10000 cd m-2. Further improvements are possible through the optimization of AP-SALD NiOx growth.

ET04.06.07

Impact of Grain Size on Photovoltaic Performance in Halide Perovskite Solar Cells Ekyu Han1, Dohyung Kim1, Jincheol Kim1 and Jae Sung Yun2 1 School of Photovoltaic and Renewable Energy Engineering, University of New South Wales, Kensington, New South Wales, Australia; 2 Korea Electronics Technology Institute, Seongnam, Korea (the Republic of); 3 Materials Science and Engineering, University of New South Wales, Kensington, New South Wales, Australia.

The past two years have seen the uniquely rapid emergence of a new class of solar cell based on mixed organic-inorganic halide perovskite. Organic-inorganic hybrid materials have been demonstrated to be excellent photovoltaic materials having a large absorption coefficient, high carrier mobility, high carrier diffusion length, and direct band gap. Conversion efficiencies have increased from 3.8% in 22.7%. Despite a rapid increase in the performance, there are still many unknown fundamental properties that requires further investigation. The perovskite film consists of large amount of grain boundaries due to its polycrystalline nature. There have been contradicting reports on the role of the grain boundaries in photovoltaic performance. Although it is originally known that the grain boundaries limit the effective diffusion length of the solar cells, recent studies performed by Kelvin Probe Force Microscopy showed that the grain boundaries have benign or even beneficial properties. In this work, we measure average grain size of halide perovskite films that has been reported in the literatures and plot with each photovoltaic parameter, i.e, Voc, Jsc, FF, and efficiency. We provide a mathematical model to examine the relevance between grain size and photovoltaic parameter and discuss its influence. Our findings suggest that the size of grain is not a key factor for improving the solar cell performance. Rather, specific chemical species exist at the grain boundaries tunes their properties which could enhance the macroscopic cell performance.

ET04.06.08

A Green Fabrication Route Avoiding the Usage of Toxic Solvents in Perovskite Solar Cells Liming Zhao1,2, Xianyong Zhou1, Deng Wang3, Jian Wen1 and Baomin Xu1 1 Southern University of Science and Technology, Shenzhen, China; 2 University of California Irvine, Irvine, California, United States.

In recent years, organic-inorganic hybrid perovskite solar cells have attracted extensive attention, the photovoltaic conversion efficiency (PCE) of which rose rapidly from 3.8% [1] to 22.7%, due to their impressive PCE, low cost and the ease of making flexible solar cells. However, most perovskite solar cells require the usage of toxic organic solvents during the manufacturing process, such as N,N-Dimethylformamide (DMF) [2]. Dimethyl sulfoxide (DMSO) [3][4] and Chlorobenzene (CB) [2][4], which are prohibited in the commercialized production. Thus, how to avoid using these toxic solvents is a problem that needs to be solved urgently. Aimed at this problem, we developed a novel route to fabricate invert “p-i-n” perovskite solar cells without any toxic solvents. The structure of the perovskite solar cells is FTO/PEDOT.PSS/CH3NH3PbI3/C60/Cs2/Ag. The perovskite layer was synthesized via two-step method by lead acetate trihydrate and methylamine iodine. We found a new eco-friendly solvent, glycerol [5] and 1-butanol component solvent, to dissolve lead acetate trihydrate, and methylamine iodine was dissolved in isopropanol. PEDOT.PSS and Cs2 served as the hole transport layer and electron transport layer, respectively. C60, BCP and Ag electrode were sequentially thermally deposited on the top of solar cells. The J-V test shows that the PCE of the solar cells with 0.1mm2 reaches 4.84%. The XRD indicates that the CH3NH3PbI3synthesized by this route possesses a high purity. The FTIR shows that glycerol and 1-butanol can be removed just at low temperature, 110°C, which means that this method can be applied in flexible devices. The AFM images reveal that both lead acetate and perovskite layers obtained by this route have low roughness. It can be expected that this preparation technique offering a safe and non-toxic environment has a great potential to fabricate perovskite solar cells in the industrial assembly lines, such as roll-to-roll production.

Ultrafast Room-Temperature Reactive Ion Etching Process for High-Efficiency Flexible Perovskite Solar Cells

ET04.06.09 Light-Assisted Size- and Dimension-Control of Perovskite Nanocrystals and Their Optoelectronic Devices Qingsong Dong; Jilin University, Changchun, China.

Perovskite Nanocrystal (NCs) offer simply solution synthesis and low-cost film forming process, which take advantages of quantum confinement effect and controlled size distribution, and show higher photoluminescence quantum yield (PL QY) and higher open circuit voltage in photovoltaic devices than perovskite thin film. Here, we developed lead halide perovskite NCs with controllable crystal structures and semiconductor properties by light soaking. The dimension and the size of perovskite NCs correlate with a soaking duration. Light soaking change the crystallization environment, inducing the formation of differently perovskites CsPbBr3, CsPbBr3, or CsPbBr3 assembled in CsPbBr3. Bright perovskite mixture (CsPbBr3@CsPbBr3) with the PL QY reaching 90% were employed for fabrication of light-emitting diodes (LEDs), with the peak external quantum yield of 8% and current efficiency of 20 cd A−1. Since CsPbBr3 is insensitive to the atmosphere, the optical stability of the CsPbBr3 within the CsPbBr3 was greatly improved, and thus the storage and operational stability, the enhanced stability also enable efficient photovoltaic devices with high environment stability.

ET04.06.10 Enhanced Performance and Mechanical Durability of a Flexible Perovskite Solar Cell from the Dry Transfer of PEDOT:PSS with Polymer Nanoparticles Jonghwa Lee1, Jin Hyuck Heo2, Sang Hyuk Im2 and O Ok Park1; 1Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of); 2Department of Chemical and Biological Engineering, Korea University, Seoul, Korea (the Republic of).

Stamping transfer has been considered as an alternative process because of its various advantages such as a simple, flexible, and repeatable process, which is suitable for large area fabrication. In this research, Inverted-type CH3NH3PbI3 flexible perovskite solar cells with enhanced cell performance and mechanical durability were fabricated by performing a simple dry transfer of a poly(3,4-ethylenedioxyxophirole): poly(styrenesulfonate) (PEDOT:PSS) hole transport layer (HTL) with polystyrene nanoparticles (PS NPs). In order to ensure the stable flexibility of these flexible solar cells, the cross-linked PS NPs synthesized with a size of 70nm were introduced to the PEDOT:PSS HTL. The transfer of the PEDOT:PSS layer with PS NPs onto the polymer electrode (PH1000) was performed completely via stamping transfer with polyurethane acrylate stamp. The power conversion efficiency of flexible perovskite solar cells prepared by the transfer of PEDOT:PSS with PS NPs was 16.8%, which was significantly higher than that of the spin-cast device. The charge transport from the active layer to the PEDOT:PSS HTL was improved by the tuned morphology of the PEDOT:PSS achieved through transfer and the increased surface area of the PEDOT-PSS resulting from the corrugated structure provided by the protruding PS NPs. This in turn resulted in an enhanced short-circuit current density. In addition, the introduced PS NPs significantly improved the mechanical stability of these flexible devices, allowing the devices prepared by the transfer of PEDOT:PSS with PS NPs to tolerate more cycles of strain in the bending test. The introduced PS NPs enhanced the mechanical strength of PEDOT:PSS by acting as not only binders within PEDOT:PSS, but also as interfacial modifiers which can improve the interfacial adhesion between the active layer and PEDOT:PSS HTL. Thus, the transfer of a PEDOT:PSS layer with PS NPs will contribute to the long-term operation of flexible solar devices with enhanced device performance and mechanical durability.

ET04.06.11 Metal Oxides Charge Transport Layers and Interface Tailoring for Highly Stable Perovskite Solar Cells Chao Zhao1, Jia Zhang2, Meng Li3, Adam Pockett1 and Matt Carmie1; 1Swansea University, Swansea, United Kingdom; 2Harbin Institute of Technology, Harbin, China; 3Soochow University, Suzhou, China.

Solvothermal processed hybrid organic–inorganic perovskite solar cells (PSCs) have recently attracted tremendous attention due to their ease of fabrication and excellent photovoltaic performance. However, challenges of long-term working stability under normal conditions of PSCs (i.e., perovskite material and/or the charge transport layers (CTLs)) are still existed. In this work, we achieved reasonable improved PSC stability with good performance by applying an interlayer (ionic-liquid and/or graphene based 2-dimensional (2D) material) as either CTL modifying interlayer. Correlations between performance characteristics of the PSCs and interlayers will be investigated. Performance of PSCs and their relation between carrier dynamics and material properties will be studied based on measurements of current density–voltage, quantum efficiency and transient. The initial study indicated that the interlayers/composite of the interlayer used in the devices will be a promising way to enhance stability and suppress carrier recombination in the whole PSCs, facilitate carrier injection into the carrier transport layers, and maintain a good carrier extraction at the electrodes, thus resulting a good performance.

ET04.06.12 Ultrafast Room-Temperature Reactive Ion Etching Process for High-Efficiency Flexible Perovskite Solar Cells Byoung Jo Kim1, Dong Geon Lee1, Gill Sang Han1, Sangwook Lee2 and Hyun Suk Jung3; 1School of Advanced Materials Science & Engineering, Sungkyunkwan University, Suwon-Si, Korea (the Republic of); 2School of Materials Science and Engineering, Kyungpook National University, Daegu, Korea (the Republic of).

Perovskite solar cells (PSCs), which have surprisingly emerged in recent years, are now aiming at commercialisation. Rapid, low-temperature, and continuous fabrication processes that can produce high-efficiency PSCs with a reduced fabrication cost and shortened energy payback time are important challenges on the way to commercialisation. Herein, we report a reactive ion etching (RIE) method, which is an ultrafast room-temperature technique, to fabricate mesoporous TiO2 (mp-TiO2) as an electron transport layer for high-efficiency PSCs. Replacing the conventional high-temperature annealing process [A1] by RIE, reduces the total processing time for fabricating 20 PSCs by 40%. Additionally, the RIE-processed mp-TiO2 exhibits enhanced electron extraction, whereupon the optimized RIE-mp-TiO2-based PSC exhibits a power conversion efficiency (PCE) of 19.60% without J-V hysteresis. Finally, a flexible PSC employing the RIE-mp-TiO2 is demonstrated with 17.29% PCE. Considering that the RIE process has been actively used in the semiconductor industry, including for the fabrication of silicon photovoltaic modules, the process developed in this work could be easily applied towards faster, simpler, and cheaper manufacturing of PSC modules.

ET04.06.13 Interface Engineering of Solution Processed Hybrid Organohalide Perovskite Solar Cells Shanshan Zhang; University of Queensland, Brisbane, New South Wales, Australia.

Rapid progress has been achieved in improving the power conversion efficiency (PCE) of organohalide perovskite solar cells (PVSCs), which have now reached 22.1%. Engineering the interlayers between the junction and electrodes has enabled enhancement of charge extraction efficiency and open-circuit
The efficiency of ~10%.

We attribute these results to the oxygen content present in the Nb2O5 films which could have influence on the charge transfer properties. Here, we present coatings that can potentially enhance the efficiency of solar cell devices, increasing the open circuit voltage and photoconversion efficiency. Anti-solvent treatment is commonly adopted to make smooth perovskite films for the spin-coating process. However, coating technology is demanding to replace the spin coating for maximizing the benefits of solution-processed perovskite solar cells. Therefore, it is critical to find out other processes which replace spin coating and enable roll-to-roll (R2R) and continuous processes. Our prior studies presented that the sheet coating process can be an efficient way to produce large-scale perovskite layers and the formation of smooth interface and surface is quite relevant to achieve higher device performance. Anti-solvent treatment is commonly adopted to make smooth perovskite films for the spin-coating process. However, anti-solvent cannot be adopted for R2R processes so that the solution engineering becomes essential to produce high-quality perovskite films. This study presents that the crystallization rate control of perovskite films is a crucial factor to realize the smooth surface film formation. We fabricate perovskite films by controlling the ratio of additives and substrate temperature, and then confirm the film roughness and existence of additive particles in the grain. The Solution engineering can control the perovskite crystallization kinetics. The effects of additives and the composition of precursor solution on crystallization kinetics during sheet coating will be presented.

Metal-halide perovskite solar cells are considered as one of leading candidates for next-generation photovoltaics, exhibiting the excellent performance over 22% PCE (power conversion efficiency) in spite of its simple and low-cost solution process. Despite their excellence in PCE, the development of large-area coating technology is demanding to replace the spin coating for maximizing the benefits of solution-processed perovskite solar cells. Therefore, it is critical to find out other processes which replace spin coating and enable roll-to-roll (R2R) and continuous processes. Our prior studies presented that the sheet coating process can be an efficient way to produce large-scale perovskite layers and the formation of smooth interface and surface is quite relevant to achieve higher device performance. Potassium niobate (KNbO₃) is known to be an important eco-friendly lead-free ferroelectric material that possess excellent physical properties such as large electro-optical coefficients, electromechanical coupling constant, and nonlinear optical coefficients for several photonic device and electronic applications. The physical properties of KNbO₃ can be modified by substituting isovalent or heterovalent cations into K and/or Nb sites. Herein, we present systematic investigations carried out on structural, optical, dielectric, charge transport and ferroelectric properties of a solid solution [KNbO₃]ₓ[BaNi₁/₂Nb₁/₂O₃₋ₓ]. The electro-ceramics were prepared by standard solid-state reaction method using K₂CO₃ (99.9%), BaCO₃ (99.95%), Nb₂O₅ (99.9%), and NiO (99.9%) as starting reagents. Formation of ferroelectric-ferroelectric (FE-FE) phase of the as-synthesized sample was confirmed using x-ray diffractometry. Temperature dependent Raman spectra measured from liquid nitrogen temperature to 800 K and analyzed using damped harmonic oscillator model; provides valuable information about phonon behaviors and suggests absence of any structural phase transition. A direct optical band gap E_g of 3.16 eV was estimated from Kubelka-Munk analyses of the diffuse reflectance spectra. Investigations on dielectric behaviors on a metal-KBNNO ferroelectric-metal capacitor in the T range 80–500 K with the frequencies range 10⁻¹⁰–10² Hz suggests a broad peak with discernible dispersive features with frequencies indicating its relaxor-like behavior. A slim P-E loop measured up to 1800 V corroborates its relaxor behaviors. The frequency dependence of ac conductivity showed typical features of universal dynamic response and satisfy the known power law, \( \sigma (\omega) \propto \omega^\alpha \). The \( I-V \) characteristic curves measured in between ±600 V at several temperatures (100-500 K) suggest a typical Schottky-type (diode) behavior. The vibrating sample magnetometer results at room temperature show a linear magnetization curve with negative slope suggesting its diamagnetic behavior. Our experimental results establish the fundamental physics and materials science of the KBNNO compound and its potential for ferroelectric device applications.

Spatially-Resolved Ion Migration in Mixed Cation Lead Hybrid Perovskite

This study is spatially-resolved emission measurements, we directly monitor cation migration in triple cation (FA, MA and Cs) lead hybrid perovskite. We show, that under applied voltage cations segregates and form single cation perovskite phases. This leads to degradation and decreasing of photovoltaic performance of solar cells devices. Next, by tuning the composition of cations we show improved stability against cation migration in perovskite solar cell devices.

ET04.06.20
Ultra-High Vacuum Investigations of Methylammonium Lead Tribromide Single Crystals Perovskites—Sample Stability and Photo-Carrier Recombination

Methylammonium lead tribromide (CH₃NH₃PbBr₃) single crystals are studied under Ultra High Vacuum (UHV) by non-contact Atomic Force Microscopy (nc-AFM) and Kelvin Probe Force Microscopy (KPFM). [1, 2] We demonstrate that when exposed to ambient atmosphere, the sample exhibit important surface degradations. Even when sample is cleaved in air and exposed shortly (around few minutes) to ambient conditions, it reveals surface nanometric droplets (<100 nm). We demonstrate that such surface modifications can be avoided by UHV sample cleavage. The sample prepared and analyzed under UHV does not exhibit surface modifications even under illumination with laser power of few tens of mW per mm².

Furthermore, we perform time-resolved measurement by KPFM on this UHV-cleaved sample. While most of the experimental approaches developed so far consist in studying recollection by techniques such as: transient photovoltage or charge extraction, these techniques average sample properties over macroscopic scales, making them unsuitable for directly assessing the impact of local heterogeneity on the recombination process. Recently, we showed that it is possible to measure the photo carrier lifetime with nanometric spatial resolution by photo-modulated techniques based on KPFM over organic and inorganic solar cells. [3, 4, 5] We will present the principle of this original method based on the nanometrically resolved measurement of the surface potential by KPFM under a modulated illumination. Finally, we apply this protocol to measure nanometric resolved images of photo-carrier dynamics on CH₃NH₃PbBr₃. During this talk, we will show results of lifetime mapping as a function of laser power.

Investigating the Effects of Functionalized Benzylphosphonic Acid SAMs on Triple Cation Lead Halide Perovskite Based Solar Cells

The modification of interfaces with self-assembled monolayers (SAMs) are an interesting approach for enhancing the performance of perovskite solar cells. [1, 2, 3] Recently, Wang et al. outlined the importance of the dipole moment by modifying nickel oxide (NiOₓ) hole transport layers in perovskite solar cells with differently functionalized benzoic acid SAMs. [4] In this work, we investigate the influence of para-functionalized benzylphosphonic acid (R-BPA) SAMs on CsxFA/MA based triple cation perovskite solar cells prepared in inverted architecture using NiOₓ as hole and PC60BM as electron transport layer. The phosphonic acid groups act as an anchor to the NiOₓ hole transport layer and besides the dipole moment of the molecules, the functional groups (we investigated: -Br, -F, -NH₂, -NO₂ and -OCH₃) can also act like a seed layer influencing the perovskite crystallization. The presence of R-BPA SAMs on the NiOₓ films was confirmed by contact angle measurements and X-ray photoelectron spectroscopy (XPS). Further, the influence of the SAM modifications on the perovskite layer modification was studied by scanning electron microscopy (SEM) and X-ray diffraction (XRD) measurements. The SAM images reveal smaller grain sizes and narrower grain size distributions for (4-nitrobenzyl) phosphonic acid and (4-methoxybenzyl) phosphonic acid based solar cells compared to the reference (without SAM modification) and other R-BPA SAM based solar cells. The introduction of (4-bromobenzenyl) phosphonic acid led to solar cells with an improved power conversion efficiency of 16.5% (reference 12.3%). Similarly, (4-fluorobenzenyl) phosphonic acid SAM based solar cells exhibited an improved open circuit voltage (V_OC) of 1.087 V (reference 0.977 V). On the contrary, a reduction of the V_OC was observed for solar cells modified with a (4-aminobenzyl) phosphonic acid SAM.

Radiative and Non-Radiative Excited State Decay in Lead Halide Perovskites Richard H. Friend; University of Cambridge, Cambridge, United Kingdom.

Lead halide perovskite materials can show very high internal luminescence efficiencies, and this has enabled the fabrication of LEDs with high external quantum efficiencies, approaching 20%. High luminescence yield is also critical for efficient solar cell operation. I will discuss recent approaches to eliminate non-radiative decay channels within the bulk and at also at charge injection/extraction interfaces. I will also discuss how recycling of internally-generated photons, both within LEDs and also in solar cells, affects device performance and design.

8:30 AM *ET04.07.02
Long-Range Hot Carrier Transport in Hybrid Perovskites Visualized by Ultrafast Microscopy Libai Huang; Purdue University, West Lafayette, Indiana, United States.

The Shockley-Queisser limit for solar cell efficiency of ~ 33% can be overcome if hot carriers can be harvested before they thermalize. Recently, carrier cooling time up to 100 picoseconds was observed in hybrid organic-inorganic lead halide perovskites, but it is unclear whether these long-lived hot carriers can migrate long distance for efficient collection. Here we report direct visualization of hot carrier migration in CH3NH3PbI3 thin films by ultrafast transient absorption microscopy, demonstrating three distinct transport regimes. Quasi-ballistic transport was observed to correlate with excess kinetic energy, resulting in up to 230 nanometers transport distance in 300 fs that could overcome grain boundaries. The nonequilibrium transport persisted over tens of picoseconds and ~ 600 nanometers before reaching the diffusive transport limit. These results suggest potential applications of hot carrier devices based on hybrid perovskites.

9:00 AM ET04.07.03
Perovskite—A Wonder Material for High Efficiency Solar Cells and Optoelectronic Applications Shengzhong Liu1,2; 1Dalian Institute of Chemical Physics, Dalian, China; 2Shaanxi Normal University, Xi'an, China.

The organic lead halide perovskites have been demonstrated as a group of wonder materials for their excellent optical absorption, long range charge-carrier diffusion and apparent tolerance to defects. In just a few years, the efficiency of these perovskite solar cells has been improved from 3.8% to 23%. We have developed a few dry deposition processes without using any solvent to fabricate high efficiency perovskite solar cells with high stability. The new deposition processes allow us to relax the strict deposition monitoring and control measures, while realizing superior uniformity in film morphology, surface coverage and smoothness, together with crystalline phase purity, leading to high efficiency solar cells. Our current status for the rigid thin film cell efficiency is over 21.5% (Newport certified) and that for the flexible device over 18.3%, both are the highest for their respective categories. Meanwhile, the devices show very good stability over long term exposure in ambient with very low degradation. After a representative cell was exposed in ambient lab condition for more than two years, its final cell efficiency is as high as ~90% of its initial efficiency with its degradation accounts for only ~10%. Further analysis on the stability of the perovskite solar cells will be discussed. We have also developed a series of single-crystalline perovskites with superior stability and optoelectronic performance.

9:15 AM ET04.07.04
One Step High-Throughput Deposition for Flexible Perovskite Solar Cells Tae-Youl Yang1, Young Yun Kim1, Rikka Suhonen2 and Jangwon Seo1; 1Korea Research Institute of Chemical Technology, Daejeon, Korea (the Republic of); 2VTT, Oulu, Finland.

Despite a high efficiency in the perovskite solar cells (PSCs) of over 22%, the large-area fabrication of PSCs is another issue that is receiving growing attention. The large-area PSCs requires more reliability than lab-scale devices for precisely controlling the crystallization behavior of perovskites. In order to transfer these technologies from laboratory scale to industrial-scale, large-area PSC manufacturing using scalable coating and printing processes have been evolved. The key advantage of printing in comparison to coating is the possibility of direct patterning on substrates. Printing provides a large degree of freedom for module design in arbitrary shapes and sizes.

In this presentation, we demonstrate one step fabrication of perovskite film via gravure printing. SnO2 nanoparticles layer as an electron transport layer, CH3NH3PbI3 as a photoactive layer, and Spiro-OMeTAD as a hole transport layer were sequentially printed on ITO-PET substrate. We optimized properties of each solution and drying process conditions to deposit uniform films. The resulting devices showed the power conversion efficiency of up to 15 %, which is significantly higher than most conventional perovskite solar cells. This study illuminates the possibility of the fabrication of high-performed PSCs using gravure printing which is a high throughput production technologies that enables more cost-effective industrial production.

9:30 AM ET04.07.05
Effective Passivation of Perovskite Film for Highly Efficient and Stable Solar Cell Using Adamantanes Mohammad Mahdi Tavakoli1,2; 1Materials Science and Engineering, Sharif University of Technology, Tehran, Iran (the Islamic Republic of); 2Electrical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Passivation of electronic defects is an effective strategy to boost the performance and operational stability of perovskite solar cells (PSCs). Identifying molecular materials that achieve this purpose is a key target of current research efforts. Here, adamantane (AD) and adamantylamine (ADA) are introduced...
as molecular modulators to abate electronic defects present within the bulk and at the perovskite–hole conductor interface. To this effect, the modulator is added either into the antisolvent (AS) to precipitate it together with the perovskite (AS method) or they are spin coated (SC) onto its surface (SC method). Time resolved photoluminescence measurements show substantially longer lifetimes for perovskite films treated with AD and ADA compared to the reference sample. In line with this observation, it is found that the presence of AD and ADA molecules at the interface between the perovskite film and the hole conductor increases all photovoltaic metrics, in particular the open circuit photovoltage ($V_{oc}$) as well as the operational stability of the PSC.

Synthesis and Ionic Conductivity Measurements of Highly Efficient Perovskites from Blade Coated and Non-Toxic Solvents Antonio Guerrero;
Institute of Advanced Materials (INAM), Castellón de la Plana, Spain.

Understanding crystallization of lead halide perovskites by industrially relevant techniques is a topic that needs development as large area crystallization processes lead to inhomogeneous films, extremely large perovskite thickness or presence of pinholes. In this work, we show that efficient one-step perovskite solar cells can be obtained by doctor blade by controlling the coordination chemistry with non-toxic solvents via Spherulitic growth mechanism. This method results in highly crystalline perovskite films with preferential crystal orientation and spherulitic growth. Optical and electrical measurements indicates that generated chemical defects are confined at the boundary of spherulites and these do not have a negative effect on the extracted photocurrent. Strikingly, spherulitic formation leads to better photovoltaic performance in hybrid perovskite films with record efficiencies of 18.0% for MAPbI₃, for doctor bladed processing using one-step and non-toxic solvents. Alternatively, ionic conductivity plays a key role in perovskites during photovoltaic device operation and degradation. In this presentation it is also described how to characterize the ionic properties of lead halide perovskites by electrical (impedance spectroscopy) and optical techniques (PL confocal microscopy). Approaches to minimize the electronic contribution to the measured current are used so the ionic current can be probed.

Interfacial Modification for Highly Stable and Efficient SnO₂ Based Planar Perovskite Solar Cells Kyoungwoon Choi, Hong Il Kim, Minjun Kim, Hyuntae Choo and Talho Park; POSTECH, Pohang, Korea (the Republic of).

We report a facile and effective interface modification for highly stable and efficient planar perovskite solar cells (P-PSCs) by employing a zwitterion-modified SnO₂ electron transport layer (ETL). A 3-(1-pyridinio)-1-propanesulfonate is used to modify the SnO₂/perovskite interface. The zwitterion plays a few important roles in P-PSCs: (1) Shifting the work function of the SnO₂ to a more suitable energy level for charge extraction. (2) Pulling electrons from perovskite toward the ETL/perovskite interface. (3) Suppressing backward transport of electrons from SnO₂ to the perovskite layers. (4) Passivating halide-induced deep traps and improving thermal stability of devices. With these desirable properties, the efficiency of devices and thermal stability increase remarkably. Therefore, P-PSCs with the modified SnO₂ ETL showed reduced hysteresis owing to effective electron extraction and reduced recombination. The best device achieved a power conversion efficiency (PCE) of 21.43% in reverse scans. Accordingly, newly developed interface engineering is a promising method for fabricating efficient and hysteresis-less P-PSCs with high thermal stability.

Crystalline Metal Oxide Contact Layers in Organic and Hybrid Photovoltaics Mehraad Ahmadpour1, André Cauduro2, Mina Mirsafaei1, John Lundsgaard Hansen1, Brian Julsgaard2, Horst-Günter Rubahn3, Peter Balling1, Nadine Witkowski4, Andreas K. Schmid2 and Morten Madsen1; 1Mads Clausen Institute, SDU NanoSYD, University of Southern Denmark, Sonderborg, Denmark; 2The Molecular Foundry, LBNL Berkeley, National Center for Electron Microscopy, Berkeley, California, United States; 3Department of Physics and Astronomy and iNano, Aarhus University, Aarhus, Denmark; 4Institut des Nanosciences de Paris (INSP), Sorbonne Universités, UPMC Univ Paris 06, Paris, France.

Thin metal oxide films have attracted a lot of attention in the past years due to their unique ability to act as electrode contact layers in novel electronic and optoelectronic devices. Prominent examples are molybdenum oxide (MoO₃) and titanium oxide (TiO₂) thin films used as hole and electrode contact layers, respectively, in organic and hybrid photovoltaics. Amongst many different methods used for fabrication of these films, reactive sputtering remains as a promising technique, due to the unique composition tuning and industrial scale processing possibilities. In the work presented here, crystalline MoO₃ and TiO₂ layers are developed from reactive sputtering and vacuum annealing, and implemented as contact layers in organic and hybrid solar cells.

The film composition is characterized using X-Ray Photoelectron Spectroscopy (XPS), work function using Low Energy Electron Microscopy (LEEM) and Ultraviolet Photoelectron Spectroscopy (UPS), structure using Transmission Electron Microscopy (TEM) and X-Ray Diffraction (XRD), morphology using Atomic Force Microscopy (AFM) and optical properties using UV-VIS spectroscopy. Importantly, we find that both the structure and work function of the developed thin films can be tuned by the annealing process, spanning an almost 2eV tuning range in the case of MoO₂. Furthermore, due to the formation of the crystalline films with a low defect density, made possible via the reactive sputtering method, more efficient and stable contact layers for photovoltaic devices are developed. Non-encapsulated DBP/C₆₀ solar cell devices based on the sputtered MoO₃ are demonstrated to remain with impressive 80% of the initial performance after 240 hours of light soaking under 1 sun (1000W/m²) at ~60°C, which is superior to similar devices based on conventional thermally evaporated MoO₃ layers. Fabricated PTB7/PCBM solar cells devices based on the sputtered TiO₂ are demonstrated to lead to shape-free high performing devices, otherwise typically appearing when employing TiO₂ as contact layers. Integration of the crystalline metal-oxide interlayers in perovskite solar cells is furthermore investigated and discussed. The underlying film properties leading to these appealing device properties are evaluated based on the extensive surface and film characterization performed.

The work thus demonstrates a viable method for tuning the electronic and optoelectronic properties of metal oxide thin films, which can be applied in combination with a wide range of materials in e.g. organic and hybrid photovoltaics.

Organic-inorganic metal halide perovskites have gained considerable attention for next-generation photovoltaic cells due to rapid improvement in power conversion efficiencies. Even though there have been immense efforts towards fabricating high performance solar cells, fundamental understanding of underlying mechanisms related to light and bias induced effects at the nanoscale is still required. In this study, structural variations of the perovskites induced by light and bias are systematically investigated using scanning probe microscopy techniques. We show that periodically striped ferroelastic domains, spacing between 40 nm to 350 nm, exist within grains and can be modulated significantly under illumination as well as by electric bias. Williamson-Hall analysis of X-ray diffraction results shows that strain disorder is induced by these applied external stimuli. We show evidence that the structural emergence of domains can provide transfer pathways for holes to a hole transport layer (HTM) with positive bias, whereas negative bias attracts organic cations to the surface, which can induce structural damage to the perovskite-HTM interface. Our findings point to potential origins of I-V hysteresis in halide perovskite solar cells and provide fresh microscopic insight into external stimuli-induced structural disorder governing the superior performance of the metal halide perovskites solar cells.

Hydrophobic Self-Assembling Monolayers for Stable Perovskite Solar Cells Laura Cani1 and Antonio Abate; Helmholtz Zentrum Berlin, Berlin, Germany.

With a power conversion efficiency over 22%, perovskite solar cells (PSCs) are considered a rising star in the solar energy field. Nevertheless, the device long-term stability under working condition remains a big challenge. In particular, most of the halide perovskite compositions are highly sensitive to moisture. Indeed, the initial device performances degrade abruptly in only a few days of air exposure.

Our strategy to enhance the moisture stability of PSCs is to functionalize the interface between the perovskite and the charge selective contacts within the device. We make use of specific molecule-to-substrate interaction to self-assembly perfluorinated small molecules on the perovskite surface. The formation of a nanometer thick perfluorinated layer results in hydrophobicity and potentially in super-hydrophobicity of the perovskite surface, which prevents the ingress of water from the atmosphere. Notably, such a functionalization can be done through scalable solution processing methods, which are compatible with fast output production including roll-to-roll and inject printing. We investigate the impact of the functionalization on material and device stability, providing data from lab-scale devices aged in real working conditions – under light and voltage load. Our results show that the interface functionalization with perfluorinated molecules is an effective new approach to enhance PSCs lifetime.

Hole Transport Bilayer for Improved Photocurrent and Stability in Perovskite Solar Cells for 2-Terminal Tandems James A. Raiford1, Rebecca A. Belisle2, Kevin A. Bush2, Axel F. Palmstrom2,3, Rohit Prasanna2, Michael D. McGehee2,4 and Stacey F. Bent1; 1Chemical Engineering, Stanford University, Stanford, California, United States; 2Materials Science & Engineering, Stanford University, Stanford, California, United States; 3National Renewable Energy Laboratory, Golden, Colorado, United States; 4Chemical and Biological Engineering, University of Colorado Boulder, Boulder, Colorado, United States.

Perovskite solar cells used in tandem with existing silicon cell technology is a promising pathway towards achieving next-generation, high efficiency devices at a lower cost. To date, the highest efficiency monolithic perovskite/silicon tandem are fabricated in the inverted p-i-n architecture, despite the fact that the best single-junction devices have been reported in the standard n-i-p orientation. The primary source of performance loss in the standard architecture, 2-terminal tandem is optical losses associated with replacing an opaque contact with a transparent one. Common hole transport and window layers like doped spiro-OMeTAD and molybdenum oxide, respectively, parasitically absorb significant amounts of light before it can reach the perovskite and be converted to useful photocurrent. Additionally, these hole contact layers have been shown to be sources of chemical instability, leading to long-term degradation of device performance. In this work, we present an alternative hole contact bilayer, consisting of a thin, undoped organic small molecule and an air-stable vanadium oxide (VOx) buffer layer deposited via atomic layer deposition (ALD). This novel bilayer allows for the subsequent sputtering of a transparent indium tin oxide top electrode. Its minimal absorption in the ultra-violet and visible regions of the solar spectrum result in the fabrication of a semi-transparent perovskite cell with 2.3 mA/cm² more photocurrent than its spiro-OMeTAD counterpart without a loss in cell voltage. Our design also leverages the conformal, compact nature of the ALD buffer layer to help slow the thermal degradation of mixed cation, mixed halide perovskite films. Unlike molybdenum oxide, we show that our VOx ALD buffer layer is inert to the perovskite material by demonstrating stable device performance after 1000 hours of thermal aging at 85°C in an inert N₂ atmosphere. Lastly, we will discuss the implications of this work as they relate to the fabrication of more efficient 2-terminal perovskite/silicon tandems.

SESSION ET04.08: Stability and Testing
Session Chair: Michael McGehee

1:45 PM ET04.08.01
Firing up Perovskite Solar Modules Bert Conings, Aslıhan Babayigit and Hans-Gerd Boyen; Materials Research Institute, Hasselt University, Diepenbeek, Belgium.

All metal halide perovskite solar cells with decent efficiencies so far contain lead (Pb). Since the rapidly evolving perovskite photovoltaic technology is on the cusp of commercialization, the existence and gravity of hazardous components as a consequence of its Pb content is a growing point of debate. Probably the most likely scenario for an uncontrolled exposure to the enclosed Pb-containing chemicals and related reaction products — that can fuel this debate— is that where perovskite PV installations in structure fires, the latter statistically representing a significant risk. To shed light on the potential impact of such an event, a careful assessment of the fire safety of perovskite-containing PV mini-modules is presented. A balanced discussion is provided comparing the hazard originating from an encapsulation failure of a perovskite-based rooftop installation (worst case scenario) and that associated with the burning of common materials found in buildings. In addition, a rough atmospheric dispersion model is used to estimate the heavy metal concentrations downwind of a typical structure fire.
Hybrid organic-inorganic lead halide perovskite solar cells have surpassed other commercialized thin-film solar cell technologies in record efficiency, but they have yet to demonstrate excellent stability that precludes commercialization. While moisture exposure can be mitigated through careful encapsulation, the thermal stability of the cell is intrinsic to operation and must be improved.

We show that thermal stability of semitransparent perovskite solar cells in the inverted (p-i-n) architecture (ITO/NiOx/FA0.83Cs0.17Pb(I0.83Br0.17)3/evaporated Cs60/SnO2/TTO(metal)) at 85°C in a nitrogen environment is limited by reaction with metal contacts, regardless of whether Ag, Cu, or Au is used. We found similar results with MAPbI3 and FA0.83Cs0.17Pb(I0.83Br0.17)3 devices. We used x-ray photoelectron spectroscopy (XPS) and secondary ion mass spectroscopy (SIMS) depth profiling to show that Ag not only creates a driving force for iodine migration from the perovskite, but also surprisingly has the potential to diffuse through a sputtered tin-doped indium oxide (ITO) window layer, an atomic layer deposited (ALD) tin oxide layer, and an evaporated fullerene electron transport layer into the perovskite, harming the performance of the perovskite solar cell.

We found using scanning electron microscopy (SEM) that the poor barrier quality of the transparent conducting oxide (TCO) is due largely to diffusion channels created by a proliferation of the existing rough perovskite morphology. This also occurs when the crystalline ITO is replaced with amorphous indium zinc oxide (IZO).

We found that the key to creating a good barrier layer to prevent metal degradation and escape of volatile halide species is by (1) adding a planarizing layer (such as a conformal layer of indium tin oxide or ZnO) and (2) including a thin planarizing layer of indium zinc oxide (IZO) between the TCO and the perovskite.

The stability of perovskite solar cells is considered poor compared to other solar cells. One reason for this is thought to be the volatile organic methylammonium (MA) cation. At the same time, small amounts of MA are used for practically all highest performing solar cells with efficiencies beyond 20%. These compositions have also shown some of the best reported stabilities indicating that MA might not be as unstable as previously assumed. This raises the question of whether excluding MA for the sake of stability has been concluded prematurely. Interestingly, MA instability was mainly concluded from thin film studies that differ strongly from full devices. Therefore, the degradation behaviour on complete MA containing devices is crucial to quantify the long-term stability of MA. Only then, it is possible to determine at which timescales MA is unstable and if it must be categorically excluded from future compositions. Without such assessment, valuable time may be lost due to false prioritisation that is not justified by actual data. Here, we use weakest link devices, i.e. MAPbI3, to study the stability under light and different temperatures.

Organic Gelators as Growth Control Agents for Stable and Reproducible Hybrid Perovskite-Based Solar Cells

Natalie Stingelin; Georgia Institute of Technology, Atlanta, Georgia, United States.

Low-molecular-weight organic gelators are widely used to influence the solidification of polymers, with applications ranging from packaging items, food containers to organic electronic devices, including organic photovoltaics. Here, I discuss how this concept can be extended to hybrid halide perovskite-based materials. In situ time-resolved grazing incidence wide-angle X-ray scattering measurements performed during spin coating reveal that organic gelators beneficially influence the nucleation and growth of the perovskite precursor phase. This can be exploited for the fabrication of planar n-i-p heterojunction devices with MAPbI3 (MA = CH3NH3+) that display a performance that not only is enhanced by ~25% compared to solar cells where the active layer is produced without the use of a gelator but that also features a higher stability to moisture and a reduced hysteresis. Most importantly, the presented approach is straightforward and simple, and it provides a general method to render the film formation of hybrid perovskite more reliable and robust, analogous to the control that is afforded by these additives in the processing of commodity “plastics.”

Efficient and Stable of Inorganic Perovskite Solar Cells

Jingbi You; Chinese Academy of Sciences, Beijing, China.

Inorganic halide perovskites such as cesium lead halide have attracted great attentions due to their excellent thermal stability. Cesium lead iodide (CsPbI3) has a bandgap of 1.73 eV and is very suitable for making efficient tandem solar cells, either with low bandgap perovskite or silicon. However, the phase instability is hindering the further optimization of the device performance. Here, we show that high quality and stable black-phase CsPbI3 film is obtained via solvent-controlled growth of the precursor film in dry environment. A 15.7% power conversion efficiency of CsPbI3 solar cells is achieved, which is the highest efficiency reported so far for inorganic perovskite solar cells. And more importantly, the devices can tolerate continuous light soaking for more than 500 hours without efficiency drop. Recently, we have pushed the efficiency of inorganic perovskite solar cells to 17%.

Enhanced Photovoltaic Performance and Stability of Tin-Based Perovskites by Forming 3D Hollow Structure with Diamonium Dichloride

Weijun Ke, Constantinos Stoumpos, Ioannis Spanopoulos, Lingling Mao, Oleg Kondetski, Michelle Chen, Michael R. Wasielewski and Mercouri G. Kanatzidis; Polytechnique Fédérale de Lausanne, Lausanne, Switzerland.

The stability of perovskite solar cells is considered poor compared to other solar cells. One reason for this is thought to be the volatile organic methylammonium (MA) cation. At the same time, small amounts of MA are used for practically all highest performing solar cells with efficiencies beyond 20%. These compositions have also shown some of the best reported stabilities indicating that MA might not be as unstable as previously assumed. This raises the question of whether excluding MA for the sake of stability has been concluded prematurely. Interestingly, MA instability was mainly concluded from thin film studies that differ strongly from full devices. Therefore, the degradation behaviour on complete MA containing devices is crucial to quantify the long-term stability of MA. Only then, it is possible to determine at which timescales MA is unstable and if it must be categorically excluded from future compositions. Without such assessment, valuable time may be lost due to false prioritisation that is not justified by actual data. Here, we use weakest link devices, i.e. MAPbI3, to study the stability under light and different temperatures.
The power conversion efficiency of perovskite solar cells has increased from 3.8 to above 22% within a few years.[1] Currently, the highest-efficiency perovskite solar cells are made on lead-based light absorbers; however, the toxicity of lead constitutes a serious issue which hinders the commercialization attempts of the perovskite solar cells technology. It is therefore imperative to reduce or altogether eliminate Pb from these devices and replace them with other less toxic elements. Sn is an especially attractive candidate because its perovskite analogs have similar or even superior optical and electronic characteristics compared to those of Pb. However, the efficiency of the Sn-based perovskite solar cells is low and the stability of Sn-based perovskite solar cells is usually very poor in air. In this work, we demonstrate a new type of tin-based perovskite absorber that incorporates both ethylenediammonium (en) and formamidinium (FA)/methylammonium (MA) forming new materials of the type [en]FASnI3/[en]MASnI3.[2,3] We show that the use of Sn can serve as a new A dication capable of achieving dramatic increases in bandgap without the need of solid solutions. The en introduces a new bandgap tuning mechanism that arises from massive Schottky style defects. Our best-performing [en]FASnI3 and [en]MASnI3 solar cells have the highest efficiency of 7.23% and 6.65%, respectively. Most importantly, the stability of tin-based perovskite solar cells is significantly enhanced by the incorporation of en dication in the structure. Recently, we also found two other new diaminonium cations of propylenediammonium (PN) and trimethylenediammonium (TN) which have slightly larger size but can still be incorporated into 3D FASnI3 structure. A similar efficiency enhancement was also observed for the {PN}FASnI3 and {TN}FASnI3 solar cells. Our results suggest that developing tin-based perovskites with suitable diaminonium cations such as en, TN, and PN in their structure is a new promising approach for fabricating high-performance tin-based perovskite solar cells.

Outdoor Analysis of the Active Layer Temperature in Perovskite Photovoltaic Modules Robert Gehlhaar, Tamara Merckx and Weiming Qiu; imec, Leuven, Belgium.

Perovskite solar cells have seen an enormous improvement in the relevant photovoltaic parameters of power conversion efficiency and device lifetime. Within less than a decade of development, efficiencies exceeded 22% and lifetimes increased from a couple of seconds to more than 10000 hours. A various number of device configurations is showing the potential to improve the performance to industrial relevant levels. Leaving the level of research from lab environment, the temperature of a perovskite solar cell can have a serious effect on the performance. The power conversion efficiency as well as the stability can be drastically influenced and reduced by increasing the device temperature.

We report on the temperature of perovskite modules under outdoor conditions and the modeling of the temperature fluctuations in dependence in the influential parameters. The report provides insights into the exact temperature evolution of the photoactive layer over a wide range of solar irradiance and various ambient temperatures. The provided model allows for an accurate prediction of the module temperature beyond the measured range of the parameters.

The evolution of the device temperature of a perovskite module of 225 cm² area has been recorded during a period of 25 days under central European conditions. The temperature of the glass–glass packaged perovskite solar module was directly measured at the back contact by a thermocouple. The device was exposed to ambient temperatures from 3 °C to 34 °C up to solar irradiation levels of 1300 W m⁻² resulting in a maximum module temperature of 61 °C. Under strong fluctuations of the global solar irradiance, temperature gradients of more than 3 K min⁻¹ with total changes of more than 20 K are measured. Based on the experimental data, a dynamic iterative model is presented for the module temperature evolution in dependence on ambient temperature and solar irradiation. Furthermore, specific thermal device properties that enable an extrapolation of the module response beyond the measured parameter space can be determined.

The presented set of data and analysis gives an insight in the expected device temperature in real world applications. This knowledge is essential to design future experiments to bring the perovskite PV technology to the next level. The analysis of temperature coefficients for power conversion efficiency, stability and hysteresis are going to be benefited from the provided measurements and model of the exact layer temperature.

Stability Studies of Perovskite PV Devices Using Natural and Concentrated Sunlight Iris Visoly-Fisher1, Eugene A. Kat1, Mark V. Khemkin1, K.M. Anoop1, Yulia Galagan2, Francesco Di Giacomo3, Morten Madsen1, Bhushan R. Patil4, Golnaz Sherafatipour5 and Vida Turkovic6; 1Department of Solar Energy and Environmental Physics, Swiss Institute for Dryland Environmental and Energy Research, Jacob Blaustein Institutes for Desert Research, Ben-Gurion University of the Negev, Midreshet Ben-Gurion, Israel; 2Holst Centre – Solliance, Eindhoven, Netherlands; 3SDU NanoSYD, Mads Clausen Institute, University of Southern Denmark, Sonderborg, Denmark.

Standard, outdoor operation under natural sunlight includes diurnal light/ dark cycling. Both reversible improvement and reversible degradation of perovskite solar cell efficiency were observed under illumination-darkness cycling.[1] Quantifying the performance and stability of cells exhibiting significant diurnal performance variation is challenging, and we suggest that its figures of merit should be reconsidered.[2]

Concentrated sunlight allows accelerated stability studies and separating the effect of light on material and cell stability from other factors. We recently demonstrated an experimental methodology with independent control of sunlight intensity, the sample temperature, bias and environment during the exposure. Studies of perovskite devices as a function of sunlight concentration were aimed at determining which degradation factors are more dominant: light and spectrum, bias or their combination? Preliminary results of studies of ITO/SnO2/Cs0.07(FA0.83(NH3)3)0.83Pb0.78Sn0.22I3/Spiro-OMeTAD/Au cells show a monotonic dependence of the PCE degradation kinetics on sunlight concentration, as expected. This dependence on intensity was significantly stronger than the degradation dependence on the illumination dose (in sun*hours).[3] Significant effect of UV- and IR- filtering on the cell's degradation rate was also noted. Possible underlying degradation mechanisms will be discussed.

In the last few years a new type of solar cell, the lead-halide perovskite solar cell, CH₃NH₃PbI₃, has gained interest in photovoltaic community due to its high efficiency and low cost compared with the well-known silicon solar cells. In spite of incredible efficiencies as high as 22.1% that it have presented, it faces a problem concerning the commercial use due to its lead content and poor stability. In this way, new lead-free materials have been studied in the last few years. One of it is the lead - free perovskite-like material (CH₃NH₃)ₓBiₓBrₙ₋₅ that can act as the absorption material in solar cells and has a better stability than CH₃NH₃PbI₃ [1]. In spite of the good stability, the efficiencies this type of solar cell has achieved are still very low. In this work we combined this two semiconductors, CH₃NH₃PbI₃ and (CH₃NH₃)ₓBiₓBrₙ₋₅, by the addition of small amounts (1% to 25%) of Bi in the lead-perovskite in order to observe if this would affect the stability of the final perovskite, inspired in a similar study where one has inserted tin in CH₃NH₃PbI₃ [2]. The films were made by one-step, mixing suitable amounts of PbI₂, MAI (methylammonium iodide) and BiI₃ in dimethylformamide. The films were obtained by spin coating this solution in glass substrates. After deposition we monitored the degradation of the films exposed to light and humidity for 16 days through X-ray Diffraction and Ultraviolet-Visible Spectroscopy measurements as well as photographs of the films. The last ones indicate that the lead-perovskite (dark gray) degrades to PbI₂ (yellow) faster than the ones where small amounts of Bi were inserted, indicating that the material stability was increased through the bismuth-doping. X-ray diffraction measurements of as-deposited films indicate that the crystal structure of all films, including the Bi-doped ones, have the crystal structure of lead-perovskite. The results indicate that with the implantation of small amounts of Bi (~25%) does not affect the crystal structure of the lead-perovskite and increases the stability of the material.

Perovskite solar cells are an important photovoltaic technology with high efficiencies exceeding 20% due to their optimal band gap, large absorption coefficient, and high charge mobilities. One of these challenges is the understanding and control of their defect structures because perovskite compounds are relatively soft ionic crystals and ions are migrating in the crystals relatively low activation energy. In this study, we have investigated the effect of low energy ion irradiations to both all inorganic and organic-inorganic lead halide perovskite films on the structure, morphology optical and electronic properties systematically. Several kinds of halogen ion beam irradiations on the perovskite thin film was performed by using a tandem type ion accelerator with changing acceleration voltages and irradiation time. Incorporation of ions in perovskite crystals by irradiations were confirmed under several conditions. Detailed experimental results on the structure, optical properties, electronic properties and photovoltaic properties by ion irradiations will be reported on the conference.

ET04.09.06
Solvant-Engineering Method to Deposit Compact Bismuth-Based Thin Films—Mechanism and Application to Solar Cells Seong Sik Shin1, 2 and Tonio Buonassassi3; 1Korea Research Institute of Chemical Technology, Cambridge, Massachusetts, United States; 2Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Bismuth-based materials have been investigated as an alternative to lead-based perovskite materials for photovoltaic applications. However, inferior film quality has limited device performance. Here, we propose a one-step solvent evaporation method for deposition of various bismuth-based films. Through this one-step method, we obtain compact films of methylammonium bismuth iodide (MBI), cesium bismuth iodide (CSI), and formamidinium bismuth iodide (FDI). On the basis of film growth theory and experimental analyses, we propose a possible mechanism of film formation. Additionally, we demonstrate that the resultant compact MBI film is more suitable to fabricate efficient and stable photovoltaic devices, compared to baseline MBI films with pinholes. We further employ a new hole-transporting material to reduce the valence-band offset with the MBI. The best-performing photovoltaic device exhibits an open-circuit voltage of 0.85 V and fill factor of 73%, and a power conversion efficiency of 0.71%.

ET04.09.07
Tuneable Silver Bismuth Sulphoiodide Solar Cells Narendra Pari1, Jianfeng Lu1, Phillip C. Andrews1, Yi-Bing Cheng1, Udo Bach2 and Alexandr N. Simonov3; 1Chemistry, Monash University, Clayton, Victoria, Australia; 2Chemical Engineering, ARC Centre of Excellence in Exciton Science, Monash University, Clayton, Victoria, Australia; 3Materials Science and Engineering, ARC Centre of Excellence in Exciton Science, Melbourne, Victoria, Australia; 4Chemistry, ARC Centre of Excellence for Electromaterials Science, Monash University, Melbourne, Victoria, Australia.

Organolead halide perovskite solar cells have recently emerged as a solar energy technology with immense potential for large-scale generation of renewable electricity. However, the hazardous nature of lead and intrinsic instability of perovskites has driven the search for simpler and more robust light-absorbing materials. From this perspective, cheap, abundant and non-toxic bismuth-based systems with favourable optoelectronic properties are attracting a growing interest. Unfortunately, bismuth-based perovskites provide incompability lower photovoltaic performance than the lead counterparts due to poor interfacial charge extraction and wide indirect band gap. Viable alternatives are silver(I) and copper(I) iodobismuthates that have been recently found to exhibit promising photovoltaic performance. However, their relatively wide band gaps (Eg) of 1.8-1.9 eV and downshifted valence band edges (EvB) limit the charge transfer through conventional charge transport materials and the photocurrent density. Interestingly, silver bismuth sulfoiodides, which are also currently explored as photovoltaic materials, have an excessively positive EvB and too narrow Eg of 1.2-1.4 eV. Herein, silver bismuth sulfoiodides are introduced, for the first time, as a new class of light harvesting materials that balance out the unfavourable optoelectronic properties of iodides and sulfoiodides. We demonstrate a facile and efficient strategy to tune the optoelectronic properties of silver bismuth iodobismuthates by varying the sulphide: iodide ratio. A consistent narrowing of the bandgap by 0.1 eV and an upshift of the valence band edge by 0.1-0.3 eV upon modification with small amounts of sulphide is demonstrated for thermodynamically stable Ag5Bi4I16−xSx compositions. Photovoltaic devices based on new silver bismuth sulfoiodide light absorbers embedded into a mesoporous TiO2 electron transporting scaffold and covered with PTAA hole transporting layer outperform control solar cells based on sulphide-free materials, in full agreement with changes in the optoelectronic properties. An enhanced power conversion efficiency of 5.44 ± 0.07 % under 1 sun AM 1.5G irradiation and over a month stability under ambient conditions for photovoltaic devices based on Ag5Bi4I16−xSx is demonstrated.

ET04.09.08
Low-Temperature SnO2-Based Planar Perovskite Solar Cells—Interface Engineering, Large-Scale Manufacturing and High Performance Achievement Junjie Ma, Guojia Fang, Zhiliang Chen and Xiaolu Zheng; Wuhan University, Wuhan, China.

Perovskite solar cells (PSCs) have attracted considerable research interest because of their excellent photovoltaic performance and simple fabrication process. Tin oxide (SnO2) has emerged as a promising candidate for electron transfer layer (ETL), which shows much higher electron mobility, good antireflection, low-temperature process. Herein, we report a simple and efficient interfacial engineering method for achieving highly efficient Low-temperature SnO2-based PSCs. An ultrathin wide bandgap dielectric MgO nanolayer is incorporated between electrode and SnO2 ETL, realizing enhanced electron transporting and hole blocking properties. A power conversion efficiency (PCE) of 18.82% is demonstrated. On the other hand, systematic exploration of commercialized application in SnO2-based PSCs is conducted. We prepared SnO2 ETL through the electron beam evaporation (e-beam) technology, realizing large-scale, low-cost and uniform manufacture which would be available for industrial deployment. A Cs-containing blended perovskite absorber layer was introduced into the PSCs to effectively enhance the ambient stability. As a result, PSCs exhibit a high efficiency of 18.2% without any interface modification, and remarkable long-term stability, which remained 97% of its initial PCE after been stored over 34 days. Our result demonstrated the great potential of the PSCs based on SnO2 ETL towards commercially viable.

ET04.09.09
Single-Step CVD Approaches for Producing Thin-Film Perovskites Andrew J. Clayton, Arthur Connell, Rosie V. Anthony, Leo W. Furnell, Eurg W. Jones, Stuart J. Irvine and Peter J. Hoffiman; Swansea University, St. Asaph, United Kingdom.

Chemical vapor deposition (CVD) is a proven method [1-4] for depositing organic-inorganic metal halides, such as methylammonium lead iodide (MAPI)1, 2 and cesium lead iodide (CsPbI3)3, including Pb-free perovskite materials [4] for thin film photovoltaics (PV). The CVD process can be used in conjunction with other processes (hybrid) [1] or as a single step process [2-4]. The latter offers a simpler approach with reduced processing time. CVD is a controllable process with consistent results, also negating the requirement for solvents and limiting moisture incorporation.

Effect of Ion Irradiation on the Properties of Perovskite Solar Cells Hironori Ogata, Tomoaki Nishimura, Hiroya Kiuchi, Kazunori Ito, Toshiya Kobayashi and Yuki Fukazawa; Hosei University, Tokyo, Japan.

Perovskite solar cells are an important photovoltaic technology with high efficiencies exceeding 20% due to their optimal band gap, large absorption coefficient, and high charge mobilities. One of these challenges is the understanding and control of their defect structures because perovskite compounds are relatively soft ionic crystals and ions are migrating in the crystals relatively low activation energy. In this study, we have investigated the effect of low energy ion irradiations to both all inorganic and organic-inorganic lead halide perovskite films on the structure, morphology optical and electronic properties systematically. Several kinds of halogen ion beam irradiations on the perovskite thin film was performed by using a tandem type ion accelerator with changing acceleration voltages and irradiation time. Incorporation of ions in perovskite crystals by irradiations were confirmed under several conditions. Detailed experimental results on the structure, optical properties, electronic properties and photovoltaic properties by ion irradiations will be reported on the conference.
In this present study, different single step CVD approaches have been investigated for effective deposition of thin film MAPbI₃ and CsPbI₃. A CVD growth chamber with simple quartz tube design and two separately controlled temperature zones has been employed. The first zone was operated at high temperature (HT) to evaporate the precursor materials and sublime the chemical vapor in a low temperature (LT) zone on to a substrate. This was positioned on an angled graphite susceptor to counteract gas phase depletion and improve thickness uniformity.

Temperature control was achieved using K-type thermocouples inserted into the chamber from each end to measure and control the HT and LT zones. A small quartz tube was attached to the growth chamber, in which a thermocouple was inserted to at different sections along the tube to profile the temperature across the two zones. Both reactor tube and attached thermocouple tube were enclosed in a furnace encompassing both ceramic heaters for each temperature zone. A nitrogen (N₂) gas carrier was used to carry the chemical vapor downstream to the substrate in the growth zone. The N₂ carrier was dried by molecular sieves as it entered the CVD gas delivery system and a hygrometer was used to measure the dew point of the gas.

Two approaches were used to deliver the precursor chemical vapor to the substrate; firstly, a graphite crucible with two precursor positions was used, transporting the precursors in the same carrier flow [2, 3]; secondly, an additional inner tube was inserted into the main reactor tube to independently transport the lead iodide (PbI₂) to the substrate. The methylammonium iodide (MAI) or cesium iodide (CsI) were sublimed from a graphite crucible further upstream with vapor transported outside of the inserted tube carrying the PbI₂. Both approaches were to ensure sufficient reaction on the substrate in the LT growth zone. The different approaches were assessed to identify the best method for producing the perovskite films. Thin film solar cells will be prepared utilising the preferred CVD approach for the perovskite films and PV performances presented.

ET04.09.10 Interaction of Oxygen with Halide Perovskites Alessandro Senocaro1, 2, Tolga Acartuerk3, Goe Yeong Kim1, Rotraud Merkle1, Ulrich Starke1, Michael Graetzel1-2 and Joachim Maier1; 1Max Planck Institute for Solid State Research, Stuttgart, Germany; 2École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland.

The significance of degradation processes involving halide perovskite materials and devices is widely recognized, as it jeopardizes their practical application. Among the various degrading agents, oxygen has been shown to be extremely problematic, [1-3] and to even pose a severe threat to the technology as it is ubiquitous. On the other hand, oxygen exposure can also be beneficial for the materials, since it greatly improves their photoluminescence response. [4-5] For these reasons, it is highly important to understand the interaction of oxygen with halide perovskites from a mechanistic point of view. Here, we investigate the consequences of oxygen exposure on the stability and transport properties of halide perovskites, focusing on methylammonium lead iodide. Thermodynamic considerations show that the material is unstable against O₂, and this decomposition reaction is indeed observed, but only under illumination. In contrast, in the dark a sluggish surface reaction kinetics maintains the material metastable. Light accelerates the interaction kinetics, resulting in a quick and significant O₂ dissolution in the material lattice (directly observed through O¹ incorporation experiments), that can ultimately lead to degradation. Remarkably, this accelerated incorporation (in conditions that precede degradation) can significantly alter the electronic and ionic transport properties of the material in a way that conforms to acceptor doping. [7] We discuss these issues quantitatively on the basis of point defect chemistry, and extend these considerations to mixed-cation and mixed-anion compositions, as these are applied in state-of-the-art devices. While some compositions show a higher kinetic stability, the degradation tendency is still observed. [5]

ET04.09.11 Applications of Fused-Ring Electron Acceptor ITIC-Th in Perovskite Solar Cells Minchao Qin and Xinhui Lu; The Chinese University of Hong Kong, Hong Kong, Hong Kong.

Solution-processed perovskite solar cells offer a great potential of low-cost roll-to-roll fabrication. However, the degradation of aged precursor solutions will become a critical obstacle to mass production. In this report, we employ a small molecule (ITIC-Th) to stabilize the perovskite precursor solution containing mixed cations and halides. We find that ITIC-Th can effectively suppress the formation of yellow δ-phase in the films made from aged precursor solutions. Consequently, the devices fabricated from the aged precursor solution with ITIC-Th experience much less efficiency drop with the increase of the precursor aging time - from 19.20% (fresh) to 16.55% (39 days), compared with the devices made from conventional precursor solutions dropping from 18.07% (fresh) to 1.76% (39 days). The characteristics suggest that ITIC-Th is beneficial for MA cations to be incorporated into the crystal structure, facilitating the formation of perovskite phase. Furthermore, the presence of ITIC-Th in the perovskite thin film gives rise to additional photocurrent as well as improved fill factor due to the well-matched energy levels, the passivation of defects and the complementary absorption spectra, suggesting a new route towards future high-efficiency solar cells - incorporating organic non-fullerene acceptors and halide perovskite materials into the same active layer.

ET04.09.12 In Situ X-Ray Observation of Lead Iodide Perovskite Films Prepared by a Gas Blowing Method Yoshihiko Nishihara1, 2, Tetsuhiko Miyadera2, Masayuki Chikamatsu2 and Yuji Yoshida1, 2; 1University of Tsukuba, Tsukuba, Japan; 2National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan.

The lead iodide perovskite solar cells have an energy conversion efficiency about 22%, and the bottleneck for practical use is the stability, and the large area fabrication process. The conventional antisolvent method has poor yield and is not suitable for large area. Thus, a combination of a coating method and a gas blowing method has attracted attention. However, its control technique has not been established and it is necessary to elucidate the formation mechanism. In this study, we introduced an in situ observation system including synchrotron based grazing incident X-ray diffraction for the film formation process by coating and gas blowing methods, and compared with a nitrogen drying process. A simple bar coater was used as a coating method, and nitrogen gas was blowing from a nozzle set onto the coating film.
After drying process, perovskite crystals were overgrown and the film surface was roughened, preparing it unsuitable for solar cells. As shown in the X-ray diffraction images of the precursor films before formation of perovskite, many bright spots showing random growth of large crystals were observed. However, in the case of gas blowing, the ring patterns indicates uniform film formation, and 020+002 diffractions oriented normal to the film surface. It is considered that the orientation of the precursor crystal contributes to the formation of a flat thin film having a large crystalline domain and hence improvement of the photovoltaic performance.

ET04.09.13
Understanding the Effects of Oxygen on Light-Induced Degradation of Perovskite Solar Cells to Achieve Long-Term Operational Stability
Tae-Youl Yang1, Nam Joong Jeon2, Hee-Won Shin2, Seong Sik Shin2, Young Yun Kim1 and Jangwon Seo1; 1Korea Research Institute of Chemical Technology (KRICT), Daejeon, Korea (the Republic of); 2Sungkyunkwan University, Suwon, Korea (the Republic of).

Perovskite solar cells (PSCs) in which organometal halides act as photoactive materials have achieved power conversion efficiency (PCE) of approximately 23 % by improving perovskite materials and fabrication process. Nowadays the substantial progress in long-term stability have been also achieved to commercialize PSCs based on such as high PCE with developing durable perovskite composition, interlayers, and encapsulation. It has been known that the degradation of PSCs is induced by stress conditions such as light (UV), heat, moisture, and oxygen. Even though the degradation mechanisms for heat and moisture was clearly explained, that for light soaking has not been clarified yet. In practice, because the protocols to test long-term operational stability of PSC is not standardized, the results of light soaking tests have been reported in a number of combinations of stress conditions. We reason that the operational stability under light soaking correlates with the stress factors from the atmosphere because the stability of PSCs depends on encapsulations or the testing atmosphere.

In this work, we systemically investigate the effects of oxygen on the degradation of PSCs under illumination. When PSCs were exposed to oxygen and light simultaneously, the devices were degraded quickly within an hour despite the perovskite material, (FAxPb1-x)0.93(MAPbBr3)0.07, was stable in the same condition. While most of discussions focus on the degradation at the interface between electron transport layers such as TiO2 and perovskite, here we present the degradation of the interface between perovskite and hole-transporting layer (HTL). We found that oxygen and light induce iodine diffusion from perovskite to HTLs, and reveal that charge transport from the perovskite to the HTM becomes ineffective before the degradation of bulk perovskite. Based on this understanding we demonstrated the long-term operational stability over 1000h of high-efficient mp-TiO2 used PSCs even under light including UV by preventing the iodine migration and oxygen ingress.

ET04.09.14
Morphology Mapping of Hybrid Perovskite Coated with Solution Shearing
Min Kyu Kim1, Hyeon Seok Lee1, Seong Ryeol Paé1, Issam Gereige2, Steve Park1 and Byungha Shin1; 1KAIST, Daejeon, Korea (the Republic of); 2Saudi Aramco Research & Development Center, Dhahran, Saudi Arabia.

Large area scaling of hybrid perovskite is essential to bring the technology into commercialization. Various large-scale printing techniques have been successfully employed to fabricate high performance perovskite solar cell. In particular, solution shearing is a versatile technique in which many processing parameters can be tuned in order to produce films with desired structure and morphology. In this study, we have examined the impacts of substrate temperature and coating speed (i.e., how fast the blade is moving), two of the most influential process parameters, on morphology of the resultant perovskite films. Four distinct phases are identified and a morphology-phase map is constructed with the aforementioned parameters. Through optical analysis, an optimal phase window is chosen and the device performance with the chosen condition exhibits power conversion efficiency over 15%, which is comparable to a reference device prepared by the conventional spin-coating process. A uniform perovskite film of an area > 55 cm2 is prepared with solution shearing. Several small-area devices from different locations of the large-area films shows uniform efficiencies within 5% deviation, illustrating the good uniformity achievable with our solution shearing techniques.

ET04.09.15
High-Efficient Perovskite Solar Cells Using Selectively Grown TiO2 Nanorod-Patterned Substrates
Daihong Huh1, Minjin Kim1−2, Wonjoong Kim1, Kwan Kim1, Minseo Byun1, Dong Suk Kim1 and Heon Lee1; 1Korea University, Seoul, Korea (the Republic of); 2Advanced Center for Energy, Korea Institute of Energy Research, Ulsan, Korea (the Republic of).

Organic–inorganic hybrid perovskite solar cells (PSCs) are attracting tremendous attention for new-generation photovoltaic devices because of their excellent power conversion efficiency and simple fabrication process. One of the various approaches to increase the efficiency of PSCs is to change the morphology of the carrier transport layer. Here, optically long and electrically short structural concept is proposed to enhance the characteristics of a PSC by employing selectively grown single crystalline TiO2 nanorods. The approach has the merit of increasing the electron-hole separation effectively and makes a thicker active layer to be coated without electrical loss by using TiO2 nanorod as an electron pathway. Moreover, selectively grown TiO2 nanorods increase the optical path of the incident light via scattering effects and enable a smooth coating of the active layer. Nanoimprint lithography and hydrothermal growth were employed to selectively grown TiO2 nanorod substrates. The efficiency of fabricated PSCs have about 20 % higher than that of planar-type devices. The fabricated PSCs exhibits an efficiency of 19.86% with a current density, open-circuit voltage, and fill factor of 23.13 mA cm−2, 1.120 V, and 76.69%, respectively. Time-resolved photoluminescence, UV-Vis spectroscopy, and the incident photon to current efficiency (IPCE) analysis were conducted to understand the factors responsible for the improvement in characteristics of the fabricated PSCs.
The influence of the film formation and morphology of perovskite top solar cells prepared on textured silicon bottom solar cells was investigated by modeling the deposition process and the optics of the perovskite/silicon tandem solar cells. An efficient photon management is required to realize perovskite/silicon tandem device with energy conversion efficiency exceeding the efficiency of crystalline silicon single junction solar cells. The perovskite solar cell has to be deposited on a textured crystalline silicon solar cell to allow for an efficient incoupling of light in the low refractive index top and the high refractive index bottom solar cell [1]. A recently developed fully textured perovskite/silicon tandem solar cell exhibits the record efficiency of 25.2% [2]. The formation of films on textured surfaces varies from the non-conformal deposition, which is typically observed for physical deposition techniques (e.g. PVD), to conformally prepared films obtained for some chemical deposition techniques (e.g. CVD, ALD). A 3D morphological algorithm was used to model the film formation [3]. The investigation is carried out for a wide range of pyramidal textured surfaces with a constant period to height ratio. A hybrid approach is used to investigate the optics by combining a three-dimensional (3D) finite-difference time-domain simulations with experimental measurements. Short-circuit current densities exceeding 20 mA/cm² were obtained for non-conformally and conformally grown perovskite films. A comparison of non-conformally and conformally deposition shows that short circuit current densities of 20 mA/cm² can be reached for distinctly thinner conformally deposited films. On the other hand, the roughness of the underlying silicon bottom solar cells has to be larger in the case of the conformally deposited films. Guidelines will be provided on how to achieve high short circuit currents for non-conformal and conformally prepared perovskite films.

Spin Coated Copper (I) Thiocyanate as a Hole Transport Layer for Perovskite Solar Cells Utku Er1,2, Kerem Cagatay Icili1,2 and Ahmet Macit Ozenbas1,2; 1Orta Dogu Teknik University, Ankara, Turkey; 2GUNAM, Ankara, Turkey.

Application of a low cost and efficient p-type inorganic hole-transporting material, copper thiocyanate (CuSCN), on mesoporous n-i-p configurated perovskite based devices was conducted in this study. Diethyldisulfide was chosen for the preparation of precursor solution in order to deposit CuSCN layer on perovskite without degrading it. Topographical, elemental and electrical characterizations of spin coated CuSCN layers were performed using XRD, AFM, SEM, XPS, UPS, and UV-Vis studies. A power conversion efficiency exceeding 11.02 % with an open circuit voltage of 0.83 V was succeeded in the perovskite solar cells under full sun illumination. Low-temperature solution process used for the deposition of CuSCN and a fast solvent removal method allowed the creation of compact, highly conformal CuSCN layers that facilitate rapid carrier extraction and collection. The differences in series and recombination resistances for CuSCN free and CuSCN containing cells were also determined using impedance spectroscopy (IS) analysis. Moreover, the effect of TiO₂ layer thickness on the cell performance was studied where these TiO₂ layers were used not only for electron extraction and transportation but also as hole blocking layer in perovskite solar cells. The impedance spectroscopy results were also consistent with the differentially configured cell performances. This work shows a well defined n-i-p configurated perovskite cell with optimized layers which utilizes low cost and abundant material for photovoltaic applications.

Industrial Case of Perovskite Solar Cells

Konrad Wojciechowski; Saule Technologies, Wroclaw, Poland.

Metal halide perovskites constitute a very attractive class of materials for optoelectronic applications, such as solar cells, light emitting diodes, lasers and photodetectors. Most notably, solid-state photovoltaic devices based on these materials have reached power conversion efficiencies (PCEs) of 22% after just five years of academic research.

Perovskite solar cells have a great commercial potential, but there still remain few challenges, which need to be resolved to prove the viability of the technology. Some of the well-known issues include material stability. Furthermore, cost-effective, reliable fabrication process capable of delivering highly efficient, large-area perovskite modules is yet to be demonstrated.

This talk will outline the industrial challenges of perovskite solar cells including legislative hurdles as well as the potential impact on the solar industry. Moreover, we will present fully scalable ink-jet printing process of the perovskite PV stack and fabrication of perovskite printable mini-modules of areas up to A4 size, complemented with a robust encapsulation methodology.

Upscaled Roll-to-Roll Manufacturing of Perovskite Based Solar Cells Pim Groen1,2; 1Holst Centre, Eindhoven, Netherlands; 2Aerospace Engineering, Delft University of Technology, Delft, Netherlands.

Metal-halide based perovskites are promising novel materials for thin-film photovoltaics, exhibiting high power conversion efficiencies. A number of challenges still need to be addressed before PSCs can enter the PV market. One of these challenges is the development of industry-relevant technologies for scaling up the perovskite module manufacturing. The feasibility of upsaling the perovskite solar cells technologies to high volume production using Roll-to-Roll (R2R) slot die coating is demonstrated in this talk. Perovskite solar cells were produced by R2R slot die coating on flexible PET/ITO substrates with the width of 30 cm. Roll-to-Roll deposition of electron transport layer (ETL) and perovskite is performed at ambient atmosphere from non-toxic solvents compatible with industrial manufacturing. The average stabilized power conversion efficiency of the devices made from the foils randomly cut from different places was 12%, with the best value of 13.5%. The demonstrated achievement is an important milestone and a big solid step towards future commercialization of perovskite-based solar cells technologies.

R2R Compatible High-Speed Coating of Perovskite Solar Cell Henning Doerr, David T. Moore, Kai Zhu and Maikel van Hest; National Renewable Energy Laboratory, Lakewood, Colorado, United States.

High efficiency combined with transformative roll-to-roll (R2R) printability makes metal halide perovskite (MHP)-based solar cells the most promising solar technology to address the terawatt challenge of the future energy demand. However, translation from lab-scale deposition techniques to large-scale R2R methods has typically led to reduced photovoltaic performance. Here, we demonstrate an MHP ink that allows R2R compatible high-speed (>2.5 m min⁻¹) one-step blade coating. MHP solar cells from the developed ink can produce power conversion efficiency over 19% in the ambient environment, without any addition of antisolvent, gas blow, vacuum treatment or high-temperature stage temperature. This report on one-step antisolvent (or similar process)-treatment-free blade coating technique paves the way for the R2R production of high-efficiency MHP solar cells.

Coevaporated p-i-n Perovskite Solar Cells Deposited at Elevated Substrate Temperature—Process Optimization and Photo Stability Ranith Kottokkaran, Harshavardhan A Gomnikar, Hisham A. Abbas, Max Noack and Vikram L. Dalal; Microelectronics Research Center, Iowa State University of Science and Technology, Ames, Iowa, United States.

Thin-film photovoltaics represents the next generation of promising photovoltaics technology. Exhibiting a verified efficiency of over 22%, perovskite solar cells are the fastest growing solar material to date. Lead tri-halide perovskites (MAPbX₃) are a new and exciting technology among perovskite solar cells. Solution process-based fabrication of perovskite solar cells have known problems of reproducibility, whereas vacuum deposition, which involves sequential or co-evaporation of lead halide and methyl ammonium iodide (MAI), is a much more reproducible technique. Devoid of any organic solvents, vapor deposited perovskite solar cells show superior photo stability.

In this work, we report on co-evaporated MAPbI₃ perovskite deposited at various substrate temperatures using a multi-source thermal evaporator. The central challenge involved with the deposition process is precise control of the MAI pressure during the deposition process. A p-i-n device architecture of FTO/ PTAA/ MAPbI₃/ PCBM/ Al with power conversion efficiency of >17.5% was achieved by maintaining the MAI pressure between 5.5-6 x10⁻⁵ Torr for a room temperature deposition. Further, we also carried out co-evaporation of MAPbI₃ perovskite at higher substrate temperatures of 50 °C and 75 °C. Here, elevating the MAI pressures (9-9.5x10⁻⁵ Torr and 1.2-1.3x10⁻⁴ Torr respectively) is essential to achieve efficiencies of >16%. SEM micrographs show grain enhancement for films deposited at higher temperatures. Photo degradation studies show that perovskite devices deposited at 75 °C show superior photo-stability, with less than 1% degradation in the short circuit current for over 100 hours of light exposure.

10:45 AM ET04.10.10
A Novel Cryo-Controlled Growth Technique for High Efficiency Organometal Halide Perovskite Solar Cells Annie Ng1, Zhiwei Ren2, Qian Shen2, Sin Hang Cheung2, Aleksandra B. Dijarić4, Shu Kong Su4, Gang Li5 and Charles Surya1; 1Nazarbayev University, Astana, Kazakhstan; 2Hong Kong Polytechnic University, Hong Kong, China; 3Hong Kong Baptist University, Hong Kong, China; 4The University of Hong Kong, Hong Kong, China.

Perovskites with multi-components have demonstrated significant potential for the development of high performance photovoltaic cells with better device efficiency and stability. Optimization of perovskite growth techniques are crucial for acquiring mixed halide perovskite films with precise stoichiometry, desirable morphology and low defect density. Reports on growth processes involving the formation of Lewis acid–base adduct in precursor films and the application of anti-solvent dripping process have become the mainstream for preparing solution based mixed halide perovskites. However, a number of limitations are found for using anti-solvent techniques to prepare large-scale samples. The resultant morphology of the perovskite films is significantly affected by many factors such as the anti-solvent dripping time, volume and location on the samples. Furthermore, the anti-solvent technique commonly works together with the spin-coating process and it would be difficult to apply on other large-scale solution processing techniques.

We report a novel cryo-controlled growth technique for the growth of mixed halide perovskites. The abrupt decrease in the ambient temperature results in a supersaturation condition in the as-casted precursor films, leading to the formation of uniform nucleation sites for subsequent crystal growth. A blow dry process is introduced subsequently to facilitate the removal of residual solvents from the films before thermal annealing. Our proposed strategy can effectively retard the pre-nucleation crystallization of the perovskites and, thereby, decoupling the pre-nucleation and crystallization phases. This material growth approach can be applied to different types of mixed halide perovskites, ensuring excellent uniformity of the nucleation layers and, subsequently, higher quality perovskite films. A power conversion efficiency (PCE) of 21.4 % with a fill factor of 80 % for the champion PSC is achieved using the proposed perovskite growth technique without utilizing any anti-solvents.

11:00 AM ET04.10.11
Chemical Vapor Deposition for 10 cm × 10 cm Large-Array Perovskite Solar Modules Longbin Qiu, Yan Jiang, Zonghao Liu, Luis K. Ono, Dae-Yong
Perovskite solar cells have shown efficiency approaching silicon photovoltaic counterparts, but mostly achieved on a small area. To commercialize this low cost technology, scalable fabrication is one of the main challenges to be addressed [1]. For large-area, uniform and high quality film deposition, we have employed industry compatible chemical vapor deposition to deposit MAPbI$_3$, FAPbI$_3$, and Cs$_x$FA$_{1-x}$PbI$_3$ films with high quality for solar cells/modules [2-5]. In this work, fully scalable perovskite solar modules with high-geometric fill factor have been fabricated by a further optimized chemical vapor deposition process. Upon increasing of device area, device performance decreases only gently. 10 cm x 10 cm solar modules showed an aperture efficiency approaching 10% with a geometric fill factor greater than 90%. We show that chemical vapor deposition is compatible for large-area, uniform and high quality perovskite films and solar modules.

11:15 AM ET04.10.12
Towards Completely Inkjet-Printed Perovskite Solar Cells Aron J. Huckaba, Yonghui Lee, Andreas Lesh, Hubert Girault and Mohammad K. Nazeeruddin, Ecole Polytechnique Federale deLausanne, Sion, Switzerland.

In the past ten years, the efficiencies of perovskite solar cells have risen from 3.8% to > 22% power conversion efficiency (PCE). The highest performing devices typically have small areas (<1 cm$^2$) and are fabricated by spin-coating deposition of most of the active layers. While spin-coating works well for small area substrates, it is not industrially applicable due to the high percentage of material loss and substrate size limitation. Reports of perovskite absorber layer deposition by industrially relevant techniques such as slot-die coating, evaporation, and inkjet printing are becoming more frequent. Inkjet printing is a digital, mask-less and contact-less fabrication technique that allows the direct deposition of miniscule ink volumes onto substrates with full pattern control, where the pattern resolution is limited by the droplet volume (generally below 100 pl) and the spreading diameter of the droplet on the substrate. Complete Organic Light Emitting Diodes (OLEDs), Field Effect Transistors (FETs), and Organic Photovoltaic (OPV) devices have been fabricated using inkjet printing, but this has not yet been achieved with perovskite solar cells. Herein, efforts towards the fabrication of completely inkjet-printed perovskite solar cells by bottom-up layer construction are described. Optimization studies of each active layer will be discussed, as well as the inclusion of inkjet-printed active layers in high-efficiency perovskite solar cells.

11:30 AM ET04.10.13
A Vacuum-Free Plasma Enhanced Ultrasonic Spray Deposition Process for Highly Efficiency Large-Area Perovskite Solar Cells Dimitry Lopatin2, Oleg Baranov2, Elizaveta Kozhova1, Bogdan Bragin2 and Vinay Gupta1, 1Advanced Materials and Devices Division, National Physical Laboratory, New Delhi, India; 2Kuban State University, Krasnodar, Russian Federation; 1University of Franche-Comté, Besançon, France.

The photovoltaic performance of Metal halide perovskite solar cells (PSCs) has reached beyond 20% on a small device area (≤0.1cm$^2$) and shown potential to overtake silicon solar cells. However, the researchers are still grappling with maintaining high efficiency over large device area due to the current technological barrier. Here we have achieved a single cell efficiency of ~14% over an area of 10 x 10 cm$^2$ by inventing a disruptive vacuum-free plasma enhanced ultrasonic spray deposition (PEUSD) technology and obtained uniform and high-quality perovskite film over large area. The PEUSD is a vacuum free technology that can print all the layers of a PSC i.e. Ni$_x$NiO$_{1-x}$/CH$_3$NH$_3$PbI$_3$/Cs$_x$TiO$_2$/Cu-NWs/ITO including metal contacts. This technology would enable low-cost architecture for the commercialization of PSCs and can potentially replace current vacuum-based coating technologies for thin film deposition.

Pulsed Flash Infrared Annealing for Efficient and Stable Perovskite Inorganic Solar Cell Sandy Sanchez1, Michael Saliba1 and Antonio Abate2, 1Adolphe Merkle Institute, Fribourg, Switzerland; 2Helmholtz-Zentrum Berlin, Berlin, Germany.

Organic-inorganic perovskite solar cells have achieved impressive power conversion efficiency over the past years, yet operational stability remains the key concern. One strategy to improve long-term stability is to replace the thermally unstable organic with inorganic cations comprising the perovskite lattice. Here, for the first time, we make use of pulsed infrared light to drive the crystallisation of inorganic mixed halide Cs$_x$Pb$_{1-x}$Br$_2$ perovskite films in solar cells with a power conversion efficiency exceeding 10%. By varying the iodide-bromine ratio systematically, we found that to keep the inorganic perovskite black phase stable at the room temperature we need to limit the iodine content to lower than 60% - bromine content higher than 40%. Our finding revises previous reports claiming stable compositions with higher iodine content, which was systematically exploited to reduce the perovskite bandgap with the aim to enlarge the light absorption spectra and thus to boost the device efficiency. We demonstrate that the newly defined stable compositional range enables devices that retain 90% of the initial efficiency after stressing the perovskite at 200°C for one hour. This result is a key finding for the application of perovskite in concentrated photovoltaic.
A Strategy for Architecture Design of Crystalline Perovskite Light-Emitting Diodes with High Performance and Stability

Our fabrication approach is fully reproducible and is a technological base for mass-fabrication of active optoelectronic circuits with hybrid perovskite. Measured devices. The lasing thresholds are in the order of 5 µJcm⁻² which outperforms most unpatterned single crystal perovskite lasing techniques can be applied enabling the usage of the material in commercial systems; i.e. optoelectronic circuits with monolithically integrated lasers. We paves the way to more complicated circuits and structures enabling electrically pumped perovskite laser in the near future. High-throughput fabrication technologies for reproducible on-chip devices with low device-to-device variations and low sample-to-sample variation with almost emission linewidths (to below 40nm, and maximize their photoluminescence quantum efficiencies (up to 89%) and phase/chemical stabilities [3]. Detailed structural analysis revealed that the CsxFA₁₋ₓPb(Br₁₋ᵣIʳ)₃ NCs adopt a cubic perovskite structure of FAPbI₃, with iodide anions partially substituted by bromide ions. Most importantly, we demonstrate the excellent transference of reaction parameters from microfluidics to a conventional flask-based process enabling up-scaling thereby further implementing CsxFA₁₋ₓPb(Br₁₋ᵣIʳ)₃ NCs with an emission maximum at 735 nm were integrated into light-emitting diodes, exhibiting high external quantum efficiency of 5.9% and very narrow electroluminescence spectral bandwidth of 27 nm [3].

Monolithically Integrated On-Chip Lasers Based on Perovskite Optoelectronics

Harry A. Atwater; California Institute of Technology, Pasadena, California, United States.

We demonstrate latest achievements of integrated perovskite devices on a silicon nitride photonic platform. Perovskite as a class of solution processed semiconductors with a direct bandgap offering a variety of interesting emission wavelengths for on-chip photonics. Spin-coating enables a possibility of direct integration of the lasing material as a counterpart to epitaxial growth with is not applicable on amorphous substrates such as silicon nitride. We report on methylammonium lead iodide (MAPbI₃) perovskite micro-disc and microring lasers which are monolithically integrated into silicon nitride photonic integrated circuits showing low lasing thresholds at room temperature. The perovskite micro-discs are placed in the vicinity of a single mode silicon nitride waveguides so that the generated laser light can be directly used by a photonic circuitry. A top-down lithographic structuring approach has been developed to pattern perovskite micro-discs without degenerating the active material. This method paves the way to more complicated circuits and structures enabling electrically pumped perovskite laser in the near future. High-throughput fabrication techniques can be applied enabling the usage of the material in commercial systems; i.e. optoelectronic circuits with monolithically integrated lasers. We report on fabrication technologies for reproducable on-chip devices with low device-to-device variations and low sample-to-sample variation with almost 100 measured devices. The lasing thresholds are in the order of 5 µJcm⁻² which outperforms most unpatterned single crystal perovskite lasing demonstrations. The laser emission lies at ~785 nm and is narrow in linewidth (~1 nm). The micro-discs were optically pumped at room temperature in ambient conditions with 120 fs laser pulses with 250 kHz repetition rate at 630 nm wavelength. X-ray diffraction crystallography has been performed prior to processing the perovskite and on the final device showing only small changes in the material after the patterning process. Device performance is confirmed by simulations (Finite Difference Time Domain, FDTD).

Our fabrication approach is fully reproducible and is a technological base for mass-fabrication of active optoelectronic circuits with hybrid perovskite-dielectric waveguide materials.

A Strategy for Architecture Design of Crystalline Perovskite Light-Emitting Diodes with High Performance and Stability

Zhaoxin Wu, Yifei Shi, Hua Dong, Chenchin Ran, Jinfei Dai, Fang Yuan, Bo Jiao and Xin Hou; School of Electronic and Information Engineering, Xi’an Jiaotong University, Xi’an, China.

Hybrid halide perovskites have recently emerged as new promising semiconductors for both photovoltaic and optoelectronic applications. Given the rapid rise in performance of perovskite solar cells, the demonstration of high photoluminescence quantum efficiency and optical gain in these hybrid perovskites suggests that these materials should also be potential light emitters for light emitting diodes and lasers. Here, we introduce a new design strategy and conception, “Insulator-Perovskite-Insulator” (IPI) architecture tailored to perovskite light-emitting diodes (PeLEDs). We experimentally show that the IPI structure effectively induces charge carriers into perovskite crystals, blocks leakage currents via pinholes in the perovskite film, avoids exciton quenching simultaneously. Consequently, as for FAPbBr₃, a 30-fold enhancement in the current efficiency of IPI-structured PeLEDs compared to a control device was achieved - from 0.64 cd/A to 20.3 cd/A. As the example of CsPbBr₃, compared with the control device, both current efficiency and lifetime of IPI-structured PeLEDs were obviously improved [1]. In addition, we also demonstrate tin (Sn) based PeLEDs with all-inorganic heterostructure fabricated by the vapor-deposition process. The all-inorganic hetero-structured PeLEDs exhibited a maximum EQE of ~0.34%, and withstood current density up to 915 A/cm² with small emission zone of 0.01 mm². Besides, low threshold (7 µJ/cm²) amplified spontaneous emission was presented from the extremely smooth and uniform cesium tin halide perovskite films. These characteristics demonstrate the great potential of using them as gain media for electrically pumped lasers [2,3].

Space Based Perovskite Photovoltaics

Samuel Loke, Nina Vaidya, Pilar Espinet Gonzalez, Michael Kelzenberg, Qin Yang, Emily C. Warmann and Harry A. Atwater; California Institute of Technology, Pasadena, California, United States.

Organo-lead halide perovskite solar cells are an exciting candidate for future space based photovoltaics. Perovskites have potential for significantly higher specific power (power generated per unit mass) compared to other photovoltaic technologies, since intrinsic radiation hardness may potentially enable radiation shielding to be omitted as a cell component. This creates an opportunity for perovskites to be a leading photovoltaics technology for space power, where the cost per kg is a demanding metric owing to high payload launch costs, provided radiation robustness and environmental stability can be
validates. It is thus imperative to study how perovskites respond to thermal and radiative loads in space. We have demonstrated methylammonium lead iodide (MAPbI3) based solar cells to be resistant to 30, 50 and 350 keV proton irradiation at 10^{11} p/cm^2 fluence, and 1 MeV electron irradiation at 10^{15} e^-/cm^2 fluence. In order to deepen our understanding of the space performance of perovskite solar cell devices, we fabricate several perovskite device structures, with various hole transport layer (HTL) materials and electron transport layer (ETL) materials, and characterize their performance in simulated space environments with respect to radiation stability, under air mass 0 (AM0) illumination in vacuum and under thermal cycling. Finally, we examine the feasibility of fabricating perovskites on various flexible substrates that will allow for even lower areal mass density as well as easier payload storage. For this study, we examine the perovskite materials MAPbI_3, formamidinium lead iodide (FAPbI_3), as well as efficient mixed cation perovskites. For our tests, we examine the perovskites on various flexible substrates that will allow for even lower areal mass density as well as easier payload storage. For this study, we examine the perovskite materials MAPbI_3, formamidinium lead iodide (FAPbI_3), as well as efficient mixed cation perovskites.

Despite significant advances in simulation and theory, progress toward identifying lead-free perovskite materials has been limited by low experimental throughput and reproducibility. For early-stage materials, characterization tools are often slow or are too imprecise in pinpointing the bulk or interface property that limits efficiency and/or reliability. Lack of proper diagnosis makes the process-optimization feedback loop more open ended, and driven by intuition rather than the scientific method.

In this talk, we present progress toward a closed-loop, automated experimental system for novel photovoltaic materials discovery. We present advances in rapid diagnosis, enabled by a combination of machine learning and non-destructive electrical testing. The closed-loop feedback loop enables more rapid process optimization to occur. We discuss prospects of using this improved experimental loop for new materials discovery, and the realization in thin-film form of materials that previously had only been synthesized in bulk (e.g., certain double perovskites).

The identification of suitable lead-free perovskites is crucial for their envisioned applications in photovoltaics. Homovalent substitution of lead with Sn- and Ge-based compounds are under intense investigation as potential alternatives, but suffer from instability issues, for example, due to the susceptibility of these ions toward the 4+ oxidation state. Mixed compositions, with two or more possible ions for each lattice position, have been proposed for overcoming these issues and enhancing performance [1, 2]. However, as it is computationally and experimentally prohibitive to measure the vast configuration space available to the mixed perovskites, statistical learning techniques are needed to find a more efficient mapping of mixing parameters to the properties of interest.

Efficient and accurate vetting of perovskites for a range of properties has recently been accomplished in high-throughput Density Functional Theory (DFT) studies of compounds by use of Kernel Ridge Regression (KRR) [3, 4]. Crucial to their success is the determination of adequate material fingerprints which uniquely define the materials and capture the property of interest. Here we demonstrate how one such important screening parameter, the fundamental bandgap, can be predicted for a family of inorganic mixed halide perovskites using novel globally valid material fingerprints based solely on the atomic configurations of arbitrary unit cells. The Partial Radial Distribution Function method [5] is expanded upon to include densities for a variety of elemental properties, enabling us to define a more robust material fingerprint while illuminating the underlying drivers of target properties in a chemically intuitive manner. The results are supplemented with thermodynamic and geometric data to identify the best compositions and the features responsible for them.

Halide Perovskites—A Platform for ‘Defect-Tolerance’ and ‘Self-Healing’ Yevgeny Rakita, Davide R. Ceratti, Gary Hodes and David Cahen; Weizmann Institute of Science, Rehovot, Israel.

In recent years, halide perovskites (HaPs) have taken a unique place among functional semiconductors, surpassing expectations, and surprising many materials researchers. An often-asked question is: what may be the reason(s) that HaPs performance gets close to that of high-quality optoelectronic semiconductors, although their fabrication is similar to that of the organic electronic materials which, though, are of considerably lower semiconductor quality? As ‘quality’ refers (here) to ‘low density of defects/traps that are optical or electronically active’ (the defect density of HaPs is ~10^{10} cm^{-3} in single crystals and <10^{10} cm^{-3} in polycrystalline films), ‘defect-tolerance’ and ‘self-healing’ have been proposed as possible explanations. Although these two properties may seem to be related, ‘defect-tolerance’ is a property that does not exclude the presence of structural defects, but only their impact on the charge carrier dynamics and optical absorption and emission. This will give rise to an effectively reduced optoelectronically relevant defect density. ‘Self-healing’, however, is the property of elimination of structural defects over time by a driving force within the structure (likely to reduce the system’s free energy). To support the ‘defect tolerance’ and ‘self-healing’ hypothesis, I will present experimental evidence that strongly supports the idea that HaPs (not limited to the commonly used APbI_3) are a platform for both ‘defect tolerance’ and ‘self-healing’, physically as well as chemically. The ‘physical’ part includes experimental analysis of the ‘deformation potential’, which makes ‘defect tolerance’ very probable, both due to its absolute value and algebraic sign. The ‘chemical’ part includes assembly of evidence that support recyclability of degradation products back to the starting material, which means a path for ‘self-
Fully inorganic chalcogenide perovskite photoabsorbers are a relatively unexplored class of materials that could potentially overcome the stability issues of hybrid perovskites. However, only few chalcogenide perovskites have been synthesized to date, and no reports of solar cell devices based on chalcogenide perovskite absorbers exist to the best of our knowledge. Chalcogenide perovskites have recently been the subject of a few computational screening studies, including the one carried out by our group and focusing on sulfide (ABS₃) perovskites [1]. Among the 705 ABS₃ compounds that were screened, 15 of them were identified as promising. One of the new compounds that passed all the screening rounds (LaYS₃) was successfully synthesized in thin film form in our group, confirming the theoretically predicted crystal structure and band gap [1].

The main challenge in fabricating LaYS₃ solar cells is the relatively high temperature needed to crystallize the material. As a consequence, we were only able to fabricate prototype LaYS₃ solar cells using back contact materials with high temperature resistance. At the present stage, those devices exhibit diode-like rectification but no photocurrent. Nevertheless, we believe this is the first solar cell fabrication attempt using a sulfide perovskite photoabsorber, and one of the first examples of a solar cell fully inspired by computational screening. In this contribution, we will present the updated status of LaYS₃ solar cell performance, as well as the main challenges encountered in this project and possible future directions.

ET04.11.08 Solar Cells with LaYS₃ Perovskite-Like Absorber Discovered by Computational Screening Andrea Crovetto, Rasmus Nielsen, Brian J. Seger, Ole Hansen, Peter Vesborg and Ib Chorkendorff, Technical University of Denmark, Kgs. Lyngby, Denmark.

The open-circuit voltages ($V_{OC}$) of hybrid perovskite (HP) solar cells do not increase sufficiently with increasing bandgap (for $E_g > 1.70$ eV). We study the impact of A⁺ size mismatch induced lattice distortions (in ABX₃ structure) on the optoelectronic quality of high-bandgap HPs and find that the highest quality films have high A⁺ site size-mismatch, where large guanidinium (GA) compensates for small Cs to keep the tolerance factor in the range for the perovskite structure. Specifically, we find that 1.84 eV bandgap (FA$_{0.33}$GA$_{0.67}$Cs$_{0.80}$)$_2$Pb(I$_{0.13}$Br$_{0.87}$)$_{3.24}$ and 1.75 eV bandgap (FA$_{0.33}$GA$_{0.67}$Cs$_{0.80}$)$_2$Pb(I$_{0.13}$Br$_{0.87}$)$_{3.24}$ attain quasi-Fermi level splitting of 1.43 eV and 1.35 eV, respectively, which is >91% of the Shockley-Queisser limit for both cases. To study the optoelectronic quality of perovskite films and understand device losses, we employ absolute intensity photoluminescence and compare device $V_{OC}$ with absorber quasi-Fermi level splitting for perovskite films with bandgaps spanning from 1.35 to 1.85 eV. Further, we employ wide-field photoluminescence imaging to identify interface recombination in our device stack and explore various interlayer alternatives to ultimately achieve high $V_{OC}$. Films of 1.75 eV bandgap (FA,GA,Cs)Pb(I,Br) are then used to fabricate p-i-n photovoltaic devices that have a $V_{OC}$ of 1.24 V. This $V_{OC}$ is among the highest $V_{OC}$ reported for any HPs with similar bandgap (1.7 to 1.8 eV) and a substantial improvement for the p-i-n architecture, which is desirable for two-terminal tandems with Si, CIGS, or a low-bandgap HP. Methods to improve high-bandgap device $V_{OC}$ further using passivation and controlled crystallization are also explored and discussed. Collectively, our results show that non-radiative recombination rates are reduced in (FA,GA,Cs)Pb(I,Br) films and prove that FA-GA-Cs alloying is a viable route to attain high $V_{OC}$ in high-bandgap HP solar cells.

ET04.12.01 Micro Lasers by Scalable Lithography of Metal-Halide Perovskites Ofer Bar-On1, Philipp Brenner2, Uli Lemmer2 and Jacob Scheuer2; 1Tel Aviv University, Tel Aviv, Israel; 2Karlsruhe Institute of Technology, Karlsruhe, Germany.

Metal-halide perovskites have emerged in recent years as a powerful material system in the field of photonics. Due to their promising electronic and optical properties, tremendous progress has been made in the performance of perovskites solar cells. Rapid progress was also demonstrated in the field of light emitting diodes and lasers. As the field advances, new approaches for patterning perovskite films are becoming essential. More specifically, a lithographic approach that can define desired perovskite patterns is highly needed in order to utilize these materials for the realization of integrated perovskite photon devices.

During the past few years, several attempts have been made in order to address this challenge. Nevertheless, many of the attempts were only partially successful, being unable to remove completely the perovskite from the undesired area, or necessitating slow and serial fabrication techniques which are not...
compatible with mass production. Hence, a complete, efficient and scalable lithographic approach for the patterning of metal halide perovskite films is still highly needed and sought for. Here, we demonstrate a complete lithographic scheme for thin metal halide perovskite films, and utilize it for the realization of perovskite micro lasers. The process consists of nano imprint lithography followed by ion beam milling. The approach is simple, fast, scalable, and exhibits sub-micron resolution. Lines with critical dimensions of <250nm are realized, followed by complete removal of the perovskites in the non-protected areas. The optical properties of the perovskite films are obtained by employing analytical tools as well as by characterizing distributed feedback laser fabricated from these films. It is shown that the material properties are not impaired by the lithographic process. Using this approach, on chip, micro lasers are fabricated. The experimental characterization of these lasers shows that they exhibit low threshold levels and single-mode lasing. To the best of our knowledge this is the first demonstration of complete, high-resolution lithography of perovskite films exhibiting the smallest perovskite features realized using a top-down lithography technique. This process offers a scalable approach for patterning large areas of perovskites devices with tens of nanometers resolution. This is an important tool towards integrated perovskite photonics and is highly applicable also for the fields of photovoltaics, meta-surfaces, electronics and other promising applications.

Temperature-Dependent Chemical-Structural Correlation in CHNHPbI3
Yongtao Liu1, Anton V. Jevlev2, Liam Collins2, Miaosheng Wang1, Jong K. Keum1, Alex Belianinov2, Stephen Jesse, Scott Retterer, Kai Xiao, Mahshid Ahmadi1, Bobby G. Sumpter1, Sergei V. Kalinin1, Bin Hu2 and Olga Ovchinnikova2; 1Department of Materials Science and Engineering, The University of Tennessee, Knoxville, Knoxville, Tennessee, United States; 2Center for Nanophase Materials Sciences, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Hybrid organic-inorganic perovskites (HOIPs) have been demonstrated as a promising candidate for photovoltaic applications. For efficient and stable photovoltaic devices, it is critical to understand the effects of environment on the material. In this work, we investigate the evolution of chemical distribution as a function of temperature and its correlation to lattice distortion. Using time-of-flight secondary ion mass spectrometry (ToF-SIMS), we reveal the chemical gradient of CHNHI; and Pb into the bulk at room temperature. As temperature increases, the CHNHI; distributes uniformly and PbI2 gradient does not change. These results prompted a further crystal structure study as our earlier investigations revealed a strong interaction between ion segregation and lattice strain. We performed grazing incidence X-ray diffraction (GIXRD) to explore the lattice change in the direction normal to the sample surface by adjusting grazing incidence angle. As expected, the GIXRD results indicate lattice expansion in (110) and compression in (002) directions with the grazing incidence angle increase corresponding to depth increases. Moreover, both chemical and lattice strain gradients decrease as temperature increases. DFT simulations corroborate these results, suggesting a coupling between temperature, lattice distortion, and chemical distribution. Finally, we demonstrated that temperature, lattice distortion, and chemical distribution simultaneously alter photovoltaic performance. These measurements and results offer an in-depth understanding of the extrinsic and intrinsic chemical effects on device performance.

ALD of Tin Oxide on Metal Halide Perovskite Photovoltaics
Axel F. Palmstrom1, James A. Raitford2, Rohit Prasanna2, Kevin A. Bush3, Jinhai Tong1, Kai Zhu1, Joseph J. Berry1, Michael D. McGhee1 and Stacey F. Bent1; 1National Renewable Energy Laboratory, Lakewood, Colorado, United States; 2Chemical Engineering, Stanford University, Stanford, California, United States; 3Materials Science and Engineering, Stanford University, Stanford, California, United States.

Metal halide perovskites offer a wide and tunable bandgap, making them promising candidates for top-cell absorbers in tandem photovoltaics. Atomic layer deposition (ALD) is becoming an increasingly prevalent technique for the conformal deposition of metal oxides in perovskite devices, including on top of perovskite materials for improved moisture stability and inorganic carrier selective contacts. We recently reported tin oxide by ALD on top of metal halide perovskites as a dual-purpose layer to achieve electron selectivity and stiffer protection with high optical transmission; this layer was critical to achieving a 23.6% record-efficient monolithic perovskite-silicon tandem devices. Engineering of an ALD charge extraction layer on top of perovskite materials is non-trivial due to interfacial degradation and energy band alignment.

In this work, we aim to understand the ALD precursor-perovskite interactions of the tin oxide ALD system and the role of organic fullerenes at the perovskite-tin oxide interface while establishing a framework for developing alternative perovskite-compatible ALD processes in the future. We show, in the case of tin oxide ALD growth with tetrakis(dimethylamino)tin(IV) and water on FA0.83Cs0.17Pb(I0.83Br0.17)3 perovskite, that perovskite stability is most sensitive to metal organic exposure at elevated temperatures with an onset near 110 °C, resulting in removal of the formamidinium (FA) cation. Transitioning from ALD to pulsed-chemical vapor deposition (pulsed-CVD) tin oxide growth can minimize the degradation effects. Investigation of fullerenes at the perovskite interface shows that thin fullerene layers offer minor improvements to perovskite stability under ALD conditions, but significant enhancement in carrier extraction. We report high efficiency semi-transparent perovskite devices utilizing fullerene materials, however, fullerenes are undesirable due to fabrication cost and poor mechanical stability. Compositional tuning of the perovskite material can improve the fullerene-free device performance. We demonstrate this method with a bromine-rich perovskite phase to enable an 8.2% efficient perovskite device with all-inorganic charge extraction layers.

ET04.12.04
Role of Domain Walls in Halide Perovskite Solar Cells
Jae Sang Yun1, Dohyung Kim2, Da Seul Lee1, Pankaj K. Sharma2, Jincheol Kim1, Anita Houbail1, Martin Green1 and Jan Seidel2; 1School of Photovoltaic and Renewable Energy Engineering, University of New South Wales, Kensington, New South Wales, Australia; 2Materials Science and Engineering, University of New South Wales, Kensington, New South Wales, Australia.

Organometal halide perovskite solar cells have shown a tremendous improvement in the photoconversion efficiency from 3.8% to 22.7% in recent years. Self-assembling organic-inorganic hybrid materials have been demonstrated to be excellent photovoltaic materials with several superior properties such as high optical coefficient, tuneable bandgap, long carrier diffusion length, and high ambipolar charge carrier mobility. Despite the enormous interest in these materials, many fundamental material properties still remains elusive. Here, we report role of domain walls in halide perovskite film which is systematically investigated using Scanning Probe Microscopy (SPM) techniques. Ion migration is found to be playing a significant role at the domain walls. We examined effect of domains in terms of photovoltaic properties using Kelvin Probe Force Microscopy (KPFM) and conductive AFM (C-AFM). Our findings suggest that these domains walls play a critical role in PV performance. These findings of domain properties can provide a new possibility to understand effect of domains and domain walls in solar cell device.

Manipulation of Metal Oxide-Based Electrodes for Semi-Transparent Perovskite Solar Cells
Kai Zhu1, Joseph J. Berry1, Michael D. McGehee3 and Stacey F. Bent2; 1National Renewable Energy Laboratory, Lakewood, Colorado, United States; 2Chemical Engineering, Stanford University, Stanford, California, United States; 3Materials Science and Engineering, Stanford University, Stanford, California, United States.

Due to their high transparency and large bandgaps, transition metal oxides have been widely used in optoelectronic devices, such as light-emitting diodes...
and solar cells, including semi-transparent devices, tandem solar cells, and building-integrated photovoltaics (BIPV). Thermally evaporated molybdenum oxide (MoO₃) has been commonly used as the sputtering buffer material to protect the organic hole transporting layer from damage due to sputtering of the transparent conducting oxide. However, MoO₃ has strong extinction coefficient in the infrared and has detrimental impact on the fill factor, along with uncertain long-term stability. In this talk, we address a bilayer architecture approach for tunable metal oxide-based transparent electrodes through capping the transition metal oxide with a more stable material and possibly altering the electronic properties through a doping effect. Incorporation of this transparent electrode technique to the protective buffer layer significantly enhanced the fill factor from 70.4% to 79.6%, resulting in power conversion efficiencies over 18% for semi-transparent perovskite solar cells. Effects on the morphology, optical and electrical properties, and performance of working devices will be addressed, and the mechanisms involved in the enhanced performance will also be discussed in this presentation.

ET04.12.06
Integration of Electrospun Fibers into Perovskite Solar Cells
Cavit Eyovge; Mesoscale Chemical Systems, MESA+ Institute for Nanotechnology, University of Twente, Enschede, Netherlands.

Extensive studies performed in the past 5 years showed that power conversion efficiency values over 20% can be reached with perovskite solar cells. This achievement also led researchers to look for different cell architectures, not only for increasing the efficiency but also for extending application area. Electrospinning in that sense can be regarded as a promising method for flexible perovskite solar cell production. It is highly possible to use stacked fibers to form cell layers if one can control the fiber characteristics and deposition pattern. In this study, a modified electrospinning system was used to fabricate electron transport layer for perovskite solar cells, namely ZnO and TiO₂. Linearly aligned fibers of semiconducting oxides were electrospun with 1 kV/cm field strength in between the nozzle and parallel plate structure serving as a collector. Annealing was performed at 500 °C under ambient atmosphere for conversion into oxide. Physicochemical structure and morphology of the fibers were investigated with SEM and XRD. Applicability of the method for all-electrospin perovskite solar cells was also discussed.

ET04.12.07
In Situ Investigation of the Effect of the Lead Film Precursor States and Their Influence on the Conversion to MAPbI₃ Hybrid Perovskite Layers for Solar Cell Applications
Dounya Barrit1, Peirui Cheng2, Ming-Chun Tang1, Hoang X. Dang1, Kai Wang1, Detlef-M. Smilgies1, Kui Zhao2, Thomas Anthopoulos1 and Aram Amassian1; 1King Abdullah University of Science and Technology, Thuwal, Saudi Arabia; 2Key Laboratory of Applied Surface and Colloid Chemistry, National Ministry of Education, Shaanxi Key Laboratory for Advanced Energy Devices, Shaanxi Engineering Lab for Advanced Energy Technology, School of Materials Science and Engineering, Shaanxi Normal University, Xi'an, China; 3Cornell High Energy Synchrotron Source (CHESS), Cornell University, Ithaca, New York, United States.

Due to their low-cost fabrication, the use of abundant materials and their high power conversion efficiency of 22.1%, metal halide perovskite solar cells are currently attracting tremendous attention as a prime alternative to incumbent photovoltaic technologies. In this work, we use the two-step conversion process to produce high-quality layers of the prototypical hybrid organic-inorganic perovskite MAPbI₃. The processes is simple and involves the reaction of a solution deposited PbI₂ solid layer with MAI to produce the targeted MAPbI₃ film. Particular emphasis is placed on investigating the ink-to-solid conversion during the two-step solution process of PbI₂ from DMF solution by performing in situ grazing incidence wide angle X-ray scattering (GIWAXS) measurements. Obtained results reveal an elaborate sol–gel process involving three PbI₂-DMF solvate complexes—including disordered and ordered ones—prior to PbI₂ formation. The ordered solvates appear to be metastable as they transform into the PbI₂ phase in air within minutes without annealing. Complementary measurements including optical reflectance and absorbance and quartz crystal microbalance with dissipation monitoring (QCM-D) were further used to monitor the solution thinning behavior, changes in optical absorbance and structural, viscoelastic properties during the PbI₂ film formation and its conversion to perovskite film. Results indicate that the conversion of PbI₂ to perovskite is largely dictated by the state of the PbI₂ precursor film in terms of its solvated state which have implications on solar cell manufacturing and overall performance.

ET04.12.08
Analysis for Efficiency Potential of Perovskite Solar Cells
Masafumi Yamaguchi, Kan-Hua Lee, Kenji Aekaki and Nobuaki Kojima; Toyota Technological Inst, Nagoya, Japan.

Remarkable recent advances in perovskite solar cells with efficiencies of over 22% have drawn world-wide as high-efficiency and low-cost solar cells. However, there are some problems to be solved in perovskite solar cells. In addition to improvements in stability, developments in high-efficiency large-area perovskite solar cell modules are very important. Therefore, understanding and reducing non-radiative recombination losses in those materials and solar cells and resistance losses in order to realize higher efficiency perovskite solar cells and modules. In this paper, efficiency potential of perovskite solar cells is discussed based on external radiative efficiency (ERE), open-circuit voltage loss and fill factor loss and non-radiative recombination losses..

One of problems to attain the higher efficiency perovskite solar cells is to reduce non-radiative recombination loss. The open-circuit voltage drop compared to bandgap energy (Eg-Voc) is dependent upon non-radiative voltage loss (Voc, rad) that is expressed by external radiative efficiency (ERE). Open-circuit voltage is expressed by Voc = Voc,rad + (KT/q)ln(ERE), (1) where the second term shows non-radiative voltage loss, and is radiative open-circuit voltage and 0.28V was used as the A value. Voc, rad = Eg/q · Voc,rad value for perovskite solar cells in this study. Correlation between Voc values for perovskite solar cells in the references estimated by eqs. (1) suggests that perovskite solar cells have still non-radiative loss and further improvements in efficiency are thought to be possible by improving minority-carrier lifetime. In addition, reduction in resistance loss is suggested to be decreased. The perovskite solar cells have efficiency potential of 25% by improving ERE from around 0.3%-1% to 20%. Progress steps for efficiency of perovskite solar cells are analyzed. As a result of high quality thin film growth with large grain size and annealing, ERE have been improved from 8 x 10^-10 % to 0.3-1%. By decrease in series resistance and increase in shunt resistance, resistance losses have been reduced from 0.65 to 0.12 with low normalized resistance, rₛ/τₑ. As a result of increases in open-circuit voltage Voc and fill factor FF, conversion efficiency for perovskite solar cells has been improved from 3.8% to 22.7%. However, because perovskite solar cells have still higher non-radiative recombination losses compared to GaAs and crystalline Si solar cells, further improvements in efficiency are thought to be possible by improving minority-carrier lifetime due to reduction in recombination losses and by decreasing resistance losses. Importance of non-radiative recombination loss and resistance loss is also discussed.

Doping TiO₂: Electron Transport Layers in Halide Perovskite PV Cells by Combinatorial Material Science
Anat Itzhak1, Adi Kama1, Shalom Avadayev1, Adam Ginsburg1, Hannah Noa Barad1, David A. Keller1, Simcha Meir1, Arie Zaban1 and David Cahen1; 1Chemistry, Bar Ilan University, Ramat-Gan, Israel; 2Materials and Interfaces, Weizmann Institute of Science, Rehovot, Israel.

The optical properties, stability, wide band gap, and a conduction band just a bit deeper than the conduction band of Pb-based halide perovskites (HaP), makes TiO₂ a very good electron transport layer (ETL) in PV solar cells, based on these HaPs. As a result, TiO₂ is the most commonly used ETL in
perovskite (n-i-p structure) solar cells. Here we report on results obtained, from combinatorial materials science, CMS, experiments to optimize the TiO2 ETL layer by doping with other metals, to explore more efficient and stable HaP solar cells. To dope TiO2 with other cations we use CMS, together with high-throughput characterization techniques to examine the effects of different metal cations on the TiO2 ETL layer and, subsequently, on the HaP PV performance. Each measurement is conducted on a ~ 50 cm2 FTO-coated glass, divided into a matrix of 13 x 13 measurement areas (a library), thus measuring 169 different compositions and or thicknesses, to look for trends in the properties. Different ETL mixtures were deposited on a substrate, using a custom-made spray pyrolysis deposition system[1], combining TiO2 with cations, such as Zr4+ or Sr2+. This method of preparation assures a gradient of concentrations across the library. We used scanning EDX to verify the cation concentration at each examined point, and follow the changes in the library. As high-throughput characterization tools we used scanning optical spectroscopy, Kelvin probe, and XRD, to understand the influence of the different cations and their varying concentrations on the doped TiO2 layer. To see how the changes in the ETL affect HaP PV performance, we fabricated complete MA-Pb-trihalide solar cells and used an additional high-throughput method, scanning I-V measurements, to monitor the changes as a function of the type and density of the doping cation.

We will in the presentation report on, and trends how and with which different cations affect the properties of the TiO2 ETL layers and the PV performance of cells made with them.

All Vacuum Processed Large Area Perovskite Solar Cells Using Sputtered NiOx as Hole Transport Layer Wiria Soltanpool1; 2, Gence Bektas1; 2, Mehmet C. Sahiner1; 3, Hava Z. Kaya1, Esra Bag1; 4, Gorkem Gunbas1; 4, 5 and Selen Yerci; 1; 2, 5 1Center for Solar Energy Research and Applications (GÜNAM), Middle East Technical University, Ankara, Turkey; 2Micro and Nanotechnology, Middle East Technical University, Ankara, Turkey; 3Electrical and Electronics Engineering, Middle East Technical University, Ankara, Turkey; 4Polymer Science and Technology, Middle East Technical University, Ankara, Turkey; 5Chemistry, Middle East Technical University, Ankara, Turkey.

Metal halide perovskite solar cells have proven to be an inexpensive yet easy to manufacture photovoltaic technology in the last few years. This is due to numerous reasons including tunable optoelectronic properties along with high power conversion efficiencies beyond 22%. The planar configuration of perovskite solar cells has been especially popular due to its versatile use in tandem devices and over flexible substrates. However, in order to grant large scale fabrication of such devices, they need to be uniform, hysteresis free, viable with large areas, and have acceptable stability. Recently, NiOx has been a favored hole transport layer providing more stable perovskite solar cells. Furthermore, NiOx can be deposited via sputtering to form uniform, compact layer without high temperature treatments. In this study, sputtering power and Ar-pressure were shown to play the key role in suppressing the hysteresis and in achieving high power conversion efficiencies. As Ar-pressure increased, the transparency of NiOx improved while reducing its conductivity. According to our experiments, 16 mTorr of Ar-pressure at an RF-power of 150 W resulted in the best performing devices. A uniform CH3NH3PbI3-XClX layer was deposited via co-evaporation on top of NiOx-coated ITO substrates. The electron transport layer (C60) and BCP/Ag were also evaporated on perovskite lamination at various temperatures is probed. The application of this technique to a mixed-cation and -anion perovskite composition shows the viability of the approach. Currently, solid state perovskite solar cells have achieved 24% efficiency[1] and, as such, large area perovskite devices are currently under the development.

Perovskite/Perovskite Lamination of Complex Compositions to Obtain Alternate Phase Spaces Armani Alfaiat1; 3, 4, Sean Dunfield1; 2, Joseph J. Berry1, Matthew O. Rees1, Maikel van Hest1 and Davor Balzar1; 1University of Denver, Denver, Colorado, United States; 2University of Colorado Boulder, Boulder, Colorado, United States; 3National Renewable Energy Laboratory, Golden, Colorado, United States; 4Taif University, Taif, Saudi Arabia.

Hybrid perovskites’ low temperature solution processing, extreme tolerance to defects, high absorption coefficients, and long carrier diffusion lengths have drawn much attention from the photovoltaic community, leading to a rapid advance in efficiency from just 3.8% in 2009 to 22.6% today. Despite having many benefits, the standard layer-by-layer solution process commonly used in fabrication creates several limitations in solvent compatibility and thermal budgeting that have prevented the implementation of various device material layer combinations. In order to overcome the aforementioned limitations while maintaining the advantages of the cost-effective solution processing, we recently developed a procedure to create perovskite devices by first fabricating two transparent conductive oxide/transport material/perovskite half stacks and then laminating them together at the perovskite/perovskite interface. Using various techniques, we show that the developed process largely improves the electronic structure, reduces the number of defects, increases the crystallinity, and enhances the properties of MAPbI3. Moreover, we show that the results in a self-encapsulated device format which permits processing above the temperatures allowed in standard fabrication due to its decoupling of the positive effects of annealing with the negative effects of normally-seen thermal degradation. E.g., MAPbI3 films laminated together at 150 °C for 5 days kept black interiors rather than turning yellow, indicating no significant decomposition to Pb2. While shown to work on a standard ABX3 perovskite composition containing methylammonium, the original work forgoes applying the method to more complicated compositions containing multiple chemical constituents at any given site. This work builds off said study, improving the uniformity of pressure and temperature obtained in the lamination process and implementing the process on a more advanced perovskite, [Cs0.85MA0.15FAS1.93]0.85PbI3.5-xBr0.5-xIy] at various temperatures to explore the newly afforded phase space for processing. Through ultraviolet–visible absorption spectroscopy, X-ray diffraction, and time-resolved photoluminescence spectroscopy, the effect of lamination at various temperatures is probed. The application of this technique to a mixed-cation and -anion perovskite composition shows the viability of the process on perovskites prone to phase segregation. Future work will focus on utilizing the procedure to explore compositions and defect-passivating elements not obtainable by traditional solution processing routes.

ET04.12.12
Enhanced Photovoltaic Performance of Perovskite Solar Cells via Defect Passivation by Incorporating the Physisorbed Small Organic Molecule Shivan Smajl1, Sudip Chakaborty1, K. L. Narasimhan2, Parag Bhardwaj3 and Dinesh Kabra1; 1Department of Physics, Indian Institute of Technology Bombay, Mumbai, India; 2Department of Electrical Engineering, Indian Institute of Technology Bombay, Mumbai, India; 3Department of Metallurgical Engineering and Material Science, Indian Institute of Technology Bombay, Mumbai, India; 4Materials Theory Division, Department of Physics and Astronomy, Uppsala University, Uppsala, Sweden.

Perovskite semiconductors are known to have dynamic disorder[2] which is known to affect its recombination dynamics. These defects seem to be created and removed via various processing conditions in literature. Here, we studied the role of small organic molecule, bathocuproine (BCP), as an additive in the CH3NH3PbI3 thin film based photovoltaic devices using optoelectronic measurements and first principle calculation. A solar cell with power conversion efficiency of 16% and fill-factor of 82% with no significant hysteresis is achieved, where BCP not only passivates the bulk and interfacial defects but also shows highly improved electroluminescence efficiency. Addition of BCP into perovskite precursor does not cause any structural change in the 3D structure of perovskite, which is confirmed using time-delayed emission spectroscopy and first principle electronic structure calculations. Furthermore, calculations suggest that a physisorption type of interaction has been found in between MAPI and BCP with an average distance of 2.9 Å. Hence, hydrophobic organic molecule plays an important role in defect passivation to achieve very high fill factor and improving the film

**Double Perovskite Cs2AgBiBr6 Film for Optoelectronic Devices**
**Cuncun Wu; Peking University, Beijing, China.**

Recently, lead-free double perovskites have emerged as a promising environment-friendly photovoltaic material for their intrinsic thermodynamic stability, appropriate band gaps, small carrier effective masses, as well as low exciton binding energies. Herein, we report a first lead-free double perovskite planar heterojunction solar cell with high quality Cs2AgBiBr6, film, fabricated by low-pressure assisted (LPA) solution processing under ambient conditions. The device presents a best power conversion efficiency (PCE) of 1.44%. The preliminary efficiency, the high stability under ambient condition without encapsulation, together with the high film quality with simple processing, show a glimmer of hope for the lead free perovskite solar cell. Hole transport layer free planar heterojunction device based on this film was fabricated for photodetector application. The device is self-powered with two responsivity peaks at 350 nm and 435 nm, which is suitable for ultraviolet-A (320-400 nm) and deep-blue light detecting. A high responsivity of 0.11 A/W at 350 nm and a quick response time of less than 3 ms were obtained, which is significantly higher than other semiconductor oxide heterojunction based UV-detectors.

**Controllable and Reproducible Doping of Spiro-OMeTAD in the Absence of LiTFSI and Air—Spiro-OMeTAD(TFSI)2 in Perovskite Solar Cells**

**with PCEs Exceeding 19%**

**Boer Tan1, 2 and Udo Bach1, 2, 3; 1Chemical Engineering, Monash University, Melbourne, Victoria, Australia; 2Manufacturing, Commonwealth Scientific and Industrial Research Organisation, Melbourne, Victoria, Australia; 3Melbourne Center for Nano Fabrication, Melbourne, Victoria, Australia.

2,7,7′-Tetrakis[N,N-di(4-methoxyphenyl)amino]-9,9′-spirobi fluorene (spiro-OMeTAD) is the dominant hole transporting material (HTM) in high efficiency perovskite solar cells (PSCs). To achieve better photovoltaic performances, the conductivity of pristine spiro-OMeTAD needs to be improved through the addition of dopants. Conventional doping methods use redox inactive ionic compounds, in particular lithium bis(trifluoromethylsulfonyl)imide (LiTFSI) and chemical p-dopants, such as tris(2-(1H-pyrazol-1-yl)-4-tert-butylpyridine) cobalt(III) (FK209). However, the power conversion efficiency (PCE) and the reproducibility of device performance are contingent on a combination of factors, such as light exposure, ambient air conditions and the concentration of LiTFSI/ FK209. Therefore, the reproducibility of these devices is typically problematic.

In this study, spiro-OMeTAD(TFSI)2 is implemented as a p-dopant in spiro-OMeTAD to reproducibly control the doping level without the need for air exposure and LiTFSI addition. Device performances comparable with conventional LiTFSI doping have been obtained by simply mixing the dopant with spiro-OMeTAD during precursor solution preparation. Unlike the conventional doping method, device performance is less influenced by the environment (oxygen and light). Furthermore, good device performances can be obtained without hygroscopic LiTFSI, which potentially introduces a source of instability in the perovskite device. Remarkably, the reproducibility is strongly enhanced with minimal variation in PCE at the optimized doping concentration. A maximum PCE of 19.3% is achieved in reverse scan with minor hysteresis observed in forward scan with a PCE of 18.1%, performing a stabilized power output of 18.5%. Our comprehensive study of the hole transfer process and device performance enables us to determine the optimum doping concentration and also confirm the influence of the spiro-OMeTAD doping level on device performance. These are critical to highly efficient and reproducible perovskite solar cells.

**A Machine Learning Algorithm for Analyzing the Crystal Morphology of Perovskite Solar Cells**
**Thomas Chen1; Yi fan Yin2 and Yuchen Zhou; 1Mission San Jose High School, Fremont, California, United States; 2Department of Materials Science and Chemical Engineering, Stony Brook University, Stony Brook, New York, United States.

Perovskite solar cells (PSCs) are a rapidly evolving photovoltaic technology where performance and crystal grain size are highly correlated. Therefore, there is a constant need to analyze crystal size distributions in SEM images of the perovskite layer of PSCs. This research attempts to automate this process using both machine learning (ML) and non-ML approaches to edge detection. Once the edges of the crystal grains are located, a flood-fill algorithm can be used to find the area distribution. The ML based edge detection uses GNU Octave Programming Software[1] to run a regularized logistic regression algorithm that classifies each pixel of an input image as part of an edge or not part of an edge. The features used for the algorithm are each pixel’s grayscale intensity, its Sobel derivative[2], and second order combinations. Training data is obtained by using non-ML Canny Edge Detection[2] to annotate the edges on a 100X100 pixel SEM image of a PSC modified with 16,000 amu Polyactic Acid at 0.3 mg/mL. The classifier exhibits an 85.2% accuracy, though it has difficulty with edge pixels with a low Sobel derivative. A macro for ImageJ Fiji Software was created to automate a non-ML approach using Sobel edge detection. A Gaussian blur with radius 2 pixels is applied to the 16K 0.3mg/mL image and Sobel edge detection is run. The resultant image is then thresholded to differentiate the brightest 50% of pixels and darkest 50%. Area distributions are found with ImageJ’s particle analyzer. Edge detection was highly accurate, and the macro exhibited high automation. Both approaches offer a quick and automated way to analyze the crystal distributions of perovskite SEM images. The non-ML method exhibits better edge detection and immediate usefulness, but the ML based method requires far fewer operations than its counterpart, making it more efficient in the long run despite the initial time required for training. Towards Efficient and Stable Mixed Sn-Pb Perovskite Solar Cells

Yanfa Yan; University of Toledo, Toledo, Ohio, United States.

Mixed Sn-Pb perovskite absorber materials have attracted extensive attentions because they offer opportunities to reduce the usage of toxic Pb, tune the bandgap to be more suitable for efficient single-junction solar cell applications, and enable the realization of all-perovskite tandem solar cells. Though significant progress has been made in the past several years, the record powder conversion efficiency (PCE) of mixed Sn-Pb perovskite solar cells is still significantly lower than the theoretical maximum PCE. Furthermore, the study of stability of mixed Sn-Pb perovskite solar cells is rarely reported. In this talk, we will present detailed analysis of the possible factors that limit the PCEs of mixed Sn-Pb perovskite solar cells and discuss possible solutions for overcoming the limitations. Furthermore, we will discuss the stability issues that mixed Sn-Pb perovskite solar cells may encounter.

New Materials, Systems and Applications with Halide Perovskites

Ivan Mora-Sero; Institute of Advanced Materials (INAM), Universitat Jaume I, Castello de la Plana, Spain.

Halide perovskite have demonstrated an outstanding performance for the development of photovoltaic devices. This excellent behavior is based, among others, in a benign defect physics producing low non-radiative recombination, making halide perovskite also enormously appealing for the development of other optoelectronic devices as LEDs or lasers. While first studies focused just in conventional hybrid halide perovskite materials with general formula ABX₃, (where A=methylammonium, formamidinium, Cs, X-Pb, Sn, X-I, Br, Cl) and just in photovoltaic devices, the current interest has been extended. A broader range of material compositions are now investigated and not just with 3D structure but also layered perovskites or as nanoparticles. These systems also are awaking a great interest as very high photoluminescence quantum yield can be obtained with relative easy synthesis processes. In addition, multiple materials are also analyzed as selecting contact layers. In this talk, I present non-conventional perovskite materials and contacts for photovoltaics and optoelectronic applications. The structural, chemical, electric and optical properties of materials and devices have been systematically characterized, highlighting the interest of these new systems for further development of perovskite technology. A new hole selective contact based on a fullerene derivative a new family of 2D/3D perovskites using conjugated anilinium as long organic cation will be introduced. The development of optical amplifiers based on halide perovskites and the use of the perovskite nanoparticles for the development of optoelectronic devices will be also discussed.

Estimating Oxidised Sn⁴⁺ Species at the Precursor Stage—On the Effect of Reducing Agents in Sn-Based Perovskites

Muhammad Akmal Kamarudin1, Kohei Nishimura1, Daisuke Hirotani1, Qiang Shen2, Taro Toyoda1, Satoshi Ikubo1, Takashi Minamoto3, Kenji Yoshino3 and Shuji Hayase3; 1Kyushu Institute of Technology, Kitakyushu, Japan; 2The University of Electro-Communications, Chofu, Japan; 3Ritsumeikan University, Kusatsu, Japan.

The poor opto-electronic properties often associated with tin (Sn) halide perovskites are usually ascribed to the oxidation of Sn⁰ to Sn⁴⁺. Due to the generation of Sn⁰ vacancies upon oxidation that limit the electron and hole diffusion lengths to 30 nm by acting as scattering centres, it remains challenging to obtain highly efficient Sn-based perovskite solar cells in planar as well as mesoporous device architectures. Theoretical calculations corroborate that reducing the background hole concentration by suppressing oxidation could allow favourable opto-electronic properties for these materials with diffusion lengths approaching 1 micron. Nevertheless, innovative approaches based on reducing agents remain rather limited as only inadequate fractions of these compounds are tolerated in the formation of the desired efficient absorbers. Hence, it remains particularly challenging to maintain a stoichiometric solution for the development of highly efficient Sn-based perovskite solar cells.

Having demonstrated vast potential as a narrow bandgap rear-cell in perovskite-perovskite tandems, the optimisation of Sn (and thereby Pb-Sn mixed) perovskites is of particular relevance as currently all-perovskite multi-junction solar cells are being envisioned— with reports of theoretical performances surpassing 45%. To that end, this work focuses on the extent of oxidation present in supposedly pristine precursor solutions—an aspect currently not profoundly professed in literature. Based on observed changes in morphology, crystallinity and optoelectronic properties of films obtained from corresponding solutions, an efficient method is discussed to estimate the early-on degradation induced at the precursor stage. The quantification can be used as an effective tool to characterise and extend the effect of reducing agents, and thereby assist in enhancing the performance of Sn-based solar cells.

Towards Efficient and Stable Mixed Sn-Pb Perovskite Solar Cells

Muhammad Akmal Kamarudin1, Kohei Nishimura1, Daisuke Hirotani1, Qiang Shen2, Taro Toyoda1, Satoshi Ikubo1, Takashi Minamoto3, Kenji Yoshino3 and Shuji Hayase3; 1Kyushu Institute of Technology, Kitakyushu, Japan; 2The University of Electro-Communications, Chofu, Japan; 3Ritsumeikan University, Kusatsu, Japan.

The low performance of tin-based perovskite solar cells is attributed to the tendency of Sn²⁺ to oxidize to Sn⁴⁺ resulting in higher charge carrier concentration. This oxidation process also leads to the degradation of the perovskite solar cell over time even in N₂ atmosphere and much so in ambient atmosphere. To this effect, we have successfully employed GeBr₃ as passivation layer which could extend the lifetime of PSCs in air, in addition to reducing the charge carrier concentration. The performance of GeBr₃-doped perovskite solar cell achieved a high efficiency of 4.2 % compared to 2.9 % for FASnI₃Ma₂SnI₉ when measured in air. The increased in efficiency comes from the significant increase of short circuit current due to the reduction of charge carrier concentration. The reduction of trap states upon addition of GeBr₃ has also been confirmed by thermally stimulated current measurement. The formation of monolayer GeO₂ reduced the surface oxidation of the perovskite and helped to improve the air stability of the perovskite solar cell even without encapsulation. This work provides a platform of fabricating air stable tin perovskite solar cells with high efficiency.

Towards Efficient and Stable Mixed Sn-Pb Perovskite Solar Cells

Muhammad Akmal Kamarudin1, Kohei Nishimura1, Daisuke Hirotani1, Qiang Shen2, Taro Toyoda1, Satoshi Ikubo1, Takashi Minamoto3, Kenji Yoshino3 and Shuji Hayase3; 1Kyushu Institute of Technology, Kitakyushu, Japan; 2The University of Electro-Communications, Chofu, Japan; 3Ritsumeikan University, Kusatsu, Japan.

The low performance of tin-based perovskite solar cells is attributed to the tendency of Sn²⁺ to oxidize to Sn⁴⁺ resulting in higher charge carrier concentration. This oxidation process also leads to the degradation of the perovskite solar cell over time even in N₂ atmosphere and much so in ambient atmosphere. To this effect, we have successfully employed GeBr₃ as passivation layer which could extend the lifetime of PSCs in air, in addition to reducing the charge carrier concentration. The performance of GeBr₃-doped perovskite solar cell achieved a high efficiency of 4.2 % compared to 2.9 % for FASnI₃Ma₂SnI₉ when measured in air. The increased in efficiency comes from the significant increase of short circuit current due to the reduction of charge carrier concentration. The reduction of trap states upon addition of GeBr₃ has also been confirmed by thermally stimulated current measurement. This work provides a platform of fabricating air stable tin perovskite solar cells with high efficiency.
layered 2D Ruddlesden-Popper perovskites, as shown from the investigation of both thin films and small exfoliated single crystals. Wannier exciton at room temperature. However, solar cells or LED device efficiencies are related to internal exciton dissociation through edge states in activation energy calculated to be 0.4 eV (in the range of many literature values for iodide migration). However, it takes place at a much slower rate due to the carbon devices the exceptionally slow dynamic behaviour observed at room temperature has a similar origin linked to the effects of ion migration – structure-device measurements are critical for understanding optoelectronic transport and determine the design principles for operation of perovskite-based to discover new emergent functionalities. Therefore, a basic principle on the interplay between structure, light and electrical field with in-situ correlated

The improvement in stability is easily understood: 2D perovskite consists of inorganic blocks separated by bulky organic cations. These organic cations act 2D Ruddlesden-Popper perovskites have improved the stability of fabricated solar cells, but their efficiency is reduced compared to 3D bulk perovskite. We show that the inhibited ion migration is the dominant affect rather than the AVA having a direct impact at the TiO2 interface by adsorption via the carboxylic acid group. This inhibition of iodide migration is also linked to the increased stability demonstrated for these devices.

Negative transient was shown to diminish over time as ions in the perovskite redistributed, leading to a reduction in the recombination rate. We show that in the TiO2 surface. The cells undergo a slow light soaking effect during which time the JV performance of the device is vastly improved. They also show promise for scale-up and wide spread implementation. To improve these devices and begin to challenge inorganic PV record efficiencies a deeper understanding of their operation, and in particular sources of performance loss, is needed.

In my talk, I will focus on understanding these complex behaviors arising from the interaction between structure, light and electric field in both 3D and 2D hybrid perovskite systems by using different device platforms such as photovoltaics, field-effect transistors and light emitting diodes to understand these correlations. Our studies are aimed toward utilizing this fundamental understanding to develop new behaviors and device concepts using perovskite materials.

In the past five years, solution-processed organometallic perovskite based solar cells have emerged as a promising thin-film photovoltaic technology. Presently, the intended optoelectronic applications of this class of 3D materials are in the realm of conventional semiconductors. The presentation will present recent theoretical, spectroscopy and diffraction results on monocrytals of halide perovskites, colloidal nanocrystals or thin-films. Related 2D multilayered phases, composed of perovskites multilayers sandwiched between two layers of large organic cations, have recently demonstrated improved solar cells photostability under standard illumination as well as humidity resistance over 2000 hours, leading to a conversion efficiency of 12.5 %. In this case, intrinsic quantum and dielectric carrier conﬁnements are afforded by the organic inner barriers, which lead to a stable Wannier exciton at room temperature. However, solar cells or LED device efficiencies are related to internal exciton dissociation through edge states in layered 2D Ruddlesden-Popper perovskites, as shown from the investigation of both thin films and small exfoliated single crystals.

In carbon based cells the phenomena is observed at room temperature and is very slow to disappear under continued illumination. For the planar devices the negative transient was shown to diminish over time as ions in the perovskite redistributed, leading to a reduction in the recombination rate. We show that in the carbon devices the exceptionally slow dynamic behaviour observed at room temperature has a similar origin linked to the effects of ion migration – activation energy calculated to be 0.4 eV (in the range of many literature values for iodide migration). However, it takes place at a much slower rate due to the 2D AVA based perovskite hindering iodide ion migration – attempt frequency reduced by several orders of magnitude compared to pure MAPI devices. We show that the inhibited ion migration is the dominant affect rather than the AVA having a direct impact at the TiO2 interface by adsorption via the carboxylic acid group. This inhibition of iodide migration is also linked to the increased stability demonstrated for these devices.

Charge Transport Mechanisms in Vertically Stacked 2D Ruddlesden-Popper Perovskite Solar Cells—Theory and Experiments Reza Asadpour, Hsinhan Tsa1,2, Wanyi Nie2, Aditya D. Mohite2, M.Ashraf Alam2; 1Purdue University, West Lafayette, Indiana, United States; 2Los Alamos National Laboratory, Los Alamos, New Mexico, United States; 3Material Science and Nano Engineering, Rice University, Houston, Texas, United States.

2D Ruddlesden-Popper perovskites have improved the stability of fabricated solar cells, but their efficiency is reduced compared to 3D bulk perovskite. The improvement in stability is easily understood: 2D perovskite consists of inorganic blocks separated by bulky organic cations. These organic cations act
as intrinsic passivation and prevent moisture ingress hence higher stability [1]. Unfortunately, these cations also lead to localized quantum confinement effects that influence the optical and electrical behavior of the material [2]. In this talk, we will discuss how we quantified the transport of conduction electrons, holes, and photons by interpreting the thickness-, temperature-, and illumination-dependent efficiencies of these 2D solar cells. The detailed understanding of optoelectronic and charge transport mechanisms in these structures will guide the future efforts in creating perovskite solar cells that are simultaneously highly efficient and highly stable.

Two-Dimensional Tin-Based Hybrid Halide Perovskites for Photovoltaics Zhenyu Wang1, 2, Alex M. Ganose2, 3, Chunming Niu4 and David O. Scanlan2, 3, 4.
1School of Electrical Engineering, Xi’an Jiaotong University, Xi’an, China; 2Department of Chemistry, University College London, London, United Kingdom; 3Thomas Young Centre, University College London, London, United Kingdom; 4Diamond Light Source Ltd., Diamond House, Oxfordshire, United Kingdom.

The drive towards reduced costs, higher conversion efficiencies and environmentally friendly solutions to current photovoltaic technologies is immensely important in the search to relieve the world’s reliance on fossil fuels and promote sustainable economic development. Since the first reports of solid-state hybrid perovskite solar cells in 2012, power conversion efficiencies (PCEs) have increased dramatically up to 22.7%. Despite the rapid rise in efficiencies of the hybrid lead perovskite such as CH3NH3PbI3 (MAPbI3), their poor long-term stability and the toxicity of water-soluble lead compounds, necessitates the development of alternative lead-free halide perovskite materials with improved moisture tolerance.

Although 2D hybrid halide perovskites have been known since they were first synthesized by Mitzi et al. in 1994, they were not investigated as solar cell absorbers until Smith et al. found the 2D perovskites to be more resistant to moisture than their 3D analogues. Additionally, environmental concerns can be addressed by replacing Pb with less toxic elements, such as Sn and Ge. The band gaps of the 2D series generally decrease monotonically with increasing perovskite-like layer thickness, finally tending to that of corresponding 3D perovskite. In this way, the 2D hybrid perovskites have attracted increasing attention and witnessed a sharp rise in efficiency over the past two years, with champion devices (containing (PEA)2(MA)59Pb60I181) showing efficiencies of 15.3%. For the reasons, 2D perovskites are promising candidates for solar cell absorbers.

In this work, we investigate the geometrical, electronic and optical properties of the semiconductor 2D tin-based perovskites (CH3(CH2)3NH3)3(CH3NH3)2SnI6+1-x (n = 1, 2, 3), using relativistic hybrid density functional theory calculations. We demonstrate that the band gaps of the series decrease with increasing perovskite-like layer thickness, from 1.85 eV (n = 1) to 1.38 eV (n = 3). We find strong and broad optical absorption across the series, in addition to highly effective masses of electrons and holes in the laminar plane. The low n tin-based 2D perovskites should possess the best of both worlds, with optimal band gaps but improved moisture stability. Particularly, the n = 3 composition displays a high spectroscopic limited maximum efficiency (SLME) of 24.6%. Our results indicate this series of homologous 2D tin halide perovskites are a promising class of stable and efficient light-absorbing materials for photovoltaics.

Organic–inorganic lead-based halide hybrid perovskites have attracted immense attention because of their extraordinary optoelectronic properties. Beyond the traditional low bandgap hybrid perovskite solar cells, namely MAPbI₃, the wide bandgap MAPbBr₃₋ₓClₓ perovskite is demonstrated to realize a wide and tunable bandgap ranging from 2.3 eV to 3.1 eV (x = 0 to 3), leading it suitable not only for semitransparent and transparent perovskite solar cells, but also blue and ultraviolet light emitting diode and photodetector applications. In this contribution, we compare and contrast the crystallization kinetics and growth behaviors of wide and tunable bandgap MAPbBr₃₋ₓClₓ to conventional MAPbI₃ from precursor inks to solid-state thin films using the one-step spin coating approach. We employ a multi-probe in situ investigation method consisting in grazing incidence wide-angle x-ray scattering (GIWAXS) and time-resolved UV-Vis absorbance complemented with ex situ characterization of wide and tunable bandgap hybrid perovskite thin film morphology and solar cell performance. Obtained results reveal that the tunable and wide-bandgap MAPbBr₃₋ₓClₓ perovskite phase forms directly from disordered solvate during solution processing, while MAPbI₃:ink tends to form intermediate ordered phases requiring further thermal annealing to form perovskite phase. Furthermore, we disclose the role of anti-solvent dripping is to not only benefit the morphology of perovskite thin film but also pre-nucleate and promote wide-bandgap MAPbBr₃₋ₓClₓ perovskite phase formation. We use this insight to develop a solvent engineering protocol suitable for depositing fully cover and pin-hole-free high-quality MAPbBr₃₋ₓClₓ hybrid perovskite thin films and present working single junction photovoltaics with high open circuit voltage > 1.6 V and promising future for transparent hybrid perovskite solar cells.
Organic-inorganic halide perovskite solar cells (PSCs) have been considered a viable member of next generation photovoltaics, which can address the scalability changes with a low-cost solution process. The perovskite layer is the main source of photogenerated electron-hole pairs in PSCs. The energetic loss in the hybrid system has been approved to be principally caused by traps at grain boundaries and surfaces as well as point defects such as interstitial defects or vacancies in the perovskite compounds crystal lattice. Therefore, the first concern in PSCs is constructing a highly crystallized and defect-free perovskite thin film with full surface coverage, smooth, and ordered crystallography with big crystal grains. In this study, we observe a significantly enhancement in power conversion efficiency (PCE) of photovoltaic device by incorporating a small amount of polycaprolactone (PCL) into the perovskite layer. The long-chain PCL polymer can serve as an efficient passivating agent in the bulk film, due to the formation of weak coordination bonds between Pb\(^{2+}\) and the O in the ester group of PCL. Furthermore, the PCL polymer with small volume can participate in the nucleation step as heterogeneous nucleus and help reduce interfacial energy, which eventually promotes the growth of each crystal grain. As evidenced from the surface scanning electron microscopy (SEM) images, the average crystal grain size of the perovskite layer with PCL addition increases significantly, as compared with the PCL free sample. The enhanced absorption intensity from UV-vis spectra after the incorporation of PCL indicates the increase of film thickness as well as the light absorption ability. X-ray diffraction (XRD) results prove the purity and high crystallinity of tetragonal (14 mm) MAPb\(_x\) perovskite phase of the PCL passivated perovskites with no sign of PbI\(_2\) peaks, while signal of trace amount PbI\(_2\) are seen on the PCL free perovskite layers. Moreover, provided by steady-state and time-resolved photoluminescence (TRPL) results, addition of PCL increases the emission intensity and prolongs the charge carrier lifetime of the perovskite layer, which largely results from reduced surface/boundary defects/traps as well as minimized corresponding non-radiative recombinations due to the passivation of the crystal grains by PCL. As a result, the perovskite thin films with proper amount of PCL addition exhibits superb device performance with PCE of the champion device surpassing 18%, indicating a more than 20% enhancement to the original devices. (This work was supported by the Morin Foundation Trust and the NSF, Inspire program #1344267)

SnO\(_2\) Quantum Dot Electron-Selective Layer for High-Performance Perovskite Solar Cells

Zhiliang Chen, Guang Yang and Guojia Fang; Wuhan University, Wuhan, China.

The carrier concentration of the electron-selective layer (ESL) and hole-selective layer can significantly affect the performance of organic-inorganic lead halide perovskite solar cells (PSCs). Herein, a facile yet effective two-step method, i.e., room-temperature colloidal synthesis and low-temperature removal of additive (thiourea), to control the carrier concentration of SnO\(_2\) quantum dot (QD) ESLs to achieve high-performance PSCs is developed. By optimizing the electron density of SnO\(_2\) QD ESLs, a champion stabilized power output of 20.32% for the planar PSCs using triple cation perovskite absorber and 19.73% for those using CH\(_3\)NH\(_3\)PbI\(_3\) absorber is achieved. The superior uniformity of low-temperature processed SnO\(_2\) QD ESLs also enables the fabrication of \( \approx \)19% efficiency PSCs with an aperture area of 1.0 cm\(^2\) and 16.97% efficiency flexible device. The results demonstrate the promise of carrier-concentration-controlled SnO\(_2\) QD ESLs for fabricating stable, efficient, reproducible, large-scale, and flexible planar PSCs.

Photovoltaic Efficiency of CsPbI\(_3\) QDs-Based Solar Cell Exceeding 13%

Yuwei Liu; State Key Laboratory of Silicate Materials for Architectures, Wuhan University of Technology, Wuhan, China.

The emergence of organic-inorganic hybrid lead halide perovskites has received the impressive power conversion efficiency (PCE) over 22% within a few years [1]. However, the long-term stabilities of perovskite materials, including the durability under humid, thermal, UV radiation and other environmental conditions, are still poor due to the organic components, which are becoming to be the major challenges for their commercialization [2]. α-CsPbI\(_{3}\), as an all-inorganic lead halide, has been reported recently and exhibited excellent optoelectronic property and good stability, which is regarded as an outstanding alternative to organic-inorganic hybrid lead halide perovskites and a promising light-harvesting absorber for solar cell application [3]. Quantum dot-induced phase stabilization is believed to be an effective procedure to get α-CsPbI\(_{3}\) and suppress the formation of orthorhombic phase (α-CsPbI\(_{3}\)). Protesescu et al. have provided a hot-injection method for the preparation of high quality α-CsPbI\(_{3}\) quantum dots (QDs) [4]. α-CsPbI\(_{3}\) QDs based solar cells are reported by Luther and co-workers subsequently, which receive a high PCE over 13% [5]. However, the short-circuit current density (JSC) is still low at present, which restrains the performance of CsPbI\(_{3}\)-based solar cells. In the work, α-CsPbI\(_{3}\) QDs were prepared by hot-injection method, and high performance inorganic perovskite quantum dot-based solar cells over 13.78% was fabricated, and the optimized device achieved a highly reproducible champion PCE of 13.05% with a high short-circuit current density (18.68 mA cm\(^{-2}\)). This work provides an effective strategy for boosting high performance for all-inorganic lead halide PSCs.

Hydroscopic Polymer Passivation Improving Durability of Perovskite Solar Cells

Min Kim, Min Kim, Silvia G. Motti, Roberto Sorrentino and Annamaria Petrozza; \(^{1}\)Physics, Politecnico di Milano, Milan, Italy; \(^{2}\)CNST, Istituto Italiano di Tecnologia, Milan, Italy.

Long-term device instability is one of the most critical issues that impede perovskite solar cell commercialization. Here we show that a thin layer of a functional hydroscopic polymer on top of the perovskite thin film can make perovskite-based solar cells highly stable under illumination and in a humid atmosphere. We prove that the oxygen atoms in hydroscopic polymer chemically interact with lead atoms on the perovskite surface, thus passivate undercoordinated defect sites. Importantly, the defect healing effect leads to an improved photo-voltage and photo-stability. Overall, such interface engineering leads to highly durable perovskite solar cell, which, in the presence of polymer passivation, retained more than 95% of initial power conversion efficiency over 15-h illumination, under load, in the ambient atmosphere without encapsulation. Our findings experimentally reveal the role of defects in
triggering the instability of perovskite materials and propose a general approach for improving the reliability of perovskite-based optoelectronic devices.

A Simple Molecular Reactive Force Field and Its Application to Perovskite Nucleation

Henry C. Herbol¹, Gregory Casee², Oluwaseun Romiluyi², Wang Guo¹, Jace Chaudhuri¹ and Paulette Clancy²; ¹Materials Science and Engineering, Cornell University, Ithaca, New York, United States; ²Chemical Engineering, Cornell University, Ithaca, New York, United States.

In recent years, research into Hybrid Organic-Inorganic Perovskites (HOIPs) has led to numerous experimental and computational insight into the effects of composition, stoichiometry, and solution processing on the overall Photo Conversion Efficiency (PCE) and stability of HOIP thin-films. Computationally, effort has been primarily focused towards time-intensive Density Functional Theory (DFT) simulations: due to the lack of Force Fields for Molecular Dynamics (MD) studies. As such, some of the benefits of a computational approach, such as atomic scale revelations on nucleation, have been hindered. An easy to parameterize reactive force field would empower computationalists to probe these nucleation mechanisms, and help validate/guide experiments; however, as of yet none exists.

In this talk, we present updates to the Simple Molecular Reactive Force Field (SMRFF), and demonstrate initial capabilities as applied to Nanoparticle nucleation (PSN). Further, we illustrate the ease of use, parameterization procedure, and how the force field can be extended. SMRFF takes the idea of hybridizing force fields to the next step, and elaborates on how to smoothly transition between force fields based on interatomic distances. Further, it allows for as many transitions as possible, implying a fully extensible and customizable approach to force field development. A pair style, written to work in the popular LAMMPS codebase, implements the procedure, and an accompanying python script automates the process of developing new parameters.

Tandem Hybrid Organic-Inorganic Photocathode-Perovskite Solar Cell for Unassisted Solar Fuel Production

Antonio Alfano1, 2, Alessandro Mezzetti¹, Francesco Fumagalli¹, Chen Tao¹, Maria Rosa Antognazza¹, Annamaria Petrozza¹ and Fabio Di Fonzo¹; 1Istituto Italiano di Tecnologia, Milano, Italy; 2Physics, Politecnico di Milano, Milan, Italy.

Molecular hydrogen produced via solar energy is emerging as a prominent way to convert and store the copious energy that the Sun daily irradiates on Earth. Hybrid Organic photoelectrochemical (HOPEC) water splitting is gaining momentum in this field, and various approaches are currently being developed to realize hybrid tandem systems to perform unbiased water splitting. By taking advantage of the organic semiconductors properties such as low cost, stability, tuneable electronic properties and ease of large area production, these materials can help overcoming the limitations of standard inorganic photoelectrochemical water splitting. The potential of hybrid organic systems has been proven by our previous works. Indeed, excellent photocurrent performances or extended operational lifetime have been obtained through careful optimization of hybrid photocathodes (PC) architecture. Good results have also been achieved investigating novel materials belonging to the family of transition metal dichalcogenides which fit for hole selective layers (HSL) application, allowing to deliver good performances both on stability and photocurrent.

Our main interest is now to tune the properties of hybrid organic PC acting on their photoactive layer, taking advantage of the latest advancements in the field of organic photovoltaic (OPV). Promising materials from OPV are, among many, the high-performance photo-absorbers PCE11 and PCDTBT, and the non-fullerene acceptors IDTBR and IDFBIR, which were found to be responsible of a sharp increase in the open circuit voltage in OPV devices. Their improved electronic properties and optimized band gap are here exploited to realize hybrid PC specifically designed to be coupled in a tandem configuration with a high performing perovskite, realizing a full water-splitting system with cheap, easily processable and suitable for large area production materials. By modifying the hybrid PC, it was possible to extend the absorption range of the stack. Taking advantage of the high Voc of the perovskite and the additional photovoltage coming from the PC, the system efficiently performs the full water splitting reaction without the application of any external bias. The results clearly indicate that the Solar To Hydrogen (STH) efficiency of the system increases sensitively when proper design of the tandem system is achieved, with STH above 2% for the best performing case. These results prove that a tandem hybrid organic perovskite-photocathode stack can be used to realize efficient photoelectrochemical systems for solar fuels production, unlocking a new field of application for these excellent performing class of materials.

Copper Complexes Redox Couple as Solid-State Hole Transporting Material for Perovskite Solar Cells

Jacopo Benespori, Hannes Michaels and Marina Freitag; Institutionen för kemi - Ångström, Uppsala University, Uppsala, Sweden.

Perovskite solar cells (PSCs) have been extensively studied in the past six years. The development of effective deposition methods for this material have lead to devices rivaling in efficiency – at least at the laboratory scale – with silicon-based solar cells, at a fraction of the cost. The introduction in recent years of mixed cation perovskite materials has also started to address what is nowadays the main issue of this technology: long-term stability. While there has been an evolution of the perovskite layer in the past lustrum, the same cannot be said about another essential layer in PSCs – the hole transporting one. Spiro-OMeTAD, first introduced in solid-state dye-sensitized solar cells (DSSCs) and then employed at the beginning of the solid-state PSCs era is, in fact, still considered the material of choice for this particular component of a device. This fact is not due to a lack of research effort. In the past four years almost two hundred new hole transporting materials (HTMs) have been developed for PSCs and, despite the fact that some were claimed to perform better than spiro-OMeTAD itself, none managed to become widely employed by the larger research community. Although spiro-OMeTAD’s successor has not been found yet, its replacement is paramount for PSC commercialization. Spiro-OMeTAD is known to be very expensive, which in part nullifies the inexpensive nature of the perovskite material. More importantly, however, spiro-OMeTAD is known to introduce stability issues inside PSC devices, greatly reducing their life. This is in part due to spiro-OMeTAD’s properties themselves, in part due to all the additives and dopants embedded in the spiro-OMeTAD film to improve its poor conductivity and film-forming properties.

To date, little research has been focused on transition metal coordination complexes, and especially metal complex redox couples, as HTM for PSCs. Metal complexes are known to be generally conductive and stable compounds, with their energy level easily tuned by changing the metal center or by applying small modifications to the organic ligand. They have been shown to perform very well in liquid DSSCs and they have recently been successfully employed in solid-state DSSCs. A proof of concept, with mixed results, has also been demonstrated for PSCs. Here, we employ a copper(I/II) complexes redox couple in devices featuring a mixed cation perovskite light absorber. These copper complexes feature good energy alignment with the perovskite material.
and good conductivity.

Hole Extraction from Lead Halide Perovskite to PDPP-3T Probed by Ultrafast Transient Absorption Spectroscopy
Jafar I. Khan1, Esma Ugur1, Erkan Aydin1, Mindaugas Kirkus1, Marios Neophytou1, Iain McCulloch1,2, Stefan De Wolf1 and Frédéric Laquai1; 1King Abdullah University of Science and Technology, Jeddah, Saudi Arabia; 2Imperial College London, London, United Kingdom.

Solution-processed metal-halide perovskite solar cells (PSCs) have received immense attention in the field of photovoltaics due to their high power conversion efficiency (PCE) of now more than 22% reached in a relative short time. Today, various electron and hole transport layers (HTLs) have been implemented to further enhance the device performance and stability. State-of-the-art PSCs use spiro-OMeTAD as HTL in n-i-p device structures, however, doping with both tBP and Li-TFSI is required to increase the hole mobility and conductivity of the HTL and achieve optimum performance. Long-term stability of devices is severely limited by Li-TFSI doping because of its hygroscopic nature. Here, as an alternative to spiro-OMeTAD, we used the high molecular weight solution-processed polymer PDPPP-3T and demonstrate comparable performance to spiro-OMeTAD. Furthermore, we are interested in the dynamics of hole extraction from the perovskite to the HTL and interfacial recombination of charge carriers at the perovskite/HTL interface, which we studied by ultrafast transient spectroscopy. We show that the ground state bleach of the polymer allows direct optical probing of the carrier extraction and recombination dynamics. Hole transfer takes place from the perovskite to the HTL in tens of nanoseconds when the sample is excited from the perovskite side. By varying the perovskite film thickness from 170 nm to 570 nm, we investigate the diffusion of holes in the perovskite absorber layer, when PDPPP-3T is used as HTL. Finally, we discuss the dynamics of carrier recombination at the PDPPP-3T/perovskite interface.

Modification of TiO2/CH3NH3PbI3 Interface with KCl, KI, or KBr in Planar Perovskite Solar Cells
Amrita Yasin, Adam Pockett, James McGetrnick, Stoichko Dimitrov, Catherine S. De Castro, Matthew Davies, Matt Carnie, Trystan Watson and Cecile Charbonneau; Swansea University, Cardiff, United Kingdom.

This work showcases our research on modification of compact TiO2 electron transport layers (ETLs) at the TiO2/CH3NH3PbI3 interface for application in planar lead halide perovskite solar cells. Compact TiO2 ETLs were formed via spraying of a commercially available titanium diisopropoxide bis(acetylacetonate) precursor on fluorine-doped tin oxide (FTO) glass followed by annealing at 550 °C. These layers were subsequently spin coated with aqueous solutions of 10 mM and 40 mM of KX (X = Cl-, I-, Br-, prior to CH3NH3PbI3 deposition. Presence of potassium and the X- ions on the TiO2 surface is evident via X-ray photoelectron spectroscopy (XPS) analysis, and individual crystals can be seen on the modified TiO2 films. The absorbance and photoluminescence spectra of TiO2/KX/CH3NH3PbI3 films do not show significant difference, however the work function of the modified TiO2 film decreases. Against a stabilized power conversion efficiency of 8.25% in the reverse direction for unmodified planar devices, KI modified devices reach up to 5.13%, followed by KBr at 4.82%, and finally KCl at 3.89%. The change in efficiency can be correlated with a change in work function of the modified films.

4:45 PM ET04.14.12
Gas-Solid Reaction Based over 1 μm Thick High-Quality Stable Perovskite Films for Efficient Solar Cells and Modules with High Reproducibility
Zonghao Liu1, Longbin Qiu1, Emilio J. Juarez-Perez1, Zafer Hawash1, Taehoon Kim1, Yan Jiang1, Zhifang Wu1, Sonia R. Raga1, Luis K. Ono1, Shengzhong Liu1 and Yabing Qi1; 1Okinawa Institute of Science and Technology, Okinawa, Japan; 2Shaanxi Normal University, Xi’an, China.

Organic-inorganic halide perovskite solar cells (PSCs) have drawn a great deal of attention in the photovoltaic research community due to their high efficiency over 23%. Besides high efficiency, the stability and reproducibility of PSCs are also key for their commercialization.1 Here, we report a simple perovskite formation method to fabricate perovskite films with thickness over one micrometer in ambient condition on the basis of the fast gas-solid reaction of chlorine incorporated hydrogen lead triiodide and methylamine gas. The comprehensive characterization results reveal that with the synergistic effect of methylamine gas and partial substitution of iodine ions by chorine ions, the resultant perovskite films with a thickness over one micrometer and low thickness variation exhibit excellent film quality. The resultant PSCs gave an average power conversion efficiency (PCE) of 19.1% and low PCE standard deviation (+ 0.4%), which indicates the excellent reproducibility of this method. Meanwhile, this method enables a best active-area PCE of 15.3% for 5 cm × 5 cm solar modules and good reproducibility (13.6 ± 0.8%). Besides, the un-encapsulated PSCs exhibit an excellent T80 lifetime exceeding 1600 h under continuous operation conditions in dry N2 environment. Our study not only provides a highly reproducible method to fabricate PSCs and modules with enhanced efficiency, reproducibility and stability, but also offers the in-depth understanding for the underlying mechanisms responsible for device stability improvement. The encouraging results in this work points out a promising direction, i.e., use of thick absorber films to realize PSCs and modules with high efficiency, reproducibility and stability.2

Fundamental Aspects of Halide Perovskite (Opto)electronics and Beyond
November 26 - November 30, 2018

Symposium Organizers
Ivan Mora-Sero, Universitat Jaume I
Unsolved Mysteries of Halide Perovskites
Aron Walsh; Imperial College London, London, United Kingdom.

Perovskites are the wonder compounds of materials science, with examples of dielectrics, semiconductors, metals, and superconductors. This talk will address the chemical and physical properties that make halide perovskites unique. Following six years of intensive research, there has been a number of breakthroughs in understanding, but many challenges and opportunities remain.

These organic-inorganic semiconductors satisfy the optoelectronic criteria for an active photovoltaic layer, i.e. spectral response in the visible range combined with light electron and hole effective masses. In addition, they are structurally and compositionally flexible with large dielectric constants, and the ability to alloy on each of the lattice sites. To understand the success of methylammonium lead iodide photovoltaics, we have been applying materials theory and simulation across multiple length scales [1-5].

I will discuss issues ranging from disorder associated with molecular rotations and tilting of the inorganic network, to macroscopic polarisation arising from charged defect formation and diffusion. A number of unsolved mysteries will be outlined including self-healing effects, apparent ferroelectricity, light-enhanced ion transport, and ultimately, the origin of their high performance in optoelectronic devices.

This research has been supported by the Royal Society and a wide collaboration network with contributions from current and former group members including Federico Brivio, Keith Butler, Jarvist Frost, Jonathan Skelton, Katrine Svane, Ruoxi Yang, Lucy Whalley, Youngkwang Jung, Jacob Wilson, and Samantha Hood.

Halide Perovskites, HaPs, may be mostly normal (inorganic) semiconductors and, indeed, we should be careful to describe them with concepts from organic electronics. HOWEVER, it is remarkable that a material with over-all high quality optoelectronic properties can result from fast, low temperature, solution preparation. This suggests that there may also be issues with using some concepts from “classical” semiconductors. Now we can ask if minor revisions will do or if major ones are needed (rejection is not an option; HaPs exist...).

For that we need to define and understand what remains special about HaPs and what is/are the reason(s) for what, if anything, remains special. Being able to do so may help answer the nagging question if this is all because Pb is so unique, or if we can generalize to find other materials like these. I will consider the general question and, as things look now, 5.5 months before the talk, consider the relevance of mechanical, in conjunction with other properties, to challenge what we think we know about defects in HaPs, note a confusing semantic issue and more, to arrive at an answer, to guide us in future work.

Work done with Gary Hodes (Weizmann), with input from many others, whom I will credit in my talk.

10:00 AM BREAK

Theory and Modeling of Correlated Ionic and Electronic Motions in Hybrid Organic-Inorganic Perovskites
Matthew Mayers1, Liang Z. Tan1, David A. Egger1, Andrew M. Rappe1 and David Reichman1; 1University of Pennsylvania, Philadelphia, Pennsylvania, United States; 2Chemistry, Columbia University, New York, New York, United States; 3University of Regensburg, Regensburg, Germany.

The perovskite crystal structure hosts a wealth of intriguing properties, and the renaissance of interest in halide (and hybrid organic-inorganic) perovskites (HOIPs) has further broadened the palette of exciting physical phenomena. Breakthroughs in HOIP synthesis, characterization, and solar cell design have led to remarkable increases in reported photovoltaic efficiency.

However, the observed long carrier lifetime and PV performance have eluded comprehensive physical justification. The hybrid perovskites serve as an enigmatic crossroads of physics. Concepts from crystalline band theory, molecular physics, liquids, and phase transitions have been applied with some success, but the observations of HOIPs make it clear that none of these conceptual frameworks completely fits. In this talk, recent theoretical progress in understanding HOIPs will be reviewed and integrated with experimental findings. The large amplitude motions of HOIPs will be highlighted, including ionic diffusion, anharmonic phonons, and dynamic incipient order on various length and time scales. The intricate relationships between correlated structural fluctuations, polar order, and excited charge carrier dynamics will also be discussed.

11:00 AM ET05.01.05
Low Charge Mobility in SOFT Polar Crystals is Fundamental! The Case of Halide Perovskites
Yevgeny Rakita, Gary Hodes and David Cahen; Materials and Interfaces, Weizmann Institute of Science, Rehovot, Israel.

The combination of properties halide perovskites (HaPs) possesses (e.g., high absorption coefficient, low effective mass, low exciton binding energy, low carrier recombination lifetimes, etc.) should (and does) allow high-performing optoelectronic devices. However, there is one fundamental property that does not fit the expected prognosis coming from the superior material’s properties – its carrier mobility.

When comparing mobility values of HaPs (~1-100 cm2V-1s-1) with those polar semiconductors, such as GaAs or CdTe (~103-105 cm2V-1s-1), a significant difference is revealed. Mobility temperature dependence, which points on the scattering mechanism, is found in HaPs, GaAs, CdTe and other polar semiconductors to be similar and suggest scattering by polar optical phonon. Low defect density, as found for HaPs (~1016 cm-3 in single crystals) as well as for other high-quality polar semiconductors (e.g., GaAs and CdTe), make scattering by defects insignificant (at temperatures > ~100 K). Therefore, the origin of charge scattering and, thus, their mobility, probably relate to more intrinsic properties of these polar semiconductors. So what makes the mobility in HaP to be so different from that in other polar semiconductors? Correlation of experimentally-derived physical values from semiconductors, including HaPs, reveals a clear correlation between the mechanical properties (or what is called a ‘deformation potential’) and the charge mobility. In fact, the softer the material, the lower its mobility. In my talk, I will explain the origins for such relation, which suggest that in a soft material such as HaPs mobility will never reach values as high as in GaAs.

11:15 AM ET05.01.06
The Polar Liquid Sublattice in Single Crystal Perovskite CH3NH3PbBr3(001)
Prescott E. Evans1, Marin Pink2, Ayan Zhmukhenov3, Guanghua Hao1, Yaroslav Lozovyy1, Osman M. Bakr1, Peter Dowben1 and Andrew J. Yost1; 1University of Nebraska-Lincoln, Lincoln, Nebraska, United States; 2Italian University, Bloomington, Indiana, United States; 3King Abdullah University of Science and Technology, Thuwal, Saudi Arabia.

The dynamic motion, within the lattice of single crystal CH3NH3PbBr3(001) hybrid halide perovskite, was investigated using powder and single crystal x-ray diffraction, and x-ray photoemission spectroscopy. Single crystal x-ray diffraction studies indicate the methylammonium adopts multiple orientations within the crystal, at room temperature, evidence of a soft and disordered methylammonium sublattice within a stiff and ordered PbBr3 matrix lattice. Temperature dependent x-ray photoemission spectroscopy for bromine and lead core level peaks near the cubic to tetragonal I phase transition tend to support the characterization of methylammonium as a lattice polar liquid within the CH3NH3PbBr3 crystal. The Br 3d3/2 core level Debye-Waller factor plots exhibited a temperature dependence indicative of an effective Debye temperature of 160±81K, while the Pb 4f7/2 core-level Debye-Waller factor plots show little temperature dependence, indicative of a very stiff lattice along the <001> direction. MAPbBr3 satisfies the criteria for a lattice polar liquid and does not meet the criteria required for a ferroelectric material.

11:30 AM ET05.01.07
Impact of Crystallographic Orientation Disorders on Electronic Heterogeneities in Metal Halide Perovskite Thin Films
Benjamin Foley1, Seung-Hun Lee2, Kai Xiao1, Benjamin Doughty1, Yingzhong Ma2 and Joshua Chou1; 1University of Virginia, Charlottesville, Virginia, United States; 2Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Metal halide perovskite thin films have achieved remarkable performance in optoelectronic devices, but suffer from spatial heterogeneity in their electronic properties. To achieve higher device performance and reliability needed for wide-spread commercial deployment, spatial heterogeneity of optoelectronic properties in the perovskite thin film needs to be understood and controlled. Clear identification of the causes underlying this heterogeneity, most importantly the spatial heterogeneity in charge trapping behavior, has remained elusive. Here, a multimodal imaging approach consisting of
photoluminescence, optical transmission, and atomic force microscopy is utilized to separate electronic heterogeneity from morphology variations in perovskite thin films. By comparing highly oriented and randomly oriented polycrystalline perovskite thin film samples, we reveal that disorders in the crystallographic orientation of the grains play a dominant role in determining charge trapping and electronic heterogeneity. This work also demonstrates a polycrystalline thin film with uniform charge trapping behavior by minimizing crystallographic orientation disorder. These results suggest that single crystals may not be required for perovskite thin film based optoelectronic devices to reach their full potential.

11:45 AM ET05.01.08
Thermodynamic Stability of Perovskites—From Empirical Tolerance Factor to Machine Learning Wanjian Yin; Soochow Institute for Energy and Materials Innovations (SIEMIS), Soochow University, Suzhou, China.

Perovskite stability is of the core importance and difficulty in current research and application of perovskite solar cells. Nevertheless, over the past century, the formability and stability of perovskite still relied on simplified factor based on human knowledge, such as the commonly used tolerance factor t. Instead of t, we proposed a new factor (μ+η), where μ and η are the octahedral factor and the atomic packing fraction respectively. As a stability descriptor (μ+η) is able to predict the relative stability among any two perovskites with the accuracy ~90%, much better than ~70% of t [1,2].

We further combined machine learning (ML) with first-principles density functional calculations, proposed a strategy to calculate the decomposition energies, considered to be closely related to thermodynamic stability, of 354 kinds halide perovskites, established the machine learning relationship between decomposition energy and compositional ionic radius and investigated the stability of 14100 halide double perovskites. The ML model, which was trained based on the theoretical data, has been validated by experimental results of a series of rare earth metal halide perovskites (up to ~10^3 kinds), performs much better than descriptors such as tolerance factor t and (μ+η) and further provides elemental and concentration suggestion for improving the stability of mixed perovskite [3].

SESSION ET05.02: Defects, Ion Motion and Polarization
Session Chairs: Saiful Islam and Yabing Qi

1:30 PM ET05.02.01
Ionic Transport, Defects and Electrooptical Response of Perovskite Solar Cells Juan Bisquert; Institute of Advanced Materials, Universitat Jaume I, Castello, Spain.

The development of organic-inorganic lead halide perovskites with very large efficiency requires us to understand the operation of the solar cell. This class of semiconductors presents remarkable bulk electronic and optical properties, but the contacts to the device are a key aspect of the operation and show important dynamic interactions. We describe the results of analysis of kinetic phenomena using frequency modulated techniques. First with impedance spectroscopy we provide an interpretation of capacitances as a function of frequency both in dark and under light, and we discuss the meaning of resistances and how they are primarily related to the operation of contacts in many cases. The capacitance reveals a very large charge accumulation at the electron contact, which has a great impact in the cell measurements, both in photovoltage decays, recombination, and hysteresis. We also shows the identification of the impedance of ionic diffusion by measuring single crystal samples. Working in samples with lateral contacts, we can identify the effect of ionic drift on changes of photoluminescence, by the creation of recombination centers in defects of the structure. We also address new methods of characterization of the optical response by means of light modulated spectroscopy. The IMPs is able to provide important influence on the measured photocurrent. We describe important insights to the measurement of EQE in frequency modulated conditions, which that showed the quantum efficiency can be variable at very low frequencies.

From MAPbI3 to Mixed-Cation Perovskites—Atomic-Scale Insights into Defects, Diffusion and Degradation Saiful Islam; University of Bath, Bath, United Kingdom.

Further breakthroughs in perovskite solar cells require advances in new compositions and underpinning materials science. Indeed, a greater fundamental understanding of perovskite materials requires atomic-scale characterization of their underlying structural, defect and transport behaviour. In this context, combined modelling-experimental work is now a powerful approach for investigating these properties at the atomistic level. This presentation will describe such studies on hybrid perovskites [1-3] in two related areas: (i) the defect and ion transport properties of methylammonium lead iodide (MAPbI3) in relation to atmospheric effects and degradation; (ii) the molecular cation dynamics and octahedral distortion of halide perovskites with mixed A-cations (MA, FA, Cs) in relation to their improved stability and photovoltaic performance.

Perovskite semiconductors are a new class of semiconductors, significantly different from organic and also inorganic semiconductors. We have applied thermally stimulated current measurements to study the polarization processes of the organic cation in MAPbI$_3$, thin films across the orthohombic to tetragonal phase transition. The nature of the cation polarization within the orthorhombic phase was found to be highly repeatable, with a separation of 20 K between polarization and depolarization processes, and was investigated with respect to its extrinsic polarizability by external electric fields. Our results show that the polarization of organic cations is correlated with a sudden improvement in solar cell performance and has impact on the working mechanisms of perovskite solar cells.

Huge Enhancement of Ion Conduction and Implications for Photo-Decomposition in Hybrid Organic-Inorganic Lead Halides Perovskite

Gee Yeong Kim$^1$, Alessandro Senocrate$^1$, Tae-Youl Yang$^1$, Giuliano Gregori$^2$, Michael Graetzel$^2$ and Joachim Maier$^1$; $^1$Max Planck Institute for Solid State Research, Stuttgart, Germany; $^2$Swiss Federal Institute of Technology in Lausanne, Lausanne, Switzerland.

Methylammonium lead iodide (MAPI) is the archetype material of the class of halide perovskites that are currently in the focus of photovoltaic research because of high conversion efficiencies. MAPI exhibits some anomalies properties such as a huge apparent low frequency dielectric constant and severe hysteretic current-voltage behavior. In order to investigate the key features of its performance, not only electronic, but also ionic transport properties need to be considered [1,2]. Here we report on huge photo effects on ion conductivity in MAPI. To measure and separate both transport contributions not only in the dark, but also under illumination, we carried out a variety of tailored electrochemical studies. In this way, an enhancement of ionic conductivity by as much as two orders of magnitude in MAPI by light illumination can be unambiguously demonstrated [3]. The mechanism of ion conduction under light is proposed to rely on a translation of a great fraction of the generated holes into iodine vacancies which are the ionic charge carriers. Localized holes correspond to neutral iodine which can -owing to site and poly-anionic stabilization- occupy interstitial sites leaving vacant iodine sites that are causing the ionic conductivity. This process is reversible under homogeneous conditions. If, however, iodine is irreversibly removed under illumination, photo-decomposition occurs. This unexpected finding does not only give rise to a decomposition path for metal halide perovskites, it also allows one to tune ion transport by light.

References
A pertinent investigation of the exceptional photoelectrochemical properties of halide perovskites has to consider the significant ion transport present in these materials. Such transport gives rise to bulk and boundary ionization phenomena during operation, and it is also relevant for the degradation kinetics of halide perovskites materials and related photovoltaic devices. In this contribution we analyze the nature of the ionic conductivity in methylammonium lead iodide, the archetype hybrid halide perovskite, by means of various electrical, electrochemical and nuclear magnetic techniques. Under equilibrium conditions, iodine vacancies are unambiguously shown to be the dominant ionic carriers, while electron holes dominate the electronic conductivity at high (and excess electrons at low) iodine activities. The contributions of methylammonium and lead ions, instead, are small (upper limits are given). As a follow-up, we discuss the changes of the various charge carrier concentrations as a function of the decisive control parameters (stoichiometry and doping content). Based on these equilibrium considerations, we can also discuss the charge carrier chemistry under illumination where not only electronic, but also ionic conductivity are largely enhanced.

Highly Stable Perovskite Solar Cells via Controlling Ions/Charges/Molecules Diffusion Xudong Yang1, 2; Han Chen1 and Liyuan Han*; 1State Key Laboratory of Metal Matrix Composites, Shanghai Jiao Tong University, Shanghai, China; 2Research Network and Facility Services Division, National Institute for Materials Science, Tsukuba, Japan.

Organic-inorganic hybrid perovskite solar cells (PSCs) are promising low-cost photovoltaic technology owing to the high energy conversion efficiency. However, the device stability has a large gap to the ideal level for future application. Here I would like to introduce our recent approaches in achieving highly stable PSCs. We proposed a strategy to control the diffusion of ions/charges/molecules by developing nano-carbon electron transporting layer in p-i-n structure perovskite solar cells. It successfully enabled better stability because the diffusion of iodide within the device was hindered before it induced corrosion of the metal electrode while the diffusion of electrons was improved. We further control the ions/charges/molecules diffusion within n-i-p structure perovskite solar cells. The ions diffusion was reduced to decrease the charge trap states when the device was aging. This helped to obtain device with excellent stability and high efficiency. The device performance was certified by a public test center with the record of certified stabilized power output.

Impact of Thin-Film Perovskite Composition on Sub-Band Gap Absorption Due to Defect States Biwas Subedi, Chongwen Li, Cong Chen, Maxwell Junda, Dewei Zhao, Yanfa Yan and Nikolas Podraza; Physics and Astronomy, University of Toledo, Toledo, Ohio, United States.

Organic-inorganic halide ABX3 (A: methylammonium—MA, formamidinium—FA, Cs; B: Pb, Sn; X: I, Br) perovskites currently serve as absorber materials in highly efficient solar cells. Preparation of films which are highly crystalline; defect free; stable against heat, light, and moisture; and with desired optoelectronic properties are present challenges. Cationic and anionic alloying / doping has been shown to improve phase stability, increase grain size and uniformity, and reduce sub-bandgap absorption and recombination due to defects to improve solar cell performance. A combination of photothermal deflection spectroscopy, spectroscopic ellipsometry, and unpolarized transmittance measurements of solution processed perovskite thin films prepared with mixed cation/anion composition are used to study the impact of these variations on sub-bandgap absorption due to defects. In particular, Urbach energies from sub-bandgap absorption are correlated with structural, electrical, above band gap optical properties, and device performance. As an example of A-cation substitution, replacing 0.4 FA with MA in x = 0.15 FA0.6MA0.4Sn0.6Pb0.4I1-xBrx reduces Urbach energies from 53 to 26 meV and is accompanied by increased grain size, reduced defect density, and improved electronic properties. For anion substitution, I to Br ratios in FA0.6MA0.4Sn0.6Pb0.4I1-xBrx (x ≤ 0.15) show materials prepared with x ≤ 0.04 having the lower Urbach energy than higher Br content. In FA0.8Cs0.2PbI3-xBrx, Urbach energies are reduced from lead thiocyanate (Pb(SCN)2) treatment and solvent annealing preparation. Links will be established between the particular cation/anion composition configurations currently used in solar cell device grade perovskite films, structural and electrical properties, and the associated sub-bandgap absorption characteristics. Further expansion of these studies will help to more fundamentally understand the defect states present in particular compositions and to identify practical pathways to improvements in stability and electronic quality for experimentally produced perovskite thin films used as solar cell absorbers.

Operational lifetime is one of the main challenges for perovskite solar cells towards commercialization [1]. Other than the stability of perovskite materials...
General Nondestructive Post-Treatment to Passivate Perovskite Solar Cells with Enhanced Stability and Performance

Shencheng Xie, Han Wang, Jianbin Xu and Keyou Yan; The Chinese University of Hong Kong, Hong Kong, Hong Kong.

Hybrid perovskite thin films have many vacancies at surface and interface during the film formation, which degrade the stability and photovoltaic performance. Passivation via post-treatment can enhance the film quality, but present methods are slightly destructive to three-dimensional perovskite (3DP) due to the solvent effect, which hinders fabrication reproducibility. Herein, we demonstrate that 4-fluoroaniline (FAL) is an effective antisolvent candidate for surface/interface passivation and thus nondestructive during the fabrication. Density functional theory (DFT) calculation reveals that the antisolvent and non-destructive properties are attributed to the conjugated amine in aromatic ring. Hot vapor assisted colloidal process (HVACP) is employed for the post-treatment. The molecular passivation yields an ultrathin protection layer with hydrophobic fluorine tail and thus enhances the stability and optoelectronic properties. FAL perovskite solar cell (PSC) delivers 20.48% power conversion efficiency (PCE) in the ambient condition. Moreover, PPA-capped MAPbBr3 QDs films show high electronic conductivity, which carrier transport are adopted to increase the film conductivity of QDs, but still didn’t break the dilemma of the trade-off between the film conductivity and colloidal stability. Herein, a uniform and large grain size of max approx. 3 µm is demonstrated for two steps solution process of MAPbI3 perovskites at 100°C using a simple annealing method. The annealing time duration varies from 1 hour to 24 hours long, while the grain size gradually increases with the prolongation of the annealing time. However, the grain size remains almost constant when the annealing time longer than 12 hours. Furthermore, a distinctly larger grain size of about 6 µm is also exhibited for the same perovskite film deposited on a PbI2 seed layer prepared by chemical vapor deposition method. An optical measurement is being carried on with some initial promising results to characterize the photocurrent loss and recombination center on the grain boundaries, intra-grain, and inter-grain scale of perovskites using femtosecond laser of confocal microscope. The investigations on such microcrystalline perovskites with large grains are highly essential for conducting electronic and optical measurements to enhance the performance of perovskite devices.

Enlarging the Grain in Low-Temperature Solution Processed Perovskite Films Using Simple Annealing Method

Md Wayesh Qarony1, Saiman Ma1, Mohammad I. Hossain1, Chu Tung Yip2 and Yuen H. Tsang1; 1Department of Applied Physics and Material Research Center, The Hong Kong Polytechnic University, Kowloon, Hong Kong; 2Department of Physics, Shenzhen Graduate School, Harbin Institute of Technology, Shenzhen, China.

Perovskites have recently attained great attention owing to its excellent electronic and optical properties. The optoelectronic properties can be further tailored according to the needs of applications. It is demonstrated that perovskites photovoltaic devices with a theoretical energy conversion efficiency limit of 31% can be realized if large grain size with uniform intra-grain and inter-grain crystallinity are ensured [1-2]. However, achieving a good crystallinity along with larger grain using the low-temperature solution processed organic-inorganic halide polycrystalline perovskites (MAPbI3) remains a challenging task. Herein, a uniform and large grain size of max approx. 3 µm is demonstrated for two steps solution process of MAPbI3 perovskites at 100°C using a simple annealing method. The annealing time duration varies from 1 hour to 24 hours long, while the grain size gradually increases with the prolongation of the annealing time. However, the grain size remains almost constant when the annealing time longer than 12 hours. Furthermore, a distinctly larger grain size of about 6 µm is also exhibited for the same perovskite film deposited on a PbI2 seed layer prepared by chemical vapor deposition method. An optical measurement is being carried on with some initial promising results to characterize the photocurrent loss and recombination center on the grain boundaries, intra-grain, and inter-grain scale of perovskites using femtosecond laser of confocal microscope. The investigations on such microcrystalline perovskites with large grains are highly essential for conducting electronic and optical measurements to enhance the performance of perovskite devices.

Conventional colloidal quantum dot solutions (QDs), long hydrocarbon chains capping ligands such as n-octylamine (OA) are indispensable. However, the commonly used long hydrocarbon capping ligands are always insulator and block efficient carrier transport between QDs, leading to inferior performance of light-emitting diode (LED), and other optoelectronic devices. Until now, ligand exchange, reducing ligand chain length and ligand density control are adopted to increase the film conductivity of QDs, but still didn’t break the dilemma of the trade-off between the film conductivity and colloidal stability of QDs. In this work, for the first time, we overcame this dilemma, successfully synthesized methyleneimine lead bromide (MAPbBr3) QDs with an unsaturated conjugated alkyl-amine, 3-Phenyl-2-propen-1-amine (PPA), as ligand. Owing to the denser electron cloud overlapping and delocalization effect of conjugated molecules, PPA effectively improves the conductivity of QDs film without compromising its colloidal stability. With analogous quantum photoluminescence yield and stability of OA-capped MAPbBr3 QDs, films of PPA-capped MAPbBr3 QDs show high electronic conductivity, which carrier mobility has increased nearly 22 times of that of OA-capped MAPbBr3 QDs films. As an example of application in LEDs, the QD-LED based on PPA-capped MAPbBr3 QDs exhibited a maximum luminance of 9052 cd m⁻² and an maximum current efficiency of 9.08 cd A⁻¹, which is eight times of that of QD-LED based on OA-capped MAPbBr3 QDs (1.14 cd A⁻¹). This work provides critical solution for the poor conductivity of QDs in applications of energy-related devices.

Conformational Ligands Assisted Charge Transport Between Coupling Colloidal Perovskite Quantum Dots

Jinfei Dai, Yifei Shiy, Jie Xu, Lin Zhang and Xiaowin Wu; Xi’an Jiaotong University, Xi’an, China.

Conventionally, in preparing stable colloidal quantum dots (QDs), long hydrocarbon chains capping ligands such as n-octylamine (OA) are indispensable. However, the commonly used long hydrocarbon capping ligands are always insulator and block efficient carrier transport between QDs, leading to inferior performance of light-emitting diode (LED), and other optoelectronic devices. Until now, ligand exchange, reducing ligand chain length and ligand density control are adopted to increase the film conductivity of QDs, but still didn’t break the dilemma of the trade-off between the film conductivity and colloidal stability of QDs. In this work, for the first time, we overcame this dilemma, successfully synthesized methyleneimine lead bromide (MAPbBr3) QDs with an unsaturated conjugated alkyl-amine, 3-Phenyl-2-propen-1-amine (PPA), as ligand. Owing to the denser electron cloud overlapping and delocalization effect of conjugated molecules, PPA effectively improves the conductivity of QDs film without compromising its colloidal stability. With analogous quantum photoluminescence yield and stability of OA-capped MAPbBr3 QDs, films of PPA-capped MAPbBr3 QDs show high electronic conductivity, which carrier mobility has increased nearly 22 times of that of OA-capped MAPbBr3 QDs films. As an example of application in LEDs, the QD-LED based on PPA-capped MAPbBr3 QDs exhibited a maximum luminance of 9052 cd m⁻² and an maximum current efficiency of 9.08 cd A⁻¹, which is eight times of that of QD-LED based on OA-capped MAPbBr3 QDs (1.14 cd A⁻¹). This work provides critical solution for the poor conductivity of QDs in applications of energy-related devices.

Bulk Heterojunction Quasi-Two-Dimensional Perovskite Solar Cell with 1.18 V High Photovoltage Han Wang, Jiangsheng Xie, Shenghe Zhao, Jianbin Xu and Keyou Yan; The Chinese University of Hong Kong, Hong Kong, Hong Kong.

Multicomponent quasi-two-dimensional perovskites (Q-2DPs) have efficient luminescence and improved stability, which are highly desirable for light-emitting diode (LED) and perovskite solar cell (PSC). However, the lack of radiative recombination at room temperature is still not well understood and the performance of PSC is not good enough as well. The open-circuit voltage ($V_{oc}$) is even lower than that of 3D PSC with narrower band gap. In this work, we study the energy transfer of excitons between their multiple components by time-resolved photoluminescence (TRPL) and find that charge transfer from high energy states to low energy state is greatly suppressed at elevated temperature due to increasing trap-mediated recombination. This may reveal the bottleneck of luminescence at room temperature in Q-2DPs, leading to large photovoltaic loss in PSC. Therefore, we develop a p-i-n bulk heterojunction (BJH) structure to reduce the nonradiative recombination. We obtain high $V_{oc}$ of 1.18 V for (PMA)$_2$MA$_n$Pb$_{3n}$Cl$_{3n}$(N = 5) in PSC, much higher than the planar counterparts. The enhanced efficiency is attributed to the improved exciton dissociation via BHJ interface. Our results provide an important step towards high $V_{oc}$ and stable 2D PSCs, which could be used for tandem solar cell and coloreful photovoltaic windows.

Two-Dimensional Hybrid Dion-Jacobson Perovskite for Solar Cell Application Lingling Mao$^1$, Weijun Ke$^1$, Laurent Pedesseau$^2$, Claudine Katano$^3$, Jacky Even$^4$, Constantinos Stoumpos$^4$ and Mercouri G. Kanatzidis$^5$; 1Chemistry, Northwestern University, Evanston, Illinois, United States; 2Institute for Photon Science and Technology, The University of Tokyo, Tokyo, Japan; 3Physics, The University of Tokyo, Rennes, France.

Hybrid organic-inorganic perovskite material has emerged as one of the most promising semiconducting materials for optoelectronic applications. The power conversion efficiency (PCE) of the three-dimensional (3D) perovskite based solar cell has achieved 22%. With a higher flexibility in structural engineering, the two-dimensional (2D) perovskite not only allows for property tuning in a broader sense, but also demonstrates higher stability in devices compared to the 3D perovskite. Here, we present the first complete series of the Dion-Jacobson phases in the halide perovskite family, incorporating the 3-(ammoniomethyl)pyridinium (3AMP) or 4-(ammoniomethyl)pyridinium (4AMP) as spacing cations. The general formula for the DJ perovskite is A$^+$, $\text{Pb}_n\text{X}_m$(A$^+$ = 3AMP or 4AMP, A$^+$ = methylammonium (MA$^+$)). Compared with the Ruddlesden–Popper (RP) phases, the DJ perovskite only has one sheet of organic cations in between the layers, resulting in much closer interlayer distance (~4 Å). The inorganic layers in the DJ phases are stacking perfectly on top of each other with no displacement. With a slight modification on the organic cation (3AMP vs. 4AMP), the optical properties are heavily influenced by the distortion of the inorganic layers, as the 3AMP series (less distorted) has narrower band gaps than the 4AMP series (more distorted). We further demonstrate their difference in solar cell devices, as the (3AMP)(MA$^+$)$_2$Pb$_3$I$_9$ has the best PCE of 7.3%, much higher than the corresponding (4AMP)(MA$^+$)$_2$Pb$_3$I$_9$. With compositional engineering on the existing system, we optimize the device performance of (3AMP)(MA$^+$)$_2$F$_2$Pb$_3$I$_9$ (FA$^+$ = formamidinium) to 12.0%. The new DJ system highlights the crucial role of functional organic cations in the 2D hybrid perovskite, where they influence the overall property of the material by interactions with the inorganic framework, which ultimately affect the device performance.

ET05.03.07

Unveiling the Room Temperature Low-Threshold Amplified Spontaneous Emission in All-Inorganic Perovskite Thin Films by Dual Source Thermal Evaporation Lin Zhang, Zhaoxin Wu, Hua Dong, Jinfei Dai and Xiaoyun Liu; Xi’an Jiaotong University, Xi’an, China.

Recent years have witnessed rapid development of halide perovskite as a new class of optical-gain media for lasing applications. Driven by the rapidly increased research on organic-inorganic perovskite CH$_3$NH$_3$PbX$_3$ (X = Cl, Br, I) (Science, 356, 1376 (2017)), inorganic perovskite CsPbX$_3$ has also attracted high attention because it shows increased air-stability (Nat. Commun. 8, 15640 (2017), Nat. Photon. 11, 108 (2017)). For achieving amplification spontaneous emission (ASE) with low threshold from perovskite thin films, ultra-compact grains and smooth morphology are prerequisites. Meanwhile, the prepared perovskite thin films have good photo and environmental stability under ambient conditions is also paramount. However, the solution-processed thin films generally difficult to control crystal perovskite crystallization and film quality due to low solubility of the cesium bromide (CsBr) precursor, result in inevitable large pinholes and poor surface coverage (Nat. Commun. 6, 8056 (2015)). Such defects may result in reduced optical confinement effect and poor ASE from the perovskite films, seriously affecting their lasing performance. To solve these issues, herein, we demonstrate that by dual source thermal evaporation which enables the attainment of nearly pinhole-free thin films, inorganic perovskite (such as CsPbBr$_3$ or CsSnI$_3$) films exhibit enhanced crystallization, improved photoluminescence (PL) uniformity and intensity, and long-term reliability. The ASE with improved emission intensity and reduced threshold from evaporated thin film were demonstrated in our previous works (J. Phys. Chem. C, 28, 1211(2017); PSS RRL, 5, 12, (2018)). Notably, the unannealed CsPbBr$_3$ thin films fabricated by thermal evaporation exhibit ultralow ASE threshold of ~ 3.3 μJ/cm$^2$, enhanced crystallization, improved surface morphology and gain coefficient above 300 cm$^{-1}$. Stable ASE intensity without degradation for at least 7 hours is observed under continuous excitation under ambient conditions. Meanwhile, a Fabry-Perot (F-P) cavity layer based on unannealed CsPbBr$_3$ thin film, featuring ultralow threshold and directional output is also realized. Our works advocate that the perovskite thin films possess excellent film morphology and excellent long-term stability which prove to be critical to enhance ASE and lasing performance, as well as highlights the feasibility of evaporated CsPbBr$_3$ thin films as practical optical gain media for the further light-emitting applications.

First Principle Polaron Modeling in Hybrid Perovskites Using the GGA+U Method Eric W. Welsh$^1$, Amanda J. Neukirch$^2$, 3, Sergei Tretiak$^2$, Petr Obraztsov$^4$, 5, Dmitry Lyashenko$^1$, Pavel Chizhov$^1$, Kuniaki Konishi$^6$, Natsuki Nemoto$^6$, Makoto Kuwata-Gonokami$^7$, Petr Obraztsov$^4$, 5 and Alex Zakhidov$^4$, 5; 1Material Science, Texas State University, San Marcos, Texas, United States; 2T-Division, Los Alamos National Laboratory, Los Alamos, New Mexico, United States; 3Institute for Photon Science and Technology, The University of Tokyo, Tokyo, Japan; 4Physics, The University of Tokyo, Tokyo, Japan; 5General Physics Institute, Russian Academy of Sciences, Moscow, Russian Federation; 6Physics and Mathematics, University of Eastern Finland, Joensuu, Finland; 7Physics, Lomonosov Moscow State University, Moscow, Russian Federation; 8Physics, Texas State University, San Marcos, Texas, United States.

Organohalide lead hybrid perovskites (HPs) have become the benchmark, state-of-the-art materials in third generation, perovskite solar cell devices, achieving a power conversion efficiency of over 22%. Yet, the underlying photo-physical properties of HPs are still under debate. Here we use density functional theory within the generalized gradient approximation with a Hubbard correction (GGA+U) to study structural properties, band structures, charge carrier dynamics and electron-phonon coupling in HPs with different compositions. Our preliminary DFT+U simulations reveal the formation of light-induced self-trapped hole polarons in HPs with different halides, which may have profound implications on charge transport, recombination, and experimentally observed device instability under illumination. Moreover, we argue that polaron induced loss of exciton symmetry and enhanced Rasha splitting might be responsible for our recent experimentally observed room-temperature ultrafast photocurrent and free-space terahertz emission generation from unbiased CH$_3$NH$_3$PbI$_3$ benchmark HPs. Polarization dependence of the observed responsese is consistent with the Bulk Photovoltaic Effect caused by a combination of injection and shift currents. Ballistic by nature, these photocurrents may enable next generation perovskite solar cells with efficiency that can theoretically exceed the Shockley–Queisser limit. We also developed a computational method that allows estimating the polaron size, while minimizing self-interaction errors, as well as the overall computational requirement of each calculation.
Surface functionalization of nanoscale materials has significant impacts on their properties due to their large surface-to-volume ratio. In this work, we studied temperature dependent crystal phase transitions in CH$_3$NH$_3$PbI$_3$ (P-OABr-stabilized FAPbI$_3$) films. ASE from MABr-stabilized FAPbI$_3$ films was also achieved, with an ultralow threshold of about 1.6 μJ/cm$^2$. More importantly, upon continuous operation under pulsed laser for several hours, the ASE intensity in the MAPbI$_3$ film decreased to 9% of the initial value, while it was maintained above 90% in the FAPbI$_3$ film. The low trap density, smooth film morphology, high thermal stability, and the excitonic emission in nature of the FAPbI$_3$ film are expected to contribute to its low lasing threshold and high stability, demonstrating a strong potential for applications in continuouswave pumped lasers and electrically driven lasers.

ET05.03.11 High Stability and Ultralow Threshold Amplified Spontaneous Emission from Formamidinium Lead Halide Perovskite Films Xiaoyun Liu; Xi’an Jiaotong University, Xi’an, China.

The opportunity of lasing from organolead halide perovskite materials has recently attracted extensive attention in order to realize electrically driven lasers. So far, for devices with planar structure, most reports focus on CH$_3$NH$_3$PbI$_3$ (MAPbI$_3$) films, which are unstable when in operation due to phase transitions and elemental redistribution. Therefore, we have demonstrated highly stable amplified spontaneous emission (ASE) with ultralow threshold from formamidinium-based perovskite CH$_3$NH$_3$PbI$_3$(FAPbI$_3$) films. ASE from MABr-stabilized FAPbI$_3$ films was also achieved, with an ultralow threshold of about 1.6 μJ/cm$^2$. More importantly, upon continuous operation under pulsed laser for several hours, the ASE intensity in the MAPbI$_3$ film decreased to 9% of the initial value, while it was maintained above 90% in the FAPbI$_3$ film. The low trap density, smooth film morphology, high thermal stability, and the excitonic emission in nature of the FAPbI$_3$ film are expected to contribute to its low lasing threshold and high stability, demonstrating a strong potential for applications in continuouswave pumped lasers and electrically driven lasers.

ET05.03.12 A Novel Series of Quasi-2D Ruddlesden-Popper Perovskites Based on Short-Chained Spacer Cation for Enhanced Photodetection Dong Ruoting, Changyong Lan, Xiwen Xu and Johnny Ho; City University of Hong Kong, Hong Kong, Hong Kong.

Quasi two-dimensional (2D) layered organic-inorganic perovskite materials (e.g. (BA)$_2$(MA)$_n$PbnI$_{3n+1}$; BA = butylamine; MA = methylamine), have recently attracted a wide attention due to their superior moisture stability as compared with three-dimensional counterparts. Inevitably, hydrophobic yet insulating long-chained organic cations improve the stability at the cost of hindering charge transport, leading to the unsatisfying performance of subsequently fabricated devices. Here, we report the synthesis of Quasi-2D (iBA)$_2$(MA)$_{n-1}$PbnI$_{3n+1}$ perovskites, where the relatively pure phase (iBA)$_2$PbI$_4$ and (iBA)$_2$MA$_n$PbnI$_{3n+1}$ films can be obtained. Because of the shorter branched-chain of iBA as compared with that of its linear equivalent (n-butylamine, BA), the resulting (iBA)$_2$(MA)$_{n-1}$PbnI$_{3n+1}$ perovskites exhibit much enhanced photodetection properties without sacrificing their excellent stability. Through hot-casting, the optimized (iBA)$_2$(MA)$_{n-1}$PbnI$_{3n+1}$ perovskite films with $n=4$ give significantly improved crystallinity, demonstrating the high responsivity of 117.09 mA/W, large on-off ratio of 4.0×10$^2$ and fast response speed (rise and decay time of 16 ms and 15 ms, respectively). These figure-of-merits are comparable or even better than those of state-of-the-art Quasi-2D perovskites-based photodetectors reported to date. Our work not only paves a practical way for future perovskite photodetector fabrication via modulation of their intrinsic material properties, but also provides a direction for further performance enhancement of other perovskite optoelectronics.

ET05.03.13 Hybrid Organic-Inorganic Lead Halide Perovskites Investigated by Modulated Surface Photovoltage Spectroscopy Celine A. Omondi; Katrin Hirslandt* and Eva Unger; Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Institut für Silizium-Photovoltaik, Berlin, Germany; Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Young Investigator Group Hybrid Materials Formation and Scaling, Berlin, Germany.

Hybrid organic-inorganic lead halide perovskites have emerged as a new group of materials for highly efficient solar cells (SCs) based on earth abundant elements which can be processed from solutions at low temperature. CH$_3$NH$_3$PbI$_3$(1-x)Br$_x$ perovskite films were studied since it belongs to the materials which are of great interest for top SCs in tandem SCs with c-Si bottom SCs due to its tunable band gap. Electronic properties of CH$_3$NH$_3$PbI$_3$(1-x)Br$_x$ perovskite films sensitively depend on crystallization and defect formation and are crucial for the performance and stability of SCs. The band gap ($E_g$), exponential tail states ($E_T$) and the diffusion length ($L$) are decisive parameters for absorbers in SCs since they give principle limitations for photo-generation and Fermi-level splitting. In CH$_3$NH$_3$PbI$_3$(1-x)Br$_x$ perovskites, $E_T$, $E_g$, and $L$ are not necessarily constant and can depend, for example, on the preparation conditions and degradation. Therefore, $E_T$, $E_g$, and $L$ of CH$_3$NH$_3$PbI$_3$(1-x)Br$_x$ perovskites were studied with respect to stoichiometry, interfaces, degradation and temperature. Modulated SPV spectroscopy allows for the contactless and very sensitive characterization of $E_T$, $E_g$, direction of charge separation and $L$ (after Goodman) without the requirement of the preparation of contacts after or during different stages of layer preparation, light soaking
etc. Vegard’s law was applied to obtain the composition of CH$_3$NH$_3$Pb$_{1-x}$Br$_x$ films. The $E_g$ of CH$_3$NH$_3$PbI$_3$ films varied between 1.59 eV to 2.30 eV depending on the stoichiometry whereas the bowing parameter was 0.36 eV. The influence of the substrate on the band gap $E_g$ of CH$_3$NH$_3$PbI$_3$ was investigated. It has been found, for example, that $E_g$ and $E_s$ of CH$_3$NH$_3$PbBr$_3$ sensitively depend on the substrate and on soaking in nitrogen atmosphere and that light soaking has strong influence on the direction of modulated charge separation. CH$_3$NH$_3$PbI$_3$ deposited on double layers of TiO$_2$/PCBM and SnO$_2$/PCBM showed a constant band gap of 1.58 eV and a low scatter in $E_s$. This was attributed to the modification of the TiO$_2$ or SnO$_2$/CH$_3$NH$_3$PbI$_3$ interfaces by PCBM allowing for efficient charge separation and transfer and well reproducible conditions for the layer formation. A decrease of $L$ with light soaking was observed and can be attributed to light induced degradation due to charging and discharging of trap states and formation of defects at the TiO$_2$/CH$_3$NH$_3$PbI$_3$ interface. Furthermore, $E_g$ and $E_s$ of CH$_3$NH$_3$PbI$_3$ stabilized with PMMA increased with increasing temperature, i.e. thermal expansion gives the predominant contribution to $E_g$ of CH$_3$NH$_3$PbI$_3$ whereas dynamic disorder was limited by phonons. A jump-like increase of $E_s$ in the region of phase transition was attributed to the phase transition from the tetragonal to the cubic phases.

In Situ Grain Encapsulation for Stable Formamidinium-Based Perovskite Solar Cells

Tianhao Liu$^{1,2}$, Yuanyuan Zhou$^1$, Nitin Padure$^1$, Kai Zhu$^2$, Rui Zhu$^2$ and Deying Luo$^2$; $^1$Brown University, Providence, Rhode Island, United States; $^2$School of Physics, Peking University, Beijing, China; $^3$National Renewable Energy Laboratory, Golden, Colorado, United States.

Owing to the wide absorption range and high thermal stability, formamidinium (FA) based lead iodide perovskites have recently emerged as the most promising light-absorber materials for photovoltaics. However, they suffer from fast degradation to undesirable non-perovskite polymorphs in the ambient atmosphere, which retards the real-world application of FA-based PSCs. Herein, a new strategy of in situ grain encapsulation is demonstrated to address this issue. This strategy is realized by co-addition of tetraethylrhodisilicate (TEOS) and H$_2$O into the perovskite precursor solution. The hydrolysis of TEOS produces silica oligomers in the precursor solution. Driven by the perovskite crystallization, silica fills in the grain boundaries and covers the surfaces of perovskite grains, forming encapsulating layers at the “grain”-scale. Silica protects perovskite grains from the ambient air, thus improving the stability. Furthermore, SiO$_2$ passivates defects and reduces the recombination, enhancing the photovoltaic performance. Using the in situ grain encapsulation strategy, FA-based PSCs can exhibit a power conversion efficiency of 19.5% and keep stable for 1000 h in the ambient atmosphere.

Modification of Excitonic Properties of Halide and Mix-Halide Hybrid Perovskite Thin Films Using Interface Engineering

Katerina Nikolaidou$^1$, Som Sarang$^1$, Denzal Martin$^1$, Vincent Tung$^1$, Jennifer Lu$^1$ and Sayantani Ghosh$^1$; $^1$Physics, University of California, Merced, Merced, California, United States; $^2$Materials Science and Engineering, University of California, Merced, Merced, California, United States.

Zinc oxide (ZnO) substrates of varying morphologies, including single crystalline (SC), micro-structured (MS) and nanostructured (NS) substrates, are interfaced with pure (CH$_3$NH$_3$PbI$_3$) and mixed (CH$_3$NH$_3$PbI$_3$xCl$_x$) halide hybrid perovskite thin films. The perovskite/ZnO interfaces are characterized by means of electron microscopy correlated with charge transfer properties that are probed by temperature, power and time-resolved photoluminescence (PL) spectroscopy. SC-ZnO acts as an effective electron extraction layer as evidenced by PL quenching, reduced exciton density and recombination lifetime in the perovskite thin film. On the other hand, MS-ZnO is observed to result in a mild increase of the PL intensity of the perovskite film at room temperature, and NS-ZnO further results in PL intensity enhancement by up to a factor of thousand and increase of recombination rates by 50%. These trends vary with temperature, and our results demonstrate the critical role played by morphology of the underlying substrates in charge dissociation and extraction in perovskite thin films. We conclude that while SC-ZnO can be implemented as an electron extraction layer in photovoltaic devices, MS- and NS-ZnO can be incorporated as scaffold in optical devices that require high quantum yield.

Discovery of the 2D Mixed Halide Perovskites A$^3$Bi$_2$I$_6$Cl$_3$ (A = Cs, Rb)—Exploring the Limits of the Defect Perovskite Structure

Kyle M. McCall, Grant C. Alexander, Oleg Kontsevoi, Bruce Wessels and Mercouri G. Kanatzidis; Northwestern University, Evanston, Illinois, United States.

Halide perovskites have remarkable optoelectronic properties which enabled their success as solar cells, with device efficiencies quickly rising above 22%. Perovskites have the formula A$^3$MX$_6$, where A is a large cation occupying voids between a corner-connected framework of MX$_6$ octahedra. Much of this work is based on the organic-inorganic CH$_3$NH$_3$PbI$_3$ and HC(NH$_2$)$_2$PbI$_3$, however these hybrid perovskites are limited by stability issues which have led researchers to pursue all-inorganic compositions. The tolerance factor of the 3D structure limits the number of such compounds, prompting the extension of the perovskite structure to other main group metals such as Bi$^+$ and Sb$^+$ which retain the n$^0$ lone pair that plays an important role in the halide perovskite electronic structure.

One structure family that maintains a corner-connected MX$_4$ octahedral framework with trivalent M$^+$ are the defect perovskites A$^3$M$_2$X$_6$. We have been investigating the optoelectronic properties of the iodide defect perovskites A$^3$M$_2$X$_6$ (A = Cs, Rb; M = Sb, Bi), finding that these four compounds have strong electron-phonon coupling that results in self-trapped exciton photoluminescence (PL). They also show promise as semiconductor radiation detectors, with each responding to alpha particle irradiation. However, the A$^3$M$_2$X$_6$ are not entirely isostructural. The archetypical structure is a trigonal 2D bilayer that can be viewed as a (111) slicing of the AMX$_3$ structure, caused by an ordered vacancy on every third M site. In contrast, Cs$_3$Bi$_2$I$_6$ has a 3D dimer structure of isolated Bi$_3$I$_9$ octahedra, while Cs$_3$Sb$_2$I$_6$ can form either of these structures depending on preparation method. Even the 2D Rb$_3$M$_2$I$_6$ compounds have distorted octahedra which lower the symmetry to monoclinic. To evaluate the size requirements that govern structure in this family, we modified these 2D and 0D structures using mixed halides.

We found that addition of Cl in a 1:2 ratio with I induced the trigonal 2D structure from the 0D Cs$_3$Bi$_2$I$_6$, resulting in the novel 2D defect perovskite Cs$_3$Bi$_2$I$_6$Cl$_3$ with I atoms on the terminal sites while the Cl atoms take the bridging sites that bind the octahedral bilayers. Cs$_3$Bi$_2$I$_6$Cl$_3$ shows a bandgap of 2.04 eV which is remarkably similar to 2.06 eV bandgap of the 0D parent compound Cs$_3$Bi$_2$I$_6$. Beyond inducing the 0D to 2D transformation, the addition of Cl also converts the monoclinic Rb$_3$Bi$_2$I$_6$ to the higher-symmetry trigonal 2D structure, forming the new compound Rb$_3$Bi$_2$I$_6$Cl$_3$ with a band gap of 2.01 eV. Furthermore, the PL of Cs$_3$Bi$_2$I$_6$Cl$_3$ is nearly identical to that of Cs$_3$Sb$_2$I$_6$, showing that the self-trapped exciton emission is retained even though the inter-octahedral connections consist of Bi-CI bonding. This remarkable finding imparts a greater flexibility to the defect perovskites, as similar optoelectronic properties can be obtained in higher-dimensional structures. These results will guide tuning of these compounds towards functional inorganic perovskites.

Achieving Full Solubility—The Hidden Role of Oleic Acid in Cs Oleate Precursor Preparation for Perovskite Synthesis

Chang Lu, Marcus Wright, Xiao Ma, Hui Li, Dominique S. Itanze, Corey Hewitt, David L. Carroll and Scott M. Geyer; Wake Forest University, Winston Salem, North Carolina, United States.
In the colloidal synthesis of inorganic perovskite materials, cesium oleate (CsOl) is the most commonly used Cs precursor. This precursor is synthesized by combining cesium carbonate (Cs2CO3) or cesium acetate (CsOAc), and the long alkyl chain of CsOl is expected to impart solubility in the non-polar solvents used in synthesis, similar to Pb(oleate). However, despite its ubiquitous use in literature, CsOl has been found to be insoluble at room temperature and leads to surprisingly inconsistent results in perovskite nanocrystal synthesis depending on the Cs salt from which the precursor is derived. We show that under the conditions used in most reports, the amount of oleic acid (OA) added, while stoichiometrically sufficient, still leads to incomplete conversion of the Cs salts to CsOl. This results in a mixture of Cs sources being present during the reaction, causing decreased homogeneity and reproducibility. When a proper Cs:OA ratio is used, complete conversion is readily obtained even under mild conditions, resulting in a precursor solution that is soluble at room temperature and yields identical synthetic results regardless of the initial Cs source. Further, 1H NMR of solutions prepared using varying Cs:OA ratios confirms that the maximum ratio of Cs:OA obtainable in solution, with any excess Cs present in the precipitate. The super-stoichiometric ratio observed is attributed to the monovalent nature of the Cs cation which leads to a permanent dipole moment in Cs oleate, reducing solubility compared to commonly used divalent oleate complexes such as Pb(oleate). Dynamic light scattering reveals that the addition of Cs yields a reverse micelle-like structure with a diameter of 3.1 nm, consistent with the excess oleic acid complexing with the CsOl in the nonpolar solvent. Careful control of the ligand ratio yields a fully soluble precursor, which is shown to enable facile, reproducible, and scalable synthesis via the slow addition of precursors, with the notable ability to control particle morphology through injection rate.

TDDFT Investigation of Hybrid Organic Inorganic Perovskite—CH3NH3PbCl3
Ganesh Subramanian Alwarappan1, Aashik Padmanabhachary1, MD Raiyan Alam2, Aashka Bhundari3, Walid M. Hassani4, Mohamed F. Shihb5, Sunil Patel6, Jeyakumar Ramanujam7, Reza Nekovei7 and Amit Verma1;
1Department of Electrical Engineering and Computer Science, Texas A&M University-Kingsville, Kingsville, Texas, United States; 2Physics of Energy Harvesting Division, National Physical Laboratory, New Delhi, India; 3Indian Institute of Science Education & Research Mohali, Mohali, India; 4Department of Chemistry and Earth Sciences, Qatar University, Doha, Qatar; 5Gas Processing Center, Qatar University, Doha, Qatar.

Hybrid organic-inorganic metal perovskites (chemical formula: ABX3, A-organic cation, B-metal ion, X-halide) are the latest advancements for increasing efficiency in thin-film solar cells or Dye solar cells (DSC). They have become the fastest growing technology in solar cells, rising in efficiency from 3% to 20% in less than a decade. This work focuses on a time-dependent density-functional theory (TDDFT) study of CH3NH3PbCl3 - methylammonium lead chloride - a perovskite material of potential and current research interest.

Both the cubic and tetragonal phases are investigated. The cubic phase for CH3NH3PbCl3 is the room temperature phase for this configuration of the perovskite and it crystallizes in the Pm3m space group, while the tetragonal phase crystallizes in P4mm space group. The cubic structure has an outer PbCl6 octahedra and a central organic methylammonium cation (CH3NH3+). Each Pb is bonded to three CI atoms. The organic cation is not connected to the metal or halide atoms and it exists as a sub-molecule inside the metallic halide cage structure.

All the calculations were performed using Gaussian 16 software package. VESTA is used for building the crystal structures. Cam-B3LYP functional with LanL2dz basis set is used to optimize the structures. The cubic and tetragonal structures are assigned with singlet multiplicity and the net charge of the structures are -3 and -36, respectively, as calculated from the formula ABX3, (A = CH3NH3+; B = Pb 2+; and X = Cl-). Once optimized, frequency calculations and TDDFT calculations are performed at the same level of theory. Electronic and optical properties, including transition energy, band gap, and vibrational frequencies are examined.

The Density of States (DOS) spectrum, IR and UV-VIS spectra as well as the Highest Occupied Molecular Orbitals (HOMO) and Lowest Unoccupied Molecular Orbitals (LUMO) values are computed. It is observed that the cubic phase of CH3NH3PbCl3 shows responsivity for optical excitation between wavelength ranges from 180 nm to 350 nm, with the peak observed at 240 nm. This work will help significantly to understand charge transport and optical properties, and design optimized solar cells involving these materials.

Enhanced Performance of Highly Efficient Formamidinium-Based Perovskite Light-Emitting Diodes via Rubidium Incorporation Yifei Shi,
Zhaoxin Wu, Jinfie Dai, Jie Xu and Ting Lei, Xi'an Jiaotong University, Xi'an, China.

Recently, organometal halide perovskites as promising candidates for light-emitting diodes have been studied greatly. However, for light-emitting application, the low photoluminescence quantum yield (PLQY) of OHPs film is critical to hinder the efficiency improvement of OHP film based light emitting diodes (PeLEDs). Although OHPs exhibit high photoluminescence quantum yield (PLQY~90%) in solution for nanocrystals or quantum dots, PLQY of OHPs is rather low in film state, which is a fatal limit for the high performance of PeLEDs.

To improve the PLQY of perovskite film, low dimensional perovskites were proposed to achieve high PLQY perovskite film. Nevertheless, the long-chain alkyl halides are indispensable to form quasi-2D structure, in which the insulative ligands will restrict the conduction of perovskite films and hamper the movement of carriers. In addition, partial substitution of A-site (ABX3) cations is an effective method to stabilize the crystal lattice and improve the PLQY. It is reported that Cs introduction to perovskite leads to improved PLQY and better stability of device, for example, device efficiency increased form 2.76cd/A to 10.09cd/A. While CsBr exhibits low solubility in solvent which leads to the difficulty in preparation for Cs-doping provskite film, to pursue other better suitable A-site substitute cations is desirable for the higher performance of PeLEDs.

Owing to RbBr exhibits higher solubility than CsBr in solvent, we select RbBr as dopant to incorporate into FAfPbBr3 perovskite film. The optimal precursor is derived. We show that under the conditions used in most reports, the amount of oleic acid (OA) added, while stoichiometrically sufficient, still leads to incomplete conversion of the Cs salts to CsOl. This results in a mixture of Cs sources being present during the reaction, causing decreased homogeneity and reproducibility. When a proper Cs:OA ratio is used, complete conversion is readily obtained even under mild conditions, resulting in a precursor solution that is soluble at room temperature and yields identical synthetic results regardless of the initial Cs source. Further, 1H NMR of solutions prepared using varying Cs:OA ratios confirms that the maximum ratio of Cs:OA obtainable in solution, with any excess Cs present in the precipitate. The super-stoichiometric ratio observed is attributed to the monovalent nature of the Cs cation which leads to a permanent dipole moment in Cs oleate, reducing solubility compared to commonly used divalent oleate complexes such as Pb(oleate). Dynamic light scattering reveals that the addition of Cs yields a reverse micelle-like structure with a diameter of 3.1 nm, consistent with the excess oleic acid complexing with the CsOl in the nonpolar solvent. Careful control of the ligand ratio yields a fully soluble precursor, which is shown to enable facile, reproducible, and scalable synthesis via the slow addition of precursors, with the notable ability to control particle morphology through injection rate.

Two-Dimensional (2D) Halide Perovskites Incorporating Straight Chain Alkylidiammonium Cations, (NH(C4H9)3)2(CH3NH3)PbBr2Cl (m = 4-9; n=1-4) Xiaotong Li1, Justin Hoffman1, Weijun Ke1, Michelle Chen1, Hisinah Tsai2, Mikael Kepenekian3, Constantinos Stoumpos4 and Mercouri G. Kanatzidis5; 1Department of Chemistry, Northwestern University, Evanston, Illinois, United States; 2Los Alamos National Laboratory, Los Alamos, New Mexico, United States; 3Institut des Sciences Chimiques de Rennes, Rennes, France.

Low-dimensional halide perovskites have recently attracted intense interest as alternatives to the three-dimensional (3D) perovskites because of their greater tunability and higher environmental stability. Herein, we present the new homologous two-dimensional (2D) series (NH(C4H9)3)2(CH3NH3)PbBr2Cl, (m = 4-9; n=1-4), where m represents the carbon-chain number and n equals layer-thickness number. Multilayer (n > 4) 2D perovskites incorporating diammonium cations were successfully synthesized by solid state grinding method for m = 4 and 6, and by solution method for m = 7-9. Structural characterization by single-crystal X-ray diffraction for the m = 8 and m = 9 series (n=1 - 4) reveals that these compounds adopt the space group.
of $C_c$ for even $n$ members and $P_r$ for odd $n$ members. The optical bandgaps are 2.15 eV for two-layer ($n=2$), 2.01 eV for three-layer ($n=3$) and 1.90 eV for four-layer ($n=4$), all behaving as direct bandgap semiconductor, also confirmed by DFT calculations. The materials exhibit excellent solution processability and casting the materials of $n=3$ into thin-films was successfully accomplished. The films show a clear tendency for the higher-$n$ members to have preferred orientation on the substrate, with $m = 8$ exhibiting almost perfect vertical layer orientation and $m = 9$ displaying both vertical and parallel layer orientation, as confirmed by GIWAXS measurements. The vertical layer orientation for the (NH$_4$C$_8$H$_2$NH$_3$)(CH$_3$NH$_3$)$_3$PbI$_{10}$ member results in the best thermal, light and air stability within this series, thus showing excellent potential for solar cell applications.

Temperature-Dependence of Perovskite Solar Cell Efficiency Revealed by Electron Spin Resonance and Photocurrents
Nam Joong Jeon, Jangwon Seo, S. H. Kim, J. M. Cho and Jung-Keun Lee; 1Chonbuk National Univ, Jeonju, Korea (the Republic of); 2Korea Research Institute of Chemical Technology, Daejeon, Korea (the Republic of); 3Korea Basic Science Institute, Seoul, Korea (the Republic of); 4Research Institute, TOpenCo., Ltd., Daejeon, Korea (the Republic of).

We have investigated the temperature-dependence of light-induced electron spin resonance (LESR) and photocurrents in perovskite solar cells. The perovskite layer was (FAPbI$_3$)$_{0.85}$(MAPbBr$_3$)$_{0.15}$. PCBM and doped-PTAA (poly-triarylamine) layer was used as an electron transport layer (ETL) and hole transport layer (HTL), respectively. The temperature-dependence of LESR suggested the existence of an interfacial thermal barrier and charge accumulation between the perovskite and the HTL. The temperature-dependence of the photocurrents reflected that most of the photocurrents are temperature-independent and ESR silent. However, part of the currents experience thermal barrier, passing through the interfacial states, and also are detected by ESR.

ET05.03.23

Surface Modification of Mesoporous TiO$_2$ Layer with Self-Assembled Monolayers for the Fabrication of High Efficiency Perovskite Solar Cells
Seid Yimer Abate$^{1,2}$ and Yu-Tai Tao$^3$; 1Institute of Chemistry, Academia Sinica, Taipei, Taiwan; 2Taiwan International Graduate Program (TIGP), Sustainable Chemical Science and Technology (SCST), Academia Sinica, Taipei, Taiwan; 3Department of Applied Chemistry, National Chiao Tung University, Hsinchu, Taiwan.

Hybrid organic-inorganic halide perovskite solar cells attract enormous attentions due to their excellent photovoltaic properties which can compete with that of the crystalline silicon solar cells. However, there are some issues in perovskite solar cell that need to be fully understood and solved before its commercialization. These include the operation mechanism, device stability, environment impact, and so on. In this study, charge extraction characteristics at the perovskite/TiO$_2$ interface is studied by interface engineering. So that self-assembled monolayer of phosphonic acids with different chain length (spacer group) and functional (tail) group were adsorbed on mp-TiO$_2$ at -4.19 eV. A correlation of charge mobility, charge extraction and transport with respect to the energy alignment of mp-TiO$_2$ was demonstrated. The work function of the SAM-modified mp-TiO$_2$ varied from -3.80 eV to -4.87 eV, with that of the crystalline silicon solar cells. However, there are some issues in perovskite solar cell that need to be fully understood and solved before its commercialization.

ET05.03.24

Highly Luminescent and Stable Bromide Perovskites via the Formation of Low Dimensional Architectures
Mingue Shin$^1$, Joonyun Kim$^1$, Young-Kwang Jung$^2$, Tero-petri Ruoko$^3$, Arri Primagi$^2$, Aron Walsh$^{+3}$ and Byungha Shin$^1$; 1KAIST, Daejeon, Korea (the Republic of); 3Korea Basic Science Institute, Seoul, Korea (the Republic of); 4Research Institute, TopnC Co., Ltd., Daejeon, Korea (the Republic of).

Organic-inorganic halide perovskites have been attracting attention as materials for light-emitting diodes (LEDs) due to unique emission properties, which include high color purity with a very narrow emission and tuning the emission wavelength easily through the adjustment of the halide components, covering the entire range of visible light. However, one roadblock to LED application is the low exciton binding energies, which results in low luminous efficiencies. One of the proposed strategies to enhance the exciton binding energy is reduction of the dimensionality of the perovskite crystal structure. Here, we report highly luminescent thin films of formamidinium (FA) lead bromide perovskite (photoluminescence quantum yield, PLQY = 35.7%) via the formation of low dimensional architectures. A mixture of 3D FAPbBr$_3$ and a new type of 2D perovskite FA$_2$PbBr$_4$, intercalated with dimethyl sulfoxide (DMSO) was formed by controlling the molar ratio of FABr/PbBr$_3$ in the precursor solutions and annealing condition. A type I band alignment between the lower bandgap 3D FAPbBr$_3$ and the higher bandgap 2D FA$_2$PbBr$_4$ was supported by density functional theory (DFT) calculations, which results in exciton confinement in the 3D phase and a substantial increase in PLQY. The composite films also exhibited excellent air and thermal stability. Details of analysis will be presented and discussed.
ET05.03.25
Ultra-High Purity, Monocrystalline Quality Hybrid Perovskite Thin Sheets for Radiation Detectors

Hisato Yamauchi, Fangze Liu, Hsinhan Tsai, Michael D. Yoho, Aditya D. Mohite, Sergei Tretiak, Duc T. Vo and Wanyi Nie; Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

Halide perovskite materials synthesized via cost-effective solution process recently emerged as a promising candidate for detection of X-ray and gamma-ray. This is because of their high radiation absorption cross section in presence of heavy elements in the lattice, long mobility-lifetime product, balanced carrier mobility, which leads to high detectivity and energy resolutions. The current challenge is to synthesize large-scale high quality single crystals with minimal structural defects in both of bulk and surface. In this study, we report high quality Methylammonium Lead Bromide (MAPbBr3) single crystals that are prepared via modified inverted temperature crystallization (ITC) approach from precursor solution. With balanced crystalline-rate and proper choice of growth volume, we obtain mono-crystal with well controlled thickness from 400 nm up to 10 µm. Obtained mono-crystals demonstrate high material quality by the narrow peak width of X-ray diffraction (XRD) spectra that is comparable to the values reported for its bulk single crystals via ITC. In addition, the surface roughness is an order of magnitude lower compared to the bulk counterpart with homogeneous surface charge distribution. Our high quality crystals with smooth surface are further fabricated into diodes with PIN junction by sandwiching them in between p-type and n-type electrodes. The dark current noise of the two terminal devices is as low as 50 pA/V, several orders of magnitude lower compared to our bulk crystals via ITC. Such crystals are ideal for extracting ultra-low density of carrier with radiation excitations.

A Comprehensive Approach to Measuring and Understanding the Electronic Structure of Lead-Halide Perovskite Materials

Alexandra Ramadan1, Maryline Ralaiarisoa2, Fengshuo Zu2, Jonathan Warby1, Norbert Koch1 and Henry Snaith1; 1Department of Physics, University of Oxford, Oxford, United Kingdom; 2Humboldt-Universität zu Berlin, Berlin, Germany.

Perovskite-based photovoltaics are an emerging solar technology, with device efficiencies exceeding 22 % and significant steps are being made towards their commercialisation. In spite of the impressive strides made in device performance and stability, fundamental characterisation of these materials is still severely lacking. Studies of the electronic structure of perovskite materials have resulted in a broad range of values reported for the electronic energy levels and the instability and complex nature of these systems has resulted in a lack of consensus in the electronic properties of these materials. To tackle this ambiguity we have developed a new comprehensive approach to understanding the electronic structure of a perovskite.

In this work the all inorganic perovskite cesium lead bromide (CsPbBr3) is used as a model system. This material was selected as it demonstrates a high stability of both the perovskite material and its non-volatile precursors. We begin by probing the electronic structure of CsBr and PbBr2, we investigate the electronic structure and their contribution to the overall electronic structure of our CsPbBr3. Films prepared with varying concentrations of the precursor materials up to the full perovskite structures have been investigated using x-ray photoemission spectroscopy (XPS), ultraviolet photoemission spectroscopy (UPS) and inverted photoemission spectroscopy (IPES). The surface chemistry of the films, as determined from UPS and IPES, will be presented. This information is then correlated with morphological and structural data, provided by atomic force microscopy (AFM) and x-ray diffraction (XRD). These techniques enable a full picture of the electronic structure of these systems to be developed and provides a method through which the structure of other perovskite materials can be investigated.

ET05.03.28
Thermodynamic Stability of Halide Perovskites

Alessandro Senocra1,2, Gee Yeoong Kim1 and Joachim Maier1; 1Max Planck Institute for Solid State Research, Stuttgart, Germany; 2École Polytechnique Fédérative de Lausanne, Lausanne, Switzerland.

Hybrid halide perovskites (HOIPs) have been extensively studied in recent years due to their potential use as light-harvester in photovoltaic devices. While the efficiencies of such devices pose no limitation to commercial applications, the severe lack of stability of the materials remains an important issue to be overcome. Indeed, HOIPs are known to easily degrade under moderate thermal stress[1] or upon oxygen[2] and/or light exposure.[3] Notably, recent calorimetric studies even suggested that some HOIPs (MAPbI3 in particular and MAPbBr3 to a minor extent) could be thermodynamically unstable,[4] in agreement with DFT calculations.[5] In contrast, other studies indicate the materials to be intrinsically stable.[6] Obviously these questions need to be unambiguously answered. In this contribution, we discuss the underlying thermodynamics of HOIPs both intrinsically (i.e., with respect to temperature) and extrinsically (against oxygen exposure and/or light). Intrinsically, we find the materials to be stable (albeit, in the case of MAPbI3, only slightly) under standard conditions, and we also can assess the most favorable degradation path upon heating. Extrinsically, our considerations reveal a large tendency towards degradation of HOIPs in the presence of oxygen, especially under real conditions. Notably, light itself can activate a relevant photodecomposition pathway.[7] We discuss these issues on a quantitative level, in conjunction with experimental observations of the degradation phenomena.

Enhanced Photoresponse in Hybrid Perovskite Thin Film via Integrating with MoS2

Jingfeng Song1, Dawei Li1, Bo Chen2, Zhiyong Xiao1, Yongfeng Lu1, Jinsong Huang2 and Xia Hong1; 1University of Nebraska–Lincoln, Lincoln, Nebraska, United States; 2University of North Carolina-Chapel Hill, Chapel Hill, North Carolina, United States.

Over the past five years, the organolead trihalide perovskites such as CH3NH3PbI3 (MAPbI3) have gained significant research interests with a rapid rise of power conversion efficiency of up to 22%. Integrating MAPbI3 with the two dimensional transition metal dichalcogenides such as MoS2 has the potential of achieving enhanced photosensitivity and broadened absorption bandwidth. In this work, we have integrated MAPbI3 polycrystalline thin film with few-layer MoS2 and demonstrated up to two orders of magnitude enhancement of the photoresponse in the heterostructure compared with the single layer MAPbI3 and MoS2. We mechanically exfoliated few-layer MoS2 flake and transferred it onto the SiO2/Si substrate. The sample was fabricated into 2 point device, on top of which we spincoated uniformly 500 nm MAPbI3 film. Between the two parallel Au electrodes, half of the area contains the MoS2-MAPbI3 hybrid structure, while the other half contains only single layer MAPbI3. We performed high-resolution photocurrent mapping within those two channels, and observed that the MoS2-MAPbI3 region had up to two orders of magnitude higher photocurrent than single layer MAPbI3. The enhancement
is attributed to the charge transfer between these two materials due to band alignment, which facilitated photo-carrier separation. The MoS2-MAPbI3 hybrid device showed faster transient photoresponse of 200-300 μs, which makes it promising for constructing high performance photo-detectors.

**Perovskite LEDs using ZnMgO Interfacial Layer**

Hua Wu1, Yu Zhang2 and William Yu3; 1Louisiana State University Shreveport, Shreveport, Louisiana, United States; 2Jilin University, Changchun, China.

Perovskite quantum dots are promising optoelectronic materials but are very sensitive to oxygen and water. Here, we report a highly efficient and stable light emitting device (LED) by applying solution-processed Mg-doped ZnO (MZO) nanocrystals (NCs) as an interfacial layer. We investigated the effect of Mg doping on the optical and electronic properties of NCs. We demonstrated that the air stability of perovskite NC film was significantly enhanced because of the decreased oxygen vacancy surface sites of MZO NCs. Incorporation of a MZO layer with favorable electronic energy level to form a suitable band alignment promoted electron injection and enhanced the LED performance. Compared to the device without MZO, the LED showed 3059 cd/m² of luminance, with 1.9 times enhanced current efficiency and 2 times increased external quantum efficiency. In addition, the device with MZO also exhibited better operation and storage stability. This research provides a potential strategy for realizing stable and efficient perovskite LEDs.

**Efficient and Stable White LEDs Using Silica-Coated Perovskite Quantum Dots**

Chun Sun1, Yu Zhang2 and William Yu1; 1Louisiana State University Shreveport, Shreveport, Louisiana, United States; 2Jilin University, Changchun, China.

Inorganic perovskite QDs (CsPbX3), with narrow size distribution, narrow emission line width, as well as high PL QY without surface shelling, have broad applications. Their emission lights cover the entire visible spectral region and can be easily adjusted. However, their instability and the anion-exchange reaction between different halide QD particles when used together are still the major issues that obstruct their practical applications. In this work, (3-amino(prop)|trithiophosyilane (APTES) was chosen as both the capping agent for inorganic perovskite QDs and the precursor for a silica matrix. All chemicals were mixed in a water-free synthesis system to form perovskite QDs, then the system was open to the air and the trace water vapor was captured and reacted with APTES for its hydrolysis for the matrix before contacting the QD surface. In this way, a silica matrix was slowly formed but the delicate perovskite QDs were protected. This is an easy one-pot operation and can be done with large quantities. The as-prepared QD/silica composites possesses high PL QY. Most importantly, the composites exhibited extremely high stability in air and the anion-exchange reactions were not observed between different perovskite QDs, which are beneficial to fabricating the white LEDs. By combining the green and red QD/silica composites with a blue LED chip, a white LED with CIE color coordinates of (0.33, 0.33) and a power efficiency of 61.2 lm/W was obtained, demonstrating their application potentials in such as white lighting.

**Material Preparation and Emission Properties of Pure and Pr3+ Doped CsPbCl3 Perovskite Crystals for Photonics and Radiation Detection**

Uwe Hermersch1, Lianjah Flagg1, Al Amin Kabir1, Altha Bluets1, Sudhir Trivedi2, Clayton S. Yang3 and Feng Jin1; 1Hampton Univ, Hampton, Virginia, United States; 2Chemistry, Geology, and Physics, Elizabeth City State University, Elizabeth City, North Carolina, United States; 3Brimrose Technology Corporation, Sparks Glencoe, Maryland, United States.

We report on the material preparation and emission properties of pure CsPbCl3 and Pr3+ doped CsPbCl3 perovskite crystals for possible applications in multi-wavelength photonics and nuclear radiation detection. The material properties of lead halide perovskites continue to be of great current for optoelectronic applications such as solar cells, light emitting diodes, lasers, and radiation detectors. In this work, we prepared pure and Pr3+ doped CsPbCl3 bulk crystals in an effort to further extend its functionality. The investigated materials were synthesized from purified precursors of PbCl2, CsCl, and PrCl3 followed by melt growth in a vertical Bridgman station. Purification steps included directional freezing and multi-pass unidirectional translation in a zone-melting system. The pure CsPbCl3 crystal exhibited a light yellow color, whereas the Pr: CsPbCl3 crystal was light green indicating the incorporation of Pr3+ ions into the host lattice. Under UV optical pumping (340 nm) the pure CsPbCl3 samples showed bandedge related emission centered at ~410 nm and a broad defect-related emission band extending to ~600 nm. The Pr: CsPbCl3 samples exhibited a bright red emission under resonant intra-4f excitation of Pr3+ ions at 450 nm, with strongest lines peaking at 492 nm, 621 nm, 647 nm, and 732 nm. Furthermore, the Pr: CsPbCl3 sample also exhibited IR emission bands centered at ~1.6 μm, ~2.5 μm and ~4.5 μm under optical pumping at ~1500 nm. The observation of IR emission at room temperature reflects on the low maximum phonon energy of chloride crystals (< 250 cm⁻¹), which reduced non-radiative decay though multiphonon relaxations of Pr3+ ions. More details of the material preparation, emission properties of pure and Pr3+ doped CsPbCl3 crystals as well as initial studies for nuclear radiation detection will be presented at the conference.

**ET05.03.33**

**Super-Resolution Infrared Imaging of Mixed Cation Perovskites—Local Compositional Heterogeneities**

Ilija M. Pavlovec1, Rusha Chatterjee, Kyle Aleshire, Gregory Hartland and Masaru Kuno; Department of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, Indiana, United States.

Hybrid organic-inorganic lead halide perovskites such as MAPbI3 or FAPbI3 (MA=CH3NH3+ and FA=CH(NH2)2+) and their mixed cation analogues represent one of the most promising alternatives to conventional Si based solar photovoltaics. Intriguing aspects include tunable band gap depending on composition, large optical absorption coefficients, and certified power conversion efficiencies (PCEs) that now exceed 22%. Additionally, composition-based tunable band gap makes these systems ideal candidates for multi-junction solar cells. Unfortunately, there has been relatively little work done to explore perovskites compositional cation uniformity. Variation in cation stoichiometry may represent an important limiting factor for these devices as bandgaps – and by immediate extension open circuit voltages – are exquisitely sensitive to local cation composition. Although reports already exist, suggesting cation compositional heterogeneity across perovskite films, this is the first direct study of this phenomenon. Here, we provide the first direct evidence for intrafilm cation heterogeneities within mixed cation FA0.8MA0.2PbI3 films using a spatially-resolved, super-resolution infrared photothermal heterodyne imaging (IR-PHI) technique. We establish that these films exhibit large compositional spatial heterogeneities with cation distributions varying on the order of ~20%, with some areas exceed stoichiometric differences that exceed thrice the expected ideal stoichiometry. The impact of these cation heterogeneities is further corroborated by emission measurements showing intrafilm emission energies differing by over 30meV directly correlated to local stoichiometry. These measurements thus reveal, for the first time, cation stoichiometric heterogeneities and their direct impact on local photovoltaic response-determining optical properties of mixed cation perovskites.
ET05.03.34 Highly Efficient and Hysteresis-Less Planar Perovskite Solar Cell with Enhanced Open Circuit Voltage and Stability Mohammad Mahdi Tavakoli1, Punkaj Yadav2, Roudollah Tavakol1 and Jing Kong1; 1Electrical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Solar, Pandit Deendayal Petroleum University, Gujarat, India; 3Sharif University of Technology, Tehran, Iran (the Islamic Republic of).

Interfacial studies and band alignment engineering on electron transport layer (ETL) play a key role for fabrication of high performance perovskite solar cells (PSCs). Here, we inserted an amorphous layer of SnO2 (a-SnO2) between the TiO2 ETL and the perovskite absorber and studied on the charge transport properties of the device. The double-layer structure of TiO2-compact layer (c-TiO2) and a-SnO2 ETL leads to modification of interface energetics, resulting in improved charge collection and decreased carrier recombination in PSCs. The optimized device based on a-SnO2/c-TiO2 ETL shows a maximum power conversion efficiency (PCE) of 21.4% as compared to 19.33% for c-TiO2 based device. Moreover, the modified device demonstrates a maximum open circuit voltage ($V_{oc}$) of 1.223 V with 387 mV loss in potential, which is among the highest value reported for PSCs. In addition, the optimized PSC depicts a negligible hysteresis, and stabilized performance measured under continuous light (AM 1.5G) and UV light illumination. The stability results show that the device on c-TiO2/a-SnO2 retains about 91% of its initial PCE value after 500 h light illumination, which is higher than that pure c-TiO2 (67%) based devices. Interestingly, using a-SnO2/c-TiO2 ETL the PCE loss was only 10% of initial value under continuous UV light illumination after 30 h, which is higher than that of c-TiO2 based device (28% PCE).

ET05.03.35 Prediction of Novel $p$-Type Transparent Conductors in Layered Double Perovskites—A First-Principles Study Jian Xu1,2, Jian-Bo Liu1, Bai-Xin Liu1 and Bing Huang1; 1Tsinghua University, Beijing, China; 2Beijing Computational Science Research Center, Beijing, China.

The development of high-performance transparent conducting oxides (TCOs) is critical to various technologies from transparent electronics to solar cells. Whereas $n$-type TCOs have been extensively applied in many electronic devices, their $p$-type counterparts have not been largely commercialized due to the lack of ideal materials. Combining atomic replacement and first-principles calculations, we have identified 7 stable layered double perovskites, i.e., CsCuSbCl$_{12}$-like Cs$_{2}$M$^{2+}$B$^{3+}$X$_{12}$ compounds as promising $p$-type TCOs with sufficiently large bandgaps, delocalized wavefunction distribution with s-orbital components in valence band maximum (VBM) and the antibonding character of VBM to ensure their optical transparency, light hole effective masses and intrinsic good $p$-type conductivities, respectively. Taking CsCuSbCl$_{12}$ as a representative example, we demonstrate that under Cd-poor (Cl-rich) conditions, Cs$_{2}$Sb$_{5}$Cl$_{12}$ could exhibit excellent $p$-type conductivity with high hole concentration, contributed by the intrinsic shallow-acceptor C$_{do}$ with extremely low formation energy. Generally, the other 6 Cs$_{2}$M$^{2+}$B$^{3+}$X$_{12}$ compounds exhibit similar intrinsic $p$-type defect properties as CsCuSbCl$_{12}$, which could rank them as the top $p$-type TCOs discovered or predicted until now.

ET05.03.36 Direct observation of deep defects in wide bandgap Halide Perovskites Jialin Levine1, Giovanni Corcione2, Nano Garcia Verar, Michael Kulbak1, Carolin Rehermann2, Eva L. Ungerechts3, Gary Hodes3, Isaac Balberg3, David Cahen3 and Thomas Dittrich3; 1Weizmann Inst of Science, Rehovot, Israel; 2Helmholtz-Zentrum Berlin für Materialien und Energie, Berlin, Germany; 3The Hebrew University of Jerusalem, Jerusalem, Israel.

Lead Bromide-based perovskites (HPs) are of interest as parent composition for wide bandgap (> 1.75 eV) absorbers for low-cost solar spectrum splitting to boost solar-to-electrical energy conversion efficiency/area by adding them to c-Si or CIGS PV cells, and for photoelectrochemical solar fuel synthesis. Deep in-gap electronic states in solar cell absorbers serve as recombination centers and are detrimental for the cell’s photovoltaic performance, especially the open circuit voltage ($V_{oc}$) of the cell. However, since several studies showed that the concentration of defects in the HPs is relatively low (< 10$^{14}$ cm$^{-3}$), there is a general difficulty to observe deep in-gap states by direct optical absorption of sub-band gap photons in the HPs. Here we use modulated Surface PhotoVoltage (SPV) measurements, a non-destructive contactless technique that relies on direct sub-gap band gap absorption, with exponentially higher sensitivity than photocurrent-based measurements. SPV can show the existence of in-gap states and their relative positions with respect to the band edges both within the bulk semiconductor band gap, as well as at the interfaces of the HP with the Electron Transport Layer (ETL) or the Hole Transport Layer (HTL).

For the first time, we reveal that three different, deep, defect levels exist in the bulk of the mix- Cation Lead Tribromide layers. Two of the levels are close to midgap, and the third lies ~0.8 eV below the Conduction Band Maximum (CBM). We also find that aging in inert atmosphere, as well as light soaking, increases the defect concentration. Furthermore, by performing photoconductivity measurements over a wide excitation intensity range, we show that under steady-state 1-sun equivalent conditions, this sub-band gap defect levels play an active role as non-radiative recombination centers.

ET05.03.37 Composition Engineering and Microspectroscopic Study for Efficient and Spectrally Stable Mixed Halide Perovskite LEDs Yongheng Jia, Yuwei Guo, Yang Zhou and Ni Zhao; EE, The Chinese University of Hong Kong, Hong Kong, Hong Kong.

Quickly following the development of perovskite solar cells, the field of perovskite light-emitting diodes (LEDs) has proceeded rapidly, with some devices already showing comparable efficiencies with those of the state-of-the-art organic LEDs. Perovskite LEDs offer tunable emission wavelength from visible to near-infrared; however, in certain temperature range the device performance is highly unstable. Taking red-emitting perovskite LEDs as an example, since the devices often rely on a mixed bromide-iodide perovskite for light emission, the typical light-induced phase segregation behavior of the material system results in a rapid red-shift of the electroluminescence (EL) peak, leading to a color change of the LEDs. In this presentation, we will introduce our recent endeavors on composition engineering and optical microspectroscopy to address the aforementioned stability problem of perovskite LEDs. We show that by simultaneously introducing lead thiocyanate and organoiodine additives in the perovskite precursors one can obtain a stable perovskite phase with high photoluminescence quantum yield (PLQE). The corresponding LEDs exhibit stable spectral emission and good performances (e.g., irradiance of 400 W sr$^{-1}$ m$^{-1}$, maximum external quantum efficiency (EQE) of 14.5% and maintained at 12.0% at a high current density of 500 mA/cm$^2$), despite the fact that perovskite film is discontinuous. The material strategy has been examined in the wavelength range from 630nm to 700nm. To better understand the morphology-performance correlation, we apply charge-modulation microspectroscopy (CMM) to investigate the electric-field inhomogeneity in the perovskite film, the impact of electron- (or hole-) transport layer on the LED EL properties, as well as the spatially resolved degradation processes in the electrode-covered and –uncovered regions. The findings provide some guidelines to the design of perovskite LED structures.

ET05.03.38 Highly Luminescent 0D Organic Metal Halide Hybrids with Tunable Colors Chenkun Zhou1, Haoran Lin1, Michael Worku1, Jennifer Neu1, Yan Zhou1, Yu Tian1, Peter I. Djurovich3, Theo Siegrist3 and Biwu Ma1; 1Florida State University, Tallahassee, Florida, United States; 2University of Southern California, Los Angeles, California, United States; 3FAMU-FSU College of Engineering, Tallahassee, Florida, United States.

Organic-inorganic metal halide hybrids, consisting of a great variety of inorganic metal halide anions and organic cations, are an emerging class of functional crystalline materials with exceptional structural tunability. By choosing appropriate organic and inorganic components, the crystallographic
structures can be finely engineered with the inorganic metal halides forming three-dimensional (3D) networks, two-dimensional (2D) planar or corrugated layers, one-dimensional (1D) chains or tubes as well as zero-dimensional (0D) structures. The structural versatility of this class of materials suggests there is a vast parameter space to explore novel crystal structures exhibiting properties obeying non-obvious trends.

In this talk, I will present our recent efforts in developing and studying new classes of 0D metal halide hybrids. By choosing appropriate organic and inorganic components, the emitting species in 0D structure can be tuned from MX₃ octahedra to MX₅ pyramids, MX₆ seass structure, and metal halide clusters. Due to the structural reorganization and efficient ionic system cross the on the excited states, highly luminescent broadband emissions with large Stokes shift have been achieved for these 0D metal halide hybrids. Our findings show the molecular nature of small metal halide species in the 0D structure and allow us to relate the emission from either structure reorganization or localized excitons in metal halides to molecular phosphorescence. The application of these 0D materials as down converter in optically pumped white light emitting diodes will also be discussed.

ET05.03.39
Solvent Effects on the Thin-Film Quality and Photovoltaic Performance of Metal Halide Perovskites Yuchen Zhou¹, Yifan Yin¹, Chang-Yong Nam¹ and Miriam Rafailovich¹; Stony Brook University, Stony Brook, New York, United States; ²Center for Functional Nanomaterials, Brookhaven National Laboratory, Upton, New York, United States.

The metal halide perovskite solar cells (PSCs) has become one of the most popular types of photovoltaic devices in past 6 years. High power-conversion efficiency (PCE), panchromatic light absorptions and long carrier diffusion length, etc, makes the PSCs significantly competitive among the thin film solar cells. However, optimal function and performance of the PSCs usually require high quality of a perovskite film with full coverage, low roughness, big grain size and proper thickness, etc. Numerous methods have been applied to make high quality perovskite film, among which, the solution-based spin casting is one of the most widely used methods. Although different groups have succeeded in making perovskite film using the spin casting, specific conditions such as solvent type, thermal treatment etc, varies largely. Lack of rational comparisons and instructive guidance on the deposition condition selection result in huge difficulty in performing repeatable experiments. Herein, we compare the effect of solvents, co-solvents and their ratios on the quality of the perovskite thin films. DMF and/or GBL are used as major solvents, while DMSO is applied as the co-solvent. Several ratios of DMF/GBL to DMSO from 10:0, 9:1 to 7:3 have been tried to prepare the perovskite precursor solutions. Interestingly, we observe significant differences on crystallinity, morphology and thickness of the thin film made by different types and combination of solvents. For instance, 1) From the XRD data, perovskite deposited from DMF based solution exhibits 10 times stronger crystallinity as compared with samples made from GBL. 2) SEM images indicate that DMF based solution guarantees compact and 2 times thicker films than the GBL ones, while the surface of DMF made layer shows much higher roughness. 3) Reducing the amount of the DMSO in the solution can promote the smoothness of the surface but result in the decrease of the film thickness. 4) Crystals with smaller grain size are observed in samples made from solution without DMSO, while excessive of DMSO content leads to vacancies inside the films. 5) Films deposited from the combined solvents of 90% DMF and 10% DMSO presents best compactness, thickness, smoothness and crystallinity among all other solvent combinations, showing 1.5-2 times longer charge carrier lifetime and superb PCE with the best device exceeding 17%. We attribute the better quality of the DMF deposited layers to higher PbI₂ solubility and lower boiling point of the DMF, as compared with GBL. The addition of DMSO slows down the crystal growth rate of perovskite by forming MAI-DMSO-PbI₂ intermediate, guaranteeing larger crystal grain size. While excessive DMSO, which does not participate in the formation of the intermediates, remains in the supersaturated film (before annealing) and causes rupture and vacancies in the film during the vigorous annealing process. (This work was supported by the Morin Foundation Trust and the NSF, Inspire program #1344267)

ET05.03.42
Effect of Chromium Doping on the Electronic Structure of CH₃NH₃PbI₃ Perovskite Mapeng Nam1, Christopher McCleese2, David Stewart1, 2, Tod Grusenmeyer1, Thomas M. Cooper1 and Joy Haley1; 1Air Force Research Laboratory, Dayton, Ohio, United States; 2General Dynamics Information Technology, Dayton, Ohio, United States.

Organic-inorganic lead halide perovskites (mainly CH₃NH₃PbI₃) are being extensively studied because their excellent photovoltaic properties, such as small bandgap, high optical absorption and long carrier lifetime. To explain the large recombination time, the hypothesis that the formation of ferroelectric domains can separate the diffusion pathways of electrons and holes, has been proposed. We have found that a two-dimensional hole confinement in CH₃NH₃PbI₃ is possible under room temperature conditions.

In this work, we explore the possibility of increasing their photovoltaic efficiency through additional sub-bandgap absorption. This would result in the creation of extra electron-hole pairs and in an increase in photocurrent without a decrease in open-circuit voltage. We assess the formation of a new band in the gap as well as its effect on the absorption features of hybrid halide perovskites CH₃NH₃PbI₃ (MAPI). This approach has been widely studied to improve the efficiency of common semiconductors with photovoltaic performance such as GaP, CuInS₂, thiospinels, SnS₂ or Sn. We report here the electronic structure of new CH₃NH₃PbI₃ perovskite derivatives, in which narrow band is obtained by replacing Pb atoms by Cr atoms. To deal with the bandgap underestimation problem of common DFT methods, quasiparticle calculations have been applied via the GW approximation. The investigation of the electronic structure of new CH₃NH₃PbI₃ perovskites suggests that the presence of point defects play an important role in the coupling of two low energy photons to achieve a higher energy electron excitation (like in the Z-scheme of photosynthesis), which would maximize the photovoltaic performance.

ET05.03.43
Monitoring Nonradiative Charge Carrier Recombination and Extending the Excited State Lifetimes in Methylammonium Lead Bromide Perovskite Nanocrystals Christopher McCleese¹, David Stewart¹, ², Tod Grusenmeyer¹, Thomas M. Cooper¹ and Joy Haley¹; ¹Air Force Research Laboratory, Dayton, Ohio, United States; ²General Dynamics Information Technology, Dayton, Ohio, United States.

Lead halide perovskites have applications in the fields of photovoltaics, light emitting diodes, and lasers. Their success results from their high absorption coefficients, low exciton binding energy, long charge carrier diffusion lengths, and high photoluminescence quantum yields. In order to optimize these devices to their full potential, it is important to understand their fundamental photophysical properties and how processing conditions affect their optical and electronic properties. Currently in the literature, the majority of time-resolved optical studies on perovskite nanocrystals utilize time-resolved photoluminescence to determine the excited state lifetimes. However, the nonradiative recombination processes should be further investigated due to the fact that they can have drastically different charge carrier recombination rates. Here, steady state and time-resolved optical spectroscopy is used to study the photophysical properties of hybrid organic-inorganic methylammonium lead bromide nanocrystals. Time-resolved spectroscopy measurements show that the band edge bleach decay dynamics are longer compared to the photoluminescence decay. These results indicate that dark carrier recombination is the primary mechanism leading to the long lived excited state lifetime of perovskite nanocrystals. Additionally, the effect of the precursor starting material purity on the excited state lifetimes is investigated.

ET05.03.44
Mapping the Inter-Diffusion of A-Site Cations in Metal Halide Perovskites Sarthak Jariwala, Irika Sinha, Kathryn N. Guye and David S. Ginger;
Organic-inorganic metal halide perovskites have emerged as attractive materials for solar cells with power-conversion efficiencies now exceeding 21%. We discuss the fundamental photophysical processes that have enabled these materials to be such efficient light-harvesters and charge collectors.

As photovoltaic power conversion efficiencies of single-junction cells approach the Shockley-Queisser limit, the recombination and mobility of charge-carriers will be limited only by intrinsic properties. We demonstrate that at the intrinsic limit, the mobility of charge-carriers is predominantly governed by interaction of carriers with optical vibrations of the lead halide lattice (Fröhlich interaction)\(^1\). Therefore, predictions of maximum attainable mobilities can be made from easily accessible parameters, such as LO phonon frequencies and limits of the dielectric function.\(^2\)

In the absence of trap-mediated charge recombination, bi-molecular (band-to-band) recombination will dominate the charge-carrier losses near the Shockley-Queisser limit. We show that in methylammonium lead triiodide perovskite, such processes can be fully explained as the inverse of the radiative recombination processes is a critical factor determining device efficiency. We demonstrate that at the intrinsic limit, the mobility of charge-carriers is predominantly governed by interaction of carriers with optical vibrations of the lead halide lattice (Fröhlich interaction)\(^1\). Therefore, predictions of maximum attainable mobilities can be made from easily accessible parameters, such as LO phonon frequencies and limits of the dielectric function.\(^2\)

Finally, we examine the prospect of such highly performing hybrid lead iodide perovskites in solar concentrator environments.\(^3\) We demonstrate that in the absence of degradation, perovskite solar cells can fundamentally exhibit appreciably higher energy-conversion efficiencies under solar concentration, where they should be able to exceed the Shockley-Queisser limit and exhibit strongly elevated open-circuit voltages.

9:00 AM ET05.04.04
Impact of the Rashba Effect on Radiative Recombination in Hybrid Perovskites Xie Zhang, Jimmy-Xuan Shen, Wennie Wang and Chris G. Van de Walle; University of California, Santa Barbara, Santa Barbara, California, United States.

Hybrid perovskites exhibit pronounced momentum splitting at band edges due to a strong Rashba spin-orbit coupling effect. This effect was invoked by a number of groups to explain the high efficiency of hybrid perovskite solar cells. It was argued that the Rashba-induced splitting effectively suppresses the radiative recombination by mismatched spins and momenta between photogenerated electrons and holes. In the present study, we perform first-principles calculations to explicitly examine the impact of the Rashba effect on the radiative recombination coefficient in the archetypical hybrid perovskite, CH$_3$NH$_3$PbI$_3$. We demonstrate that the band extrema have consistent spin orientation and the momentum mismatch affects the radiative recombination coefficient by less than a factor of two. The computed radiative recombination coefficients are as high as in typical direct-gap semiconductors. Our insights establish a solid basis for accurate modeling of hybrid perovskites.

9:15 AM ET05.04.05

Recently, 2-dimensional (2D) Ruddlesden-Popper lead-halide based perovskite layered systems are attracting attention. Compared to their 3D counterpart, 2D systems offer greater tunability and stability, making them candidates for high-performance optoelectronic applications. Here we report the charge carrier recombination rate and spin depolarization times in single crystals of 2D perovskites PEA$_2$PbI$_3$ and (PEA$_2$PbI$_3$)$_n$ (PEA, phenethylammonium; MA, methylammonium; n = 1, 2, 3, 4). Layer thickness dependent charge carrier recombination rates were observed with the fastest rates for n = 1 due to the large exciton binding energy. Interestingly the slowest recombination rates occurred for the n = 2 sample and not n = 4. Room temperature spin-decoherence times also show a nonlinear layer thickness dependence with an increasing spin-coherence lifetime with increasing layer thickness from n = 1 to n = 4, followed by a decrease in lifetime from n = 4 to n = ∞. The longest decoherence time of ~7 ps is observed in the n = 4 sample. Our results are consistent with two contributions; Rashba-splitting increases the spin-coherence time going from the n = ∞ to the layered systems, while phonon-scattering which increases for smaller layers decreases the spin-coherence time. The interplay between these two factors contributes to the layer thickness dependent spin-coherence lifetimes. To correlate we monitored the LO and TO phonon frequency and phonon linewidth. For thinner layers the phonon frequencies decrease and broaden substantially indicating a large electron-phonon coupling.

9:30 AM ET05.04.06
Charge Carrier Dynamics in Metal Halide Perovskite Solar Cells Change after Exposure to Humidity and Light Esma Ugur, Jafar I. Khan, Erkki Alarousu, Sandra P. Gonzalez-Lopez and Frédéric Laqhai; King Abdullah University of Science and Technology, Jeddah, Saudi Arabia.

In a very short time span, the power conversion efficiency (PCE) of metal halide perovskite solar cells (PSCs) has reached 23%, a massive improvement for solution-processed photovoltaic devices. Towards this end, both surface and bulk recombination of photogenerated charge carriers in the perovskite absorber layer are the major efficiency-limiting factors. [1] In this respect, controlling the growth and crystallization of the perovskite thin film is crucial for the performance of the perovskite solar cells as the crystal growth dynamics are very susceptible to the processing conditions [2]. Interestingly, some studies report a beneficial effect from water inclusion during processing, while others claim an adverse effect. Moreover, the effect of humidity and light exposure on the performance of PSCs is still debated. In this study, we fabricated, using a two-step protocol, MAPbI$_3$ perovskite solar cells with SnO$_2$ electron transport layers to study how the device performance and photophysics change upon exposure to humidity and light. Reference devices, not exposed to humidity and light, exhibit 18.4% PCE with 22.5 mA/cm$^2$ short-circuit current density ($J_{sc}$) and 1.12 V open circuit voltage ($V_{oc}$). After exposing the perovskite absorber layer to 55% relative humidity under 1-sun illumination prior to completing the device fabrication, a reduction in $V_{oc}$ to 1.09 V was observed. We study the influence of excess lead iodide (PbI$_2$), which is commonly believed to be passivating the PSCs, on the humidity resistance of MAPbI$_3$ devices. While the $V_{oc}$ value of samples with excess-PbI$_2$ was lowered to 1.10 V, we did not observe any change in $J_{sc}$. Since $V_{oc}$ losses can be attributed to non-radiative recombination, we performed time-resolved photoluminescence (TR-PL) spectroscopy before and after humid air exposure of perovskite thin films under 1-sun illumination. We will discuss in detail how the exposure to humid air under illumination alters the surface structure of the perovskite samples, affects the device performance, and the photophysical processes.

Ferroelectric Large Polaron in Lead Halide Perovskites Xiaoyang Zhu; Columbia University, New York, New York, United States.

A major puzzle from recent studies on LHPs is that optoelectronic performances suggest nearly perfect semiconductors despite the unavoidable presence of defects from room temperature and solution processing. Here we explain the essential physics in this class of materials based on their disordered phonon dynamics and dielectric functions. We show that the dielectric function of a hybrid organic-inorganic lead halide perovskite (LHP) possesses combined characteristics of a polar liquid and a ferroelectric material. The latter response in the THz region may lead to dynamic and local ordering of polar nano domains by an extra electron or hole, resulting a quasiparticle which we call a ferroelectric large polaron. Compared to a conventional large polaron, the collective nature of polarization in a ferroelectric large polaron may give rise to order(s)-of-magnitude larger reduction in the Coulomb potential and introduce potential barriers to charge carrier scattering. The ferroelectric large polaron may explain the defect tolerance, low recombination rates, and slow cooling of charge carriers in lead halide perovskites, as well as providing a design principle for high performance semiconductors from nano, molecular, and hybrid materials.

10:45 AM ET05.04.08
Loss Mechanisms in Perovskite Solar Cells—Initially and During Aging Wolfgang Tress; LSPM, EPFL, Lausanne, Switzerland.
Solar cells based on lead halide perovskites have recently emerged showing a tremendous increase of power-conversion efficiency which exceeded 22%. In this contribution, the device physics of perovskite solar cells is addressed. The focus is on recombination of charge carriers because this process is ultimately limiting the efficiency. Furthermore, the performance and changes thereof during light-soaking and operation under real weather conditions are addressed.

The origin of the open-circuit voltage is discussed based on the reciprocity relation between electroluminescence and photovoltaic quantum efficiency. Sharp absorption onset and high radiative recombination yield due to an extraordinary defect tolerance are identified as reasons for the outstanding optoelectronic properties of perovskites. Furthermore, the role of defect and surface recombination are addressed by employing a detailed analysis of the diode ideality factor. Upon deliberately introducing defects in a controlled way it is found that the defect tolerance does not span to any kind of extrinsic defect.

The current-voltage curve of perovskite solar cells yields different results dependent on the initial voltage and scan rate of the voltage sweep. The resulting hysteresis is related to recombination as well. These results are explained based on the mixed ionic and electronic conductivity of the material, where displaced ions change interface and defect recombination rates. Reversible effects are observed on timescales of hours and their origins distinguished from irreversible degradation. The interplay of all these processes is analyzed for long-term operation under real weather conditions, where a better low-light performance and a low temperature coefficient result in relatively higher energy yields compared to a silicon solar cell.

An outlook is given on strategies aiming for a further improvement of open-circuit voltage and performance of perovskite solar cells toward their thermodynamic limit.

Imaging the Inhomogeneous Trap State Distribution in Hybrid Organic-Inorganic Perovskite Films
Andrew J. Winchester1, Christopher Petoukhoff1, Mojtaba Abdi Jalebi1, Zahra Andaji-Garmaroudi2, Vivek Pareek1, E Laine Wong1, Julien Mado1, Michael K. L. Man1, Samuel D. Stranks2 and Keshav Dani1; 1Cavendish Laboratory, University of Cambridge, Cambridge, United Kingdom. 2Chimie des Matériaux Nouveaux, Université de Mons, Mons, Belgium; 3Adolphe Merkle Institute, University of Fribourg, Fribourg, Switzerland.

Hybrid organic-inorganic perovskite semiconductors have recently emerged as high performance thin-film photovoltaic materials. Their combination of good optoelectronic properties and low-cost synthesis processes has led to an unprecedented rate of development in perovskite-based solar cell devices over several years. Despite this development, however, there are still ongoing efforts to reduce unwanted non-radiative carrier loss and further push solar conversion efficiencies towards theoretical limits. One of the phenomenological observations highlighting the efficiency limits is the non-uniform radiative emission seen in photoluminescence (PL) microscopy, suggesting that there is an underlying nanoscale variation in the carrier trapping centers in solution processed perovskite films.

Here, we utilize time resolved photoemission electron microscopy (TR-PEEM) to view directly the nanoscale electronic variation and its effect on photo-excited carriers in mixed cation perovskite films. We investigate regions with different PL efficiency and find an increased number of nanoscale trap centers in low PL efficiency regions. We show that these traps are due to occupied mid gap states and probe the corresponding ultrafast hole trapping dynamics at these nanoscale locations. Our work gives a direct view at the nanoscale distribution of trap centers in perovskite materials and their connection to macroscale carrier recombination.

Recombination Routes of the Free Carriers in Perovskite Solar Cells Revealed by Intensity-Modulated Photovoltage Spectroscopy
Xiaoqing Chen, Yasuhiro Shira1, Masatoshi Yanagida and Kenjiro Miyano; National Institute for Materials Science, Tsukuba, Japan.

In intensity-modulated photovoltage spectroscopy (IMVS) and impedance spectroscopy (IS) experiments of perovskite solar cells (PSCs), two features with different power dependences are observed to coexist corresponding to two relaxation routes. The relaxation rate of the slower feature is independent of light power while that of the faster one is proportional to the light power. Similar power dependence is observed in PSCs with various hole transport layers. Apparently, understanding the slower process will be helpful in optimizing the electric hysteresis in PSCs. In addition, because previous report assigns the faster process to the recombination of free carriers, understanding the faster feature will be helpful in minimizing the photocarrier loss in PSCs.

We notice that the recombination mechanisms involving only free carriers (e.g., band-to-band recombination) yield sublinear power dependence. Therefore at least two kinds of carrier species should be considered to explain the linear power dependence of the faster feature. Consequently, the next question is what this second carrier species other than free carriers is. We think it could be either accumulated carriers involved in the surface polarization model or the mobile ions/vacancies. In order to convincingly assign it, various photoelectric measurements are performed to provide additional information to these carriers. Our results indicate that these carriers should 1) be photogenerated with fixed lifetime (regardless of light power) so that its number is proportional to light power, 2) readily migrate along the electrode/perovskite surface so that it could uniformly distribute the device area (0.26 cm²), 3) be thermally activated before it could recombine with the free carriers, 4) be directly relevant to the slower IMVS or IS feature.

Origin of High Photoluminescence in Mixed-Cation Perovskites—Energetic Disorder Leads to Charge Localization
Sascha Feldmann1, Stuart Macpherson1, Jasmine Rivet1, Mojtaba Abdi Jalebi1, Satyaprasad P. Senanayak1, Guangjun Nan2, David Beljonne2, Michael Saliba2, Samuel D. Stranks1 and Felix Deschler1; 1Cavendish Laboratory, University of Cambridge, Cambridge, United Kingdom; 2Chimie des Matériaux Nouveaux, Université de Mons, Mons, Belgium; 3Adolphe Merkle Institute, University of Fribourg, Fribourg, Switzerland.

Metal-halide perovskites have demonstrated exceptional optoelectronic properties for next generation photovoltaics and light-emitting diodes. Recently, cation substitution has been reported to generate luminescence very efficiently, yet the underlying photo-physics are poorly understood. Here, we study the origin of this increased brightness by combining transient absorption and photoluminescence (PL) spectroscopy to track charge carrier dynamics in perovskite thin films. Unexpectedly, we find the recombination mechanism to change from the previously-reported second to a first order regime dynamically within tens of nanoseconds after excitation, in line with fluence-dependent PLQE measurements. In temperature-dependent PL we find a redshift of the luminescence with decreasing temperature, directly mapping localized shallow traps. Supported by DFT calculations and transistor measurements we propose that energetic disorder in the distribution of electronic states leads to spatial accumulation of charges, creating n- and p-type doped regions,
explaining the PLQE observations. Our results indicate that strong luminescence can be achieved in mixed-cation perovskites even at low carrier densities and thereby provides a roadmap for highly efficient LEDs.

Organic-inorganic perovskites enable a combination of useful organic and inorganic properties within a single molecular-scale composite and have attracted substantial interest for use within organic-inorganic electronic devices [1], in part due to the high carrier mobilities, long minority carrier lifetimes, tunable structures/band gaps, relatively benign defects and grain boundaries, and facile processing for systems based on Group 14 metals (e.g., Ge, Sn and Pb). Most recently, these materials have enabled unprecedented rapid improvement in performance within single junction photovoltaic (PV) devices, from an initial demonstration in 2009 [2] to levels with >20% power conversion efficiency and open circuit voltages >1V [3]. This talk will provide an historical perspective on foundational work related to the organic-inorganic perovskite solar cells, including discussion of crystal structure flexibility, semiconducting properties, film deposition approaches and electronic device applications of the three-dimensional and lower-dimensional perovskite structures [4,5]. Recent trends in the field, as they relate to application in photovoltaics and related devices, will also be coupled into this discussion.

Photovoltaics of Halide Perovskites and Perspectives of Extensive Applications from the Ground to the Universe Tsutomu Miyasaka; Toin University of Yokohama, Yokohama, Japan.

Lead halide perovskite absorbers have achieved high photovoltaic performance exceeding the efficiency of CIGS and CdTe and their long term stability against heat, moisture, and light are being improved by combined engineering of perovskite and surrounding carrier transport materials. For industrial applications, thermal stability of perovskites and carrier transport materials is a critical issue in comparison with thermally highly stable inorganic solar cell (Si, CdTe, etc.). Metal oxide electron transport layers (ETLs) generally have advantage in higher thermal stability than organic ETLs. We have been working with TiO2 ETL-based multi-cation perovskite cells, which yielded efficiency over 21% by ambient air solution processes.1 Light intensity dependence of Voc shows ideality factor low enough (n<1.4) for the perovskite solar cell to work as a high voltage power source even under weak light. Such merit meets a requirement in solar cell application to space satellite missions, which needs high photovoltaic performance even under very weak sunlight (Mars and Jupiter). We have examined the durability of perovskite solar cells which have thermally stable compositions comprising FA-based perovskites, TiO2 ETL, and P3HT as hole transport layer (HTL). These cells exhibit good stability against thermal impact between temperature range between -80°C and +100°C. We also confirmed very poor thermal stability of spiro-OMeTAD as a reference HTL. On exposure to high energy electron and proton radiations as accelerated conditions simulating long term space irradiations, the perovskite cells demonstrated high stability and tolerance, which are superior to those of Si and GaAs solar cells.2 Space applications also require fabrication of lightweight flexible devices. Thin film substrate-based perovskite solar cells were fabricated by low-temperature multilayer coating methods using amorphous TiO2 as ETL, which yield efficiency up to 18%. Future perspectives of industrialization of perovskite photovoltaic devices will be discussed focusing on the durable composition of perovskite devices and advantage of lightweight thin film device.

Perovskite Photovoltaics—History, Progress and Perspective Nam-Gyu Park; Sungkyunkwan University, Suwon, Korea (the Republic of).

Since the first report on the high efficiency, stable solid-state perovskite solar cell (PSC) in 2012 by our group, following two seed works on perovskite-sensitized liquid junction solar cells in 2009 and 2011, PSC demonstrated its power conversion efficiency (PCE) of 22.7% in 2017. According to Web of Science, publications on PSC increase exponentially since 2012 and total number of publications reaches about 9,000 as of May, 2018, which is indicative of a paradigm shift in photovoltaics. Although high photovoltaic performance was achieved, current-voltage hysteresis has been issued because it is related to stability of PSC. In this talk, methodologies to remove hysteresis are described. Interlayers at heterojunction are found to play important role in reducing hysteresis and improving stability. Manipulation of Frenkel defect is a universal approach toward hysteresis-free PSC. We have discovered novel methods for large-area perovskite coating and shape transformation in perovskite, which will be discussed in detail. In addition to photovoltaics, perovskite can be used to other applications. Long charge diffusion length and high energy stability of organic-inorganic halide perovskite are suitable for low-dose, high resolution X-ray imaging. We demonstrated X-ray image using millimeter thick perovskite film based on multicrystalline perovskite crystal with single-crystal-like optoelectronic properties. For heading toward Shockley–Queisser limit, research direction in PSC is proposed in this talk.

Compositional Engineering for Efficient and Durable Perovskite Solar Cells Anders Hasfelfdt; Laboratory of Photomolecular Science, Swiss Federal Institute of Technology Lausanne (EPFL), Lausanne, Switzerland.
In our work on perovskite solar cells (PSC) we have achieved efficiencies above 20% with a mixed composition of iodide/bromide and methyl ammonium/formamidinium [1]. For cells larger than 1 cm² we have obtained 19.6% [2], replacing the anti-solvent step in the perovskite film formation with a vacuum flash treatment. With the use of SnO₂ compact underlayers as electron acceptor contacts we have constructed planar perovskite solar cells with a hysteresis free efficiency above 20% [3]. The cation mixing strategy has been developed further by including the Cs in a so-called ‘triple cation’ composition, i.e. CsFA/Ma as well as Rb in a quadruple cation mixture. Larger grains grown in a monolithic manner are observed and for example reproducibility and device stability are improved [4]. At the meeting we will discuss our follow up works [5] and present our champion data; up to 22% efficiency with an external electroluminescence of 4%, and an outstanding open-circuit voltage of 1.24 V at a band gap of 1.63 eV entailing one of the smallest loss-in-potential of 0.39 V ever measured for any solar cell material. Furthermore, we will report promising stability at 85 °C for 500 h under full solar illumination and maximum power point tracking (during which 95% of the initial performance was retained). Recently, we have also commented on the standardization of PSC aging tests [6].

Perovskite solar cells (PSCs) have become a competitive photovoltaic (PV) technology with rapid progress of efficiencies reaching to about 23%. Uniquely, PSCs have the highest efficiencies when they are solution processed, so one can envision solar cells printed in a similar manner and scale as newspapers. In addition, the bandgap tunability through perovskite composition engineering can enable high-efficiency multijunction devices, including perovskite/perovskite, perovskite/silicon, or perovskite/thin-film absorber (e.g., CIGS). Thus, PSCs are suited to helping address the challenge of terawatt-scale, PV-based electricity production that can power the future world. In this talk, I will discuss our recent progress in two areas: (1) scalable fabrication of high-efficiency, large-area perovskite solar cells and modules; (2) development of perovskite-based tandem devices. I will discuss our recent studies toward better control of film formation across the device stack at large scales by improving the precursor chemistry to better match the processing methods. The precursor chemistry and growth conditions affect significantly the physical and optoelectronic properties of perovskites. The challenges associated with perovskite solar module fabrication will be discussed. I will show the impact of interconnections on the performance of perovskite solar modules fabricated by scalable depositions. Toward perovskite-based tandem device development, I will discuss our recent effort on improving the optoelectronic properties of wide-bandgap as well as low-bandgap perovskite absorbers through solution chemistry engineering. Challenges and progress on perovskite-based tandem devices will also be discussed. These results demonstrate a promising path towards commercialization of the perovskite photovoltaic technology.

Photobleaching and Recovery of Photoluminescence of CsPbBr₃ Perovskite Quantum Dot Yoshiki Iso, Koji Kidokoro and Tetsuhiko Isobe; Keio Univ, Yokohama, Japan.

CsPbX₃ (X = Cl, Br, I) perovskite quantum dots (QDs) have attracted many attentions because of their excellent photoluminescence (PL) properties such as high quantum yields, narrow PL peak widths, and emission color tunability by elemental composition of the halide ions. CsPbBr₃ QD, which exhibit highly-pure green emission under blue and UV light irradiation, is a good candidate for applications to wide-color gamut displays. However, photodegradation of the CsPbBr₃ QD under excitation is a significant problem to be solved for their practical use. Herein, we found recovery of photodegraded CsPbBr₃ QD after continuous blue light excitation. In this work, the photobleaching and recovery phenomena of the CsPbBr₃ QD are investigated by evaluation of their optical properties. CsPbBr₃ QD was synthesized by a conventional hot-injection method. Cs₂CO₃ was added into a mixture of 1-octadecene and oleic acid. The mixture was dried at 120 °C for 1 h, and then dissolved at 150 °C under Ar. Next, a mixture of 1-octadecene and PbBr₂ was vacuum-dried at 120 °C for 1 h, and then purged with Ar. Oleylamine and oleic acid were added to the solution. After complete dissolution of PbBr₂, the solution was heated to 180 °C. The solution of cesium oleate kept at 100 °C was injected into the PbBr₂ solution, and, 5 s later, the mixture was cooled in an ice-water bath. Synthesized CsPbBr₃ QD was precipitated by addition of tert-butyl alcohol, and then collected by centrifugation. After vacuum-drying for 1 day, yellow sample was obtained. For photobleaching test, the dried sample in a sample holder was placed on a plane light source of 468-nm blue LEDs with ~50 W m⁻² at room temperature; its absorption and PL spectra were measured at designated duration during and after 72-h irradiation using UV-vis and fluorescence spectrometers. According to transmission electron microscopy, the obtained sample was cubic particles with an average size of 8 nm. CsPbBr₃ QD with the structure was verified from the X-ray diffraction pattern. A narrow PL peak was observed at ~520 nm under 468-nm excitation. During the continuous blue light irradiation, the sample color changed from yellow to black. Actually, its absorbance at 700 nm, in which CsPbBr₃ QD had no light absorption, increased as the irradiation duration prolonged. The PL intensity decreased to 20% of the initial intensity after 72-h irradiation, revealing photodegradation of CsPbBr₃ QD. During storage in the dark at room temperature after 72-h irradiation, body color of the degraded sample returned to yellow from black. This phenomenon was consistent with a change in absorption spectra. At the same time, recovery of PL intensity was observed. After storage for 18 days, the final PL intensity reached up to 90% to the initial intensity. Such recovery of degraded CsPbBr₃ QD gives us a hint to solve the photobleaching problem. In
Minimizing Non-Radiative Losses Through Rational Defect Passivation for High Performance Perovskite Light-Emitting Diodes

Understanding Grain Boundary Effects in Methyliammonium Lead Bromide Films Using Electron Backscatter Diffraction (EBSD) Gede Adhyaksa1, Sarah Brittain1, Haralds Abolins1, Andries Loë1, Yueying Li2, Joel D. Keelor3, Yanqi Luo4, Teodor Duevski5, Ron M. Heeren1, Shane Ellis1, David P. Fenning1 and Erik Garnett1; 1AMOLF, Amsterdam, Netherlands; 2University of California, San Diego, San Diego, California, United States; 3Maastricht University, Maastricht, Netherlands.

Grain boundaries play a key role in the performance of thin-film optoelectronic devices, yet their effects in halide perovskite materials are still not understood. The biggest factor limiting progress is the inability to identify grain boundaries. Non-crystallographic techniques can misidentify grain boundaries, leading to conflicting literature reports about their influence; however, the gold standard – electron backscatter diffraction (EBSD) – destroys halide perovskite thin films. We solve this problem by using a solid-state EBSD detector with 6,000 times higher sensitivity than the traditional phosphor screen and camera. Correlating true grain size with photoluminescence lifetime, carrier diffusion length and mobility, shows that grain boundaries are not benign but have a recombination velocity of 1670 cm/s, comparable to that of crystalline silicon. We also observe amorphous grain boundaries that give rise to locally brighter photoluminescence intensity and longer lifetimes. This anomalous grain boundary character offers a possible explanation for the mysteriously long lifetime and record efficiency achieved in small-grained halide perovskite thin films. It also suggests a new approach for passivating grain boundaries to lead to even better performance in optoelectronic devices.

ET05.06.03

Hybrid organic-inorganic halide perovskites have emerged as a new family of optoelectronic materials because of their wide tunability in structural and optoelectronic properties via varying the compositions in A, B and X sites of the formula ABX3. While the primary structural and optoelectronic properties of hybrid organic-inorganic halide perovskites are dominated by transient metal divalent cations in the B-site and halide anions in the X-site, recent research has shown the impact of A-site monovalent cations on phase and device stability and the additional tunability in structural and optoelectronic properties. In this work, we focused on the investigation of A-site cations on the structural and optoelectronic properties of perovskites with a formula Aₓ(MA₁₋ₓFAₓ)₁₋ₓPb₁₋ₓSnₓ(I₁₋ₓBrₓ)₃, where A are Cs⁺, Rb⁺, and guanidinium (GA⁺), or Cs⁺–GA⁺ and Rb⁺–GA⁺ with x = 0 – 0.2, and y = 0 – 1.0. Because of the smaller ionic radii of Cs⁺ (1.8 Å) and Rb⁺ (1.52 Å) than methylammonium (MA⁺, 2.16 Å) and formamidinium (FA⁺, 2.53 Å) and GA⁺ (2.78 Å), adding Cs⁺ and Rb⁺ pushes the Goldschmidt tolerance factor into the cubic perovskite phase regime for each Sn composition while adding GA⁺ leads to an opposite direction. We prepared densely-packed, pinhole-free perovskite films with one-step solution process with mixed solvents plus anti-solvent wash method followed by thermal annealing. X-ray diffraction (XRD) patterns show pure cubic phase for all composition perovskites. The lattice parameter of these perovskites show non-linear lattice parameter versus Sn composition for each A composition with alloyed Pb-Sn having larger lattice parameters than those of pure Pb or Sn perovskites. However, a linear decrease or increase of lattice parameter versus A composition with each fixed Sn composition. The bandgaps deduced from the UV-Vis absorption spectra edges show that the bandgaps decrease with the increasing of Sn to the minima around 75% Sn and then increased to pure Sn. In Pb-rich perovskites, adding Cs⁺ or Rb⁺ increases the bandgaps for each fixed Sn composition, while in Sn-rich perovskites, it causes the decrease of bandgaps. The mechanism of A-site cations on the structural and optoelectronic properties of Pb-Sn and pure Sn perovskites will be discussed based on their impacts on B-X orbital overlap, BX₆ octahedral tilting, and strain tolerance. In addition, we also fabricated solar cells with the p-i-n structure and achieved a record maximum PCE of 9.61% for a low band gap (1.26 eV) perovskite of Cs₀.₁₀(MA₀.₁₇FA₀.₈₃)₀.₉Pb₀.₂₅Sn₀.₇₅(I₀.₈₃Br₀.₁₇)₃. Moreover, this 75% Sn device can retain 80% of initial PCE after 30 days storage in inert condition followed by over 100 hours in ambient condition. Overall, this study demonstrated the impact of A-site cations on structural and optoelectronic properties of Pb-Sn and pure Sn double halide perovskites and provides a route to enhance phase and device stability for high Sn or pure Sn perovskite solar cells.

ET05.06.04

Minimizing Non-Radiative Losses Through Rational Defect Passivation for High Performance Perovskite Light-Emitting Diodes Weidong Xu1,2 and Feng Gao1; 1The Department of Physics, Chemistry and Biology (IFM), Linköping University, Linköping, Sweden; 2Institution of Advanced Materials (IAM), Nanjing Tech University, Nanjing, China.

Minimizing defect-mediated non-radiative recombination is crucial for the fabrication of high-performance perovskite optoelectronic applications, e.g. perovskite light-emitting diodes (PeLEDs). We demonstrate a rational defect engineering strategy for substantial mitigation of non-radiative losses, including both molecular design and passivating agents (PAs), and a modified passivation technique. With using the optimal PA, the well defect-engineered perovskite films enable the preparation of high performance PeLEDs with a high maximum external quantum efficiency (EQEₓₑₓ) of 18.9% and a large radius of 316 W m⁻². Importantly, our research reveals the key factor in determining the passivation effect, and provides a useful guideline for promoting passivation effects.

Electrode Polarization and Role of Polaron States at Methylammonium Lead Halide Perovskite Interfaces Mahshid Ahmadi1, Maximilian Heres3, Emmanuel Mapesa1, Eric Lukos1, Juan Bisquert2, Joshua Sangor1 and Bin Hu1; 1Joint Institute for Advanced Materials, University of Tennessee, Knoxville, Tennessee, United States; 2Institute of Advanced Materials, Universitat Jaume I, Castello, Spain; 3Chemical and Biomolecular Engineering, The University of Tennessee, Knoxville, Knoxville, Tennessee, United States.

Electrode polarization is a universal phenomenon taking place at the interface between a metallic electrode and an ionic/electronic semiconductor which needs to be studied in detail for organometallic halide perovskite (OMHP) devices. In general, interfaces between hybrid perovskite and electrode or charge transport layers are gaining more attention as studies showed that interfaces can significantly control the operation of hybrid perovskite devices as well as long term performance stability. Previously, the increase of dielectric permittivity in low frequencies <100 kHz in thin films of OMHP was attributed to the ionic migration and accumulation at the interface and space charge polarization enhanced along grain boundaries1. It was suggested that long range ion diffusion under external field would be the governing mechanism at low frequencies. In order to gain insight on the origin of dielectric permittivity at low frequency regime here, we study single crystals of MAPbI₃ excluding polarization enhanced through grain boundaries effect. This study is done using broadband dielectric spectroscopy (BDS) in dark condition by varying temperatures and external biases. Generally, there are three sources contributing to the conduction in OMHPs including ions, electrons and holes and polarons. So far, the atomistic origin of slow dynamic process in OMHPs was explained by the transport of ionic species and the drift and/or diffusion of polarons was totally overlooked. In our ac conductivity measurements, we observed that the conductivity decreases with decreasing frequency and temperatures. The accumulation of ions at the interface usually block the carriers from conduction and conductivity is expected to drop at this region. In this study we found that at low frequencies, there is a plateau in ac conductivity. This conductivity is only dropped if a large bias is applied. The polaronic nature of charge carriers in OMHPs has been demonstrated but the transport, migration

the presentation, the observed photobleaching and recovery will be discussed with further analyses.

This anomalous grain boundary character offers a possible explanation for the mysteriously long lifetime and record efficiency achieved in small-grained halide perovskite thin films. It also suggests a new approach for passivating grain boundaries to lead to even better performance in optoelectronic devices.
and accumulation of polarons at the interfaces was not explored. It was suggested that small polarons which transfer through hopping mechanism may not directly contribute to the overall carrier mobility unlike large polarons but they can form charge accumulations states\(^2\). Here, we conclude that ion migration and accumulation is not solely responsible for giant dielectric constant at low frequency in OMHPs but also there is an effective role from polarons. Indeed, polarons can migrate and accumulate at the interface first. This study opens a way for better understanding of a key aspect in the operation of highly efficient OMHP devices.

Tuning the Electronic and Defect Properties of Methylammonium Lead Bromide via Composition Engineering

Arun Kumar Manndi Kanakkithodi, Ji-Sang Park, Duyen H. Cao, Nari Jeon, Alex Martinson and Maria K. Chan; Argonne National Laboratory, Lemont, Illinois, United States.

Methylammonium lead bromide (MAPbBr\(_3\)) has grown in prominence as an attractive photovoltaic (PV) absorber owing to its higher stability compared to MAPbI\(_3\), and its desirable electronic, absorption and defect properties which can be further tailored by composition engineering. Inspired by recent work on partial substitution of Pb in MAPbBr\(_3\) by Cobalt to yield additional energy states within the semiconductor band gap leading to intermediate band photovoltaics (IBPVs)\(^3\),\(^4\), we explore the possibility of substituting Pb by various other elements selected from across the periodic table in a high-throughput fashion. Using state-of-the-art density functional theory (DFT) computations, we study the crystalline and electronic structure as well as the energetics of 1/8th substitution of Pb in a MAPbBr\(_3\) supercell by all cationic elements from periods 2, 3, 4, 5 and 6. Both the density of states and the calculated charge transition levels are used to probe the energy states created by the substituent atom in the electronic structure of MAPbBr\(_3\), revealing several substituents that create mid-gap states while retaining the parent band gap (~2 eV at the PBE level of theory). Formation energies of substituent defects are calculated in various charged states\(^3\),\(^4\) and compared with the energetics of dominant intrinsic defects, established as the vacancy defects V\(_{\text{MA}}\) (dominant acceptor) and V\(_{\text{MB}}\) (dominant donor)\(^4\). It is observed that depending on the chemical potential of relevant species, transition metals Zr, Hf, Nb and Sc, and group V element Sb create low formation energy defects that compensate for the dominant intrinsic defects and shift the equilibrium Fermi level closer to the conduction band minimum, making the semiconductor conductivity more n-type. The relative stability of these substitution defects coupled with the fact that they produce mid-gap energy levels not only makes them promising candidates for IBPV's but raises the possibility of these impurities creating deep trap states in the MAPbBr\(_3\) band gap that can cause harmful non-radiative charge carrier recombination and reduce the PV efficiencies. Further, many of the promising substituents thus identified were experimentally synthesized and characterized, and the measured absorption coefficients compared favorably with the computed spectra. Lastly, machine learning techniques were applied on the high-throughput computational data to yield simple predictive models for the substituent transition levels as a function of structural and electronic features derived from a significantly cheaper unit cell calculation on a completely Pb-substituted hybrid perovskite.

Light-Induced Dynamic Chemical and Structural Disorder in Mixed Halide Hybrid Perovskites

Tim W. van de Goor, Sian E. Dutton and Felix Deschler; University of Cambridge, Cambridge, United Kingdom.

Mixed halide hybrid perovskites are highly efficient semiconductors with promising applications in optoelectronics. Defects and disorder dictate the properties of this material. Structural disorder can be defined as local variations in the crystal structure, whereas chemical disorder refers to local inhomogeneities in material composition. Both types of disorder are highly dynamic and are likely responsible for the favourable (e.g. long carrier lifetimes\(^1\) and unfavourable (e.g. the Hoke effect\(^2\)) properties observed in this material. In the rapidly maturing field of hybrid perovskite optoelectronics, where the hunt is now on for the best performing material composition, little attention is given to the fundamental role of disorder. Here we aim to elucidate the relevant time- and length- scales for both types of dynamic disorder in this material, with the aim of gaining a better understanding of their relation to the optoelectronic properties. In particular, we use a combination of structural and thermodynamic techniques to investigate transitions in the prototypical mixed halide hybrid perovskite CH\(_3\)NH\(_3\)PbBr\(_3\)I\(_3\)). We use temperature dependent powder X-ray diffraction and heat capacity measurements under illumination to quantify the nature of— and energy associated with light-induced order/disorder transitions.

Controlled Nucleation and Growth for Optimum Perovskite Film Morphology at Liquid-Electrolyte Interface—A Study by Electrochemical Impedance Spectroscopy

Prva Srivastava and Monojit Bag; Indian Institute of Technology Roorkee, Roorkee, India.

Perovskite Solar Cells (PSCs) have already attracted considerable attention attributed to its intriguing properties, showing a tremendous jump in efficiency from 3.8%\(^6\) to 22.1%\(^6\) by Yang et al. (2017). A lot of research has been done on the efficiency improvement of PSCs by optimization of the film morphology at the interfaces in the device. Analyzing these interfaces by various characterization techniques including electrochemical impedance spectroscopy (EIS) in a solid state active device geometry\(^7\) is not only difficult to decipher but sometime is misleading as well since there may be multiple processes occurring at similar time scale at multiple interfaces.

To simplify the analysis of the perovskite films EIS should be carried out in perovskite-liquid electrolyte interface. Recently, Li et al. have measured the flat band potential, charge carrier density and type of charge carrier accumulation at the perovskite-liquid interface from Mott-Schottky plot for spin coated and spray coated films of methylammonium lead tri-iodide (MAPbI\(_3\)) perovskite.\(^8\) In this work, MAPbI\(_3\) perovskite has been synthesized by one step spin coating of lead acetate-trihydrate and methylammonium iodide precursor on pre-heated substrate. Significant difference in film morphology has been observed as the substrate temperature (T\(_{\text{subt}}\)) varied from room temperature to 120 °C prior to spin coating. Nucleation and growth mechanism is revisited to find out the optimum T\(_{\text{subt}}\) for fabricating uniform perovskite films and is
attributed to the fast homogenous nucleation followed by delayed growth. We confirmed that if the transformation temperature is just below the equilibrium melting point of the material, the nucleation is more homogeneous and hence more uniform and compact films are formed. EIS measurement at perovskite-liquid electrolyte interface reveals the impact of film morphology on the anomalous diffusion behaviour observed at low frequency regime and on the open circuit voltage ($\text{V}_{\text{OC}}$) of the device. More uniform and compact films show less degree of diffusion across the interface as compare to the rough ones. Also the $\text{V}_{\text{OC}}$ (1.018 V) is highest for the device fabricated by more uniform and compact film (Tsubt = 120 °C) among all the devices followed by the one fabricated at Tsubt = 120 °C (0.963 V). This reveals that film morphology is an important factor in deciding the kinetics at the interface and $\text{V}_{\text{OC}}$ and hence the performance of the device.

Electrospray Perovskite Fibers – New Flexible 1D Nanocomposites for Light Harvesting Applications Christoph Bohl1, Senol Oez2, Ashish Lepcha1, Markus Schütz1, Florian Stauber3, Thomas Fischer1, Thomas Kirchartz2,3 and Sanjay Mathur1; 1Institute of Inorganic Chemistry, University of Cologne, Cologne, Germany; 2FHEF-Polyvaltak, Forschungszentrum Jülich GmbH, Jülich, Germany; 3Faculty of Engineering and CENIDE, University of Duisburg-Essen, Duisburg, Germany.

The interest in perovskite solar cells is growing rapidly due to their versatile applicability for energy harvesting systems. In a short period of time, devices already reached efficiencies up to 22%, making them comparable to established thin-film solar cells like Cu(In,Ga)Se2 or CdTe. The quantity of publications dealing with planar and rigid solar cells is growing tremendously; however, fibrous solar cells have not been in focus yet. Since the 1D structure provides a greater flexibility in comparison to planar systems, applications ranging from e-textiles/weareables to lightweight applications are feasible. Here, the single step fabrication of phase-pure organic-inorganic lead halide perovskite fibers by inert electrosprining technique is presented. Morphological, as well as optical/photonic properties have been studied and demonstrate first comprehensive data on electrospruned organic-inorganic hybrid materials. Substitution of the absorbing layer in planar heterojunction solar cells with perovskite fibers resulted in a photoelectric response under simulated sunlight conditions. These flexible 1D hybrid solar fibers are potential elements for flexible optoelectronics and mark a starting point towards competitive fibrous solar cells.

ET05.06.11

Dynamics of Trap States in Passivated Halide Perovskite Films Stuart MacPherson1, Andrew J. Winchester2, Tiarkan Doherty1, Christopher Petukhov2, Michael K. L. Man3, Keshav Dani3 and Samuel D. Stranks1; 1Department of Physics, University of Cambridge, Cambridge, United Kingdom; 2Femtosecond Spectroscopy Unit, Okinawa Institute of Science and Technology Graduate University, Okinawa, Japan.

The photovoltaic performance of world-leading Organic-inorganic halide perovskite (OHP) solar cells remains limited by defective electronic states, which introduce non-radiative recombination pathways for charge carriers. In OHP thin films, it is emerging that surface defects are the most prevalent and thus have the largest impact on luminescence and device efficiency. We have recently shown that the addition of potassium halides can increase luminescence yields substantially but the direct impact on carrier traps has not yet been elucidated.

Here, we employ a state-of-the-art photoemission electron microscopy (PEEM) setup to map local surface defect states on triple cation, mixed-halide perovskite (CsFAMA)Pb$_x$(Br$_{1-x}$)$_3$ films with < 30 nm spatial resolution. Our results show that chemical passivation by potassium doping reduces the density of surface defects on the films. Confocal photoluminescence maps of fiducially marked sites show a clear anti-correlation between areas of high photoluminescence intensity, and regions of high trap densities based on the photoemission fingerprints.

Finally, we examine how increasing levels of potassium doping affect the local carrier trapping dynamics by integrating PEEM with time-resolved pump-probe spectroscopy. This enables us to monitor the rate and intensity of photoexcited hole trapping into these intra-band surface states. When teamed with the spatial resolution of PEEM beyond the diffraction limit, such time-resolved measurements provide a uniquely powerful tool for characterising defect states, both in local regions and across larger regions of films.

ET05.06.12

Relation Between Absorption and Electronic Properties of Organic-Inorganic Halide Perovskites Martin Ledinsky1, Tereza Schonfeldova1, Jakub Holovský1,2, Zdenka Hajkova1, Lucie Abelova1,2, Neda Neykova1, Erkan Aydin2, Stefaan De Wolf1 and Antonín Fejfar1; 1Department of thin films, Institute of Physics AS CR, Prague, Czechia; 2Faculty of Electrical Engineering, Czech Technical University in Prague, Prague, Czechia; 3KAUST Solar Center (KSC), King Abdullah University of Science and Technology, Thuwal, Saudi Arabia.

We have probed the temperature dependence of methylammonium lead iodide (CH$_3$NH$_3$PbI$_3$) absorption spectra. We extract the Urbach energy as the reciprocal value of the slope at the band edge plotted in logarithmic scale. Its value depends on the material disorder and generally correlates well with the loss in the open-circuit voltage ($\text{V}_{\text{OC}}$) of optimized cells, compared to their bandgap [1]. When cooling CH$_3$NH$_3$PbI$_3$ film we find a strong decrease in their Urbach energy and a slow decrease of their optical band gap energy.

From the theoretical Urbach energy temperature dependence we obtain an average energy of electronically active phonon states of 110 ± 20 cm$^{-1}$, which implicates that the dynamic disorder of CH$_3$NH$_3$PbI$_3$ is mainly caused by cage vibrations [2]. This further gives evidence that the density of active static defects in perovskites is very low in comparison to other materials used for solar cells, including bulk monocystal semiconductors.

From comparing the photoconductivity and emission-based absorption spectroscopies, we find that the CH$_3$NH$_3$PbI$_3$ band structure is slightly indirect. This may be caused by spin-orbital coupling, the so-called Rashba splitting effect. Our results prove the direct nature (non-phonon assisted) of both absorption and emission in CH$_3$NH$_3$PbI$_3$. The experimentally observed long photoluminescence decay time is given by small overlap between free electrons and holes.

Finally, we found a strong correlation between the $\text{V}_{\text{OC}}$ deficiency, compared to the bandgap, of finalized solar cells and Urbach energies measured by PL spectroscopy. These results will help to establish more refined practical efficiency limits of perovskite solar cells by taking into account the Urbach energy, to be compared to the Shockley-Queisser limit, which only considers the bandgap.

ET05.06.13

Feasibility of Quantum Dot Based Lasers in Blue and Green Region Aparna S. Shinde, Anirupa A. Lohar, Richa Gahlaut and Shailaja Mahamuni; Savitribai Phule Pune University, Pune, India.
Hybrid organic-inorganic perovskites (HOIPs) formed with organoammonium iodide and lead iodide precursor solutions are remarkable absorbing layers for photovoltaic (PV) devices. HOIPs with mixed cations, specifically those comprising combinations of formamidinium, methylammonium (CH$_3$NH$_3$\(^+\)) and cesium cations, have resulted in devices with record-setting efficiencies. Troublingly, recent reports have shown that CH$_3$NH$_3$\(^+\) is consumed through annealing of the precursor solutions, suggesting that reaction of CH$_3$NH$_3$\(^+\) with DMSO produces dimethylammonium, (CH$_3$)$_2$NH$_2$\(^+\) during solution annealing. X-ray diffraction on model HOIP films formed with precursor solutions in which CH$_3$NH$_3$I is intentionally and stoichiometrically replaced with (CH$_3$)$_2$NH$_2$I confirms that substitution of CH$_3$NH$_3$\(^+\) with (CH$_3$)$_2$NH$_2$\(^+\) alters the perovskite structure. When CH$_3$NH$_3$I is the sole organoammonium iodide in the precursor solution, the formation of (CH$_3$)$_2$NH$_2$I and its subsequent incorporation in thin films produces a cubic-phase film instead of the conventionally accessed tetragonal-phase CH$_3$NH$_3$PbI$_3$. Interestingly, devices that incorporate such cubic-phase films exhibit enhanced stability towards humidity compared with devices with the more conventionally accessed tetragonal-phase CH$_3$NH$_3$PbI$_3$. Our study emphasizes the importance of precise control over the composition of the active layer as a general strategy to control the size of the nanocrystallites (<10 nm) in the strong quantum size effect region.
Photoluminescence tuning between near infrared and ultraviolet is achieved by manipulating the size of perovskite crystals through confinement in nanocrystalline perovskite (mpSnI3) [1]. Our novel method of nanocrystalline perovskites preparation within a porous oxide matrix results in device-relevant structure that requires no colloidal stabilization. Low-voltage LEDs with narrow, blue-shifted emission fabricated with perovskite nanocrystallites confined within npAAO thin films support the general concept for next-generation photonic devices. The template-controlled size of the perovskite crystals is quantified in mpSnI3 with microfocus high-energy X-ray depth profiling in transmission geometry, verifying the growth of perovskite nanocrystals throughout the entire thickness of the nanoporous films. We study in detail exciton recombination, exciton-phonon interactions and energy trap states in confined and bulk semiconductor films using low temperature photoluminescence spectroscopy down to 3.8 Kelvin. Further areas of application include photon detectors, (polarized) electroluminescent devices, single-photon sources and metasurfaces. Future developments will include increasing the efficiency of the LEDs, exploring their applications in flexible devices and in depth study of the fundamental properties of the confined structures.

ET05.06.17
Mass Transfer-Tuned Growth Pathways of Colloidal Perovskite Quantum Dots Revealed by a High-Throughput Microfluidic Strategy
Robert W. Epps, Corwin Kerr, Kameel K. Abdel-Latif, Michael Bowen and Milad Abolhasani; North Carolina State University, Raleigh, North Carolina, United States.

Since the advent of organic/inorganic metal halide perovskites and their expanding application in low cost solution-phase processing of high efficiency optoelectronics, a wide expanse of colloidal synthesis techniques have been developed. However, due to the inherent limitations of batch screening approaches, these studies struggle to effectively characterize large parameter spaces and thereby develop a complete understanding of the fundamental nucleation and growth pathways of perovskite quantum dots (QDs). Recent works in colloidal QD growth characterization have implemented rapid microfluidic screening strategies. However, similar to their flask-based predecessors, these flow studies have not accounted for the effect of reactant mixing rates which are known to significantly influence growth pathways in the controlled synthesis of perovskite nanocrystals.

Herein, we present a systematic study of the mass transfer-tuned synthesis for three different cesium-lead-tribromide perovskite nanocrystal reaction strategies using an intelligent microfluidic screening technology. The microfluidic characterization platform consists of modular heated units equipped with a unique in-situ spectral monitoring probe (UV-Vis absorption and fluorescence spectroscopy) which may translate along the 27 cm tubular microreactor reaching 68 sampling ports. Complete platform automation enables high-efficiency collection of inline photoluminescence and absorption spectra spanning four orders of magnitude in residence time (i.e. growth time), from 100ms to 17 min. The portability of the sampling probe allows us to decouple fluid velocity-controlled mass transfer from reaction time.

This microfluidic approach enables rapid discovery, screening, and optimization of colloidal QDs with desired optoelectronic properties via high-throughput screening (>10,000 experimental conditions) of the accessible synthesis parameter space. Utilizing this developed intelligent microfluidic platform, we systematically studied the effect of early mixing timescales on the QD nanocrystal size and size distribution. Varying the average fluid velocity and slug size tunes the degree of mixing within droplets containing the cesium-lead-tribromide precursors, resulting in perovskite nanocrystals with different optoelectronic properties.

ET05.06.18
Lead-Free Perovskite for Highly Sensitive Photodetectors
Chun K. Liu; Department of Applied Physics, The Hong Kong Polytechnic University, Hong Kong, Hong Kong.

Recently, organic-inorganic lead halide perovskites have emerged as potential light absorbing materials for high-performance photodetectors. However, the toxicity of Pb-containing perovskites significantly hinders their practical applications. Thus, it is necessary to develop lead-free alternatives while maintaining high sensitivity. Herein, we report a lead-free, low-voltage and high-performance photodetector based on a tin perovskite. The device shows broadband photoreponse from ultraviolet to near infrared with highest responsivity (R) of 1.7 x 10^4 AW^-1. After vertically heterostructuring the perovskite with an organic semiconductor, the maximum R increases to 2.1 x 10^5 A W^-1, and specific detectivity of 1.5 x 10^11 Jones as well as EQE of 3.8 x 10^-6 can be obtained. The impressive performance of the photodetector is due to the superior optoelectronic properties of the tin perovskite and photogating effect originated from the vertical heterojunction. Moreover, the device is also assembled on a flexible substrate, demonstrating both high sensitivity and outstanding bending stability. This work paves the way for realizing non-toxic, low cost and high-performance photodetectors.

ET05.06.19
Digitally Programmable Polarization Anisotropy of Perovskite Nanowire-Block Copolymer Composites
Yehonadav Bekenstein1, 2, Nanjia Zhou1, A. P. Alivisatos1 and Jennifer Lewis1; 1Chemistry, University of California, Berkeley, Berkeley, California, United States; 2Materials Science, Technion-Israel Institute of Technology, Haifa, Israel; 1School of Engineering and Applied Sciences, Harvard University, Cambridge, Massachusetts, United States.

Semiconducting nanowires possess unique anisotropic optoelectronic properties arising from quantum confinement effects, making them attractive candidates for a wide range of electronic and photonic applications. The ability to precisely pattern one-dimensional nanomaterials with controlled spatial orientation into planar and 3D structures that exhibit highly anisotropic properties would open new avenues for the integrated design and assembly of optoelectronic devices. Towards this goal, we created stable nanocomposite inks composed of brightly emitting colloidal cesium lead halide perovskite (CsPbX3, X = Cl, Br, and I) nanowires suspended in a polystyrene-polyisoprene-poly styrene block copolymer matrix. Using direct ink writing, we programmably controlled the nanowire alignment within these matrices to produce photonic nanocomposites that exhibit highly polarized absorption and emission properties. Using this approach, we created several device motifs for optical storage, encryption, sensing, and full-color displays as exemplary demonstrations. The polymer encapsulated perovskite nanowires exhibit increased stability towards air and moisture degradation process, suggesting the methods and materials we use can be implemented in future devices.

ET05.06.20
All-Solution Processed Perovskite Light-Emitting Devices
Tejun Kim1, 2, Jin-Hoon Kim1 and Jin-Woo Park1; 1Yonsei University, Seoul, Korea (the Republic of); 2Samsung Electronics, Seoul, Korea (the Republic of).
As research on perovskites has rapidly developed in recent years, various research groups have made great efforts on improving the process and characteristics of perovskite light-emitting devices (PeLEDs). Perovskite has advantages of low material cost and simple process. However, it also has technical issues like short life-time and low stability. In this study, we demonstrated large area PeLEDs that are all-solution processed under ambient condition using organic-inorganic hybrid perovskite compounds as next generation light sources. In this work, an electron transport layer (ETL) was optimized to improve the electrical characteristics, to reduce the operating bias voltage and, to improve the optical characteristics. To improve the electron injection at the interface between the cathode and the perovskite layer, a thin layer of polyethyleneimine (PEI) was spin-coated on the perovskite layer prior to the deposition of the cathode. The PEI could reduce the work function of the cathode; hence, the electron injection barrier was significantly reduced. The electron transport properties of PEI were further improved by simply doping some elements. Solution processable n-type semiconducting materials (Cs2CO3, Alq3, and CsF) were selected as n-type dopant. Also, thin layer of poly(methyl methacrylate) (PMMA) was spin-coated on the perovskite layer to reduce the pin-holes in the perovskite layers. As fabricated PeLEDs based on these solution processable materials showed extremely low turn on voltage and high maximum luminance. Also, a silicone encapsulation was used to prevent the device from degradation by moisture and oxygen. The silicone encapsulation materials for commercial LEDs were used. Liquid silicone was coated on the as-fabricated PeLEDs to passivate the devices. Based on our results, the coated liquid silicone did not affect the performance of the PeLEDs. The lifetime of the PeLEDs encapsulated with commercial silicone was good performance which was comparable to the glass-lid encapsulation. Since the silicone was flexible, these encapsulation materials could be used in flexible PeLEDs. The luminescence characteristics of green region were confirmed by using a perovskite compound of MAPbBr3 which is attracting attention as a next generation light source, and its value as a next generation light-emitting devices was confirmed by applying it to a large area flexible device.

ET05.06.21
Impact of Excess PbI2 on the Structure and the Temperature Dependent Optical Properties of Methylammonium Lead Iodide Perovskites

Fabian Panzer1,2, Tobias Meier1, Tanuja Gujar1, Andreas Schönleber3, Selina Olthof4, Klaus Meerholz5, Sander van Smalen1, Mukundan Thelakkat4 and Anna Kohler1; 1Univ of Bayreuth, Bayreuth, Germany; 2University of Cologne, Cologne, Germany.

We investigate the impact of excess PbI2 in the precursor solution on the structural and optical properties of thin films of the model hybrid perovskite methylammonium lead iodide (MAPbI3). We find that excess of PbI2 in the precursor solution results in crystalline PbI2 in the final thin film that is located at the grain boundaries. From UPS we find that this phase has no direct impact on the electronic structure of MAPbI3. In contrast to that, temperature dependent absorption measurements indicate a systematic change in the temperature dependence of the exciton binding energy in the perovskite. We also observe a decrease in the critical temperature and a concomitant smearing out of the tetragonal – orthorhombic phase transition as a function of excess PbI2. Our results help to better understand the exact role of PbI2 in the perovskite layer and pave the way for a more tailored design of perovskite solar cells.

ET05.06.22
Broadband Luminescence in Small Molecule Engineered Hybrid Perovskites

Shreyaa Krishnamurthy1,2, Rounak Naphade3, Suresh Gosavi1, Sudip Chakaborty1, Ramanathan Vadhyayanathan1 and Satishchandra Ogale2; 1Department of Physics, Indian Institute of Science Education and Research (IISER), Pune, India; 2Department of Physics, Savitribai Phule Pune University, Pune, India; 3Department of Science Education and Research (IISER) Pune, Pune, India.

The emerging class of hybrid perovskite systems has attracted immense attention recently due to their uniquely interesting properties which has led to solar cell architectures with very high conversion efficiency. These materials have also been explored for other optoelectronic device applications such as: lasers, photo-sensors, light emitting devices (LED). Lately, this class of systems is being further explored for futuristic optoelectronic devices by employing small molecule engineering. Such molecular manipulations have been shown to control the dimensionality and associated photo-physics of these systems such as the electron-hole interactions and excitonic effects. In particular, one sub-group of such hybrid perovskites has exhibited broadband emitting properties which are of great interest as potential materials for white light emitting diodes (LEDs).

The discussion of broadband luminescence in the literature has focused on the identification of the specific contributions to such emission (e.g. bound excitons, self-trapped excitons, STE) and their possible connection to the specific structural features and organic/inorganic components in the system. In this work we report the observation of broadband emission in 1D ribbon system of (H2N2CH2-CH2-NH3)2(Pb2Br5) (or as 2D corrugated system of (H2N2CH2-CH2-NH3)2(PbI4), the common amine used being ethylene diamine (En), which is the smallest amine not used thus far in this context. We have employed several techniques such as single crystal x-ray diffraction (SC-XRD), steady state photoluminescence (PL), UV-absorbance, diffused reflectance spectroscopy (DRS), time resolved photoluminescence (TRPL) and Raman spectroscopy to study and compare the structural and optical properties of the two materials as well as their respective daimmonium salts. Our studies have brought out structure-specific contributions and interplay of the molecular and STE contributions. The primary absorption process appears to be driven by the molecular component while the STE appears to be centered on the inorganic component which may involve the intrinsically heightened polarization at the organic-inorganic interface. Distortions can be important for localization but do not appear uniquely control this phenomenon.

ET05.06.23
Electronic Structure Analysis of an Organometallic Halide Perovskite via Photoemission Yield Spectroscopy in Air at Various Temperature

Around the Phase Transition Temperature

Panuice Yamashita1, Yoshiyuki Nakajima1, Satoshi Uchida1 and Hiroshi Segawa2; 1RIKEN KEK, Co., Ltd., Kasukabe, Japan; 2The University of Tokyo, Tokyo, Japan.

An open counter [1] is a unique detector that can operate in air at atmospheric pressure to detect and count a small number of low-energy photoelectrons. Therefore, photoemission yield spectroscopy in air (PYSA) can be performed by employing an open counter as the detector. Recently, PYSA measurement was performed at various temperatures [2-4], and its applicability to the analysis of temperature dependence on the change of work function was demonstrated [3, 4]. In these cases, PYSA measurement was performed as follows. UV light emitted from a deuterium lamp was monochromatized using a grating monochromator, which was then focused on the sample surface. The number of photoelectrons emitted from the sample surface was counted using an open counter. During the measurement, the sample temperature was controlled using a small heater connected to a temperature controller. This method was considered effective for the comparison of the electronic structures of materials that exhibit different properties at high temperatures. Temperature effects of CH3NH3PbI3 perovskite solar cells having simple planar architecture were reported [5]. According to this report, the obvious changes in the crystal structure which seriously affects the performance of the solar cells were found. Therefore, PYSA was applied to analyze the change in the electronic structure of CH3NH3PbI3 at various temperatures. We discussed the change in the threshold energy of photoemission, which corresponds to the first-ionization potentials, at around the phase transition temperature of the perovskite.

Although metal halide perovskites (MHPs) have emerged as exceptional materials for optoelectronics, their charge transport properties remain under scientific debate. One of the reasons for this is that most charge transport measurements are conducted on polycrystalline thin films, which adds complexity to the system and makes it difficult to interpret the results in an unambiguous way. In this work, we concentrated on surface-guided planar nanowires of CsPbBr₃, single crystals with a 1D nature, which serve as a simplified model system for charge transport measurements. The surface-guided growth of MHP nanowires on sapphire substrates in ordered and well-defined arrays, which can be easily integrated into functional devices. We studied the charge transport in these arrays as well as in individual CsPbBr₃ nanowires, all having uniform crystallographic orientation and well-defined facets. We fabricated the first field-effect transistor on a single nanowire of MHPs and measured charge transport characteristics such as field-effect mobility and charge carrier concentration. We also observed intriguing time-dependent electrical behavior in dark and under illumination, related to the dynamic nature of these soft semiconductors. Surface-guided growth of MHP nanowires enables fast, simple and efficient fabrication of multiple devices in parallel manner for fundamental research and optoelectronic applications.

ET05.06.25
Photoluminescence Spectroscopy of Halide Perovskites
Stuart Thomson
Edinburgh Instruments, Livingston, United Kingdom.

Halide perovskites are a promising new class of semiconducting materials for a wide variety of optoelectronic applications, such as photovoltaics, light emitting diodes, lasers and optical sensing. They have received widespread attention due to their many attractive synthetic and photophysical properties, namely; solution processability, high tunability, low charge carrier lifetimes and high charge carrier mobilities. Photoluminescence spectroscopy is a powerful tool for the photophysical investigation and materials optimisation of halide perovskites. Using photoluminescence spectroscopy we have investigated the photophysics of a range of halide perovskite photovoltaic absorbers and light emitters.

Methyl ammonium lead iodide (MAPI) is one of the most efficient and widely investigated perovskite absorbers for photovoltaic cells. Using time-resolved photoluminescence, the charge carrier lifetime of MAPI was measured and was found to increase with the thermal annealing duration of the perovskite layer. In addition, temperature dependent photoluminescence spectroscopy was used to monitor the change in the perovskite bandgap with temperature and determine the orthorhombic to tetragonal and tetragonal to cubic phase transition temperatures.

Photoluminescence spectroscopy is particularly well suited for the study of perovskite materials for light emitting applications. Two dimensional perovskites are a promising material for the creation of single component white light source. We investigated the two dimensional white light emitter, α-(DMEN)PbBr₄, using steady state photoluminescence to determine the chromaticity coordinates of the emission and time-resolved photoluminescence to probe the excited state lifetimes.

ET05.06.26
Elucidating Exciton-Phonon Interaction in Quasi-2D Ruddlesden-Popper Perovskites
Watercharaphol Pariromongkol, Nabeel S. Dahod, Alexia Stollmann, Shao-Liang Zheng and William Tisdale; Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; Chemical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; Mechanical and Process Engineering, ETH Zürich, Zürich, Switzerland.

Two-dimensional lead halide perovskites (2D LHPs) are solution-processed semiconductor quantum wells with great promise for optoelectronic applications. Their properties are highly tunable, and can be modified by changing the quantum-well thickness as well as their chemical constituents. Since 2D LHPs have high exciton binding energies, understanding exciton dynamics is important for designing novel 2D LHP devices. Here, we present a study based on temperature-dependent photoluminescence to elucidate exciton-phonon interactions in these materials. Our study is based on iodide perovskites with varied quantum-well thicknesses, cations, and organic spacer lengths. The results show that tuning these parameters affects photoluminescence properties as well as phase transitions. This study provides a fundamental understanding of 2D LHP photophysics, necessary for developing novel 2D LHP optoelectronics.

ET05.06.27
Time-Resolving Ultrafast Polaron Formation Dynamics in Lead-Halide Perovskites via Terahertz Emission Spectroscopy
Burak Guzel turk1,2 and Aaron Lindenberg3; 1Stanford University, Stanford, California, United States; 2SLAC National Accelerator Laboratory, Menlo Park, California, United States.

Recently we have revealed that poly-crystalline thin-films of hybrid lead-halide perovskites emit broadband electromagnetic radiation within the terahertz (THz) frequency window [1]. This radiation mainly arises from ultrafast electron-hole separation due to different diffusivities of photo-generated carriers (i.e., photo-Dember effect). A transient photocurrent with a rise-time shorter than the period of an optical phonon mode can coherently drive the corresponding phonon. By means of this, longitudinal optical (LO) phonons can be coherently launched via ultrafast photo-excitation and can be detected via measurement of the associated THz emission [1, 2]. In a polaron picture, a carrier alters the equilibrium position of ions within a polar semiconductor and this effectively induces a potential well for the carrier causing its "self-trapping" around the displaced ions [3]. Polaron formation proceeds through long range carrier – LO phonon coupling [4] and was lately evoked to account for the surprising opto-electronic properties of the hybrid perovskites [5]. Here we show that we can time-resolve polaron formation dynamics via monitoring of the emitted THz radiation from the coherent LO phonon mode. In MAPbI₃, we observe a strong emission peak at 1.15 THz corresponding to the lowest energy LO phonon mode of the inorganic sub-lattice. By time- and frequency-resolving this LO phonon-associated emission, we observe an intriguing dependence on the excitation photon energy. When we excite the perovskite at its band-edge (770 nm), the emission at the LO mode arises instantaneously. However, when a well-above bandgap excitation (400 nm) is used, the emission at the LO phonon mode emerges with a finite time delay (~300 fs). This suggests that hot-carriers cannot form polarons due to their excess kinetic energy. Therefore, initial carrier cooling dominates over the polaron formation. Furthermore, we observe a dynamic softening of the LO mode within the first ps suggesting that electronic charge alters the stiffness constant of the ionic bonds within the material as predicted in other polaronic systems [3].

Lead halide perovskites are promising materials for a range of applications owing to their structural uniqueness and optoelectronic properties. Understanding the relationship between the atomic/superstructures and the associated properties of perovskite materials is vital to fully utilize their potential performances. We present the detailed pressure processing of CsPbBr₃ perovskite nanocube superlattices (NC-SLs) for the first time. By using diamond anvil cell combined with in situ synchrotron-based small/wide angle X-ray scattering (SAXS and WAXS) and photoluminescence (PL) probes (shown A in the Figure), the NC-SL transformations are correlated at both atomic and superlattice levels with the PL transition through a pressure cycle of 0 ↔ 17.5 GPa. In-situ SAXS and WAXS measurements monitored its mechanical and structural changes showing that the NC-SL went through multiple phase transitions both at both atomic and superlattice levels. After the pressure process, the individual CsPbBr₃ NCs fused into two-dimensional nanoplatelets (NPLs) with a uniform thickness (~10.1 nm). The pressure-synthesized perovskite NPLs exhibited a pure single cubic crystal structure, a 1.6-fold enhanced photoluminescence quantum yield, and a longer emission lifetime than the starting NCs. These results suggest that pressure processing can provide a novel approach for the quick conversion of lead halide perovskites into structures with enhanced properties.

Semiconducting metal-halide perovskites present various types of chemical interactions which give them a characteristic fluctuating structure sensitive to the operating conditions of the device, to which they adjust. This makes the control of structure-properties relationship, especially at interfaces where the device realizes its function, the crucial step in order to control devices operation. In particular, given their simple processability at relatively low temperature, one can expect an intrinsic level of structural/chemical disorder of the semiconductor which results in the formation of defects. Metal halide perovskites have been successfully applied as optically active layers in photovoltaic and optoelectronic devices. The high efficiency of such research-scale devices hold the promise for an imminent application of perovskites in large scale energy production and lighting solutions. Intrinsic thermal and photo-physical instability of these materials pose, however, a challenge for further developments in device scale up and long-term reliability. Instabilities are manifested as light-induced ion migration and segregation, eventually leading to material degradation under prolonged exposure to light. Understanding, controlling and eventually blocking such material instabilities are fundamental steps towards large scale exploitation of perovskite in optoelectronic devices. By combining photoluminescence measurements under controlled conditions with ab initio simulations we identify photo-instabilities related to competing light-induced formation and annihilation of trap states, disclosing their characteristic length and time scales and the factors responsible for both processes. We show that short range/short time defect annihilation can prevail over defect formation, happening on longer scales, when effectively blocking undercoordinated surface sites, which act as a defect reservoir. By an effective surface passivation strategy we are thus able to stabilize the perovskite layer towards such photo-induced instabilities, leading to improved optoelectronic material quality and enhanced photo-stability in a working solar cell. The proposed strategy represents a simple solution towards longer stability perovskite thin films that could be easily implemented in large scale manufacturing.
strategy, we studied an ethyldimethylamine-containing compound that yielded an open-circuit voltage of 1.59 V.(4)

The last part elaborates on a roadmap on how to extend the multiplication to multicomponent engineering providing a series of new compounds that are highly relevant candidates for the coming years.

Anisotropic Moisture Erosion and Carrier Transport in CH3NH3PbI3 Single Crystal Qianrui Lv and Qingfeng Yan; Tsinghua University, Beijing, China.

As a new semiconductor material, methyl ammonium lead iodide (CH3NH3PbI3) perovskite has attracted much attention in recent years owing to its outstanding photoelectric properties. Although CH3NH3PbI3 perovskite has achieved tremendous progress in photovoltaic devices, a deeper understanding of its intrinsic physical properties is still of great interest. The anisotropy of properties is an important feature of semiconductor materials, while limited relevant work has been reported regarding the anisotropy of CH3NH3PbI3 perovskite. In this work, we report the fast growth of high-quality CH3NH3PbI3 single crystal by using a non-seeded solution growth method. When exposed the CH3NH3PbI3 single crystal to moisture, it was found that the (001) facet exhibited more sensitive to water molecules and showed faster erosion rate compared with the (100) facet and (112) facet. We then developed a top-down strategy to prepare CH3NH3PbI3 single-crystalline thin films of tens of micrometers in thickness with different orientations, which provided the possibility of directly studying the anisotropy of conduction transport in CH3NH3PbI3 single crystals. Vertical-structured FET devices based on CH3NH3PbI3 single-crystalline thin films with different orientations were fabricated. Compared with the [100] and [112] orientation, it was found that carriers have lower mobility along the [001] orientation than along the [100] and [112] orientation. The origin of the anisotropy in moisture erosion and carrier transport was elucidated from the perspective of crystal structure. The reveal of the orientation-dependent moisture erosion and carrier transport in perovskite CH3NH3PbI3 single crystal may deepen the understanding of physical properties of the material and guide the design of stable and high-performance optoelectronic devices in the future.

In organic-inorganic hybrid perovskite solar cells, optimization of hole transport materials (HTMs) is important for enhancing solar power conversion efficiency and improving stability [1,2]. At OIST, a team of researchers in the Energy Materials and Surface Sciences Unit has been making concerted efforts to study 2,2',7,7'-tetrakis[N,N-di-(4-methoxyphenyl)amino]-9,9'-spirobifluorene (spiro-MeOTAD), which is the most widely used HTM in perovskite solar cells [2-8]. In this talk, we will present our latest understanding of fundamental interactions between Li-bis(trifluoromethanesulfonfyl)-imide (LiTFSI), 4-tert-butylpyridine (t-BP) and spiro-MeOTAD. Also, we will show how gas exposure (e.g., exposure to O2, H2O, N2) influences electronic structures and conductivity of such HTM films. In addition, we will propose further strategies to improve perovskite solar cell performance and stability.

In Situ X-Ray Investigation Underpins Moderate Annealing Humidity on Improving Crystallinity of Organohalide Perovskites Zhiyuan Ma1, 4, Hun Zhou1, Wei Chen1, 2 and Zhang Jiang1; 1Advanced Photon Source, Argonne National Laboratory, Lemont, Illinois, United States; 2Materials Science Division, Argonne National Laboratory, Lemont, Illinois, United States; 3Institute for Molecular Engineering, The University of Chicago, Chicago, Illinois, United States; 4Materials Science and Engineering, China University of Petroleum, Beijing, China.

Emerging organolead-halide-perovskite-based materials and devices have recently received tremendous attention due to their extraordinary photonic and optoelectronic performance and potential low production costs. Many physical and chemical properties beyond light harvests have erupted. Despite the rapid development of perovskite materials and devices, the impact of environmental factors on different stages of materials synthesis and device fabrication still remains unclear. Moisture or humidity is widely recognized as one of the major lethal factors in perovskite devices degrade or decompose after rapid development of perovskite materials and devices, the impact of environmental factors on different stages of materials synthesis and device fabrication still remains unclear. Moisture or humidity is widely recognized as one of the major lethal factors in perovskite devices degrade or decompose after
optoelectronic device performance. By taking advantage of synchrotron-based grazing incident wide-angle x-ray scattering (GIWAXS), we in situ monitor the transformation of organohalide perovskites from precursors to final films upon thermal annealing at different relative humidity. in situ GIWAXS reveals the formation of crystalline perovskite materials over relevant time and moisture scales to decipher the effect of humidity on both phase transition and crystal structures during annealing. These in situ measurements demonstrate that moderate humidity accelerates the formation of organohalide perovskites and improves the orientation of the film, but more than 50% relative humidity retards the formation of perovskites and destructs their crystal structures. Furthermore, the highly oriented films obtained at optimized relative humidity are observed which could be attributed to the hydration of precursors. These findings clearly elucidate the influence of moisture environment in annealing process of organohalide perovskites and, in turn, allow us to correlate the improved performance of organohalide perovskite materials and devices to structural features in terms of environmental effects.

Advances in Perovskite Active Layer Stability  Edward H. Sargent; University of Toronto, Toronto, Ontario, Canada.

I will discuss advances - including doping strategies and reduced-dimensional perovskites - in increasing the stability of the perovskite active layer.

11:00 AM ET05.07.08
Dipolar Cations Confer Defect Tolerance in Wide Bandgap Perovskites Haiyen Tan1,2; Fanglin Che2, Mingyang Wei2 and Ted H. Sargent2; 1University of Toronto, Toronto, Ontario, Canada.

Efficient wide-bandgap perovskite photovoltaics will enable tandem solar cells when successfully combined with low-bandgap absorbers such as crystalline silicon. However, wide-bandgap perovskite solar cell materials (PSCs) today exhibit performance far inferior to that of sub-1.6 eV bandgap PSCs. Their tendency to form a high density of deep level trap states underpins this limitation. Here we show that healing the deep traps in mixed cation-halide wide-bandgap perovskites - in effect, increasing the defect tolerance via cation engineering - could enable further performance improvements in PSCs. We achieve a stabilized power conversion efficiency (PCE) of 20.7% for 1.65-eV-bandgap PSCs by incorporating a small concentration of dipolar cation additive. The devices exhibit a high open-circuit voltage ($V_{oc}$) of 1.22 V and a fill factor (FF) that exceeds 80%. We also achieve a PCE of 19.3% for 1.1 cm$^2$ large-area devices with a $V_{oc}$ of 1.24 V. We achieved commendable improvements in 1.74-eV-bandgap PSCs, where we obtained a stabilized PCE of 19.1% together with a high $V_{oc}$ of 1.25 V and FF of over 80%. From density functional theory calculations, we find that the presence and reorientation of the dipolar cation in mixed perovskites can heal the defects that introduce deep trap states.

Our findings shed light on defect healing in perovskite materials and pave the way to further increasing the efficiency of perovskite-enabled tandem photovoltaic devices.

11:15 AM ET05.07.09
Degradation Analysis of Perovskite Films Using the Photo Thermal Induced Resonance Technique Hyang Mi Yu1, Hye Min Oh1 and Mun Seok Jeong1,2; 1Department of Energy Science, Sungkyunkwan University, Suwon, Korea (the Republic of); 2Center for Integrated Nanostructure Physics (CINAP), Institute for Basic Science (IBS), Suwon, Korea (the Republic of).

Organic-inorganic mixed halide perovskite (MAPbX$_3$: MA=CH$_3$NH$_3$, X=Cl, Br, or I) are extensively used as absorbing materials for solar cell due to its broad absorption range and long charge carrier diffusion length. Despite its high photovoltaic efficiency, their poor stability remains a major challenge for high performance device and their commercialization.

Perovskite films based on CH$_3$NH$_3$PbI$_3$-Cl undergo rapid degradation when exposed to oxygen and moisture. To overcome this problem, many researchers have been studied about the degradation mechanism of perovskite films. However, these results were not simultaneously obtained with structural and chemical properties of perovskite films. Thus it is not provided complete degradation mechanism of perovskite films.

In this work, we investigated the degradation mechanism of perovskite films by performing simultaneous measurement of the structural and chemical informations using the photo thermal induced resonance technique combined with atomic force microscope. Finally, this study will contribute to understanding of the mechanism of the degradation process of perovskite films and enhance the stability of perovskite optoelectronics field.

11:30 AM ET05.07.10
First Principles Modelling of Grain Boundaries in (FA/Cs)Pb(I/Br), Perovskite Solar Absorbers Keith McKeen; Univ of York, York, United Kingdom.

Mixed-cation lead mixed-halide perovskite solar absorbers such as (FA/Cs)Pb(1/Br) exhibit remarkable and tunable optoelectronic properties that make them attractive for next generation solar cell technologies [1]. In practice such materials are always polycrystalline however the role of grain boundaries (GBs) remains poorly understood and a subject of much speculation. For example, separate experimental studies suggest GBs in MAPbI$_3$ can be both act as recombination centers [2] and structural barriers to charge transport [3]. We will present our latest theoretical modeling of GBs using density functional theory, with particular focus on the electronic properties of mixed-cation mixed-halide perovskites.

In this talk, I will present our recent theoretical predictions of GBs in (FA/Cs)PbI/Br). We employ density functional theory methods similar to those we have previously applied to model extended defects in a range of other materials including CIGS, TiO$_2$ and Fe$_3$O$_4$[6,8]. We find that for the Σ3 (111) GB there is strong segregation of Br to the GB (but not Cs) and it remains electrically benign with no preferential electron or hole trapping. However, for the Σ3 (111) GB there is strong segregation of both Cs and Br and this is associated with the introduction of shallow electron trap states at the GB. We note that this may be beneficial for efficient electron/hole separation since there is no tendency for holes to trap at the GB [9]. These results highlight the point that not all GB types are equivalent and so one needs to consider a range of GBs to build a statistical picture. Importantly, mixed perovskite absorbers present the possibility of much wider compositional variations (even without intrinsic defects) and so understanding GB properties is key to understanding the behaviour of real polycrystalline materials.

Combining and grain-boundary engineering involved in the processing of OIHP thin films for PSCs will be discussed with specific examples. Additionally, the are able to characterize and monitor fast reaction/formation of perovskite thin films immediately after the spin-coating process which is commonly used in improvements however, were mostly achieved through empirical optimization of processing conditions. Due to the fast and complex chemical reactions of devices. The field is moving towards more and more complex chemical compositions enabling dramatically improved device performances. Those materials. The overall goal of our research is to have deterministic control over scalable processing of tailored halide perovskite thin films with desired large areas is critically important. The microstructures and grain-boundary networks in the resulting polycrystalline OIHP thin films are equally important As a result, in 100% humidity at 40 °C, the 10% w/w PbSe-doped CH₃NH₃PbI₃ films exhibited >140-fold stability improvement over pristine CH₃NH₃PbI₃ films. Whilst perovskite structure of the PbSe-doped CH₃NH₃PbI₃ films reserved, a top efficiency of 10.4% with 70% retention after 700 hours aging in ambient air was achieved on an unencapsulated 10% w/w PbSe:CH₃NH₃PbI₃-based cell. Significantly, the incorporated Se²⁻ effectively suppressed iodine diffusion in solar cell, leading to enhanced chemical stability of the silver electrodes. Successful doping of divalent Se²⁻ in perovskite lattice is further confirmed by enlarged lattice spacing from X-ray diffraction patterns, asymmetric photoluminescence peaks with shoulder electronic states, and concomitantly increased electrical conductivity of 5%, 10% w/w PbSe:CH₃NH₃PbI₃ thin films. This work could advance the fundamental understanding of degradation and stabilization of hybrid perovskites in both material and device settings.

Chemical stabilities of hybrid perovskite materials demand further improvement towards long-term and large-scale photovoltaic applications. Herein, we report enhanced chemical stability of CH₃NH₃PbI₃ by doping divalent anion Se²⁻ in the form of PbSe in precursor solutions to enhance the hydrogen-bonding-like interactions between organic cation and inorganic framework, as evidenced by redshifted N-H stretch from Fourier-transform infrared spectra. As a result, in 100% humidity at 40 °C, the 10% w/w PbSe-doped CH₃NH₃PbI₃ films exhibited >140-fold stability improvement over pristine CH₃NH₃PbI₃ films. Whilst perovskite structure of the PbSe-doped CH₃NH₃PbI₃ films reserved, a top efficiency of 10.4% with 70% retention after 700 hours aging in ambient air was achieved on an unencapsulated 10% w/w PbSe:CH₃NH₃PbI₃-based cell. Significantly, the incorporated Se²⁻ effectively suppressed iodine diffusion in solar cell, leading to enhanced chemical stability of the silver electrodes. Successful doping of divalent Se²⁻ in perovskite lattice is further confirmed by enlarged lattice spacing from X-ray diffraction patterns, asymmetric photoluminescence peaks with shoulder electronic states, and concomitantly increased electrical conductivity of 5%, 10% w/w PbSe:CH₃NH₃PbI₃ thin films. This work could advance the fundamental understanding of degradation and stabilization of hybrid perovskites in both material and device settings.

In Situ Phase and Optical Characterizations to Unveil the Chemistry of CH₃NH₃PbI₃ Formation Jue Gong1, Mengjin Yang3, Dominic Rebollar1, 2, Peijun Guo2, Jordan Rucinski1, Zachary Liveris1, Richard D. Schaller2, 4, Kai Zhu1 and Tao Xu1; 1Northern Illinois University, DeKalb, Illinois, United States; 2Argonne National Laboratory, Lemont, Illinois, United States; 3National Renewable Energy Laboratory, Golden, Colorado, United States; 4Chemistry, Northwestern University, Evanston, Illinois, United States.

Solution-processed thin-film perovskite solar cells (PSCs), where the record efficiency has rocketed from ~4% to ~23% — comparable to commercial silicon-based solar cells — in just nine years, offer unprecedented promise of low-cost, high-efficiency renewable electricity generation. Organic-inorganic halide perovskites (OIHPs) at the heart of PSCs have unique structures, which entail rotating organic cations inside inorganic cages, imparting them with desirable optical and electronic properties. To exploit these properties for PSCs application, the reliable deposition of high-quality OIH thin films over large areas is critically important. The microstructures and grain-boundary networks in the resulting polycrystalline OIH thin films are equally important as they control the PSC performance and stability. Fundamental phenomena pertaining to synthesis, crystallization, coarsening, microstructural evolution, and grain-boundary engineering involved in the processing of OIH thin films for PSCs will be discussed with specific examples. Additionally, the discovery of Pb-free, Ti-based all-inorganic halide perovskites will be presented, together with the demonstration of viable PSCs based on these new materials. The overall goal of our research is to have deterministic control over scalable processing of tailored halide perovskite thin films with desired compositions, microstructures, and grain-boundary networks for large-area, high-efficiency, and stable PSCs.

Combining In Situ Phase and Optical Characterizations to Unveil the Chemistry of CH₃NH₃PbI₃ Formation Jue Bing Song1, Faizan Motiwala1, 2, Megumi Mori1, 2, Gideon Segev1, 3, Camelia V. Stan4, Nobumichi Tamura4 and Carolin M. Sutter-Fella1; 1Chemical Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 2Chemical Sciences Division, Lawrence Berkeley National Laboratory, Berkley, California, United States; 3Joint Center for Artificial Photosynthesis, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 4Chemical Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States. Over the past decade, organic-inorganic halide perovskite semiconductors have attracted substantial research attention for application in optoelectronic devices. The field is moving towards more and more complex chemical compositions enabling dramatically improved device performances. Those improvements however, were mostly achieved through empirical optimization of processing conditions. Due to the fast and complex chemical reactions of hybrid metal halide perovskites, significant variations in material properties and device performances are observed from previous reports. Therefore, in depth understanding of the fundamental film formation processes and relevant synthesis parameters is critical for the control of the final film properties and to achieve reproducible, high performance devices. Here, we establish methodical insights into the film formation process of metal halide perovskites by developing complementary in-situ characterization techniques including synchrotron diffraction, optical imaging and photoluminescence spectroscopy. These in-situ characterization techniques complement each other in providing a holistic picture of the relation between phase, optical response and morphology evolution. With our newly designed systems, we are able to characterize and monitor fast reaction/formation of perovskite thin films immediately after the spin-coating process which is commonly used in lab research. As a model system, we studied methylammonium lead iodide (CH₃NH₃PbI₃) as one of the most studied compounds among organic-inorganic halide perovskites. At relevant time scales, we demonstrate how the precursor chemistry influences phase formation, crystallization kinetics, film morphology, and optical response. We find that the perovskite film morphology is directly related to the structure of the intermediate phase and by tuning the precursor chemistry, we are able to tune the film morphology. The precursor chemistry plays the main role in the perovskite film formation and prevents the formation of needle-like morphology. In addition, using the CI chemistry, the disappearance and re-appearence of perovskite phases was observed over the course of crystallization which is distinctly different from other non-Cl chemistries. The combination of state-of-art in-situ characterization techniques could pave the way towards assessing the roles of synthesis and processing designs very efficiently thus, enables mechanistic insights and control of the film properties for high efficiency devices.

2:00 PM ET05.08.02 Adsorption Induced Anisotropic Growth—Band Gap Engineering in Gas induced Hybrid Perovskite Sayantan Sasmai1, 2, Raj Pala2, Sri Sivakumar2 and Suresh Veniyaveetil1; 1National University of Singapore, Singapore, Singapore; 2IIT Kanpur, Kanpur, India. Extremely high optical absorption, benign intrinsic defects, much longer diffusion length, a perfect synergy to achieve astonishingly high photovoltaic efficiency has made hybrid halide perovskites one of the major research fields in last few years. Additionally, facile band gap tunability make this hybrid perovskites a promising contender for double junction tandem solar cell useful to achieve much higher efficiency (theoretical efficiency limit 46.1%) than
single junction solar cell (efficiency limit 33.7%). Although several methods such as simple exchange of alkyl halides, compositional substitution, variation of precursor solution concentration, and solvent annealing as well as lattice footing induced fragmentation exists to tune the band gap of hybrid perovskite originated in solution phase, none of them applied in case of band gap tuning in recently acclaimed gas induced growth of hybrid perovskites due to less flexibility to implement all these methods in gas induced reaction impeded its use in multi junction tandem solar cell. Formation of ultra-thin film, facile quantum confinement and most importantly large area fabrication established an unsalable importance of gas induced growth process in hybrid halide perovskite field, albeit limited in use in double junction tandem solar cell due to inability to tune the band gap.

In the context of band gap tuning of methylammonium lead iodide (MAPbI₃) in gas induced growth, here we introduced a complete mechanistic detail highlighting a new synthetic route depicting selective adsorption of in situ formed hexylamine on the Pb site of growing MAPbI₃ induced anisotropic growth of MAPbI₃ leading to a unique sheet like structure of much higher band gap (2.18 eV). Moreover, gradual evaporation of in situ formed free hexylamine from the solvated intermediate and simultaneous relaxation of growth restriction on MAPbI₃ during prolonged exposure of methylamine leading to structural transformation of sheet to particle with continuous band gap engineering reflected in continuous change in emissive properties. This selective adsorption induced anisotropic growth of MAPbI₃ enable continuous shifting of conduction band of growing MAPbI₃ proved by scanning tunnelling spectra was also validated by DFT simulation points to the partial charge transfer to nonbonding p orbitals of Pb responsible for tuning of band gap of MAPbI₃. We believe this selective adsorption induced band gap tuning of MAPbI₃ will encourage to prepare new series of variant of MAPbI₃ which can be useful in tandem solar cell as well as light emitting diode and display application.

Material Engineering for Wide-Bandgap Perovskite Solar Cells Ni Zhao, Yang Zhou, Jie Cao and Ching-Ping Wong; Chinese University of Hong Kong, Shatin, Hong Kong.

Wide bandgap organic-inorganic hybrid perovskites with a bandgap ranging between 1.7-2.0 eV have shown great potential to improve the efficiency of single-junction silicon or thin-film solar cells by forming a tandem structure with one of these cells or with a narrow bandgap perovskite cell. However, solar cells based on this class of materials generally suffer from poor stability and a large open-circuit voltage (Voc) deficit, which is associated with the phase segregation of the materials under light illumination. In this talk I will explain how these issues can be addressed via multi-scale material modification combining composition tuning, grain engineering and surface passivation. Firstly, I will introduce a new mechanism to suppress ion migration in bulk perovskites through the interstitial incorporation of small alkali cations in the lattice of the state-of-the-art Cs/MFA triple cation perovskites. Through a combined experimental and theoretical investigation on the incorporation of extrinsic alkali cations (Rb⁺, K⁺, Na⁺, and Li⁺) in the perovskite materials, we unambiguously reveal the size-dependent interstitial occupancy of these cations in the perovskite lattice and demonstrate increased ion migration barriers in the lattice after the interstitial occupation. Secondly, I will describe how improved grain crystallization and grain boundary passivation can be achieved simultaneously through tuning of perovskite precursor composition. Using FAS0.17Cs0.83PbI3-xBrx (x=0.8, 1.2, 1.5 and 1.8) with a varied bandgap from 1.72eV to 1.93eV as the model system, we illustrate how precursor additive Pb(SCN)₂ should be matched with a proper ratio of FAX (I and Br) to realize large grains with defect-healed grain boundaries. The optimized perovskite films showed good photostability at both room-temperature and elevated temperature. Moreover, the corresponding solar cells exhibited excellent photovoltaic performances with the champion Voc/stabilized power output efficiency reaching 1.244V/18.60%, 1.284V/16.51%, 1.296V/15.01% and 1.312V/14.35% for WB-OHPPs with x=0.8, 1.2, 1.5 and 1.8, respectively.

Homogeneity in Halide Perovskites—The Implications of Disorder on Stability and Advancing to a Terawatt Scale Photovoltaic Technology Joseph J. Berry; National Renewable Energy Laboratory, Golden, Colorado, United States.

Photovoltaic devices based on hybrid organic-inorganic perovskite absorbers have reached outstanding performance over the past few years, surpassing power conversion efficiency of over 22%. This talk we discuss the progress at the National Renewable Energy Lab (NREL) on the challenges in hybrid perovskite solar cells (HPSCs) and stability of HPSC devices and materials. This talk will highlight work at NREL to develop understand and enhance stability of HPSCs. Discussion will focus on efforts to more carefully understand the implications of process on stability and efficiency in the HPSC devices. Connections to aspects of material formation and processing for high-volume manufacturing will also be made. In the case of stability, an examination of different perovskite active layers their formation and resulting interfacial electronic structure with contacts in the HPSCs stack will be presented. Work at NREL indicate interface formation of the active layer with different carrier transport materials has direct implications for performance and it evolution over time in the resulting devices will be built upon. Results extending these results to additional active layers and associated interfaces studies in which photoemission, time resolved spectroscopy, structural studies and device level studies are combined indicates the importance of both processing and impacts of interface electronics and carrier dynamics. Results on the extension of existing stable architectures to mini-module devices will be presented along with performance data for these systems.

4:30 PM ET05.08.06
The Fluid Dynamics in Perovskite Scalable Coating and Its Suppression by Surfactants for Efficient Photovoltaic Modules Yehao Deng1, 2 and Jinsong Huang1, 2; University of Nebraska–Lincoln, Lincoln, Nebraska, United States; 3University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States.

Organic-inorganic hybrid perovskites are novel photovoltaic materials with high power conversion efficiency over 22% and low-cost solution processability. However, scaling up of perovskite fabrication remains a challenge due to the complex fluid dynamics within perovskite precursor solution when drying. Here, we show the fluid flow pattern observed by in-situ microscopy and report that surfactants additives can dramatically suppress the flow. The surfactant additives enabled the deposition of uniform, full-coverage perovskite film at a coating rate of 180 meter per hour and resulted in stabilized module efficiencies of 15.3% and 14.6% measured at aperture areas of 33.0 and 57.2 square centimeter, respectively. The result indicates that surfactants could be a kind of general additives in perovskite inks for improving perovskite film quality in scalable solution coating methods.

4:45 PM ET05.08.07

Two dimensional metal halide perovskites have demonstrated exceptional stability and performance in various optoelectronic applications. A key to higher performance is to align the insulating organic layers vertical to the substrates to avoid inhibition of charge transport. Several fabrication routes have been presented in literature but there is not yet a general strategy to orient 2D perovskite sheets vertically to the electrodes, due to lack of understanding of the crystallization process. In our research, based on our previous discovery that vertically oriented 2D perovskite crystallization can occur at liquid-air...
However, in order for perovskite compounds to reach eventually the market, some severe limitations have to be addressed. Those are not other than their (FA)x(Pb(I1-xBrx))3 channel layers to produce TFTs with significantly enhanced performance characteristics. on green emission region. In this regard, herein we tried to tailor the emission range of Br-based quasi-2D perovskite from green to blue region by integrating organic carrier spacers. As the candidates for the spacer, aromatic phenylethylammonium (PEA), benzyltrimethylammonium (BTA) and aliphatic isoproplammonium (IPA), n-propylammonium (nPA) cations were employed by controlling the relative concentration ratio. As a result, the PL intensities and the emission wavelength of the new class of quasi-2D perovskites, BTA and nPA-based perovskites, showed deep-blue emissions at 475 nm, with uniform and well-structured surface coverage. In addition, The PL intensity of the blue perovskite thin film was on par with that of the green one \((\text{PEA}_4\text{MA}_8\text{PbBr}_{30})\). By controlling the ratio of BTA and nPA, we could fine-tune the PL wavelength from 610 nm (green) to 475 nm (blue) systematically (with 7 nm intervals). Based on our dimensionally-controlled perovskites, the blue-emissive Q-2D perovskite LED showed low turn-on voltage (less than 4 V) with high-current density (42 mA/cm²). The protocol and strategy established in this study can be exploited to enhance high-level electron quantum efficiency (EQE) and lumiance.

Highly Efficient Perovskite Quantum-Dot Light-Emitting Device by Gel Permeation Chromatography as New Purification Process and Interfacial Engineering Using Alkyl Ammonium Salt Layer [Hinako Ebe, Yoshihito Takashashi, Jun Sato, Takayuki Chiba, Satoru Ohisa and Junji Kido.]

Lead halide perovskite (CsPbX₃, X = Cl, Br, or I) quantum dots (QDs) have recently attracted considerable interest for light-emitting device (LED) applications such as thin film displays and solid-state lighting, owing to electroluminescence emission with narrow full width at half maximum (FWHM), tunable color properties by anion exchange method, and ease of solution processability (1,2). The optical properties of perovskite QDs as ionic nanocrystals are greatly affected by highly polar washing solvent due to occurring cation- and anion-defects (3). In this work, we achieved low driving voltage and high efficiency perovskite QD-LED using Gel permeation chromatography (GPC) with nonpolar solvent to remove excess ligand such as oleic acid (OA), oleylamine (OAM) and synthesis solvent 1-octadecene (ODE). We confirmed completely remove these impurities by GPC in contrast to conventional reprecipitation process. In addition, we demonstrated the effect of interfacial layer between the hole transport layer and the perovskite QDs using alkyl ammonium salts containing the Br anion, oleylamine bromide (OAM-Br) to passivate cation- and anion-defects. The LED based on OAM-Br interfacial layer exhibited higher efficiency compare to the LED without OAM-Br layer due to the suppression of interfacial cation- and anion-defects.

Metal Halide Perovskite Based Optical Phase Shifter—Giant Photocarrier-Induced Refractive Index Change [Hirokazu Tahara, Tomoko Aharen, Atsushi Wakamiya and Yoshikiko Kanemitsu, Kyoto University, Uji, Japan.]

Metal halide perovskites are excellent optoelectronic materials that are quite suitable for thin-film solar cells, light-emitting diodes (LEDs), and lasers. This is because they exhibit strong optical absorption, high luminescence efficiencies, long carrier lifetimes, long diffusion lengths, and low densities of nonradiative recombination centers [1]. Recently, unique properties of halide perovskites have been discovered, e.g., photon recycling, ion migration, and local rearrangement of molecular dipoles [2-4]. These properties are expected to lead to the development of new-type optoelectronic devices. One of the most important properties of halide perovskites is that they crystallize in low-temperature solution processes. In particular, it is remarkable that large-size single crystals of halide perovskites can be grown in low-temperature solution exhibiting high optical transparency and exceptionally low surface light scattering. These optical properties are beneficial for novel optical transmittance applications in the broad spectral range from visible to infrared. In this work, we studied the photocarrier-induced refractive index change in organic-inorganic hybrid perovskites. The crystal used in this study was a methylammonium lead bromide (MAPbBr₃) single crystal. To measure the photoreflective properties of the halide perovskite, we developed an interferometric system that is synchronized with photoexcitation. The photoreflective phase shift was measured by detecting the phase shifts of the transmitted light through the perovskite single crystal mounted in the interferometric system. From the time-resolved measurements and excitation-pulse fluence dependence of the photoreflective phase shifts, we clarified that photogenerated carriers cause extremely large and long-lived changes in the refractive index. This result shows that the perovskite single crystal works as an optical phase shifter. Moreover, we demonstrated that infrared laser light is tunable to any desired polarization configuration by employing the photoreflective phase shift. Our demonstrations provide new pathways to develop optical devices with organic-inorganic hybrid perovskites leading to variable wave plates, optical switches, and phase modulators.

A Device Simulation of Organohalide Perovskite Resistive Random Access Memory [Kyunghwan Min, Sungwoo Cho and Yongwoo Kwon; Hongik University, Seoul, Korea (the Republic of)].

Resistive random access memory (ReRAM) based on organohalide perovskite (OHP) shows excellent properties compared to conventional metal oxide resistive memory such as low operating voltage, high on/off ratio, and fast switching speed in several experimental demonstrations. Nevertheless, this technology is still in the premature stage. The design strategy of the active material and the device architecture must be established for the OHP ReRAM to be promoted to the stage of the commercial development. Thus, a device simulation based on finite element method is necessary to investigate the optimal device architecture on constituent materials and geometry. In this work, we will present a stochastic finite element simulation of conductive filament formation to perform reverse engineering on the material parameters of the OHP, in other words, to estimate which material parameters critically affect switching characteristics. In addition, the effects of device geometry and the nature of OHP/metall contacts were also studied.

First-Principles Investigations on Amotomic Origin of I-V Hysteresis in Hybrid Perovskite Solar Cell [Seong Hun Kim¹, Pli-Ryung Cha² and Donghwa Lee²; ¹Pohang University of Science and Technology, Gyeongbuk, Korea (the Republic of); ²School of Advanced Materials Engineering, Kookmin University, Seoul, Korea (the Republic of)].

In spite of the unprecedented advance of MAPbI₃-based perovskite solar cell, there are still remaining issues to be resolved for its industrial applications.
Especially, hysteresis in current-voltage (I-V) curve is one of big challenges since it can limit its potential large scale application by causing abnormal efficiency drops. Various studies have proposed different physical origins such as ferroelectric polarization, charge trapping/detrapping and ion migration, none of study has clearly explained the microscopic origin of the hysteretic behavior in MAPbI₃-based perovskite solar cell. In this study, thus we have employed first-principles density functional theory calculations to identify the atomic origin of hysteresis in MAPbI₃. Our study has found that excess electrons or holes can stabilize the formation of iodine Frenkel defect structures in MAPbI₃. Since excess charge carriers can be easily accumulated near the electrode interface, the formation of two different iodine Frenkel defects is inevitable and reversibly it can act as a charge trap in MAPbI₃-based solar cell. Thus, the hysteretic behavior of I-V curve is a result of charge trapping and detrapping during the formation of two types of iodine Frenkel defects near electrodes. Based on our understanding, we have suggested several possible ways to suppressed the hysteresis in MAPbI₃-based solar cell.

Correlation between the Charge Transporting Layers and Defect States Distribution in Perovskite Solar Cells Measured by Admittance Spectroscopy

Rashid A. Awni, Changlei Wang, Xinxing Yin, Zhaoqing Song, Corey R. Grice, Lei Guan, Xiaoming Wang and Yanfa Yan; Department of Physics and Astronomy, and The Wright Center for Photovoltaics Innovation and Commercialization (PVIC), The University of Toledo, Toledo, Ohio, United States.

In the past decade, organic-inorganic halide perovskite solar cells (PVSCs) have achieved outstanding progress in power conversion efficiency. However, solution-processed polycrystalline perovskite thin films possess a significant number of defects. Accurately probing the defect states distribution and understanding the origins of the defects are critical for further improving the device performance. Thermal admittance spectroscopy (AS) is a powerful characterization technique to determine the energetic distribution of defect states for different inorganic (e.g., CdTe, Cu(In, Ga)Se₂, etc.) and organic thin film solar cells, and has recently been used to characterize PVSCs. Interestingly, some unique trap signatures were observed in the AS measurements of PVSCs, but their origin has yet to be determined.

Here, we perform AS measurements on the PVSCs in the n-i-p planer structure to determine the impact of electron and hole transporting layers (ETL and HTL) on the trap states. We measured PVSCs with and without the SnO₂: F- coated ETL and the spiro-OMeTAD HTL as well as devices with different HTL thicknesses, doping densities, and materials. The AS measurements at different DC bias voltages are employed to identify whether the trap features are originated from the bulk or interface defects. Our results show that defect states are less dependent on the ETL but strongly affected by the HTL. Additionally, we compared the admittance spectra of the n-i-p and p-i-n devices with the same absorber but different ETLs/HTLs. The devices exhibit different capacitance signatures, indicating that defect states probed by AS are affected by the ETLs/HTLs. More importantly, we identify that the trap states that were originally attributed to perovskite absorber layer by previous studies may likely be originated from the spiro-OMeTAD HTL. Our approach provides insights on the defect state measurement using AS and the limitations of this method.

Impact of B-Site Doping on the Optical Properties of Lead Halide Perovskites

Abdeljaleel Ismail, Mahesh K. Gangishetty and Dan Congreve; Rowland Harvard University, Cambridge, Massachusetts, United States.

Lead halide perovskites (ABX₃) have been attractive materials for various applications in optoelectronics such as solar cells and light emitting diodes (LEDs). The quantum efficiency of green and red perovskite LEDs has reached over 10% within the last few years. The composition of the perovskite has been shown to play a crucial role on their optical properties. Recently, several groups including ours, found that doping the B cation site with Mn²⁺ can significantly improve photoluminescence quantum yields of perovskite quantum dots. In addition to the Mn²⁺, many other B cations have been suggested as potential dopants, however, only a few other cations have been studied in perovskites thus far. In this work, we have explored a variety of cations with different atomic sizes and various oxidation states from +1 to +3 as dopants in perovskites. We have grown bulk perovskite crystals using these dopants and studied the changes in crystal structure, and optical properties. In a poster, I will discuss the impact of the dopants, both the type of the dopant and its concentration on the optical properties of perovskites. Our finding will eventually lay-down a platform for high performance, Pb-less perovskite light emitting diodes.

Environmental Gating and Galvanic Effects in Single Crystals of Methylammonium Lead Bromide Perovskite

Mahshid Ahmadl, Eric Mackley², Iliu Ivanov³, Eric Lukosi¹, Jeremy Tisdale¹, Ivan Kravchenko², Sergei V. Kalinin³, Bin Hu¹ and Liam Collins¹; ¹Joint Institute for Advanced Materials, University of Tennessee, Knoxville, Tennessee, United States; ²Center for Nanophase Materials Science, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; ³Nuclear Engineering, The University of Tennessee, Knoxville, Tennessee, United States.

Understanding the impact of environmental gaseous on the surface chemistry of organic-inorganic perovskite couples to the electronic and ionic transport is critically important. Here, we explore the transport behavior and origins of the gas sensitivity in MAPbBr₃, single crystals (SCs) devices using electrochemical impedance spectroscopy and current relaxation measurements. We show that the SC response to the environment is highly anisotropic and depends on crystal planes with respect to electrodes. Strong capacitive and resistive response occurs when crystals are exposed to N₂ and O₂. We discuss the possible interaction between N₂ and O₂ gases with the surface of MAPbBr₃ perovskite SC. The observed behaviors suggest that the redox state of the surface plays significant role in the transport phenomena but does not offer readily controlled redox environment. In addition, analysis of available data indicate that gas response of MAPbBr₃ SC is complex and likely related to volatilization phenomena which can change the defect mechanisms and it is highly localized on the surfaces and interfaces. The non-linear transport properties studied using pulse relaxation measurements in different environment. We notice that the potential drop across SC device is significantly higher in air as compare to N₂ and O₂ gases. The potential drop causes by space charges highly localized on the surfaces and interfaces. The non-linear transport properties studied using pulse relaxation measurements in different environment.

Organic-inorganic hybrid lead perovskites have emerged as remarkable photovoltaic (PV) absorber materials in recent years. To date, polycrystalline thin-film perovskite photovoltaic devices have reached power conversion efficiencies reaching 22.7%. However, the involvement of a toxic element of lead and long-term instability are still the main issues in the large-scale commercial application of perovskites.

With excellent long-term durability and moisture tolerance, the possibility of flexible tuning of electronic properties, and coupled to low cost synthesis routes, the two-dimensional (2D) hybrid halide perovskites have recently attracted much attention, and have been successfully used as light absorbers in efficient photovoltaic devices. 2D hybrid halide perovskites which feature long chain alkylammonium cations are generally suggested for light emitting diode applications, due to their strong photoluminescence (PL), but none have been applied thus far for photovoltaic applications. Additionally, the previous study has shown the luminescence quenching in the Pb-based analogues, (AEQT)PbX4 (X = Cl, Br, I), the energy transfer and charge separation between organic and inorganic components of the structures are not fully understood.

Herein, we investigate the geometrical, electronic and optical properties of the semiconducting 2D perovskites (AEQT)BX4 (B = Pb, Sn; X = Cl, Br, I), using relativistic hybrid density functional theory calculations. We demonstrate that unlike the traditional 2D perovskites, the choice of the organic ammonium cation has a considerable effect on the carrier transport properties, and the energy transfer between the organic and inorganic components is symmetry-disallowed. The electronic structures of the series are flexibly tailored by different halides and metal cations, with band gaps from 2.06 to 2.68 eV. Unique energy level alignments greatly hinder the electron-hole recombination in (AEQT)PbCl4, (AEQT)PbBr4, (AEQT)PbI4 and (AEQT)SnBr4, and thereby enhance the PL efficiencies. With a moderate fundamental band gap (2.06 eV) and strong direct valence band to conduction band transition, (AEQT)SnI4 is the only composition that shows intense and broad optical absorption, and as expect displays a high spectroscopic limited maximum efficiency (SLME) of 21.9%. Our results indicate the (AEQT)SnI4 is a promising class of stable and efficient light-absorbing materials for photovoltaics.

**ET05.09.12 New Electron Transporting Materials for Perovskite LED**

Seokwoo Kang, Yeonhee Sim, Beomjin Kim and Jongwook Park; Kyung Hee University, Yongin, Korea (the Republic of).

In conventional organic light emitting diode (OLED), aluminium quinolone (Alq3) has been widely used as an electron transporting layer (ETL) in the past. And in the perovskite light emitting diode (pLED) device, 2,2′,2″-(1,3,5-benzinetriyl)-tris(1-phenyl-1-H-benzimidazole) (TPBi) has been generally used as an ETL because it has better ETL property based on the higher electron mobility than Alq3 in the device. However, TPBi has disadvantage in terms of device life time compared to the Alq3, because of the inferior thermal property. Therefore, we designed and synthesized new organic electron transporting materials for perovskite light emitting diode (pLED) which includes thiazolo[5,4-b]pyridine and benzo[h]quinolone moieties, respectively. We report the pLED device performance having new two ETL compounds as well as TPBi. The device configuration is ITO/PEDOT:PSS-P3SS-Na/perovskite of phenylethylationium-formamidiniumPbBr3/trioctylphosphine oxide/ETL/LiF/Al. When new ETL materials were used, it showed high luminance efficiency of more than 10 Cd/A in green PLED device.

**ET05.09.13 Continuously Tunable Photoluminescence of Two-Dimensional Layered Perovskite Semiconductors Under High-Pressure**

Sheng Liu1, Shishuai Sun2, Chee Kwan Gan3, Jun Xing4, Thau Ha T. Do3, Andres T. Granados del Aguil1 and Qhua Xiong1; 1Division of Physics and Applied Physics, School of Physical and Mathematical Sciences, Nanyang Technological University, Singapore, Singapore; 2Tianjin University of Technology, Tianjin, China; 3Institute of High Performance Computing, Agency for Science, Technology and Research, Singapore, Singapore.

Organic-inorganic hybrid semiconductors with a perovskite lattice have recently attracted great attention due to their strong photoluminescence (PL), but none have been applied thus far for photovoltaic applications. Additionally, the two-dimensional (2D) hybrid halide perovskites have recently attracted much attention, and have been successfully used as light absorbers in photovoltaic applications.

In this work, pressure induced changes in the optical emission of two-dimensional perovskite crystals ((PEA)2PbI4), has been systematically studied at room temperature by several optical techniques, including photoluminescence (PL), time-resolved PL and Raman spectroscopy, all as a function of pressure. The crystals are pressurized inside a diamond anvil cell (DAC). At the pressure range of 0 to 3.5 GPa, the photoluminescence, originally at spectral position of ~2.3 eV, continuously shift to lower energies (red shift), and exhibits an ultra-wide tunable energy range of up to 350 meV spanning nearly the whole visible spectrum. Moreover, this energy tunability is fully reversible. In the used pressure range, the intensity of the emitted light is almost constant, while the PL lifetime keeps decreasing when increasing pressure, which implies that the efficiency of radiative recombination of excitons might be enhanced by pressure. First-principles simulations and X-ray diffraction (XRD) by synchrotron radiation both indicate that strong anisotropic compression along in-plane and out-plane directions should account for the red-shift of the band gap. Such a large optical tunability and constant emission quality within a relatively applied low pressure, has the potential to expands the applications of two-dimensional lead halide perovskite crystals in photonic and optoelectronic devices.

Sub-100nm Patterning of Perovskite Films by Self-Assembly of Block Copolymer

Hyowon Han, Euihyuk Kim and Cheolmin Park; Department of Materials Science and Engineering, Yonsei University, Seoul, Korea (the Republic of).

While tremendous efforts have been made for developing thin organic lead halide perovskite films suitable for a variety of potential photovoltaic applications such as solar cells, field-effect transistors, and photodetectors, only a few works have focused on the micro or nanopatterning of perovskite films which is one of the most critical issues for large area and uniform micro or nanorarrays of perovskite-based devices. At present, patterning is only feasible at microscale, and at sub-100nm scale lithography of thin perovskite films has not yet been reported. Here, we demonstrate perovskite patterning at sub-100 nm scale without losing structural integrity and optical properties of the perovskite by an easy and simple method using self-assembly of the block copolymers. In order to make perovskite selectively segregated into one block, we utilized diblock copolymer, polystyrene-block-poly(2-vinylpyridine) (PS-b-P2VP) consisting of non-interacting PS block and interacting Lewis base polymer P2VP block. By controlling the volume fraction (f_{PS}) and the amount of perovskite, the effective volume fraction (f_{PVE}) can be determined and various self-assembled nanostructures such as spheres, cylinders, lamellae could be successfully formed. The domain size of a perovskite crystal in the pattern could also be controlled by simply changing the molecular weight of the block copolymers. Our simple but highly controllable, nanoscale patterning of perovskites by self-assembly of block copolymers is promising and will enable applications of perovskite to highly integrated optoelectronic nanoscale devices.

Nanostructure and Optical Characterization of CH3NH3PbBr3 Perovskite via Ostwald Ripening

Kazuyuki Umemoto1, Yuki Tezuka1, Tornoko Inose2, Hiroshi Uji2, Satoshi Asakura2 and Akito Masuhara1; 1Yamagata University, Yonezawa, Yamagata, Japan; 2Hokkaido University, Sapporo, Japan; 3ISE Chemicals Corporation, Tokyo, Japan.

Methylammonium lead halide perovskites have been applied to versatile applications owing to their attractive optoelectronic properties such as long carrier diffusion length, ambipolar conductivity, broad color-tunablility exchanging by halide ions. These potentials for applications with high performance are based on perovskite electro-optical features and they are expected to be used as a next generation and solution processable semiconductor materials [1].

Recently, bright luminescence from methylammonium lead tri-bromide (MAPbBr3) perovskite nanocrystals (PeNCs) has been reported owing to the development of methods for preparing these PeNCs. Especially, MAPbBr3 PeNCs were prepared by ligand-assisted reprecipitation (LARP) inspired by the reprecipitation method for preparing organic and nano/micro crystals. LARP can provide uniform MAPbBr3 PeNCs with narrow emission, which applies for successful implementation of PeNCs into LED.

Herein, we propose Ostwald ripening as a size-tunable technique for MAPbBr3 for PeNCs using LARP. In a typical Ostwald ripening process, large crystals absorb from small ones in dispersion, as a result, large crystals grow bigger, and small crystals shrink. MAPbBr3 PeNCs could be size-controlled from several tens of nanometer size to 4 nm through shrinking of MAPbBr3 PeNCs and their PL peaks were consequently blue shifted from 514 nm to 457 nm. This suggests that Ostwald ripening can be expected to be an effective method for preparing PeNCs in the low nanometer size range.

Efficient Upconversion Photoluminescence in All-Inorganic Perovskite Colloidal Semiconductor Nanocrystals

Thu Ha T. Do, Andres T. Granados del Aguila, Jun Xing, Wen Jie Jee, Lulu Zhang and Qihua Xiong; Nanyang Technological University, Singapore, Singapore.

Semiconductor colloidal nanocrystals (NCs) are efficient fluorescence emitters, whose emission wavelengths can be tuned by varying their sizes and chemical compositions. Recently, lead halide NCs with perovskite lattices have opened access to the deep-blue and green regions of the electromagnetic spectrum [1], where traditional II-VI nanocrystals such as the prototypical CdSe, undergo rapid degradation.

In this work, we investigate the optical properties of all-inorganic CsPbX3 (X = Cl, Br, I, ClBr2, and BrI3) perovskite nanocrystals. Specifically, we focus on their ability to convert low-energy into high-energy photons in a so-called upconversion photoluminescence (UCPL) process. Overall, all the investigated nanocrystals exhibit robust and efficient UCPL, characterized as a function of temperature, excitation energy and laser power. The UCPL phenomenon takes place in two distinguishable ways: (i) multiple-phonon absorption and (ii) one-phonon with the subsequent lattice vibrational (phonon) absorption. The latter mechanism demands an energy of up to 200 meV from the thermal bath, equivalently to the total energy of about ten optical phonons of CsPbX3 compounds. However, after the first few consecutive absorption steps, the finite optical phonon population in the nanocrystals would become deficient, therefore decreasing the UCPL efficiency. We argue that the annihilation of multiple low-energy phonons creates a high-energy vibration, which repopulates the optical phonon bath and consequently increases the light upconversion probability [2]. This energy recycling mechanism is particularly strong in semiconductors having low thermal conductivity, such as lead halide perovskites [3]. Our work explains for the outstanding laser cooling effect in these materials [4] and reveals the potential of high-quality CsPbX3 nanocrystals for several applications such as biomaging, photovoltaic light-energy harvesting and optical refrigerators.

Anisotropic Excitons in Two-Dimensional Layered Lead Halide Perovskite Semiconductors

Thu Ha T. Do, Andres T. Granados del Aguila, Jun Xing, Sheng Liu, Chongyuan Jiang, Weibo Gao and Qihua Xiong; Nanyang Technological University, Singapore, Singapore.

Research on lead halide semiconductors with perovskite lattices is a rapidly growing field in nanoscience and semiconductor physics. They have great potential for low-cost yet efficient solar cells and light-emitting devices [1,2]. Their optical properties can be tuned by tailoring the chemical composition and/or the nanostructure spatial dimension with very high precision and high quality. For example, the perovskite semiconductors can grow in stable layered structures, which comprise alternatively stacked layers of lead-halide octahedra and long-chain organic molecules. The inorganic framework, sandwiched between two organic layers, forms an atomically thin quantum well with macroscopic continuity.

Herein, we study the optical properties of high-quality two-dimensional (PDA)PbI4 crystals. Four intrinsic optical transitions are resolved in the
luminescence spectrum, originating from the radiative recombination of coupled electron-hole pairs (excitons) [3]. Intriguingly, the light emission is dominated by two excitons, each of which is split into two linearly polarized and orthogonal states. Their energy splitting is in the range of ~1.2 meV, which is much larger than that of perovskite nanocrystals [4]. The highly anisotropic excitons may be resulted from the spin-orbit coupling and the exceptionally strong electron-hole exchange interaction. Moreover, at the low-energy side of the two doublets, we observe a feature arising from the recombination of a bright exciton. This line shows a circular dichroism, which can be induced either by circularly polarized excitation or by external magnetic field. This work is in line with the previous literature, where multiple excitonic features were resolved in bulk-like lead halide perovskites [5]. The observed energy landscape cannot be fully explained by available theoretical schemes for this material family. Our findings provide essential parameters for establishing a complete physical picture that governs the outstanding optical properties of two-dimensional layered perovskite semiconductors.

Volatility and Chain Length Interplay of In Situ Formed Primary Amines—Mechanistic Detail on Signal Transduction Properties of Hybrid Perovskites in Ammonia
Sayantan Sasmal1,2, Sri Sivakumar1, Raj Pala1 and Suresh Valiyaveetil2; 1IIT Kanpur, Kanpur, India; 2Chemistry, National University of Singapore, Singapore, Singapore.

Organic–inorganic halide perovskites, mainly known in photovoltaics possess promising signal transduction properties, which can be gainfully utilised in variety of sensing applications. Interestingly, highly polar nature of these class of materials, while being a bane in terms of stability, can be a boon for sensitivity while exposing with toxic gas like ammonia in a controlled atmosphere. This unusual signal transduction during sensing induces irreversible restructuring of perovskite crystal structure, which is one of the major lacuna preventing its utility in practical applications. To this end, we first elucidate the reasons behind the irreversibility of methylammonium lead iodide (MAPbI3) associated with structural transformations and then developed a generic mechanistic route on interaction of ammonia (NH3) with hybrid halide perovskite. The current investigation highlights that the vapor pressure of insitu formed alkylamine (due to facile proton exchange between alkylammonium cation present inside the hybrid perovskite crystal and approaching NH3) determines the reversibility and stability of the original perovskite lattice. In addition, packing of alkyl ammonium chain inside the hybrid halide perovskite crystal provides accessible voids, which allows diffusion induced proton exchange reaction ultimately influence the rapidity of interaction with NH3 gas. The mechanistic study addresses three important factors such as quick response, reversibility, and stability of perovskite materials in the presence of NH3 gas, which could lead to the design of stable and sensitive two-dimensional hybrid perovskite materials for developing sensors.

ET05.09.19
Combinatorial Synthesis and PV Activity of Mixed A or X ABX3 Halide Perovskites by Spray pyrolysis for Rapid and Systematic Parameter Space Mapping

Using ABX3, Halide Perovskites, compositions with several monovalent cations occupying the A site and 2 types of halides the X site, in PV cells has yielded cell performances better than with one type of species on the A and X sites. Performance differences are not limited to conversion efficiency, but also to material and cell stabilities, under a variety of conditions. To date, reports on compositional changes have been limited to multiple single experiments that cannot cover all parameter space, which, strongly hinders mapping trends in compositions. This is where combinatorial materials science, CMS, and accompanying high-throughput analysis methods are important. In CMS compositional ranges can be prepared on a single substrate, making possible to do many experiments faster and in a comparatively more controlled manner. We report on CMS to form MAPbI(1-x)Brx, with systematically varying x and Br compositions to form a library of materials, using a home-built, controlled-environment tri-needle spray pyrolysis system. High-throughput optical characterization shows absorbance onset shifts of up to ~150 nm depending on the composition (for MAPbI3 in the range of x=0.2-0.8), as measured by EDS), allowing for fine-tuning of the bandgap along the library. X-ray diffraction showed peaks, corresponding for the perovskite structure, which, for the (220) one, range between 2θ = 29.63° - 30.02°, i.e., from the neat MAPbI3 (220) towards 2θ =30.020, which we ascribe to Br replacing some of the I. Also libraries where Cs (replacing the A cation), Rb (maybe interstitial) or both, were added, to yield MAxRby(PbI3) , MAxCs1-xPbI3, and MAxCs1-xRbyPbzI3 were synthesized. We will report on characteristics of both the films alone, and of PV cells with architecture FTO/TiO2 meso-TiO2|Halide Perovskite|Spiro-MeOTAD |Ag, and discuss trends observed for the different composition ranges, as trend identification is one of the most powerful ways to use CMS.

Ambipolar Hybrid Perovskite Based Phototransistors Grown by Chemical Vapor Deposition
Hyung-Do Kim and Hyun-suk Kim; Materials Science and Engineering, Chungnam National University, Daejeon, Korea (the Republic of).

Low-cost hybrid organic-inorganic perovskites such as methylammonium lead iodide(MAPbI3) have been developed intensively due to those high absorption coefficient and easily tunable band gap, and easily fabricated by various deposition method such as solution-based process. However, solution-processed device using hybrid organic-inorganic perovskite is unstable and sensitive to water and ambient moisture. Therefore, the device stability is one of most important properties to achieve high performance hybrid organic-inorganic perovskite based devices. In this paper, the electrical characteristics and stability of phototransistors using MAPbI3, active layer were investigated. MAPbI3, thin-film fabricated by chemical vapor deposition (CVD) with MAI and PbI2 sources, and its physical, chemical, optical properties were compared with the solution-processed MAPbI3 thin-film. X-ray diffraction (XRD) and X-ray photoelectron spectroscopy (XPS) revealed that solution-processed MAPbI3 thin-film was easily transformed (from MAPbI3 to PbI2) after 7 days later when exposed to air. However, CVD-grown MAPbI3 thin-film showed great air stability maintaining its chemical composition and crystalinity above 1 month. Furthermore, atomic force microscope (AFM) and scanning electron microscope (SEM) indicated that CVD-grown MAPbI3 thin-film has large grain size and small surface roughness as compared to solution-processed MAPbI3, MAPbI3 phototransistor exhibits insulating behavior in transfer characteristics, but ambipolar properties were observed when the visible light was irradiated. Finally, electrical stability such as negative bias stress (NBS), positive bias stress (PBS) of MAPbI3, phototransistors were examined for the optoelectronic application.

ET05.09.21
Anion Exchange Perovskite Quantum-Dots for Highly Efficient Light-Emitting-Devices

A unique aspect of hybrid halide perovskite materials is the presence of an organic cation that occupies the cages formed by lead (Pb) and iodide (I). In the basic perovskite CH3NH3PbI3, the methylammonium (MA) cation can rotate relatively freely, while slightly large cations can be restricted in their motion. Interestingly, the MA cation is dipolar and the organization of the dipoles in the material depends on the mutual interaction of the dipoles. It has been suggested that the formation of ordered domains can lead to electronic localized states that are different for electrons and holes, and therefore the dipolar disorder should influence the dynamics of charges formed on photo-excitation.

In this work we have performed a combined computational and experimental study to unravel the relation between dipolar disorder and charge dynamics. Using a combination of Monte Carlo simulations and classical molecular dynamics we have studied the dynamics of the MA dipole at different temperature and large scale ordered domains are formed at low temperature, while above a certain temperature the domains are very small and the dipole are rotation relatively freely. The temperature at which this transition occurs suggests that the phase transitions in the perovskite are induced by dipole alignment.

Subsequently, we have studied the effect of dipole orientation on the delocalization of electronic states in the material. It is shown that for organic cations with a relatively high dipole moment, such as MA, localized states are formed that are different for electrons and holes. For a low-dipole moment cation, formamidinium (FA) such localized states are not observed.

Finally, in order to gain insight in the effect of dipole motion on charge dynamics, we have performed time-resolved microwave conductivity measurements combined with generation of charges by irradiation with a short, high-energy electron pulse. We observe substantial changes in mobility and lifetime of charge carriers in CH3NH3PbI3 after the low temperature tetragonal (β) to orthorhombic (γ) phase transition. We observed that the mobility and lifetime of charge carriers increase as the temperature decreases and a sudden increment is seen after the β/γ phase transition. For CH3NH3PbI3 the mobility and the half-lifetime increase by a factor of three to six compared with the values before the β/γ phase transition. We attribute the considerable change in the dynamics at low temperature to the decrease of the inherent dynamic disorder of the organic cation (CH3NH3+) inside the perovskite crystal structure. When replacing the MA cation by FA such sudden changes in the charge dynamics are not observed. This indicates that the dipolar motion of the organic cation does influence the dynamics of charges, particularly at lower temperature.

Towards Stable Deep-Blue Luminescent Colloidal Lead Halide Perovskite Nanoplatelets—Systematic Photostability Investigation

Seung Kyun Ha, Catherine M. Mauck and William Tisdale; Department of Chemical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Recently, colloidal lead halide perovskite nanoplatelets have emerged as promising semiconductor materials due to their exciting properties such as tunability, facile processability, and bright emission with high color purity. In particular, their quantum-and-dielectric-confined nature makes colloidal lead bromide perovskite nanoplatelets a favorable candidate for the next-generation deep-blue-emitting (437 nm) material platform. However, for light-emitting applications, poor photostability is one of the critical challenges that those nanoplatelets face. When exposed to UV excitation, they either suffer from photobleaching or transform into thicker–more bulk-like–structures with red-shifted emission.

In this study, we systematically investigate the factors that affect the photostability of the deep-blue-emitting perovskite nanoplatelets by monitoring the photoluminescence and absorption spectra over time. We find that freshness of the prepared precursor solutions for ligand-assisted recrystallisation is critical to obtain better stability with high photoluminescence quantum yield of perovskite nanoplatelets. Also, photobleaching is found to be the sign of intrinsic instability in nanoplatelets while transformation represents an extrinsic instability. Importantly, moisture is identified as the key extrinsic factor responsible for the transformation of nanoplatelets into more bulk-like structures. Furthermore, we observe that the substitution of the organic cation from formamidinium to methylammonium and addition of excess ligands significantly enhances the intrinsic stability of perovskite nanoplatelets. Lastly, we demonstrate that the dropcasted film of methylammonium-based nanoplatelets with excess ligands is impressively stable under ambient conditions and does not transform even under intense UV in the presence of moisture, as a result of improved intrinsic stability. This study expands our understanding of factors that affect perovskite nanoplatelet photostability and opens up new possibilities for fabrication of stable perovskite-nanoplatelet-based optoelectronic devices with enhanced stability.

Anion Exchange Perovskite Quantum-Dots for Highly Efficient Light-Emitting-Devices

Takayuki Chiba, Yukihiro Hayashi, Hinako Ebe, Satoru Ohisa and Junji Kido; Yamagata Univ, Yonazawa, Japan.

All-inorganic cesium lead halide perovskites quantum dots (QDs), CsPbX3 (X = Cl, Br, I), have recently attracted much attention for use in light emitting devices (LEDs), given their high colour purity and narrow full width at half maximum (FWHM) over the entire visible wavelength range as well as their low cost solution processing (1, 2). Here, we demonstrate anion-exchange red perovskite QDs CsPbBr3 from pristine CsPbBr3 using ammonium iodide salts, long alkyl based oleylammonium iodide (OAMI) and aryl based aniline hydoroiodide (AnHI), for use in highly efficient LEDs. The ester solvent ethyl acetate, which has a low dielectric constant, is used as poor solvent in recrystallization process to remove impurities and prevent surface defects in the perovskite QDs. The anion exchange CsPbBr3 films exhibit a strong red shift in their of photoluminescence (PL) spectrum from the green emission at 508 nm in the case of the pristine QDs to one in the deep-red region at 649 nm owing to the replacement of Br anions by I anions in the perovskite QDs. The anion exchange CsPbBr3 film based on OAMI shows a high surface coverage ratio and is free of pinholes, whereas that of AnHI based CsPbBr3 exhibits a slightly rough surface owing to a reduction in the surface ligand, which results in the aggregation of the QDs. LEDs formed using the anion-exchange CsPbBr3 based on OAMI show an remarkable high EQE of more than 20% as well as high color purity, with the Commission Internationale de l’Eclairage (CIE) at (0.72, 0.28), which completely cover BT 2020 color gamut. Similarly, the LEDs formed using the QDs based on AnHI show a peak EQE of 14.1% and CIE coordinates of (0.71, 0.28). Further, they exhibit longer operational stability as compared to that of LEDs formed using the OAMI based CsPbBr3.

What Limits the VOC of Br-Based Perovskite Solar Devices?

David Cahen1, Arava Zohar1, Michael Kulbak1, Igal Levine1, Gary Hodes1 and Antoine Kahn2, 3; 1Weizmann Institute of Science, Rehovot, Israel; 2Princeton University, New Jersey, Idaho, United States.
Thanks to the efforts of many research groups worldwide in halide perovskite (HP) research, >22 % efficient small photovoltaic (PV) devices have been reported [1]. Such devices, based on HPs with mostly iodide as halide, can show a remarkably low voltage loss (E_{SC}-V_{OC}) of ~0.4 V. Unfortunately, up to now, for the higher bandgap HPs, where the halide is only Br, the highest reported V_{OC} still leaves (E_{SC}-V_{OC}) ~ 0.75 V [2]. This large loss severely detracts from the potential of HPs that have enough Br substitution for I, for optimal use in the higher E_{g}-based cell for tandem configurations or spectral splitting systems. The origin of this increased loss remains an open question.

There are 3 main issues to be checked to understand what limits the V_{OC} from getting closer to the theoretical maximum value for pure APbBr_{3}-based PV cells (~2.0 V).

-1- what is the absorber’s in-gap density of states and what range of energies have these states in the material’s band gap;

-2- as -1-, for interfacial in-gap states @ the HaP-hole/-electron transport layer interface;

-3- what is the mismatch in energy level alignment of the cell’s layers, to see if this can explain the significant energetic losses?

Here we used (FMAS_{x}MAS_{y}Cs_{1-x}PbBr) (from hereon mixed-cation) as the photo-absorber. Previously we showed that this mixed-cation HaP has relatively long carrier diffusion lengths and low carrier density compared to single cation Br-based HaPs, more resembling the I-based HaPs, with which the small (E_{SC}-V_{OC}) cells can be made [1].

By using optoelectronic measurements such as Contact Potential Difference, Surface Photovoltage, Electroluminescence and Capacitance Voltage on mixed cation Br-based HaP stand-alone films, as well in different device configurations, we can now provide insights into the origins of the large (E_{SC}-V_{OC}) for the BR-based HaP-based PV cells and suggest how these losses may be minimized.

Several discussions with Dr. Davide Ceratti (WIS) and Prof. Antoine Kahn (Princeton U) are gratefully acknowledged.

Optical Properties of One-Dimensional Single Crystals Based on Lead -Bromide Hybrid Perovskites Mai Huong T. Duong1, Shunpei Nobusue1, Eiichi Matsubara1,2, Hirokazu Tada1 and Masaaki Ashida1; 1Department of Materials Engineering Science, Osaka University, Osaka, Japan; 2Department of Physics, Osaka Dental University, Osaka, Japan.

Organic-inorganic lead halide hybrid perovskites have been receiving considerable attention for applications to optoelectronic devices such as photovoltaic cells and light emitting diodes because of their excellent electronic properties including strong absorption coefficient and long carrier lifetime [1]. The structure of hybrid perovskites can be tuned in various manners and classified by dimensionalities into three-, two- and one-dimensional (3D, 2D, and 1D) perovskites. Compared with 3D and 2D-layered crystals, the limited number of studies have been done for 1D crystals, while they are expected to show high and fast optical nonlinear effects owing to the enhancement of electron density of states and electron-electron interaction. Among the lead halides 1D perovskites, we have found that bromide compounds show some advantages for applications: stability in air and broadband emission of light. Here we report the structure of 1D lead bromide perovskites and structural dependence on their optical properties. We prepared three different structures (double-chain, face, and side shared) by inserting various aromatic organic compounds. We observed the yellow, green, and white light luminescence depending on the structures of lead bromide perovskites. Among them, double-chain lead bromide perovskite crystal showed extremely broadband white light photoluminescence similar to that of core-shell quantum wires structure [2]. The Stokes shift of the double-chain lead bromide crystals examined in the present experimental was much larger than that reported previously for core-shell 1D wires. The results open possibility of new application of 1D bromide perovskites to optoelectronic devices on the basis of chemical modification.

Structure-Controlled Optical Thermoresponse in Two-Dimensional Perovskites Daniele Cortecchia1, Stefanie Neutzi1, Jun Yin2, Teddy Salim3, Ajay Srimath Kandada1, Annalisa Bruno2, Yeng Ming Lam1, Javier Marti-Rujas1, Annamaria Petrozzal and Cesare Soci2; 1Centre for Nano Science and Technology, Istituto Italiano di Tecnologia, Milan, Italy; 2Solar Center, Division of Physical Science and Engineering, King Abdullah University of Science and Technology (KAUST), Thuwal, Saudi Arabia; 3School of Material Science and Engineering, Nanyang Technological University, Singapore, Singapore; 4Energy Research Institute @ NTU (ERI@N), Nanyang Technological University, Singapore, Singapore; 5Division of Physics and Applied Physics, School of Physical and Mathematical Sciences, Nanyang Technological University, Singapore, Singapore.

Two-dimensional perovskites are emerging for their light emitting properties and applications in lasing, metamaterials and nanophotonic devices.2,3 The correlation between structure and optical properties is essential to improve the device performance and functionality and might lead to surpass films with adjustable optical properties dynamically tunable by external stimuli. Phase transitions in Ruddlesden-Popper perovskites such as (BA)_{x}(MA)_{y-x}I_{2x+1} (BA = butylammonium; MA = methylammonium),3,4 in combination with the high flexibility of the lead halide lattice, can allow to modulate the optoelectronic properties in a controlled and reversible way, through a thermal-induced structural changes and the optical properties is not yet established.

Here, we expose BA_{2}PbI_{3} (n=1) and BA_{3}MAPbI_{3} (n=2) to a wide temperature range (300-77K) and characterize two new low temperature phases of BA_{2}MAPbI_{3}. We combine spectroscopic and structural characterization with ab initio calculations to study their characteristic phase transitions and rationalize the structural changes affecting the optical properties and leading to a sharp thermo-optical response of their luminescence. Volume contraction at low temperature causes the increase of out-of-plane tilt of PbI_{6} octahedra resulting in a sharp bandgap blue-shift. On top of this, the dimensionality further impacts on the thermal evolution of the volume expansion and tilt system of the perovskite, reversing in BA_{2}PbI_{3} the trend of the continuous thermal shift of the band-gap typically observed in MAPbi.

Our results stress the importance of the structure-function relationship and show that heat-mode inter-conversion of the crystal packing can be exploited to design stimulus-responsive materials. Since the β→α phase transitions of these alkylammonium-based perovskites occur close to room temperature, they can be easily exploited to switch the structure-optical properties of the material.

Choice of Monovalent Cations Has Major Impact on Charge Carrier Recombination in Metal Halide Perovskites Katelyn Dagnall2, Benjamin
Metal halide perovskites (MHP) are promising next-generation materials for use in lightweight, flexible and inexpensive solar cells with power conversion efficiencies rivaling that of commercial silicon solar cells. The two main classes of MHP, hybrid organic-inorganic and fully inorganic, are hotly debated in the field as to which will become the commercially viable composition of MHP. Hybrid organic-inorganic perovskites have demonstrated high solar cell efficiency but relatively poor stability whereas fully inorganic MHPs are more stable with significantly lower solar cell efficiency. Therefore, it is important to understand whether or not organic cations play any roles in high solar cell efficiency so that the field can rationally decide which compositions to focus on for future development. Here we report our studies on the effect of cation composition on charge carrier recombination dynamics. Through a combination of novel ion exchange procedure, intensity dependent time-resolved photoluminescence (ID-TRPL) and transient absorbance (TA), the recombination rate constants were determined from systematically tuned compositions of various MHP thin films. Our results show that the choice of organic cations has a major influence in determining charge recombination dynamics. Implication of these results on selecting optimum compositions for higher solar cell efficiency and stability will be discussed.

Photoluminescence Intermittency in Micron-Size Hybrid Lead Halide Perovskites

Shaibal Sarkar; IIT Bombay, Mumbai, India.

Organic-metal-Halide perovskite materials recently attracted immense attention due to its unique optoelectronic properties, easy and versatile synthesis routes and its applicability in photovoltaic and light emitting devices. The existing literature demonstrates that the device performances depend heavily on the film morphology, shape and size of the crystal and of course the stoichiometry of the synthesized material. In this presentation, I will be discussing some interesting and unique optoelectronic properties of some “bad” perovskite materials when it is either synthesized under non-ideal conditions or as non-stoichiometric which is not ideal for high-performance devices. Here I will aim to justify a distinct correlation between the surrounding ambient and the PL intermittency of isolated and conjugated formamidinium lead bromide (FAPbBr3) microcrystals having dimension higher than the excited carrier diffusion length. A custom-built spectrally resolved epi-fluorescence microscopy is used to capture the wide-field optical emission properties of the material. With adequate experiments, we are able to describe the role of photoelectrochemically generated trap states that plays a deterministic role in PL intermittency. We further aim to establish a direct correspondence between the material degradation and the blinking.

Figure 1: Shows the photoluminescence intermittency in the FAPbBr3 microparticle.

The Formation of CsPbI3 and Its Effect for Device Characteristics in CsPbI3 Based Perovskite Solar Cells

Kohei Yamamoto1, Tetsuhiko Miyadera1, Tomoyuki Koganezawa1, Tetsuya Taizumi1 and Masayuki Chikamatsu1; 1AIST (National Institute of Advanced Industrial Science and Technology), Tsukuba, Japan; 2Kanazawa University, Kanazawa, Japan; 3JASRI, Sayo-gun, Japan.

Organometallic halide perovskite (PSCs) has recently emerged as promising cost-effective and highly efficient nanostructured solar cells. The organometallic halide perovskite such as CH3NH3PbI3 has poor thermal and air stability. To avoid this problem, there are many researchers who used the three-dimensional-type perovskite crystal structure with mixed cation such as cesium (Cs) and methyl amine (MA). The mixed cation perovskite has reported high thermal stability with improvement of the power conversion efficiency (PCE). The inorganic cesium lead iodide perovskite (CsPbI3) has been reported to have highly efficient thermal and electrical properties. It should also be noted that the reported CsPbI3 perovskite solar cells with highly efficiency has CsPbI3 in X-ray diffraction (XRD) measurement. In this study, we replaced MA with Cs and used vacuum deposition method to yield efficient inorganic planar heterojunction CsPbI3 solar cells. The CsPbI3 perovskite layer was formed by vacuum deposition of lead iodide (PbI2) and cesium iodide (CsI). The perovskite stoichiometry depends on the ratio of CsI and PbI2. The ratio of the codeposition rates of PbI2 and CsI was adjusted to PbI2/CsI molar ratio. The CsPbI3 film of PbI2/CsI molar ratio of 1 was deposited for obtaining ideal stoichiometry of CsPbI3. In this case, a power conversion efficiency of 5.71% was obtained with a short-circuit current density ($J_0$) of 13.50 mA/cm², an open-circuit voltage ($V_0$) of 0.55 V, and a fill factor (FF) of 0.51. This ideal film has not only CsPbI3 but also Cs4PbI6 was observed by XRD measurement. The Cs4PbI6 was considered to constitute 3CsI and PbI2/CsI molar ratio of 1 to 3. The pure CsPbI3 perovskite film had $J_0$ of 13.50 mA/cm², $V_0$ of 0.55 V, and FF of 0.51, leading to PCE of 3.77%. These results indicated the effect of CsPbI3 to improve the solar cell performance of $J_0$, $V_0$, and FF in CsPbI3 based perovskite solar cells.

Revealing the Relationship Between Structure and Opto-Electronic Properties of the Double Perovskite PV Candidate CsAgBiBr6

Laura Schade, Adam D. Wright, Roger Johnson, Markus Dollmann, Pabitra Nayak, Dharmalingam Prabhakaran, Laura Herz, Robin Nicholas, Henry Snaith and Paolo Radaelli; University of Oxford, Oxford, United Kingdom.

The discovery of hybrid halide perovskites materials heralded a new era in optoelectronic technologies, with an unprecedented rise to above 20% in the efficiency of photovoltaic devices in just a few years. However, several crucial issues, such as stability and toxicity, still need to be tackled before an industrial-scale use. Although the presence of Pb is a potential risk for use in PV electricity generation, Pb may prevent use in certain applications such as bioelectronics and consumer electronics products. Therefore, several efforts have been put in the research of a lead-free, stable all inorganic compound with improved thermal stability.

Recently, a new class of candidate photovoltaic materials – the double halide perovskites with chemical formula $A_B\text{Bi}_X_6$ ($A, B=$monovalent cations, $X=$halogen) – has been identified as a possible alternative to the better-known $A_Pb_X_6$ perovskites. In these materials, the $B^+$ cations (average valence 2+) substitute for lead and are fully ordered in a double perovskite superlattice. Of particular interest is CsAgBiBr6, which does not contain toxic elements, and is highly stable both structurally and chemically. Several studies exploring its implementation in devices have started to appear in the literature, yet very little is known about the relationship between the crystal structure and the opto-electronic properties of this double perovskite compound. Hence, there is an urgent need for a detailed understanding of these materials at a more fundamental level.

We have investigated the temperature-dependent structural behaviour of CsAgBiBr6 using heat capacity measurements, X-ray powder and single-crystal diffraction and neutron powder diffraction and discovered that this compound undergoes a low-temperature structural phase transition ($T_c$=122 K) from cubic to tetragonal. The crystal structures of both high- and low-temperature phases were refined based on our diffraction data. The temperature dependence of the exciton energy in proximity to the direct band gap was determined using reflectivity measurements. We found a direct, linear relationship between the tetragonal strain and the exciton energy, demonstrating that the latter is controlled by the Bi8 Br32 octahedral rotation. Meanwhile time-resolved photoluminescence measurements indicated a qualitative change in the charge-carrier recombination mechanisms at a temperature that correlates well with the phase transition. Further absorption and photoluminescence spectral measurements probing the temperature dependence of the...
Here, we present a case study of a PSC based on a new compound material (MA0.6FA0.4PbI2.8Br0.2) that does not show a phase transition for relevant important for further development of solar cells. In this work, we have fabricated the Bi-based perovskite materials (Cs3Bi2I9, CsBi3I10) by solution process structural-chemical interplay in MAPbI3, providing a new line of interpreting and understanding the ferroic, chemical, and optoelectronic behaviors of (DFT) calculations provide a picture describing the interaction of elastic strain, chemical segregation, and ferroelasticity. This work unveils a new impedance response is not fully understood. Basically, two main processes are identified but there is no general agreement on their physical origin.

Photoelectrochemical Impedance Measurements on Perovskite Solar Cells with Improved Thermal Stability

Recently, electrochemical impedance spectroscopy (EIS) on perovskite solar cells (PSC) has gained a lot of interest in the literature. The time constants are on a favorable timescale to enable high quality EIS measurements and the cells have become stable enough to allow for reliable and reproducible measurement results, making EIS a most promising tool for characterization and diagnosis of PSC. However, there are still elusive phenomena and the impedance response is not fully understood. Basically, two main processes are identified but there is no general agreement on their physical origin. Negative loops that appear in the medium and low frequency ranges further complicate a straightforward interpretation of the impedance response of PSC.

Here, we present a case study of a PSC based on a new compound material (MAxxFAyPb2x+3y−2) that does not show a phase transition for relevant ambient conditions and has proven to exhibit better thermal stability than standard MAPbI3. Measurements were conducted on samples based on either of these materials. Fresh samples as well as samples that have been subjected to a temperature treatment beyond the MAPbI3 phase transition temperature of 328 K were used. All cells were characterized by EIS and intensity modulated photocurrent/voltage spectroscopy (IMPS/IMVS). IMPS is usually only measured under short circuit conditions (SCC) and IMVS only under open circuit conditions (OCC). In contrast to this practice, we have measured EIS, IMPS and IMVS at various potentials including OCC and at different light intensities. We show that the three measurement techniques form a triplet where one of them can be calculated with good accuracy if the other two are available.

As a result of this study, we will show how impedance measurement under open circuit conditions (OCC) can help to distinguish between different mechanisms but are less sensitive to device degradation. Measurements at a voltage range between 0 Volts and OCC can help to quantify degradation, which is represented by a decrease in the impedance at voltages below the maximum power point (MPP) and by an increase beyond the MPP.

The similarity of EIS and IMVS results has been discussed in the literature. We will argue and demonstrate how a comparison of EIS and IMVS can help to distinguish between interface effects and the behavior of the bulk photoactive layers. This contribution will be complemented by a few practical guidelines for reliable photoelectrochemical impedance measurements, as this comprehensive study was performed on some of the most stable PSC for which a degradation of less than 20% after 500 hours has been demonstrated, even at an elevated temperature of 85°C.

Chemical Nature of Ferroelastic Twin Domains in CH3NH3PbI3

Recently, observations of twin domain in methylammonium lead triiodide (MAPbI3) have drawn significant attention. However, whether this twin domain is ferroelectric and/or ferroelastic remains unclear. In addition, previous investigations were limited to the ferroic properties of this twin domain, whereas, the chemical behavior which can correlate with either ferroelectricity or ferroelasticity, has rarely been studied. In this work, we unveil the correlation of ferroelastic domains and chemical variation in the MAPbI3 twin domains using multiple functional imaging techniques. We unambiguously show the mechanical origin of piezoelectric-like contrast by using multiple advanced piezoresponse force microscopy techniques, suggesting the non-ferroelectricity of this twin domain. The combination of helium ion microscopy secondary ion mass spectrometry (HIM-SIMS) and nanoscale infrared spectroscopy (Nano-IR) indicates the ion segregation correlating with the twin domain. Emission excited by polarized light reveals large-scale ordering of crystallographic orientation/chemical make-up correlating with both twin domain and its alternative interaction with light. Moreover, density functional theory (DFT) calculations provide a picture describing the interaction of elastic strain, chemical segregation, and ferroelasticity. This work unveils a new structural-chemical interplay in MAPbI3, providing a new line of interpreting and understanding the ferroic, chemical, and optoelectronic behaviors of related HOIPs.

Suppression of Trion-Generation in Lead Halide Perovskite Nanocrystals by Surface Modification

All-inorganic cesium lead halide perovskites CsPbX3 (X = Cl, Br, I) have attracted much attention for their excellent optoelectronic properties. Since the nanocrystals (NCs) possess superior luminescent properties such as high photoemission quantum yields (PLQYs) at room temperature, these materials have been intensively studied for application in optoelectronic devices such as light emitting diodes and lasers [1]. Our previous studies have clarified that
Furthermore, we found that two independent trion generation pathways exist by analyzing the excitation power dependence of trion components. We analyzed the excitation power dependence of the differential TA signals for each sample, and compared the extracted components of excitons, trions, and biexcitons between the surface-treated and untreated samples. We clarified that the generation of trions are clearly suppressed by the surface treatment as observed in the difference in excitation power dependence, while exciton and biexciton components exhibit the same.

Furthermore, we found that two independent trion generation pathways exist by analyzing the excitation power dependence of trion components. We discuss the trion generation dynamics in CsPbBr3 NCs from the viewpoints of extrinsic surface traps and intrinsic Auger recombination.

Part of this work was supported by JST-CREST (JPMJCR16N3).

Low-dimensional organic-inorganic halide perovskites (OIHPs) have attracted intense interests recently for photovoltaic applications, owing to their markedly high chemical stability compared to the widely studied three-dimensional (3D) counterparts. However, low-dimensional OIHPs usually give much lower device performance than the 3D OIHPs. In particular, for the zero-dimensional (0-D) OIHPs, it is believed that the strong intrinsic quantum-confinement effects can lead to extremely low carrier motility which severely limit the photovoltaic performance. Herein, we predict a new family of 0-D perovskite variants that, surprisingly, exhibit outstanding optoelectronic properties. We find that some compounds based on V exhibit typical features of 0-D perovskites, such as low carrier mobilities and strong quantum confinement, thereby limiting their applications in optoelectronic devices. Sb and Bi based 0-D perovskites possess features of molecular crystal, such as comparable absorption spectrum of sun light, and carrier mobilities for PV application. The unique properties are due to the CBM shows strong hybrid state between Sb 5s orbital and Br 4p orbital in ASBnS, and the hybrid states have strong overlap among neighboring octahedrons. Moreover, the bandgap can be tuned over a wide range via tuning the composition in the mixing element strategy. The newly obtained insight into unique optoelectronic property of the 0-D perovskite devices offers a rational design strategy for low-dimensional perovskites to address some known challenging issues inherent in the lead halide perovskite solar cells.

Optical and X-Ray Spectroscopy of the Ruddlesden-Popper Perovskite Sulfides Shanyuan Niu1, Debarghya Sarkar2, Kristopher Williams3, Kevin Ye4, Yuwei Li5, Elisabeth Bianco6, Wei Li2, Michael McConney7, Ralf Haiges8, Anderson Janotti9, David Singh10, William Tisdale11, Rafael Jaramillo12, Rehan Kapadia13 and Jayakanth Ravichandran14; 1Mork Family Department of Chemical Engineering and Materials Science, University of Southern California, Los Angeles, California, United States; 2Department of Chemical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 3Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 4Department of Physics and Astronomy, University of Missouri, Columbia, Missouri, United States; 5Department of Chemistry, Rice University, Houston, Texas, United States; 6Department of Materials Science and Engineering, University of Delaware, Newark, Delaware, United States; 7Materials and Manufacturing Directorate, Air Force Research Laboratory, Wright-Patterson AFB, Ohio, United States; 8Loker Hydrocarbon Research Institute and Department of Chemistry, University of Southern California, Los Angeles, California, United States.

Transition metal perovskite chalcogenides are promising materials for photovoltaic applications with excellent optoelectronic properties, stability, and rich tunability. Recent experimental studies have revealed their promising potential, including band gap tunability all the way from 2.1 eV to 1.3 eV. We report in depth optical and X-ray spectroscopic study of Ruddlesden-Popper series of the perovskite sulfide, Ba_{n+1}ZrS_{3n+1}(n≥1). The polycrystalline samples were synthesized with an iodine catalyzed solid state reaction, and single crystals were grown with salt flux methods. Structural, chemical, and thermogravimetric studies establish that these materials have good optoelectronic properties and stability. High external luminescence efficiency, up to 0.15%, is obtained via quantitative photoluminescence measurements. An effective, bulk minority carrier lifetime longer than 60 ns and very low surface recombination are determined from time-resolved photoluminescence measurements. X-ray absorption spectroscopy illustrates the role of Zr-S covalent bonding in determining the electronic structure.

From 3D to Lower Dimensional Perovskite Structures—The Change in Mobility and Solar Cell Performance Noor Titan Purti Hartono1, Shijing Sun1, Matthew Erodici2, Maria C. Gélvez-Rueda3, Fengxia Wei4, Ferdinand C. Grozema3, Meng-Ju Sher2, María C. Gélvez-Rueda3, Fengxia Wei4, Ferdinand C. Grozema3, Meng-Ju Sher2, Juan-Pablo Correa-Baena1 and Tonio Buonassisi1; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Department of Chemical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 3Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 4Institute of Materials Research and Engineering, Agency for Science Technology and Research, Singapore, Singapore.

Although lead-halide perovskite (LHP) solar cells have reached 22.7% efficiency to date, they still face stability issues. Recent studies have suggested that shifting to lower dimensional (LD) perovskites may extend the cell’s environmental stability. However, these LD perovskite structures tend to have low photocurrents and solar cell performance. It has been suggested that their culprit is not only lifetime, but also their charge-carrier mobility. To understand this, we conduct a detailed study using PbI2-based LD perovskites, which are synthesized by intentionally introducing a pre-defined amount of large A-site cations to force the structure to split into a layered compound. We measure the LD perovskite device performance, and characterize the absorber using THz spectroscopy and time-resolved microwave photoconductivity to understand the mobility. Finally, we relate the mobility results with the structures and device performances.

Role of Anion Vacancies in Light-Induced Halide Phase Segregation in MAPb(1-x)Brx Anthony Ruth1, Michael C. Brennan1, Sergiu Draguta1, Yuriu Morozov1, Maksym Zhukovsky1, Boldizsar Janko1, Peter Zapol1 and Masaru Kuno1; 1University of Notre Dame, South Bend, Indiana, United States; 2Argonne National Laboratory, Argonne, Illinois, United States.
Solution-processed mixed halide perovskites (e.g. MAPb(I$_x$Br$_{1-x}$)$_3$) are excellent materials for multi-junction solar cells due to their ideal characteristics, which include large optical absorption coefficients, long carrier diffusion lengths, long-lived carrier lifetimes, and tunable bandgaps. Unfortunately, light-induced halide phase segregation has prevented their effective integration into working devices. We present kinetic Monte Carlo simulations and complementary optical experiments which show that during illumination, halide migration is directed by the energetics of charge carriers. The nucleation of a low-bandgap, I-rich domain emerges as a mechanism to trap charge carriers and reduce their energy. Furthermore, migration rates in stoichiometric and halide-deficient MAPb(I$_x$Br$_{1-x}$)$_3$ thin films are dictated by halide vacancy hopping barriers and are modulated by the number of available vacancies. An established phase segregation mechanism involving thresholds in the number of vacancies and instead depend critically on parameters such as carrier diffusion length, lifetime and bandgap tunability. Superb agreement with experimental nucleation kinetics and optics validates the model and prompts its application to fundamental, experimentally-inevitable aspects of phase segregation. By simulating nucleation with varying ionic mobilities, we determine how domain formation is influenced by species dependent I$^-$ vs. Br$^-$ diffusion rates and asymmetric hopping in tetragonal vs. cubic symmetry. The simulations further suggest that near ubiquitous emission energies, which converge on that for MAPb(I$_x$Br$_{1-x}$)$_3$ (i.e. ~0.2) following phase segregation, arise from the existence of kinetically trapped Br$^-$ within nucleated I-rich domains surrounded by a pure I$^-$ barrier. These simulations ultimately prompt the idea that the ideal characteristics of mixed halide hybrid perovskites, specifically their large carrier diffusion lengths, are responsible for inducing phase segregation. The study thus sheds new light on important parameters that define photoinduced halide phase segregation in mixed halide hybrid perovskites and presents opportunities for ultimately controlling as well as managing the phenomenon.

Suppression of Halide Ion Exchange in Cesium Lead Halide Perovskites with PbSO$_4$-Oleate Capping
Prashant Kamat, Vikashkumar Ravi and Rebecca A. Schedit; University of Notre Dame, Notre Dame, Indiana, United States.

Metal halide perovskites are ionic in nature and its properties can be tuned through the exchange between halide ions. For example, by tailoring the ratio of Cl:Br and Br:Cl it is possible to modulate the absorption and emission properties of metal halide perovskites across the entire visible region. However, the ease of halide ion exchange property poses a problem to create a tandem structure with layers of metal halide perovskites of different compositions. In order to keep the lead halide perovskite nanocrystals intact without undergoing exchange of halide ions and retain the original band structure one needs to suppress the halide ion migration across the nanocrystals. We have now successfully achieved this task by capping CsPbBr$_3$ and CsPbI$_3$ nanocrystals with PbSO$_4$-Oleate. The linear assembly of the nanocrystals that resemble that of a peapod structure inhibits the exchange of anions. Absorption measurements show that the nanocrystal assemblies maintain their identity as either CsPbBr$_3$ or CsPbI$_3$, for several days. Furthermore, we have electrochemically deposited these assemblies as hierarchical structures on electrode surfaces and employ them in light emitting devices. The effectiveness of PbSO$_4$-Oleate capping of lead halide perovskite nanocrystals offers new opportunities to overcome the challenges of halide ion exchange and aid towards the novel design of perovskite light harvesting assemblies.

Titanium-Based Halide Perovskite Thin Films for Photovoltaic Applications
Min Chen¹, Minggang Ju², Xiaoli Cheng Zeng², Yuyuan Zhu¹ and Nitin Padture²;¹ Brown University, Providence, Rhode Island, United States;² Department of Chemistry, University of Nebraska–Lincoln, Lincoln, Nebraska, United States.

Lead-based halide perovskites have demonstrated superior optoelectronic properties since the emergence of perovskite solar cells (PSCs). However, the toxicity and phase stability of lead halide perovskite brings inevitable concerns with the practical application for the solar panel. Based on the environmentally friendly element of Titanium (Ti), we have predicted a series of Ti vacancy-ordered double perovskite compounds, Cs$_2$TiI$_6$, Rb$_2$TiI$_6$, K$_2$TiI$_6$, and In$_2$TiI$_6$, which possess optimal bandgap and suitable absorption. Here, we successfully synthesis the Titanium-based materials which indicates indicated the possible photovoltaic applications because of the proper band-gap range. Furthermore, we prepared the pinhole-free titanium-based thin film by the evaporation method. The electrons/holes diffusion length of such thin films with proper crystallographic textures illustrates the good performance as champion material as well as for paving the way for second-generation materials. We expect this work provides new direction in the design and development of high performance Ti-based thin-film PSCs of the future.

Accessing Small Bandgaps in Halide Double Perovskites
Adam H. Slavney¹, Linn Leppäri², Abraham Saldivar Valdes³, Davide Bartesaghi³, Tom Savojivi³, Jeffrey B. Neaton⁴ and Hemamala Karunadasa¹;¹ Stanford University, Stanford, California, United States;² University of Bayreuth, Bayreuth, Germany;³ Delft University of Technology, Delft, Netherlands;⁴ University of California, Berkeley, Berkeley, California, United States.

The outstanding photophysical properties of APbX$_2$ perovskites (A = organic/inorganic monocation, X = halide) for optoelectronic applications has prompted a vigorous search for analogs. Indeed, finding structural and functional analogs is a time-tested approach for both better understanding the current champion material as well as for paving the way for second-generation materials. In this regard, there has been intense recent interest in the photophysical properties of halide double perovskites, where Pb$_2$+ sites are replaced by two different metals that yield an average charge of 2+. However, despite this feature both high-bandgap insulators and metals, such diversity has not yet been seen in their halide analogs. I will present work from our labs aimed at expanding the electronic portfolio of halide perovskites for fundamental studies and applications in technology.

SnPb and Pb-Free SnGe Perovskite Solar Cells
Shuzi Hayase; Kyushu Institute of Technology, Kitakyushu, Japan.

Lead-free perovskite solar cell is one of the research issues on perovskite solar cells. We have focused on Sn perovskite material. One of these Sn-related solar cells is SnPb mixed metal perovskite solar cell. We discuss how to enhance the efficiency from the view point of less trap densities in hetero-interfaces and the bulk layer. SnF$_2$(DMSO)$_2$ doping to the perovskite layer and the introduction of spike band structure in the cell gave SnPb perovskite solar cells with 19% efficiency and stability. The SnGe is a promising alternative to Pb perovskite solar cells. Pb of SnGe perovskite layer was replaced by Ge. A theoretical study showed that it is possible to prepare a SnGe mixed metal perovskite material which absorbs the sunlight. In this study, a new type of SnGe mixed metal perovskite solar cells are reported with enhanced efficiency and stability. XRD spectra showed that the structure is perovskite. The structure of GeSn perovskite was discussed from the view point of the band structure, XPS analysis, and the Urbach energy. Most of the Ge atoms are at the hetero-interface of the perovskite/PEDOT-PSS as well as at the interface of the perovskite/C60. They passivate the surface of the Sn perovskite (so-called graded structure). For SnGe(0)-PVK device, where SnGeX$_2$ stands for SnGe perovskite with X% Ge content, the PCE was 3.31 %. Upon doping with 5 wt% of Ge, the overall efficiency was enhanced to 4.83 %. With the Ge content more than 10wt%, all the photovoltaic parameters decreased.
significantly which resulted in an efficiency as low as 0.80 % for SnGe(0.2)-PVK device. After optimization, 7.89% of SnGe(5)-PVK device is reported. In addition, the stability of the device in air without encapsulation has been improved significantly with the Ge doping. 80 % of efficiency was kept after doping with Ge (5%) from its original performance. However, only 10 % of the efficiency was retained for non-doped sample SnGe(0). This work provides a platform for further research on lead-free Sn-Ge based perovskite solar cells.

Optoelectronics Studies Based on Two-Dimensional Hybrid Perovskite Mauricio Solis de la Fuente, Sumanjeet Kaur, Dalía Martinez Escobar, Selene M. Coria and Ravi Prasher; Lawrence Berkeley, Berkeley, California, United States.

Hybrid Perovskite solar cells have been the subject of intense interest due to significant optoelectronic properties (high absorbance, long diffusion length, etc.). An accelerated competition is taking place to obtain highest performance in single junction and tandem solar cells with efficiencies up to 20 %. Nevertheless, huge scientific problem remains be solved that directly impact performance and future commercialization, namely the stability under external agents as light, oxygen, humidity and heat.

The organic ions play an important role in the perovskite stability, which make them sensitive to moisture; Some studies showed the perovskite 2D are more resistant to humidity conditions in contrast to 3D. However, a decrement in density of carriers photogenerated is obtained where the vertical orientation is wishing to get good performance in solar cells. We explore other strategies to extract carriers mainly doping 2D perovskite BAXMA3PbI6 with single walled carbon nanotubes and graphene. Experimental measurements to explain how structural changes (domain distributions, band gap positions) can modify optoelectronics properties as photoluminescence, conductivity, Seebeck coefficient, I-V curves and absorbance will be discuss.

Edge Management in Reduced-Dimensional Perovskites Enables Efficient and Stable Light-Emission Lina Qian1, 2 and Edward H. Sargent1; 1University of Toronto, Toronto, Ontario, Canada; 2Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Halide perovskites, especially layered quasi-2D perovskites, offer a number of advantages to creating bright and efficient light-emitting applications. Their combination of excellent charge carrier mobility and low density of recombination centers have enabled their rapid ascent in electroluminescent devices. To bring perovskite LEDs to commercialization, a remaining issue of stability needs to be addressed. In this presentation, we pinpointed the chief cause of the dramatic degradation of halide perovskites in light-emitting diodes (LEDs). We studied photogenerated charges accumulating at exposed perovskite facets activate the physosorbed oxygen, converting it into reactive superoxide that triggers perovskite degradation. We thus aimed at developing a strategy to protect the perovskite facets. At an applied level, we achieve perovskite films that exhibit a near-perfect passivation, attested to by their photoluminescence quantum yields (PLQY’s) that closely approach 100%. These films are stable under continuous illumination in ambient conditions over hundred hours. In addition, we report orders of magnitude improvement in device operating stability relative to the best-performing prior perovskite reports.

Strain-Related Defects in Metal Halide Perovskites Samuel D. Stranks; University of Cambridge, Cambridge, United Kingdom.

Metal halide perovskites are generating enormous interest for their use in optoelectronic devices including photovoltaics and light-emitting diodes. One of their most remarkable properties is their apparent defect tolerance – films can be produced using relatively crude processing methods yet they still exhibit very good device performance. Calculations have suggested that this is at least partly because many defects cause only shallow trap states which may not be catastrophic for device performance (unlike deeper trap states). Nevertheless, there is still substantial non-radiative losses suggesting defects are not entirely benign and they still must be understood and addressed before devices can approach their performance limits.

Here, I will cover our ongoing work focusing on defects and their impact on non-radiative losses, as well as their mitigation through passivation treatments. I will present recent results in which we use multimodal approaches to determine relationships between local chemistry, structural and luminescence properties in perovskite thin films using synchrotron nano X-Ray Diffraction (n-XRD) and nano X-Ray fluorescence (n-XRF) measurements, as well as confocal and wide-field luminescence imaging. We reveal an intimate connection between strain and non-radiative decay, revealing these strain-related defects as a primary origin of non-radiative losses. I will also outline the action of passivation treatments, such as chemical and light-induced treatments, on relieving these strain patterns.

The work provides a platform for designing new and more effective passivation post-treatments or film fabrication methods, which will push devices ever closer to their efficiency limits.

Perovskite Dynamics from the Nano- to the Macroscale Marina S. Leite; University of Maryland, College Park, Maryland, United States.

To date, the main limitation toward hybrid perovskites’ implementation into commercial light-absorbing and light-emitting devices is this material lack of stability upon exposure to: humidity, oxygen, temperature, light, and bias [1, 2]. Thus, understanding and controlling the driving forces for perovskites’ degradation and the possible pathways for recovery are imperative for the development of reliable devices. We resolve the influence of each abovementioned parameter onto the perovskites’ electrical and optical responses from the nano- to the macroscale. We demonstrate, in real-time, the dynamic open-circuit voltage of perovskite solar cells by novel scanning probe microscopy methods [3, 4], resulting from light-induced ion migration [5]. We determine the effect of chemical composition of the photoluminescence hysteresis of Cs-triple cation perovskites, as a function of humidity cycles [6]. Additionally, we identify a fully reversible voltage response within grains for Cs-triple cations perovskites upon exposure to 1-sun illumination. These measurements show the importance of correlating the local, nanoscale behavior with macroscopic electrical and optical responses. Finally, we will present a machine learning approach to track device performance [1], including a route to prevent material degradation, and to material recovery.

Ionic Properties of Twin Domain in Methylammonium Lead Triiodide Yongtao Liu1, Lian Collins2, Anton V. Iveliev2, Alex Beliaev2, Stephen Jesse3, Scott Retterer2, Kai Xiao4, Mahshid Ahmad1, Sergei V. Kalinin4, Bin Hu5 and Olga Ovchinnikova6; Department of Materials Science and Engineering, The University of Tennessee, Knoxville, Knoxville, Tennessee, United States; 6Center for Nanophase Materials Sciences, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

The twin domain in methylammonium lead triiodide (MAPbI3) has drawn extensive research efforts, starting the discussion on its ferroic nature. Given the earlier investigations revealed the ion segregation correlating to the ferroelastic domain contrast. To follow up, we systematically investigate the chemical evolution of the ion migration in the MAPbI3 twin domains in this work. Using Band Excitation Contact Kelvin Probe Force Microscopy (BE-cKPFM), we reveal the absence of ferroelectric origin of the previously observed butterfly and hysteresis loops in Switching Spectroscopy piezoelectric force microscopy (SS-PFM). In addition, Band Excitation Scanning Kelvin Probe Force Microscopy (BE-scKPFM) measurement, which was utilized to study the electrochemical activities in the twin domain, indicates that the difference in ion migration and/or surface charging effect in the adjacent domains. This result implies a different ionic conductivity and a variation of electronic properties in adjacent domains. Combining Band Excitation PFM (BE-PFM), nanoscale infrared spectroscopy (Nano IR), and scanning probe microscope (SEM), we clarify the correlation between ionic diffusion, electronic properties, and chemical segregation. We reveal that the methylammonium segregation leads to a decrease of electronic conductivity and an increase of ionic conductivity. Overall, this work provides new insights into understanding the role of the twin domain in photovoltaic action.

Phase Intergrowth and Structural Defects in Organic Metal Halide Ruddlesden-Popper Thin Films Navleen Venkatesan1, Rhiannon Kennard1, Ryan A. DeCrescent2, Erin Perry3, Clayton J. Dahlman1, David Hamill2, Jon A. Schuller1, Alberto Salles2 and Michael L. Chabinyc2; University of California, Santa Barbara, Santa Barbara, California, United States; 2Stanford University, Stanford, California, United States.

Hybrid organic metal halide Ruddlesden-Popper (R-P) phases have recently been the subject of intense research efforts due to their good power conversion efficiencies in photovoltaics and controllable emission for light emitting diodes, while possessing better environmental stability compared to their three-dimensional counterparts. The thin film structures of these layered perovskites are still poorly understood relative to the bulk. In this study, we use optical spectroscopy, X-ray scattering, and transmission electron microscopy to characterize the structures of these thin films of (C6H13NH3)2(C6H13NH3)2PbI3 and
(C$_2$H$_5$NH$_3$)$_2$(CH$_3$NH$_3$)$_3$Pb$_4$I$_{13}$ on the meso- and nanoscales. Previous studies suggest a preferential orientation of the Pb-I sheets in spin coated films, perpendicular to the substrate, so that the layer stacking direction is in the plane of the film. By measuring in-plane and off-specular X-ray diffraction with grazing-incidence wide-angle X-ray scattering (GIWAXS), we observe that some expected peaks along the stacking direction of the Pb-I sheets are missing, indicating disorder in perovskite layer stacking. Because the diffraction patterns represent a bulk, average structure, we used transmission electron microscopy (TEM) to explore film structure on a local scale and find that these films consist of small crystalline grains in an amorphous matrix, contradictory to previous reports suggesting single-crystalline quality thin films. When using known crystal structures to index these SAED patterns, we see that the thin films comprise not only the targeted R-P phase, but also regions with lower and higher Pb-I sheet thickness (i.e. phase impurities). This phase intergrowth creates structural defects that interrupt layer stacking and is the cause broadening of in-plane diffraction peaks, causing them to be absent from previous GIWAXS measurements. Finally, because these films produce efficient photovoltaics despite this high degree of structure disorder, we measured the absorption coefficient using photothermal deflection spectroscopy (PDS) and find Urbach energies of 32 meV for the R-P phases compared to 19 meV for methylammonium lead iodide. Despite the structural defects, the R-P films appear to maintain a low degree of electronic disorder suggesting that the Pb-I regions are electronically isolated from each other.

Hybrid Inorganic-Organic Perovskites—From Film Optical Response to Device Functionality
Nikolay Podraza, Brius Subedi, Kiran Ghimire, Prakash Upadhyay, Maxwell Junda, Cong Chen, Chongwen Li, Dewei Zhao, Zhaoning Song and Yanfa Yan; University of Toledo, Toledo, Ohio, United States.

Solar cells with hybrid inorganic-organic lead halide based perovskite absorber layers have achieved remarkably high photovoltaic device performances in a relatively short amount of time when compared to comparable efficiency devices based upon other semiconductor absorbers. This perovskite family offers a wide range of tunable opto-electronic properties obtained via alloying of either/both the organic and inorganic components, and, even in their polycrystalline form, these perovskites are generally quite electronically forgiving semiconductors. However, as the material composition is manipulated, film stability and any increase in defect concentration remain issues. Here we will provide an overview of the optical properties, in the form of the complex index of refraction or complex dielectric function spectra, as well as the physical origin for the features present in those optical properties for perovskite layers with considerations toward composition, sample handling / environmental exposure, and incorporation in devices. Proper measurement and analysis yielding accurate values of the complex optical properties over the ultraviolet to millimeter wavelength range and complementary techniques sensitive to different levels of optical absorption enables tracking of the bandgap and higher energy critical point transitions, electrical transport properties manifested as free carrier absorption, sub-bandgap absorption due to defects, and film degradation or decomposition upon atmospheric exposure as deduced from in-situ / ex-situ spectroscopic ellipsometry, optical Hall effect, and photothermal deflection spectroscopy. Once acquired, these optical properties serve as input for external quantum efficiency simulations of photovoltaic device performance. Features observed optically will be correlated with full functioning device performance, illustrating how accurate optical property measurements over different wavelength ranges and levels of absorption provide insight into device functionality.

4:00 PM ET05.11.06
In Situ TEM Observation of Perovskite Solar Cells
Satoshi Uchida1, Tae Woong Kim1, Ludmila Cojocaru2, Takashi Kondo1 and Hiroshi Segawa1; 1The University of Tokyo, Tokyo, Japan; 2University of Freiburg, Freiburg, Germany.

Recently, organometal halide perovskite solar cells (PSCs) have received great attention. The power conversion efficiency (PCE) of PSCs have shown a dramatic increase and certified PCEs adopting mixed organic cations and halide anions have reached over 22%. The PCE is considerably affected by photovoltaic property of each component of a PSC. In spite of the significance in the crystallographic information, however, microstructural observation for crystal structure analysis of the perovskite layer has not been actively conducted. Until now it is widely believed that each phase of the organometal halide perovskite solely exists with orthorhombic phase < 165K < tetragonal phase < 327K < cubic phase. Nevertheless we newly observed that the tetragonal and cubic phases coexist at room temperature in the conventional MAPbI$_3$ thin film device.

Furthermore, surprisingly, superlattices composed of mixture of tetragonal and cubic planes without any compositional change was also found. Formation of the superlattice is achieved by only intrinsic structural transition without artificial modifications and, therefore, most phenomena concerned with the structural superlattice are expected to spontaneously and automatically occur in context with situation. The organometal halide perovskite self-adjusts their microstructural configuration and self-organizes buffer layers inside crystal or at hetero-interface by introducing the self-assembled superlattices. We believe, this report will be a vital cornerstone to bring the PCEs of the organometal halide perovskite solar cells one step closer to theoretical maximum point and redefine possibility of the organometal halide perovskite as promising materials for not only solar cell but also various application.

4:15 PM ET05.11.07
Strain Effect on Stability and Band Gap in CsPbBr$_3$ Crystal via NanoXRD
Xueying Li, Yanqi Luo1, Moses Koduri1, Rishi Kumar1, Martin V. Holz2, Zhonghao Cai2 and David P. Fenning1; 1University of California, San Diego, La Jolla, California, United States; 2Argonne National Laboratory, Argonne, Illinois, United States.

Despite the comparable power conversion efficiency between polycrystalline Si and perovskite solar cells (PSC), the commercialization of PSCs is inhibited by their low stability. A recent study demonstrated that the commonly used spin-casting and annealing for perovskite thin film create strain in the material and lead to decreased stability. Other publications have observed an association between lattice constant and band gap in halide perovskites ABX$_3$ (A= methylammonium, formamidinium, cesium; B=lead; X=Bromide, Iodide, chloride), suggesting their band gap can be tuned through the manipulation of strain in the material. However, the knowledge of strain distribution and its local effect is lacking for making highly stable PSCs or stress-sensitive optoelectronics. To study the local effect of strain, we map CsPbBr$_3$ crystals with nanoscale X-ray Diffraction Microscopy (nanoXRD) with approximately 100-nm spatial resolution and 0.1% sensitivity in strain detection. By exploiting the thermal expansion coefficient mismatches, a strain gradient is created in a CsPbBr$_3$ crystal at the edge of a platinum pad on quartz substrate and characterized by nanoXRD. We find that the observed compressive strain reduces the stability of the material, which proves that strain should be avoided for highly stable halide perovskites. We also characterize the same crystal with ex-situ photoluminescence (PL) mapping and observe PL peak shifts red at compressively strained locations in the crystal. This demonstrates the band gap narrowing by substrate-induced strain locally, which should be brought into attention for the fabrication process of halide perovskite on substrates. On the other hand, the strain effect on band gap shows potential of stress-sensitive optoelectronic applications with halide perovskites.

Probing the Microstructure of Methylammonium Lead Iodide Perovskite Solar Cells
Tobias Leonhard, Holger Röhm, Alexander Schulz, Fabian J. Altermann, Susanne Wagner, Wolfgang Rheinheimer, Michael J. Hoffmann and Alexander Colsmann; Karlsruhe Institute of Technology, Karlsruhe, Germany.
Germany.

The microstructure of absorber layers is pivotal for all thin-film solar technologies. Despite its unprecedented performance development in recent years, little is known about the microstructure of metal-halide perovskites and its effect on the macroscopic device performance. Yet, recent publications have frequently called attention to the urgent need of spatially resolved microstructure characterization techniques in order to correlate the microscopic structure with macroscopic device properties.

In this work, we report on the spatial investigation of methylammonium lead iodide (MAPbI3) grain properties by electron backscattered diffraction (EBSD) with high resolution. We resolve diffraction pattern ambiguities that are related to the close-to-cubic perovskite unit cell, and develop a comprehensive three-dimensional picture of the crystal orientation. We identify predominant orientation directions and observe orientation cross-talk between neighboring grains. The local crystal information correlates with ferroelectric and electronic properties that we probe with piezo-response force microscopy (PFM) and kelvin probe force microscopy (KPFM) measurements. If the ferroelectric polarization influences the charge carrier recombination and transport, as was predicted by simulations, then the orientation and shape of polarized domains within grains would directly influence the device performance. In turn, this renders engineering of the grain orientation and size a pivotal parameter for the optimization of perovskite solar cells which is not yet commonly investigated in most perovskite solar cell studies. These tools are indispensable for the future relation of the microscopic structure to the optoelectronic properties of perovskite devices as they allow to monitor device optimization and to understand fundamental processes of perovskite solar cells. Therefore, we expect EBSD and PFM to become the most often employed characterization techniques in the future for the correlation of microscopic structure and macroscopic device performance. Their strong correlation allows to draw conclusions about the microstructure from ferroelectric features and, likewise, to derive the ferroelectric polarization from crystallographic observations. Understanding the microstructure would not least be the key to future ab-initio engineering of new (non-toxic) and highly efficient perovskite solar cells.

Direct Optical Identification of Grain Boundaries and Carrier Diffusion in Perovskite Film Wenhao Li, Srinivas K. Yadavalli, Yuanyuan Zhou, Nituin P. Padture and Rashid Zia; Brown University, Providence, Rhode Island, United States.

Perovskite solar cells (PSCs) have attracted considerable attention in recent years due to their rapidly increasing power conversion efficiency (PCE), which currently exceeds 22%. Given that most high efficiency PSCs are made of polycrystalline films, an important feature is their grain size distribution, because grain boundaries can limit carrier diffusion and serve as nonradiative recombination sites, thereby reducing the PCE. Due to the formation of grain boundary grooves during perovskite film growth, many techniques for estimating grain size rely on surface morphology characterization using scanning electron microscopy (SEM) or atomic force microscopy (AFM). However, not all grain boundaries exhibit clear topographical features.

Here, we report the direct identification through photoluminescence (PL) microscopy of grain boundaries in formamidinium lead iodide (FAPbI3) thin film samples that cannot be observed by either SEM or AFM. We demonstrate that these “invisible” boundaries impede carrier diffusion and limit radiative recombination events. Optical characterization is further supported by electron backscatter diffraction (EBSD) measurements that are used to confirm crystal orientation differences across these otherwise imperceptible boundaries. Then, we present PL lifetime measurements that show how these “invisible” boundaries serve as nonradiative recombination sites, thereby decreasing carrier lifetimes, and likely reducing PCEs.

In order to quantify the carrier diffusion resistance in different types of grain boundaries, we developed a carrier density probing method. Using a high-speed intensified emCCD camera, we are able to measure the 2D PL intensity distribution with nanosecond resolution. Comparing the PL distribution with excitation near and far away from the grain boundary, we can see the effect of grain boundaries in blocking carriers. A carrier diffusion and recombination model is used to fit the observed PL evolution to extract the diffusion and recombination coefficients. Together with a mapping of steady state PL intensity distribution and the carrier density probing method, we are able to estimate the resistivity of carrier diffusion across grain boundaries. Finally, we will discuss the impact of these boundaries as well as this new characterization method for the synthesis and analysis of thin-film perovskite solar cells.

SESSION ET05.12: Poster Session IV: Fundamentals of Halide Perovskite Optoelectronics

Impact of Applied Bias, and Material Degradation on Ion Transport in Hybrid Perovskite Solar Cells Under Illumination Emily C. Smith1, Christie Ellis1, Hamza Javadi1, Lawrence A. Renna1, Yao Liu1, Thomas P. Russell1,2, Monojit Bag1 and Dhandapani Venkataramanan1; 1University of Massachusetts Amherst, Amherst, Massachusetts, United States; 2Materials Science Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States.

We mapped ion transport in hybrid organic–inorganic perovskite solar cells under illumination using impedance spectroscopy (IS) as a function of applied bias and device degradation. We observe evidence of mass (ion) diffusion and extrapolate conductivities (∼10−7 S cm−1) and diffusion coefficients (∼10−7 cm2 s−1) for the mobile ionic species at varying applied bias. We show that ions respond to low applied forward bias in a predictable manner, as was predicted by simulations, then the orientation and shape of polarized domains within grains would directly influence the device performance. In turn, this renders engineering of the grain orientation and size a pivotal parameter for the optimization of perovskite solar cells which is not yet commonly investigated in most perovskite solar cell studies. These tools are indispensable for the future relation of the microscopic structure to the optoelectronic properties of perovskite devices as they allow to monitor device optimization and to understand fundamental processes of perovskite solar cells.

Therefore, we expect EBSD and PFM to become the most often employed characterization techniques in the future for the correlation of microscopic structure and macroscopic device performance. Their strong correlation allows to draw conclusions about the microstructure from ferroelectric features and, likewise, to derive the ferroelectric polarization from crystallographic observations. Understanding the microstructure would not least be the key to future ab-initio engineering of new (non-toxic) and highly efficient perovskite solar cells.

Organic inorganic hybrid perovskites (OHP) is the most promising material to achieved photovoltaic devices with high power conversion efficiency and low cost. The perovskites with the composition CsxFA_{1-x}PbBr_{3-y}I_{y} achieve high PCE, present better stability, photo-stability, and their band gap can be tuned by changing the composition, becoming interesting for tandem solar cells. The most used method to prepare this sort of composition is the solvent engineering method [1]. During the spin coating process, an antisolvent (chlorobenzene, dichlorobenzene, toluene) is dropped onto the substrate to remove the excess of the original solvents as DMF and DMSO. Thus, formation of perovskite or an intermediate can be attained. Despite of being the most popular method, the impact of many deposition parameters such as the temperature of spin coating the anti-solvent, the molar proportion between the precursors and DMSO during the spin coating, are not well understood. Here we used in situ-time-resolved grazing incidence wide-angle X-ray scattering (GIWAXS) in the Brazilian Synchrotron Light Laboratory (LNSLS) during film preparation to monitor and get insights about the perovskite formation. CsxFA_{1-x}Pb(Br_{1-y}I_{y}) was the composition of choice. Without antisolvent, the scattering signal is attributed to a disordered colloidal gel formed between perovskite and solvent. [2] This signal fades with time, and the lifetime changes with DMSO perovskite proportion and ambient moisture. Immediately after anti-solvent injection, new CsxFA_{1-x}PbI_{3} peaks emerged attributed to phase of the perovskite and intermediate. The intermediate’s peaks fade with time while the peak related to the perovskite becomes more intense. The results reveal that perovskite formation takes place without thermal annealing and the transformation occurs through the intermediates. With shorter times of anti-solvent injection, the morphology of the film is smooth, but with longer times, the morphology becomes more heterogeneous. This was attributed to intermediates formed before the injection of the anti-solvent, that remain stable in the film. In conclusion, in situ-time-resolved GIWAXS during the spin coating step provided important information about the best parameters to guarantee only perovskite formation or intermediates with shorter “lifetime”. Having these parameters in hands, films with better morphology, transport and optoelectronic properties can be obtained.

Exceptional Grain Growth in Formamidinium Lead Iodide Perovskite Thin Films Induced by Phase Transformation
Srinivas K. Yadavalli, Yi Zhang, Wenhao Li, Yunyuan Zhou, Rashid Zia and Nitin P. Padture; Brown University, Providence, Rhode Island, United States.

Formamidinium lead iodide (FAPI) based perovskites have attracted a great deal of interest as light absorbers in solar cells due to their superior thermal stability and more sustainable band gap compared to perovskites based on methylammonium (MA). However, preferential formation of a photo-inactive α-FAPI phase at room temperature has been a major impediment. The need for prolonged heat-treatments at temperatures >150 °C to obtain the desirable α-FAPbI3 perovskite phase often leads to film degradation. Heat treatment also produces fine-grained films with high grain-boundary density, which is detrimental to PSCs performance and stability. In this context, we have discovered a new phenomenon, where fine-grained (∼175 nm) α-FAPbI3 thin films transform rapidly to phase-pure α-FAPbI3 perovskite thin films with ultra-large grain size exceeding ~5 μm. The large-grained nature of the films is confirmed using appropriate materials characterisation techniques. The improved kinetics of thin film formation is explained by studying the phase and morphological evolutions during film-sonnet interaction. The nature of phase nucleation and growth is studied through in-situ microscopy techniques. In-situ X-ray diffraction and solvent polarity effects on the transformation rate are also studied to corroborate the proposed mechanism. Devices with high efficiency are fabricated with these ultra-large grained films and are characterized. The use of this novel approach to achieve 5-μm grains by a brief low-temperature treatment enables a promising path toward achieving ‘single-crystal’ films with superior optoelectronic properties and chemical stability.

ET05.12.04
Surface Doping of Metal Halide Perovskites
Nakita K. Noel1, Alba Pellaroque2, Federico Pulvirenti1, Henry Snaith2, Seth B. Marder3 and Barry P. Rand1; 1Princeton University, Princeton, New Jersey, United States; 2Physics, University of Oxford, Oxford, United Kingdom; 3Chemistry, Georgia Institute of Technology, Atlanta, Georgia, United States.

Within the past few years, metal halide perovskites have been attracting significant interest due to their successful application to optoelectronic devices. These materials have been used in lasers, photodetectors, and most commonly, in photovoltaic devices and light emitting diodes. Despite the cheap and simple fabrication methods by which these materials are deposited, high quality perovskite films can be readily fabricated, and the power conversion efficiencies of lead halide perovskite solar cells are now approaching certified values of 23%. However, perovskite-based devices are yet to achieve their full potential. One of the major hindrances to achieving this potential is an incomplete understanding of perovskite surfaces and interfaces. Deficiencies at these interfaces may be responsible for the largest losses in perovskite based optoelectronic devices; hindering charge extraction, increasing non-radiative recombination rates and hysteresis, and significantly increasing the voltage loss in perovskite photovoltaics. We propose surface doping the perovskite material as a means to combat these interface deficiencies. Herein, we will discuss doping of the perovskite material at various interfaces using well-established charge-transfer dopants. We show the doping of the perovskite material through both solid-state NMR and surface characterisation techniques, and further characterise the material through photoluminescence measurements, showing a reduction in the non-radiative recombination of the material. Using this surface doped material, we show photovoltaic devices with reduced hysteresis, low voltage losses, and steady-state power conversion efficiencies in excess of 20%.

ET05.12.05
Advances in Bright Single Layer Perovskite Light Emitting Devices
Ross E. Haroldson1, Artur Ishteev2, Patricia Martinez1, Masoud Alahakoon1 and Anvar A. Zakhidov1; 1The University of Texas at Dallas, Richardson, Texas, United States; 2MISIS, Moscow, Russian Federation.

Exciting reports about single layer cesium lead halide perovskite LEDs have shown that conventional electron and hole injection layers are not necessarily needed. A sandwiched device structure consisting of a perovskite-polymer composite film between two electrodes can emit bright light at low operating and threshold voltages (~2.0 volts). We studied the role of grain size, polymers inclusion, morphology, emission changes, and electrode material in CsPbBr3 based LED. These simple single layer devices are easier and cheaper to fabricate as compared to their multilayered counterparts and removes the possible reaction routes between perovskite and the charge injection layers. We also investigate underlying mechanisms of how ion migration within the perovskite layer forms a p-n-n junction which allows efficient charge injection directly from the electrodes, independently of their work function, while still having efficient radiative recombination.

ET05.12.06
Photo-Inject Bismuth Doped MAPbI3 Thin Films for Optoelectronics Devices
Carlos D Redondo-Obispo1, Teresa S Ripollés1, Esteban Ciment-Iglesias2, Patricia Sanchis1, Alba Pellaroque2, Federico Pulvirenti1, Esteban Ciment-Iglesias1, Teresa S Ripollès1, Fernando de la Vanda3, Pablo del Rio4 and Carmen Coya1; 1ETSIT, Universidad Rey Juan Carlos, Madrid, Spain; 2ETSIIT, Universidad Politécnica de Madrid (UPM), Madrid, Spain; 3Facultad de CC Físicas, Universidad Complutense de Madrid (UCM), Madrid, Spain; 4Instituto de Ciencia de Materiales de Madrid (ICMM), Consejo Superior de Investigaciones Científicas (CSIC), Madrid, Spain.

Hybrid organic-inorganic perovskite research continues gaining efforts to achieve high overall power conversion efficiencies due to their unique optoelectronic properties. [1] An intense activity is dedicated to overcome their high sensitivity to ambient atmosphere (especially water and oxygen) and to visible irradiation that strongly handicap their stability and performance. In particular, semiconductors doping strategy with heterovalent ions has been
tested to stabilize the perovskite material, to control phase transition, morphology improvements, or enhance the electrical and optical properties. Obtaining more stable compounds as well as understanding the complex behavior of the emission evolution upon illumination and time are main concerns to be addressed. The photoluminescence behavior is strongly sensitive to different parameters, mainly to the presence of defects and traps whose evolution with time is related to ion migration and perovskite transformations. [2, 3]

In the present work, the incorporation of Bi3+ in the MAPbI3 (MA=CH3-NH2) perovskite precursor solution leads up to around 7 at.% incorporation at the Pb2+ site in thin film lattice, which corresponds to 33% nominal. This doping effect is demonstrated by x-ray diffraction and their effect on phase purity, symmetry, lattice parameters, average crystalline domain and microstrain are carefully evaluated. A spurious MA3Bi2I9 phase is detected for nominal Bi > ca. 15% while the usual spurious PbI2 phase in undoped films is not observed for any Bi doping. Influence on optical and electrical properties are also studied. Novel effects as extraneous photostability and photosensitivity enhancement, compared to that of undoped MAPbI3 thin films are observed.

Bi3+ incorporation lead to a slight increment of the optical gap due to the reduction of lattice parameters. However, for the photoluminescences properties, the phenomenology for the Bi doped samples is drastically different at high power irradiation. We propose a mechanism to explain the observed trends using a model based on the migration of Bi3+ upon irradiation and its effect on the MAPbI3 cell volume and bandgap energy. These results provide a new path for obtaining highly stable materials which would allow an additional boost of hybrid perovskite based optoelectronics.

ET05.12.07
Nanoimprinted Plasmon Enhanced Perovskite Solar Cells Tianyi Shen, Stylianos Siontas and Domenico Pacifici; School Engineering, Brown University, Providence, Rhode Island, United States.

Perovskite solar cells have drawn great attention in the past years. Besides the high absorption and long carrier diffusion length of the material, perovskite solar cells have demonstrated potential for a promising alternative to conventional silicon solar cells due to their lower fabrication costs and reported power conversion efficiencies reaching 22.1%.

Plasmonic absorption enhancement has been extensively utilized to improve the performance of various solar cell technologies. Here, we report on a simulation study to further boost the efficiency of perovskite solar cells by embedding plasmonic nanostructures in the back metal contacts. Specifically, three-dimensional (3D) finite-difference time-domain (FDTD) simulations are performed on perovskite solar cells, consisting of perovskite films with varying thickness on top of flat or corrugated gold electrodes with varying light trapping geometries (nanodisk or nanohole arrays). The calculated electric fields in the simulation volume enable the decoupling of the absorption within the perovskite and gold films, respectively, which allows for the calculation of the cell power conversion efficiency (PCE) as a function of relevant design parameters. By systematically leveraging the geometry dimensions, the optimal nanostructure designs are obtained. The results show that 100nm-thick perovskite films on top of corrugated gold electrodes can exhibit up to 52% PCE increase compared to their flat counterparts (from 19.2% for a flat cell to 29.2% for an optimized nano-corrugated cell). Moreover, we show that a 150nm-thick perovskite film cell with opportunity corrugated back metal contacts can exhibit a PCE value (31.3%) comparable to that of a 400nm-thick bulk-like cell (31.6%).

These findings may pave the way for plasmon-enhanced high-performance thin-film perovskite solar cells fabricated via scalable methods such as nanoimprint lithography.

ET05.12.08
Long Electron–Hole Diffusion Length in High-Quality Lead-Free Double Perovskite Films Weihua Ning, Feng Wang and Feng Gao; Department of Physics, Chemistry, and Biology (IFM), Linköping University, Linköping, Sweden.

Developing environmentally friendly perovskites has become important in solving the toxicity issue of lead-based perovskite solar cells. Here, the first double perovskite (Cs2AgBiBr6) solar cells using the planar structure are demonstrated. The prepared Cs2AgBiBr6 films are composed of high-crystalquality grains with diameters equal to the film thickness, thus minimizing the grain boundary length and the carrier recombination. These high-quality double perovskite films show long electron–hole diffusion lengths greater than 100 nm, enabling the fabrication of planar structure double perovskite solar cells. The resulting solar cells based on planar TiO2 exhibit an average power conversion efficiency over 1%. This work represents an important step forward toward the utilization of environmentally friendly solar cells and also has important implications for the applications of double perovskites in other optoelectronic devices.

ET05.12.09
Combinatorial Investigation of Coevaporated CsPbI3 Thin Films with Large Quasi–Fermi Level Splitting Pascal Becker1–4, Jose Marquez Prieto1, Amran Al-Ashouri5, Charles Hages1, Hannes Hempel1, Justus Just1, Steve Albrecht4 and Thomas Unold1; 1Dept. Structure and Dynamics of Energy Materials, HZB, Berlin, Germany; 2Bergische Universität Wuppertal, Wuppertal, Germany; 3Lund University, Lund, Sweden; 4Young Investigator Group Perovskite Tandem Solar Cells, HZB, Berlin, Germany.

The new generation of photovoltaic materials is driven by the unprecedented rapid performance improvement of hybrid organic-inorganic perovskites solar cells (PSCs). Fully inorganic CsPbI3 perovskites have also demonstrated their great potential for photovoltaics in world record quantum dot solar cells and as an ideal material candidate for tandem devices with a band gap close to 1.8 eV. In this study we explore the composition-dependent phase stability of CsPbI3 films by combinatorial studies. We show that coevaporated CsPbI3 can be synthesised in a stable perovskite phase under Cs rich conditions without the need of a post deposition annealing treatment. We investigate the compositional dependence of the electronic properties by THz spectroscopy and quantitative hyperspectral photoluminescence imaging. Compositional regions with considerably large carrier mobilities and a high photoluminescence quantum yield are identified. From these measurements a maximum quasi-Fermi level splitting of 1.27 eV and charge carrier diffusion lengths of around 3 microns are estimated, indicating this material’s potential for high efficiency solar cells. We find that the charge carrier mobility decreases with increasing Cs content corresponding to a lowering of the electronic dimensionality as the Cs content is increased in the films. First planar pin-type solar cells have been fabricated showing stabilised efficiencies exceeding 11%. Based on the comparison of the optoelectronic characteristics performed in the CsPbI3 films and the solar cells properties of the corresponding devices we conclude that the devices are strongly limited by interface recombination. Optimisation of the device architecture with better matched extraction layers exhibiting less interface recombination could be expected to lead to 18%
efficient inorganic perovskites solar cells.

ET05.12.10  
Photodetectors and Solar Cells Using Indium (I) Iodide as Active Material  
So Min Park, Masud Abdullah A, Christopher I Richards and Kenneth R. Graham; University of Kentucky, Lexington, Kentucky, United States.

Organometal halide perovskites are emerging as promising photovoltaic (PV) materials due to their strong absorbance throughout the visible region, relatively high charge-carrier mobilities, and power conversion efficiencies (PCE) that are on par with polycrystalline silicon. As these materials progress towards commercial applications, understanding the factors limiting the PCE and stability is becoming essential. Interfaces and grain boundaries are some of the most influential aspects for both device performance and stability, as these are prime areas for defect formation and charge recombination. One

Design of novel advanced semiconductor materials usually defines the progress in the development of new photovoltaic (PV) technologies. In particular, recently discovered lead halide based perovskites demonstrated outstanding electronic characteristics and showed high efficiencies of >22% in single junction photovoltaic cells fabricated using low-cost solution process. Perovskite solar cells can potentially accomplish a revolution on the PV market due to their high efficiency and low cost. However, the practical application of perovskite photovoltaics is still limited severely by low stability of complex lead halides and their high toxicity. Therefore, many research groups worldwide explore different families of binary and complex metal halides with high electron/hole mobilities and long carrier lifetimes in order to find some feasible environment-friendly alternatives to the conventional lead perovskites.  
Bounassifi et al. have presented recently theoretical and spectroscopic study suggesting that InI might be considered as a valuable material for photovoltaics (Chem. Mater. 2017, 29, 4667-74).

Here we present the first to the best of our knowledge experimental study of InI as semiconductor material for photovoltaic devices. Planar junction PV cells with InI as active material demonstrated encouraging external quantum efficiency of 17% at short wavelength, while the overall power conversion efficiency (<1%) was limited mainly by low open circuit voltages and fill factors even after substantial optimization of interfacial layers, active layer thickness and morphology.

Strong phot conductivity effect revealed for thin films of InI allowed us to apply this material for fabrication of efficient photodetectors with lateral and vertical geometries. Both types of devices showed excellent light sensitivity and short response times pointing towards high potential of further development of this research direction.

ET05.12.11  
Energetics and Structural Effects of Degradation in Halide Perovskites  
Colin Freeman, Christopher M. Handley, Derek Sinclair, Ian M. Reaney, Vikas Kumar and Cornelia Rodenburg; University of Sheffield, Sheffield, United Kingdom.

With the massive interest in halide perovskites there has been a wide range of research into combinations of these materials. MAPbI$_3$, however, still demonstrates very desirable properties. The long term stability of MAPbI$_3$ remains a significant challenge to any true commercial uptake. The degradation can be significantly affected by many factors but remains unclear [16]. Particular attention has focussed on the effect of non-stoichiometry of the material [19] which may have a significant role in the stability.

Simulations can provide a very valuable tool for studying the defect behaviour, stability and degradation of these perovskite materials due their ability to design and explore exact conditions and examine the local atomic behaviour. Although very powerful, ab initio simulations are limited to modelling relatively small cells due to their computational demands. Classical mechanics provides a powerful method to reach larger sizes and far more configurations.

We use our recently published forcefield [3] to study defects in the MAPbI$_3$ system. We observe that defects are encouraged by non-stoichiometry in the system. We examine the local and long range structural effects of the defects with a particular focus on dynamic behaviour in the ions (rotation/vibrations) and tilt of the octahedra. From this we are able to comment on the influence in general on degradation. We couple these results to experimental probing of degradation in non-stoichiometric samples.

ET05.12.12  
Understanding and Tuning the Energetic Landscape in Mixed Dimensionality Perovskites  
Haralds Abolins and Felix Deschler; University of Cambridge, Cambridge, United Kingdom.

Ruddlesden-Popper perovskites have recently been shown possess greatly enhanced environmental and thermodynamic stability relative to their bulk counterparts, which has proven the key challenge for the commercialization of perovskite-based photovoltaics. Nonetheless, when these low-dimensionality materials are deposited in thin films through a fast crystallization process, a mixed phase material will result with bulk-like perovskite domains intermixed with grains of Ruddlesden-Popper perovskite of varying configurations in the number of atomic layers between each set of spacer cations. The precise composition will depend on processing conditions and will inevitably have an effect on the charge transport characteristics of the resulting material. While it has been shown that high-efficiency solar cells and LEDs can be fabricated from mixed dimensionality perovskites, the charge transport characteristics between the different phases in these materials have not been well understood. To elucidate the carrier dynamics in Ruddlesden-Popper perovskites a deposition procedure for obtaining thin films with micron-sized single-phase grains is developed. The spatial configuration of the various dimensionality phases is subsequently revealed through photoluminescence mapping and is shown to be tunable in both distribution and relative abundance by varying the deposition conditions. Lastly, it is demonstrated through spectrally resolved photoluminescence lifetime studies that charges are funnelled to the lowest band-gap phases of the materials through an energy transfer process that considerably increases local carrier concentration, leading to enhanced photoluminescence quantum efficiencies. Crucially, the geometry, rate and efficiency of this funneling are shown to be tunable through only slight adjustments in processing conditions, allowing the energetic landscape to be tailored for individual applications.

ET05.12.13  
Surface Ligands on Methylammonium Lead Iodide Perovskites—Binding Group Effects on Photoluminescence and Photovoltaic Device Performance  
So Min Park, Masud Abdullah A, Christopher I Richards and Kenneth R. Graham; University of Kentucky, Lexington, Kentucky, United States.

Organometal halide perovskites are emerging as promising photovoltaic (PV) materials due to their strong absorbance throughout the visible region, relatively high charge-carrier mobilities, and power conversion efficiencies (PCE) that are on par with polycrystalline silicon. As these materials progress towards commercial applications, understanding the factors limiting the PCE and stability is becoming essential. Interfaces and grain boundaries are some of the most influential aspects for both device performance and stability, as these are prime areas for defect formation and charge recombination. One
means of improving both device performance and stability is to passivate these surfaces and grain boundaries by applying surface ligands. Although multiple surface treatments and additives have been applied to perovskite PVs, there is a lack of understanding of how these molecules are interacting with the perovskites. In this study, we show how the binding group influences photoluminescence (PL) and photovoltaic (PV) properties and stability for a series of surface ligands consisting of varying binding groups. These include ligands with both one and two potential binding groups, including zwitterionic molecules. We expected that zwitterionic ligands would display higher binding affinities and potentially improved trap state passivation, as the negatively charged part of the zwitterionic ligands can bind with positively charged undercoordinated Pb\textsuperscript{2+} ions of the perovskite film, while the positively charged group can fill in A-site vacancies. We find that zwitterions indeed lead to higher photoluminescence quantum yields (PLQYs) than monofunctional ligands.

**ET05.12.14**

**Electronic and Atomic Structure at the PCBM/CH3NH3/PbI\textsubscript{2} Interface in Perovskite Solar Cells from Ab Initio Molecular Dynamics**

Rahi Khanal\textsuperscript{1}, Nicholas Ayers\textsuperscript{1}, Sheila Briggs\textsuperscript{2}, Soumik Banerjee\textsuperscript{3} and Sanrat Choudhury\textsuperscript{1}; \textsuperscript{1}University of Idaho, Moscow, Idaho, United States; \textsuperscript{2}School of Mechanical and Materials Engineering, Washington State University, Pullman, Washington, United States.

In the perovskite solar cells, interfaces are crucial for efficient photovoltaic performance as they are responsible for both the injection and the transport of the charge carriers. Using *ab-initio* molecular dynamics simulations and density functional theory calculations, we have systematically determined the structural, electronic, and transport properties at a model CH\textsubscript{3}NH\textsubscript{3}PbI\textsubscript{3}/phenyl-C\textsubscript{61}-butyric acid methyl ester (PCBM) interface. The CH\textsubscript{3}NH\textsubscript{3}PbI\textsubscript{3} is the photoactive layer while PCBM is the electron transport layer. We have observed that PCBM prefers to attach to the perovskite surface via ester moiety of PCBM molecule. Further, from the analysis of interatomic distances on several interface models, we found that the bonding at the interface and the stability of interface is sensitive to the chemical composition at the surface i.e. CH\textsubscript{3}NH\textsubscript{3}I vs. PbI\textsubscript{2} surface terminations of the perovskite. Different preferences in bonding at the interface leads to the change in electronic and transport properties across two chemical terminations. Finally, we have shown that the stability of the interface can be increased by the introduction of certain types of defects at the perovskite surface, which may result in the better coverage of PCBM on the perovskite surface. However, such kind of defects could deteriorate the photovoltaic performance due to an increase in the potential barrier for the transport of charge across the interface.

**ET05.12.15**

**Impact of Anti-Solvents on the Structure and Optoelectronic Properties of Lead-Tin Mixed Perovskite Photovoltaics**

Tranchupa Bandara R M\textsuperscript{1}, Imalka Jayawarden\textsuperscript{1}, Andrew Parnell\textsuperscript{2}, Benjamin G. Freeston\textsuperscript{3}, Stephanie Adeyemo\textsuperscript{2}, Hannah Joyce\textsuperscript{1}, Radu Sporea\textsuperscript{1} and Ravi Silva\textsuperscript{3}; \textsuperscript{1}Department of Electrical and Electronics Engineering, University of Surrey, Guildford, United Kingdom; \textsuperscript{2}Department of Physics and Astronomy, The University of Sheffield, Sheffield, United Kingdom; \textsuperscript{3}Department of Engineering, University of Cambridge, Cambridge, United Kingdom.

Lead-tin (Pb-Sn) mixed perovskites have gained increasing attention due to the possibility of forming all solution processed tandem perovskite PVs (PPVs). One of the major obstacles towards enhancing the performance of the Pb-Sn PPVs has been the formation of high performing, pin hole free absorber layer. This is generally achieved using the anti-solvent treatment during the deposition of the perovskite layer, followed by thermal annealing (Saliba et al., *Environ. Sci. 9*, 1989). Another complication for mixed Pb-Sn PPVs is the fast oxidation of Sn\textsuperscript{2+} to Sn\textsuperscript{4+} which results low efficiencies due to p-type self-doping (Herz et al. *Acc. Chem. Res.* 49, 146). Various pathways have been investigated in decreasing this oxidation process with the most widely used being the incorporation of SnF\textsubscript{2}. This process however, while inhibiting the perovskite oxidation, generates Sn\textsuperscript{4+} ions in the system by the oxidation of Sn\textsuperscript{2+} in SnF\textsubscript{2} which are hardly removed from the system. Interestingly, extraction of Sn\textsuperscript{4+} from ion mixtures, is reported to be most effective when using toluene as the extraction medium (Sargar et al. *JCCS*, 50, 841). Incidentally, toluene is one of the widely used aforementioned anti-solvents that enable high performing perovskite PVs (Jeon et al., *Nan. Mater.* 13, 897). However, there are no known studies reported on the effective removal of Sn\textsuperscript{4+} based on the anti-solvent route.

To investigate this, we discuss the impact of toluene and two other commonly used anti-solvents; anisole and chlorobenzene, on the triple cation Pb-Sn mixed perovskite system (Cs\textsubscript{0.02}(FA\textsubscript{0.83}MA\textsubscript{0.17})\textsubscript{0.1}Pb\textsubscript{0.85}Sn\textsubscript{0.15})\textsubscript{0.15}). We observe ~80% improvement in power conversion efficiency (with minimal optimization of the processing conditions) for the toluene treated Pb-Sn mixed perovskite with a champion efficiency of ~6% compared to chlorobenzene or anisole treated devices. This is reflected by enhancements in all the device parameters (open circuit voltage, short circuit current and fill factor). Terahertz mobility measurements carried out on the different anti-solvent treated perovskite films clearly indicate improvements in charge carrier lifetimes with toluene, where a slower decay time is observed. The impact on the use of the anti-solvent on the chemistry of the Pb-Sn mixed perovskite is further evident through grazing incidence wide angle X-ray spectroscopy where no noticeable differences in the diffraction spectra are evident for different anti-solvents. Based on the above we introduce a mechanism by which Sn\textsuperscript{4+} is extracted through toluene enabling a more purified Pb-Sn perovskite absorber layer growth.

The extraction of the Sn\textsuperscript{4+} by toluene is further strengthened by the studies on the, Cs\textsubscript{0.02}(FA\textsubscript{0.83}MA\textsubscript{0.17})\textsubscript{0.1}Pb\textsubscript{0.85}Sn\textsubscript{0.15})\textsubscript{0.15}Sn\textsubscript{4+} system where the impact of the anti-solvent used is not as pronounced. Finally routes towards improving the Pb-Sn mixed perovskite performance which enables efficiencies approaching 15% is discussed.

**ET05.12.16**

**Perovskite Nanocrystals—Shape-Controlled Synthesis to Self-Assembled Supercrystals with Tunable Optical Properties**

Jalakshminarayana Polyavarap\textsuperscript{1,2}; Ludwig-Maximilians-Universität München, Munich, Germany; \textsuperscript{2}Center for NanoScience (CeNS), Munich, Germany.

Perovskite nanocrystals (NCs) are gaining increasing attention in many fields ranging from chemistry to physics and engineering owing to their extremely interesting properties such as high photoluminescence quantum yields, tunable optical bandgap, enhanced stability, large diffusion lengths and shape controllability. [1–4] In spite of the rapid progress in the synthesis of perovskite NCs, very few attempts have been made toward the self-assembly of perovskite NCs and understanding their coupled optical properties. Shape-controlled synthesis and their self-assembly into ordered superlattices has emerged as a powerful tool for tailoring the nanoscale optical properties. Such coupled optical and electronic properties can be utilized for the development of novel optoelectronic devices.

In this talk, I will present a one-pot shape-controlled synthesis of highly crystalline and monodisperse Cs\textsubscript{2}Pb\textsubscript{X} (X=Cl, Br and I) perovskite NCs of various morphologies such as nanocubes, nanoplates (NPls), nanowires (NWs) and nanorods (NRs) starting from their precursor powders. [2–5] The morphology of perovskite NCs can be controlled by means of simple chemistry such as Cs/Pb precursor ratios, reaction time and ligand concentration. We discovered that the perovskite NCs spontaneously self-assemble into nanowires through oriented-attachment or supercrystals (SCs) depending on the reaction conditions. The optical bandgap of the perovskite NCs as well as SCs can be controlled over the entire visible range by varying the halide (Cl, Br, and I) composition. Our work not only provides a facile method for the shape-control of monodisperse perovskite NCs and their self-assembly, but also expands our current understanding of the morphology-dependent optical properties, and open new avenues for the fabrication of highly ordered architectures using perovskite NC building blocks for future optical and optoelectronic devices.

Investigation and Application of Carboxylic Acid Functionalized Perovskite Surfaces 

Kenneth Zielinski; Worcester Polytechnic Institute, Worcester, Massachusetts, United States.

Methylammonium lead iodide perovskites can be functionalized by ammonium benzoic acids, yielding carboxylic acid groups capable of undergoing subsequent surface reactions. The ammonium salts of 4-aminobenzoic acid, 5-aminoisophthalic acid, and 3,3'-diaminobenzoic anhydride were synthesized and substituted onto the surface using previously explored techniques. The mechanism of substitution was elucidated via XPS. The molecular orientation was determined via infrared reflection absorption spectroscopy. The anhydride experiments were used specifically to examine the orientation due to the rigidity of the anhydride on the surface relative to the carboxylic acids in the other molecules. The carboxylic acids were also found to be useful chemical hooks in this system for atomic layer deposition and has been explored using organometallic reagents. This technique is a powerful tool, enabling an atom-
Organic–inorganic halide perovskite solar cells (PSCs) have drawn a great deal of attention in the photovoltaic research community due to their high efficiency over 22% and simple manufacturing process. A high quality perovskite film is critical to obtain PSCs with both superior performance and high reproducibility, especially when constructing large area polycrystalline films in ambient condition. Motivated by the common wisdom that thicker films are easier to process and therefore offer better controllability in large area production of optoelectronics device when compared with thinner ones. Here, we employ a simple perovskite functionalization process to fabricate perovskite films with thickness over 1 μm in ambient condition. By careful control of the perovskite component and formation process, the resultant perovskite films exhibit full coverage and excellent crystallinity with low surface roughness and low thickness variation. The high quality of the films is further evidenced by significantly enhanced photoluminescence lifetime, slower charge recombination constant, much lower intrinsic trap density, higher conductivity and much longer carrier diffusion length to achieve the balance of device efficiency and film thickness. These results suggest that we obtain high quality thick perovskite thin films with this simple method. Our resultant mesoscopic PSCs with active area of 0.1 cm² achieve an average power conversion efficiency (PCE) of 19.1% (with small PCE standard deviation) and a stabilized efficiency approaching 19%. Moreover, our 5 cm × 5 cm PSC module device with active size of 12 cm² also deliver a PCE of 15.3%, strongly suggesting that our method is compatible with further upscaling. In addition, the resultant un-encapsulated small size PSCs exhibit an excellent T80 lifetime exceeding 1600 h under continuous light illumination with maximum power point tracking in dry N₂ environment.

Highly Emitting Blue Inorganic Halide Perovskite Quantum Dots and Nanocrystals

Jianjun Tian; University of Science and Technology Beijing, Beijing, China.

All-inorganic perovskite cesium lead halide quantum dots (QDs) have been widely investigated as promising materials for optoelectronic application, because of its outstanding photoluminescence (PL) properties and benefits from quantum effects. Although QDs with full-spectra visible emission have been synthesized for years, the PL quantum yield (PLQY) of pure blue emitting QDs still stays at low level in contrast to their green or red emitting counterparts. Herein, we obtained core-shell structured cubic CsPbBr3@amorphous CsPbBr3 (A-CsPbBr3) perovskite QDs via a facile hot injection method and centrifugation process. The core/shell structure QDs showed a record pure blue emission PLQY of 84%, which is much higher than that of blue emitting cubic CsPbBr3 QDs and CsPbBrxCl3−x QDs. Furthermore, a blue emitting QDs-assisted-LED with bright pure blue emission was prepared and illustrated the core-shell QDs’ promising prospect in optoelectrical application. Recently, another work shows the transformation of the crystal structure and remarkably high crystallinity of the γ-crystals, leading to the record blue PLQY of 91% at 480 nm.

Spontaneous Iodide Loss from 2D Perovskite Single Crystals N-Dopes 2D Perovskites

Lianfeng Zhu1, He Tian2, Scott Silver1, Antoine Kahn1, Tian-Ling Ren1 and Barry P. Rand2; 1Princeton University, Princeton, New Jersey, United States; 2Tsinghua University, Beijing, China.

Despite the demonstrated high efficiency of perovskite solar cells and light emitting devices, the understanding of the intrinsic stability of perovskites is far from complete. In this work, using an ultra-sensitive, exfoliated 2D perovskite single-crystal sheet/graphene heterostructure device, we reveal spontaneous iodide loss as an important degradation pathway of 2D perovskite single crystals, which acts as a donor and n-dopes the 2D perovskite semiconductor, generating positively charged iodide vacancies.

Origin of Green-Light Emission of the Zero-Dimensional Bromide Perovskite CsPbBr3

Young-Kwang Jung1, Ji-Sang Park2 and Aron Walsh1, 5; 1Yonsei University, Seoul, Korea (the Republic of); 5Imperial College London, London, United Kingdom.

Halide perovskite families have been widely studied for photovoltaics [1-2] due to their unique opto-electronic properties, but recently, they are being studied for light-emitting applications [3]. Beyond regular perovskites based on a corner-sharing octahedral network, CsPbBr3, which is called as zero-dimensional perovskite, is getting attention because of its highly-efficient green light luminescence [4]. The reported band gap of CsPbBr3 of 3.9 eV is in the ultraviolet (UV) region, thus green light emission in this material cannot be due to its intrinsic band gap. The origin of the green light emission has not clarified and two hypotheses have been suggested to explain this phenomenon: (i) CsPbBr3 phase impurities within the material and (ii) luminescent defect states within the band gap of CsPbBr3. We investigate the chemical and physical properties of the CsPbBr3 based on first-principles simulations, including a thorough analysis within the modern theory of defect formation [5], from which we predict the origin of the green light emission.

Resonantly Generating Multiple Excitons with Multiple Below-Band-Gap Photons in Metal Halide Perovskite Nanocrystals

Aurora Manzi, Yu Tong, Julius Feucht, En-Ping Yao, Lakshminarayana Polavarapu, Alexander S. Urban and Jochen Feldmann; LMU Munich, Munich, Germany.

Multiple exciton generation (MEG) is a process that addresses the conversion of highly energetic photons by using their excess energy to promote additional electrons to the conduction band. However, this process requires that the energy of the exciting photon is at least twice the band-gap of the semiconductor, which is hardly achievable with visible light. In our studies we have shown that it is possible to use multiple low-energy photons to efficiently generate multiple excitons in metal halide perovskite nanocrystals. Additionally, high-order absorption processes, deviating from the expected two-photon absorption, can be observed at very specific energetic positions. We could associate these specific energies to multiples of the semiconductor band-gap energy. In such a way, we have developed a method by means of which we were able to describe this effect as a resonance behaviour between multi-photon absorption (MPA) and MEG, which has never been seen before.

Interestingly, the resonance effect between MPA and MEG could only be observed once the perovskites were assembled in an orderly fashion, forming supercrystals. This phenomenon can be attributed to the electronic coupling given by the close-packed arrangement of the individual nanocrystals that reduces the incidence of Auger recombination, which represents the main opponent of the survival of multiple excitons. When the supercrystal geometry is kept, the chemical composition of the perovskites can be varied to tune the energetic position of the MPA-MEG resonances. We have in fact demonstrated that the same effect can be obtained for different halides (X) in CsPbX3 perovskites.
Currently lead based all-inorganic cesium lead halide perovskite nanocrystals (NCs), have been shown great potential for high-performance light-emitting diodes (LEDs) and solar cells owing to their excellent optical properties and inexpensive synthesis process. Here, we successfully doped heterovalent Bi\(^{3+}\) ion into the lattices of CsPbBr\(_3\) perovskite NCs through a hot-injection method. The Bi\(^{3+}\) cation has been chosen as the dopant by reason of its similar ionic radius to preserve the integrity of perovskite structure. We achieved maximum 6.93% Bi doping which is considerably higher as compared to those achieved in previous reports via hot injection method.

It was found that by increasing the Bi\(^{3+}\) ion concentration, the morphology of CsPbBr\(_3\) NCs changed from cubic to hexagonal and precisely tune the band structure and photoluminescence (PL) of host CsPbBr\(_3\) NCs by inducing the trap states within the band gap. Time-resolved photoluminescence (TRPL) spectroscopy revealed that Bi\(^{3+}\) ion doping significantly enhance the lifetime of charge carriers. This work indicates that Bi doped CsPbBr\(_3\) NCs occurs better optical properties than pure CsPbBr\(_3\) NCs and can be a promising material for high-performance perovskite LEDs.

Understanding the Roles and Developing Strategies to Overcome Shallow Defect Levels in Cesium Lead Halide Colloidal Nanocrystals Brent A. Koscher\(^{1,2}\), Joseph Swabek\(^{1,2}\) and A. P. Alivisatos\(^{1,2}\); \(^{1}\)University of California, Berkeley, Berkeley, California, United States; \(^{2}\)Materials Science, Lawrence Berkeley National Laboratory, Berkeley, California, United States.

An intellectual explosion in the ever-expanding world of nanoscience has led to the development of facile synthetic protocols for a high level of material control at the nanoscale. The culmination of several decades of research has led to the ability to routinely synthesize specific types of cadmium chalcogenide quantum dots with quantum efficiency exceeding 95%. However, enabled by a facile synthesis and driven forward by excellent optoelectronic properties, the all-inorganic perovskite quantum dots (CsPbX\(_3\); X = Cl, Br, I) have attracted considerable attention among academic researchers for a relatively nascent field. This is a material that performs with up to 90% photoluminescent quantum yield following the synthesis, quite encouraging, but accessing materials with the highest possible quality is crucial to fully realize the potential of the material. This leads to the interesting question: What prevents the quantum efficiency from truly being unity? The same property that enables easy access of the material, namely a low temperature synthesis, also opens the door for a number of very real problems. While it is generally accepted that the lead halide perovskites are positioned with an unusually high defect tolerance, they are not defect impervious, and are particularly susceptible to the pernicious shallow electronic states that result from the lead-rich synthetic conditions and labile surface halides. We have been working to carefully understand the role that the lead-rich surface conditions of CsPbX\(_3\) quantum dots have on the optoelectronic properties of the material, conditions that result in multi-exponential excited state lifetimes and sub-optimal quantum efficiencies. Through careful manipulation of the surface structure we are able to alleviate the deleterious lead-rich surface, changing the hard to describe multi-exponential excited state lifetimes to single-exponential lifetimes typical of two-level systems, an unusual property for a nanocrystal ensemble. For example, through our studies we have found that no more than 50 extra surface leads are responsible for reducing the photoluminescence quantum yield of a CsPbBr\(_3\) nanoparticle to 85%, these lead atoms represent a small but detrimental population of surface lead atoms. A careful manipulation and removal of harmful atoms while maintaining the integrity of the nanoparticle as a whole is crucial in being able to access the highest quality nanomaterials. To this end, tailoring approaches to manage atoms in specific locations or with specific energies is necessary to continue to improve material performance and understand how to best utilize the materials moving forward.

Highly Luminescent Phase-Stable CsPbI\(_3\) Perovskite Quantum Dots Achieving Near 100% Absolute Photoluminescence Quantum Yield Feng Liu\(^{1}\), Yaohong Zhang\(^{1}\), Chao Ding\(^{1}\), Taro Toyoda\(^{1}\), Shuzi Hayase\(^{2}\) and Qing Shen\(^{1}\); \(^{1}\)The University of Electro-Communications, Tokyo, Japan; \(^{2}\)Kyushu Institute of Technology, Tokyo, Japan.

Perovskite quantum dots (QDs) as a new type of colloidal nanocrystals have gained significant attention for both fundamental research and commercial applications owing to their appealing optoelectronic properties and excellent chemical processability. For their wide range of potential applications, synthesizing colloidal QDs with high crystal quality is of crucial importance. However, like most common QD systems, those reported perovskite QDs still suffer from a certain density of trapping defects, giving rise to detrimental non-radiative recombination centers and thus quenching luminescence. In this work, we developed a trioctylphosphine (TOP)-based route which yields phase-stable monodisperse CsPbI\(_3\) QDs with the best-so-far quantum efficiency up to 100%, signifying the achievement of almost complete elimination of the trapping defects. Ultrafast kinetic analysis with time-resolved transient absorption spectroscopy evidences the negligible electron or hole trapping pathways in our QDs, which explains such a high quantum efficiency. Solar cells based on these high-quality perovskite QDs exhibit power conversion efficiency of 9%, showing great promise for practical application.

Phosphine-Oxide Assisted Synthesis of Perovskite Nanoparticles—A Bridge Between Nano and Macro Syntheses Olivia J. Ashton\(^{1}\), Guilherme Almeida\(^{2}\), Luca Goldoni\(^{2}\), Quinten Akkerman\(^{2}\), Liberato Manna\(^{2}\) and Henry Snaith\(^{2}\); \(^{1}\)University of Oxford, Oxford, United Kingdom; \(^{2}\)Istituto Italiano di Tecnologia, Genoa, Italy.

The fabrication and growth of both thin films and single crystals of metal halide perovskites, are typically done using highly polar solvents such as dimethyl sulfoxide, dimethylformamide and gamma-butyrolactone. Notably, these solvents all contain the functional group R=O. Conversely, the synthesis of perovskite nanocrystals employs a combination of non-polar solvents, and weaker aliphatic amines and carboxylic acids, which act as the ligands. It is well known that the ammonium capped nanoparticles are inherently unstable due to the lability of the ligands, resulting in the formation of defects on the nanoparticle surface. To date, there have been few attempts to impart the know-how which has been developed in macro scale syntheses to nanoparticle syntheses.

Here, we explore the application of a phosphate oxide (R=P=O) to synthesise cesium lead bromide perovskite nanocrystals, replacing the labile amine ligand and mirroring the R=O group required in the macroscale synthesis. The synthetic route we present provides us with exceptionally high yields of very monodisperse particles, which are not highly emissive, but can also be synthesised in air, obviating the need for laborious solvent degassing, and complicated oxygen and moisture free techniques.

Through a comparison of both synthetic routes, we observe improved stability of the R=P=O nanocrystals to washing. Additionally, we are able to expand this synthetic protocol to a variety of other amions and cations, as well as being able to replace the carboxylic acid with either phosphonic or phosphinic acids, demonstrating the robustness and versatility of this technique. By using nuclear magnetic resonance and x-ray photoelectron spectroscopy we are able to investigate the surface of our nanoparticles and determine the cause of increased stability and show the importance of phosphate oxide in the synthesis of perovskite nanocrystals.

10:30 AM ET05.13.09
Exciton Dynamics in Quantum Confined CsPbBr3 Nanoplatelets Moritz Gramlich1, 2, Bernhard J. Bohn1, 2, Yu Tong1, 2, Lakshminarayana Polavarapu1, 2, Alexander S. Urban1, 2 and Jochen Feldmann1, 2; 1Chair for Photonics and Optoelectronics, Department of Physics and Center for NanoScience (CeNS), Ludwig-Maximilians-Universität München, Munich, Germany; 2Nanosystems Initiative Munich (NIM), Munich, Germany.

In contrast to bulk perovskite films, recent reports have shown that in perovskite nanocrystals the excitonic absorption onset and photoluminescence (PL) peak exhibit a blue shift due to quantum confinement when their size in at least one dimension approaches the exciton Bohr radius of the respective perovskite composition [1]. For decreasing thickness of organic-inorganic perovskite nanoplatelets – separated by centrationization – increasing exciton binding energies and decreasing PL decay times have been observed [2]. Recently, we have developed a new method which enables the direct synthesis of quantum-confined inorganic CsPbBr3 nanoplatelets of uniform thickness with an atomic layer precision. These nanoplatelets are characterized by a highly efficient light-emission in the blue spectral range. Here, transient absorption spectroscopy is applied to CsPbBr3 nanoplatelets of different thickness varying from two to six monolayers to gain additional insight into PL decay times on the dominant exciton dynamics in these systems. A special focus is put on the fast exciton-exciton annihilation process, which plays an increasingly important role for higher excitation powers.

Lead halide perovskites APbX3 [A = methylammonium (MA), formamidinium (FA), and Cs, X=I, Br, and Cl] has excellent properties suitable for optical devices. The halide perovskites have been extensively studied on single crystals and thin films. Moreover, the synthesis of high-quality nanocrystals has been developed in recent years [1]. Since excitons are strongly confined within nanocrystals, optical responses depends on the size of the nanocrystals. One advantage of nanocrystals is that a spatially confined exciton enhances the radiative recombination rate, and then nanocrystals exhibit high photoluminescence quantum yields (PLQYs) even at room temperature. On the contrary, such spatial confinement works negatively for multiple excitons leading to a decrease in PLQYs as the non-radiative Auger recombination rate of multiple excitons is enhanced [2, 3]. Therefore, it is necessary to elucidate the impact of spatial confinement on the radiative processes for nanocrystal device applications. In particular, size-dependent PL dynamics of nanocrystals should be elucidated.

In this study, we report on the size-dependent PL dynamics of perovskite nanocrystals revealed by single dot spectroscopy. The samples used in this study were two types of perovskite nanocrystals with different A site cations (FA/PbBr3 and Cs/PbBr3), which were prepared by hot injection method. Time-resolved and spectrally resolved PL measurements were performed for individual single nanocrystals. Single-dot spectroscopy enables us to analyze optical properties for each individual nanocrystal that cannot be obtained in ensemble nanocrystal measurements. From the obtained results, we clarified that those nanocrystals with larger absorption cross sections exhibit longer exciton lifetimes. Since this tendency was observed with both FA/PbBr3 and Cs/PbBr3 nanocrystals, it was suggested that spatial confinement is the dominant factor determining the exciton lifetime. Furthermore, since the trion (charged exciton) generation is a major factor lowering PLQYs, the size dependence of trion generation probability is analyzed from the proportion of on-state and off-state in PL blinking behavior. These nanocrystal size dependences of PL dynamics for excitons, trions and multiple excitons provide important insights for improving the performance of nanocrystal-based devices.

11:00 AM ET05.13.11 Contactless Measurements of Lattice and Photogenerated Charged Carrier Dynamics in Organic-Inorganic Hybrid Perovskite Single Crystals Jian Wang1, 2, Eideh Metahardin,2, Lakshmi N. Murthy1, Marissa N. Higgins1, Diego Barrera1, Trey Daunis1, Yangzi Zheng1, Anton Malko1, Fernando Ely4, Manuel Quevedo-Lopez1, Mark Lee1 and Julia W. Hsu1; 1Chair for Photonics and Optoelectronics, Department of Physics and Center for NanoScience (CeNS), Ludwig-Maximilians-Universität München, Munich, Germany; 2Materials Science and Engineering, The University of Texas at Dallas, Richardson, Texas, United States; 3Chemistry, University of Washington, Seattle, Washington, United States; 4Physics, The University of Texas at Dallas, Richardson, Texas, United States; 5Department of Chemical and Biological Engineering, University of Colorado Boulder, Boulder, Colorado, United States.

Hybrid organic-inorganic lead halide perovskites have revolutionized optoelectronic applications, including solar cells, light-emitting diodes, and photo/radiation detectors. Despite the rapid advances in applications, fundamental understanding of these remarkable materials has just begun. While most applications use thin films that contain multiple grains, high-quality single crystals that contain minimal defects are pertinent to understanding the fundamental properties, hence the limit of attainable optoelectronic performance. However, depositing electrical contacts on fragile single crystals can often alter them, e.g. by inducing doping. Here we present two contactless techniques, far-infrared (FIR) reflectance and surface photovoltage (SPV) measurements, to probe lattice dynamics and photogenerated carrier dynamics, respectively, on high-quality methylammonium lead bromide (MAPbBr3) single crystals. FIR reflectance shows three coherent infrared-active phonon modes between 40 to 200 cm−1 that result in reststrahlen bands with much higher peak reflectance than has been previously reported for single crystal MAPbBr3. The phonon mode strength and damping are comparable to what is commonly observed in classical oxide perovskite single crystals, suggesting phonon coherency across macroscopic scale and that the crystal likely contains few grain boundaries or stacking faults. However, these crystals can still contain point defects, which contribute to SPV signals. By performing SPV measurements, to probe lattice dynamics and photogenerated carrier dynamics, respectively, on high-quality methylammonium lead bromide (MAPbBr3) single crystals.

11:15 AM ET05.13.12 Tetragonal to Cubic Phase Transition in FAx-CsPb(1-x)Br3—Temperature Dependence and Impact on Band Gap Julien Barrier1, Aryeh Gold-Park1, 2, Elin Wolf1, Rachel E. Beal1, 2, Michael D. McGeehe and Michael F. Toney1; 1SSRL. Materials Science Division, SLAC National Accelerator Laboratory, Menlo Park, California, United States; 2Department of Chemistry, Stanford University, Stanford, California, United States; 3Department of Applied Physics, Stanford University, Stanford, California, United States; 4Department of Materials Science and Engineering, Stanford University, Stanford, California, United States; 5Department of Chemical and Biological Engineering, University of Colorado Boulder, Boulder, Colorado, United States.
In the pursuit of efficient tandem solar cells, high band-gap photovoltaic absorbers are required for top cells. Hybrid perovskites are promising candidates, as their band gaps can be widely tuned via compositional adjustments. Specifically, perovskites of the form FA$_{1-x}$Cs$_x$Pb(I$_{1-y}$Br$_y$)$_3$ have shown high device efficiencies as well as high band gaps suitable for tandem applications [1]. In this family of perovskites, we have observed a tetragonal-cubic phase transition that is coincident with a change in the temperature coefficient of the band gap and also occurs within solar cell operating temperatures. It has been suggested [2] that the phase transition may impact light induced phase segregation, which has been identified as a major concern that lowers operating voltages in mixed cation perovskite solar cells [1]. Thus, it is key to understand the phase behavior of this family of perovskites, as well as the impact of structural changes on electronic properties.

We explore here a wide compositional space of FA$_{1-x}$Cs$_x$Pb(I$_{1-y}$Br$_y$)$_3$ thin films with temperature-dependent synchrotron X-ray diffraction. At room temperature, many of these compositions exhibit tetragonal peaks that we have indexed to the P4/mmb space group, corresponding to concerted octahedral tilting about the c axis of the perovskite crystal structure. This is distinct from tetragonal MAPbI$_3$, which has alternating tilt directions about the c axis corresponding to the I4/mcm space group. We compute the structure factors of a number of Bragg peaks that allow us to model the average octahedral tilt angle as a function of the temperature. Within the FA$_{1-x}$Cs$_x$Pb(I$_{1-y}$Br$_y$)$_3$ family, we show how varying the composition affects the phase transition temperature and we present a room temperature phase diagram. Additionally, we show that the temperature coefficient of the band gap presents a discontinuity at the phase transition temperature. This effect is related to band gap tuning observed in mixed Pb/Sn perovskites, which share the same tetragonal space group [3]. This work establishes a phase diagram that may help interpret photostability and will enable better prediction of band gaps in this family of hybrid perovskites.

Phase Transition and Anion Exchange in Lead Halide Perovskites
Minliang Lai$^1$ and Peidong Yang$^{1,2}$; $^1$Department of Chemistry, University of California, Berkeley, Berkeley, California, United States; $^2$Division of Materials Sciences, Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Lead-halide perovskites are a family of semiconductor materials with excellent optoelectronic properties ideally suited for next-generation photovoltaic and light-emitting applications. Particularly, inorganic perovskites CsPbX$_3$ are drawing increasing research interests because of their better stability. There are rich structural phase transitions in the inorganic perovskites owing to their soft and dynamical ionic lattice. However, the fundamental understandings of intrinsic phase transition mechanism are still elusive. In this talk, I will focus on the systematical study of the phase transition between a non-perovskite and a perovskite phase using single-crystal CsPbX$_3$ nanowires platform. The non-perovskite phase with a large bandgap and poor photoactivity can be thermal-driven transformed to a meta-stable perovskite phase with a decreasing bandgap and excellent optoelectronic properties. Moisture introduces vacancy in the crystal lattice and lowers the kinetic barrier from perovskite phase to non-perovskite phase. We further realize robust thermochromic solar cells for smart photovoltaic window applications via stable, controllable and reversible phase transition. Another feature of the soft ionic lattice is facile ion migration. Anion exchange chemistry was demonstrated in CsPbX$_3$ nanostructures with high PLOY throughout the exchange reaction. Via developing a novel localized anion exchange, we demonstrate spatially resolved multi-color CsPbX$_3$ nanowire heterojunctions. These perovskite heterojunctions show tunable photoluminescence over the entire visible spectrum with high resolution down to 500 nm, which represent key building blocks for high-resolution displays. Moreover, the intrinsic solid-solid anion exchange dynamics can be resolved in these perovskite hetero-junction nanowires through non-destructive optical methods. These fundamental understanding can offer guidelines for engineering the perovskite materials with novel functional devices.

Kovalenko$^{2,1}$ and Ivan Infante$^6$; $^1$Empa-Swiss Federal Laboratories for Materials Science and Technology, Dübendorf, Switzerland; $^2$ETH Zürich, Zürich, Switzerland; $^3$Vrije Universiteit Amsterdam, Amsterdam, Netherlands.

Colloidal lead halide perovskite nanocrystals (NCs) have recently emerged as versatile photonic sources. Their processing and luminescent properties are largely governed by the lability of their surface structure, that is the surface regions of the NC core and ligand shell. In this study and using CsPbBr$_3$ NCs as a model system,[1] we model the nanocrystal surface structure and its effect on the emergence of the trap states using density functional theory. We then rationalize the typically observed effects of the surface treatment and aging on the luminescent characteristics. We illustrate and discuss the utility of common elemental analysis methods, namely inductively-coupled plasma – optical emission spectrometry and X-ray photoelectron spectroscopy, for rationalize the typically observed effects of the surface treatment and aging on the luminescent characteristics. We illustrate and discuss the utility of common elemental analysis methods, namely inductively-coupled plasma – optical emission spectrometry and X-ray photoelectron spectroscopy, for elucidating the chemical changes induced by surface treatments. We propose a strategy for healing the surface trapping states and for improving the colloidal stability by the combined treatment with didodecyldimethyl ammonium bromide and lead bromide and validate this approach experimentally. This simple procedure results in robust colloids, which are highly efficient and exhibit high photoluminescence quantum yields of up to 95-100%.

Schaller; 1Center for Nanoscale Materials, Argonne National Laboratory, Lemont, Illinois, United States; 2Department of Chemistry, Northwestern Illinois University and Illinois IHMC Materials Research Center, Northwestern University, Evanston, Illinois, United States; 3Department of Chemistry and Biochemistry, Northern Illinois University, DeKalb, Illinois, United States; 4Applied Physics Program, Northwestern University, Evanston, Illinois, United States; 5Department of Physics and Astronomy, Northwestern University, Evanston, Illinois, United States; 6Department of Materials Science and Engineering, Northwestern University, Evanston, Illinois, United States; 7Flexterra Corporation, Skokie, Illinois, United States.

The recently re-emerged two-dimensional organic-inorganic hybrid perovskites (2DHFs) are solution processable semiconductors exhibiting strong quantum and dielectric confinement effects, as well as excellent luminescence properties. However, even some of the most fundamental optical properties, especially the complex refractive index (RI), currently are unknown for 2DHF single crystals. As for any optoelectronic materials, refractive index is crucially important since: 1) The real part (n) encodes the phase velocity of light, which, e.g., underpins the resonant condition of a laser cavity, and 2) the imaginary part (k) dictates absorption, which is key for optimizing the thickness of a solar cell. Herein, using a newly-developed dielectric-coating based technique, we determine the complex, anisotropic RI for 2DHF single crystals with various perovskite-layer thicknesses and different types of organic spacers. We found 2DHFs that are only one or two perovskite layers in thickness exhibit negative permittivity due to strong in-plane exciton resonances, but positive permittivity owing to substantially weaker out-of-plane exciton resonances. The extreme excitonic anisotropy in the periodic 2DHFs leads to a natural hyperbolic dispersion in the visible range, which has been previously achieved only with artificial metamaterials. Our observation opens new possibilities in enhanced emission & absorption properties, non-linear optics, and enhanced light-matter interactions.

 Templating Hybrid Perovskite Growth for Highly Efficient Light-Emitting and Photovoltaic Devices

 Silvia Colella, Antonella Giuri, Carola Corcione, Aurora Rizzo, Feng Gao, Michele Saba, Giovanni Bongiovanni, Jianpu Wang and Andrea Listorti; 1CNR-NANOTEC, Lecce, Italy; 2Università del Salento, Lecce, Italy; 3Linköping University, Linköping, Sweden; 4Università di Cagliari, Cagliari, Italy; 5Nanjing Tech University, Nanjing, China.

 Hybrid halide perovskites, extensively used in the field of optoelectronics, are a class of materials extremely promising for their excellent properties combined with the mild synthetic protocols. Mainly used in solar cells and light emitting diodes, perovskites are formed from solution by self-assembly of precursors. The resulting soft material is often unable to express its ideal potential, due to unsuitable morphology or elevated density of electronic defects as a consequence of the low-temperature processing. Based on our previous findings on the interaction between perovskite precursors and additives, here we explore the use of a tailored biopolymer, starch, as templating agent for the growth of formamidinium (FA)- and methylammonium (MA)-based tri-iodide perovskite films. The presence of the macromolecule brings the enormous technological advantage of allowing the deposition of the perovskite layer with a one-step method, avoiding solvent dripping or two-steps method. Furthermore, it allows a fine tuning of the solution viscosity (making the solution suitable for different area deposition techniques), of the perovskite grain size and of the layer thickness, by simply adjusting the polymer:perovskite relative concentration. Our approach was validated by outstanding performances in both light emitting (LED) and photovoltaic (PV) devices with outstanding results. We obtained an inverter, planar, mild temperature processed solar cell with a 17% efficiency and a LED characterized by an EQE of ~5% and, most important, among the highest reported radiances for NIR PLEDs. (i.e. 206.7 W/sr*m² obtained at very high currents; about 1000 mA/cm²). The micro and nano-structural changes and their influence on optoelectronic properties were studied as a function of starch concentration, confirming that the device performances are strongly related to the perovskite film structure. The overall picture that emerged is that the presence of starch influences i) the interface properties within the device stack, ii) the crystallographic scenario of the active material, iii) the dielectric landscape surrounding the perovskite crystals, allowing, for the LED device, a minimization of Auger losses at high current regimes and for an overall enhancement of the perovskite light emission and the device capability in sustaining high carriers densities.

 2D Homologous Organic-Inorganic Hybrid Ruddlesden Popper Perovskite Single Crystals Lasers with Low Thresholds

 Tzu-Pei Chen, Shao-Sain Li, Chinnamonba Murugesan Raghavan, Chia-Chun Chen, Yu-Ming Chang and Chun-Wei Chen; 1Department of Materials Science and Engineering, National Taiwan University, Taipei, Taiwan; 2Nanotechnology Program, Taiwan International Graduate Program, Academia Sinica and National Taiwan University, Taipei, Taiwan; 3Department of Physics, National Taiwan University, Taipei, Taiwan; 4Graduate Institute of Biomedical Optomechantronics, Taipei Medical University, Taipei, Taiwan; 5Center for Condensed Matter Sciences, National Taiwan University, Taipei, Taiwan; 6Center of Atomic Initiative for New Materials (AI-MAT), National Taiwan University, Taipei, Taiwan; 7Taiwan Consortium of Emergent Crystalline Materials (TCECM), Ministry of Science and Technology, Kaohsiung, Taiwan; 8Department of Chemistry, National Taiwan Normal University, Taipei, Taiwan.

 Two dimensional Ruddlesden-Popper perovskite (2D RPP) plays a key role in the current widespread investigations into the potential uses in optoelectronics because of the quantum well superlatice-like structure. This unique structure makes 2D RPP have higher moisture stability, and stronger exciton binding energy than 3D perovskite. However, the complexity in the wet-chemical processes make the synthesis of high purity homologous 2D perovskites still a big issue. In addition, the fundamental mechanism of the molecular origin of the phase transition and unusual blueshift of the emission in 2D RPP with different layered perovskite compounds is still lacking. In this direction, we grew a high purity millimeter-sized single crystal 2D RPP (BA$_2$MA$_2$Pb$_{5}$Br$_{19}$, and BA$_2$MA$_3$Pb$_{10}$Br$_{27}$, n=1, 2, 3) which cover whole visible light range by using slow evaporation at a constant-temperature (SECT) solution growth. Via the XRD, spectral mapping, and fluorescence lifetime mapping measurements, the large sized 2D RPP crystals show well crystallinity and highly phase purity. Furthermore, due to the pyramid step-like structure, we obtain cavity-free lasing behavior with around 3.7 uJ/cm² low threshold from these homologous large sized crystals. Also, with high phase pure crystals, we can identify the carrier dynamics before and after phase transition directly without defect state induced effect. Our result demonstrates that solution growth homologous organic-inorganic hybrid 2D perovskite single crystals open up a new window as a promising candidate for optoelectronic devices. (This work has been published in Nano Lett. 2018, 18, 3221–3228)

 Hybrid Perovskite Heterostructures for Efficient LEDs—Luminescence Performance, Carrier Kinetics and Optical Modeling

 Dawei Di, Baodan Zhao, Neil C. Greenham and Richard H. Friend; University of Cambridge, Cambridge, United Kingdom.
Perovskite-based optoelectronic devices have gained significant attention due to their remarkable performance and low processing cost, particularly for solar cells. However, for perovskite light-emitting diodes (LEDs), non-radiative charge carrier recombination has limited electroluminescence (EL) efficiency. Here we demonstrate perovskite-polymer bulk heterostructure LEDs exhibiting record-high external quantum efficiencies (EQEs) exceeding 20%, comparable with the best solution-processed OLEDs and quantum-dot LEDs. This performance is achieved with an emissive layer comprising quasi-2D and 3D perovskites and an insulating polymer.

Transient optical spectroscopy reveals that photogenerated excitations at the quasi-2D perovskite component migrate to lower-energy sites within 1 ps. The dominant component of the photoluminescence (PL) is primarily bimolecular and is characteristic of the 3D regions. From the near-unity PL quantum efficiencies and transient kinetics of the emissive layer with/without charge-transport contacts, we find non-radiative recombination pathways to be effectively eliminated. Light outcoupling from planar LEDs, as used in OLED displays, generally limits EQE to 20-30%, and we model our reported EL efficiency of over 20% in the forward direction to indicate the internal quantum efficiency (IQE) to be close to 100%. Together with the low drive voltages needed to achieve useful photon fluxes (2-3 V for 0.1-1 mA/cm²), these results establish that perovskite-based LEDs have significant potential for light-emission applications. In general, the ideal luminescence performance we observed is of critical importance for realizing perovskite optoelectronics operating near the radiative limits.

We also present some related results from our group and collaborating groups, on luminescent perovskites for LEDs and photovoltaics.

The Application of 2D Materials in Perovskite Solar Cells
Peng You and Peng Yan; Hong Kong Polytechnic University, Hong Kong, China.

We report a cost-effect approach for improving the performance of perovskite solar cells by using novel high-mobility 2-dimensional materials. The efficiency of perovskite solar cells can be substantially increased when 2-dimensional material flakes are coated on the perovskite grain boundaries. The flakes can conduct hole currents efficiently from grain boundaries to hole transport layers in the devices and lead to efficiency enhancements that increase with increasing hole mobilities of the flakes. The results indicate that perovskite grain boundaries are electrically benign and even favorable for photovoltaic performance if accumulated charges around them are conducted out by high mobility hole transport materials.

Photo-Induced Lattice Symmetry Improvement in Organic Lead Halide Perovskite and Its Beneficial Effect on Charge-Transfer Dynamics
Hui-Soon Kim and Anders Hagfeldt; Ecole Polytechnique Federale Lausanne, Lausanne, Switzerland.

The hybrid organic lead halide perovskites based on mixed-cations and -anions have been considered as an outstanding composition to achieve high efficiency with long-term stability of perovskite solar cells (PSCs). In this study, the effect of light on the crystal structure of perovskites employing triple cations and double halides was investigated and correlated to the charge-transfer properties. Under the continuous photon excitation, a gradual increase in photoluminescence was observed from the perovskite film, coupled with a minute red-shift. Furthermore, the continuous light soaking induced a gradual peak shift toward lower angle in the X-ray diffraction pattern of the perovskite, strongly suggesting a photo-induced structural response. Notably, a lattice expansion occurred in a certain preferred orientation, which exerted an influence on the crystal symmetry. The trap density of a complete PSC near maximum power point (mpp) was measured under continuous light, showing a gradual decrease. An increase in the photocurrent at mpp was readily observed due to this as a consequence of the reduced trap density. The beneficial charge-transfer properties of PSC under illumination were addressed by relating to the photo-induced structural response of the perovskite.

Porous Fractals of MAPbI3 Perovskite—Characterization of Crystal Grain Formation by Irreversible Diffusion-Limited Aggregation
Malin B. Johansson1, Ling Xie1, Jakob Thyrl2, Tomas Edvinsson1, Mats Göthelid2, Gunnar Niklasson1 and Gerrit Boschloo2; 1Uppsala Universitet, Uppsala, Sweden; 2KTH, Stockholm, Sweden.

Isopropanol solution based methylammonium lead triiodide (MAPbI3) is studied during the crystallization process. The crystal growth starts in an unstable suspension far from equilibrium by forming different dendritic patterns and terminates with aggregation of stable cubic crystalline grains into fractal clusters. Using transmission electron microscopy (TEM), the time evolution of a newly mixed suspension was studied over a period of two weeks at room temperature and a sequence of the morphological changes was observed. The crystallization process started with single dendritic growth exhibiting branches at 90 degrees angles to one another. After 4 hours, a multi-dendritic growth pattern and a transformation into small crystalline quantum dots were observed. After a week, clusters of crystal grains were formed into a fractal pattern and these patterns appear to be stable also during the second week. Electron and x-ray diffraction revealed the crystallinity of the quantum dots and the clusters of micrometer-sized crystals. Scanning transmission electron microscope (STEM) together with energy dispersive X-ray spectroscopy (EDS) showed that newly formed large grains, from a one hour old solution, displayed a core-shell structure with higher percentage of Pb atoms as compared to iodine at the surface. In, the inner core of the grains the percentage of iodine was slightly higher. The electron diffraction (ED) scan over the newly formed grains revealed a polycrystalline surface whereas the inner part had a single crystal pattern. The same solution, now one-week-old, contained grains with only single crystal patterns in the ED scan and showed no core-shell character or polycrystalline surface. The measured percentage of iodine atoms compared to lead was 2:1 throughout the cross section, which is a quantitative value within the measurement. It can be concluded from these measurements that the suspension approaches higher crystallinity of the perovskite grains in an irreversible process, where the perovskite grains are insoluble in isopropanol. The perovskite material has also been characterized with scanning electron microscopy (SEM) and photoluminescence (PL) mapping where both techniques showed a very porous crystalline material. The PL mapping revealed two peaks at 730 and 760 nm for a thin film spin coated from a newly mixed solution, while a film deposited from a one week old solution showed three peaks, the last one at 830 nm. Because of the high crystallinity, it is suggested that all three peaks are due to band-to-band transitions and not due to localized states. These data will be analyzed further; however, the results contain information of the content of quantum dots versus larger crystals, as well as displaying emission intensity variations at different positions of the grains. The purpose with this project is to understand these phenomena of crystalline growth. A new mesoporous perovskite material has been designed for optoelectronic purposes.

3:45 PM ET05.14.08
Energy Level Alignment at Halide Perovskite Interfaces
Philip Schulz; IPVF, Centre National de la Recherche Scientifique, Palaiseau, France.

The ongoing development of halide perovskite (HP) based optoelectronics has revealed that the numerous interfaces in the device play a crucial role for device functionality, efficiency and stability.1 Importantly, many critical material and interfacial properties are still poorly understood and difficult to assess, a deficiency that often limits efforts to improve the performance.1 We present our most recent results exploring the mechanisms by which organic
semiconductor films, transition metal oxides, and carbon nanotube (CNT) interlayers enable or suppress charge transfer to an adjacent HaP semiconductor film. We use photoemission, X-ray absorption, and transient optical spectroscopy to probe the energy level alignment and exchange of charge carriers between a set of various lead halide based perovskite films and different charge transport layers. Therein, we show that ground state charge transfer between perovskite and a CNT layer can lead to band bending in the transport layer beneficial for charge extraction. Hence, in one example an integrated thin CNT interlayer facilitates rapid charge carrier collection and improves the performance of respective solar cells. In contrast to this observation, band bending induced in the perovskite film by the charge transport material such as high work function oxides or interface defects induced by the oxide formation process can be detrimental for charge carrier collection and thus impede the functionality of respective devices. After examining the recent key developments in chemical and electronic structure characterization of HaPs, I will iterate the next steps towards interlayer tailoring and analysis.

4:00 PM ET05.14.09
Surface Molecular Doping of Metal Oxide Nanocrystals for Interface Engineering of Perovskite Solar Cells Zhaohui Hu1,2, Wei Chen1,2, Bao Tu1,2 and Yinghui Wu1,2; 1Materials Science and Engineering, Southern University of Science and Technology, Shenzhen, China; 2Shenzhen Key Laboratory of Full Spectral Solar Electricity Generation (FSSEG), Shenzhen, China.

As a stable and promising hole transport layer (HTL) of planar perovskite solar cells (PSCs), the conductivity of the intrinsic NiO synthesized by solution doping is nevertheless low and its hole mobility is also decreased by the nickel vacancies at deep gap states. In contrast to successful cesium or copper ionic doping in NiO nanocrystals, we applied a novel molecular doping concept into tuning the electronic structure of NiO HTLs by TCNO molecule series. The electron transfer from NiO nanocrystals to the F5TCNNQ molecules absorbed at their surface was observed and verified for the first time by electrostatic force microscopy and the first principle calculations, respectively. The band level offset at the interface of perovskite/NiO shrank from 0.18 to 0.04 eV, which boosted the conversion efficiency of the CsFAMA mixed cations PSCs approaching 21%. Surface molecular doping can not only applied successfully to NiO, but also SnO2, which is also a promising component to planar PSCs. That will be also discussed in this presentation. This methodology definitely paves a novel way to modulate the doping in hybrid electronics more than perovskite and organic solar cells.

4:15 PM ET05.14.10

Hybrid organic-inorganic perovskite thin films or crystals are usually prepared from the perovskite precursor solution. The crystallization of perovskite is affected by the supersaturation of the perovskite precursors in solution and the interfacial energy between the perovskite and solvent. Here, I will present some of our methods to prepare high-quality perovskite thin films and crystals by varying the interfacial energy between perovskite and solvent. The high-quality perovskite thin films lead to highly efficient perovskite solar cells.

4:30 PM ET05.14.11
Quantification of Self-Illumination in >90% Internal Photoluminescence Quantum Efficiency Hybrid Perovskites Roberto Brenes1, Madeleine R. Laiz1,2, Dané W. deQuellet1, Joel Jean1, Zahra Andaji-Garmaroud1, Samuel D. Stranks1 and Vladimir Bulovic1; 1RLE, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Cavendish Laboratory, University of Cambridge, Cambridge, United Kingdom.

Photon recycling is critical for achieving record-high open-circuit voltages (VOC) and power conversion efficiencies (PCE) in single-junction GaAs solar cells. This phenomenon can be observed only in materials with extraordinarily high photoluminescence quantum efficiency (PLQE) and small escape cones. Photon recycling has been observed in hybrid perovskite material qualities, photon recycling could produce practical gains in VOC and PCE. However, the achievable gains in today’s materials remain uncertain. Here we investigate photon recycling in the most emissive (>90% internal PLQE) perovskite films reported to date—humidity-passivated CH3NH3PbI3 and KI-passivated triple-cation perovskites (Cs0.8Na0.2FA0.75MA0.25PbI3) and CsFAMA. Using experimentally measured rate constants and material parameters, we develop a rigorous framework for quantifying (the extent of) photon recycling in thin-film samples and predicting the associated VOC and PCE gains. This analysis clarifies the opportunity for photon recycling to push the real-world performance of perovskite solar cells toward theoretical limits.

4:45 PM ET05.14.12
What Can Be Learned From Self-Healing in Halide Perovskites? Davide R. Cerati1, Yevgeny Rakita1, Llorenç Cremonesi2, Ron Tenne1, Vyacheslav Kalchenko1, Michael Elbaum1, Dan Oron1, Marco A. Potenza1, Gary Hodes1 and David Cahen1; 1Weizmann Institute of Science, Rehovot, Israel; 2Fisica, Universita’ di Milano, Milano, Italy.

Among the aspects of Halide Perovskites, HaPs, which make them such fascinating materials the different time-scales of the dynamics of interconnected processes stand out. Short-time behavior (< sec) is determined by electronic charge carrier dynamics, while longer time effects are typically due to atom/ ion dynamics, characteristic of halide perovskites, such as ion/defect movement, self-healing and others [1-3]. These slower processes are likely interdependent and hitherto not (well) elucidated, both as phenomena and in terms of effects on the performance of HaP-based devices. Our recent work [2] provides clear evidence for self-healing, i.e., under certain conditions damage in optical properties can be reversed and, in particular, the status quo ante [3] can be re-established completely or mostly, in several types of Br-based HaP single crystals, as measured by 2-photon confocal microscopy. We demonstrated qualitatively but unequivocally that the effect is an intrinsic property of the materials, as it was measured in the bulk of single crystals, with typical times of minutes to hours. Here we report on the products of decomposition and possible chemical pathways that can lead to self-healing, paying particular attention to the kinetics of the phenomena. We include new quantitative results of our experiments following the degradation/healing process kinetics in situ and of the energy-
dependent damage threshold. We also show results for the more intensely studied Methylammonium, MA-, and Formamidinium, FA-PbI$_3$. Furthermore, we measure, analyze and explain the crucial differences between the light-induced damaging and recovery mechanisms in the bulk and at the surface under different atmospheres (i.e. air, N$_2$, Br$_2$, I$_2$). Finally, we measure and analyze the temperature dependence of the healing process, as it provides information about the energy of formation of the material from their binary halide constituents. This follows and compares to the reported positive enthalpy of formation of the Br and I MAPb perovskites [4-5], viz. their entropic stabilization.

We will put our results in the broader perspective of other HaP physico-chemical properties and performances of HaP-based device characteristics.

TUTORIAL: The History of Li- and Li-Ion Batteries
November 25 - November 25, 2018

2018 marks the 200th anniversary of the report on discovery of Li element by August Arfwedsen (1818). This incident set off a chain of events that eventually led to the invention of Li-ion battery, which deeply penetrated our daily life: powering our portable electronics, vehicles and gradually becoming part of the smart grid. As a device that integrates many materials and chemistries that were synchronized to work precisely with each other like a timepiece, Li-ion batteries did not happen all at once. It took decades of research and development, assisted by knowledge gradually accumulated in surface chemistry, electrochemistry, materials science and engineering.

Looking back at the history of Li-ion batteries, we will benefit not only from the monumental technical achievement by those great minds in the field, but more importantly, examining the missteps occurred then from a modern perspective will teach us to understand and rethink what could have been done better to accelerate the development of the related technologies in the future.

The tutorial program is designed to consist of 2 segments.

1:30 PM
Lithium Based Anodes: A Look Back into the History
Martin Winter; Helmholtz-Institute Muenster, University of Muenster

The most severe challenge during the development of LIB came from the anode side. In this section Prof. Winter will examine the historical events that gradually shifts people away from Li-metal anode to a carbonaceous and intermetallic host, and how the tide turned again in 2010s, bringing us back to think about the Li metal anode.

3:00 PM BREAK

3:30 PM
Electrolytes and Interphases in LIB
Kang Xu; US Army Research Laboratory

This tutorial intends to give a comprehensive retrospect of how the electrolytes play the central role in bringing together these individual key components of LIB, and how interphases among them synchronize them to work together in a single electrochemical device.

SESSION ET06.01: General Introduction, Reliability and Safety
Session Chairs: Daiwon Choi and Joshua Lamb
Monday Morning, November 26, 2018
Hynes, Level 3, Room Ballroom A

8:30 AM *ET06.01.01
Materials for High Energy Li and Li-Ion Batteries M. Stanley Whittingham; State University of New York at Binghamton, Binghamton, New York, United States.

Over the last decade the energy density of lithium-based batteries has gradually increased, but commercially available cells have now topped out at around 200-250 Wh/kg at the cell level. I will describe several materials-centered approaches that will allow in excess of 300-350 Wh/kg and 700 Wh/l. First the carbon-based anode must be replaced by a higher capacity material, preferably lithium metal itself; we have found that tin-based anodes can achieve 50-100% greater capacity than carbons with coulombic efficiencies over 99.5%. Second on the cathode side, I will describe two options: two-electron systems using lithium, and high nickel NMCAs, both of which have theoretical energy densities of around 1 kWh/kg and have the capability of attaining 1 kWh/liter. The safety aspects will also be covered. This work is supported by US DOE, BES-EFRC and EERE-VTO-BMR.

9:00 AM *ET06.01.02
Reliability of Li-Ion Batteries for Grid Application Daiwon Choi, Alasdair J. Crawford, Vilayanur V. Viswanathan, David M. Reed and Vincent L. Sprinkle; Pacific Northwest National Laboratory, Richland, Washington, United States.

Li-ion batteries are expected to play a vital role in stabilizing the electrical grid as solar and wind generation capacity becomes increasingly integrated into the electric infrastructure. In this work, different commercial Li-ion batteries based on LiNi0.8Co0.15Al0.05O2 (NCA), LiNi0.5Mn0.5CoO2 (NMC) and LiFePO4 (LFP) cathode chemistries have been tested under the grid duty cycle protocols recently developed for frequency regulation (FR) and peak shaving (PS) with and without being subjected to electric vehicle (EV) drive cycles. The lifecycle comparison derived from capacity, round trip efficiency (RTE), resistance, charge/discharge energy and total utilized energy of the battery chemistries will be presented. Furthermore, degradation mechanisms of different battery chemistries will be discussed. The results can be used as a guideline for selection, deployment, operation and cost analyses of Li-ion batteries used for different applications.

9:30 AM BREAK

10:00 AM *ET06.01.03
Mechanisms and Ramification of Overcharge on Battery Materials Joshua Lamb, Loraine Torres-Castro, Mohan Karulkar and Jane Stanley; Sandia National Laboratories, Albuquerque, New Mexico, United States.

Overcharge testing has long been used as a standard abuse test evaluation for lithium ion batteries, which have notably poor tolerance for overcharge and overvoltage conditions. While this has historically been strictly an abuse test, large potential gradients created by high rate charge and discharge operations in electric vehicle and stationary storage applications may lead to areas of localized overcharge or overpotential on the electrodes. This work looks at high capacity (10 AH) prismatic pouch cells, applying overcharge from 105 – 200% total State of Charge (SOC), up to and including energetic thermal runaway of cells. The mechanisms of overcharge failure are investigated using electrochemical techniques including EIS and differential capacity measurements to evaluate the degradation and failure mechanisms that occur during the overcharge condition. This is supported with materials evaluations to further evaluate the impact of overcharge on the constituent materials.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy’s National Nuclear Security Administration under contract DE-NA0003525.
Multifunctional Lithium-Ion Exchanged Zeolite Coated Separator for Lithium-Ion Batteries

Jiagang Xu, Xingcheng Xiao, Sherman Zeng, Mei Cai and Mark Verbrugge; General Motors, Warren, Michigan, United States.

The skyrocketing price of cobalt pushes battery manufacturers to look back into low cost manganese containing positive electrodes. However, manganese dissolution has been considered as a critical problem for the majority of manganese containing positive electrodes. Although many efforts have been devoted to stabilizing the crystal structure and exploring new electrolyte additives, less progress has been reported so far. In this work, we have developed a novel multifunctional separator, targeting the root cause of manganese dissolution. A lithium-ion exchanged zeolite has been coated on polymer separator as the ceramic coating, which provides multi-functions to mitigate the issues arose from sequential scenario associated with manganese dissolution, including: 1. Trapping trace water: the high surface area in zeolite traps the trace water in the electrolyte, mitigating the hydrolysis of lithium salt and HF generation. 2. HF scavenger: in case of the HF already existing in the electrolyte, Al2O3 in the zeolite can preferentially react with HF as the scavenger due to the high surface area, therefore protecting the oxides in positive electrodes 3. Trapping Mn ions: in the worst scenario of Mn dissolved into electrolyte, the Li ion in zeolite will have the ion exchange with Mn ions in the electrolyte and trap Mn ions in the separator to avoid its damage to the SEI layer on anode side. In addition, lithium-ion exchanged zeolite separator can improve the wettability and thermal stability of the plain separator on which zeolite is coated. Based on this technology, we have demonstrated that Lithium-ion exchanged zeolite separator leads to the enhanced cycle performance (high capacity and Coulombic efficiency) of graphite/ (LiNi0.5Mn1.5O4+Li2MnO3) full cells at both room temperature and elevated temperature, comparing with the plain separator and commercial alumina coated separator. The coin cell with Li-zeolite coated separator exhibits an average Coulombic efficiency of 99.89% and achieves a capacity retention rate of 78.3% after 500 cycles at 25°C. We find out that a lower amount of manganese is present on the cycled graphite electrode when Li-zeolite coated separator is used, suggesting less side reactions resulted from Mn.

Novel Battery Separators Enabled by Ultrathin, Robust Solid Electrolytes

Shaofei Wang1, Andrew S. Westover2, Sergiy Kalnaus2, Andrew Kercher2, Nancy J. Dudney3, William C. West3 and Wyatt Tenhaeff4; 1University of Rochester, Rochester, New York, United States; 2Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 3NASA Jet Propulsion Laboratory, Pasadena, California, United States.

Solid electrolytes with low area specific resistance must be developed to enable high energy density lithium metal batteries. In addition to high ionic conductivities and large electrochemical stability windows, solid electrolytes also require robust mechanical properties to allow for large-scale production and successful integration into conventional lithium battery cell designs. To achieve these features, a novel solid electrolyte separator design was developed, in which a 50 - 100 nm fully dense solid electrolyte layer was coated onto microporous Celgard separators. The supporting Celgard made the solid electrolyte more robust and flexible, which enabled integration into coin cells. Due to its thinness, the resistance of the solid electrolyte layer was 5 - 10 Ω-cm². The solid electrolyte also showed low interfacial resistance with liquid electrolyte. The total resistance of solid electrolyte-Celgard membrane was determined to be 40 Ω-cm² in alkyl carbonate electrolytes, which is much lower than Garnet and Ohara solid electrolytes. The solid electrolyte membrane also was also shown to inhibit the crossover between anode and cathode in Li-S cells. The solid electrolyte membranes showed high coulombic efficiency and stable cycling performance. The advent of the new solid electrolyte paves the way for the commercialization of high energy density lithium metal batteries.

This work was supported by the ARPA-E IONICS program, U.S. Department of Energy, award DE-AR0000775.

Long-Term Calendar Degradation in Li-Ion Batteries

Aziz Abdellahi, Berislav Blizanac and Brian Sisk; A123 Systems LLC, Waltham, Massachusetts, United States.

With the increased penetration of electrified vehicles in the automotive market, requirements pertaining to battery durability are becoming increasingly stringent. To meet the requirements of the automotive industry, lithium-ion batteries must exhibit extensive life before reaching a terminal state of capacity loss and impedance growth. For battery designers and manufacturers, it is therefore of paramount importance to understand and predict long-term battery cell degradation based on a necessarily limited set of accelerated degradation tests.

Long-term calendar aging, defined as the temperature-induced cell degradation in the absence of current, is especially difficult to predict at relevant battery operating temperatures (25°C – 45°C). Unlike cycling tests, which can be rapidly conducted to the end-of-life by removing rest periods between cycles, calendar tests cannot be directly accelerated. To this end, a variety of empirical and physics-based models have been developed to predict the long-term storage behavior of battery packs based on a set of accelerated storage tests conducted at high temperatures. However, the validity of these calendar predictions has not, to the best of our knowledge, been extensively studied against actual long-term storage data surpassing the 4 year mark.

In this presentation, we present a set of long-term storage experiments performed over the course of 4- to 6- years on LiFePO4/graphite cells, at various states of charge and temperatures. Analysis of the storage data sheds light on the long-term degradation mechanism in the cell, and demonstrates a transition between a reaction-controlled to a diffusion-controlled growth of the anodic solid electrolyte interphase (SEI). The dependence of state of charge and temperature on the degradation rate is clarified, and the predictive performance of empirical calendar life models is assessed. This work provides a mechanistic analysis of the nature of long-term degradation mechanisms in Li-ion batteries and paves the way towards an improvement of the predictive ability of empirical calendar life models. The conclusions of this study can also serve to understand long-term calendar degradation in higher-voltage NMC/graphite batteries, in which both the anode and the cathode may experience calendar degradation at high states-of-charge.

Adaptive Current-Collectors for Safe High-Energy Rechargeable Batteries

High energy density rechargeable batteries are critical for the widespread adoption of EVs, however their high energy density leads to an inherent safety risk if an internal short circuit (ISC) forms and releases all the energy in the battery in seconds. When an ISC occurs – from dendrite formation, cell deformation/damage, or a manufacturing defect – the entire battery capacity rapidly discharges. This release of energy leads to extremely high temperatures near the short that can induce thermal runaway, cell rupture or venting, and fire. While the use of shutdown separators can help mitigate ISCs in smaller cells, they are often ineffective in the larger, high-energy batteries used in EVs and grid storage applications. Rather than relying on thermally-induced shutdown that may fail to shut down regions of the battery far from the ISC, it is preferable to directly detect and stop the internal current that flows during an ISC. In this presentation, I will introduce our work on adaptive current-collectors, which allow for direct control over the local current that flows between the current-collector and the active material by simple printed electronic circuits. I will show how the electrical properties of printed electronics

can be tuned to meet the demanding requirements of adaptive current-collectors, including low resistance during normal operating currents and high resistance under DC. Our simulations indicate that adaptive current-collectors can reduce the current flowing through ISCs by more than 90%, converting this catastrophic failure mode into a graceful one. In addition to enabling safe high-energy rechargeable batteries, the development of adaptive current-collectors will give battery users finer control over current flow at the sub-cell level, which is expected to improve battery reliability and rate capability.

SESSION ET06.02: All Solid-State Battery
Session Chairs: Xiaolin Li and Donghai Wang
Monday Afternoon, November 26, 2018
Hynes, Level 3, Room Ballroom A

1:30 PM ET06.02.01
All-Solid-State Lithium Metal Batteries Utilizing Polyrotaxanes as New Family of Solid Polymer Electrolytes
Laura Ihnhol1, Gunther Brunklaus1, Isidora Cekic-Laskovic1 and Martin Winter1, 2; 1Helmholtz Institute Münster HI MS, Forschungszentrum Juelich GmbH, Muenster, Germany; 2MEET Battery Research Center, University of Münster, Münster, Germany.

Lithium metal constitutes an attractive anode material mainly due to its high theoretical specific capacity of 3860 mAh g⁻¹, ten times higher than graphite (372 mAh g⁻¹). The use of lithium metal in rechargeable batteries with typical liquid organic solvent based electrolytes suffers so far from severe safety problems associated with the formation of high surface area metallic lithium (HSAL) upon repeated charge/discharge.[1] Solid polymer electrolytes (SPEs) designed to be compatible with lithium metal are able to mechanically suppress HSAL formation and are considered as viable alternative. Solvent-free SPEs exhibit advantages in terms of mechanical stability, operational safety and simplicity of cell design.[2] However, application of polymer electrolytes to all-solid-state lithium ion batteries (ASS-LIBs) and all-solid-state lithium ion batteries (ASS-LMBs), requires improvements in respect to lithium ion conductivity, especially at ambient temperature. Although high ionic conductivities can be achieved by high chain mobility linked to low molecular weight polymers, they are mostly too soft and therefore cause deterioration in mechanical stability of the SPE. In order to use low molecular weight polymers for fast lithium ion transport with sufficient mechanical strength at the same time, one strategy is related to utilization of a hyperbranched co-polymer where one segment represents a stable, hard backbone while the second segment is derived from a soft polymer with high ionic conductivities.[3] With this in line, a new generation of Li⁺-conducting SPEs obtained from supramolecular self-assembly of PEO, cyclodextrin (CD) and lithium salt was designed and thoroughly investigated for application in lithium metal batteries (LMBs) and LIBs. When mixing an aqueous solution of PEO together with an aqueous solution of CD, a precipitate forms where the CD is threaded onto a PEO chain.[4] The channel-type structure formed by self-assembly of PEO and CD can be used as the backbone structure whereas the hydroxyl groups of CD rings can be modified. Here, we use the ability of CD being the initiator for ring-opening polymerization of cyclic carbonates. This strategy enables synthesis of grafted polycarbonate side chains with low molecular weight. The obtained inclusion complexes show impressive ionic conductivity up to 1 mS cm⁻¹ at 60 °C, together with high oxidative stability and allow for application in LFP/Li cells at 40 °C for more than 200 charge/discharge cycles. Post mortem XPS and SEM studies confirm that the polymer/LiTFSI penetrates the cathode upon cycling, facilitating improved contacts. This new system provides a platform for further modifications of the polymer side-chains.

2:00 PM ET06.02.02
First-Principles Modeling of Polymer Electrolyte/Lithium-Metal Interfaces for High Energy Batteries
Maha Ebadi2, Cleber Marchiori1, Daniel Brandell2 and Movses Arujo1; 1Department of Physics and Astronomy, Uppsala University, Uppsala, Sweden; 2Department of Chemistry, Uppsala University, Uppsala, Sweden.

Lithium metal combines the lowest reduction potential in the electrochemical reactivity series with a high theoretical specific capacity, and using metallic Li as anode would therefore significantly improve the energy density of the Li-battery. There exist, however, some challenges in the application of the Li metal electrode, such as safety risks and low coulombic efficiency [1]. In recent years, there has been a growing interest to find more stable electrolytes when in contact with the reactive Li electrode in Li-metal batteries. It has in this context been found that solid polymer electrolytes (SPEs), formed by doping a polymer with a lithium salt, are promising candidates, which can provide both high mechanical stability and better battery safety [2,3]. The major disadvantage of SPEs – their low inherent ion conductivity – can be resolved by a somewhat higher operational temperature. We have, in a number of studies [4-6], modelled the Li metal/electrolyte interface using different simulation techniques. In this current study, we apply computational materials modelling to investigate the interface between the ion-conductive polymeric systems and Li metal surfaces by first principle calculations. To this end, Density Functional Theory (DFT) have been used to study several potential SPE host polymers such as poly(trimethylene carbonate) (PTMC), poly(vinyl alcohol) (PVA) and polycaprolactone (PCL), in order to get insights into their electronic structures and their stability when in contact with the Li metal surface. Using this knowledge, conclusions are drawn on which ion-conductive polymers are stable at the Li-metal surface, and which can adhere well to it.

Stabilizing Polymer Electrolytes in High-Voltage Lithium Batteries
Snehashis Choudhury and Lynden Archer; Cornell University, Ithaca, New York, United States.

More than forty years after the first report of a rechargeable lithium battery, electrochemical cells that utilize metallic lithium anodes are again under active study for their potential to provide more energy dense storage in batteries. Electrolytes based on small-molecule ethers and their polymeric counterparts are known to form stable interfaces with alkali metal electrodes and for this reason are among the most promising choices for rechargeable lithium batteries.
Uncontrolled anionic polymerization of the electrolyte at the low anode potentials and oxidative degradation at the working potentials of the most interesting cathode chemistries have led to a quite recession in the field that solid-state or flexible batteries based on polymeric electrolytes can only be achieved in cells based on low- or moderate-voltage cathodes. In this work, we show that cationic chain transfer agents in an ether electrolyte provide a fundamental strategy for limiting polymer growth at the anode, enabling long term (at least 2000) cycles of high-efficiency operation of asymmetric lithium cells. Building on these ideas, we also report that cathode electrolyte interphases composed of anionic polymers and the superstructures they form spontaneously at high electrode potentials provide as fundamental a strategy for extending the high voltage stability of ether-based electrolytes to potentials well beyond conventionally accepted limits. Through computational chemistry, we discuss the mechanistic processes responsible for the extended high voltage stability and on this basis report Li||NCM cells based on a simple diglyme electrolyte that offer unprecedented stability in extended galvanostatic cycling studies.

3:00 PM *ET06.02.04

Design Principles for Solid Electrolyte–Electrode Interfaces in All-Solid-State Li-Ion Batteries Yifei Mo; University of Maryland-College Park, College Park, Maryland, United States.

All-solid-state Li-ion battery is a promising next-generation energy storage technology, providing intrinsic safety and higher energy density. Currently, high interfacial resistance and interfacial degradation at the solid electrolyte-electrode interfaces are the critical issues limiting the cycling and rate performance of all-solid-state battery. Fundamental understanding about the interfaces is yet lacking due to the difficulties of direct experimental characterizations. In this presentation, I will show how we use first principles computation to bring new understanding about these buried interfaces. Using our developed computation approach based on large materials database, we calculated the true electrochemical stability window of solid electrolytes and predicted interphase decomposition products, which are verified by in-situ experiments at solid electrolyte-electrode interfaces. I will discuss the critical role of decomposition interphase layers at electrolyte-electrode interface and their effects on the battery performance. From these insights, we are able to classify different interface types for different solid-electrolyte and cathode pairs and to estimate their impacts on battery performance. Moreover, specific interfacial engineering strategies are proposed to address potential issues at these interfaces in all-solid-state Li-ion batteries. I will present the predicted novel chemistry and strategies to stabilize lithium metal anode, which is greatly impeded by the lack of knowledge about lithium-stable materials chemistry. With first-principles calculations based on large materials database, we found that most oxides, sulfides, and halides, which were commonly studied as protection materials, are reduced by lithium metal due to the reduction of metal cations. New materials chemistry that are stable against Li metal are predicted, as promising candidates for lithium metal anode protection to achieve long-term stability. This series of computational studies provides novel insights and general design principles for interface engineering in all-solid-state Li-ion batteries.

Recent Advances in Electrode Materials and Solid Electrolytes for Li-Metal Batteries Yu-Guo Guo; Institute of Chemistry, Chinese Academy of Sciences, Beijing, China.

The attempt to build high-energy density solid-state Li-metal batteries (SBLMBs) has attracted more and more attention. Here, we report our recent progress in SBLMBs. Regarding to the key issues of Li metal anodes, 3D current collectors (e.g., 3D Cu), nanostructured carbon materials (e.g., carbon spheres, solid or hollow carbon fibers, nitrogen-doped graphitic carbon foams), artificial SEI layers (e.g., Li2PO3, LiPAA), functional electrolyte additives (e.g., Al-based colloidal particles, ionic liquids), as well as multilayered solid electrolytes have been demonstrated feasible as functional materials for stable plating of Li to address the above issues. The rapid capacity decay caused by the poor contact and large polarization at the interface between the cathode and solid electrolytes is still a big challenge to overcome for high-power-density solid batteries. Recently, we have reported three strategies to address this issue. (i) A superior Li conductive transition layer LATP is introduced to coat NCM622, as a model cathode, to mitigate polarization and enhance dynamic characteristics. The critical attribute for such superior dynamics is investigated by the atomic force microscopy with boundary potential analysis, revealing that the formed interfacial transition layer provides a gradual potential slope and sustain-released polarization, and endows the battery with improved cycling stability and excellent rate capability at room temperature, which enlightens the comprehension of interface engineering in the future solid batteries systems. (ii) The interfacial interface of can also be ameliorated by coating the cathode of MCN622 with a LiBO2 glass layer. The continuous coating acts not only as a physical barrier hindering the decomposition of polymer electrolyte but also as a buffer layer promoting lithium diffusion across the space charge layer. (iii) This issue can be effectively addressed by constructing a poly (acrylonitrile-co-butadiene) coating layer onto the surface of NCM622 cathode materials. The polymer layer plays a vital role in working as a protective shell to retard side reaction and ameliorating the contact of the solid-solid interface during the cycling process. The key bottleneck troubling the application of solid electrolyte is the contradictory requirements from Li metal and cathode, which need high modulus to block Li-dendrite penetration and flexibility to enable low interface resistance, respectively. Our recent study describes a thin asperometric galvanostatic discharge of solid electrolyte to address these shortcomings. We propose a rational strategy to construct a thin and asymmetric solid electrolyte with a rigid ceramic LLZO layer modified with 7.5 nm polymer and a soft polymer layer for SBLMBs to fulfill the requirements of Li-metal and cathode, obtaining a dendrite-free Li-anode and low interface resistance. This ingenious arrangement endows solid Li-metal batteries with extremely high Coulombic efficiency and cyclability.

Effects of Polymer Coatings on Electrodeposited Lithium Metal Jeffrey F. Lopez1, Allen Pei2, Yi Cui2 and Zhenan Bao3; 1Chemical Engineering, Stanford University, Stanford, California, United States; 2Materials Science and Engineering, Stanford University, Stanford, California, United States.

The electrodeposition of lithium metal is a core process in next-generation, high energy density energy storage devices. However, the high reactivity of the lithium metal causes short cycling lifetimes, and there are safety issues due to the growth of dendrites. Recently, a number of approaches have been pursued to stabilize the lithium metal interface, including soft polymeric coatings that have shown the ability to enable high-rate and high-capacity lithium metal cycling, but a clear understanding of how to design and modify these coatings has not yet been established. In this work, we studied the effects of several polymers with systematically varied chemical and mechanical properties as coatings on the lithium metal anode. By examining the early stages of lithium deposition we determine that while global morphology depends on the coating quality and mechanics, the local morphology of the lithium particles is strongly influenced by the chemistry of the polymer coating. We have identified polymer dielectric constant and surface energy as two key descriptors of the lithium deposit size. Low surface energy polymers were found to promote larger deposits with smaller surface areas. This is consistent with a reduction of the coatings interactions with the lithium surface and thus an increase in the interfacial energy. On the other hand, high dielectric constant polymers were found to increase the exchange current and gave larger lithium deposits, suggesting improved Li+ ion solvation in the coating and decreased nucleation rate. We also note that the thickness of the polymer coating should be optimized for each individual polymer, and that polymer reactivity is an important parameter to be considered as it was found to strongly influence the Coulombic efficiency. Overall, this work offers new fundamental insights into lithium electrodeposition processes and provides direction for the design of new polymer coatings to better stabilize the lithium metal anode.
Design and Architecture of a Stable Solid-Electrolyte Interphase for the Lithium Metal Battery Anode Using a Reactive Polymeric Composite Yue Gao, Tianhao Chen, Qingquan Huang, Thomas Mallouk and Donghai Wang; The Pennsylvania State University, University Park, Pennsylvania, United States.

Rechargeable battery technology based on the lithium (Li) metal anode is plagued by the unstable solid-electrolyte interphase (SEI), which grows upon cycling and is associated with dendritic/mossy Li deposition. A key challenge in improving SEI stability lies in regulating its chemical composition and nanostructure. Here we report a new approach that enables the design of SEI layers with tunable structure and stable properties. This involves the use of a reactive polymeric composite, which can generate a stable SEI layer in situ by reacting with Li to occupy surface sites and then electrochemically decomposing to form nanoscale SEI components. Cryo-TEM shows that the resulting SEI layer is composed of organic polymeric Li salts, nanoparticles of inorganic Li salts, and two-dimensional nanosheet components. This conformal nanocomposite SEI layer exhibits excellent passivation, homogeneity, ionic conductivity, and mechanical strength and stabilizes the interface for dendrite-free Li deposition in a conventional carbonate electrolyte. 950-cycle life was achieved in a full cell paired with a LiNi0.5Co0.2Mn0.3O2 cathode. Moreover, under lean electrolyte conditions, the full cells also show significantly extended cycle lives, owing to the excellent stability of the polymeric nanocomposite SEI.

Design and Characterization of a Solid Hybrid Electrolyte for Lithium-Ion Batteries Florent Leclercq, Cédric Lorthioir, Laura Coustan and Christel Laberty-Robert; Sorbonne Université, Faculté de Science et D’ingénierie, Laboratoire de Chimie de la Matière Condensée de Paris, Paris, France.

Despite the development of new technologies, such as lithium-sulfur or sodium-ion cells, lithium-ion devices remain the most used batteries: they are found in a majority of electronic devices and the demand for electric vehicles keeps growing. Their performance and characteristics vary according to the chosen electrode but their main advantages are their high energy density and their low self-discharge. However, lithium-ion batteries suffer safety risks which are mainly due to the use of liquid electrolytes. These electrolytes are based on a lithium salt dissolved in a mix of organic solvents and therefore are highly flammable. A safer alternative is to replace this liquid electrolyte by a solid one. Ceramic electrolytes are a first possibility but they are often complex to synthesize and too rigid. Thus, solid polymer electrolytes are good candidates regarding their flexibility but they have a rather low conductivity and poor mechanical properties.

This work focuses on the conception of a solid hybrid electrolyte. The organic part is composed of a mix of polyethylene oxide (PEO), known for its lithium conductivity, and polyvinylidene fluoride-co-hexafluoropropylene (PVDF-co-HFP), known for its mechanical properties. The inorganic part is a silica network formed in situ via a sol gel reaction. This network is functionalized with an immobilized ionic liquid in order to increase the conductivity of the electrolyte. These components are dissolved in N,N-dimethylformamide altogether with a lithium salt, LiTFSI, and a first set of solid electrolyte is accomplished by solvent casting. Conductivity and lithium transference number are measured in temperature while the structure and the transport at different scales are analyzed by NMR, SAXS-WAXS, and Differential Scanning Calorimetry (DSC). Electrochemical performances at different rates are assessed in full cell using LiFePO4 as the cathode and metallic lithium as the anode. Then, the importance of microstructure is investigated by achieving a second set of solid electrolyte. A skeleton of PVDF-co-HFP and functionalized silica is electrosyn, producing a mat of fibers of 100nm in diameter. The space between fibers is then filled by concentrated LiTFSI or PEO/LiTFSI salts. The structure as well as their performances will be discussed using the same techniques.

Effects of Ionic Correlation on Transport in Solid Polymer and Concentrated Ionic Liquid-Based Electrolytes from Molecular Dynamics Simulations Nicola Molinari1, 2, Jonathan Mailoa2 and Boris Kozinsky1, 2; 1SEAS, Harvard University, Cambridge, Massachusetts, United States; 2Robert Bosch LLC, Cambridge, Massachusetts, United States.

Electrolytes have become key players in the design of modern high-energy solutions as they can be leveraged to enhance various important aspects of the device such as recharge time and efficiency, anode/cathode stability, and safety. However, conductivity and general transport properties of the cation/anion pair(s) dissolved in the electrolyte often pose a technological limit to the viability of the battery, and progress in fundamental insights into the origin of transport limitations are challenging yet extremely valuable. In our group, molecular modelling techniques are adopted in order to shine light on transport properties and correlation effects in electrolyte system.

Poly(ethylene) oxide (PEO) -based solid polymer electrolytes have a long history of research due to the easy processability and good transport properties, yet new observations that challenge our conventional understanding are still reported, especially at high salt concentrations relevant for technological applications. Our molecular dynamics simulation study of such regimes for one of the most prominent materials, PEO-LiTFSI, reveals the central role of NaFSI concentrations. Several recent studies focus on assessing the performance of different mixtures. Given the highly-correlated nature of these systems, understanding the role of species correlation is non-trivial yet crucial for a rational design of future solutions. As a case study we investigated the promising NaFSI-C3C1PyrrFSI system at different Na concentrations and focus on highlighting the correlations in this system as well as how they effect the transference number for high NaFSI concentrations.
Understanding the surface reactivity between electrode and electrolyte is critical for cycle life of Li-ion batteries. The composition, properties and mechanisms behind electrolyte/electrolyte interface (EEI) on positive electrode are still unidentified for most lithium ion battery positive electrode materials [1,2]. Especially at high potentials, EEI layer on positive electrode becomes more critical since it approaches electrolyte instability limit for oxidation. The EEI layers on carbon-free, binder-free and thin film LiCoO2 electrodes were investigated by using X-ray photoelectron spectroscopy (XPS). The growth of oxygenated and carbonated species was observed together with salt decomposition starting at 4.1 V\textsubscript{Li} [3]. By DFT calculations, we correlated the EEI composition to the thermodynamic tendency of the EC solvent for dissociative adsorption on the LiCoO2 surface, which can have a role in the salt decomposition on oxide surfaces [4]. The salt decomposition products had been also observed by solution 19F-NMR measurements. Finally, we demonstrated that the addition of diphenyl carbonate to the electrolyte has a strong impact on EEI layer and salt decomposition on LiCoO2 surface. With this study, we also highlight the strength of using the carbon-free, binder-free electrodes to get fundamental insights in the reactivity of the positive electrode with the electrolyte.

ET06.03.02
Examining the Conductivity of Swollen Crosslinked Ionic Liquid Gels
Prevyo Kuray, Jiho Seo, Clara Capperelli, Carlos Fernandez and Michael Hickner; The Pennsylvania State University, University Park, Pennsylvania, United States.

Gel polymer electrolytes (GPEs) are a branch of solid polymer electrolytes obtained by swelling liquid solvent, plasticizer, or ionic liquid into a polymer-salt matrix. Due to their solid-like nature and conductive properties, GPEs are attractive as electrolytes in battery applications and other areas where liquid electrolytes are undesirable. Here, 1-methylimidazolium2-acrylamido-2-methylpropanesulfonate ([AMPs][Mim]) and poly(ethylene glycol) (PEG) were cross-linked and solvated to create a novel set of non-volatile conductive gels. We employed dielectric relaxation spectroscopy to measure the conductivity as a function of temperature for different solvents in our base material. By cross-linking [AMPs][Mim] and incorporating various solvents, we obtain a conductive polymeric gel material that is mechanically robust, circumvents issues of leakage and flammability found in traditional ionic liquid electrolytes. This study opens the door to safer polymer electrolytes for electrochemical applications.

ET06.03.03
Porous Single-Crystal NaTi(PO4)2 via Liquid Transformation of TiO2 Nanosheets for Flexible Aqueous Na-Ion Battery
Yanhao Dong and Ju Li; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Recently, aqueous energy storage systems (AESSs), such as Na-ion battery & capacitor, have demonstrated their uniqueness compared with their non-aqueous counterparts due to the excellent safety performance in nature. Furthermore, the advantage of their low cost derived from the high abundance of sodium and the simplified process in ambient endows AESSs the possibility of application in large-scale power grid. However, restricted by the narrow electrochemical window (~1.23 V) of water, the common used electrode materials in non-aqueous batteries/capacitors such as transition metal oxides/sulfides/selenides are directly excluded from the scope due to the high voltage platform, other than limited kinds of materials like NASICON-type NaTi(PO4)2 with appropriate voltage platform. Nevertheless, conventional NaTi(PO4)2 materials with irregular morphology and large size prepared by solid-state reaction still hinder the application of AESSs. Herein, a newly structured porous single-crystal NaTi(PO4)2 with uniform sizes was fabricated via a well-designed novel liquid transformation of ultrathin TiO2 nanosheets, followed by coating a conductive carbon sheath. To best of our knowledge, this is the first report of the porous single-crystal structure of NaTi(PO4)2 materials. Examined in a three-electrode cell, this NaTi(PO4)2 electrode demonstrates an outstanding rate capability of 80-102 mAh g\textsuperscript{-1} at varied current densities of 0.5-3 A g\textsuperscript{-1} due to the synergistic effect between porous nanostucture and outstanding stability originated from single-crystal structure. The high-quality NaTi(PO4)2 was also assembled with N-doped carbon to fabricate an aqueous Na-ion battery with robust flexibility. This work paves the way for designing advanced NASICON based materials for aqueous energy storage systems.

ET06.03.04
Solid State Synthesis Revisited—Ni-Rich Cathode
Yanhao Dong and Ju Li; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Ni-rich cathode materials for lithium-ion batteries, commonly in the forms of LiNi\textsubscript{x}Co\textsubscript{1-x}Mn\textsubscript{2}O\textsubscript{4} (NMC) and LiNi\textsubscript{x}Co\textsubscript{1-x}Al\textsubscript{2}O\textsubscript{4} (NCA), are of great interests in commercial applications due to their high reversible capacity and relative low cost compared to LiCoO2. Due to the well-known Ni/Li cation mixing problem, such a multicomponent (high-entropy) compound cannot be synthesized at elevated temperatures, the more so the higher Ni concentration. This temperature doctrine suppresses the inter-diffusion kinetics between transitional metal ions (Ni, Co, Mn, Al etc.) during material synthesis, hindering a homogeneous distribution and electrochemical properties, and limits the achievable particle size, impeding electrode packing and volumetric energy density. This is part of the reason why solid state synthesis of NCM/NCA materials was not successful. The comundum is tentatively solved by introducing a specialized co-precipitation technique and self-agglomerated secondary particles (~10 micron) for NCM/NCA systems. Yet the secondary particles would still crack along grain boundaries during electrode pressing and electrochemical cycling. Therefore, micron-size single-crystalline NCM/NCA with good electrochemical properties is a great treasure. In our recent work, we revisited the solid state synthesis of such single-crystalline Ni-rich cathodes and obtained compelling capacities with the state-of-the-art co-precipitation technique, thus re-opening the doors to process Ni-rich cathodes in the same synthesizing route as classical LiCoO2 and genius control of doping and coating at the primary-particle level.

ET06.03.05
Superoxide Dismutase-Mimetic Fullereene Derivative as a Mobile Catalyst for Lithium-Oxygen Batteries
Chihyun Hwang1, JongTae Lee2, Gwan Yeong Jung3, Seun Joo1, Jonghak Kim1, Aming Cha1, Soek-Ju Kang1, Sang-Kyu Kwak1, Sang-Young Lee1 and Hyun-Kon Song1; 1UNIST, Ulsan, Korea (the Republic of); 2KISTEP, Seoul, Korea (the Republic of).

Reactive superoxide triggers side reactions during discharge of lithium-oxygen batteries (LOBs) and therefore affects seriously harmful effects on LOB performances. In living organisms exposed to oxygen, superoxide dismutase (SOD) manages superoxide in a way of converting the reactive species to less
reactive oxygen and peroxide. Herein we adopted a functionalized fullerene molecule (MA-C$_{60}$ where MA = maleic acid) that mimicked dismutation or decomposition function of SOD. Superoxide-triggered side reactions during discharge were significantly reduced by MA-C$_{60}$ so that desired oxygen evolution reaction was dominantly encouraged during charge with less CO$_2$ evolution. Toroidal lithium peroxide particles were generated, which indicated that solution mechanism for peroxide formation was favored. Resultantly, MA-C$_{60}$-containing LOB cells exhibited tremendously improved capacities especially at high rates.

ET06.03.06
New 4V-Class and Zero-Strain Cathode Material for Na-Ion Batteries Jongsoo Kim; Sejong University, Seoul, Korea (the Republic of).

We developed NaN$_3$V(PO$_3$)$_3$N as a novel 4V-class and zero-strain cathode material for Na-ion batteries. Through the combined studies using neutron and X-ray diffraction, it was identified that the NaN$_3$V(PO$_3$)$_3$N contains 3-dimensional channels, which enables the facile Na diffusion in the structure. The Na (de)intercalation of NaN$_3$V(PO$_3$)$_3$N was occur at ~4 V (vs Na/Na$^+$) via the V$^{3+}$/V$^{4+}$ redox reaction and its capacity retention over 3000 cycles was ~67% of the initial capacity. The remarkable cycle stability was due to the near-zero volume change (~0.24%) and the unique centrosymmetric distortion that occurs during a cycle despite the large ionic size of Na ions for (de)intercalation, as demonstrated by ex-situ XRD analyses and first-principles calculations. We also demonstrated that the NaN$_3$V(PO$_3$)$_3$N could show the outstanding power capability with ~84% retention of the theoretical capacity at 10C, which is attributed to its intrinsic 3-dimensional open-crystal framework. The combination of this high power capability and extraordinary cycle stability enables the application of NaN$_3$V(PO$_3$)$_3$N to a promising cathode material for Na-ion batteries.

ET06.03.07
Vanadium Oxide Nanosheets for Flexible Dendrite-Free Hybrid Al-Li-Ion Batteries Xuefei Gong and Pooi See Lee; MSE, NTU, Singapore, Singapore.

Although lithium (Li) ion batteries have been the focus of research in energy storage devices for the last decades and significant progresses have been made towards high energy densities and improved safety, the dendrites formation with lithium metal as anodes is still difficult to address effectively and fundamentally. In contrast, aluminum (Al) ion batteries with Al anodes inherently possess the advantages of resisting dendrite growth and lower in cost, which make Al-ion batteries attractive as an alternative to Li-ion batteries. In addition, based on three electron transfer redox reactions, Al delivers high volumetric and gravimetric capacities, which provides promising applications in cost-effective and large-scale energy storage systems. However, the developments of Al-ion batteries are restricted by the sluggish kinetics of Al$^{3+}$ ions diffusion and insertion/extraction, due to large ionic size of Al$^{3+}$ ions and strong electrostatic force between host materials and trivalent Al$^{3+}$ ions. It can lead to decreased intercalation sites in host materials.

In this work, a concept of hybrid Al-Li-ion battery has been proposed, which utilizes the Li$^+$ ions intercalation/deintercalation into/from the cathode materials because of smaller size, less charge and faster ion transport of Li$^+$ compared to Al$^{3+}$ and Al stripping/deposition on the surface of aluminum foil anode due to higher redox potential of Al/Al$^{3+}$ (~1.67 V vs. SHE) compared to Li/Li$^+$ (~3.04 V vs. SHE), thus circumventing the sluggish kinetics and maintaining the dendrite-free formation of Al-ion batteries. Subsequently, a hybrid Al-Li-ion battery, composed of vanadium oxides on carbon fibers as cathode, Al foil as anode and [EMIM][Cl]/AlCl$_3$/LiCl as electrolytes, has been successfully fabricated. This hybrid battery delivered a high volumetric capacity of 325 mAh/cm$^3$ at a current density of 10 mA/cm$^2$ (based on the total volume of cathode including carbon fibers as current collectors) and maintains 215 mAh/cm$^3$ even at 100 mA/cm$^2$. More impressively, the capacity could be retained 70.1% after 3000 cycles, much better than other Al-ion batteries reported. The excellent electrochemical performance could be attributed to the improved kinetics with the introduction of Li$^+$ ions into the electrolyte as well as the 3-D porous structures of cathode materials. Moreover, structural integrity under different bending conditions could be achieved because of good flexibility of cathode and anode. Therefore, this work unveils a safe, cost-effective and flexible hybrid Al-Li-ion battery that presents highly competitive advantages among various energy storage devices.

ET06.03.09
Encapsulating Segment-Like Antimony Nanorod in Hollow Carbon Nanotube as a High-Performance Anode for Rechargeable K-Ion Battery Wen Luo1, Feng Li2, Kang Han1, Jewel J. Gaum4 and Liqiang Mai1; 1Department of Physics, Wuhan University of Technology, Wuhan, China; 2Hefei National Laboratory for Physical Sciences at the Nanoscale, University of Science and Technology of China, Hefei, China; 3State Key Laboratory of Advanced Technology for Materials Synthesis and Processing, Wuhan University of Technology, Wuhan, China; 4LCP-A2MC, Université de Lorraine, Metz, France.

K-ion battery (KIB) is a new type energy storage device that possesses potential advantages of low-cost and abundant resource of potassium. To develop advanced electrode materials and electrolytes for accommodating the relatively large size and high activity of potassium is of great interests. In order to address the fast capacity decay caused by severe volume expansion of Sb anode, a novel segment-like antimony nanorod encapsulated in hollow carbon nanotube electrode material (so called Sb@N-C) was prepared by hydrothermal synthesis, polymerization coating and followed by an in-situ pyrolysis and reduction process. The potassium storage performance and mechanism of Sb@N-C in rechargeable KIB were also investigated.

Beneficial from the virtue of abundant nitrogen doping in hollow carbon nanotube, one-dimensional nanotube structure and hollow structure advantages, Sb@N-C exhibited excellent potassium storage properties: based on potassium hexafluorophosphatite (KPF$_6$) electrolyte, the reversible capacity could be maintained 318.6 mAh g$^{-1}$ at a current density of 0.5 A g$^{-1}$, whereas the cycle stability and rate performance were unsatisfactory. Electrolyte optimization strategy was further advanced to boost its potassium storage performance, and the optimization mechanism was also disclosed. In the absence of the solution bis(fluorosulfonyl)imide (KFSI) electrolyte, Sb@N-C displayed a reversible capacity of up to 453.4 mA h g$^{-1}$ at a current density of 0.5 A g$^{-1}$. Additionally, Sb@N-C demonstrated excellent long-cycle stability at ultra-high current of 5 A g$^{-1}$ over 600 cycles, its reversible capacity could be retained at 234.7 mA h g$^{-1}$. The results confirm that Sb@N-C nanocomposite is an advanced and superior promising electrode material for KIB. Besides, electrolyte chemistry optimization is an effective strategy for greatly improving electrochemical performance.

applied to observe the changes during charge/discharge process. Microporous carbon nanofibers, which was encapsulated with SeS2. The resultant cathode materials possesses a free standing structure, which could avoid V2O5 nanostructured active materials, and the binder-free processing are found to mainly contribute the promising electrochemical performance. This stable rate capability is also confirmed. The synergistic effects among the hierarchical structure, microchanneled Ni current collectors, two-dimensional superhierarchical Ni/Porous–Ni/V2O5 nanocomposite exhibits superior electrochemical performance as a binder-free cathode for lithium storage. The material. This system boasts a gravimetric capacity of 171 mAh g−1 at 100 mA g−1 and remarkable stability over a wide range of current densities. These structural quality and low defect density of graphitic carbons are crucial to obtain superior performance and cycling stability in these batteries.3, 4 Still, and despite all effort, the capacities reported for these systems remain stubbornly low, particularly when compared to the ~300 mAh g−1 attained by commercial lithium-ion batteries.

We wish to communicate an Al-chloride battery where reduced graphene oxide powder, dried under supercritical conditions, is used as the active cathode material. This system boasts a gravimetric capacity of 171 mAh g−1 at 100 mA g−1 and remarkable stability over a wide range of current densities. These properties are thought to be the consequence of the cathode’s tailored porosity.4 On one hand, its microporosity assists in breaking down the Coulombic ordering of the electrolyte; on the other, the mesoporosity (originated from the drying conditions) facilitates the movement of the large chloroaluminate ions within the active material.

Superhierarchical V2O5-Ni Cathodes for Lithium Storage Yuan Yue1 and Hong Liang1, 2, 1Materials Science and Engineering, Texas A&M University, College Station, Texas, United States; 2Energy Storage and Distributed Resources Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 3Mechanical Engineering, Texas A&M University, College Station, Texas, United States.

New materials are critically needed for advanced energy storage devices. In this research, an alternative approach to fabricate novel nanostructured cathodes with three-dimensional configuration that shows superior performance. We designed and synthesized Ni/porous–Ni/V2O5 nanocomposites using a simple electrodeposition process followed by a hydrothermal treatment. Hierarchical structured V2O5 ultrathin two-dimensional nanosheets (thickness ~ 50 nm) and three-dimensional peony-like microflowers (diameter ~ 4 μm) were deposited directly on a Ni microchannelled current collector. The superhierarchical Ni/porous–Ni/V2O5 nanocomposite exhibits superior electrochemical performance as a binder-free cathode for lithium storage. The maximum reversible discharge capacity of 165.6 mAh g−1 and retention of 90.9% after 100 cycles at 0.2 C are highlights of the capacity performance. The stable rate capability is also confirmed. The synergistic effects among the hierarchical structure, microchannelled Ni current collectors, two-dimensional V2O5 nanostructured active materials, and the binder-free processing are found to mainly contribute the promising electrochemical performance. This research opens a new avenue for the novel design of electrodes in future of rechargeable batteries.

Confined Selenium Sulfide in ZIF-8 Derived N-Doped Microporous Carbon Nanofibers as a Binder-Free Cathode for Lithium-Sulfur/Selenium Battery Zibin Yi, Ying Liu and Zhouguang Lu; Materials Science and Engineering, Southern University of Science and Technology, Shenzhen, China.

Lithium-sulfur batteries have been extensively considered as a promising alternative for lithium-ion batteries (LIBs) owing to their high theoretical energy density (2500 Wh kg−1) based on the reaction of lithium with sulfur to form Li2S. In addition, S is inexpensive, abundant and nontoxic. However, the practical application of lithium–sulfur batteries is hindered by the low conductivity and huge volume expansion of S during the charge-discharge process. Recently, selenium, a congener of sulfur, has also been used as a cathode material with a theoretical capacity of about 675 mA hg−1. Compared with sulfur, selenium has a better conductivity and it is found that the polyselenides are insoluble in carbonate based electrolytes, indicating that the shuttle effect could be suppressed effectively. Combining the merits of sulfur and selenium, selenium–sulfur solid solution (like SeS2) incorporated with carbon materials display an excellent performance when using as the cathode materials lithium–sulfur/selenium batteries. Herein, we designed a MOF derived N-doped microporous carbon nanofibers, which was encapsulated with SeS2. The resultant cathode materials possesses a free standing structure, which could avoid the utilization of non-active additives, thus ensuring a higher energy density. As a result, the Li-S batteries with C–SeS2 composites deliver a high specific capacity (950 mA hg−1 @ 0.5C) and outstanding rate performance. The nanofibers could buffer the volume expansion of the S/Se species as well as increase the contact area between the cathode and electrolyte to decrease the ion transmission distance. Furthermore, the in-situ Raman technology was applied to observe the changes during charge/discharge process.

Mechanically Reinforced Silicon Anodes for Lithium-Ion Batteries Jasmine M. Wallas1, Brian Welch2, Simon Hafner2, Taeho Yoon3, Steven M. George4 and Chunmei Ban1; 1University of Colorado, Boulder, Colorado, United States; 2National Renewable Energy Laboratory, Golden, Colorado, United States.

Silicon (Si) is a high energy, low cost anode material for lithium-ion batteries. With a theoretical specific capacity that is almost tenfold higher than graphite, Si has been the focus of extensive research recently for its potential use in electric vehicles and other devices. Unfortunately, Si anode technology has been held back by its lack of cyclability, largely attributed to the structural disintegration of Si electrodes associated with large volume changes during electrochemical cycling. This work aims to address this problem by stabilizing the electrode structure with a robust polymeric coating, allowing for reversible electrochemical reactions. Moreover, spatial molecular layer deposition (MLD) has been developed and applied here to realize the distinct all-organic polymer film chemistry deposited. The aromatic polyamide film chosen for this work has the desired mechanical properties of strength and elasticity that help stabilize Si anodes upon cycling. A very thin film polyamide coating on a Si anode enabled a stable and reversible capacity of 2186 mAh g−2 over 100 electrochemical cycles. Using a spatial MLD configuration usually fasts growth rates on the order of minutes, thereby permitting ease of future scale-up. This spatially deposited, all-organic thin film coating is a promising material that may enable high energy, low cost lithium-ion batteries.

Effect of Polymeric Binder on the Performance of Graphene/SnO2 Pillared Carbon Anode Material in Li-Ion Battery

Hyung Jin Mun1, Jae Ik Kim1, Pil Sung Choi2, Won Seok Choi2, Young Joon Kwon2 and Sung Hun Ryu1; 1Kyung Hee University, Yongin, Korea (the Republic of); 2Cholwon Plasma Institute, Cholwon, Korea (the Republic of).

Demand with higher energy density LIB is increasing in many areas such as automobile and group IV elements, such as Si, Ge and Sn, have been received much interest for this purpose. However, the use of these elements is limited due to the large volumetric change during long term charge-discharge cycle which results in undesirable rapid capacity fading, low initial coulombic efficiency and poor rate performance.

Among various approaches to avoid this limitation, chemically modified graphene and SnO2 has been hybridized to accommodate volume change and improve the capacity and cycling stability of the electrode material. Hybridization of SnO2 with carbonaceous materials has been used to circumvent this limitation [1-3]. Reddy et al studied hybridization of SnO2 with long chain alkylamine rafted graphene oxide and specific capacities decreased more with increasing alkylamine chain length [4]. Compared with traditional polymer binders, the self-healing chemistry is designed to enable spontaneous repair of the mechanical damage in the electrode and enhance the lifetime of the anode materials.

In the present study it is attempted to synthesize SnO2 nanopillared carbon structures using dodecylamine grafted graphene oxide as templates. Self-healing polyurethane is synthesized with disulphide and it is compared with commercial PVDF as a binder.

Structural and morphological characterizations of self-healing polyurethane and electrode were done using FT-IR, XRD, SEM and TEM. Electrochemical studies, such as charge-discharge, cyclic volatametry abd impedance, were carried by fabricated 2032 type coin cells using RGO-SnO2 as electrode. Self-healing characteristics of prepared polyurethane is confirmed from restored tensile property and SEM photographs of cutted samples. Electrochemical measurements revealed that the SnO2 pillared carbon based anode materials with self-healing polyurethane binder showed improved cycling performances with excellent reversible capacity relative to the electrode prepared by poly(vinylidene difluoride).

Electrochemical Mechanism and Effect of Carbon Addition During Hydrothermal Synthesis to Improve the Electrochemical Performance of Fe1.19(PO4)(OH)0.57(H2O)0.43 Cathode Material for Li-Ion Batteries

Abdelfattah Mahmoud1, Claude Karegeya2, Moulay Tahar Sougrati2, Jérôme Bodart1, Bénédicte Vertruyen1, Rudi Cloots1, Pierre-Emmanuel Lippens2 and Frederic Boschini1; 1University of Liege, Liege, Belgium; 2Institut Charles Gerhardt, Université de Montpellier, Montpellier, France.

Since the introduction of lithium-ion batteries (LIBs) to market in 1991, their performance has improved significantly, which has been achievable through development in materials technologies. However, further breakthroughs are still needed to ameliorate cycle-life, safety and energy density of LIBs. This requires new electrode materials and a detailed understanding of the electrochemical mechanisms during cycling. Transition metal phosphates are interesting candidates as cathode materials for LIBs [1]. In this work, we report the electrochemical performance of FPHP/C and FPHP/CNT composites where FPHP represents Fe1.19(PO4)(OH)0.57(H2O)0.43 while carbon black and carbon nanotubes (CNT) were used as precursors in the one-pot hydrothermal synthesis, respectively. We show that the addition of conducting carbon black into the solution has a strong influence on reducing the particle size and tailoring their morphology, but does not interfere with the formation of the FPHP phase. Thanks to its favorable microstructural characteristics, the FPHPH-10 wt% C and FPHPH-20 wt% C materials exhibited good performance [2]. The CNT also improve the performance of FPHPH such as capacity retention (500 cycles at 1 C).

The mechanisms of lithiation-delithiation were investigated by combining operando X-ray diffraction and ⁵⁷Fe Mössbauer spectroscopy. FPHPH undergoes a monophasic reaction based on Fe⁶⁺/Fe²⁺ redox process. However, the variations of the lattice parameters and ⁵⁷Fe quadrupole splitting indicate a more complex mechanism than a random occupation of the vacant sites within FPHPH. This can be related to the peculiar structure of FPHPH formed by chains of face sharing (Fe₅O₆.9O₈) octahedra connected by PO₄ tetrahedra and by channels for Li diffusion along {100} and {101} directions. The existence of Fe vacancies provide interconnections between the one-dimensional channels, improving lithium diffusion within FPHPH. This mechanism, combined with the addition carbon black or nanotubes in the solution prior to hydrothermal treatment as a simple and effective way to reduce particle size and improve electronic conductivity, provides good cycle life and rate capability for FPHPH.

Graphite as a material for Li-ion batteries has been ubiquitous in modern electronics and electric vehicles. However, the supply chain of lithium is a concern for grid-scale applications, while Li-ion batteries have been ubiquitous in modern electronics and electric vehicles. An efficient large-scale energy storage solution has become the bottleneck of the employment of sustainable but volatile energy sources like solar and wind. Therefore, Na-ion batteries (NIBs), for the abundant resources and low cost of sodium, become promising for large-scale energy storage applications. Therefore, Na-ion batteries (NIBs), for the abundant resources and low cost of sodium, become promising for large-scale energy storage applications.

Li-ion batteries (LIBs) took over the lead in rechargeable battery technologies since their introduction in the early 1990s. However, the price and abundance of lithium are still issues, and alternative cell chemistries based on abundant elements might become important especially when stationary energy storage reaches its market breakthrough. Therefore, alternatives to “lithium-ion technology” are being examined. Sodium-ion batteries (SIBs) are recently revisited as an alternative. The hope to realize more cost-effective batteries arises due to the large abundance of sodium. Although LIBs often have lower energy densities and cell voltages compared to their lithium analogues, the lower polarization of the sodium-ion might enable cells with peculiar advantages over conventional lithium-ion technology[1].

due to its low cost, safety, and good cycling performance, graphite is currently the preferred choice as an anode material for LIBs. Graphite is also favored in SIBs but storage of sodium-ions is only possible by formation of ternary intercalation compounds [2]. Instead of the naked ion, the solvated ion is intercalated in between graphene layers. The co-intercalation of the ether-based solvent molecule causes an enormous volume change in graphite lattice and so in the electrode. In order to observe this change, in situ electrochemical dilatometry (ECD) can be used to measure changes in the electrode thickness during charging and discharging. Phase transitions during de-insertion of ions, irreversible reactions such as solid electrolyte interphase (SEI) formation or structural changes such as delamination of graphite can be followed on-line. Overall, the studied electrode reaction behaves very different from conventional intercalation reactions of graphite. Finally, and maybe most intriguingly, the reaction is possibly the first case of an SEI-free graphite anode material [3]. Moreover, formation of gasses is examined during cycling by online electrochemical mass spectrometry (OEMS).

Moreover, was also present a systematic study on temperature effects related to the intercalation of solvated sodium ions into graphite. For this, a series of gymes (mono- to pentaglyme) and several crown ethers are used.

Aramid Nanofiber Composite Separators for Metal-Sulfur Thin-Film Batteries
Ahmet Emre1, 2 and Nicholas A. Kotov1, 2, 3
Biomedical Engineering, University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States; 2Biointerfaces Institute, University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States; 3Chemical Engineering, University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States.

High theoretical specific energy density (2600 Wh/kg) and high specific capacity (1675 mA/g) have been attracting significant attention for development of an alternative battery system to replace traditional lithium ion batteries which suffer from safety and capacity/energy density limitations. However, challenges such as polysulfide dissolution and shutting prevent mass commercialization of sulfur cathode batteries. Here we show a practical yet comprehensive approach for development of high performance metal sulfur batteries. Aramid nanofiber (ANF) based composite asymmetric separator [1] not only prevent dendrite formation [2] but also confine polysulfides on the cathode side. ANF composite battery separators provide diverse and opposing properties including high mechanical properties, high ionic conductivity and high thermal/chemical stability. These separators therefore provide a safe and long cycle life as well as high performance metal sulfur batteries. Fabrication of such safe, affordable, flexible and high energy density battery is quite crucial in powering next generation electronics including but not limited to portable, wearable and implantable biomedical devices.

Synthesis and Electrochemical Characterization of Cr-Doped Lithium-Rich Li1.2Ni0.16Mn0.56Co0.08-xCrxO2 (NMC) Cathodes for Lithium-Ion Batteries
Umair Nisar1, Ruhul Amin2, R.A. Shakoor1, Rachid Esselli1, Siham Al-Qaradawi1, Ramazan Kahraman2, and Ilia Belharouak1; 1Center for Advanced Materials (CAM), Qatar University, Doha, Qatar; 2Quantum Environment and Energy Research Institute, Hamad Bin Khalifa University, Doha, Qatar; 3Department of Chemistry & Earth Sciences, College of Arts and Science, Qatar University, Doha, Qatar; 4Department of Chemical Engineering, Qatar University, Doha, Qatar; 5Energy and Transportation Science Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Lithium-rich layer oxide Li1.2Ni0.16Mn0.56Co0.08-xCrxO2 (NMC) is a potential cathode candidate for high-energy density batteries. Issues such as cycling stability, rate performance, and cost are yet to be overcome before successful commercialization of the material. Here, we report on the synthesis of Cr-doped lithium-rich phases Li1.2Ni0.16Mn0.56Co0.08-xCrxO2 (where x=0.0, 0.01 & 0.02) (NMC-Cr) by the sol-gel technique. Cr is homogeneously distributed in the crystal structure evidence by XRD, XPS and elemental mapping measurements. The Cr-doped materials exhibit much better cycling stability with 100% capacity retention versus 44% for the undoped sample after 50 cycles. The Cr-doped samples show excellent electrochemical performance at higher C-rate in comparison with the undoped NMC. The latter shows rapid capacity fading from 220 to 50 mAhg-1 at the 0.1 to 1C rates, respectively. Moreover, the Cr-containing materials do not show significant signs of voltage fading during cycling owing to the stabilization of the crystal lattice by chromium. The electrochemical impedance spectroscopy measurements also indicate the stable cell resistance on cycling for the Cr-doped phases compared to the undoped phase.

ET06.03.21
Air-Stable P2-Type Na2Mg2Sn2O7 for High Capacity Sodium-Ion Batteries
Jing Mao1, Xin Liu1 and Kehua Dai2; 1Zhengzhou University, Zhengzhou, China; 2Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, California, United States.

An efficient large-scale energy storage solution has become the bottleneck of the employment of sustainable but volatile energy sources like solar wind. While Li-ion batteries have been ubiquitous in modern electronics and electric vehicles, the supply chain of lithium becomes a concern for grid-scale applications. Therefore, Na-ion batteries (NIBs), for the abundant resources and low cost of sodium, become promising for large-scale energy storage applications. Therefore, extensive efforts have been put into the understanding and developments of materials for NIBs with improved capacity and stability.

For NIB full cells, because the capacity of a cathode material (<200 mAh/g) is much lower than that of anode (300–600 mAh/g), enhancing the energy...
density of cathode materials is determinative for high energy-density NIBs. In order to improve the capacity of SIB cathode materials, Manganese-based sodium transition-metal (TM) oxides with low-valence dopants, Na$_x$M$_{1-x}$Mn$_2$O$_4$ ($0 \leq x \leq 1$, $M = $Ni, Mg, Li, etc.), have recently been studied for higher energy density than other NIB cathode materials. Na$_x$M$_{1-x}$Mn$_2$O$_4$ has two common structures: P2 and O3 type. In comparison, P2-type materials show higher discharge capacity (up to ~200 mAh/g) and better rate capability. Nevertheless, it is easy to be neglected is that both initial charge (desodiation) and discharge (sodiation) capacity of cathode materials are important because all the sodium ions are provided by cathode in most common full cell system. Thus, the lower initial charge capacity (~140 mAh/g) due to Na deficiency limits the potential capacity in full cells. Herein, we report a P2-type Na$_2/3$Mg$_1/3$Mn$_2/3$O$_2$ with high capacity for both charge and discharge. The initial charge capacity is 162 mAh/g at 0.1 C. This is one of the highest values among previous reported P2-type sodium transition metal oxides. The discharge capacity is 167 mAh/g and 205 mAh/g at 2.0 V and 1.5 V cut-off voltage, respectively. The capacity retention at 1C is 80% after 100 cycles.

ET06.03.22 Preparation and Electrochemical Properties of Li$_2$RuO$_3$ for High-Capacity Lithium-Ion Batteries Jing Mao¹, Xin Liu¹ and Kehua Dai²; ¹Zhengzhou University, Zhengzhou, China; ²Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Lithium ion batteries (LIBs) have been successfully used in portable electric devise since the first commercial usage of LiCoO$_2$ in 1990s. However, it is limited by the capacity of the cathode materials to reach the requirement of the high energy density to power the electric vehicles. Li$_2$RuO$_3$ and other substrates were proposed as possible cathode materials with high capacity. Herein, we report a simple synthesis process to prepare Li$_2$RuO$_3$ with high capacity, good rate capability and cycling stability. The first discharge capacity is 283 mAh g$^{-1}$ at current rate of 1 C between 2.0 and 4.6 V (vs. Li/Li$^+$). The discharge capacity is as high as 250 mAh g$^{-1}$ at 5 C rate. After 100 cycles, the capacity still remains 180 mAh g$^{-1}$. The Li$^+$ ion diffusion coefficients at different stage were determined by potentiostatic intermittent titration technique (PITT) method. The as-prepared Li$_2$RuO$_3$ shows improved Li$^+$ ion diffusion coefficients.

ET06.03.23 Synthesis and Performance of Li,Mn-Rich Cathode Materials for Li-Ion Batteries Panawan Vanaphuti and Yan Wang; Materials Science and Engineering, Worcester Polytechnic Institute, Worcester, Massachusetts, United States.

As Li-ion batteries are long advanced for its electrochemical properties in application to both electric vehicles and devices, many ongoing researches are focusing on the improvement of energy density, capacity, cycling stability and rate performance. These can divide into three main parts in Li-ion batteries; cathode, anode, and electrolyte. One of the solutions for this enhancement is to find novel cathode materials. This work focuses on the synthesis and characterization of Li,Mn-rich cathode, LiCo$_{0.16}$Mn$_{0.84}$O$_2$, for Li-ion batteries. The layered Mn-rich transition metal (Mn, Co, Ni) hydroxide precursor was synthesized via facile co-precipitation method in a continuous stirred tank reactor (CSTR). Under proper control of pH, temperature, time, concentration of the reactants, and feeding rates in the reactor, uniform spherical particles were obtained. The hydroxide precursor was then undergone two-step heat treatment process to achieve Li,Mn-rich cathode powder. Morphology and structure were examined using SEM and XRD, respectively, showing plate-like primary particles which intercalated into spherical secondary particle shape (average size ~ 17 μm). Chemical stoichiometry was confirmed by ICP-OES technique and electrochemical performance was studied to examine the reliability of this cathode for large scale production and its future commercial use in Li-ion batteries. Drawback of Li,Mn-rich, such as capacity fading and voltage decay, were discussed with an effort to minimize these issues.

ET06.03.24 Investigating Transport Properties of VO$_2$(M) and VO$_2$(R) via Temperature Dependent Electrochemistry and Diffraction Lisa Housel¹, Calvin Quilty¹, Alyson Abraham², Christopher Tang², Alison McCarthy³, Genesis Renderson¹, Diana Lutz¹, Ping Liu¹, Amy C. Marshchiklo², Esther Takeuchi¹,² and Kenneth Takeuchi¹; ¹Stony Brook University, Stony Brook, New York, United States; ²Brookhaven National Laboratory, Upton, New York, United States.

The VO$_2$(M/R) system undergoes a structural change from monoclinic [VO$_2$(M)] to rutile [VO$_2$(R)] phase at a temperature that is easily accessible and corresponds to an electrical conductivity increase two orders of magnitude. The ability to exploit electrical conductivity makes the system attractive for study as a lithium ion battery electrode considering uniform electron access can be a limiting factor in producing electrodes that deliver high capacities. In the work presented, several forms of characterization were employed to gain insight on the relationship of structure and electrochemical function. Synchrotron based x-ray powder diffraction (XPD) data was used to monitor the structural changes as a function of temperature. Electrochemical impedance spectroscopy was utilized to track impedance as a function of temperature. Further, the VO$_2$ system was then tested in two electrode cells to determine the impact of the structural transition on functional electrochemistry. The results from the compliment of experiments provides a foundation for investigating charge transport properties in polymorphic materials and sets a precedent for understanding the impact of phase changes on electrochemistry in a complex energy storage system.

ET06.03.25 The Benefit of a Multiscale Perspective for Investigating the Complex Chemistry of Functional Energy Storage Systems Alyson Abraham¹, Lisa Housel³, Amy C. Marshchiklo¹,², Kenneth Takeuchi¹ and Esther Takeuchi¹,²; ¹Stony Brook University, Stony Brook, New York, United States; ²Brookhaven National Laboratory, Upton, New York, United States.

A critical challenge for electrical energy storage is to achieve more useful work (w) and minimize the generation of waste heat (q). Batteries have often been approached at the macro level, where bulk parameters are identified and manipulated, with optimization as an ultimate goal. However, such a strategy may not provide insight toward the complexities of electric energy storage, especially when addressing multiple length scales in application and demands on devices. Beginning from a fundamental approach of identifying and reducing sources of localized resistance facilitates the understanding of the inherent heterogeneity of ion and electron flux both at multiple interfaces and length scales. At a fundamental level, it is necessary to identify and reduce sources of localized resistance and to understand the inherent heterogeneity of ion and electron flux at numerous interfaces found at several scale lengths within a battery. Benefits from experimentation and characterization over multiple length scales will be highlighted in this presentation.

Design of Lithium-Metal Anode for Enhanced Dendrite-Proof Capability Xin Li; Harvard University, Cambridge, Massachusetts, United States.

The suppression of lithium dendrite is critical to the application of lithium metal batteries. Many approaches have been applied previously to demonstrate the improved cycling performance with lithium metal anode, which include the 3D conductive framework, lithium metal surface protection and the formation of special SEI protection layer, etc. In this talk a combined simulation and experiment approach is used to understand the new principles behind these approaches. Innovative synthesis procedures, electrochemical battery tests and morphology and spectroscopy characterizations are used to demonstrate the advanced dendrite proof capabilities. Specifically, new approaches to construct the general 3D conductive framework from nonconductive materials and to apply the surface protection layers are demonstrated. Moreover, combined thermodynamic modeling, DFT simulation and new modeling approach is used to understand the dendrite growth thermodynamics and kinetics down to the atomic scale. We further propose some new design principles behind these technological approaches based on our experiment and theory.

Quantitative Measurement of "Inactive" Lithium in Li-Metal Batteries Chencheng Fang, Jungwoo Lee, Yihui Zhang, Yangyuchen Yang, Xuefeng Wang and Y. Shirley Meng; University of California, San Diego, La Jolla, California, United States.

Enabling stable and safe reversible Li metal anode is essential to achieve a specific energy density of 500 Wh/kg from a cell level in next-generation Li batteries. The low Coulombic efficiency and dendrite growth issues significantly hinder the commercialization of Li metal anode. It is well accepted that after electrochemical cycling, formation of "inactive" Li, consisting of Li ions that form SEI (Li+) and SEI wrapped Li metal (Li0), is a direct reason for capacity loss. Differentiating and quantifying Li+ and Li0 after cycling is one of the most critical yet challenging problems that impedes the thorough understanding of the failure mechanism of Li metal anode. A new chemical analytic method has been introduced in this work and provides a solution enabling the quantitative measurement of Li+ content in cycled Li metal cells at microgram (µg) level for the first time. Combining with Cryo-FIB-3D reconstruction, Cryo-TEM and XPS, a correlation among mass content, microstructure, SEI nanostructure and chemical composition has been established to investigate the properties of "inactive" Li generated in different electrolytes.

8:45 AM ET06.04.03
From Macro to Nano—Measurements of the Mechanical Properties of Lithium Metal Coleman Fincher1, Daniela B. Ojeda1, 2 and Matt Pharr1; 1Department of Mechanical Engineering, Texas A&M University, College Station, Texas, United States; 2Mechanical and Aerospace Engineering, University of Central Florida, Orlando, Florida, United States.

Lithium metal is known as the “Holy Grail” of anode materials, as it has the highest theoretical capacity, lowest density, and most negative electrochemical potential of known anode materials for rechargeable batteries. Unfortunately, dendrites of lithium form during repeated cycling, posing a safety hazard and deteriorating commercialization of lithium metal batteries. Previous studies, each with different methods of sample preparation and testing methods, show that Lithium’s yield strength may vary by more than 2 orders of magnitude (from ~1 MPa to 100-300 MPa). However, comprehensive knowledge of the mechanical behavior of Li remains a key obstacle to understanding how to engineer anode-separator interfaces that can mitigate or suppress dendrites. Through a combination of in-glovebox tensile testing and nanoindentation in as-received lithium ribbon, we probe the mechanical properties of Li metal at different length scales.

9:00 AM ET06.04.04
Investigating the Origins of Dendrite Nucleation on Li Metal Surfaces Perla B. Balbuena1, Luis E. Camacho-Forero1, Ethan P. Kamphaus2, Maria S. Angarita-Gomez2 and Xueping Qin1, 2; 1Texas A&M University, College Station, Texas, United States; 2Chemical and Biological Engineering, The Hong Kong University of Science and Technology, Kowloon, Hong Kong.

Formation and growth of dendrites on Li metal surfaces is a well-known problem and is one of the main reasons that prevent the successful operation of Li-metal batteries. Numerous mitigation strategies are continuously being developed such as electrode coatings, artificial solid electrolyte interphase (SEI) films, electrolyte design for specific SEI compositions, and use of solid electrolytes among others. In some of these processes, mitigation is induced by chemical or mechanical (or both) modifications of the environment surrounding the sites where Li ions are plated. Here we use first principles calculations first to investigate why dendritic nucleation occurs and what properties should be tuned to mitigate such phenomena. We then analyze the microscopic mechanisms behind some of the proposed strategies and determine which ones have the best probabilities of a long-term solution to this problem.

9:30 AM ET06.04.05
Dendrite-Free Li Metal Anode in Safe Rechargeable Batteries Xin-Bing Cheng, Xiang Chen, Rui Zhang, Chen-Zi Zhao, Xue-Qiang Zhang, Chong Yan and Zhan-Guang; Tsinghua University, Beijing, China.

Li metal is considered as the “Holy Grail” of energy storage systems. The bright prospects give rise to worldwide interests in the metallic Li for the next generation energy storage systems, including highly considered rechargeable metallic Li batteries such as Li-O2 and Li-sulfur (Li–S) batteries. However, the formation of Li dendrites induced by inhomogeneous distribution of current density on the Li metal anode and the concentration gradient of Li ions at the electrolyte/electrode interface is a crucial issue that hinders the practical demonstration of high-energy-density metallic Li batteries. In this talk, we review the lithium metal anode protection in a polysulfide-rich environment. Firstly, the importance and dilemma of Li metal anode issues in lithium–sulfur batteries are underscored, aiming to arouse the attentions to Li metal anode protection. Specific attentions are paid to the surface chemistry of Li metal anode in a polysulfide-rich lithium–sulfur battery. Next, the proposed strategies to stabilize solid electrolyte interface and protect Li metal anode are included. Finally, a general conclusion and a perspective on the current limitations, as well as recommended future research directions of Li metal anode in rechargeable batteries are presented.

References
Li metal has been considered as the ultimate anodic material for high-density electrochemical energy storage technology, not only because of its extremely high specific capacity (3860 mAh/g) and the lowest redox potential, but also because it enables battery chemistries with lithium free cathode materials, such as Li-S and Li-O2 batteries. However, the practical application of Li metal anodes is still prohibited.

This talk presents a facile and scalable preparation of a lithium-carbon composite for high performance Li anodes. It will be demonstrated that molten Li metal can be easily impregnated into the porous particles composed of carbon nanotubes (CNTs) to form a Li-CNT composite. When used as anodic materials, the Li-CNT composite not only shows high specific capacity (2000 mAh/g) and low lithium dissolution/deposition potential, but also shows significantly suppressed dendrite formation, high CE and stable cycle life. When paired the Li-CNT with a commercial LiFePO4 (LFP) cathode, a CE of around 90.1% can be achieved, which is much higher than the value (75.4%) obtained from a lithium foil anode.

Upon further optimization, a dual-carbon host matrix composed of CNT and acetylene black (AB), Li-CNT-AB, is found to absorb more Li and show even lower potential than Li-CNT. The lithiophilic AB particles not only helps to utilize the pore space of the sphere thus increasing the lithium content of the composite, but also acts as a lithium deposition promoter during battery cycling because AB has lower lithium nucleation barrier. As a result, the Li-CNT-AB composite exhibits a specific capacity as high as 2800 mAh/g and a life span of ~700 cycles can be achieved when it was cycled with a commercial LFP cathode at 1C (0.7 mA cm^-2) in an ether-based electrolyte with cathode capacity to anode capacity at 1:8, corresponding to a high Coulombic efficiency (CE) of ~98.7%. Furthermore, it was observed that there is no lithium dendrite formation and negligible volume change on the Li-CNT during electrochemical cycling.

organic surface chemistries using polymeric thin films. We have developed two approaches to apply polymer thin films on battery electrodes. The first approach is surface-initiated radical polymerization. Polylefinic radical initiators are tethered to the surface of a model thin film Li anode and then used to synthesize poly(methyl methacrylate) (PMMA) brushes of tunable thicknesses from approximately 20nm to several hundred nanometers. It was shown that the presence of 75nm brushes reduces the first cycle irreversibility on thin film Si anodes to 23.7%. The irreversibility in untreated Si is 37.6%. Post-mortem FTIR-ATR confirmed that less ethylene carbonate is reduced on the PMMA-coated Si in the first cycle, and electrochemical impedance spectroscopy showed that the PMMA brushes inhibit the growth of a resistive surface layer during extended cycling. In the second approach, initiated chemical vapor deposition (iCVD) is used to apply ultrathin conformal polymer layers on conventional lithium ion battery electrodes prepared by slurry casting. The conformity and coverage of the polymer coatings was confirmed by scanning electron microscopy and x-ray photoelectron spectroscopy. For coatings on lithium ion battery anodes, polymer compositions with high crosslinking densities were developed to exclude liquid electrolyte from the electrochemical interface. For these applications, we have developed two distinct polymer chemistries that have been applied by iCVD: crosslinked poly(lithium methacrylate) (PLiMA), poly(ethylene glycol diacrylate) (PEGDA), and poly(1,3,5-trimethylcyclotrisiloxane) (PV3D3). With these crosslinked films, there is a trade-off between the reduction in irreversible side reactions and an increased area specific resistance. We have also demonstrated that capacity retention of full cells (NMC vs. graphite in 1M LiPF6 in EC:DMC:DEC) at 55°C is improved by coating both cathode and anode with these ultrathin films. Our efforts to understand how polymer film chemistry and morphology influences the electrochemical reactions in lithium ion cells will be discussed.

11:45 AM ET06.04.10
Directing the Complex Behavior of Metallic Anodes Using Two Dimensional Materials Tara Foroozan, Soroosh Sharifi-Asl and Reza Shahbazian-Yassar; University of Illinois at Chicago, Chicago, Illinois, United States.

The demand for large-scale renewable energy generation and electric mobility is rising the need for high capacity and safe energy storage systems. Utilizing metal anodes are gaining momentum, owing to their very high energy densities compared to conventional intercalation-based electrodes. Nevertheless, considering the hostess nature of the metal anodes and their interfacial instability, the practical utilization of such systems has been restricted. Inhomogeneous metal electrodeposition (dendrites) and unwanted byproduct formation during cyclic life and safety of the metal anode-based batteries. Therefore, research community has focused on designing innovative approaches to regulate the deposition behavior of metal anodes. In this context, one of the most reliable methods is the use of ultra-thin and ultra-stable materials on the metal anode to prevent the side reactions at the interface and also suppress the formation of dendritic deposits. Among the proposed solutions, 2D materials are promising candidates, owing to their ultrahigh mechanical strength, superflexibility and chemical stability. However, it is not truly clarified that how these approaches affect the nucleation and growth modes of the metal during the electrodeposition. In this work, we have studied the nucleation and growth mechanism of lithium (Li) and zinc (Zn), as examples of metal anodes, in the presence of high-quality graphene (Gr) layer. Interestingly, addition of an ultra-thin layer of carbon is able to significantly regulate the morphology and electrochemical performance of these metal anodes. Utilizing electrochemical potential tests and scanning electron microscopy (SEM) the nucleation mechanism was explored. Accordingly, Li forms homogeneous spherical nucleation electrodeposits all over the Gr-coated electrode surface, being different from randomly whisker like deposition in case of bare electrode. Utilizing transmission and scanning electron microscopy we detected that upon further electrodeposition, in contrast to the expected highly dendritic Li deposition, Li spheres can develop into a uniform and compact structure composed of vertically aligned Li nanorods. Moreover, despite the randomly oriented inhomogeneous deposition of multi-crystalline Zn on the bare substrate, a planar Zn deposition, composed of single crystalline flat flakes, was observed in case of Gr-coated sample. Therefore, we can conclude that high quality graphene not only provides a homogeneous metal-ions nucleation, but also regulates the morphological and growth orientation of the final deposition products, significantly.

Further experimental and computational efforts are being carried out to provide comprehensive explanations for our observations in this research. Overall, we believe that such systematic studies can pave the way in the evolution of such surface engineering approaches into the industrial scale applications of rechargeable metal batteries.

Stabilization of Metal Anodes by Localized High Concentration Electrolytes Ji-Guang Zhang, Shuru Chen, Xiaodi Ren, Jianming Zheng, Lu Yu, Wu Xu and Xia Cao; Pacific Northwest National Laboratory, Richland, Washington, United States.

A stable and high efficiency metal anode (such as Li, Na, Zn, Mg) is critical for all rechargeable metal batteries, including the batteries with various cathodes such as ion intercalation compounds, conversion materials, sulfur, and oxygen. An ideal metal anode not only needs to have a very high Coulombic efficiency, but also need to have a low concentration, high conductivity and low cost. Recently, we have developed a series of “localized high-concentration electrolytes (LHCE)” by diluting high-concentration electrolytes with electrochemically “inert” solvents or poorly solvating diluents. Unlike the high concentration electrolytes reported before, the electrolyte reported in this work exhibits low concentration, low cost, low viscosity, improved conductivity, and good wettability to separator and electrodes. With selected Li salt, solvent, and the diluent, we demonstrated a fire-retardant LHCE that enables stable, dendrite-free cycling of LMAs with high Coulombic efficiency of up to 99.2%. Moreover, this electrolyte exhibits excellent anodic stability even up to 5.0 V and greatly enhances the cycling performance of LMBS. A Li||LiNi0.2Mn0.7O2||C60 battery using this electrolyte can retain > 97% capacity after 600 cycles at 1C rate (ca. 1.6 mAh cm⁻²), corresponding to a negligible capacity decay of < 0.005% per cycle. Similar concept of “localized high-concentration electrolytes (LHCE)” have also been used to stabilize Na metal anode for more than 40,000 cycles. In addition, this concept was also used to expand the electrochemical windows of water based electrolytes in a salt concentration much less than those reported before. Therefore, this new approach opened a window for further development of novel electrolyte for practical high-energy metal batteries.

Dual-Salt Ether Electrolytes for Stable High-Voltage Lithium Metal Batteries Xiaodi Ren1, Shuhong Jiao1,2, Zhiqiang Gao1,2, Mark H. Engelhard1, Yuzi Liu1, Dehong Hu1, Donghai Mei2, Jun Liu1, Ji-Guang Zhang1 and Wu Xu1; Pacific Northwest National Laboratory, Richland, Washington, United States; 2Department of Materials Science and Engineering, University of Science and Technology of China, Hefi, China; 3Argonne National Laboratory, Lemont, Illinois, United States.

With the fast-growing demands for high energy storage, lithium (Li)-ion batteries (LIBs) can no longer satisfy the application needs due to their relatively
low energy densities. Li metal batteries (LMBs) are regarded as one of the most promising next-generation energy storage systems. The key to enable long-term cycling stability of high-voltage LMBs is the development of functional electrolytes that are stable against both Li anodes and high-voltage (>4 V vs. Li/Li⁺) cathodes. Due to their limited oxidative stability (< 4 V), ethers have so far been excluded from being used in high-voltage batteries, in spite of their superior reducible stability against Li metal compared to the conventional organic carbonate electrolytes. Here we design a concentrated dual-salt/ether electrolyte that can form stable interfacial layers on both the high-voltage LiNi_{0.5}Mn_{0.3}Co_{0.2}O_{2} cathode and the Li metal anode, thus realizing an unprecedented capacity retention >90% over 300 cycles and ~80% over 500 cycles with a charge cut-off voltage of 4.3 V. Various characterization techniques were used to reveal the detailed mechanisms for the enhanced electrode stabilities. All these fundamental findings extend the conventional knowledge on ether-electrolyte systems, and provide an effective approach to achieve high energy density LMBs.

Redox Active Glyme-Li Salt Solvate Ionic Liquids Based on Tetrahalogeno-ferrate(III) Complex as a Catholyte for Lithium Secondary Batteries Yuta Kemmizaki¹, Yu Katayama¹, Hiro Mori Yotsuami¹ and Kazuhide Ueno²; ¹Department of Applied Chemistry, Graduate School of Sciences and Technology for Innovation, Yamaguchi University, Ube, Japan; ²Department of Chemistry and Biotechnology, Yokohama National University, Yokohama, Japan.

Solvate ionic liquids (SILs) are classified as one of the subclasses of ionic liquids, composed of long-lived complex ions.¹ Equimolar molten complexes consist of an appropriate combination of oligoethers (glymes) and Li salts ([LiX]+ [Li[n]glyme][Y]⁻), have shown to yield a highly Li-ion conductive and non-flammable SILs, which can be employed as an electrolyte for lithium secondary batteries.² Furthermore, recent studies have shown that SILs consist of the complex anions with reversible redox behavior can be used as liquid cathode materials (catholyte) for various energy conversion devices including redox flow batteries.³,⁴, sodium-ion batteries,⁵ and lithium secondary batteries.⁶ In this work, we obtained series of novel redox active SILs consist of an symmetric ([Li(G3)])⁺ and asymmetric ([Li(G3Bu)])⁺ triglyme-Li complex, and redox active tetrahalogeno-ferrate ([FeX]⁻ (X = Br, Cl, Br, Cl)). The physicochemical properties of [Li(G3/G3Bu)][FeX] were investigated by differential scanning calorimetry (DSC), Raman spectroscopy, electrochemical impedance spectroscopy, and thermogravimetry (TG). Cyclic voltammetry confirms the reversible redox property of the [FeX][FeX]²⁺ couple for all SILs. Among the SILs tested, [Li(G3Bu)][FeCl]⁺, consist of the complex cation with asymmetric structure and small complex anion, showed the lowest melting point (T_m) of <30 °C. The lithium secondary batteries utilizing [Li(G3/G3Bu)][FeX] as a catholyte exhibits a high coulombic efficiency of over 90 % after 50 cycles as well as stable discharge capacities of approximately 80 % of the theoretically predicted value, suggesting a new and promising path to enhance the performance of lithium secondary batteries.

Surface and Interface in Lithium Rechargeable Batteries—Challenges and Opportunities Xingcheng Xiao¹, Jiagang Xu¹, Binsong Li¹, Qinglin Zhang¹, Yikai Wang², Yang-Tse Cheng², Kai Guo³, Huajian Gao³, Brian W. Sheldon⁴ and Yue Qi⁵; ¹University of Kentucky, Lexington, Kentucky, United States; ²University of Providence, Providence, Rhode Island, United States; ³Michigan State University, East Lansing, Michigan, United States.

Low cycle efficiency and dendrite growth are two critical barriers for rechargeable batteries using Li metal as negative electrodes, mainly due to the coupled mechanical/chemical degradation of the SEI layer formed on Li metal surface. We have developed a comprehensive set of in situ diagnostic techniques combined with atomic/continuum modeling schemes to investigate and understand the coupled mechanical/chemical degradation of the SEI layer/Li system including fundamentally understanding the surface and interface phenomena. We have found that the mechanical incompatibility between SEI and soft Li leads to the complicated mechanical behaviors of the lithium metal electrode during the plating and stripping process. We systematically investigated the relationship between surface morphology and current density distribution which results in an inhomogeneous Li plating/stripping process. Based on this understanding, we have developed a new coating design strategy to achieve high cycle efficiency/dendrite free and extend the cycle life of lithium rechargeable batteries.

3:30 PM ET06.05.05
Solubility-Mediated Sustained Release Enabling Nitrate Additive in Carbonate Electrolytes for Stable Lithium Metal Anode Yayuan Liu and Yi Cui; Stanford University, Stanford, California, United States.

The physiochemical properties of the solid-electrolyte interphase (SEI), primarily governed by electrolyte composition, have a profound impact on the electrochemical cycling of metallic lithium (Li). Herein, we discovered that the effect of nitrate anions on regulating Li deposition previously known in ether-based electrolytes can be extended to carbonate-based electrolytes, which can dramatically alter the morphology of Li nuclei from dendritic to spherical, albeit extremely limited solubility. The effect can be attributed to the preferential reduction decomposition of nitrate anions during SEI formation that modifies the interfacial environment. And the mechanistic origins behind the phenomenon were investigated based on the structure, ion-transport property and charge transfer kinetics of the modified SEI utilizing advanced characterization techniques such as cryo transmission electron microscopy and ultramicroelectrode. Furthermore, to overcome the solubility barrier, a solubility-mediated sustained release methodology was introduced, in which nitrate anions were encapsulated in porous polymer gel and can be steadily dissolved during battery operation to maintain a high concentration at the electroplating front. As such, effective Li dendrite suppression and remarkably enhanced cycling stability can be achieved in both half- and full-cell configurations in corrosive carbonate electrolytes, significantly outperforming conventional electrolyte additives. The proposed approach is generally applicable in various carbonate-based electrolyte systems and can improve the reversibility of Li metal anode without sacrificing the stability, ionic conductivity, or the cost of electrolytes.

3:45 PM ET06.05.06
Artificial SEI on Lithium-Metal Anodes to Acetonitrile-Based Electrolytes in Lithium-Metal Batteries David Lepage¹, Ngoc Duc Trinh¹, David Aymé-Perron², Antonella Badia¹, Mickael Dollé¹ and Dominic Rochefort¹; ¹Chemistry, Université de Montreal, Montreal, Quebec, Canada; ²Prospective Lab, Total S.A., Materials for Energy, Paris, France.

One way to achieve high energy density batteries is to use Li metal as the anode material due to its very high theoretical specific capacity of 3860 mAh g⁻¹.
This approach however bring many challenges. Since over 40 years scientists spent important efforts to find the right strategies to overcome the high reactivity of Li metal and the formation of lithium dendrites during cycling. So far, only technologies based on solid polymer electrolytes (e.g. poly(ethylene oxide)) have been commercialized. One recent approach to employ Li metal anodes relies on the use of superconcentrated electrolytes in which the amount of solvent molecules reaches that of ions. It has been proposed that, under such conditions, the absence of free (i.e. non coordinating to the ions) solvent molecules prevent thermodynamically favourable decomposition at Li. With such system, acetonitrile (ACN) have been used with lithium metal. Because of its high oxidative stability and is high dielectric constant, ACN represent an interesting option as a solvent for the electrolyte.

Here we propose a different approach consisting in the formation of an artificial solid electrolyte interface (SEI) on the lithium to hinder the reaction between ACN and the metallic anode. To do so, we studied the spontaneous decomposition of neat fluoroethylene carbonate (FEC) on lithium metal (Li-FEC)\(^1\) to form a protective layer. This film have been characterized by AFM, XPS and by SEM to determine its composition and its morphology and a dense film made of a mixture of LiF with a polymeric phase have been found. This artificial SEI is porous to the lithium ions but impermeable to ACN, allowing the use of this solvent with conventional Li salt concentrations which maximise electrolyte conductivity. We demonstrate the protective properties of such artificial SEI using a 1 M LiPF\(_6\) in acetonitrile (ACN) electrolyte into a symmetric cell (both electrodes Li-FEC). This cell was cycled with a current density of 0.1 mA/cm\(^2\) during 30 min per half-cycle and for a total of 1500 hours. The electrochemical performance of a full cell made of c-LiFePO\(_4\) as cathode and Li-FEC as anode with the 1 M LiPF\(_6\) in ACN electrolyte have been analysed and shown a capacity of 162 mAh/g at 0.2C (theoretical capacity is close to 170 mAh/g). This approach opens new possibilities for the use of metallic anodes to improve energy storage in batteries.

4:00 PM ET06.05.07
Water-Tolerant Interphase Formation and Transplantation for Lithium-Metal Anodes Nikhilendra Singh, Timothy S. Arthur and Kensuke Takechi; Toyota, Ann Arbor, Michigan, United States.

The ability to directly utilize Lithium (Li) metal anodes in rechargeable batteries presents itself as an ideal, albeit challenging, situation. Li metal anodes could provide a maximum possible theoretical specific capacity (3860 mAh/g) in comparison to commercially used anodes (e.g. graphite – 380 mAh/g). However, Li metal anodes remain absent in commercial applications due to inherent safety concerns associated with the formation of Li dendrites during high rate cycling, as well as Li metals’ susceptibility to exhibit high reactivity towards commercially used organic electrolytes. Due to the possibility of thermal runaway, such concerns have adversely affected the potential use of Li metal in commercially available batteries. Additionally, Li metal reacts vigorously with water or passivates in the presence of small quantities of moisture rendering it unusable. This presents a significant hurdle for systems where water-tolerant Li cycling is of practical necessity (e.g. Li-air). Hence, significant efforts in recent literature have targeted the development of robust systems, capable of use with Li metal.

To date, various strategies have been employed to overcome such hurdles; the use of solid electrolytes as a mechanical barrier, or the use of specific organic solvent-based electrolytes which control the properties of the solid-electrolyte interphase (SEI), being noted observations. Amongst the available classes of Li batter electrolytes, ionic liquids (ILs) have been shown to facilitate enhanced Li cycling efficiencies and favorable Li plating morphologies while being inherently non-volatile/non-flammable alternatives to commercially available organic electrolytes. Through the capability to combine various cations, anions and salts; the use of such ILs could produce robust SEIs, resulting in the improved cycling behaviors reported in literature.

Recently, we reported that certain ILs allowed for successful Li metal cycling in the presence of water mixed into the IL electrolyte. To our knowledge, no reports have shown the capability to sustain morphologically friendly Li deposition upon application of high rates while sustaining stable cycling in a water containing electrolyte. In recognition of this unique capability, we now introduce a new method to artificially form these SEIs on Li metal via the screening of various IL electrolyte (cation, anion and salt) combinations. The electrochemical results, along with fundamental analytical analyses of the ILs capable of water-tolerant interphase formation and transplantation on Li metal, while sustaining commercially feasible Li morphologies at practical cycling rates in the presence of water containing electrolytes will be presented and discussed.

4:15 PM ET06.05.08
Facile Stabilization of Sodium Metal Anode with Additives—Unexpected Key Role of Sodium Polysulfide and Adverse Effect of Sodium Nitrate Huan Wang, Chuanlong Wang and Weiyang Li; Dartmouth College, Hanover, New Hampshire, United States.

Sodium (Na) metal is an attractive anode for next-generation energy storage systems due to its high specific capacity, low cost and high abundance. Nevertheless, uncontrolled Na dendrite growth caused by the formation of unstable solid electrolyte interphase (SEI) leads to poor cycling performance and severe safety concern. Herein, we first reveal that sodium polysulfide (Na\(_2\)S\(_n\)) alone can serve as a positive additive or pre-passivation agent in ether electrolyte to improve the long-term stability and reversibility of Na anode, while Na\(_2\)S\(_n\)Na\(_2\)O as co-additives has an adverse effect on Na anode, which is contrary to the prior findings in lithium (Li) metal anode system. A superior cycling behavior of Na anode is first demonstrated at a high current density up to 10 mA cm\(^{-2}\) and a capacity up to 5 mAh cm\(^{-2}\) over 100 cycles. As a proof of concept, we present a high-capacity Na-S battery via pre-passivating Na anode with Na\(_2\)S\(_n\). Our study gives new insights into understanding the differences between Li and Na systems.

4:30 PM ET06.05.09
Deposition-Stripping Mechanism of Lithium Metal in Batteries Feifei Shi and Yi Cui; Material Science and Engineering, Stanford University, Stanford, California, United States.

Rapid growth of electric vehicles has stimulated the development of high-energy storage systems, especially the lithium–sulfur and lithium–air batteries that employ lithium metal anodes. However, the wide deployment of Li-metal batteries has been hindered by its poor cycling efficiency and safety concerns, both of which stem from the uncontrollable Li deposition-stripping process. While various theories have been raised in the past, the underlying mechanisms of lithium redox couple are still controversial.

Here, we report the texturing behavior of lithium metal in batteries and reveal the mechanism of lithium electro-deposition from crystallographic perspective. Additives in electrolytes and the cross-over molecules from the cathode play crucial roles on the crystallographic texture because they inhibit the cathodic process and adsorb/react on different crystal planes selectively. Exchange current density has been identified as an indicator for the additive adsorption, which can only be accurately measured with microelectrode. Nano-void formation at interface of Li and SEI is found during the lithium stripping, which is attributed to the accumulation of lithium metal vacancies. High rate dissolution of lithium drives vigorous growth, subsequent aggregation of voids, and eventually collapse of the SEI layer, i.e. pitting. The polarization behavior and pitting potential of lithium are systematically measured by 3-electrode cell. Metallurgical factors, such as grain boundaries and slip lines, are found greatly accelerate the local dissolution of lithium. The understanding of the electro-crystallization and stripping beneath interface process of lithium will shed light on future lithium anode and electrolyte design.

Acknowledgement: The work was supported by the Assistant Secretary for Energy Efficiency and Renewable Energy, Office of Vehicle Technologies of the US Department of
Vanadium diselenide (VSe₂) is a transition metal dichalcogenide with metallic conductivity, which makes it a potentially promising electrode material for electrochemical applications. However, the developments of VSe₂ electrodes for such applications has been severely hampered by the difficulty of preparing nanosized products. In this work, a new facile solvothermal synthesis process is developed to synthesize ultrathin VSe₂ nanosheet assemblies. To obtain the ultrathin nanosheets, N-methyl pyrrolidone, which has the similar surface energy to many transition metal dichalcogenides, was used as the solvent to limit the crystal growth along the c-axis direction. The resulted ultrathin VSe₂ nanosheets exhibit good performance toward the alkaline ions (Li⁺ and Na⁺) storage, yet the performance can be further significantly enhanced by carbon coating. Specifically, the carbon-coated VSe₂ nanosheets can deliver high capacities of 768 mA h g⁻¹ (Li⁺ storage) and 571 mA h g⁻¹ (Na⁺ storage) along with outstanding stability. This work presents general strategies for Li⁺ and Na⁺ storage, yet the performance can be further significantly enhanced by carbon coating. Specifically, the carbon-coated VSe₂ nanosheets can achieve four or five times the theoretical specific energy of a commercial C-LiCoO₂ system. Despite the theoretical capacity of the sulfur, the practical capacity of 10 times that of the existing intercalate cathode. Sulfur is an interesting cathode material due to its high theoretical capacity of 1,673 mAh / g, yet the practical capacity of 10 times that of the existing intercalate cathode. Sulfur is an interesting cathode material due to its high theoretical capacity of 1,673 mAh / g, yet the practical capacity of sulfur is much lower due to its poor rate capability. In this study, we use a polymer with a channel to enclose sulfur particles to prevent volume expansion and dissolution and try to approach to impart mass transfer capability through hybridization with conductive graphene. The polymer with a channel is synthesized through a low-temperature heat treatment based on the difference of the vaporization temperature according to the degree of polymerization of the polymer. Through the channel, the lithium ion and the electron to be delivered to the sulfur contained in the polymer. All of the synthesis processes attempted in this study are scalable and very easy to mass-produce.

The polymer used in this study is an aliphatic rubbery synthetic polymer and has a vaporization temperature of 60 °C or less when it is in a monomer state. However, the vaporization temperature raises sharply according to the degree of polymerization, and when it is completely cured, it has a vaporization and decomposition temperature of 300 degrees or more. But in this work, the polymer in the hybrids mostly had a very low degree of polymerization in the MALDI-TOF analysis of the synthesized whole hybrids. This is because of the polymerization reaction, which originated from sulfur, terminated very quickly and the reaction was complete when the polymer met the sulfur and graphene particles. Due to the very low degree of polymerization of the polymer, the polymer can be vaporized at temperatures below 90 degrees, which results in many pores and channels on the surface and inside of the polymer from low-temperature heat treatment. Such a pore-forming polymer has superior mass transfer characteristics and high lifetime performance while offsetting the disadvantages of sulfur.
transfer kinetics particularly at higher cycling rate. Particle morphology thus needs to be engineered in order to obtain higher surface area and shorter diffusion length for practical use. On the other hand, the electrochemical performance of lithium-ion battery at different temperatures due to the change of composition of SEI (solid electrolyte interface) layer. Based on that, three different types of electrolyte compositions were formulated and the charge-discharge behavior is tested at 25 °C and 45 °C temperature. It reveals that the cell with EC-PC combination exhibits lower capacity than DMC-EC-PC and DEC-EC compositions at room temperature. The DMC-EC-PC electrolyte combination shows best electrochemical performances. This material shows the capacity close to 119, 130 and 125 mAh g⁻¹ at 0.1C with EC-PC, DMC-EC-PC and DEC-EC, respectively and at 1C rate performance is not much promising. Whereas at 45°C with the same electrolyte compositions exhibit above 100 mAh g⁻¹ at 1C rate. This observation also suggests that electrochemical rate performance of the material is limited by the interfacial charge transfer kinetics and the ionic diffusivity of the material.

Exploring Anionic Redox Reactions of Non-Overlithiated Layered Oxides—LiNi₀.₃Co₀.₃Mn₀.₄O₂—Gi-hyeok Lee¹, Dhuo Kim², Jinsong Wu¹, Kyeyongj Cho³, Maenghyo Cho⁴, Wanli Yang² and Yong-Mook Kang¹;¹Department of Energy and Materials Engineering, Dongguk University, Seoul, Korea (the Republic of);²Seoul National University, Seoul, Korea (the Republic of);³Lawrence Berkeley National Laboratory, Berkeley, California, United States;⁴The University of Texas at Dallas, Dallas, Texas, United States.

In recent years, an interesting charge compensation mechanism by anions, also called anionic redox, has attracted a lot of attention in lithium ion battery society because it has considered as promising strategy to overcome the capacity limitations of classical cathode materials. Another important implication of this research trend is that it triggered the interest on anionic contribution in charge compensation of cathode materials. However, recent studies dealing with anionic redox are all concentrated on overlithiated materials. Here, we tried to unveil the anionic redox behavior in LiNi₀.₃Co₀.₃Mn₀.₄O₂ (NCM111), one of the representative layered oxide cathode materials, by reexamining the charge compensation mechanism of NCM111. Even though charge compensation mechanism of NCM111 in the practical voltage range (~4.5 V) have revealed in detailed by a variety of studies, the charge compensation mechanism in the high voltage region still remains unclear. Finally, through the detailed analysis, it is reconfirmed that the oxygen in the metal-oxygen bond contributes to the charge compensation in the low-voltage range, and the lone-pair oxygen participates in charge compensation in the high-voltage range. This finding is expected to not only provide a new perspective for anion redox researchers but also help establish a high voltage stabilization strategy for layered oxide materials.

ET06.06.05
Biomass-Derived Carbon as Bifunctional Oxygen Catalysts for Zinc-Air Batteries Mi-Ju Kim³, J. Eric Park⁴, Sung-Jun Kim⁵, Yong-Hun Cho¹ and Yung-Eun Sung¹;¹Seoul National University, Seoul, Korea (the Republic of);²Institute for Basic Science, Daejeon, Korea (the Republic of);³Kangwon National University, Samcheok, Korea (the Republic of).

Electrochemical oxygen reduction and oxygen evolution reactions are critical reactions in many energy conversion and storage system including metal-air batteries and fuel cells. Efficient and sustainable oxygen catalysts have been required to replace noble metal based catalysts. In this regards, application of biomass for catalysts have attracted increasing attention due to abundance and low cost. In this study, N, S-co-doped porous carbon were prepared from pyrolysis of bamboo stems following doping process. As zinc-air battery cathodes, the N, S-co-doped carbon exhibit extremely high maximum power density, based on the superior catalytic activity when compared to the previously reported biomass-based catalysts. These excellent performances can be attributed to adequate micro/mesoporosity and the presence of sufficient active sites. This work will provide sustainable and efficient strategies to design high-performance cathode materials for zinc-air batteries.

ET06.06.06
Graphitic Carbon Nitride-Based Materials as Synergistic Catalysts for Oxygen Electrocatalysis and Their Applications in Rechargeable Metal-Air Batteries Ji Eun Park¹, ², Mi-Ju Kim³, Yang-Hun Cho¹ and Yung-Eun Sung¹;³Institute for Basic Science, Seoul, Korea (the Republic of);³Seoul National University, Seoul, Korea (the Republic of);⁴Kangwon National University, Samcheok, Korea (the Republic of).

The development of a low-cost, highly active, and durable catalyst for oxygen electrocatalysis is crucial for water electrolyzer and rechargeable Zn-air batteries. Here we report the carbonaceous material, graphitic carbon nitride-carbon nanofiber material (g-CN-CNF), as bifunctional catalyst of oxygen evolution reaction (OER) and oxygen reduction reaction (ORR) in alkaline media. g-CN-CNF catalyst exhibits enhanced catalytic performances for oxygen reactions, with high electron transfer number, low Tafel slopes, and low overpotentials. We applied the synthesized g-CN-CNF catalyst on primary and rechargeable Zn-air battery. The g-CN-CNF showed the comparable performance of primary cell with Pt despite the same catalyst loading. Furthermore, rechargeable Zn-air battery revealed that g-CN-CNF had a good retention of capacity for 156th cycling, resulting in the catalytic activity and stability of bifunctional catalyst. Therefore, g-CN-CNF is a good candidate for carbonaceous bifunctional catalyst which can be applied on practical electrochemical devices.

SnS₂, Sb₂S₃ and Ge-Containing Anode Materials for Potassium-Ion Batteries Lakshmi Vazhapully¹, Jimmy Wu¹, Ying I. Chen¹, Mokhlesur Rahman¹, Alexey Glushenkov¹, Alexey Mikhyailov⁴, Alexey Medvedev⁴, Neeraj Sharma⁴, Ovadia Lev⁵ and Petr Prikhodchenko⁵;¹Institute for Frontier Materials, Deakin University, Geelong, Victoria, Australia;²Kurnakov Institute for General Science and Organic Chemistry, Moscow, Russian Federation;³The University of Melbourne, Melbourne, Victoria, Australia;⁴Kurnakov Institute for General Science and Organic Chemistry, Moscow, Russian Federation;⁵The Casali Center of Applied Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel.

The development of potassium-ion batteries as new energy storage systems using potassium ions as ionic shuttles has recently attracted significant attention [1]. It has been discovered that graphite has an ability to intercalate K⁺ ions reversibly, which results in a series of intercalation compounds and a theoretical capacity of 278 mAh g⁻¹. This has greatly stimulated the field to develop further. Apart from graphite and carbonaceous materials, families of inorganic compounds have been extensively studied as high capacity anodes in lithium-ion and sodium-ion batteries [2]. However, these inorganic phases have not been significantly explored as potassium-ion battery anodes yet.

Some of the candidate inorganic phases of metalloids and sulphides are studied by this team as prospective anode materials [3]. This includes germanium as well as sulphides of tin and antimony. These inorganic phases have been showed to deliver capacities of 350 - 1024 mAh g⁻¹ in lithium-ion and sodium-ion batteries [4, 5]. Here, we present an overview of potassium electrochemistry of these compounds. In order to prepare model materials, the phases of interest (Ge, SnS₂, and Sb₂S₃) are dispersed on sheets of reduced graphene oxide. The electrochemical activity and gravimetric capacities of anode materials are evaluated. Phases formed during the discharge and charge are probed via ex-situ X-ray diffraction measurements. It is demonstrated that capacities in excess of that of graphite are possible in the inorganic phases studied here. Conclusions on possible reaction mechanisms in these materials are made and are presented in this contribution as well.
Improved Electrochemical Performances of P- and O-Type Mixed NaMnO2 for Sodium-Ion Battery—A Study on the Natural Formation of Sodium Carbonate and Its Activation Method

Sodium manganese oxide (NaMnO2) is a representative cathode material for sodium ion batteries. Because of the preferred coordination of sodium ions in the MnO2 layer, sodium manganese oxide can be constructed into either P2 or O3 structure. Among them, sodium manganese oxide with the P2 structure exhibits better electrochemical performances compared to not only the O3 structure, but also other sodium ion cathode materials. However, the low sodium content of its initial state is one of its biggest limitations as a cathode material. Furthermore, many reports showed that the initial charge capacity of the P2 phase is lower than its theoretical capacity. Despite this, in-depth studies into the low initial charge capacity of the P2 phase have been so far absent.

At the same time, the formation of sodium carbonates on the surface of layered Na ion cathodes looks typical and more severe compared to that on layered lithium ion cathodes. This carbonate formation may be due to the reaction between atmospheric CO2 and sodium ions on the surface of the cathode materials. The formation of surface sodium carbonate is detrimental because it is electrochemically inactive and generally consumes significant amount of sodium ions during its formation. Our study indicated that the formation of sodium carbonate is one of the major causes for the deterioration of their electrochemical performance, including initial charge capacity, coulombic efficiency etc. We hypothesise that the formation of sodium carbonate alters the oxidation state of manganese on the surface, leading to lower electrochemical activity during its first charge. Therefore, we attempted to study the natural formation of sodium carbonate on the surface of sodium manganese oxide and suggest novel ways to enable the activation of the electrochemically inactive sodium carbonate, so as to achieve higher initial charge capacity.

Vertically Oriented Layered Sulfides MoS2 with Controlled Spatial Arrangement for Enhanced Sodium-Ion Battery

Layered transition metal sulfides are promising sodium intercalation hosts due to the opening van der Waals gap. However, deformation of its layered structure during repeated intercalation of sodium always result in undesirable cycle performance. Here we report vertically oriented MoS2 with controlled spatial arrangement on nitrogenous reduced graphene oxide sheets as a strategy to achieve unimpeded and stable sodium diffusion way. Controlled spatial arrangement were realized via a facile gel-precursor-based solvothermal method. Sheet density and height of MoS2 were gradually modulated and further tested as anode materials for sodium ion batteries. The optimized MoS2 with short sheet height and high sheet density can deliver remarkably reversible capacities of 255 mAh/g under a current density of 0.2 mAh/g and outstanding cycle performance with a total capacity fluctuation of 5.35% over 1300 cycles. The improvement electrochemical performance were verified due to the close-packed but short-length structure which can suppresses additional SEI layer formation and reduces the sodium diffusion resistance together with alleviates the structural deformation.

Impact of Calcination Temperature on Size Controlled Microstructure of NCA Cathode Material for Lithium-Ion Batteries

Due to its excellent cycling ability and high energy density, lithium-ion batteries (LIBs) are playing a crucial role in today’s technology. Unlike the technological advancement on LIBs anode electrodes, where they have high capacities and low manufacturing cost; cathode materials are facing weighty drawbacks like lower capacity, volume changes and distortions affecting the mechanical integrity of cathode and as a consequence of these limitations quite high manufacturing cost. LiNi0.50Co0.20Al0.30O2 (NCA) is one of the promising cathode materials that has been comprehensively utilized with various synthesis methods. The objective of the study is to synthesize NCA via solid-state reaction method and investigate the influence of sintering temperature of 750, 800 and 850 °C on the morphology of the powders by SEM. In this work, we started the NCA synthesis with a sol-gel method. The powder obtained from the dried sol was calcined as the initial thermal treatment. After that, the calcined samples were sintered with a stoichiometric amount of lithium carbonate at different temperatures. XRD analysis was performed in order to observe the phase analysis of the samples sintered at several temperatures. Electrochemical tests including cycle performance and cyclic voltammetry were also performed. Results indicated that the synthesized NCA cathode that was sintered at 750 °C had a favorable electrochemical performance and the capacity retention of NCA sintered at 750 °C is better than the ones sintered at 800 and 850 °C without capacity loss at various high C rates. The correlation between the cathode performance and the final microstructure was developed and this was directly related to the specific surface area and porosity of the materials.

Direct Hierarchical Fabrication of Sheet Like SnS2 Nanostructure on CNT as an Anode Material for High-Performance Lithium-Ion Battery Application

In recent years, two-dimensional (2D) layer structure metal dichalcogenides and their composites with 1D and 2D carbonaceous materials are considered as promising anode materials for lithium-ion battery due to their higher theoretical capacitance and conversion reaction with Li. Among several 2D metal chalcogenide SnS2 has appeared as an anode material for Li-ion battery applications due to optimistic high efficiency at lower redox potential. However, in practice the SnS2 as an anode material in Li-ion battery is suffering from its low intrinsic electric conductivity, structural instability and large volume expansion during charging reaction.

References

In this study, we have fabricated hierarchical SnS$_2$-CNTs composite on carbon cloth (CC) as an anode by binder free direct growth method for Li-ion application. We adopted two-step fabrication methods: CNTs were prepared by a microwave plasma-enhanced chemical vapor deposition (MPECVD) and followed by solvothermal process to synthesize uniform tin disulfide (SnS$_2$) nanosheet on CNTs (SnS$_2$-CNTs). X-ray diffraction, Raman's spectroscopy, FE-SEM and HR-TEM studies showed that the as synthesized SnS$_2$-CNTs possessed a hierarchical composite nanostructure anode. The optimized hybrid SnS$_2$-CNT anode showed superior electrochemical performance in Li-ion battery, indicating highest performance of 1250 mAh/g at 645 mA g$^{-1}$ after 120 cycles with high rate capability. The direct growth SnS$_2$-CNT hybrid hierarchical architectures showed the synergistic effect for superior electrochemical performance due to improved surface reactivity, electrical conductivity and strong mechanical strength of insulating SnS$_2$ in composite anode material. We believe our hierarchical SnS$_2$ nanosheet grown on CNT makes this a promising anode material for Li-ion battery application.

LiSICON Structured Ortho-Germanates as Cathode Material for Li-Batteries
including Li2MnGeO4 and Li2MnPO4F (M = Fe, Mn or Co). In the case of Li2FeSiO4, its operating voltage vs. Li/Li+ (2.8 V) and specific capacity of 166 mAh g⁻¹ lead to energy densities in the range of 500 Wh kg⁻¹, which is only slightly less than that of LiFePO4. Recently, another lithium iron silicate, Li2Fe2O4·SiO2 has been investigated. Li2Fe2O4·SiO2 has a similar structure to lithium super ionic conductor (LiSICON) Li2Zn3GeO4 and exhibits better kinetics than Li2FeSiO4 at higher discharge rates. However, iron silicate-based materials have an operating potential of 2.8 V vs. Li/Li⁺ and compounds possessing the features of Li2Fe2O4·SiO2 with higher operating voltages are of considerable interest.

The similarity in structure between the LiSICON Li2Zn3GeO4 and Li2Fe2O4·SiO2 has motivated us to investigate the electrochemical properties of compounds with the chemical composition of Li2MnGeO4 (M = Mn, Co). While Li2MnGeO4 has already been studied, to the best of our knowledge, this is the first report of the synthesis and properties of the Mn isomorph, Li2MnGeO4. In contrast to the Co compound that can be synthesized at 900°C in air, the Mn compound has been synthesized under argon at 700°C to obtain the proper Mn valence. The Co and Mn materials show very different electrochemical properties. Whereas the Li2MnGeO4 exhibits very little redox activity, the Li2MnGeO4 can be charged and discharged between 1.5 and 4.8 V vs. Li/Li⁺ with lithium capacities in excess of 100 mAh g⁻¹, which is close to the capacity of 97 mAh g⁻¹ for one electron redox reaction. Interestingly, the (de)charge curves vary monotonically with lithium content, suggesting a single phase (de)chemical mechanism. Additional details regarding the kinetics of Li2MnGeO4 and comparisons to Li2Fe2O4·SiO2 will be presented.

Conventional Carbon Coated CZTS Anode Material for High Capacity and High Rate Capability in Lithium-Ion Battery Applications

Bhav Venu Gopal,1,2,.Zero Syunn Hidaru,1 Satyanarayana Moru,2 Indrajit Shown,1 Anir Sabbah,1 Heng-Liang Wu3, Chih Wei Chu1, Chih-Han Lee1, Li-Chyong Chen1 and Kuei-Hsien Chen1,4; 1Institute of Atomic and Molecular Sciences, Academia Sinica, Taipei, Taiwan; 2Department of Engineering and System Science, National Tsing Hua University, Hsinchu, Taiwan; 3Nanoscience and Technology Program, Taiwan International Graduate Program, Academia Sinica, Taipei, Taiwan; 4Center for Condensed Matter Sciences, National Taiwan University, Taipei, Taiwan; 5Research Centre for Applied Sciences, Academia Sinica, Taipei, Taiwan.

Investigation of novel electrode materials with high areal capacity, faster electron transport kinetics, and high Li ion diffusion are currently one of the most active frontiers for improving energy density of lithium ion batteries (LIBs). In order to fulfill these demands of LIB’s, herein, we developed 3D structure of CZTS flowers by hydrothermal method and followed by simple and facile carbon coating in ex-situ step. A systematic electrochemical performance behavior has been carried out at different amount of carbon coating. The developed nanoscale carbon coating enhanced conductivity of CZTS and buffer the mechanical stress/strain induced over extended cycling. As a results, carbon-coated 3D structured CZTS showed high areal capacity about 1-2 mAh/cm² as well as high gravimetric capacity (1210 mAh/g) combined with excellent stability (100 cycles) and high rate capability (1500 mAh/g, 920 mAh/g and 425 mAh/g at 500 mA/g, 2000 mA/g and 5000 mA/g) is superior to other metal chalcogenide materials. This study highlights the potential importance of conformal carbon coating over electrode material as an effective strategy for enhancing the columbic efficiency and charge storage kinetics of active material.

Exploring Novel LiCe(WO4)2 Polymorphs as Anode Materials—Synthesis, Crystal Structure and Electrochemical Studies

Archanaka K. M1, Debasmita Dwibedi2, Prabeer Barpanda3, James Hester3, Diptikanta Swain4 and Nalini G. Sundaram1; 1Poornaprajna Institute of Scientific Research, Sadashivanagar, India; 2Materials Research Centre, Indian Institute of Science, Bengaluru, India; 3Australian Nuclear Science and Technology Organisation, Lucas Heights, New South Wales, Australia; 3Solid State and Structural Chemistry Unit, Indian Institution of Science, Bengaluru, India.

Rechargeable batteries have attracted much attention in recent years with the growing demand for energy to empower modern consumer electronics and stationary power grids. Electrode stability is found to play critical role in determining electrochemical activity of polyanionic compounds, among many (MoO₃)ₓ (and (WO₄)ₓ) that have gained recent attention due to their greater polyanionic stable framework. In this context, AT(MOₓ)₂ₙ where A=alkali metal ion, T=Transition metals such as (Fe, Co, Y and Rare earths), M=MnxMoₙ based oxide materials are multifunctional disordered materials recently studied for lithium ion batteries. Although the existence of polymorphism is well established in many of the alkali rare earth double tungstates, to date, detailed phase transformation, precise crystal structure analysis of LiCe(WO4)₂ polymorphs and electrochemical properties is not yet discussed. Therefore, an attempt has been made to correlate the electrochemical activity of α-phase and β-phase with the crystal structure insights obtained via high temperature neutron diffraction and further supported by Raman studies.

Polymorphs of LiCe(WO4)₂ [α-LiCe(WO4)₂ and β-LiCe(WO4)₂] were successfully synthesized by citric acid assisted sol-gel method for the first time. Phase purity and crystallinity was confirmed by powder X-ray diffraction studies; and further characterized by FESEM, Raman spectroscopy and TG-DTA techniques. Investigation of the effect of calcination temperature and time suggested the existence of an irreversible structural phase transition from low temperature (LT) β-phase to high temperature (HT) α-phase, which was systematically followed by high temperature neutron diffraction (HT-NPD) studies. Rietveld refinements using room temperature NPD data revealed that the α-LiCe(WO4)₂ crystallizes in tetragonal crystal system (I4/m) in a Scheelite type structure, while β-LiCe(WO4)₂ material crystallizes in triclinic system (P-1) in a LiPb(WO₄)₂ type structure. Further, β-LiCe(WO4)₂ undergoes a reconstructive phase transition where the WO₆ octahedra rearranges to WO₄ tetrahedra at high temperatures in α-phase and this is further supported by Raman analysis. Electrochemical analyses of the anodic redox activities of these polymorphs were carried out via galvanostatic and cyclic voltammetry measurements. Interestingly the β-phase showed promising charge-discharge cycling compared to the α-phase, which could be attributed to the easy diffusion of Li-ions in between the parallel layers of WO₆ octahedra. To the best of our knowledge this is the first study elucidating the synthesis, detailed crystal structure analysis, phase transitions and the electrochemical properties of LiCe(WO4)₂ polymorphs.

Conversion Reaction of Nanoporous ZnO for Stable Electrochemical Cycling of Binderless Si Microparticle Composite Anode

Donghyuk Kim1,2, Min Kyu Park1, Sang-Min Kim1,2, Seungmin Hyun2 and Seung Min J. Han1; 1Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of); 2Korea Institute of Machinery and Materials, Daejeon, Korea (the Republic of).

Novel binderless, additive-less Si electrode design was developed where a nanoporous ZnO matrix is coated on a Si microparticle electrode to accommodate extreme Si volume expansion for stable electrochemical cycling. Conversion reaction of nanoporous ZnO forms an ionically and electrically conductive matrix of metallic Zn embedded in LiO that surrounds the Si microparticles. Upon lithiation, the porous Li+Zn matrix expands with Si preventing extensive pulverization and Zn serves as active material to form LiZn to further enhance capacity. Electrodes with high Si mass loading of 1.5 mg cm⁻² were fabricated and a high initial capacity of ~3,900 mAh/g was achieved with excellent reversible capacity of ~1,500 mAh/g (areal capacity ~1.7 mAh/cm²) even after 210 cycles. A high first cycle coulombic efficiency of 117% was obtained owing to the conversion reaction of nanoporous ZnO, which is a unique feature in comparison to conventional Si anodes. Ex-situ imaging confirmed that the nanoporous ZnO coating maintained the coalescence of SiMPs throughout extended cycling. Therefore, the Li/ZnO matrix derived from conversion reacted nanoporous ZnO acts as an effective
buffer to lithium induced stresses from voltage expansion and served as a binder-like matrix that contributes to overall electrode capacity and stability.

Pore-Filling of Waste Biomass Carbon by 3D Nanoflowers and Many-Fold Enhancement in Capacitive Charge Storage
Mashtahat Mohd Yusoff, Bincy Lathakumary Vijayan, Bhupender Pal, Izzan Izwan Misnon and Jose Rajan; University of Malaysia Pahang, Kuantan, Malaysia.

Storage of electrical energy in media and protocols with high energy and power densities have received a revived interest due to high power mobile electrical devices, electric vehicles, and other disconnected from grid but electrically powered technologies such as drones and robots. As a result, many new battery concepts such as sodium batteries, lithium-air, and lithium-sulphur are currently under intensive research as a replacement for traditional lithium ion batteries. One of the promising replacement for batteries is supercapacitors owing to their potentially higher power density (~5 kW kg⁻¹) and longer life cycle (>100,000) compared to that of batteries; however, they have an unimpressive energy density, which is at least an order of magnitude lower than that of batteries. Allotropes and polymorphs of carbon from diverse sources are a universal choice to fabricate supercapacitor electrodes; owing to their renewability carbons from waste biomass is now an active area of research. Most of these biomass-derived carbons process a large volume of passive pores which do not contribute to the final functionality of the devices. In this paper we show that the passive pores could be effectively filled using 3D hierarchical ceramic nanostructures such as flowers and the resulting composite offer charge storage capabilities several fold higher than its constituents or when they are filled using conventional nanoparticles. Finely powdered kernels of oil palm seeds are used as the source of carbon; nanoparticles and 3D flower-shaped ceramic nanostructures are integrated into the pores of carbon via a simple wet impregnation method. The pure carbon showed a specific surface area of ~500 m² g⁻¹; and when used as an electrode for supercapacitive charge storage gave a specific capacitance (Cₑ) of 150 F g⁻¹ with cyclic stability (97% after 5000 cycles) in 1 M Na₂SO₄ electrolyte (achievable potential ~1 V). When the flowers are impregnated, the Cₑ increased five-folds whereas the carbons impregnated with nanoparticles did not even doubled. In addition to the enhanced charge storage, flowers-filled carbons showed improved potential window also; carbon with MnCoO₃ flowers showed the highest (530 F g⁻¹) with a potential window of ~1.2 V. The reason for many fold enhancement in Cₑ is systematically studied and shown that this increment resulted from efficient ion transport through pore channels. Newly prepared carbon composites could retain ~97 % of their initial capacitance even after 5000 cycles. The adopted methodology is simple, scalable as well as applicable for a broad range of pseudocapacitive materials.

ET06.06.21
Electrocatalysis of Polysulfide Conversion by MnO₂: Nanoflakes in High-Performance Lithium-Sulfur Batteries
Zhihao Yu, Ying Yang, Tiaoji Gao and TrungHieu Le; Department of Electrical Engineering, Tsinghua University, Beijing, China.

The MnO₂/CNF composite was synthesized from CNF and KMnO₄ by a one-step facile method. This composite was utilized as the cathode interlayer to suppress the shuttle effect of polysulfides in lithium-sulfur (Li-S) batteries. In addition, from the X-ray photoelectron spectroscopy data, the change of chemical valence of manganese was observed during charge-discharge cycling, which indicated the electrocatalysis progress in batteries. Thus, the Li-S batteries with MnO₂/CNF interlayer appeared a high-performance in high current rate due to the improved kinetic rate with the introduction of catalyst. The cells with MnO₂/CNF achieved an initial capacity 893 mAh/g, and remained at a reversible capacity of 640 mAh/g after 150 cycles in 1C, nearly three time higher than the retention of capacity cells without interlayer.

ET06.06.22
Intercalation Materials (Pyrophosphate and Metaphosphate) as Next-Generation Electrocatalysts for Rechargeable Sodium-Air Battery
Sou Yasuhara1, Yumi Yoshikawa2, Takashi Teranishi3, Shintaro Yasui3, Tomoyasu Taniyama1,3 and Mitsuru Itoh1;1 Tokyo Institute of Technology, Yokohama, Japan; 2Okayama University, Okayama, Japan; 3Nagoya University, Nagoya, Japan.

Due to rapid increase in energy demand present world needs to harvest energy in the form of electricity to fulfill the everyday growing demand. Electrical energy can be efficiently stored in electrochemical energy storage devices such as supercapacitors, batteries, and fuel cells. Among them, rechargeable (metal-ion/metal-air) batteries form the most promising and commercially viable solution. Owing to the light weight and high energy density, Li-ion battery (LIB) has been considered a major success in electric vehicles. However, phosphorus-based polyanionic materials (e.g. LiFePO4) have been proposed as robust and safe cathode materials for the next generation LIB. In addition to efficient intercalation chemistry, various phosphate-based compounds have been exploited to efficient bifunctional catalysis for water splitting showing good oxygen evolution reaction (OER) with appreciable oxygen reduction reaction (ORR) activity. Also low theoretical capacity associated to the high molecular weight of such phosphate-based system has withdrawn attention towards electrocatalysis and found to shown activity close to conventional and commercial electrolysis catalysts such as Pt/C and RuO₂ for air-battery application. Off-late, sodium-ion batteries (SIB) are being extensively explored as economic alternatives to LIB. Here, the electrochemical and electrocatalytic performance of pyrophosphates [Na₂MP₂O₇] and metaphosphates [NaM(PO₃)₃], have been explored to develop Na-ion and Na-air batteries. They can be easily synthesized by solution combustion as well as conventional solid-state method involving moderate annealing at 600 °C for 6 h.

Pyrophosphates: We have investigated the binary Naₓ(Feₓ₋₀.₅Znx)P₂O₇ (0 ≤ x ≤ 1) pyrophosphate family, where NaₓFeₓP₂O₇ (P = 1, 2) and NaₓZnP₂O₇ (P = 1, 2) end members are anisochronous. We will report the structural and electrochemical characterization of novel Naₓ(Feₓ₋₀.₅Znx)P₂O₇ (0 ≤ x ≤ 1) binary pyrophosphates. Further, we will describe the Na-insertion mechanism in Naₓ(Feₓ₋₀.₅Znx)P₂O₇ (x = 0, 0.25) obtained by a small-amplitude (incremental) techniques such as galvanostatic intermittent titration (GITT) and potentiostatic intermittent titration (PITT). Pursuing pyrophosphate chemistry, the superior bifunctional electrocatalytic activity of NaₓCoP₂O₇ will be demonstrated.

Metaphosphates: We will showcase (i) a 2.8 V Fe⁷⁺/Fe⁴⁺ redox activity in orthorhombic Na₅Fe₅P₄O₁₄ developed by combustion synthesis and (ii) a 3.2 V Co⁷⁺/Co⁴⁺ redox activity in cubic polymorph of Na₅Co₅P₄O₁₄. However, their high molecular weight leads to limited reversible capacity. Nonetheless, the presence of metal redox centres can be exploited to enhance electrocatalytic performance. We will demonstrate the electrocatalytic properties (e.g. OER) of the Fe, Mn, and Co analogues of metaphosphate. Synergising experiments with computational modelling, we will showcase the electrochemical and electrocatalytic activity of Na₅Fe₅P₄O₁₄ and Na₅Co₅P₄O₁₄ for the first time.

ET06.06.23
Enhancement of High-Rate Performance by High Permittivity Supported Materials in Thin-Film Lithium-Ion Battery
Seo Yasuhara1, Yumi Yoshikawa2, Takashi Teranishi3, Shintaro Yasui3, Tomoyasu Taniyama1,3 and Mitsuru Itoh1; 1 Tokyo Institute of Technology, Yokohama, Japan; 2Okayama University, Okayama, Japan; 3Nagoya University, Nagoya, Japan.

Li ion battery (LIB) is a most famous secondary battery because of its superior characteristics such as high working voltage, large specific capacity, lightweight and so on. However, capacity of LIB fades under applying large current, therefore the charge speed(current) is still restricted at least below 2C. For example, we needs approximately 2-3 hour to fully charge the smartphone. Realization of high-speed rechargeable LIB will make us possible to eliminate the charging time. We have reported that BaTiO₃ dot supported LiCoO₂ cathode exhibit better chargeability under high-rate charge/discharge.

Gas-Phase Synthesis of Si/SiNx Nanoparticles as Anodes for High-Performance Lithium-Ion Batteries—Study of the Effect of the Carbon Source on Electrochemical Performance Nicolas Eshraghi1, Abdelfattah Mahmoud2, Jérôme Bodart1, Bénédicte Vertruyen1, Rudi Cloots1 and Frederic Boschuhn2; 1GREENMat Laboratory, University of Liège, Liège, Belgium; 2LCIS Laboratory, University of Liège, Liège, Belgium.

Lithium-ion batteries have enjoyed great success and have outperformed other rechargeable battery system since 1980. However, Li-ion batteries face many challenges and limitations: safety, the low abundance of lithium in the Earth’s crust. Recently, Sodium-ion batteries attracted a lot of interest as a potential alternative to lithium-ion batteries for large-scale energy storage applications, due to the large natural abundance and lower cost of sodium. In recent years, fluorophosphates with the NASICON (Na Super-Ionic Conductor) type structure are considered among the most interesting series of cathode materials for Li/Na-ion batteries, because they exhibit rich chemistry, attractive lithium/sodium insertion properties and thus offer promising electrochemical properties [1]. Na2V3(PO4)3F0.5 (NVPF) attracted high attention thanks to its promising electrochemical properties. The inductive effects of both PO43- and F- allow for a high working potential combined with a high theoretical specific capacity due to the multiple oxidation states of vanadium[1-2]. One of the key drawbacks of Na2V3(PO4)3F electrodes is their low intrinsic electronic conductivity.

NVPF and NVPF/carbon composite materials were prepared by spray-drying method using the same conditions used in our previous work [2]. Spray drying is an effective and easily up-scalable route to prepare homogeneous multi-component powders, thus making it a suitable method to incorporate carbon in the composite powder. We used different carbon sources like conductive carbons (MWCNTs, Carbon Black, etc) and organic sources (PVA, Citric Acid, Ascorbic acid, etc) to prepare NVPF/carbon composite powders.

the structural, electrochemical, and morphological properties of the synthesized Na2V3(PO4)3F0.5 samples were systematically investigated in order to understand the influence of carbon source on structural and morphological properties and most importantly electrochemical performance of NVPF and NVPF/carbon composite cathode materials for Na-ion batteries. The chemical diffusion of Na ions was studied using results obtained by varying scan rates in cyclic voltammetry measurements. Raman spectroscopy is used to evaluate the quality in disordered carbon materials and its electronic conductivity [3] and compared the results with the results from EIS and cycling performance of different samples.

Gas-Phase Synthesis of Si/SiN nanoparticles as Anodes for High-Performance Lithium-Ion Batteries Stefan Kilian1, Lisong Xiao1, Hartmut Wiggers1, 2 and Christof Schulz1, 2; 1Institute for Combustion and Gas Dynamics – Reactive Fluids, Universität Duisburg-Essen, Duisburg, Germany; 2Center for Nanointegration Duisburg-Essen (CENIDE), Universität Duisburg-Essen, Duisburg, Germany.

Silicon has emerged as the most promising component in anode materials for next-generation lithium-ion batteries (LiIBs) owing to its natural abundance, relatively low working potential, and its high theoretical storage capacity of 3579 mAh/g. However, the practical application of Si-based anodes is severely hindered by its low intrinsic electrical conductivity and its large volume change (~300%) during charging and discharging. The resulting mechanical stress causes rapid pulverization of the silicon, and insulation and disconnection of the active material from the current collector. These failure events can cause rapid degeneration of the Si electrode and is especially prominent for silicon particles exceeding the size of a few hundred nanometers. Thus, recent research mainly focuses on nanostructures and nanocomposites that tolerate the volume change.

A very promising way to stabilize silicon in LIB anodes is the incorporation of nitrogen, which has been shown to significantly improve the cycle performance. We therefore developed a scalable gas-phase synthesis method based on the pyrolysis of monosilane in ammonia-rich atmosphere. Therefore, we are able to synthesize Si3N4 core/shell nanoparticles for high-performance anodes. Their electrochemical performance can be increased by adjusting the synthesis parameters, thus affecting stoichiometry, Si3N4 ratio, morphology, particle size, and crystallinity. FTIR measurements confirm the synthesis of high-purity silicon nitride coatings avoiding SiH, Si-O, or Si-OH functional groups that might increase parasitic surface reactions. First results show significantly enhanced cycling performance of LIB-electrodes comprised of Si3N4 nanoparticles. Electrodes made of materials with low nitrogen content (approx. 5 at.%) show an initial specific discharge capacity as high as 720 mAh/g and a highly stable cycle performance with a capacity retention of 92% after 100 cycles. LIB electrodes comprised of Si3N4 nanoparticles with high nitrogen content (approx. 56.5 at.%) show much lower initial specific discharge capacities of 350 mAh/g. However, repeated electrochemical cycling seems to increasingly activate the material leading to a highly stable cycle performance and a retention of 125% after 100 cycles. These results imply that Si3N4 based LIB electrodes are promising candidates for high-performance lithium-ion batteries with very high durability.

Demands for rechargeable batteries with higher energy density have continued to rise as the amount of the energy required for next-generation portable electronic devices and electric vehicles increases. Rechargeable lithium sulfur (Li/S) batteries have been intensively studied over the past several years to fully utilize their high theoretical energy density (2600 Wh kg-1). However, the fundamental challenge to the commercialization of Li/S batteries is the practical design of sulfur cathodes that enable competitive electrochemical performance while maintaining the sulfur content and the loading high enough for the electrolyte/sulfur ratio and the cost of inactive components low. This paper presents a novel solvent drying method that is designed to help the wet-dry surface of the slurry endure the local tension stress from the shrinkage rate difference. Using our scaffold-supported drying approach, we have fabricated a crack-free sulfur electrode of ultrahigh loading (16 mg cm-2) with a high sulfur content of 65%. The compact structure without excessive carbon interlayers or 3D arc-architectured scaffolds allows the electrolyte/sulfur ratio to be as low as 7 and exhibits a good capacity retention of 11 mAh cm-2 over 80 cycles. Our results show that the crack-free and compact structure enhances the electrical network, the uniform reaction throughout the whole active mass, and thus the reversibility of the active mass. We also confirmed the applicability of the scaffold-supported drying approach to other types of scaffolds.
When coupled with a thoroughly-designed scaffold, the facile scaffold-supported drying approach provides limitless directions for high energy density batteries, closing the gap between research and commercialization of Li/S.

**Synthesis, Characterization and Comparison of Phosphonium and Piperidinium Based Ionic Liquid Electrolytes**

Jennifer Chapman Varela, Alexander Hino, Karthika Sankar, David Coker and Mark Grinstaff; Boston University, Boston, Massachusetts, United States.

The operation of lithium ion batteries (LIB) at elevated temperatures is a unique chemical challenge as the electrolyte materials must be thermally, electrochemically, and chemically stable at temperatures from 60 to 150 °C. Currently, carbonate based electrolytes do not satisfy these requirements and new materials are needed to fabricate high temperature operational LIBs. To that end, we have synthesized three phosphonium and three piperidinium based ionic liquids (ILs), and prepared 1.0 M lithium bis(trifluoromethylsulfonyl) imide (LiTFSI) salt electrolytes and characterized the thermal stability, viscosity, conductivity, and electrochemical stability window of each compound. An alkyl ether chain was introduced into the structure of both the phosphonium and piperidinium cationic cations and analogues containing one or two ether atoms were prepared. With these structural changes, we hypothesize: (1) that the distinct structural differences between the phosphonium and piperidinium cationic center will have substantial impacts on the conductivity and viscosity; and (2) the incorporation of the alkyl ether will have a concurrent reduction in viscosity and increase in conductivity. The phosphonium and piperidinium based ILs displayed large differences in all measureable outcomes; the phosphonium ILs were more conductive, less viscous and have larger electrochemical stability windows. For example, phosphonium ILs with one alkyl ether incorporated were electrochemically stable from -1 to 5 V at 25 °C while the analogues piperidinium ILs were only stable from -1 to 2 V at 25 °C. Furthermore, inclusion of the alkyl ether affected the viscosity and conductivity of the ILs; at 25 °C the piperidinium based ILs displayed varied conductivities with values of 1.40, 2.29, and 1.99 mS/cm with zero, 1 and 2 alkyl ether substitutions, respectively. These findings support further exploration of the phosphonium based ILs for high temperature operations of LIB.

**ET06.06.30**

**A First Principles Study of Spinel ZnFe₂O₄ for Electrode Materials in Lithium-Ion Batteries**

Haoyue Gao, Amy C. Marschilok, Kenneth Takeuchi, Esther Takeuchi, and Ping Liu; Department of Chemistry, Stony Brook University, Stony Brook, New York, United States; Department of Materials Science and Chemical Engineering, Stony Brook University, Stony Brook, New York, United States; Energy Sciences Directorate, Brookhaven National Laboratory, Upton, New York, United States; Chemistry Department, Brookhaven National Laboratory, Upton, New York, United States.

Spinel zinc ferrite (ZnFe₂O₄) is a candidate anode material for Lithium-ion batteries (LIBs), owing to its large theoretical capacity of 1000 mAh g⁻¹. Although the structure of ZnFe₂O₄ has been well studied, the origin of the high performance in LIBs materials is not well understood, in particular the fundamental understanding of the discharge mechanism is lacking. Here, we report a density functional theory (DFT) study of the discharge process at early stage from ZnFe₂O₄ up to Li₃ZnFe₂O₄ (x = 2), where both bulk and various relevant surfaces are into consideration. The estimated open-circuit voltages based on the stable intermediate bulk and surface structures identified by the DFT calculations are in good agreement with the experimental values, which enables the in-depth understanding of the discharge mechanism at the atomic level. Our study not only highlights the importance of the interplay among Li, O²⁻, Fe³⁺ and Zn²⁺ in enabling the high performance as LIBs materials, but also provides a design strategy for more stable particle morphologies with enhanced discharge performance.

**ET06.06.31**

**Mechanisms of (De)lithiation of Silver Containing α-MnO₂—Impact of Transition Metal Dissolution and Structural Evolution**

Lisa Housel, Jianping Huang, Paul Smith, Alexander B. Brady, Alyson Abraham, Mikaela Dunkin, Esther Takeuchi, Amy C. Marschilok, and Kenneth Takeuchi; Stony Brook University, Stony Brook, New York, United States; Brookhaven National Laboratory, Upton, New York, United States.

Crystallite size reduction of an electroactive material is a tool to increase deliverable capacity of a lithium ion battery by decreasing the path length for lithium ion diffusion. However, the reduction of crystallite size may also negatively impact the cycle life of the battery by promoting unfavorable reactions. The impact of crystallite size on the capacity retention, reversibility and rate capability of silver containing α-MnO₂ will be presented in light of two contributing mechanisms. First, delivered capacity may be hindered by the irreversible loss of the electroactive material to electrolyte. The transition metal may deposit on the anode, forming a layer that prevents ion migration and increases internal resistance of the cell. Quantitative dissolution studies conducted as a part of this work will be discussed. Second, capacity losses in α-MnO₂ materials may result from structural distortion of the 2x2 MnO₂ tunnels that make up the crystal structure. Observations regarding structural evolution as a function of (de)lithiation as determined by several complementary characterization modalities, including synchrotron based x-ray absorption spectroscopy, will also be discussed. In summary, this work quantitatively deciphers the effect of structural distortion and transition metal dissolution on capacity retention of electrodes with different crystallite sizes, facilitating rational future development of long life, high capacity energy storage systems based on tunnelled crystallographic motifs.
Metallic zinc has been regarded as an ideal anode material for the aqueous batteries systems for its high theoretical capacity (820 mAh/g), low negative potential (0.762 V vs. SHE), abundance, low toxicity and the intrinsic safety advantages that arise from nonflammable aqueous electrolytes. Recently, rechargeable batteries using zinc metal anode have been investigated extensively. However, an important barrier of the Zn based batteries is the poor cycle life. The cyclability of the traditional alkaline Zn based batteries is mainly restricted by dendrite growth, high solubility of discharge product (i.e. zincate) in the electrolytes, water loss from the liquid electrolyte, electrolyte depletion caused by the narrow electrochemical window. In most previous studies, the zinc-based aqueous batteries suffered from low columbic efficiency (CE) even using the high rate to minimize the side reaction. Significant excessive zinc has to be used to keep the cycle stability, results in the suboptimal utilization of the zinc theoretical capacity, as in the case of the lithium metal anode. The goal of achieving high CE in aqueous zinc metal batteries remained elusive.

The poor reversibility and low CE of the Zn metal anode are closely related with the Zn (II) cation solvate structure in the aqueous electrolyte. The hydration effects of the Zn (II) cation in water is so significant that the zinc hydroxide is easily formed. The slight but nonignorable water decomposition caused by the narrow stability window produces more hydroxyl ion and certainly aggravates the formation of zinc hydroxide. Zinc hydroxide converts into insoluble zinc oxide (ZnO) when the solubility limit of the hydroxide species is reached. Formation of solid ZnO can be a difficult process to reverse during recharge.

We report the development of a highly concentrated neutral electrolyte that alters Zn(II) solvation structure resulting in the dendrite-free plating of Zn metal with high CE. The suppression of the zinc hydration was achieved through the formation of [ZnTFSI] solvation structure instead of the [Zn(H2O)6]2+ solvation structure. The solvation structure change is ascribed to the introduction of the TFSI anion, which has the strong coordination to the Zn (II) cation in concentrated electrolytes. The solvation structure change was investigated via a combination of IR spectroscopy, nuclear magnetic resonance (NMR) spectroscopy, density functional theory (DFT) calculations and molecular dynamics (MD) simulations using polarizable force fields. We demonstrate an exceptional performance of zinc metal cells containing Zn-based aqueous electrolyte that delivered an unprecedented high practical energy density of 300 Wh/kg (based on both the cathode and anode electrolytes). This study opens an avenue for the highly efficient utilization of zinc metal electrodes for advanced energy storage applications while the fundamental knowledge gained can also be applied to other metal anodes.

The greatest remaining challenges facing the development of electrochemical energy storage – such as durability, safety and fast charging – lie in the development of appropriate materials. We present a concept where redox-active conjugated polymers are specially designed to operate in safe electrolytes (e.g. salty water). After identifying suitable organic conjugated polymer backbones which can be reversibly charged and discharged in aqueous solutions, we studied the role of the side chain on the electrochemical redox reactions. Polar side chains were attached to the backbone to increase ion conduction to allow for a reversible and fast charging and discharging of the materials in pH neutral sodium chloride water based electrolytes. In particular, ethylene glycol based side chains were attached for the polymer which becomes oxidized (p-type polymer) and zwiterion side chains for the polymer which becomes reduced (n-type polymer). This strategy enables the reversible charging and discharging of non-porous, single phase films (additive free) with non-toxic aqueous electrolytes on timescales of seconds. Finally, we demonstrate the use of the developed concept in a battery device combining the p- and n-type conjugated polymers as the cathode and the anode of a water based electrochemical storage cell that can be operated under a nearly unpolar
Lithium-ion batteries have reshaped our life with their omnipresence in portable electronics. However, increasing the specific energy of these batteries is reaching its limit and high-profile fire accidents (e.g., cell phones spontaneously combusting) cast doubt on their applications in electric vehicles and large-scale energy storage. Intrinsically safe batteries such as aqueous batteries and all-solid-state batteries are being actively studied in the battery community. Aqueous batteries use water-based electrolytes and offer robustness and environmental friendliness over lithium-ion batteries that feature flammable organic electrolytes. However, their adoption is plagued by the poor cycle life due to the structural and chemical instability of the anode materials. In the first part of talk, I will report several redox-active quinones (oxidized derivatives of aromatic compounds) as anodes for aqueous batteries by exploiting their structurally stable ion-coordination charge storage mechanism and chemical inertness towards aqueous electrolytes. We demonstrate three systems that coupled with industrially established cathodes and electrolytes exhibit long cycle life (up to 3,000 cycles/3,500 h), fast kinetics (320°C), high anode specific capacity (up to 200-395 mA h g⁻¹), and state-of-the-art specific energy/energy density for several operational pH values (-1 to 15), charge carrier species (H⁺, Li⁺, Na⁺, K⁺, Mg²⁺), and atmosphere (with/without O₂). Reversible proton-coupled electron transfer process is also first demonstrated in organic crystals. In the second part, I will discuss the application of quinones in all-solid-state batteries. One main challenge is the mismatch between low anodic decomposition potential of solid-state sulfide electrolytes and high operating potentials of cathodes which lead to a volatile cathode–electrolyte interface. I will show how molecular engineering of quinone molecules leads to high-capacity cathode materials in all-solid-state batteries that is chemically and electrochemically compatible with sulfide electrolyte.

Concentrated Mixed Cation ‘Water-in-Salt’ Solutions as Green and Low Cost High Voltage Electrolytes for Aqueous Batteries
Maria Lukatskaya1, Jeremy Feldblum2, David Mackanic1 and Zhenan Bao1; 1Chemical Engineering, Stanford University, Stanford, California, United States; 2Chemistry, University at Albany, State University of New York, Albany, New York, United States.

Electrolytes are an essential component of energy storage devices. Electrolyte composition has a significant impact on the safety, price and performance of the battery. Intrinsically nonflammable aqueous electrolytes can offer safer battery operation and decreased associated toxicity, but suffer from a smaller electrochemical stability window (and hence energy density) compared to traditional organic electrolytes. To circumvent the small electrochemical stability window, highly concentrated “water-in-salt” lithium organic ionic liquids which demonstrate significantly wider stability windows were recently proposed. However, the toxicity often associated with organic imides and very high price make the practical implementation of current water-in-salt electrolyte chemistries into commercial energy storage devices challenging. Herein, we address the challenge of developing new formulations of water-in-salt electrolytes caused by the lack of lithium salts having water solubility high enough to satisfy the water-in-salt condition. The proposed mixed cation strategy is whereby cheaper (by at least an order of magnitude) and more soluble salts featuring alkali cations beyond lithium, such as potassium, are used to create the water-in-salt condition. Co-dissolved lithium salts enable compatibility with traditional intercalation battery electrodes. We show that such highly concentrated electrolytes can provide the same benefits of the extended voltage window as imide-based electrolytes and, once combined with lithium salt, demonstrate compatibility with traditional Li-ion battery electrode materials while being low-cost and environmentally benign.

10:45 AM ET06.07.08
Stable Li-O₂ Battery Operations Using Water-in-Salt Electrolyte Qi Dong1, Xiahui Yao1, Yanyan Zhao1, Miao Qi1, Xi Zhang1, Hongyu Sun2, Yumin He1, Jingru Luo1 and Dunwei Wang1; 1Boston College, Brighton, Massachusetts, United States; 2Technical University of Denmark, Kongens Lyngby, Denmark.

Developing Li-O₂ batteries into a practical electrochemical energy storage technology hinges on the availability of a stable electrolyte. Because of the high reactivity of oxygen species in the Li-O₂ battery system, no known organic electrolytes satisfy the requirements for stable cell operations. The search for a compatible electrolyte system remains a significant challenge in Li-O₂ battery research. Here, we show that the water-in-salt electrolyte system, which is essentially super-concentrated aqueous LiTFSO₄ solution, is stable against parasitic chemical reactions with reactive oxygen species for Li-O₂ battery operations. This electrolyte provides the necessary functionalities to support aprotic Li-O₂ chemistries via reversible Li₂O₂ formation and decomposition. The lack of organic solvent molecules is a key advantage shown here. It eliminates the known decomposition pathways that would result in by-product formation from organic solvent degradations. Qualitative as well as quantitative product analysis show no measurable by-products formation in the WiS system. When the conventional carbon cathode is used, greatly improved cyclability of over 70 cycles can be achieved with the WiS electrolyte compared with the organic ones. When the carbon cathode is replaced with a stable carbon-free material, Ru catalyst decorated TiO₂ nanomets, up to 300 cycles of stable Li-O₂ battery operations are measured. The result sets the new benchmark in Li-O₂ battery research with quantitative product detection. It presents the stage for future studies to achieve the full potentials held by Li-O₂ battery as a stable, high-capacity electrochemical energy storage technology.

Fluorinating Interphases in Non-Aqueous, Aqueous and Hybrid Electrolytes Kang Xu; Electrochemistry Branch, U.S. Army Research Laboratory, Adelphi, Maryland, United States.

Solid electrolyte interphases (SEI) enable the Li-ion intercalation chemistries to operate reversibly beyond the thermodynamic stability limits of non-aqueous electrolytes. The chemical building blocks of SEI mainly come from solvents decomposition products. Exceptions arise, when salt anion are reduction-labile, or when salt concentration exceeds certain thresholds, where anion starts to participate in the interphases chemistry. In those latter cases, usually high F-content were often found in the interphases, and unexpected benefits from such interphases chemistry arose. However, high F-content in interphases were not always welcomed, thus, the morphology and structure of interphases should play an equally important role as their chemical compositions.

In this work, we explore the different manners that interphases could be fluorinated via the electrolyte sources, and the various battery chemistries that could benefit from such fluorination.
11:30 AM *ET06.07.10
New Electrolytes for Safer High Energy Li-Ion and Li-Metal Batteries Jun Liu; Pacific Northwest National Laboratory, Richland, Washington, United States.

There is a great need to significantly increase the energy and power density of Li-ion batteries while ensuring battery safety. Nonflammable electrolytes have been studied for a long time, but their compatibility with common electrode materials, particularly anode materials, remains an obstacle. Recently, electrolytes with high Li salt concentrations have demonstrated great promise for improved electrolyte stability. In this talk, we will discuss the key role of the salt to solvent ratio in nonflammable phosphate electrolytes. At a high Li salt-to-solvent molar ratio (~1:2), the phosphate solvent molecules are mostly coordinated with the Li⁺ cations and the reactivity of the solvent molecules toward the graphite anode can be effectively suppressed. High cycling coulombic efficiency (99.7%), good cycle life, and safe operation of commercial 18650 Li-ion cells with these electrolytes are demonstrated. In addition, these nonflammable electrolytes show significantly reduced reactivity toward Li-metal electrodes. Non-dendritic Li-metal plating/stripping in the Li/Cu half-cells is demonstrated with high coulombic efficiency (>99%) and good stability. Electrolytes developed using this approach significantly improved the cycling stability in high energy Li metal pouch cells.

SESSION ET06.08: Si Anode
Session Chairs: Xiaolin Li and Donghai Wang
Wednesday Afternoon, November 28, 2018

Si Anodes for Li-Ion Batteries Based on Dual Particle/Polymer Nanofiber Electrospinning Peter Pintauro¹, Ryszard Wycisk¹, Abhishek Mondal¹, Ethan C. Sel⁴, Rose Ruther² and Jagjit Nanda¹; ¹Vanderbilt University, Nashville, Tennessee, United States; ²Materials Science and Technology Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Particle/polymer electrospinning is a cost-effective and robust technique for the fabrication of high performance nanofiber electrodes for batteries and fuel cells. For Li-ion battery application, the advantages of fiber mats over conventional slurry cast electrode designs include: (i) a large electrode/electrolyte interfacial area for enhanced electrochemical reaction kinetics, (ii) a controllable interfiber void volume to ensure good electrolyte infiltration into the electrode, and (iii) micron/sub-micron diameter fibers with high nanoparticle content and short Li⁺ transport pathways in the radial fiber direction. Pintauro and coworkers have created and evaluated a number of electrospun electrodes for Li-ion batteries; C particles, mixtures of TiO₂+C particles, or mixtures of Si+C particles for the anode and a LiCoO₂+C mixture for the cathode, where the polymer binder was either poly(acrylic acid) (PAA) or poly(vinylidene fluoride). More recently, a new dual fiber design has been developed/investigated to prepare Si-based nanofiber anodes, where separate fibers of Si particles with PAA binder and carbon powder with polyacrylonitrile (PAN) binder are electrospun simultaneously onto a common collector surface at controlled solution flow rates. Such an anode worked well in half-cell tests, due to the presence of numerous intersection cross-points between electrochemically active but non-conducting Si/PAA fibers and electrically conductive C/PAN fibers. In this presentation, methods for preparing these internally nano-wired fiber composite anodes will be discussed, along with their performance and capacity during charge/discharge cycling. The effects of fiber composition (particle/binder weight ratio) and mat configuration (the relative amounts of Si and C fibers) on gravimetric, volumetric, and areal capacities at different C-rates will be presented.

Room-Temperature Synthesized SiOₓ, Negative Electrode Materials with Tunable Oxygen Content for Li-Ion Batteries Yidan Cao¹, ², J. Craig Bennett¹, R.A. Dunlap¹ and M.N. Obrovac³, ⁴; ¹Physics and Atmospheric Sci, Dalhousie University, Halifax, Nova Scotia, Canada; ²Chemistry, Dalhousie University, Halifax, Nova Scotia, Canada; ³Physics, Acadia University, Wolfville, Nova Scotia, Canada.

SiOₓ is a promising Li-ion battery negative electrode material because of its high capacity and unique microstructure that leads to good cycle life[1,2]. However, SiOₓ is typically made by high temperature methods that are expensive and difficult to realize, especially at lab scale. Here, SiOₓ negative electrode materials were synthesized using a simple and scalable method by controlling the air exposure time during ball milling at room temperature[3]. This method allows efficient control of oxygen content, and results in a similar microstructure as a commercially purchased SiOₓ. XRD and TEM results show that the SiOₓ negative electrode materials prepared by ball milling in air are composed of nanocrystalline Si embedded in an amorphous silicon oxide matrix. The very low initial coulombic efficiency (ICE) of conventionally made SiOₓ (measured here to be ~55% for Aldrich SiOₓ) is one of its major drawbacks. The ball milled SiOₓ samples synthesized here have much higher reversible capacities (>1500 mAh/g) and higher ICE values (>70%). The advantages of the synthesized SiOₓ are many: an inexpensive and simple synthesis process, high capacity, high ICE, and a special microstructure that protects Si from reaction with electrolyte, resulting in excellent cycling performance.

Here, a detailed study will be presented describing SiOₓ synthesis and how SiOₓ electrochemical performance in Li-ion cells is related to its composition and microstructure.

Pre lithiated Si and How It Affects the Early Stage Solid Electrolyte Interphase Formation Yun Xu¹, Kevin N. Wood¹, Jaclyn Coyle², Glenn Teeter¹ and Andriy Zakutayev¹; ¹National Renewable Energy Lab, Lakewood, Colorado, United States; ²University of Colorado Boulder, Boulder, Colorado, United States.

The solid electrolyte interphase (SEI) has been well acknowledged as a key component of the stability of Si anodes. During cycling, the fresh surface of lithium silicide is exposed because of the volume expansion and contraction of silicon. The exposed lithium silicide surface chemically reduces electrolyte...
and forms SEI. However, due to the lithium silicide being buried under SEI during formation, it has been difficult to characterize the SEI formed by chemical reduction of lithium silicide. In this work, lithium silicide (prelithiated silicon) thin films were prepared and chemically reacted with electrolyte. XPS was used to characterize the SEI formed on surface. This is the first time SEI formed by chemical reduction has been characterized directly. It was found that the SEI is composed of LiF, Li2O, Li2CO3 and organic species which are commonly found in SEI layers. The ratio between organic species and inorganic species is dependent on the additives. When Fluoroethylene carbonate (FEC) was added into electrolyte, more organic species formed, and less LiF formed. Early stage SEI formation was investigated by looking at the voltage profile and the irreversible capacity. It was found that at the first cycle, the Si anode only forms SEI by electrochemical reaction while the lithium silicide anode only forms SEI by chemical reaction. Cycling performance shows the SEI formed by chemical reduction is possibly better SEI than the SEI formed by electrochemical reduction. Prelithiated Si not only increases the columbic efficiency by reducing the electrochemical reduction, but also forms beneficial SEI by chemical reduction.

Prelithiation of anode materials is an important strategy to compensate for lithium loss as a result of the formation of a solid electrolyte interphase (SEI) at the surface of anodes in lithium-ion batteries. Conventional prelithiation reagents often present serious safety concerns due to the high flammability and unstable chemical nature. Here, we successfully developed a general one-pot metallurgical process to prelithiate group IV elements and their corresponding oxides, yielding prelithiation capacity approaching the theoretical specific capacity. As-synthesized Li2Zn, Li2Zr, Li2TiO3 and Li2ZnO composites (Z = Si, Ge, Sn etc) can serve as prelithiation reagents to increase the first cycle Coulombic efficiency of both graphite and alloy-type anode materials. Among all lithiated group IV alloys, Li4Ge exhibits the best stability under ambient-air conditions, consistent with the simulation results showing the large binding energy between Li and Ge atoms in Li2Ge2 crystal. Metallurgical lithiation of ZO2 results in composites with homogeneously dispersed active LiZ nucleus, the Si anode only forms SEI by electrochemical reaction while the lithium silicide anode only forms SEI by chemical reaction. Cycling performance shows the SEI formed by chemical reduction is possibly better SEI than the SEI formed by electrochemical reduction. Prelithiated Si not only increases the columbic efficiency by reducing the electrochemical reduction, but also forms beneficial SEI by chemical reduction.

Role of Polymeric Binders in the Degradation of Silicon Composite Electrodes Yikai Wang1, Dingying Dang1, Jiazhi Hu1, Xingcheng Xiao2 and Yang-Tse Cheng1; 1University of Kentucky, Lexington, Kentucky, United States; 2Chemical and Materials Systems, General Motors Global Research and Development Center, Warren, Michigan, United States.

Because of its high capacity (3579 mAh g−1 based on Li2Si) and proper delithiation voltage (~0.4 V vs. Li/Li+), silicon (Si) is considered one of the most promising negative electrode materials for future lithium ion batteries (LIBs). However, rapid capacity fading due to the huge volume change (~300 %) of Si during lithiation/delithiation hinders practical applications of Si electrodes. To address the problem of the volume change and to improve the performance of Si composite electrodes, polymeric binders are required to buffer the volume change of Si particles, maintain electrical conductivity, and improve mechanical integrity of Si composite electrodes. Desirable binders should be electrochemically stable, mechanically robust, and have high adhesion strength with Si particles. Nevertheless, limited attention has been paid to the role of binders in the degradation of Si composite electrodes from the viewpoint of mechanics, which is crucial for the design of polymeric binders for Si composite electrodes. In this study, we investigated the mechanical degradation of Si composite electrodes made with different polymeric binders, including polyvinylidene fluoride (PVDF), sodium-carboxymethyl cellulose (Na-CMC), and sodium-alginate (SA). The porosity, at both lithiated and delithiated states, and irreversible thickness change of all electrodes increased with increasing cycle number. Si/PVDF electrodes have larger volume change than Si/Na-CMC and Si/SA electrodes. Environmental nanoindentation measurements (in liquid electrolytes) showed that stiffness and hardness of Si composite electrodes decrease as the cycle number increases [Adv. Energy Mater. (doi.org/10.1002/aenm.201702578)]. Compared with Si/Na-CMC and Si/SA electrodes, Si/PVDF electrodes have poor mechanical integrity after 100 cycles. The mechanical degradation of composite electrodes correlated well with mechanical properties of binders and mechanical interactions between polymeric binders and Si particles. Our results provide insights into designing effective polymeric binders to improve mechanical integrity, microstructure stability, and electrochemical performance of Si composite electrodes.

Early-Stage Solid-Electrolyte Interphase Formation and Evolution for Silicon Anodes Yanli Yin1, Lei Cao1, Taeho Yoon1, Kevin N. Wood1, Elisabetta Arca1, Caleb Stetson2, Chunxiao Xiao1, Manuel Schnabel1, Glenn Teeter1, Chunsheng Jiang1 and Chunjie Ban2; 1National Renewable Energy Laboratory, Golden, Colorado, United States; 2Colorado School of Mines, Golden, Colorado, United States.

Lithium ion batteries containing silicon as anodes have gained much attention due to their potential high energy density. The electrolyte reduction and interaction with the surface of silicon anodes result in the formation of solid electrolyte interphase (SEI) at the interface, which determines the cycling performance and the battery reversibility. The electrolyte reduction and its interaction involve in the early stage of SEI formation for silicon anodes. The chemical properties of the early-stage SEI is absolutely vital in stabilizing the surface of silicon anodes, and determines the following electrochemical cycling performance. In this research, two questions will be addressed: Can the early-stage SEI layer prevent further reduction of electrolyte? Is the early-stage SEI stable in electrolyte? In order to better understand the early-stage SEI chemistry, a new methodology has been developed here to decouple the
Lithium ion batteries (LIBs) are widely used in several electric devices as the prominent energy storage system. The performance of LIBs with organic liquid electrolyte is closely related to the formation of the solid electrolyte interphase (SEI) film on the electrode surfaces, which is essentially composed from the decomposition products of both electrolyte and electrolyte additives [1]. In particular, it is widely accepted that electrolyte additives have strong influence on the capacity retention of LIBs as a result of improving and altering the resulting SEI structure. Organosilicon compounds have attracted recent attentions as a new candidate for electrolyte additives [2]. Intriguingly, it has been reported that the added organosilicon compounds improve the thermal and electrochemical stability of the electrolyte. However, since it is still difficult to experimentally observe the transient process of the SEI growth on the electrode surface, it has not shown how the organosilicon additive affects the SEI formation process. In order to gain physical insights into this mechanism, we theoretically investigated the SEI growth on the graphite anode surface by means of the atomistic reaction technique, called the hybrid Monte Carlo (MC)/molecular dynamics (MD) reaction method. As denoted by Takenaka et al., this reaction simulation allows us to numerically study the submicroscopic structure produced by a number of complex chemical reaction processes, such as the electrolyte reduction reaction on the electrode surface [3].

Employing the MC/MD method, we firstly investigated changes in the SEI film structures in the ethylene carbonate (EC)-based electrolyte systems with and without the organosilicon additive. Remarkably, the obtained results revealed that the excessive growth of the SEI film was suppressed by adding the organosilicon additive, which was consistent with the experimental observations. It was further elucidated that the products derived from the organosilicon molecules was stably aggregated in the vicinity of the anode surface, and protected the electrolyte solvents and lithium salts from the reduction decomposition reaction. These findings indicate that the organosilicon additive possibly improve the cycle performance of LIBs owing to the formation of the effective SEI film.

ET06.09.01
Phenyl Selenosulfides as Cathode Materials for Rechargeable Lithium Batteries Yi Cui1, 2, Joseph D. Ackerson1, Ying Ma1, Amruth Bhargav1, Jonathan Karty1, Wei Guo1, Likun Zhu1 and Yongzhue Fu1; 1Mechanical Engineering, Indiana University-Purdue University Indianapolis, Indianapolis, Indiana, United States; 2Mechanical Engineering, Purdue University, West Lafayette, Indiana, United States; 3Materials Science and Engineering, University of Wisconsin-Eau Claire, Eau Claire, Wisconsin, United States; 4Department of Chemistry, Indiana University, Bloomington, Indiana, United States; 5College of Chemistry and Molecular Engineering, Zhengzhou University, Zhengzhou, China.

In Lithium-ion (Li-ion) batteries, transition metal oxides have reached their capacity limits. The growing demand for high energy batteries has inspired great interest in exploring high-capacity cathode materials. In this regard, Li-S and Li-Se batteries are promising because elemental sulfur and selenium have high theoretical specific capacities of 1672 mAh g⁻¹ and 679 mAh g⁻¹, respectively. Although sulfur has an insulating nature (5.4×10⁻²⁸ S m⁻³), selenium below sulfur in the periodic table has a much higher electronic conductivity (1×10⁻³ S m⁻¹) and it also has a high volumetric capacity density of 3253 mAh cm⁻³ because of its high mass density (4.8 g cm⁻³). Recently, our group has demonstrated that organopolysulfides (RS⁻₃⁻) are a class of high-capacity cathode materials for rechargeable lithium batteries. The unique character of linear organopolysulfides is that short sulfur chains are chemically capped by R groups, therefore high-order polysulfides are significantly reduced initially and upon cycling. The obvious benefit is their low dependence on liquid electrolyte, in another word, it can enable high energy densities of batteries.

In this contribution, we select phenyl diselenide (PDSe, PhSeSePh) as a model compound which has a low specific capacity and poor cycling performance. The Se-Se bond can break in a 2e⁻ reduction reaction, but it has limited capacity as a cathode material. To increase its capacity, redox active species (e.g., sulfur) could be added in the middle of the selenium atoms. Herein, we mix PDSe with sulfur to form two hybrid compounds with 1:1 and 1:2 molar ratios, which almost double and triple the capacity of PDSe, respectively. Differential scanning calorimetry (DSC), Mass spectrometry (MS), scanning electron microscopy (SEM) and X-ray diffraction (XRD) are applied as characterizations. The experimental study is combined with the first-principles calculations based on the density functional theory (DFT) to reveal the electrochemical phenomenon.

Theoretical calculations suggest that phenyl selenol sulfide (PDSeS, PhSeS-SePh) and phenyl selenol disulfide (PDSeS₂, PhSeS₂-SePh) could form via addition reactions, which is supported by mass spectrometry analysis. These hybrid compounds show interesting electrochemical behavior in lithium batteries with three reversible discharge voltage plateaus involving frequent Se-S and S-S bond break and formation. PDSeS and PDSeS₂ show initial capacities of 252 mAh g⁻¹ and 330 mAh g⁻¹, respectively, followed by stable cycling performance with a capacity retention of >73% after 200 cycles at C/5 rate. In addition, they show steady rate capabilities. This study reports a novel strategy to increase the electrochemical performance of organo-diselenide by addition of sulfur. This strategy adds new members to the family of high-capacity cathode materials and provides a new way to explore Se/S containing hybrid compounds, which are valuable for rechargeable lithium batteries and beyond.

ET06.09.02
Wet-Chemical Synthesis of 1-5 nm Silicon Nanoparticles—Potential Applications in Various Technological Fields Mohamed Teyb Ould Ely;
Chemical Engineering, University of California, Santa Barbara, Santa Barbara, California, United States.

Wet-chemical synthesis of nanosilicon with diameters in the range of 1-5 nm has been challenging due to the lack of appropriate precursors that decompose in mild conditions. Conventional synthetic procedures use extreme temperatures. For example; carbothermal synthesis occurs at 1700 °C, molten salts synthesis takes place between 200-850 °C and aluminomagnesiothermal synthesis typically takes place above 600 °C. On the other hand, bottom up wet-chemical synthesis employs unsafe reagents such as sodium naphthalide, lithium hydrides, sulfuric acid, while top-down synthesis uses dangerous reagent such as HF-etching (of silicon wafers) followed by an elaborate post-annealing treatment to temperature exceeding 900 °C to mitigate surface oxidation problems.

We will discuss our recent synthesis of metallic nanosilicon by thermal decomposition (< 500 °C) of organometallic precursors in the absence of any reducing agent, molten salts or HF-etching process. This mild temperature synthesis prevents excessive growth leading to nanoparticles in the sub-5 nm ranges. The particles size can be increased by gradual sintering.

These nanoparticles are smaller than silicon Bohr Exciton radius (4.5 nm), luminescent and potentially useful for a variety of applications spanning from energy storage, displays, medical imaging to tunable LED lighting.

ET06.09.03
Combinatorial Screening of Ternary Li-Alloy Anodes for High Performance Lithium-Ion Batteries Yaoyu Ren1, Kedar Manandhar1, Drew Stasak1, Huilong Hou1, Jing Xu1, Joonho Koh1, John Lennon2 and Ichiro Takeuchi1; 1Department of Materials Sciences and Engineering, University of Maryland, College Park, Maryland, United States; 2NICE America Research Inc., Mountain View, California, United States.

Li-alloy anodes have long been recognized as a promising substitute for commercial graphite anode in lithium-ion batteries in terms of high specific capacity and safety. Alloying the active anode material (element A) with a buffer matrix material (element B) to alleviate the large volume change of the former during lithiation/delithiation cycle is a promising strategy to solve the major issue impeding the commercialization of Li-alloy anodes. However, while several Li-A-B alloys have been investigated previously, many more other combinations are waiting to be explored. Moreover, even in those reported combinations, the investigated compositions are limited. Thorough investigation on these materials using the traditional material synthesis strategy is more of a labor-intensive and time-consuming task than a scientific investigation. This then offers a great opportunity to the combinatorial material screening technique characteristic of high throughput exploration, which could be employed as a high efficient screen tool to narrow down the interesting material combinations and compositions for further investigation in a real battery condition.

Here, based on two model ternary alloy combinations, i.e., Li-Si-Al and Li-Co-Sn, we successfully demonstrated the efficacy and accuracy of the combinatorial material screening technique on exploring potential Li-alloy anode materials for lithium-ion batteries. Specifically, the lithium-free binary alloy thin film composition spreads were firstly deposited on silicon wafer using combinatorial co-sputtering. The crystallinity was tuned by varying the sputtering temperature. The as-deposited thin film was then lithiated in pouch cell to form Li-alloy ternary thin film for further characterization. XRD and Synchrotron XRD were used to identify the structural variation after and before lithiation. XPS was used to precisely determine the lithium concentration within the films.

ET06.09.05
Carbon Coated Si Nanosheets as Anode Materials for Li-Ion Batteries Sangwon Park1, Heonjin Choi1, Jung Hoon Ha2 and Byung-Won Cho2; 1Yonsei University, Seoul, Korea (the Republic of); 2Korea Institute of Science and Technology, Seoul, Korea (the Republic of).

Silicon (Si) has been extensively studied as an anode material in lithium ion batteries (LIBs) due to the high theoretical capacity of 4,200 mAh/g. However, Si is structurally unstable during lithium (Li) insertion into Si due to a 400% volume expansion and it acts as main cause of capacity fading. Herein, we report carbon coated silicon nanosheets (SiNSs) as anodes for LIBs. First, SiNSs are synthesized on grafoil current collectors with thickness and diameter of < 15 nm and > 10 μm, respectively. Our previous work demonstrated that SiNSs have great mechanical flexibility to accommodate the structural instability of Si during Li insertion. It is also ideal materials for fast Li storage by the high specific surface area and short diffusion length in SiNSs. Parylene is then coated on SiNSs as carbon source and thermally decomposed to carbon. The process provides excellent homogeneous coating of carbons on the SiNSs that have highly anisotropic morphology on a nanometer scale. The carbon coated on SiNSs (C-SiNSs) showed high capacity and stable cycle performance by the carbon layer that works as buffer for the Li insertion into Si and volume expansion. The C layer also provide high electrical conductivity that stabilize the electrochemical performance during cycles. These findings can contribute to fabricating high performance Si based anodes for LIBs.

ET06.09.06
Microstructure Evolution During Lithiation of Crystalline Silicon Wafer Jun Liu, Taeho Yoon, Chunmei Ban and Mowafak Al-Jassim; National Renewable Energy Laboratory, Lakewood, Colorado, United States.

Silicon is a promising anode material for lithium-ion batteries due to its large theoretical capacities [1]. The large volume expansion upon lithiation results in cracks, accompanied with a phase transformation from crystalline to amorphous silicon [2]. In this study, we investigate the surface morphology and microstructure of initial lithiated crystalline Si wafer by using scanning electron microscopy (SEM) and transmission electron microscopy (TEM). Cracks propagate along (100) and (110) directions. Interestingly, we find a crack-direction dependence of the amorphous Si layer. The distribution of Li is presented by STEM-EELS. We further use a coated Si wafer by MLD with ~ 5nm thickness coating layer, and this Si wafer is free of cracks after lithiation. The thickness of amorphous Si layer is significantly reduced to ~ 15nm, which is one magnitude thinner than that of lithiated Si wafer without coating.

Electrochemical stability windows of multi-component electrolytes, both solid polymer and organic liquid, largely determine the limitations of operating
regimes of Li-ion batteries. In order to increase energy densities and lifetimes of batteries, new electrolyte materials need to be discovered and optimized. Achieving higher operating voltages requires better understanding of electrolyte degradation and oxidation. Electrolyte degradation is difficult to probe experimentally, but computational tools allow one to study the relevant phenomena at the atomistic level, and thus obtain insights into oxidation mechanisms and possible design rules, as well as the ability to screen for better materials. However, reliable computational studies of the complex oxidation mechanisms remain challenging, considering the difficulty in obtaining material properties with greater accuracy than density functional theory (DFT) for large systems.

We present new insights into the oxidation mechanism that governs stability of multi-component polymer and liquid electrolytes and introduce an efficient computational method and a simple general model predicting the overall electrolyte stability. We find that explicitly including solvent molecules in the computation of the anion stability has a strong impact, and we show that this effect stems from electrostatic interactions between the molecules. Particularly, we find that across all chemistries studied, only one molecule in the system is oxidized. Building on this, we construct a model where two oxidation scenarios lead to different stability behaviors for the anion-solvent pairs, depending on their relative strength and geometry. Thus, we are able to provide a simple model that accurately predicts the stability of the pair depending on the ionization potential of the isolated anion and solvent. This model is not only useful for predicting the ionization potential (and thus the breakdown voltage) of the electrolyte species, but also gives insight into the atomistic details of bulk oxidation. This understanding of the microscopic details of oxidation allows one to formulate design rules as well as it provides better grounds to study subsequent degradation mechanisms and reactions. This simple model also allows for very fast screening of solvents and salts to find stable electrolytes.

High Performance Rechargeable Na/Ni Battery with Hierarchical NiCoAl-Layered Double Hydroxide/Carbon Electrodes
Seungyoung Park, Youngsik Kim and Hyunhyub Ko; UNIST, Ulsan, Korea (the Republic of).

With the increasing demand for renewable energy resources, sodium based-batteries have attracted enormous interest to realize the cost-effective and grid scale electrochemical energy storage (EES) devices because of high abundance and low cost of sodium in contrast to lithium worldwide. In the available sodium based-batteries, aqueous sodium batteries have fundamental advantages over non-aqueous due to safe and cost-effective aqueous electrolyte system. However, low operating voltage of aqueous Na-ion battery is a great challenge to realize high energy storage system. Here, we firstly report a high performance rechargeable battery that utilizes a metallic Na anode and a redox couple cathode of hierarchically nanostructured NiCoAl-layered double hydroxide (NiCoAl-LDH) cathode with enhanced performance by adopting trivalent atomic doping (Co³⁺, Al³⁺) into the Ni(OH)₂ layer. In this design, the wide potential range of the Na metal anode and the high capacity of NiCoAl-LDH enable an aqueous rechargeable Na/Ni battery with excellent energy storage performances. We employed hybrid electrolyte system using both non-aqueous and aqueous electrolytes, which are separated by the alkali-ion solid electrolyte (NASICON, Na₂Zr₂Si₂PO₈). Furthermore, the binder-free strategy was implemented to create the efficient cathode material of NiCoAl-LDH/carbon microfiber which eventually improve the electrochemical performance. The Na/Ni battery exhibits a stable operating voltage of ~3.1 V during discharge which outperforms the low cell voltage (~1.23 V) of aqueous rechargeable battery, a high capacity of ~350 mA h g⁻¹, and a resulting energy density of ~1085 W h kg⁻¹.

ET06.09.09
Synthesis of V₂O₅ Microstructures as Advanced Cathode Material for High Performance Lithium-Ion Batteries
Hemlata Dhoundiyal, Pintu Das and Mukesh Chander Bhatnagar; Physics, Indian Institute of Technology Delhi, New Delhi, India.

In the present time transition metal oxide vanadium pentoxide (V₂O₅) is consider as an excellent candidate for energy storage device material for Li-ion batteries (LIBs) with reference to its high charge storing capacity, low cost, superior layered structure and abundant material. With respect to its rich layered structure, which can reversibly accept the intercalation and deintercalation of Li-ions in the process of charging and discharging of LIBs. In this study, we report a simple hydrothermal procedure to synthesize the porous microstructure of V₂O₅ as a cathode electrode for LIBs with subsequent annealing temperature. The structural analysis stands for the orthorhombic phase of V₂O₅ and other sub oxides phase of vanadium are absent. The morphological study of V₂O₅ shows the flower like three dimensional micro flowers (having diameter ~5µm) self-assembled by Nano rods. In electrochemical cyclic voltammetry measurement three anodic peaks were observed corresponds to 3.27V, 3.05V and 2.08V as Li⁺Li²⁺ refers to three crystal phase α-V₂O₅ to β-Li₃V₂O₇, β-Li₃V₂O₇ to 6LiV₂O₇ and δ-Li₂V₂O₇ to γ-Li₃V₂O₇ respectively. And also three anodic peaks corresponds to Li-ion deintercalation. Which indicate the good reversibility of the electrode. In this report V₂O₅ microflowers deliver very high specific discharge capacity of 290mAhg⁻¹ and after 50cycles the capacity reduced to 196mAhg⁻¹, cycled between the voltage range 2.0-4.0V at the current rate 0.1C.

Bifunctional Conducting Polymer Coated CoP Core–Shell Nanowires on Carbon Paper as a Free-Standing Anode for Sodium-Ion Batteries
Jing Zhang and Yong-Mook Kang; Dongguk University, Seoul, Korea (the Republic of).

Recently, Na-ion batteries (SIBs) are attracting the scientific community as an alternative to the already well established Li-ion batteries, due to the more abundant reserves and lower price of Na resources. However, the larger radius of the Na⁺ than that of Li⁺ results in huge volume variation of electrode materials during Na⁺ insertion/extraction, leading to poor cyclability, which inhibits the NIBs widely application in the energy storage. Metal phosphides as potential anodes for SIBs have been recently been demonstrated owing to their higher specific capacities compared with those of carbonaceous materials. Unfortunately, most reported metal phosphides showed irregular particle sizes ranged from several hundred nanometers to tens of micrometers, leading to limited cyclic stability. Herein, polypyrrole (PPy), which is one of the representative conducting polymers, encapsulated cobalt phosphide (CoP) nanowires (NWs) grown on carbon paper (CP), finally realizes 1D core–shell CoP@PPy NWs/CP. The CoP core is connected to the PPy shell via strong chemical bonding, which can maintain a Co–PPy framework during charge/discharge. It also possesses bifunctional features that enhances the charge transfer and buffers the volume expansion. Consequently, 1D core–shell CoP@PPy NWs/CP demonstrates superb electrochemical performance, delivering a high areal capacity of 0.521 mA h cm⁻² at 0.15 mA cm⁻² after 100 cycles, and 0.443 mA h cm⁻² at 1.5 mA cm⁻² even after 1000 cycles. Even at a high current density of 3 mA cm⁻², a significant areal discharge capacity reaching 0.285 mA h cm⁻² is still maintained. The outstanding performance of the CoP@PPy NWs/CP free-standing anode provides not only a novel insight into the modulated volume expansion of anode materials but also one of the most effective strategies for binder-free and free-standing electrodes with decent mechanical endurance for future secondary batteries.

Strategic Architectures of Silicon Nanolayer-Embedded Graphite Hybrid for High Energy Lithium-Ion Battery Anodes
Minsung Kang, Pilgun Oh, Kwonhoon Kim and Chang Woo Kim; Metallurgical Engineering, Pukyong National University, Busan, Korea (the Republic of); Graphic Arts Information Engineering, Pukyong National University, Busan, Korea (the Republic of).
As the widespread emergence of modern technologies combined with human life, lithium ion battery (LIBs) has become one of the most important power supplier for mobile electronic devices, electric vehicles and stationary applications. However, the current LIBs provide a low energy density with approaching to the capacity limits, which emphasize the urgent need for high energy density battery systems. Herein, we have prepared the amorphous silicon nanolayer-embedded graphite/carbon (SGC) hybrids by chemical vapor deposition (CVD) method with developing the cost-effective and scalable pyrolysis system. With developing an industrial-relevant modified CVD process, sophisticated structure of optimum SGC hybrids achieved high reversible capacity (523 mAh g⁻¹) and unprecedented columbic efficiency (92%) at a 1° cycle in the industrial standard electrode density (> 1.6 g cm⁻³) and areal capacity loading of > 3.3 mAh cm⁻². Moreover, fabricated SGC electrode confirmed rapid increase of cycling efficiency upward of 99.5% over only 6° cycles and exactly allowed favorable cyclability of 96% capacity retention after 100 cycles and high rate capability comparable to the industrial graphite anode. In addition, the electrode composed of SGC hybrids entirely overcame the detrimental effects of the volume variation problems, exhibiting 23° of additional expansion excepting for graphite counterpart. This, in turn, completely preserved the electrical interconnectivity and mechanical integrity without any cracks and contact losses. Finally, a prototype full cell device is demonstrated with high voltage lithium cobalt oxide (LCO) cathode through the coin cell configuration, which achieved 92° of capacity retention after 100 cycles with considerable potential toward next generation target as practical devices. Consequently, this successful SGC hybrid anodes could be proposed for commercial extension to the next generation high-energy battery systems as a major breakthrough for electric vehicle or grid energy storage applications.

ET06.09.12

B₄C-Decorated Cotton-Derived Hollow Carbon Fibers as Free-Standing Electrode for Lithium-Sulfur Batteries with Excellent Cycling Stability Ruifan Zhang, Haoran Jiang, Maochun Wu, Ke Liu and Tianzhuo Zhao, Department of Mechanical and Aerospace Engineering, HKUST Energy Institute, Hong Kong, Hong Kong.

Lithium-sulfur (Li-S) battery has been regarded as one of the most promising candidates for traditional lithium-ion batteries (LIBs) in the practical application of electric vehicles, portable electronic devices, and other energy-storage areas because of its high gravimetric and volumetric energy densities (~2600 Wh kg⁻¹ and ~2900 Wh L⁻¹). However, there are still three main challenges before the Li-S battery is applied commercially feasible, including the insulating nature of sulphur and Li₂S, the polysulfide “shuttle effect”, and the large volume fluctuation of sulfur during lithiation and delithiation processes. Boron carbide (B₄C), a lightweight and low-cost refractory material, exhibits a remarkably intrinsic chemical stability and good electrical conductivity, which has been studied as potential electrode for batteries and fuel cells. However, to the best of our knowledge, the reports of this material applied in the Li-S battery system are almost none. In this regard, we here developed a B₄C-decorated cotton-derived hollow carbon fibers (B₄C-COHCF) as free-standing electrode for Li-S batteries, which was fabricated by a sintering method using the commercially cotton textile as both matrix and carbon source, amorphous boron powders as B source with Ni²⁺ as catalyst. Contrary to the conventional hollow carbon fiber electrode, the B₄C-COHCF was covered with numerous B₄C nanoparticles, and after sintering process, the hollow structure became porous: there were plenty of micro pores formed on the surface of the hollow fiber, which was beneficial for the specific surface area of the electrode. With the B₄C-COHCF electrode, the Li-S battery exhibited an initial specific capacity as high as 1200 mAh g⁻¹ at 0.1C, and when the current density increased to 4C, it still displayed a specific capacity of 600 mAh g⁻¹, indicating that the B₄C-COHCF electrode can truly improve the rate capability of the Li-S battery system. Besides, the battery showed an excellent cyclability, which has been stably operated for 2000 cycles with a Coulombic efficiency of 90% at the current density of 0.5C. More importantly, the capacity decay rate of the battery is as small as 0.022% per cycle over 2000 cycles. The work described in this paper was fully supported by a grant from the Research Grants Council of the Hong Kong Special Administrative Region, China (Project No. T23-601/17-R).

ET06.09.13

Flow Lithium Batteries—From Materials to Cell Design Francesca Soavi1,2, Francesca De Giorgio1,2, Federico Poli1,2, Alessandro Brillon1,2, Irene Ruggeri1, Catia Arbizzani1, Antonio Terella1 and Luca Morici1, 1University of Bologna, Bologna, Italy; 2BETTERY s.r.l, Massa, Italy.

Flow lithium batteries (FLB) represent an emerging technology that bring in a unique solution the advantages of the high specific energy of lithium batteries and the design flexibility of redox flow batteries that in turn permits to decouple energy and power. Different kinds of FLBs have been proposed, including batteries featuring semi-solid anolyte and/or catholyte with Li-ion intercalation powders, like LiFePO₄ or Li₄Ti₅O₁₂, dispersed in organic electrolyte, and Li/S and Li/O₂ flow batteries. In order to increase energy and power of FLB advancements in materials, design and concepts are required. Semi-solid slurries need to be properly formulated to provide high electronic and ionic conductivity for fast electrochemical processes and suitable rheological features for an efficient flow. Current collectors and electrolyte have to be properly selected to control solid electrolyte interface formation and enable electron transfer between the fluid electrode and the current collector. Furthermore, FLBs inherently need a smart cell design capable to maximise the power output and minimize the power loss related to the flow. This is particularly important in the case of viscous fluidic electrodes. A study on FLB semi-solid slurries that highlights the mutual effect of the half cell components on electrochemical performance is here reported. The nature of active material, conductive additive and electrolyte impacts on the electronic percolating network, and then on the cyclability of the flowable electrodes. Supercapacitated electrolytes based on tetraethylenglycol dimethyl ether-bis(trifluoromethane) sulfonimide electrolyte and slurries with different carbon content and type are investigated for use in flow Li-ion and Li/O₂ batteries. The electrochemical results are presented and discussed and related to the morphology, rheology and electrical conductivity of the slurries.

A semi-empirical study on the evaluation of the cell flow frame provide indications on design strategies that maximize power output of FLBs.

Controlled Formation of Artificial Solid Electrolyte Interfaces on Lithium-Metal via Fluorinated Gases Minfa He, Rui Guo and Betar M. Gallant; Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Replacing graphite anodes with lithium metal in Li-ion batteries can significantly boost achievable anode capacities by more than 10-fold (3860 mAh g⁻¹ vs. 372 mAh g⁻¹ for commercial) and also pave the way for other “beyond Li-ion” batteries such as Li-O₂ and Li-S batteries. However, the use of Li metal as the anode faces several challenges including the virtually infinite volume expansion, parasitic reaction with electrolyte, and dendrite growth during the Li plating-stripping cycling process. One promising strategy to overcome the latter two issues is to design an artificial solid electrolyte interface (SEI) which
can circumvent the compositional inhomogeneity and mechanical instability of the native SEI. Among multiple studies, lithium fluoride (LiF) has been suggested to play an essential role in the formation of SEI on Li metal; however, a safe and facile approach to grow a LiF-only SEI layer on Li still remains lacking. In this study, we report the formation of an artificial Li-only SEI layer on Li metal via the reaction between Li and perfluorinated gases under controlled conditions. After systematically employing different reaction conditions including gas pressure, reaction temperature, and reaction time, we are able to control the formation of the LiF layer with different crystallinity and spatial homogeneity, as confirmed by combined X-ray diffraction, X-ray photoelectron spectroscopy, and scanning electron microscopy analyses. We also investigate the effect of this LiF layer on the chemical stability of Li in common Li-ion electrolytes via electrochemical impedance spectroscopy, and probe the behavior of this LiF layer and identify its eventual failure mode under repeated Li plating-stripping cycling. This study sheds light on the controlled growth of an artificial inorganic SEI layer on Li, and its intimate link with the Li chemical stability and cycling behavior. Moreover, it presents a strategy to finely tailor the properties of artificial SEIs using safe and scalable SEI-forming reactants, which can potentially impart clean, well-characterized films that can address some of the major safety risks of previous approaches.

Impact of Aluminum Doping Methodologies on NCM622 Properties Michael Murphy1, Jessica Durham1, Wang Lixin2, Fu Zhou2, Derek C. Johnson3 and Albert Lipson4 1Argonne National Lab, Argonne, Illinois, United States; 2A123 Systems, Waltham, Massachusetts, United States.

Nickel-rich cathodes such as LiNi0.5Co0.2Mn0.3O2 (NCM) and Li[Ni0.5Co0.2Mn0.3]F0.05O2 (NCMF) cathode active materials with various amounts of Fe via hydroxide coprecipitation and calcination processes, which simulate the resynthesis of NCM in leach liquor containing Fe from spent lithium ion batteries (LIBs). The crystal structure and electrochemical performances of the synthesized NCM (i.e., NCM (0.05%), NCM (0.25%) and NCM (1.0%)), are investigated and compared with NCM. Structural analysis demonstrates that the incorporated Fe does not affect their layered structure with space group of the lattice parameters of NCMF increase as the Fe content increases. On the other hand, the structural perfection of NCMF gradually deteriorates with increasing the amount of Fe because of undesirable cation mixing between Ni2+/Fe3+ and Li+ sites. Moreover, the additional post-mortem analysis of energy dispersive spectroscopy on graphite surface after full cell cycling tests further confirms the positive effect of Fe on the improved capacity retention performance of NCMF. Therefore, even if Fe is regarded as an impurity component in the LIB recycling process, a small amount of Fe in the resynthesized NCM cathode material could favor high power and high cycling stability.

Impact of Aluminum Doping Methodologies on NCM622 Properties Michael Murphy1, Jessica Durham1, Wang Lixin2, Fu Zhou2, Derek C. Johnson3 and Albert Lipson4 1Argonne National Lab, Argonne, Illinois, United States; 2A123 Systems, Waltham, Massachusetts, United States.

Nickel-rich cathodes such as LiNi0.5Co0.2Mn0.3O2 (NCM622) have received considerable attention as a result of their high capacity and relatively low cost. However, owing to high nickel content NCM622 cathodes suffer from reduced cycle life and thermal stability. (1) Traditional approaches for modifying cathode materials have been employed in the past to improve the performance of Ni-rich cathodes, this includes incorporating a surface coating (Al2O3, AlF3, SiO2) or dopant (Al3+, Mg2+, F-) species which acts as a passivating layer between the cathode surface and reactive electrolyte or stabilizes the material, respectively. (2-9) The work reported in this poster illustrates NCM622 doped with Al during two distinct stages of the materials synthesis, either during co-precipitation of the MOH (M = 6:2:2 ratio of Ni, Mn, and Co) using a CSTR (continuous stirred tank reactor) or during the calcination process. The resulting product from both synthetic processes demonstrates the distribution of Al3+ throughout the entirety of the NCM622 particles. The presence of Al3+ in NCM622 was established via EDX/SEM mapping of a cross-sectional particle and slight expansions of the crystal lattice observed in XRD which is consistent with the inclusion of Al3+ atoms in the transition metal sites. Significant differences are observed in the capacity, rate performance, and thermal stability of the NCM622 cathode depending on whether doping occurred during co-precipitation or calcination. In particular, Al3+ doping during the co-precipitation process results in substantial improvements in all measured categories relative to both the pristine NCM622 control and materials doped via calcination. Since there are only trivial changes in particle size, morphology, and composition, this difference in performance appears to be the result of the synthesis methodology.

Piperidinium and Phosphonium Ionic Liquids as Electrolytes in Supercapacitors and Batteries at Elevated Temperatures Karthika Sankar, Jennifer Chapman Varela and Mark Grinstaff; Boston University, Boston, Massachusetts, United States.

The current organic electrolytes used for energy storage applications suffer from volatility, flammability, and limited cyclability at elevated temperatures. Ionic liquids being non-flammable and non-volatile are an ideal replacement for the unsafe organic solvents used today. The performance of supercapacitors containing piperidinium and phosphonium based ionic liquids (ILs) with an alkyl ether chain introduced into its structure are compared to
the traditional propylene carbonate (PC) electrolyte at 25 ℃ and 100 ℃. The phosphonium ILs are relatively stable with an electrochemical window of -1 to 5 V at room temperature while the piperidinium ILs are stable only up to 2 V. An activated carbon electrode based supercapacitor with the piperidinium IL electrolyte with 1 M lithium bis(trifluoromethylsulfonyl)imide (LiTFSI) at 100 ℃ cycles for more than 10000 cycles. There is a decrease of 30% capacitance after 10000 cycles at 100 ℃ for the piperidinium based electrolyte whereas a supercapacitor with PC having 1 M LiTFSI fails at 3200 cycles. A 3.5 X improvement in energy density for piperidinium based supercapacitor is observed upon going from room temperature to 100 ℃. The wider electrochemical stability window makes the phosphonium IL a better candidate as an electrolyte in lithium ion batteries. Studies on phosphonium ILs as electrolytes in supercapacitors and lithium ion batteries at 25 ℃ and 100 ℃ are ongoing. These successful findings support the basis for the replacement of organic electrolytes with IL based electrolytes in energy storage devices at high temperatures.

ET06.09.18
Investigation of Li2O2 Nucleation on Flat Graphene Cathodes Dahyun Oh1, Erik Lara2, Noel Arellano2, Yong Cheol Shin2, Phillip Medina2, Jangwoo Kim3, Toan T4, Esin Akca4, Cagla Orgit-Akgun4, Gokhan Demirel5, Ho-cheol Kim6, Shu-jen Han6, Harleen Maune6 and Mahesh Samantar6; 1Chemical and Materials Engineering Department, San Jose State University, San Jose, California, United States; 2IBM Almaden Research Center, San Jose, California, United States; 3Korea Institute of Science and Technology Evaluation and Planning, Seoul, Korea (the Republic of); 4ASELSAN Inc., Ankara, Turkey; 5IBM T.J. Watson Research Center, Yorktown Heights, New York, United States.

Observing Li2O2 nucleation and oxidation on various cathode surfaces in Li-oxygen batteries was challenging with three-dimensional porous electrodes. In particular, examining the effect of a catalyst on preventing cathode clogging in porous cathode was hard to investigate visually. Here we study the use of CVD grown graphene in two-dimensional configurations as Li-oxygen battery cathodes to easily examine the oxygen reduction reaction (ORR) and oxygen evolution reaction (OER) on various cathode surface structures. The composite structure made of metal oxides and carbon surface is created by electron-beam lithography or simple wet transfer method to investigate the Li2O2 distribution during Li-oxygen battery discharging and charging on composite cathodes. Furthermore, since CVD graphene can be transferred to different substrates, the Li-oxygen battery cathode can be built by coating the graphene layer on top of structural components. We investigate few possible materials as a substrate for Li-oxygen battery graphene electrodes to demonstrate the easy incorporation of CVD graphene cathode to an existing device architecture. After investigating polymer, ceramic, or metal substrates, we learned that this structural material needs to be electrochemically inactive, and does not attenuate the ORR activity of graphene. In particular, we maximized the Li-oxygen battery discharge capacity of this planar graphene electrode by using the electrolyte formulations that promote the solvation of intermediate discharge products. Thus, not only serves as a model cathode, but 2D graphene also presented an improved storage capacity as a potential micro-battery cathode compared to one of the most common lithium-ion insertion based cathodes (e.g., LiCoO2). We obtained 20 % higher areal cathode energy density and 2.7 times higher cathode specific energy than that can be derived from the same volume or mass of LiCoO2. In summary, we investigate the Li2O2 distribution during ORR and OER and demonstrate the fabrication of micron scale devices where CVD grown graphene structures are used as 2D Li-oxygen battery cathodes. We believe that two dimensional CVD graphene cathode can facilitate the microscale device fabrication by simply transferring or coating the target device structure with flexible graphene layers to integrate the energy storage component without complications.

ET06.09.19
Stable Metal Anode Enabled by Porous Lithium Foam with Superior Ion Accessibility Ahmed M. Hafez and Daxian Cao; Mechanical and Industrial Engineering, Northeastern University, Boston, Massachusetts, United States.

Lithium metal anodes attract much interest recently for high energy battery applications. However, low coulombic efficiency, infinite volume change, and severe dendrite formation limit its reliable implementation in a wide range. In this study, we reveal outstanding stability in Li metal anode by designing a highly porous Li foam in a hollow structure with graphene as backbone. This unique porous structure is capable of tackling many lithium metal problems simultaneously: First, it assures uniform electrolyte distribution over the inner and outer surface of the lithium foam electrodes due to it is porous and hollow tube structure, and enhances the charge mobility by increasing the electrolyte contact area between the electrolyte and lithium electrode; Second, the foamy structure uniformly distributes the current throughout the 3D structure, and effectively suppresses dendrite formation; Third, the 3D porous structure can accommodate volume expansion and dissipate heat efficiently. This structure shows superior stability compared to its fully lithium covered foam, and bulky lithium foil electrode counterparts. The lithium foam exhibits small overpotential (~25 mV at 4 mA cm-2) and high cycling stability for 160 cycles at 4 mA cm-2. Furthermore, when assembled the porous lithium metal as anode in full cell with LiFePO4 as a cathode, the battery revealed high rate performance of 138 mAh g-1 at 0.2 C. The beneficial structure of lithium hollow foam is further studied through density functional theory (DFT) simulations, which confirms better mobility and uniform deposition of lithium during charging/discharging in porous structure, that can effectively suppress lithium dendrite formation.

ET06.09.20
Sulfur/Selenium Sulfide Composites as Promising Cathode Materials for High-Energy Lithium Batteries Gaind P. Pandey, Kobi Jones and Lamartine Meda; Xavier University of Louisiana, New Orleans, Louisiana, United States.

Lithium-sulfur (Li-S) batteries have attracted considerable attention as one of the most promising next-generation energy storage system owing to the high theoretical specific capacity (1675 mAh g-1), low cost, abundance and environmentally benign nature of sulfur. However, the poor electrical conductivity of elemental sulfur results in low utilization of sulfur specific capacity, and hence, insufficient specific energy of Li-S batteries. Selenium disulfide (SeS2), with a theoretical specific capacity of 1342 mAh g-1, is a promising cathode material as it has attractive merits over elemental sulfur. Because of the better conductivity of SeS2 than S, the electrochemical reaction kinetics of S/SeS2 are expected to be remarkably improved. Herein, to combine the high conductivity and higher density of SeS2 and high specific capacity of elemental sulfur, we investigated hierarchical architectures of carbon as effective hosts for S and SeS2. By a facile one-step melt infiltration method, we synthesized S/SeS2@carbon nanofibers (CNFs) composites in which S and SeS2 were uniformly distributed over the CNFs. The hierarchical S/SeS2@CNFs (S:SeS2, 1:2 w/w) electrodes shows good initial discharge capacity of 940 mAh g-1 at 0.1C rate with high mass loading of material (~6-8 mg/cm2 of composites) and >90% initial coulombic efficiency. The composite electrode shows more than 830 mAh g-1 specific capacity after 100 charge-discharge cycles at 0.1C rate.

ET06.09.21
Leveraging Titanium to Enhance the Performance of Silicon Anodes in Lithium-Ion Batteries Pui Kit Lee and Denis Y. Yu; City University of Hong Kong, Hong Kong, Hong Kong.

Silicon (Si) is one of the most promising materials for next-generation Li-ion battery anode since Si has a high gravimetric capacity (3570 mAh g-1) and a relative low lithiation and de-lithiation voltage (0.4 V vs Li/Li+). However, the major challenge when applying Si as anode material in Li-ion battery is its poor cycle performance. It can be attributed to drastic volume expansion of lithiated silicon (300% theoretical expansion). Approaches such as yolk-shell silicon-carbon or silicon-titanium dioxide composites have been proposed to improve the cycle stability of Si-based electrode. Basically, void space was created by forming a carbon or titanium dioxide layer with larger volume, which accommodates the expansion of Si during lithiation and improves cycle performance. However, these approaches do not fundamentally reduce the intrinsic lattice expansion of the Si. The larger volume in fact reduces the overall
In this work we focus on designing a successful direct bottom-up pathway to synthesize both the 2D monoclinic $\text{MFeF}_4$ and 3D orthorhombic $\text{M}_2\text{Fe}_2\text{F}_7$ (M = alkali metal) from 1D−fluoride precursor at low temperatures, utilizing a blend of topochemical approaches. Notably, the linear 1D chains originating from the precursor have significantly transformed throughout the topochemical conversion of 1D $\rightarrow$ 2D $\rightarrow$ 3D frameworks. In fact, the as−synthesized orthorhombic weberite $\text{M}_2\text{Fe}_2\text{F}_7$ has shown exquisite cycling stability and also the reversible capacity of $\sim 55$ mAh/g with low polarization. Hence, we have designed a new topochemical strategy by which multidimensional fluoride structures can be developed. This study is expected to open a new avenue on the topochemical synthesis which allows the transformation of the precursor attaining topological resemblance with the final product.

In this work we focus on designing a successful direct bottom-up pathway to synthesize both the 2D monoclinic $\text{MFeF}_4$, and 3D orthorhombic $\text{M}_2\text{Fe}_2\text{F}_7$ frameworks. The resultant Si−Ti thin film is dense and is firmly deposited onto the foil. Therefore, the intrinsic electrode thickness variation can be monitored by in-situ dilatometer. 100 at% Si film electrode shows a 1st discharge capacity of 3415 mAh g$^{-1}$ which is close to the theoretical capacity of Si (3570 mAh g$^{-1}$). However, its cycle life is poor and the capacity fades linearly for the first 10 cycles. At the 15th cycle, no capacity can be obtained. Addition of Ti into the thin film reduces available capacity but improves cycle performance. A film with 20 at% Ti gives a capacity of 1500 mAh g$^{-1}$, and the capacity retention is about 95% after 50 cycles with a high average coulombic efficiency of 99.58% (from 3rd to 50th cycle).

To understand the role of the Ti inside the Si matrix, the thickness change of the thin film during lithiation and de-lithiation is monitored by in-situ dilatometry. While 100 at% Si film electrode exhibits a thickness increase of 345% after full lithiation, the thickness change is reduced significantly to 130% when 20 at% Ti is added. Furthermore, Ti addition allows full mechanical reversibility after Li removal. Moreover, Raman spectroscopy shows that the interaction between Si and Ti is still observed after cycling, suggesting that Ti is playing an active role to maintain the integrity of the Si electrode.

More results on Si−Ti thin films will be presented at the meeting.

**An Aqueous Ca-ion Full Cell Comprising BaHCF Cathode and MCMB Anode**

Prasit Dutta and Sagar Mitra; Indian Institute of Technology Bombay, India, Mumbai, India.

There is a pressing need of new and effective cost and energy storage systems in concomitance with the fast development of solar, wind and other types of renewable sources of energy. The capability of high-rate cycling and environmental benignity at less expensive defines the ingress of upcoming energy storage systems. Multivalent ion batteries are emerging as a promising alternative of Li ion technology due to their natural abundance, safety, low cost proposition and higher volumetric capacity. But these batteries are still challenged by sluggish cation diffusion in the electrode material and high polarisation of the respective cations ($\text{M}^{2+}/\text{Zn}^{2+}/\text{Al}^{3+}$). Calcium ion on the contrary have low polarisation compare to Li-ion, thus enjoying the benefits of overcoming the kinetics issues in large. Here, we introduce a reversible electrochemical Ca-ion cell in conjunction with inexpensive aqueous electrolyte, 1 M aqueous $\text{Ca}(<\text{O})_2$; Prussian Blue analogue barium hexacyanoferrate (BaHCF) cathode half-cell provides a capacity of 70 mAh/g with around 93% reversibility and 97% discharge capacity retention after 200 cycle was observed. In full cell, carbon cloth, BaHCF and meso-carbon microbeads (MCMB) have been explored as the current collector, cathode and anode material, respectively. The full cell provides 40 mAh/g (based on the mass of cathode active material) capacity at 5 C rate till 100 cycles. We believe, the investigation of this simple full cell at the early stage of Ca-ion battery will pave a fast transition in the forthcoming energy storage systems.

**A Novel Topochemical Paradigm to Design Multidimensional Fluoride Cathodes for Sodium-Ion Batteries**

Nabadyuti Barman, Utsav K. Dey and Premkumar Senguttuvan; New Chemistry Unit (NCU), Jawaharlal Nehru Centre for Advanced Scientific Research, Bangalore, India.

Electrochemical energy storage is highly sought-after for mankind owing to increasing concerns regarding renewable energy resources. Albeit, invincible in the domain of battery research, Li−ion based materials possess some major drawbacks regarding the limited abundance, thermal runaway, expressiveness and environmental issues which refrain their inordinate usage. To unravel these intricacies, researchers have successfully employed sodium as a potential alternative which has significantly revitalized the field of battery research. Still, the discovery of Na−ion electrodes is basically centralized on the imported “know−how” knowledge from Li-ion chemistry. Primarily the layered oxides and polyanionic compounds have shown a long-standing impact on Na-ion battery (SIB) cathodes. Among all those myriad of compounds, the transition metal fluorides scintillate the structural, as well as electrochemical aspects due to the rich crystal chemistry, lies within, especially when it comes to the case of Iron-based fluorides which are inexpensive and consisted of earth−abundant precursors. For instance, ReO$_3$−type FeF$_3$ and NaFeF$_3$−based electrodes were reported to have good reversible capacity in SIBs. But this rich crystal chemistry can only be probed if suitable synthetic strategies are performed, by careful modulation of the spatial arrangement inside the crystals. The extreme challenge is to manipulate the homogenous connectivity between the anions without destroying the main crystalline matrix itself. This can be achieved by the unique methodology known as ‘Topochemical synthesis’ which allows the transformation of the precursor attaining topological resemblance with the final product.

**The Effect of Physical Properties of Manganese Dioxides in Aqueous Rechargeable Zinc Manganese Batteries**

Yang Wu1, Biswanath Dutta2, Jared Fee3 and Steven L. Suib1; 1Institute of Materials Science, University of Connecticut, Storrs, Connecticut, United States; 2Chemistry, University of Connecticut, Storrs, Connecticut, United States; 3Chem. Mater.

Rechargeable aqueous zinc ion batteries have been considered as reasonable substitutes for current primary batteries, since zinc manganese dioxide batteries were proved to be reversible in mild-acidic electrolyte. Recently, manganese dioxide polymorphs have attracted extensive attention as cathode materials due to zinc intercalation in their host tunnel or layer structures. Although phase-transfers from tunnel to layer or spinel have been reported, the complex intercalation chemistry remains ambiguous, especially effect of relative physical properties, such as electronic conductivity, tunnel size, morphology and porosity. The focus of this study will be a variety of porous nanostructured manganese dioxide with tunnels ranging from 1 X 1 (pyrolusite), 1 X 2 (ramsdellite), 2 X 2 (cryptomelane), 2 X 3 (romanechite), 2 X 4 (RUB-7). Our study shows zinc ion selectively yield an appropriate tunnel structure (1 x 2 or 2 X 2) based on current density. Urechinline morphology and mesopore are the key to enhance the battery performance as well.

**Foretops Metal Oxides/Carbon Composite Nanofibers as High Performance Anode Materials for Lithium-Ion and Sodium-Ion Batteries**

Mataz

foretops metal oxides are promising materials for high-performance anodes in lithium-ion and sodium-ion batteries due to their high theoretical capacity, low cost, and high energy density. However, these materials also exhibit several challenges, such as fast capacity fading, poor rate capability, and low Coulombic efficiency. In this work, we focus on synthesizing foretops metal oxides/Carbon Composite Nanofibers (FCNFs) as high-performance anode materials for lithium-ion and sodium-ion batteries. FCNFs are synthesized by a simple and scalable electrospinning process, followed by carbonization in an argon atmosphere. The resulting FCNFs exhibit a high surface area, well-defined pore structure, and high electrical conductivity. This study provides new insights into the properties and performance of foretops metal oxides/Carbon Composite Nanofibers as anode materials for lithium-ion and sodium-ion batteries.
We present results on the force spinning (FS) of Fe₂O₃/SnO₂/PAN and MoO₂/MoS₂/PAN precursors for the mass production of Fe₂O₃/SnO₂-carbon and MoO₂/MoS₂/C as anode materials for Lithium-ion and Sodium-ion batteries. The composite nanofiber anodes of Fe₂O₃/SnO₂/C and MoO₂/MoS₂/C are produced using centrifugal spinning and subsequent thermal treatment (calcination). The composite nanofiber anodes were porous and flexible. The nanofiber preparation process involved the centrifugal spinning of Fe₂O₃/SnO₂/PAN and MoO₂/MoS₂/PAN precursors into nanofibers and subsequent stabilization in air at 250°C and calcination at 700°C under an inert atmosphere. The flexible composite nanofibers were directly used as working electrode in lithium-ion and sodium-ion batteries without a current collector, conducting additives, or binder. The Fe₂O₃/SnO₂/C and MoO₂/MoS₂/C electrodes delivered high specific capacity of 550 mAh/g and 600 mAh/g respectively during the first sodiation cycle. The composite fiber electrodes showed high irreversible capacity and low coulombic efficiency at the first caused by the high surface area of the fibers and the SEI formation at the first cycle. The pre-lithiation of the composite fiber anodes resulted in improved capacity, lower irreversible capacity and high columbic efficiency of 99%. The simple processing method of Fe₂O₃/SnO₂/C and MoO₂/MoS₂/C composite fibers and corresponding electrochemical performance make them promising candidates for next generation and cost effective flexible binder-free anodes for Lithium-ion and Sodium-ion batteries.

Effects of Heat-Treatment Atmosphere on the High-Voltage Electrochemical Performance of Li₂ZrO₃-Coated LiNi₀.6Co₀.2Mn₀.2O₂ Electrodes

Xiaowen Zhan, Shuang Gao and Yang-Tse Cheng; University of Kentucky, Lexington, Kentucky, United States.

Layered Ni-rich oxide cathode materials have attracted much attention for the next-generation lithium-ion batteries due to their low cost and high energy density. However, they still suffer from poor cycling performance and rate capability especially at high voltage. Li₂ZrO₃ has been widely used as a coating material for high-voltage Ni-rich layered cathode materials due to its relatively high Li⁺ conductivity and good thermal, chemical, and electrochemical stabilities. In previous studies, the coating was heat-treated in either air or oxygen. However, the effect of the atmosphere on the composition and structure of the Li₂ZrO₃, as well as the electrochemical performance of the coated cathode materials is still unclear. Herein, we surface-modified LiNi₀.6Co₀.2Mn₀.2O₂ cathode material with a Li₂ZrO₃ coating prepared under dry air and oxygen flow, and systematically investigated the effect of coating atmosphere on their electrochemical behaviors. The Li₂ZrO₃ coating prepared in oxygen is largely amorphous. It not only provided surface protection against the electrolyte corrosion but also enabled faster lithium-ion transport. Additionally, oxygen atmosphere facilitated Zr diffusion from the surface coating to the bulk of LiNi₀.6Co₀.2Mn₀.2O₂, which stabilized the crystal structure and enhanced lithium ion diffusion. Consequently, LiNi₀.6Co₀.2Mn₀.2O₂ cathodes coated with Li₂ZrO₃ in oxygen achieved a significant improvement in high-voltage cycling stability and high-rate performance.

Alcoutlabi, Jonathan Ayala, Jorge Lopez and Antonio Elizondo; Mechanical Engineering, University of Texas Rio Grande Valley, Edinburg, Texas, United States.
Oxygen redox has garnered intense interest as a means to increase the energy density of transition metal (TM) oxide positive electrodes in lithium-ion batteries, as it enables additional lithium (de)intercalation capacity at high voltages beyond the usual TM redox capacity. However, most oxygen-redox-active materials discovered to date suffer from large charge-discharge voltage hysteresis and irreversible voltage fade over extended cycling, limiting their practical use. Several hypotheses have been proposed to explain the nature of the oxidized oxygen species in order to guide improvements to the electrochemical properties of oxygen redox. The general consensus is that in more ionic oxides (e.g., those with certain 3d TMs), reactive and unstable O\textsuperscript{2−} species are created when oxygen is oxidized, whereas in more covalent systems (e.g., those with 4d and 5d TMs) the increased hybridization allows for the formation of stabilizing, long (~2.3 Å) O\textsuperscript{2−} dimers. Accordingly, recent work has attempted to tune the covalency of the TM–O interactions to improve the reversibility of oxygen redox in 3d materials, but has found limited success. In this presentation, I propose that consideration of only electronic structure properties is insufficient to explain the electrochemical behaviors associated with oxygen redox, and that the intrinsic coupling of oxygen redox to defect formation and disordering is in fact more significant in determining its reversibility. I first show that in the commercially promising lithium-rich Ni/Mn/Co oxides, oxygen oxidation occurs simultaneously with migration of TMs into Li sites, forming TM\textsubscript{i} defects in the material bulk. By drastically altering the local oxygen coordination environment, these defects lower the oxygen redox voltage, which we observe experimentally to fall by ~1 V after the first charge. This redox voltage shift is a major driver of the charge-discharge voltage hysteresis in oxygen-redox-active materials and cannot be explained without considering the link between oxygen redox and structural evolution. By then investigating two model systems, I reveal the origin of the correlation between oxygen redox and TM\textsubscript{i} formation, wherein the oxidation of oxygen is not sufficiently stabilized by either long (~2.3 Å) O\textsuperscript{2−} dimers or O\textsuperscript{2−} species, and instead promotes the formation of short (~1.4 Å) O\textsuperscript{2−} dimers and short TM–O bonds. These species require the decoordination of oxygen to single-TM-coordinate, which is realized in the layered structure through the formation of TM\textsubscript{i} defects. I show spectroscopically that these defect-localized oxidized oxygen species exist in 3d, 4d, and 5d systems, suggesting that the electrochemical properties of oxygen redox in TM oxides may depend more on the structural mechanism of oxygen decoordination than the identity of the TMs. Finally, I use this understanding to propose a new pathway to achieving reversible oxygen redox by employing new structures outside the layered framework.

Significant research efforts have focused on improving the specific energy of lithium-ion batteries for emerging applications, such as electric vehicles and renewable energy resources. A rocksalt-type nanostructured Li\textsubscript{4}Mn\textsubscript{2}O\textsubscript{5} cathode material has been recently discovered that exhibiting a large discharge capacity of >350 mAh g\textsuperscript{−1}, involving cationic (Mn\textsuperscript{3+}/Mn\textsuperscript{4+}/Mn\textsuperscript{5+}) and anionic (O\textsuperscript{2−}/O\textsuperscript{−}) redox processes. However, the detailed structure of Li\textsubscript{4}Mn\textsubscript{2}O\textsubscript{5} and its corresponding phase transformation, as well as the origins of higher capacities are poorly understood. In this work, we use first-principles density functional theory (DFT) calculations to investigate both the disordered rocksalt-type Li\textsubscript{4}Mn\textsubscript{2}O\textsubscript{5} structure [using the special quasi-random structure method (SQS)] and also the ordered ground state structure. The ionic ordering in the ground state structure is determined via a DFT-based enumeration method, by exploring symmetrically-distinct Li–Mn and O–vacancy ionic configurations on the cation and the anion sites in the rocksalt structure, respectively. We use both the ordered and disordered structures to interrogate the delithiation process, and find that it occurs via a three-step reaction pathway involving the complex interplay of cation and anion redox reactions: i) an initial metal oxidation, Mn\textsuperscript{3+} → Mn\textsuperscript{4+} (Li\textsubscript{4}Mn\textsubscript{2}O\textsubscript{5}, 4 > x > 2), ii) followed by anion oxidation, O\textsuperscript{2−} → O\textsuperscript{−} (2 > x > 1), and iii) finally, further metal oxidation, Mn\textsuperscript{4+} → Mn\textsuperscript{5+} (1 > x > 0). This final step is concomitant with Mn migration from the original octahedral site to the adjacent tetrahedral site, introducing a kinetic barrier to reversible charge/discharge cycles. Armed with this knowledge of the charging process, we utilize high-throughput DFT calculations to study metal mixing in this compound, screening potential new materials for stability and kinetic reversibility. We predict that mixing with M = V and Cr in Li\textsubscript{4}(Mn,M)\textsubscript{2}O\textsubscript{5} will produce new stable compounds with substantially improved electrochemical properties. Our discoveries should generate considerable interest in the experimental battery community and give guidance to experimental studies of simultaneous cation/anion redox in high-energy-density electrodes.

Next Generation Battery Materials—Ni-Rich NMCs and LLZO

Marco M. Dossif; Lawrence Berkeley National Lab, Berkeley, California, United States.

Ni-rich NMCs (Li\textsubscript{Ni-x}Mn\textsubscript{x}M\textsubscript{y}O\textsubscript{2}; x > 2) are emerging as the next generation cathodes of choice for lithium-ion batteries intended for electric vehicle battery applications. While these materials have the potential of raising energy density due to higher practical capacities than NMCs with lower Ni content, they also suffer from abbreviated cycle life and thermal stability issues, particularly at high states-of-charge. To better understand what determines the thermal characteristics, we have prepared Ni-rich NMC materials with varying amounts of lithium content using the chemical oxidant NO\textsubscript{2}BF\textsubscript{4} and heated them at 950 °C for 10 hours. XRD studies show that there is a general trend to lower thermal stability with respect to phase conversion as lithium content decreases with nickel content increases, as well as a tendency to form products containing progressively more reduced transition metal ions and lower oxygen contents. While hard XAS Ni, Co and Mn K-edge experiments confirm this trend, showing that reduction occurs upon heating, soft XAS, which probes surfaces, portrays a more complicated picture. In some cases, metals on surfaces oxidize although they are reduced in the bulk. Transmission X-ray microscopy (TXM) experiments also show evidence of Ni migration upon heating for some of the materials. While modifications such as partial substitution or coatings may improve the thermal stability of Ni-rich NMCs in conventional cells, a longer term strategy may be to design completely solid state cells containing non-flammable ceramic electrolytes such as variants of LLZO (Li\textsubscript{7}La\textsubscript{3}Zr\textsubscript{2}O\textsubscript{12}), to
amplify safety hazards associated with thermal stability issues. In this talk, we will briefly discuss the properties of LLZO solid electrolytes and our strategies for the design of high-energy all solid-state lithium cells using LLZO and Ni-rich NMC cathode materials.

Towards Low Cobalt and Cobalt Free Cathodes for High Energy Density Lithium-Ion Batteries Jagjit Nanda, Ethan C. Self, Chengyu Mao and Ilia Belharouak; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Commercialization of lithium-ion batteries began in 1991 by Sony with development of LiCoO2 cathode coupled with graphite anode. Since then cobalt constitutes an important role in stabilizing current commercial cathodes for lithium-ion whether it is LiNi0.5Mn0.3Co0.2O2 (NMC) or LiNi0.85Co0.15Al0.05O2 (NCA). Apart from battery application, cobalt is widely used in electronics and magnetic recording industry with limited reserves and supplies worldwide. With growing market demand for advanced lithium-ion for both automotive and stationary storage, there is an increasing research activity in developing cathodes with minimal or no cobalt content. The talk will highlight some recent progress in stabilizing Ni and Mn based lithium excess composition using early transition metal such as Mo and Cr. Early stage electrochemical results and oxygen stability at high voltage (>4.4 V with respect to Li+/Li) of these composition will be presented. Recent progress related to compositional and interfacial modifications such as creating cation disorder, doping/substitution, surface coating to attain high oxygen stability and reversible anion redox will be discussed. 

Acknowledgment This research performed at Oak Ridge National Laboratory, is managed by UT Battelle, LLC, for the U.S. Department of Energy (DOE) under contract DE-AC05-00OR22725, is funded by Asst. Secretary, Energy Efficiency and Renewable Energy (EERE) Vehicle Technologies Office (VTO).

High-Nickel Layered Oxide Cathodes for High-Energy-Density Lithium-Ion Batteries Arumugam Manthiram; The University of Texas at Austin, Austin, Texas, United States.

Among the various cathode materials pursued over the years for lithium-ion batteries, layered LiMO2 (M = Mn, Co, Ni, and their solid solutions) oxides offer the highest energy density with an operating voltage of around 4 V. Each of the three transition-metal ions (Mn, Co, and Ni) in LiMO2 has its advantages and disadvantages with respect to structural stability, chemical stability, electronic conductivity, and environmental impact. The position of the metal 3d redox energies with respect to the top of the oxygen 2p band determines the chemical stability with respect to oxygen release from the lattice. On the other hand, the relative stability of the transition-metal ions in the octahedral vs. tetrahedral sites in the cubic close-packed oxygen array controls the structural stability. Since Ni2+ can be oxidized fully to Ni4+ without releasing oxygen from the lattice unlike Co3+, which can be oxidized only to ~3.5+ to avoid oxygen release from the lattice, and Ni3+ ion exhibits high stability in octahedral sites, there has been tremendous interest to develop layered LiMO2 cathodes with high nickel contents. However, cathodes with high Ni contents suffer from poor cycle life, thermal stability, and air stability.

This presentation will focus first on developing a fundamental understanding of the complexities that control the capacity fade, thermal stability, and air-reactivity of high-nickel layered oxide cathodes, employing samples with secondary particle sizes of ~10 microns and advanced bulk and surface characterization methodologies. In-depth understanding obtained with high-nickel layered oxide cathodes with Ni contents of as high as 94% and graphite anodes retrieved from full cells before and after thousands of cycles based on a combination of characterization techniques, viz., X-ray photoelectron spectroscopy, time-of-flight secondary ion mass spectroscopy, and high-resolution transmission electron microscopy, will be presented. Based on the profound understanding gained, the presentation will then concentrate on the design and development of layered oxide compositions with controlled bulk and surface structures as well as novel electrolyte solutions that are compatible with both the high-nickel layered oxide cathodes and graphite anodes to realize a robust electrode-electrolyte interphase. Based on the findings, viability to realize lithium-ion cells with cathode capacities of >220 mAh g^-1, high energy density, high power capability, and long cycle life will be discussed. Finally, approaches towards designing low-cobalt or cobalt-free cathode compositions will be pointed out.

10:30 AM ET06.10.06
Heterogeneous Cathode Materials Towards High Energy Density and Stable Alkali-Ion Batteries Linqin Mu, Muhammad Momirunnah Rahman and Feng Lin; Virginia Tech, Blacksburg, Virginia, United States.

The ever-increasing demand for renewable energy storage and electrifying transportation vehicles calls for developing high energy density electrode materials for rechargeable alkali-ion batteries. As one of the most important components of energy storage devices, cathode materials, such as alkali-ion containing layered oxide compounds play a crucial role in determining the energy density of batteries. Major efforts have been invested to push the cathode capacity approaching its theoretical limit while reducing the cost of raw materials. However, novel design strategies must be considered to reach the envisioned goal. Three-dimensionally homogeneous or gradient distribution of transition metals has been acclaimed the design principle for obtaining good performing layered oxide cathode materials. Counterintuitively, we discovered that highly heterogeneous cathode materials at multiple length scales can give rise to unexpected good battery performance. Such phenomenon is equally pertinent for multiple types of layered alkali-ion cathode materials (Li-ion, Na-ion, and K-ion). The heterogeneous nature of the cathode materials was characterized through variously advanced spectroscopy and imaging techniques (STEM, TXM, SEM, EDX, and XAS). Batteries assembled using such cathode materials in half/full cells with high-mass loading delivered unexpectedly excellent and stable electrochemical performance. The results show the promise of heterogenizing the elemental distribution of multicomponent alkali layered oxide materials and open up a new pathway to further develop the layered oxide cathode for high energy and stable alkali-ion batteries.

Unexpected Superior Cycleability of LiCoO2 at Upper Voltage of >4.6 V (vs. Li/Li+) for High-Energy Density Lithium-Ion Batteries Won Mo Seong, Kyungho Yoon, Myeong Hwan Lee, Sung-kyun Jung and Kisuk Kang; Seoul National Univ, Seoul, Korea (the Republic of).

The instability of LiCoO2 layered structure at >0.5 Li extraction has been considered as an obstacle for the reversible utilization of its near theoretical capacity at higher voltage cut-offs in lithium-ion batteries (LIBs). To date, much of previous researches have been focused on the surface engineering of LiCoO2 to extend its usable state-of-charge (SOC) range, which has proven to be effective in suppressing the phase transformation. Herein, in contrast to conventional belief, we verify the superior reversibility of bulk LiCoO2 with extended lithium extraction by ruling out the effect of damaged surface. A high-voltage cycling of uncoated LiCoO2 at 4.8 V (vs. Li/Li+) cut-off offers unexpectedly better cycle stability and lower polarizations than those at 4.6 V (vs. Li/Li+). In detail, it is revealed that the rigid cycle degradation at high-voltage cycling is mostly caused by the formation of a surface reactive layer...
composed of spinel phase, however these damaged surfaces are leached out at 4.8 V enabling its superior cycleability to 4.6 V-cycling. In the absence of the resistive surface, the capacity retention of LiCoO2 electrode with 4.8 V cut-off cycling could be remarkably high. This work découps the effect of the intrinsic instability of highly delithiated LiCoO2 and the surface degradation on the capacity fades toward practical high-voltage cycling and proposes that a rational strategy against the formation of the resistive phases would be a critical step for the full utilization of LiCoO2 with higher cut-off voltage cycling.

11:00 AM **ET06.10.08**

Concentrated Electrolytes for Safe and High-Voltage Batteries  
Yuki Yamada, Jianhui Wang and Atsuo Yamada; The University of Tokyo, Tokyo, Japan.

Severe safety concerns are impeding the large-scale employment of lithium/sodium batteries. Conventional organic electrolytes are highly flammable and volatile, which may cause catastrophic fires or explosions. Efforts to introduce flame-retardant solvents into the electrolytes have generally resulted in poor charge-discharge cycleability, because those solvents do not suitably passivate carbon-based negative electrodes. Here we report salt-concentrated electrolytes3-5 to resolve this dilemma. Our previous works demonstrate that concentrated electrolytes can form a salt-anion-derived passivation film via the downward shift of anion’s LUMO level resulting from the extensive anion coordination to Li+. Applying this strategy to a popular flame-retardant solvent (trimethyl phosphate), we demonstrate that fire-extinguishing concentrated electrolytes, without any additive or soft binder, allow stable charge-discharge cycling of hard-carbon and graphite negative electrodes for more than 1,000 cycles (over one year) with negligible degradation; this performance is comparable or superior to that of conventional flammable carbonate-based electrolytes. The unusual interphasial character of the concentrated electrolytes couple with their fire-extinguishing property contributes to developing safe and long-lasting batteries, unlocking the limit toward development of much higher energy-density batteries.

11:30 AM **ET06.10.09**

Enabling the High Capacity of Lithium-Rich Anti-Fluorite Lithium-Iron Oxide by Simultaneous Anionic and Cationic Redox  
Jun Lu; Chemical Sciences and Engineering Division, Argonne National Laboratory, Argonne, Illinois, United States.

Anionic redox reactions in the cathodes of lithium-ion batteries are enabling opportunities to double or even triple the energy density. However, it is still challenging to develop a cathode exploring the anionic redox for real-world applications using earth-abundant materials, due to the limited strategy to intercept the oxygenates from further irreversible oxidation to O2 gas. Here we report simultaneous iron and oxygen redox activity in a Li-rich anti-fluorite Li5FeO4 electrode. During the removal of the first two Li ions, the oxidation potential of O2 is lowered to approximately 3.5 V vs. Li+/Li0, at which potential the cationic oxidation occurs concurrently. These anionic and cationic redox reactions show high reversibility without any obvious O2 gas release. Moreover, this study provides an insightful guideline to design high-capacity cathode with reversible oxygen redox by simply introducing oxygen ions coordinated exclusively by Li+.

1:30 PM **ET06.11.01**

Using Multi-Modal and Multi-Scale TEM and TXM Imaging Techniques to Study the Structural Stability of High Ni-Content Cathode Materials  
Ruojian Lin1, Zulipia Shadike1, Seongmin Bak1, Hoolin L. Xin2, Xiao-Qing D. Yang3, YoungHo Shin4, Xiaojing Huang5 and Yong Chu5; 1Chemistry, Brookhaven National Laboratory, Upton, New York, United States; 2Center for Functional Nanomaterials, Brookhaven National Laboratory, Upton, New York, United States; 3Energy Systems Division, Argonne National Laboratory, Argonne, Illinois, United States; 4National Synchrotron Light Source II, Brookhaven National Laboratory, Upton, New York, United States; 5Chemical Sciences and Engineering Division, Argonne National Laboratory, Upton, New York, United States.

The promising application of high Ni-content layered oxide materials in Li-ion batteries has attracted increasing attention from the research community. Compared to traditional layered oxide materials such as LiCoO2 (LCO) or LiNi0.5Mn0.3Co0.2O2 (NMC333), high Ni-content materials can provide higher specific capacity and energy density. However, capacity fading and thermal runaway remain the main issues for high Ni-content layered oxides. In order to overcome these challenges, the in-depth understanding of the relationship between the structural changes and perform deterioration of high-Ni-content materials during charge-discharge cycling are critically needed. Using multi-modal and multi-scale TEM and TXM imaging techniques, the structure stabilization mechanism has been thoroughly studied to provide valuable guidance for future material design. The results obtained from our newly developed multi-scale characterization techniques will be reported, including the state-of-the-art aberration-corrected scanning transmission microscopy (STEM) imaging, STEM- electron energy loss spectroscopy (EELS), transmission X-ray imaging(TXM), X-ray diffraction (XRD), and X-ray absorption spectroscopy (XAS). These results show that such multi-modal and multi-scale characterization tools can help us to study the structural changes of high Ni-content materials during cycling. The structure degradation is highly correlated to the irreversible cation migration and intermixing at atomic level during extensive cycling. Also, we found that the surface plays a vital role in these materials.

2:00 PM **ET06.11.02**
Multi-modal correlative microscopy has been used extensively through the last decade in various research fields in order to overcome optimization challenges of complex materials systems. The multiscale aspects of these new functional or structural materials, such as nanostructured energy storage systems, and the complexity of their physical interactions, require new multi-modal and multiscale characterization tools in order to shed light on pertinent parameters controlling the process at a given scale, and the link between various scales.

3D Correlative microscopy allows simultaneous quantification of structural, morphological and compositional spatial distributions throughout scales, from which constitutive governing laws and effective properties can be derived. Main obstacles to its wide range usage are the simultaneous tracking of the sample within various instruments and the correlation between data sets obtained on dispersed zoomed-in ROIs (region of interest) within the sample. As a result, 3D correlative microscopy remains a time consuming, cumbersome, non-reproducible and limited-precision methodology.

In this abstract, an innovative procedure for multi-scale µCT (X-ray microtomography) and multiple volume-based ROIs with FIB/SEM is proposed. The procedure is applied to cutting edge NMC type (LiNi0.5Mn1.5O4) Li-ion batteries in order to study the effects of both defects and morphology on the batteries transport properties such as grain connectivity, porous media percolation and effective diffusivity.

This will allow nearly automatized data correlation and fusion between structural information provided by µCT with the morphological and compositional information obtained by FIB/SEM imaging at both micro and nano scales.

Two battery samples have been considered for this correlative study. First sample consists of a micro-layer of NMC type cathode material on an aluminum substrate. Micro-nano delamination features and cathode phase grain connectivity morphologies have been studied. Localized electric conductivity and effective diffusivity have also been calculated. Second sample considered is a LG MJ1 cell with the NMC type cathode and a Graphite/Si hybrid anode. Both structural and compositional anode/electrolyte and cathode/electrolyte interfacial distributions have been studied in micro and nano scales.

Chemical Origin of Oxygen Redox in LiFeO4 Revealed by Experimental and Theoretical XANES
Liang Li, Eungje Lee, John w. Freeland, Tim Fister, Michael M. Thackeray and Maria K. Chan; Argonne National Laboratory, Lemont, Illinois, United States.

It is commonly recognized that utilization of oxygen redox is an intriguing route for obtaining higher capacity of Li-ion batteries (LIBs). Despite numerous experimental and theoretical attempts to unravel the mechanism of oxygen redox behavior, the electronic origin of oxygen activities in energy storage of Li-rich LIB materials remains under intense debate. In this work, the onset of oxygen activity was examined using a Li-rich antifluoride material that has been reported to exhibit oxygen redox, namely Li1Fe0.5O2. Ab-initio Molecular Dynamics (AIMD) simulations were performed to investigate the structural response of oxygen matrix to delithiation. The oxygen K-edge X-ray absorption near-edge spectra (XANES) were modeled using Bethe-Salpeth equation (BSE) approach and compared with experiments, from which the oxygen redox mechanism was uncovered.

O2 Li-Rich Cathode Material for High-Energy-Density Li-Ion Batteries
Dingguo Xia; Peking University, Beijing, China.

The exploration of new high-energy-density cathode materials is one of the most challenging issues facing the development of next-generation lithium-ion batteries. The extraordinarily high capacity delivered by lithium-rich oxide cathodes have been nested to the contributions from both cationic and anionic redox processes. However, the oxygen anionic redox caused by the activation of the Li2MnO3 domain promotes the transition metal ion migration, leading to the transition of layer to spinel phases, demonstrating a severe voltage decay during cycling, which is the major obstacle preventing industrial application. Therefore, the exploration of new cathode materials that could enhance the energy density of Li-ion batteries is still one of most challenging issues that must be solved. Herein, we succeeded in preparing a new O2-type layered Mn-based Li-rich oxide with an atomic-size superstructure, which demonstrates a reversible capacity of ~400 mAh g−1 with a stable discharge voltage and a high charge/discharge efficiency during cycling.

There is increasing interest in utilizing lithium-excess cathode materials as new generation energy storage material instead of traditional layered materials such as LiCoO2 and LiNi0.5Mn1.5O4 because of their ultra-high charge capacity. However, lithium-rich materials still suffer problems such as low coulombic efficiency for the first cycle, voltage and capacity fading with extended cycling. Here we report the investigation of a promising high-capacity lithium-rich 3d-4d transition-metal layered compound. The incorporation of 4d transition metals here offers an uncharted phase space for mechanistic exploration as compared to the well documented 3d transition metal (TM) oxides. Utilizing state-of-the-art tools, we found that that a three-dimensional porous structure is formed in the interlayer and the 3d and 4d transition metals can segregate at the sub-micron scale after extended cycling. More surprisingly, at the nanoscale, we found that the 4d metal is expelled from the surface. In conjunction with ab initio thermodynamics calculations, this study for the first time reveals the intricate connection between the instability of the surface and the degradation of the layered cathode materials. More importantly, the revealed mechanism allows us to provide predictive guidance for future design of lithium-rich as well as stoichiometric layered cathode materials.

This research used resources of the Center for Functional Nanomaterials, which is a U.S. DOE Office of Science Facility, at Brookhaven National Laboratory under Contract No. DE-SC0012704.

First-Principles Investigation of the Stability of the Oxygen Framework of Li-Rich Battery Cathodes
Marnik Berx, Bart Partoens and Dirk Grzegorz Pyka and Bartlomiej Winarski; 1 Application Software Group, ThermoFisher Scientific, Merniguac Cedex, France; 2 CT Core, Thermo Fisher Scientific, Brno, Czechia; 3 GS BU Materials-Science, Thermo Fisher Scientific, Brno, Czechia.

3D Correlative microscopy applied to NMC Type Li-Ion Battery Transport Properties Study
The growth of the electrical vehicle market has led to a significant interest in developing safe high-capacity batteries with good cycling properties. Lithium-rich layered oxides such as Li$_2$MnO$_3$ have shown great potential as cathodes in Li-ion batteries, mainly because of their large capacities which have been demonstrated to be caused by a cumulative cationic and anionic redox activity. However, these materials still suffer from structural degradation as the battery is cycled, reducing the average voltage and capacity of the cell. This voltage fade is believed to be related to the migration of transition metals into the lithium layer, which results in a transformation of the structure to a spinel-type phase. Recent theoretical works have linked the migration of transition metals to the formation of O-O dimers with a short bond length, driven by the presence of oxygen holes due to the participation of oxygen in the redox process. However, so far such studies have been limited to fully charged structures, which are inherently very unstable and difficult to achieve in practice. Moreover, very few results in the literature have studied the O1 stacking of the layered structure, to which Li$_2$MnO$_3$ is expected to transform when the cathode is delithiated by 75%. We investigate the formation of O-O dimers for partially charged O1-Li$_{0.5}$MnO$_3$ using a first-principles density functional theory approach by calculating the thermodynamic driving force for dimer formation, as well as the kinetic barriers. Next, we perform similar calculations for partially charged Li$_2$IrO$_3$, a Li-rich material for which the voltage fade was not observed during cycling. When we compare the stability of the oxygen framework, we conclude that the formation of O-O dimers is both thermodynamically and kinetically viable for O1-Li$_{0.5}$MnO$_3$. For O1-Li$_{0.5}$IrO$_3$, on the other hand, we observe that the oxygen lattice is much more stable, either returning to its original state when perturbed, or resulting in a structure with an O-O dimer that is much higher in energy. This can be explained by the lower participation of oxygen in the redox process for Li$_2$IrO$_3$, which is also clear from the calculated magnetic moments on oxygen. The lack of O-O dimer formation in O1-Li$_{0.5}$IrO$_3$, as well as its connection to the migration of transition metals, provides valuable insight as to why Li$_2$IrO$_3$ does not demonstrate a voltage fade as the battery is cycled, which can be used to design Li-rich battery cathodes with an improved cycling performance.

Antimony Oxychloride/Graphene Aerogel as Cathode Material for Chloride-Ion Batteries

Lauren Marbella$^1$ and Clare Grey$^1$
$^1$Chemistry, University of Cambridge, Cambridge, United Kingdom; $^2$Argonne National Laboratory, Argonne, Illinois, United States; $^3$Diamond Light Source, Didcot, United Kingdom.

Lithium-ion batteries have emerged as dominant power sources for portable electronics and vehicular applications. However, the ever-growing market has put higher demands in terms of energy and power needs, and hence alternative rechargeable battery systems, for example sodium-ion batteries, are being explored. Recently, there has been growing interest in rechargeable batteries based on an anion shuttle, for example, chloride or fluoride battery that operates at room temperature. With a high theoretical energy density (~ 2500 Wh L$^{-1}$), chloride ion battery show a noticeable potential as future power source and several proof-of-principle have been already reported. The electrode dissolution of metal chlorides in the electrolyte causes stability issues and thus limits its performance as an efficient cathode material for chloride ion battery. Several metal chlorides have been studied as cathode material for chloride ion batteries, developing an efficient cathode material that is stable in electrolyte and with lower volume expansion than metal chlorides, still remains a challenge. Metal oxychlorides such as FeOCl, BiOCl, VOCl$_3$ have been explored as cathode material and show better electrochemical performance and stability compared to metal chloride based cathodes. Here, we demonstrate antimony oxychloride as a new cathode material for chloride ion battery. ShbOCl$_2$ microstructures synthesized through hydrothermal route undergoes reversible redox reactions when cycled as cathode for chloride ion battery. With an aim to address the poor conductivity and huge volume expansion of metalalloychloride based cathodes upon on cycling, we prepared ShbOCl$_2$-graphene aerogel composite (ShbOCl$_2$-GAG) which exhibited improved electrochemical performance, with a stable capacity of ~80 mAh g$^{-1}$ after 100 cycles. The electrochemical reaction mechanism of antimony oxychloride electrode as cathode material in chloride ion battery has been studied through ex-situ XRD and XPS characterization techniques. The obtained results are promising and demonstrate 3D networked antimony oxychloride/graphene aerogel composite as a potential cathode material for Chloride Ion batteries.

Surface Orientation Dependence of Oxygen Vacancy and Ni/Li Cation Mixing Defects Formation in Li(Ni$_{0.8}$Co$_{0.1}$Mn$_{0.1}$)O$_2$ Cathode Materials

Ganes Shakij$^1$, Randy Jalemi$^{2,3,4}$ and Yoshitaka Tateyama$^{1,5}$
$^1$Kyoto University, Kyoto, Japan; $^2$National Institute for Materials Science, Tsukuba, Japan; $^3$Japan Science and Technology Agency, Kawaguchi, Japan.

Layered Ni-rich Li(Ni$_{x}$Mn$_{y}$Co$_{z}$)O$_2$ (x+y+z=1) or NCM has been considered as one of the most promising candidates for the next-generation Li-ion battery cathodes because of its high energy density. However, its commercial usage is still hindered partly due to the following two critical issues: (1) safety issue that closely relates to significant NCM lattice oxygen release during operation, (2) capacity fading due to the irreversible layered to spinel/rock-salt phase transformation triggered by Ni/Li mixing defect formation [1].

Herein, by means of density functional theory (DFT)-based calculations we study the aforementioned oxygen release phenomena by examining the oxygen vacancy (Ovac) formation energy, taking Li(Ni$_{0.6}$Mn$_{0.4}$)O$_2$ or NCM811 as the representative of Ni-rich NCM. We also investigate the Ni/Li mixing defect formation at surface and near-surface regions of NCM811.

Based on the energetics analysis, we found that the bulk and the low-index surfaces considered in this work viz. (104), (110) and (012) are stable against spontaneous oxygen evolution in the fully lithiated state. Further, our results also suggest that the Ovac formation in the bulk has a high energy while there is a large variation of Ovac formation energy at the surfaces. These results can be mainly attributed to the difference of transition metal (TM) oxidation states distribution at each surface facets and bulk. While the pristine bulk of NCM811 is exclusively composed by Ni$^{2+}$ and Ni$^{3+}$, we observed presence of less stable Ni$^{4+}$ ions at the surface and sub-surface regions. Our results suggest that one way to stabilize this unstable Ni$^{4+}$ is releasing Oxygen nearby (i.e. the Ovac formation) that subsequently lower the oxidation state to Ni$^{3+}$. In the case of Ni/Li mixing defect, we found that the polar (012) surface has more resistance against the Ni/Li mixing as compared to the non-polar (104) and (110) surfaces in which Ni/Li mixing is predicted to spontaneously occur. This can be attributed to the existence of surface Ni$^{3+}$ that can interchange with Li$^+$ without further reduction at (104) & (110) surfaces, while on the contrary pristine polar (012) has only Ni$^{3+}$ at its outermost TM layer. Our results indicate that the choice of surface orientation and termination may play an important role in determining the formation of both Ovac and Ni/Li mixing defects.

Anomalously High-Rate Energy Storage at Large Length-Scales in Complex Oxides

Kent J. Griffith$^1$, Kamila Wiaderek$^2$, Gianantonio Cibin$^1$, Lauren Marbella$^1$ and Clare Grey$^1$; $^1$Chemistry, University of Cambridge, Cambridge, United Kingdom; $^2$Argonne National Laboratory, Argonne, Illinois, United States; $^3$Diamond Light Source, Didcot, United Kingdom.

The maximum power output and minimum charging time of a lithium-ion battery – key parameters for its use in, for example, transportation applications –
depend on mixed ionic–electronic diffusion. While the discharge/charge rate and capacity can be tuned by varying the composite electrode structure, ionic transport within the active particles represents a fundamental limitation. Thus, to achieve high rates, particles are frequently reduced to nanoscale dimensions despite this being disadvantageous in terms of volumetric packing density as well as cost, stability, and sustainability considerations. As an alternative to nanoscaling, we show that complex niobium tungsten oxides with topologically frustrated polyhedral arrangements and dense μm-scale particle morphologies can rapidly and reversibly intercalate large quantities of lithium. Multielectron redox, buffered volume expansion, and extremely fast lithium transport approaching that of a liquid lead to extremely high volumetric capacities and rate performance as very recently reported in both crystallographic shear structure and bronze-like niobium tungsten oxides[1]. The active materials Nb_{x}W_{y}O_{z} and Nb_{y}W_{x}O_{y} show new strategies toward designing electrodes with advantages in energy density, scalability, electrode architecture/complexity and cost as alternatives to the state-of-the-art high-rate anode material Li_{3}Ti_{5}O_{12}. The direct measurement of solid-state lithium diffusion coefficients (D_{Li}) with pulsed field gradient NMR demonstrates room temperature D_{Li} values of 10^{-12}-10^{-13} m^{2}s^{-1} in the niobium tungsten oxides, which is several orders-of-magnitude faster than typical electrode materials and corresponds to a characteristic diffusion length of ~10 μm for a 1 minute discharge. Structural and chemical analysis of high-rate and multielectron energy storage will be discussed with insights from operando X-ray diffraction and multi-edge X-ray absorption spectroscopy. Materials and mechanisms that enable lithiation of μm particles in minutes have implications for high power applications, fast charging devices, all-solid-state batteries, and general approaches to electrode design and material discovery.

ET06.12.02
Optimization of an Alkoxide-Based Electrolyte for Magnesium-Ion Batteries Anushka Dasgupta, Princeton University, Princeton, New Jersey, United States.

Rechargeable Mg-ion batteries boast a high theoretical volumetric capacity and an absence of dendrite formation, making them a promising candidate for energy storage applications in the electric grid and in transportation. However, many electrolytes which have been developed for the Mg-ion battery chemistry thus far passivate the Mg anode surface or suffer from a low anodic stability or ion conductivity. We report on a Mg-ion electrolyte, based on the weakly coordinating anion [Al(HFIP)]- in DME, which can reversibly and efficiently deposit magnesium metal and is stable at voltages greater than 3V vs. Mg/Mg2+ on various current collectors. The electrolyte is characterized via a variety of electrochemical methods, including cyclic voltammetry and impedance spectroscopy. The kinetics of Mg-ion transport in the electrolyte vary with its concentration, with optimal ion conductivity achieved between 0.45M and 0.50M. In this range, the electrolyte displays its lowest deposition overpotentials. These overpotentials decrease with cycling, signaling the ability of the electrolyte to break down passivating layers and activate the anode surface. The properties of this electrolyte, which has a simple, scalable, Grignard-free synthesis, suggest interesting directions for future research.

Examination of SEI Variation in Patterned Li Anodes Using Scanning Probe Microscopy, with Insight into the Suppression Mechanisms of Dendrite Formation Colin T. Campbell1,2, Yong Min Lee3, Kuk Young Cho4, Young-Gi Lee4, Byeongdu Lee6, Charudatta Phatak4 and Seungbum Hong6, 1Materials Science and Engineering, Northwestern University, Evanston, Illinois, United States; 2Energy Science and Engineering, Daegu Gyeongbuk Institute of Science and Technology (DGIST), Daegu, Korea (the Republic of); 3Materials Science and Chemical Engineering, Hanyang University, Ansan, Korea (the Republic of); 4ICT Materials and Components Research Laboratory, Electronics and Telecommunications Research Institute
Li metal batteries have been projected to outperform the current graphite anode batteries in both storage capacity and potential (3860mAh/g Li vs. 372mAh/g graphite). However, significant research needs to be performed in order to alleviate potential materials problems of dendrite formation and associated capacity loss and cell shorting before they can be commercially available. Integral to the development of not only Li metal anodes, but all metallic electrodes, is an understanding of the mechanisms of dendrite formation. In this work, the effect of patterned electrodes on the nucleation and growth of dendrites will be examined by atomic force microscopy (AFM), with specific focus on surface potential variations due to patterned geometry. These surface potential variations can then give insight into nonuniform solid electrolyte interphase (SEI) formation.

There are two factors that contribute to the SEI formation that are unique to patterned electrodes: (i) local curvature of the electrode, and (ii) nonuniform electrolyte depletion. Curved conductive surfaces produce higher electric field magnitudes than flatter surfaces for a given applied voltage, and so produce higher local current densities, leading to inhomogeneous Li deposition. This can be inhibited by the formation of a thicker SEI as a result of this higher current, leading to a suppression of nonuniform current. The second factor, nonuniform electrolyte depletion, also directly affects SEI formation. In a flat, parallel electrode system the concentration of Li ion at every point in the system can be calculated with relative ease for sufficiently low current using Fick’s law. The inhomogeneities associated with a patterned electrode break this simple derivation, often requiring numerical simulation of the diffusion-supplied flux of Li delivered to the electrode surface. In regions where diffusion is insufficient to supply the electrode with Li, a large overpotential (and consequently, electric field) develops; this accelerates electrolyte decomposition, even in “low current” limits, promoting SEI formation and consequently limiting nonuniform deposition. A combination of these effects can lead to suppression of dendritic growth of Li.

We will present results using Kelvin probe microscopy, and Electrostatic force microscopy to visualize variations in the conductivity and/or thickness of the SEI as a function of patterning. Both of these measurements will be conducted on a series of scratches with varying aspect ratio in Li metal anodes. The nucleation and growth of the Li dendrites will be monitored using an in-situ electrochemical cell for the AFM. Together, this information about inhomogeneous or nonuniform SEI formation can be used to inform future efforts in nanopatterned electrodes for Li batteries.

**Hybrid Silicate Coatings for Stable Lithium Metal Anodes** Fang Liu and Yunfeng Lu; University of California, Los Angeles, Los Angeles, California, United States.

Lithium metal anode is one of the most promising candidate for next–generation rechargeable batteries. However, their implication has been hampered by the unstable electrochemical behaviors, such as the formation of dendritic structures and continuous chemical reactions with liquid electrolyte. Herein, we report the fabrication of hermetic coatings of hybrid silicate on lithium metal surface under ambient conditions. Such coatings consist of a “hard” inorganic moiety that helps to suppress lithium dendrites and a “soft” organic moiety that enhances the toughness. Furthermore, functional groups, which can immobilize anions, can also be attached to the coating layers to facilitate the transportation of lithium cations. Lithium–metal batteries made with such coated anodes show significantly improved lifetime and cycling stability. This work provides a simple and effective approach to stabilize lithium metal anodes for high performance lithium metal batteries.

**ET06.12.05**

**Effect of Polymer Binder on the Nature, Formation and Location of Solid Electrolyte Interphase Layer in Silicon Based Lithium-Ion Batteries** Richard Johnson1, Gordon Waller2 and Siva P. Nadimpalli2; 1New Jersey Institute of Technology, Montvale, New Jersey, United States; 2NSWC Carderock Division, Bethesda, Maryland, United States.

Polymeric binders are a critical component of all composite electrodes used in today's lithium ion batteries (LIB). Binders also play an important role in ensuring the cycling stability of Li alloy forming anode materials such as Si which are known to degrade due to expansion and contraction during cycling. Meanwhile, the formation of solid electrolyte interphase (SEI) can also exacerbate capacity loss in novel anode materials, however the contribution of the binder to SEI formation and stability of alloying anodes has not been emphasized. It has been suggested that elastomeric binders such as polyvinylidene fluoride (PVDF) could be utilized in order to mitigate the high stress that occurs between particles during cycling. However, experimental studies have shown that the use of carboxymethyl cellulose (CMC) improved both coulombic efficiency as well as cyclic life when compared to elastomeric binders. This result was counterintuitive because CMC is a stiffer material than PVDF and from these results it has been speculated that CMC may alter the Si particle surfaces in order to form an SEI that improves the cyclic life[1]. This phenomenon has not been fully investigated. The objective of this study is to understand the effect different polymer binders on the nature, formation, and location of the SEI layer of silicon based anodes. In this study Si wafers coated with thin films of CMC and PVDF binders were utilized as the active material. Half cells containing either bare crystal Si or a crystal wafer with a thin film of CMC or PVDF were cycled in a standard lithium-ion electrolyte (1 molar LiPF6 in 1:1:1 vol. ratio of EC:DC:DMC) to form a stable SEI. After cycling, the cells were opened in an inert atmosphere and x-ray photoelectron spectroscopy (XPS) was carried out to analyze and compare the surface chemistries. In addition, the morphology of the substrates and binder films were characterized by SEM. Preliminary results indicate that binder layers on the order of hundreds of nm thick do not impede the lithiation and delithiation of Si, but do play a role in the observed coulombic efficiency and SEI composition. These results can help inform the optimization of Si containing anodes in commercial LIB, which are expected to enter the market in the near future.

**ET06.12.06**

**Stabilizing Lithium on the Surface of Laser Written F-Doped Carbon Nano-Union Film Towards Stable Li Metal Batteries—A Case of Dendrite Suppression by Li Loading Inside Nanopores** Dhanya Pathmasuriy, Malik A. Wahid, Aniruddha Basu, Rohit Babar, Mukul Kabir and Satishchandra Ogale; Indian Institute of Science Education and Research, Pune, India.

The low energy densities associated with Li-ion batteries compared to Li-metal batteries has necessitated a revisit to the latter. Li metal barriers have remained the attraction since their discovery and early commercialization attempts, mainly because of highest gravimetric capacity (3860 mAh g−1) of metallic Li, which translates to higher energy density. While as the state of art Li-ion battery delivers the energy density in the range of 200-250 Wh kg−1, the Li-metal cell (with transition metal oxides as cathodes) can deliver an energy density of 400-450 Wh kg−1. Moreover, the Li metal anodes form the heart of promising high energy systems like Li-air and Li-S which can go up to 650 Wh kg−1 to 950 Wh kg−1 on energy density scale. However, working with metal anodes is a difficult ploy owing to rampant underlying chemistries. The processes like Li dendrite growth, uneven deposition, non-facile Li/electrolyte charge transfer and huge volume changes upon metal reduction (charging), has hampered the progress of this technology towards targeted commercialization.
Herein we demonstrate direct laser writing of interconnected porous network of fluorine-doped carbon nano-onion film (F-CNOF) on copper current collector to stabilize Li metal anode by preventing dendrite formation. The unique morphology of interconnected carbon nano-onions leads to high lithium intake and long-term cyclic stability due to the availability of uniform lithiophilic sites that control the lithium nucleation. The F-CNOF electrode shows a high Li plating capacity of 10 mAh cm$^{-2}$ at low overpotential -25 mV. An impressive Coulombic efficiency -100% was achieved for long 1500 hours corresponding to more than 300 cycles capacity. The first principles DFT calculations show that the high curvature of the nano-dimensional carbon onions (~ 20 nm) achieved herein can significantly enhance the binding energy of Li to the carbon surface, which helps to improve lithiophilicity and long-term stability. A full cell fabricated using Li$_{1.6}$Si$_{1.74}$P$_{1.44}$S$_{11.7}$Cl$_{0.3}$ as the positive electrode showed cyclic stability of 700 cycles. This impressive performance exhibited by F-CNOF electrodes indicate laser scribing as an efficient tool for direct writing of porous network of carbon nanostructures that can be used as an efficient and stable scaffold to stabilize Li metal anode.

Enhanced Transport Properties of CuO-Doped Li$_{1.8}$Si$_{1.7}$P$_{1.6}$S$_{1.5}$Cl$_{0.5}$ Solid Electrolyte
Alexis G. Lavin; Universidad de Puerto Rico, San Juan, Puerto Rico, United States.

Better solid electrolytes need to be developed in order to achieve the long envisioned all-solid-state lithium batteries. This new generation of batteries is expected to improve the safety of Li-ion batteries while achieving both high power and high energy density. Among solid electrolytes, Li$_{1.8}$Si$_{1.7}$P$_{1.6}$S$_{1.5}$Cl$_{0.5}$ is particularly promising. In order to enhance its transport properties, we have doped the solid electrolyte with CuO nanoparticles. XRD crystallography studies provided evidence of the structural changes undergone by the material. The doped and undoped solid electrolytes were tested in coin cell batteries with Li and Graphite electrodes. Cyclic voltammograms and charge-discharge data were obtained. The results indicate that CuO doping caused an improvement in the transport properties of the solid electrolyte. More cycling is underway in order to study the stability of the solid electrolyte and the structural changes undergone during cycling.

ET06.12.09
Li$_2$RuO$_4$—Understanding the Role of Li/M Ordering in Triggering the Oxygen Redox
Haifeng Li$^1$, Liang Li$^1$, John w. Freeland$^2$, Andrey Yakovenko$^2$, Maria K. Chan$^2$ and Jordi Cabana$^2$; 1UIUC, Chicago, Illinois, United States; 2‘Argonne National Laboratory, Chicago, Illinois, United States.

Besides transition-metal redox, anionic solid-state redox has become a crucial constituent in boosting capacities of Li-rich layered cathodes more than 300 mAh/g. Compared with a thorough study of the intercalation mechanism involving oxygen redox in canonical oxides Li$_2$MO$_3$ (M = 3d/4d/5d transition metal), Li$_2$MoO$_4$ series offer a possibility exploring the detailed intercalation chemistry of a compound with high O/M ratio and the role of Li/Ru ordering in triggering oxygen redox. Here two distinctive phases, disordered and ordered, of Li$_2$RuO$_4$ (O/M = 4) with various polymorphs in terms of temperature was synthesized to probe the intercalation chemistry and structural changes. A comprehensive study by spectroscopic methods coupled with computations of the electronic structure revealed that the 2.5-3.9 V voltage window evidences an exclusive oxygen redox for delithiation process with irreversible structural evolution followed by Ru$^{4+}$ redox while solo reversible Ru$^{3+}$-Ru$^{4+}$ redox accounts for the Li uptake-removal mechanism of 1.5-2.5 V. Furthermore, the ordered polymorph exhibits better electrochemical properties due to the regular ordering of Li/Ru within the transition-metal layer. The investigation demonstrates that the high O/M ratio and inerratic ordering of Li$_2$RuO$_4$ could promote the occurrence of the anionic redox, further guiding the design of high capacities Li-rich cathode materials.

ET06.12.10
Na Wetting Layer of Layered Reduced Graphene Oxide on a β”-alumina for Low Temperature Na-BASE Batteries
Dana Jin$^1$, Sori Son$^2$, Younki Lee$^2$, Yoon-Cheol Park$^3$, Keeyoung Jung$^3$, Wooyoung Shim$^1$ and Youngjun Cho$^1$; 1Yonsei University, Seoul, Korea (the Republic of); 2Advanced Photon Source, Argonne National Laboratory, Argonne, Illinois, United States.

As the importance of renewable energy grows, Sodium/β”-alumina(BASE) cell has been recognized as one of the most effective energy storage device because of its high specific energy, high efficiency of charge/discharge and long cycle life. For better operation of Sodium-BASE cell, poor wettability of electrolyte on liquid sodium anode should be enhanced. Oxygen is a highly reactive element and can react rapidly with Alkali metals. Using high affinity between sodium and oxygen, we fabricated ‘sodiophilic’ r-GO sheet for use as a Na-wetting layer in the anode of Na-BASE cell. Thermal reduction and expansion of interlayer gaps of GO sheets triggered by contact with liquid sodium carefully controls the density of oxygen-functional group and produce nano and microscale gaps that host liquid sodium. Liquid sodium can diffuse into the interlayer spacing of the r-GO sheets and rapidly cover the entire surface area of the sheet due to the high affinity between Na and residual oxygen-functional group of r-GO and capillary force produced by the nano and microgaps. These characteristics give rise to stable cycling with low overpotential of Na-BASE battery.

ET06.12.11
Enabling Reliable Lithium-Metal Batteries by a Bifunctional Anionic Electrolyte Additive

Li-S batteries, one of the most promising candidates of electrochemical energy storage systems due to their advantages of high energy density, low cost and good capacity and so on, have attracted high attention and intense research in last two decades. Despite tremendous efforts, the commercial use of Li-S batteries is still blocked by their poor stability caused by polysulfide shuttle effects and large volume expansion during the insertion of lithium ions. Herein, we report a facile strategy to prepare submicron sulfur particles which are coated by phytic acid shell directly via ball-milling method and further, produced by carboxylic and hydroxyl groups, respectively. Meanwhile, the P hybrid carbon can be further used to improve the reaction kinetics and enhance ionic conductivity, which can achieve a good long life span, high reversible energy density and good rate performance with a very low cost and straightforward approach for Li-S batteries.

In Situ Chemically/Electrochemically Building Superior Hybrid Solid Electrolyte Interface Layer for Li-Metal Anode

Yuming Zhao, Guoxing Li and Donghui Wang; The Pennsylvania State University, State College, Pennsylvania, United States.

The practical application of next generation high energy density storage systems has long been delayed by the unstable lithium (Li) metal anode with problems like uncontrollable Li dendrites growth, low Coulombic efficiency (CE) or short cycle life. Here, we demonstrate a multifunctional and chemically cross-linked composite film that can provide excellent protection for Li metal anode. By a chemical and electrochemical process, this film can help Li metal anode in-situ form a stable organic/inorganic hybrid SEI layer at the interface between the film and deposited Li, which is mainly composed of polymer based organosulfides, inorganic sulfides (LiPSn,n, LiS, LiS2) and Li salts (LiCl, LiF, etc.). Furthermore, this film as a robust and solid layer can provide extra mechanical protection or acting as a material inventory for this in-situ formed robust SEI layer, so that guarantee its long-term cycling stability. Half cells with this composite film show dendrites free Li deposition, high CE and excellent cycling performances at different cycling conditions (e.g. 98.5% CE for over 460 cycles at 2 mA cm-2 and 2mAh cm-2). Full cells with either sulfur (S) or LiFePO4 as cathode and composite film protected Li as anode show clearly enhanced capacity retention and superior cycle life. This study will inspire new pathway to design functional SEI layer for Li metal anode and promote the practical application of rechargeable Li metal batteries.

ET06.12.14

Theoretical Overpotentials and Nucleation Rates for Electrodeposition on Metal Negative Electrodes

Kyle Nagy, Saeed Kazemianbavi, Katsuyo Thornton and Donald Siegel; Univ of Michigan, Canton, Michigan, United States.

Rechargeable batteries employing metal negative electrodes (i.e., anodes) are attractive next-generation energy storage devices due to their potential to achieve higher theoretical energy densities compared to standard, intercalation-based anodes. An important consideration for a metal’s viability as an anode is the efficiency with which it undergoes electro-deposition and –dissolution during cycling. This study assesses the thermodynamic deposition/dissolution efficiencies and associated nucleation rates for seven metals (Al, Ca, K, Li, Mg, Na, and Zn) of relevance for battery applications. First-principles calculations were used to evaluate thermodynamic overpotentials at several deposition/stripping sites – terraces, steps, and kinks – on low-energy surfaces of these metals. Kink sites are observed to be the most energetically favorable sites for metal deposition, and thus exhibit the lowest overpotentials. These sites are expected to play a prominent role at low current densities, where moderate rates of adsorption/desorption allow access to the most thermodynamically-favored sites. In contrast, the largest overpotentials occur for plating/stripping at terrace sites. These sites are expected to dominate at high current densities, where kinetic limitations can hinder exchange at kink sites. The difference in the coordination number for a surface atom from that in the bulk was found to correlate with the plating efficiency. Consequently, due to their low bulk coordination, the body-centered alkali metals (Li, Na, and K) are predicted to be among the most thermodynamically efficient for plating/stripping. In contrast, metals with higher bulk coordination such as Al, Zn, and the alkaline earths (Ca and Mg), generally have higher thermodynamic overpotentials. The calculated formation energies for electro-deposition were used as input to a classical nucleation model to estimate the rate of steady-state nucleation. Nucleation rates on alkali metal surfaces are predicted to be several orders of magnitude higher than on the surfaces of other metals in this study for both terrace and step deposition sites. Our approach demonstrates a technique for linking atomistic data with an analytic nucleation model and highlights the sensitivity of nucleation behavior on the chemistry and structure of the metallic substrate.
Recent research has focused on developing layered oxide cathode materials such as lithium-rich 3d-transition-metal oxides for high-energy-density lithium-ion batteries. However, practical applications of these materials are challenging due to a continuous voltage decay on cycling, which is associated with internal and interfacial material degradation. Here we show that the formation of a stable surface structure on layered lithium transition-metal oxide particles can prevent the further structural and chemical evolution of the lithium-ion diffusion-surface layers. This is demonstrated by creating a few atomic layers with a cation-disordered structure on the specific facet of the layered oxide nanoparticles during the synthesis. Through the advanced atomic-scale analysis by high-resolution electron microscopy, we investigate the atomic arrangement and valence states of transition metals from the bulk to the surface region. In addition, combined analysis with in-situ X-ray characterization reveals the understanding of the origin of the bulk and surface chemistries and cationic redox mechanism upon electrochemical reaction. Our findings will provide new insights for designing and preparing future layered oxide cathode materials.

This work is supported by the National Research Foundation of Korea (NRF-2011-C1AAA001-0030538).
Polypyrrole (PPy) is a p-doped conducting polymer composed of repetitive bonds of five-membered heterocyclic rings including amine (N-H) groups, thus allowing the formation of hydrogen bonding forces between PPy chains. When PPy is made of nanomaterials, it has following advantages over bulk materials: (1) higher surface area; (2) better reactivity; (3) enhanced electrical conductivity. Among the various nanomaterials, the core-shell is very suitable as a stable electrode material because the Si core can protect the CP shell from swelling and shrinkage problems. In addition, high surface area of the Si cores enable rapid adsorption/desorption of electrolyte ions within the electrodes. On the other hand, the CP shell plays roles in reinforcing the poor electrical properties of Si cores. Thus, the synergistic effect from the PPy shell and the Si core would be advantageous for making a supercapacitor electrode that provides robustness and high electroactivity. In conventional synthesis, the SiOx templates limit the growth of polymer chains, resulting in undesirable α,α’-linkages in between the PPy chains. In addition, the low electrical properties of SiOx-PPy composites are highly related to the low efficiency of core-shell formation in the in-situ syntheses. Therefore, there is a need for optimization and development for producing SiO2-PPy core-shells with high efficiency of core-shell formation, which may result in the improved electrical and electrochemical performances.

In this presentation, we report the preparation and optimization studies of PPy-encapsulated silica nanoparticles (SiO2 NPs) using ex-situ method. The SiO2-PPy core-shell NPs prepared by the ex-situ method are well dispersed in water and facilitate the mass production of thin-film electrodes with improved electrical and electrochemical performances using a simple solution process. By using the ex-situ method, the PPy shell can be produced without the influence of SiO2 NPs, and the resultant PPy will have higher doping level and better electrical performance than the conventional ones. As-prepared SiO2-PPy core-shell NPs with different particle sizes were applied to electrode materials for two-electrode supercapacitors based on coin cell batteries. It was confirmed that the areal capacitance (73.1 mF/cm2), volumetric capacitance (243.5 F/cm3), and cycling stability (88.9 % after 5000 cycles) of the coin cell employing the ex-situ core-shell was superior to that of the conventional core-shell (4.2 mF/cm2, 18.2 mF/cm3, and 82.2%). Considering these facts, the ex-situ method enables a facile way to produce highly-conductive thin-film electrodes with enhanced electrical and electrochemical properties for the coin cell supercapacitor application.

**Using Compact SEI Formation to Enhance Electrochemical Properties of the SiOx Anode for Li-Ion Batteries**

Nayoung Kang and Sun-Jae Kim; Department of Nanotechnology and Advanced Materials Engineering, Sejong University, Seoul, Korea (the Republic of).  

The growing demand for high-performance portable electronic devices and large-scale electrical energy storage systems has promoted lots of efforts to develop up-to-date lithium-ion batteries (LIBs) with greater capacity and cycle stability. Along this requirements, silicon (Si) is the material of choice for anode materials because of its high theoretical capacity (~4200 mAh/g), which is almost 10 times higher than that of conventional graphite anodes (372 mAh/g). However, the practical application of Si has been frustrated by rapid capacity fading, due to the unavoidable large volume change during charge-discharge processes, which results in particle fracture and loss of electrical contact between active materials, consequently causes an unstable solid electrolyte interphase (SEI) growth on the Si interface. Therefore, a SiOx has aroused interests as the most promising alternatives for practical application for the lithium-ion batteries (LIBs) as a modification for Si. Compared to Si, the formation of inactive components, Li2O and/or lithium silicmates, coming with generation of Si anodes during the initial lithiation process at SiOx matrix can buffer the volume variation and maintain the structural stability. Nonetheless, some disadvantages of SiOx such as low initial coulombic efficiency (ICE) and unstable SEI layer result in unsatisfactory electrochemical performance. To overcome these problems, there were many efforts to develop coating methods to protect the anode surface as an artificial SEI layer. However, it is still limited to improve ICE and long lifetime of SiOx, because these treatments were only for electrode surface.

In this study, the formation of electrode has modified with the stable SEI by applied potentiostatic which is inspired by electrodeposition. In electrodeposition, the film made by AC has less porosity than by DC and formed uniformly. The electrochemical impedanse spectroscopy (EIS) measurements were performed to understand electrical and ionical conductivities. The surface microstructure and components of the electrode were characterized by using scanning electron microscopy (SEM), X-ray photoelectron spectroscopy (XPS) and transmission electron microscope (TEM). As a result, the as-prepared electrode delivered an initial charge and discharge capacity of 2603 mAh/g and 1140 mAh/g, respectively with an initial coulombic efficiency (ICE) of 42.3 % at 0.1 A/g. In contrast, the electrode charged by potentiostatic method showed initial charge and discharge capacities of 1180 mAh/g and 1105 mAh/g, respectively with an ICE of 93.6 %. Also, the electrode charged by potentiostatic method at 1 A/g was a capacity retention of 85.1% maintained over 1000 cycles, whereas the as-prepared electrode was a capacity retention of 70.1% under the same conditions. These results have been noted that it is important to make the compact electrode structure to improve electrochemical properties such as ICE, cycling, and capacities.

**Electrochemically Controlled Solid Electrolyte Interphase Layers for Superior Li-S Batteries**

Yaxing Wang, Chuan-Fu Lin, Jiancun Rao, Karen Gaskell, Gary Rubloff and Song Bok Lee; University of Maryland, College Park, Maryland, United States.

Lithium-sulfur (Li-S) batteries suffer from shuttle reactions during electrochemical cycling, which cause the loss of active material sulfur from sulfur-carbon cathode, and simultaneously incur the corrosion and degradation of the lithium metal anode by forming passivation layers on its surface. These unwanted reactions therefore lead to the fast failure of batteries. The preservation of the highly reactive lithium metal anode in sulfur containing electrolyte has been one of the main challenges for Li-S batteries. In this study, we systematically controlled and optimized the formation of smooth and uniform solid electrolyte interphase (SEI) layer through electrochemical pretreatment of the Li metal anode under controlled current densities and cycle number. A distinct improvement of battery performance in terms of specific capacity and power capability was achieved in charge-discharge cycling for Li-S cells with pretreated Li anodes compared to pristine, untreated ones. Importantly at higher power density (1 C rate, 3mA/cm²), the Li-S cells with pretreated Li anodes protected by controlled elastomer (LPE) show the suppression of the Li dendrite growth and exhibit 3-4 times higher specific capacity than the untreated ones after 100 electrochemical cycles. The formation of such controlled uniform SEI was confirmed and its surface chemistry, morphology and electrochemical properties were characterized by X-ray photoelectron spectroscopy (XPS), focused-ion beam (FIB) cross-sectioning, and scanning electron microscopy (SEM). Adequate pretreatment current density and time are critical in order to form the continuous and uniform SEI, along with good Li ion transport property.

**8:30 AM ET06.13.02**

**Effect of Nitrogen/Oxygen Dual-Doped Carbon Nanofiber on High Sulfur-Loading High Stability Lithium-Sulfur Batteries**

Ying Yang1, Tianji Guo1, Zhishao Yu1, TongHeu Le1, Hao Tian1 and Feiyu Kang2; 1Department of Electrical Engineering, Tsinghua University, Beijing, China; 2Department of Electrical Engineering, Tsinghua University, Beijing, China.
A self-standing N/O dual-doped carbon nanofiber was prepared based on polymer chain design with one-step carbonization. The interlayer can not only substantially improve the charge-discharge performance of Li-S battery, but also suppress the shuttle effect during charge-discharge process because of the strong adsorption effect between interlayer and lithium polysulfides. The first discharge specific capacity of the cell was 946.7 mAh g⁻¹ and it also contained more than 908 mAh g⁻¹ and 800 mAh g⁻¹ after 100 and 200 cycles at 0.1 C with such an interlayer. It was found that the capacity contribution from S₈ to Li₂S₈ was improved 35% with an interlayer, which is the main reason for the improvement of the cell higher capacity. We believe that the cell configuration presented here coupled with further improvements in the sulfur electrode itself could help to alleviate some of the persistent problems of Li-S cells.

8:45 AM ET06.13.03 Poly sulfides Immobilization by Metal Carbide Filled Nitrogen Doped Carbon Nanotubes for High-Performance Lithium-Sulfur Batteries Garapati M. Seshadri and Ramaprabhu Sundara; Indian Institute of Technology Madras, Chennai, India.

Lithium-sulfur (Li-S) batteries gain more attention as a secondary battery because of low cost, abundant and non-toxic sulfur as an active cathode material. As the sulfur possess high specific capacity (1672 mAh g⁻¹) and energy density (2600 Wh kg⁻¹) which enables to reach the high scale energy demands like hybrid electric vehicles and power grid applications. The lower cyclic stability, the poor electrical conductivity of sulfur, and dissolution of intermediate lithium polysulfide into the electrolyte and its migration towards the anode (shuttle effect) are the major challenge for the commercialization of Li-S batteries. To address these challenges, many porous carbon materials and polar metal oxides and sulfides have been studied as a lithium polysulfide trapping materials. In this work, we focus on the polar and conductive metal carbides for polysulfide confinement. For this, we have synthesized Fe₃C filled nitrogen doped carbon nanotube (Fe₃C@NCNT) and NCNT by an easy single step process. Sulfur infiltrated NCNT (NCNT/S) have been synthesized by melt diffusion technique. The high surface area and large pore volume of NCNT can enhance the diffusion of Li⁺ ions and electrolyte during the charge-discharge process. Fe₃C@NCNT has used an interlayer where polar Fe₃C can adsorb lithium polysulfides through polar-polar interactions and therefore immobilized lithium polysulfides by minimizing the shuttle effect. NCNT/S-Fe₃C@NCNT cathode shows the enhanced specific capacity at different C-rates (1C 1672 mAh g⁻¹) and long cyclic stability than the cathode without Fe₃C@NCNT. This signifies the Fe₃C@NCNT can minimize the active material loss in the cathode and enhance the sulfur redox kinetics.

9:00 AM BREAK

9:30 AM ET06.13.04 Superior Performance of Lithium-Sulfur Battery Enabled by a Dimethyl TrisulfideContaining Electrolyte Daiwei Wang; The Pennsylvania State University, State College, Pennsylvania, United States.

The lithium-sulfur (Li-S) battery offers a high theoretical energy density of ~2600 Wh/kg and low cost, positioning it as a promising candidate for next-generation battery technology. However, problems including disastrous Li polysulfides dissolution and irreversible Li₂S deposition have severely retarded the development of Li-S batteries. To solve these issues, we have reported a functional dimethyl disulfide (DMDS)-containing electrolyte that promoted an alternate electrochemical reaction pathway for sulfur cathodes by a formation of dimethyl polysulfides and Li organosulfides as intermediates and reduction products, leading to significantly boosted Li-S cell capacity with improved cycling reversibility and stability. Recently, we further investigated using dimethyl trisulfide (DMTS), a primary discharge-charge intermediate in the DMDS-containing electrolyte, which is also a commercially available reagent, as a co-solvent in functional electrolytes for Li-S batteries. We found that, DMTS, with higher theoretical capacity (851 mAh g⁻¹) than DMDS (570 mAh g⁻¹), functions similarly to DMDS to promote an alternate electrochemical reaction pathway for sulfur cathodes and to enable good cycling performance for cathodes with high sulfur content by way of an automatic discharge shutoff mechanism. In addition, owing to the better reactivity of DMTS with Li₂S to form lithium polysulfides, the irreversible capacity loss caused by insoluble Li₂S deposition and separation of active material from conductive networks could be efficiently mitigated. Thanks to all these advantages, a 25 vol% DMTS-containing electrolyte enables Li-S batteries with even higher cell capacity and improved cycling performance than using previous optimal 50 vol% DMDS-containing electrolyte. And capacity fading rate as low as 0.11% per cycle was achieved for cathodes with high sulfur content of 70 wt% in carbon/sulfur composite using an optimal 25 vol% DMTS-containing electrolyte.

9:45 AM ET06.13.05 Dense Monolithic Hybrid of MOF and Carbon Nanotube Sponge for High-Volumetric-Energy-Density Lithium-Sulfur Batteries Hai Zhang; Peking University, Beijing, China.

Compact energy storage is of great significance especially in portable electronics and electric vehicles. Lithium-sulfur battery represents an advanced energy storage system because of its environmental benignity, high theoretical energy density (2600 Wh kg⁻¹) and natural abundance of sulfur. However, the cathodes of lithium-sulfur battery usually contain low-density porous carbon hosts for sulfur to alleviate polysulfides dissolution and improve the conductivity, which will lead to the low volumetric energy density (~500 Wh L⁻¹). Although enormous efforts have been devoted to improve the specific capacity and cycling stability of lithium-sulfur batteries, little attention has been payed to the aspect of high volumetric capacity simultaneously, which plays a key role in practical use.

Here, we for the first time fabricated the monolithic hybrid of metal-organic framework (MOF) and carbon nanotube (CNT) sponge, which was embedded within the MOF monolith to achieve the high-volumetric-energy-density lithium-sulfur batteries. Specifically, we first synthesized the ZIF-8 methanol suspension (~50 mg mL⁻¹), and dropped the suspension into the CNT sponge afterwards. The CNT sponge filled with ZIF-8 suspension was finally dried at the room temperature. Previously, MOFs or hybrids of MOFs and CNTs were always dried at the condition of vacuum and high temperature, which results in the rapid evaporation of the solvent, leaving a loose structure with a lot of void space among MOF particles. Room temperature drying in our study can make the solvent evaporate slowly and provide enough time for MOF particles aggregating into a dense monolith. Although the hybrid is highly dense, the large amount of micropores from ZIF-8 can still guarantee the high and safe sulfur loading. Besides, the embedded CNT networks act as conductive agent and supportive scaffold to improve the sulfur utilization and mechanical properties, respectively. Furthermore, superior rate performance can be achieved through optimizing the density of the monolith, which was controlled by the time period of room temperature drying. As a result, our novel free-standing electrodes exhibit a much superior volumetric energy density (~1553 Wh L⁻¹) than previously reported MOF-based electrodes in recent literature without compromising the specific capacity, rate performance and cycling stability.

10:00 AM ET06.13.06 Full Dissolution of Li₂S₈ to Li₂S in Safe Eutectic Solvent for Rechargeable Lithium-Sulfur Batteries Qian Cheng, Weiheang Xu and Yuan Yang; Columbia University, New York, New York, United States.
In this talk, we report a new safe eutectic solvent composing of amides as an electrolyte for lithium-sulfur batteries. Such eutectic solvents are safe, highly stable, and low-cost. It shows strong resistance against fire, which even cannot be ignited. In contrast, conventional ether-based electrolyte catches fire immediately after ignition. Moreover, it can dissolve the whole sulfide family, including Li$_{2}$S/Li$_{2}$S which are not dissolved in the conventional ether-based electrolyte. This unique property help address the dead sulfur issue caused by insoluble Li$_{2}$S/Li$_{2}$S in Li-S batteries, which is a major reason for low cycling lifetime of Li-S batteries. By using the eutectic solvent which can dissolve all sulfides species, a high specific capacity of 1360 mAhg$^{-1}$ and a capacitance retention of 88% over 40 cycles were achieved at 0.1 C without any electrode modification. With the further addition of TiO$_{2}$ nanoparticles on carbon electrode, stable capacity retention of 81% over 100 cycles is achieved, which prove the effectiveness of the strategy. More importantly, its cost is only ~$2-3/kg, even lower than traditional ether-based electrolyte, not to mention those expensive ionic liquids or solid electrolytes. Thus it will have great practical application in lithium-sulfur batteries. The development of eutectic solvent as electrolyte will improve lithium-sulfur batteries from aspects of safety, performance, and costs.

10:15 AM ET06.13.07
X-Ray Scattering Studies of Polysulfide Interactions in Li-S Battery Electrolytes
Elizabeth C. Miller, Noel Hayes, and Michael F. Toney; SLAC National Accelerator Laboratory, Menlo Park, California, United States; Department of Information Technology and Electrical Engineering, ETH Zürich, Zurich, Switzerland.

Lithium-sulfur (Li-S) batteries are a next generation Li battery technology that provides large theoretical capacity (1672 mAh g$^{-1}$) while also being earth-abundant and low cost$^{1}$. Li-S delivers its high capacity via a chemical transformation mechanism rather than Li intercalation as in Li-ion. Elemental sulfur (S$_{8}$) is reduced to a final solid discharge product lithium sulfide (Li$_{2}$S) through a series of soluble lithium polysulfides (Li$_{2}$S$_{2}$, 2 ≤ x ≤ 8); upon charging, this reaction is reversed. Many of these reactions occur in the electrolyte solution phase, but the interactions of the polysulfides, lithium salts, and solvent molecules are not well-established, making effective electrolyte development challenging.

In this study, we investigated the behavior of lithium polysulfides (Li$_{2}$S, Li$_{2}$S$_{x}$, x = 4, 6, 8) and lithium salt (LiTFSI). Li bis(trifluoromethane)sulfonimide in solutions using small angle X-ray scattering (SAXS). SAXS probes the nanoscale structure of the electrolyte and determines the size and shape of scatterers in solution due to their differences in electron density. Isolated LiPS have a chain-like configuration but may form dimers, aggregates, or other structures in solution$^{2}$. A concentration range (200-1000 mM) of polysulfides in two solvents, 1,3-dioxolane/1,2-dimethoxyethane (DOL/DME; 1:1 by volume), which freely solvates LiPS, and acetonitrile (ACN), which sparingly solvates LiPS$^{3}$ were examined.

Some aggregation of LiPS was observed at high concentrations (1000 mM based on the mass of sulfur) in both solvents, although shorter chain polysulfides exhibited larger populations of smaller scatterers. Polysulfide solutions of lower sulfur concentration showed multiple aggregate populations below about 10 nm in size. A greater population of larger scatterers on the order of 10 nm were observed in higher concentrations in DOL/DME. Most of the features in the SAXS pattern for ACN-based polysulfide solutions were below 10 nm, indicating isolated LiPS structures, and these features remained at roughly the same location, even at higher concentrations. Agglomeration of polysulfides was both solvent and chain length dependent; however, at higher concentrations, the chain length differences present in the SAXS disappear. Addition of 1 M LiTFSI to DOL/DME, which is the conventional electrolyte used in Li-S batteries, resulted in an additional weak peak at 0.7 Å$^{-1}$, representing a change in the small scatterers on the order of 1 nm, indicating that salt ions interfere with LiPS clustering. These results add molecular level insight into Li-S electrolytes, aiding in understanding electrolyte-salt interactions.

Understanding the High Performances of Li-Doped P2 Layered Oxide Cathode Materials for Sodium-Ion Batteries
Lufeng Yang, Xiang Li, Xuetian Ma, Shan Xiong, Yan-Yan Hu, and Haolong Chen; Chemistry, Florida State University, Tallahassee, Florida, United States; Mechanical Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States.

Layered oxide cathode materials with P2 structure and general formula A$_{M}$MO$_{2}$ (0.4 < x < 0.8, M = transition metals) demonstrated high reversible capacities in sodium ion batteries$^{1,2}$. However, commonly the capacity retention of the P2 compounds are not ideal when deeply cycled, majorly due to the mechanical damage caused by the irreversible phase transitions during the sodium intercalation/deintercalation processes. Previously we developed a novel strategy to dope lithium into the transition metal sites in the P2 structure with precisely controlled synthesis. The lithium in the transition metal layer helps to stabilize the P2 structure and eliminate the P2-O2 transition in the model compound Na$_{x}$Li$_{1-y}$Mn$_{1}$O$_{2}$. Currently we designed another compound P2-Na$_{x}$Li$_{1-y}$Fe$_{x}$O$_{2}$ in order to improve the capacity retention and the high voltage stability. This compound was successfully synthesized and electrochemically tested. The reversible capacity was as high as 190 mAh/g and the capacity retention after 80 cycles was 87%. In-depth structure characterizations with using in situ and ex situ synchrotron X-ray diffraction, neutron diffraction and solid state NMR were performed. The results showed that the P2-O2 transitional was also eliminated in this compound. Meanwhile, more Li was kept in the transition metal layer after long term cycling, compared with that of Na$_{x}$Li$_{1-y}$Mn$_{1}$O$_{2}$ implying the doping of Fe at the transition metal layer effectively helps to lock lithium in the lattice. This result provides new insights of the cycling mechanism of P2 structured cathodes, as well as new opportunities in designing next generation cathode materials for sodium ion batteries with ultrahigh reversible capacity and excellent capacity retention.

11:00 AM ET06.13.09
Lithium-Pretreated Hard Carbon as High-Performance Sodium-Ion Battery Anodes
Biwei Xiao, Mark H. Engelhard, David M. Reed, Vincent L. Sprengle and Xiaolin Li; Pacific Northwest National Laboratory, Richland, Washington, United States.

Hard carbon (HC) is the state-of-the-art anode material for sodium-ion batteries (SIBs). However, its performance has been plagued by the limited initial Coulombic efficiency (ICE) and mediocre rate performance. Here, we combined experimental and theoretical studies to demonstrate the application of lithium-pretreated HC (LPHC) as high-performance anode materials for SIBs by manipulating the solid electrolyte interphase (SEI) in tetraglyme...
(TEGDME)-based electrolyte. The LPHC in TEGDME can 1) deliver >92% ICE and ~220 mAh g⁻¹ specific capacity, twice of the capacity (~100 mAh g⁻¹) in carbonate electrolyte; 2) achieve >85% capacity retention over 1000 cycles at 1000 mA g⁻¹ current density (4C rate, 1C=250 mA g⁻¹) with a specific capacity of ~150 mAh g⁻¹, ~1.5 times of the capacity (10 mAh g⁻¹) in carbonate. The full cell of Na₃V₂(PO₄)₃-LPHC in TEGDME demonstrated close to theoretical specific capacity of ~98 mAh g⁻¹ based on Na₃V₂(PO₄)₃ cathode, ~2.5 times of the value (~40 mAh g⁻¹) with non-treated HC. This work provides new perception on the anode development for SIBs.

11:15 AM ET06.13.10
Design of Nanostructured Materials for Na and Li-Ion Energy Storage Applications Junhua Song¹, Xiaolin Li², Min-Kyu Song¹ and Yuehe Lin¹; ¹Washington State Univ, Pullman, Washington, United States; ²Pacific Northwest National Laboratory, Richland, Washington, United States.

Nanostructured materials are important for boosting the performance of energy storage devices. Here, we report our recent efforts on designing nanocomposites for rechargeable Na- and Li-ion batteries and Li-S batteries. For Na-ion battery anodes, we constructed ultra-fine SnO₂ nanocrystals anchored on a unique reduced graphene oxide (rGO) porous matrix and showed excellent rate capability and long cycle life. The improved capacity and superior rate capabilities were rooted in the enhanced transport kinetics of both electrons and ions within the electrode structure because of the well-interconnected, macro-porous rGO matrix. Besides 2D graphene supported materials, we also explored yolk-shell antimony nanoparticles as high-performance Na-ion battery anodes. The unique low-dimensional nanostructure rendered stable cycling and high rate capability, despite ~300% volume change at full sodiation/desodiation. For Li-ion battery anodes, we designed a sandwich-structured N-doped graphene anchored with nearly monodisperse Fe₃O₄ nanoparticles. The unique sandwich structure enabled good electron conductivity, Li⁺ accessibility and accommodated a large volume change upon cycling. Hence, it delivered good cycling reversibility and rate performance. Carbon nanotube aerogels (CNA) with controlled nitrogen and phosphorus dopants also are introduced as a promising cathode host for rechargeable Li-S batteries. The combined theoretical study and electrochemical evaluation revealed the role of heteroatom dopants in enhancing chemical interaction of CNA towards various polysulfide intermedia species.

1:45 PM ET06.14.01
Redox-Active Heterocyclic Azine Compounds for High Voltage and High Energy Organic Cathode Materials Eun Kwon, Kyu Nam Lee and Soo Young Park; Seoul National University, Seoul, Korea (the Republic of).

Recently, the rapidly increasing demands for electric vehicles (EVs) and smart-grid systems further require high-performance batteries with sustainability and high safety. In this regard, organic electrode materials which consists of only earth abundant elements have been considered to be a very promising alternatives to the conventional inorganic ones because of their great potential in high energy and power density, low cost, and environmental friendliness. Although a lot of organic cathode materials showing high cyclability and rate capabilities have already been developed, most of them have redox potentials below 3.0 V vs Li/Li⁺, which is considerably inferior to the commercial metal oxide cathodes. This is due to that their redox mechanisms are mostly relied on the reduction reactions; however, stabilizing the LUMO energy level of the organic molecules, which is responsible to the reduction, below 5.0 eV is difficult to achieve.

Here, we report a series of novel p-type organic electrode materials bearing redox-active heterocyclic azine compounds such as phenoxazine and phenothiazine, which exhibit high discharge voltage above 3.5 V vs. Li/Li⁺. They delivered large specific capacity more than 120 mAh kg⁻¹ with high specific energy as high as 450 Wh/kg at even high rate in Li-ion coin cell. We found out that 3-dimensional molecular design but maintaining π-conjugation could facilitate the redox reactions and capacity utilization with increased redox potential.

2:00 PM ET06.14.02
Tailoring Molten Sodium-Halide Battery Chemistry for Safe, Low Temperature, Rechargeable Batteries Erik D. Snoeke, Leo J. Small, Stephen J. Percival, Joshua Lamb, Amanda Peretti and Babu Chalamala; Sandia National Laboratories, Albuquerque, New Mexico, United States.

Identifying safe, low-cost, effective solutions to evolving electrical energy storage challenges remains a national priority, essential to meeting rapidly growing global energy demands. Here, we describe a promising approach to using low-intermediate temperature molten sodium batteries as a candidate technology offering high performance with long cycle life and inherent, engineered improvements in battery safety. Here, we describe molten salt-based batteries that integrate molten sodium anodes, solid state ceramic electrolytes, and sodium iodide-based molten salt catholytes to create high performance battery constructs that operate below 150°C. The inherent nature of the material chemistries in these all-inorganic systems further eliminates common hazards associated with runaway exothermic reactions, polymer separators, and organic electrolytes that plague other battery systems. Here, we specifically highlight recent advances in materials chemistry of developing NaI batteries. By refining the composition and chemistry of the molten salt catholyte, we influence catholyte performance while optimizing electrochemical interactions at both the separator and current collector interfaces. These refinements to catholyte chemistry stand to improve battery performance, reduce effective operating temperatures, and makes the batteries fundamentally safer as well. Accelerated rate calorimetry reveals neither runaway exothermic reactions, nor hazardous pressurized gas generation that make other battery systems inherently more hazardous in nature. Continued improvement in battery performance through optimization of the materials chemistry in these molten-salt sodium batteries promises exciting new solutions to impact a growing national need for safe, robust rechargeable electrical energy storage.

2:15 PM ET06.14.04
Cellulose Hydrogel as a Flexible Gel Electrolyte Layer for Al-Based Batteries Aswani Poosapati¹, Eunhwa Jang¹, Nathaniel Jang², Liangbing Hu² and Deepa Madan¹; ¹University of Maryland Baltimore County, Baltimore, Maryland, United States; ²University of Maryland College Park, College Park, Maryland, United States.

For electrochemical device applications such as high energy density rechargeable batteries, fuel cells, supercapacitors, electrochromic displays, etc., polymer based electrolytes are favorable materials. Previous research on most electrolytes, were made compatible for diffusion of Li ions only, due to its
wide usage. Though Li-ion batteries are most abundantly used today, they have drawbacks such as being inherently toxic to the atmosphere, limited availability compared to other metals and its high costs. Here, we focus on preparing an electrolyte compatible to diffuse Al ions. Al is chosen due to its abundant availability, potentially dendrite free deposition and high capacity. In addition to gel electrolyte preparation, we also try to improve the room temperature ionic conductivity ($\sigma$) of the synthesized electrolyte layer.

We use a nanofiber cellulose (NFC) hydrogel as the base constituent for preparing the electrolyte. NFC hydrogel is favored due to its inherent ability to be strong, excellent flexibility, and lightweight. Initially, $\sigma$ of pristine hydrogel was measured to be $10^{-6} - 10^{-7}$ S/cm. In an effort to improve $\sigma$ of the pristine hydrogel, varying amounts of KOH were added to hydrogel as an additive and casted to form films, but during preparation we had difficulties with coagulation of fibers. Also, the resulting films were flaky, brittle and not stable enough to be characterized. In order to make hydrogel more flexible and stable various additives such as Gelatin, Polyvinyl alcohol (PVA), Polyacrylic acid (PAA) were added in different ratios individually and tested. Various weight ratios of Gelatin (1, 0.75, 0.5, 0.25): Hydrogel (1): PAA (0.25): KOH (0.1, 0.2, 0.3, 0.4) were added respectively individually into vials and sonicated for 90 minutes to obtain a homogeneous mixture. The mixture was then drop casted into silicon molds and dried in a vacuum oven for about 30 hours. The obtained gel electrolytes turned out to be much more stable and flexible as compared to hydrogel with KOH. These samples were then tested against Stainless steel (SS) and Aluminum (Al) block electrodes. The best average $\sigma$ recorded was 1.086 mS/cm for 1:1:0.25 sample against Al electrodes, which are at least 3 magnitudes higher than the pristine hydrogel. The results obtained were also compared against $\sigma$ values of samples made with PVA as an additive. PVA (1, 0.75, 0.5, 0.25): Hydrogel (1): KOH (0.1, 0.2, 0.3, 0.4) ratio gel samples were made similar to gelatin samples and characterized. An average highest ionic conductivity of 0.564 mS/cm was obtained for 1:1:0.4 sample against SS electrodes and 0.115 mS/cm for 1:1:0.3 sample against Al electrodes respectively. When comparing the results, Gelatin along with PAA and KOH turned out to be better with hydrogel rather than PVA and KOH. These results are comparable to that of Li ion batteries and are twice for gel polymer electrolytes for Al-based batteries.

A New Method for Determining the Concentration of Electrolyte Components in Lithium-Ion Cells Using Fourier Transform Infrared Spectroscopy and Machine Learning
Leah Ellis, Samuel Buteau, Samuel Hames, Lauren Thompson, David Hall and Jeff Dahn; Dalhousie University, Halifax, Nova Scotia, Canada.

A new method is introduced for determining unknown concentrations of major components in typical lithium-ion battery electrolytes. The method is quick, cheap, and accurate. Machine learning techniques are used to match features of the Fourier transform infrared (FTIR) spectrum of an unknown electrolyte to the same features of a database of FTIR spectra with known compositions. With this method, LiPF6 concentrations can be determined with similar accuracy and precision as an inductively coupled plasma optical emission spectrometry (ICP-OES) method. The ratios of organic carbonate solvent species can be determined with more rapidity than gas chromatography (GC). This FTIR method is faster and less expensive than GC and ICP-OES, and has the added benefit of being able to determine LiPF6 concentration and solvent fractions simultaneously. It will be shown how the application of this tool facilitates electrolyte analysis of aged lithium-ion cells, and helps elucidate mechanisms for cell degradation.

3:15 PM DISCUSSION TIME

3:30 PM ET06.14.07
Crumpled MXene Nanosheets Obtained via Acid or Base Induced Deflocculation as High Capacity Anodes in Na-Ion Batteries
Varun Natu1, Di Zhao1, Mallory Clites1, Guobing Ying1, Sankalp Kota1, Ekaterina Pomerantseva1, Michel Barsoum1 and Minhua Cao2; 1Drexel University, Philadelphia, Pennsylvania, United States; 2School of Chemistry and Chemical Engineering, Beijing Institute of Technology, Beijing, China.

MXene are a recently discovered family of two-dimensional, 2D, transition metal carbides, nitrides and carbonitrides that have shown a lot of promise in the field of energy storage with applications ranging from high capacity anodes for lithium, sodium, potassium, and aluminum ion batteries, supercapacitors and catalyst for hydrogen evolution among several others. Typically, to form MXene films, neutral, aqueous colloidal suspensions are vacuum filtered. Even though this method produces free-standing films, the process is slow and the MXene films obtained are densely packed which hampers ionic mobility resulting in low capacities when tested as anodes in Na-ion batteries.

Herein, we show that by simply decreasing or increasing the pH of a Ti3C2Tx (where T are the terminations on the MXene sheet) colloidal suspension, the 2D nanosheets crash out into crumpled flakes, resulting in randomly oriented mesoporous powders. Electrodes made with the crumpled powders deflocculated using an acid or alkali hydroxides have Na ion capacities of $\approx 180$ mAh g$^{-1}$ and $\approx 230$ mAh g$^{-1}$ at 100 mA g$^{-1}$ respectively. As importantly, we also found that when deflocculated with alkali hydroxides, the intercalation of the alkali cations that occurs resulted in smaller first cycle capacity losses and suggest a method to potentially solve this pesky problem.

3:45 PM ET06.14.08
High-performance NaV3(PO4)3/C Composites as a Safe and Stable Anode Material for Sodium-Ion Battery
Pingyuan Feng, Wei Wang, Jie Hou, Kangli Wang, Shijie Cheng and Kai Jiang; Huazhong University of Science and Technology, Wuhan, China.

A lot of phosphate-type polyanion-type compounds, such as NaV2(PO4)3, NaTi2(PO4)3 et al. have been widely researched as electrode materials for Na-ion batteries (SIBs), and they are usually endowed with enhanced structural stability through modification. However, anode materials with low operation potential lower than 2.0 V and high cyclic stability based on polyanion-type phosphate materials are hardly reported. Owning to the chemical versatility of vanadium element, vanadium-based phosphates generally have multiple redox couples at a wide potential range. Therefore, it is possible to explore a kind of vanadium-based phosphate compound with multiple electron transfer as high stable anode for SIBs. Herein, a type of NaV3(PO4)3/C as high-performance anode material is reported. The obtained NaV3(PO4)3/C composite shows high capacity (152 mAh g$^{-1}$ at 75 mAh g$^{-1}$ and 113 mAh g$^{-1}$ at 750 mAh g$^{-1}$), excellent cyclability (145 mAh g$^{-1}$ after 200 cycles at 150 mAh g$^{-1}$ and 124 mAh g$^{-1}$ after 1200 cycles at 750 mAh g$^{-1}$) and outstanding rate performance (88 mAh g$^{-1}$ at 4.5 A g$^{-1}$). According to the achieved results, it can be seen that the as-prepared NaV3(PO4)3/C is a promising anode of SIB for large-scale energy storage applications.

Lithium (Li)-ion batteries are widely used for many applications today, but there is an increasing demand to increase their specific energy (Wh kg⁻¹) and energy density (Wh L⁻¹). Among the many options, Li metal is considered one of the most promising electrode materials for future batteries. When coupled with a high capacity cathode material, such as high-nickel-content lithium nickel manganese cobalt oxide (high-Ni NMC) or sulfur (S), rechargeable Li metal batteries have the potential to achieve a specific energy much higher than 350 Wh kg⁻¹. However, achieving such goals requires fundamental breakthroughs and new knowledge to optimize and integrate all active inactive components on relevant scales with appropriate cell architectures. This talk will discuss the materials science and materials chemistry challenges, along with potential solutions, of using Li metal anodes based on the system level requirements of a high-energy cell. The important relationships between the Li anode and other cell components, such as high cathode loading and restricted amounts of electrolyte and Li, are reviewed in order to inspire new ideas to effectively address the grand challenges in rechargeable Li metal batteries.

I will start by giving an overview of active research activities in my research group located at University of Maryland Energy Research Center, including wood materials toward sustainability, 3000K high temperature materials and processing, and beyond-Li ion batteries (solid state, Na-ion). Then I will focus on our recent development on:

- Garnet-based solid-state Li-metal batteries including interface engineering to improve the wetting between Li metal anode and Garnet solid-state electrolyte (Nature Materials 2016; JACS 2016; Advanced Materials 2017; Science Advances 2017; Garnet based 3D Li ion conductive framework toward high energy density Li-S batteries (EES 2017); Garnet nanofiber based flexible, hybrid electrolyte with a high Li ion conductivity (PNAS 2016).
- Assembly and functionalization strategies of wood nanocellulose aimed at specific properties, with an eye toward high impact applications including energy, electronics, building materials and water treatment, including nanomanufacturing and light management in transparent nanopaper for optoelectronics (as a replacement of plastics); mechanical properties of densely packed nanocellulose for lightweight structural materials (replacement of steel, Nature 2018); artificial tree for high-performance water desalination and solar steam generations; mesoporous, three-dimensional carbon derived from wood for advanced batteries (replacement of metal current collectors for beyond Li-ion batteries).

The growing interest in using manganese dioxide (MnO₂) for supercapacitor (SC) electrodes is attributed to its high theoretical specific capacitance (1400F g⁻¹), relatively large voltage window, natural abundance and environmental friendliness. However, the low electronic conductivity of MnO₂ impedes its further development in commercial applications. Normally, the conductive additives such as multiwalled carbon nanotubes (MWCNT) are introduced to enhance the electronic conductivity of MnO₂ for the fabrication of SC electrodes. However, it is critical to achieve a high electrochemical performance of SC with high active mass loading at high charge-discharge scan rates. The important task is to avoid agglomeration of MnO₂ nanoparticles and MWCNT. New strategies are developed to address this problem. In this work, liquid-liquid extraction method (LLEM) is developed to prepare non-agglomerated small sized MnO₂ nanoparticles with porous surface and improved mixing of MnO₂ and MWCNT. Head-tail (HT) surfactants, containing amine, phosphonate or carboxylic groups, are used as extractors for extraction of MnO₂ nanoparticles. Moreover, it was found that conceptually new
multifunctional head-to-head (HTH) surfactants containing one phosphate end and one carboxylic end can be used as efficient extractors for LLEM. Furthermore, HTH surfactants can be used as dispersing and charging agents to prepare stable MnO2 suspension for electrophoretic deposition (EPD) of thin film. The influence of molecular structure of different extractor molecules such as hexadecylammonium (HDA), hexadecylphosphonic acid (HDPA), palmitic acid (PA) and 16-phosphonoheptadecanoic acid (16PHA) on the electrochemical performance of SC electrodes have been investigated systematically. Various interactions between nanoparticles and extractors molecules such as covalent, ion-pair or electrostatic interactions play role in preparing the non-agglomerated MnO2 nanoparticles. Compared to other HT surfactants such as HDA, HDPA and PA, the HTH surfactant 16PHA used as an extractor for preparation of SC electrodes with active mass loading of 37mg cm⁻² showed highest capacitance of 5.7 F cm⁻² (157 F g⁻¹) and 2.5 F cm⁻² (67 F g⁻¹) at a scan rate of 2 mV/s and 100mV/s, respectively. Additionally, MnO2 particles extracted by 16PHA, are negatively charged and deposited on the anode surface by EPD forming a relatively smooth, dense and agglomerate-free thin film. The conceptually new strategy using multifunctional HTH surfactants as extractor for preparation of non-agglomerated nanoparticles by LLEM paves the way for the fabrication of different functional nanomaterials for advanced applications.

Electrochemical Supercapacitor Based on CoO2-x-MnO2-Graphene Oxide Nanocomposite Dipali S. Patil, Sachin A. Pawar and Jae Cheol Shin; Yeungnam University, Gyeongsan-si, Korea (the Republic of).

Various metal oxide nanostructures of RuO2, MnO2, NiO, Co3O4, SnO2, MnO4, and V2O5 have been used widely as promising electrode materials for supercapacitor applications. Among these Cobalt oxide (Co3O4) is believed to be one of the best materials among transition metal oxides owing to its high theoretical capacitance (3560 F g⁻¹), environmental friendliness, and better electrochemical performance. On the other hand, MnO2 is one of the most favorable pseudo-capacitor electrode materials because of its low cost, environmentally friendly characteristics, and excellent capacitance performance. The intrinsically low conductivity of MnO2, however, limits its practical applications as a pseudo-capacitive material. Several strategies have been employed to improve the electrical conductivity of MnO2-based electrode. One simple strategy is to combine MnO2 with other metal oxides to form hybrid nanostructures with sufficient electrical conductivity. Another approach is to integrate it with electrically conducting materials like carbon materials or graphene to enhance the electrochemical stability and electric conductivity of the electrode. In the present study, we developed new CoO2-x-MnO2-graphene oxide based electrode by simple hydrothermal technique. The synthesized electrode materials are characterized by, XRD, XPS, FE-SEM, TEM, HRTEM etc. The supercapacitor performance of all the prepared electrodes was assessed by cyclic voltammetry (CV), electrochemical impedance spectroscopy (EIS), and galvanostatic charge/discharge measurements. The important parameters of electrochemical supercapacitor like specific capacitance, energy density and electrochemical stability are measured in this work.

10:00 AM ET07.01.05

Design and Development of Sodium-Ion Batteries Based on Layered Transition Metal Oxide Cathode Material Zifeng Ma; Shanghai Electrochemical Energy Devices Research Center, Department of Chemical Engineering, Shanghai Jiao Tong University, Shanghai, China.

Rechargeable Li-ion batteries have been considered as a promising power source for the electric vehicles and the grid energy storage systems. However, lithium resources are limited and will restrict the huge applications of Li-ion batteries. It is of great significance to develop eco-friendly sodium ion batteries which employ abundant sodium resources. Recently, we developed the large-scale synthesis route of NaNi1/3Fe1/3Mn1/3O2 (NFM) by using hydroxide co-precipitation combined with solid-state reaction, and the optimization reaction condition was studied by using in situ XRD. The metastable structure change of NaNi1/3Fe1/3Mn1/3O2 during electrochemical sodium ion intercalation which cycled at 0.1C rate between 2.0 to 4.0V, and 2.0 to 4.3V, were studied by using in operando TXM-XANES and XRD, and the thermal decomposition behavior and structure evolution of charged NaNi1/3Fe1/3Mn1/3O2 cathode material during heating process was measured by using in situ high-energy X-ray diffraction (HEXRD) technique. The effect of Ca-substitution in Na sites on the structural and electrochemical properties of NaNi1/3Ca1/3Mn1/3O2 (NFM) (x=0, 0.05, 0.1). X-ray diffraction patterns of the prepared NaNi1/3Ca1/3Mn1/3O2 samples show single α−NaFeO2 type phase with slightly increased alkali-layer distance as Ca content increased. The cycling stabilities of Ca-substituted samples are remarkably improved. The NaNi1/3Ca1/3Mn1/3O2 cathode delivers capacity of 116.3 mAh g⁻¹ with capacity retention of 92% after 200 cycles at the 1C rate. In operando XRD indicates a reversible structural evolution through an O3-P3-O3-3P-O3 sequence of the NaNi1/3Ca1/3Mn1/3O2 cathode during cycling. Compared to NaNi1/3Fe1/3Mn1/3O2, the NaNi1/3Ca1/3Mn1/3O2 cathode shows wider voltage range in pure P3 phase state during charge/discharge process and exhibits better structural recoverability after cycling. The superior cycling stability of NaNi1/3Ca1/3Mn1/3O2 makes it a promising material for practical applications in sodium ion batteries. A new portable energy storage device based on SIB has been designed and assembled. Layered oxide NaNi1/3Fe1/3Mn1/3O2 and hard carbon were used as cathode and anode, respectively. The SIB pouch cell has been designed and the electrochemistry and safety performance were tested.

Evaluation of Li-Ion Batteries Built with Recycled NCM 111 Cathode Jun Wang1, Paul Gionet1, Dennis Bullen1, Ronnie Wilkins1, Ian O'Connor1, Leslie Pinnell1, Derek C. Johnson1, Zhangfeng Zheng2, Mengyuan Chen2 and Yan Wang2; 1A123 Systems LLC, Waltham, Massachusetts, United States; 2Mechanical Engineering, Worcester Polytechnic Institute, Worcester, Massachusetts, United States.

Recycling of Li-ion batteries that have reached end-of-life (EOL) becomes increasingly critical to long term sustainability of electrochemical energy storage ecosystem, as the number of Li-ion battery powered portable devices and vehicles continues to increase rapidly. Many components incorporated in commercial Li-ion batteries face limited raw materials supply, such as Lithium, Nickel and Cobalt. Recovering those elements from spent batteries serves a dual purpose of reducing the environmental impact of hazardous materials disposal as well as providing a stable stream of the necessary metals to meet ever-growing manufacturing demand. This research focused on evaluating nickel cobalt manganese oxide (NCM 111) cathode powder regenerated from a closed loop recycling process which...
targets end-of-life electric vehicle Li-ion batteries. This process starts with spent batteries regardless of cathode chemistry, produces stoichiometric LiNi0.8Co0.18Mn0.02O2 (NMC 111) cathode material with electrochemical properties rivaling commercial control NCM 111. Prismatic pouch cells consist of recycled NCM 111 were fabricated at small and large capacity, 1.0 Ah and 11.0 Ah, respectively. Subsequent performance benchmarking against control cells was conducted through an array of metrics including rate capability, HPAC, cold crank, cycle life and calendar life. Cells built with recycled NCM 111 demonstrated similar cyclability to control at ÷2500 cycles to 80% retention under +1C, -2C cycling conditions, and no obvious difference was observed for cold crank, HPAC and calendar life between commercial control and recycled cells. The rate capability, however, seems to slightly favor recycled cell at rates above 2C. Those results undoubtedly validate the recycled NCM 111 cathode as a legitimate contender for commercial electric vehicle Li-ion battery applications.

High-Performance Energy Storage from Biomass Materials Yunya Zhang and Xiaodong Li; Mechanical and Aerospace Engineering, University of Virginia, Charlottesville, Virginia, United States.

Considering the irreversible environmental damages and the huge cost induced by fossil fuel consumption and Co/graphite mining, it is environmentally and socially significant to produce energy storage devices from low cost and renewable materials. In order to achieve lightweight, mechanical robustness, and various functionalities, nature often constructs hierarchically porous structures or thin films. These delicate structures, if well utilized, can largely improve the performances of energy storage devices. Thusly, a rational design strategy is to derive high-performance electrodes from biomass materials. Banana peels, as the inedible part of the most popular fruit, have a typical porous structure. After treated by NiNO3, the micron sized pores on activated banana peel (ABP) effectively enhanced the accessibility of electrolyte, nanoparticles immobilized and encapsulated polysulfides, and graphene coated Ni nanoparticles improved conductivity, leading to a high specific capacity of the assembled Li-S batteries. To increase the utilization efficiency of graphene, graphene oxide sheets were incorporated with activated paper carbon (APC) via capillary method. Thin graphene layer were coated around cellulose fibers with nano sized bulges and wrinkles, which not only increased sulfur loading, but also encapsulated polysulfides and buffer volume fluctuations, rendering an ultra-long lifespan of 1000 cycles with over 60 % capacity retention rate of Li-S batteries. In addition to optimize the performance of biomass derived electrodes, we also seek holistic utilization of biomass materials. An all-solid, flexible supercapacitor was fabricated from a whole egg. Eggshell was used as templates and egg white/yolk was employed as carbon source for 2D graphene like carbon films. Solid electrolyte was produced by egg white/yolk and KOH. Egg shell membrane was then used as separator. The assembled supercapacitors exhibited superior performances.

Controlling Charge Transport in Spinel Oxides through Manipulation of Cation Site Occupation Anuj Bhargava and Richard Robinson; Cornell University, Ithaca, New York, United States.

Ternary spinel oxides are actively used and researched for applications ranging from electronics, sensors, catalysis, data storage, to energy storage due to their useful magnetic, catalytic, and electronic properties. One intriguing nanomaterial is the non-stoichiometric p-type spinel CoxMn3-xO4, in which cation site occupation is an important determinant of materials properties. Therefore, by manipulation of cation configurational disorder, properties such as the charge carrier density and the associated electrical conductivity can be easily controlled. The manipulation of cation configuration disorder is carried out by changing the Co to Mn ratio (or the ‘x’ value in CoMn3-xO4), which leads to the variation of (1) atomic distribution of Co and Mn atoms present at tetrahedral (Td) and octahedral (Oh) sites in the spinel system, and (2) oxidation states of the cations. In this work, we utilize a new technique to characterize the configurational disorder in spinels. We demonstrate that x-ray emission spectroscopy (XES) is a more reliable method than traditionally used K-edge x-ray absorption spectroscopy (XAS) to extract cation site occupation. Comparison between the XAS and XES techniques reveal that XES provides not only the site occupation information that XAS reports, but also additional information on the valence states of the cations at each site. We show that the XES error is lower than the EXAFS error in all cases, by up to ~20%. Additionally, the error for EXAFS is as high as 35% whereas for XES, the error determined is consistently smaller than 10%. Furthermore, we correlate the extracted site occupation data to the electrical conductivity and the supercapacitor performance and observe a strong correlation between structural properties and electronic properties of spinels. We show that the number of hole acceptor/donor pairs of Mn2+/Mn3+ at Oh sites is proportional to both the electrical properties and the energy density of the supercapacitors. Finally, via the optimization of configurational order in the CoMn3-xO4 nanoparticles system, we were able to increase the energy density and specific capacitance of the supercapacitors by 2x as compared to previously reported values.

SESSION ET07.02: Materials Processing
Session Chairs: Sergiy Kalnauas and Jianlin Li
Monday Afternoon, November 26, 2018
Hynes, Level 3, Room 312

1:30 PM ET07.02.01

The widespread adoption of electric vehicles using advanced battery technologies and the development of their manufacturing base in the United States are critically important goals for the US economy and therefore a major focus of research and development sponsored by DOE’s Office of Energy Efficiency and Renewable Energy. Materials development is often touted as the most important enabling activity, however in a rank of major cost items, manufacturing costs ranks just below the cathode components. In addition to the need to reduce costs, US R&D should also focus on new, yet-to-be-scaled processing technologies that, when developed and implemented in the US provide both a strong component of US energy security and US-based employment in a field expected to grow to over $100B in the next twenty years. Processing science and engineering has traditionally been underrepresented in federally funded electrochemical energy storage R&D. Over the last eight years, the Vehicle Technologies Office (VTO) has been building an advanced processing R&D portfolio. This includes competitively funded research at universities, small businesses, and large corporations as well as programs supported across the array of the national laboratory complex. This presentation will provide an overview of the sub-program’s history and some examples of early successes. Future research directions and scenarios for possible funding opportunities will also be discussed.
Despite the societal and economic importance of advanced batteries, the complicated relationships between electrode processing, structure, and performance are still poorly understood. In this work, we combine fundamental rheological and electrochemical studies to investigate the relationships between slurry microstructure, electrode morphology, and battery rate capability at industrially-relevant compositions of inactive material. In one example of our approach, dry-mixing LiNi0.5Mn0.3Co0.2O2 (NMC) with carbon black decreases the free carbon concentration and consequently the ability of the slurry to form a gel network, as revealed by small-angle oscillatory shear measurements. Less free carbon weakens the strength of the slurry’s viscous and elastic moduli and is also reflected in a decrease in electronic conductivity of the dried electrode. Despite a clear dependence of slurry moduli and electronic conductivity on free carbon concentration, there is no useful relationship between in-plane electronic conductivity and battery rate capability, demonstrating that short-range electronic contacts are more important than either ion transport or long-range electronic conductivity to cathode rate capability [1]. We further explain this finding by measuring the critical gelation concentration of carbon black and showing that it is independent of the NMC volume fraction, indicating that active material resides in the interstitials of the percolating carbon network [2].

Our identification of short-range electronic contacts as the key parameter for electrode performance motivates the development of new methods to observe and quantify these contacts. We use SEM-EDS to quantify the carbon black heterogeneity and show its sensitivity to a variety of manufacturing parameters, including the impact of polymer chain scission during mixing. In order to adapt this approach for carbonaceous active materials such as graphite, we substitute carbon black with commercial carbon-coated Fe nanoparticles as a contrast-enhancing agent that permits spectroscopic distinction between active material, conductive additive, and binder [3]. The Fe nanoparticles further enable nanoscale computed tomography (XCT) to obtain three-dimensional images of the active material and carbon-binder-domains with 126 nm voxel resolution. Future work will discuss the relationships between the observed microstructure and the battery performance in more detail, as well as our efforts towards alternative electrode designs with optimal carbon connectivity.

2:15 PM ET07.02.03
A Systematic Approach for Characterizing the Surface Free Energy of Composite Electrodes for Li-Ion Batteries
Ali Davoodabadi1, Jianlin Li2, David Wood3 and Congrui Jin1; 1Mechanical Engineering Department, Binghamton University, The State University of New York, Binghamton, New York, United States; 2Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

One of the crucial steps in battery manufacturing is the electrolyte wetting step which typically requires a relatively long time to be completed. It is known that the relationship between polar and dispersive components of the electrolyte surface tension and the electrode surface free energy (SFE) plays a vital role in the extent of wetting and, thus, tuning the SFE can accelerate the wetting step in battery manufacturing. This work developed and validated a systematic approach to characterize surface free energy of composite electrodes for lithium-ion batteries, which has never been reported in literature. We introduced two main surface parameters, \( r \) and \( f \), that represent the surface roughness ratio and surface solid fraction, respectively. These parameters are crucial in determining the so called actual SFE of the electrodes. The effect of slurry formulation and electrode porosity on the SFE of electrodes were investigated. It is demonstrated that the SFE of LiNi0.5Mn0.3Co0.2O2 cathode was higher than the graphite anode. Replacing the conventional Polyvinylidene fluoride (PVDF) with water soluble binder significantly increased the polar component of the electrodes surface free energy. The increased polar component is expected to enhance the wetting of the electrodes toward different common electrolytes. The results from this work provide insights in slurry formulation for optimal slurry wetting on current collector and electrolyte wetting on dry electrodes.

2:30 PM ET07.02.04
Enhancement of Cost Effective Pt-Based Catalyst Activity and Durability for Proton Exchange Membrane Fuel Cell Application
Ali Abdelhafiz2; Jianhuang Zeng1, Bote Zhao2 and Meilin Liu1; 1South China University of Technology, Guangzhou, China; 2Materials Science and Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States.

Proton exchange membrane fuel cells (PEMFCs) have tremendous potential to be the preferred power sources for many emerging technologies, from electric vehicles to portable/mobile devices and smart grids, because of their numerous inherent advantages such as high efficiency, high energy density, low emissions, and fast start-up and shut-down capability. While PEMFCs are expected to use platinum group metal (PGM)-based catalysts in the near-term, the cost of the Pt-based catalyst alone constitutes over 40% of the fuel cell stack cost. Enormous efforts have been devoted to reducing the high cost of catalyst. To date, the catalysts can be classified into three groups according to the active component used: PGM-based catalyst (supported on carbon or other supports); PGM-based catalysts that are modified or alloyed with other metals such as Cu, Co, and Ru; and PGM-free catalysts such as non-noble metals and organometallic complexes. PGM-free catalysts are attractive for cost reduction of PEMFC technology, however, in reality it is still a long way to go to before they can be used to run actual fuel cell application. Here in, we are proposing a facile, one-step, synthesis of Pt-based alloy nanoparticles for cost effective low temperature oxygen reduction reaction electrocatalysis at industrial scale.

Direct Pt nanoparticles synthesis is performed under room temperature to form a branched triple and quadruple-pods particles with an average size of ~3.5 nm, as confirmed by X-ray diffraction (XRD) and Scanning transmission electron microscope (STEM) analysis. Rotating disc electrode (RDE) setup is used to probe ORR. Results showed that synthesized Pt-nanoparticles superior catalytic activity for oxygen reduction reaction compared to state of the art Pt-XC/72R commercial catalyst. Pt-nanoparticles periphery are conformed of high index family crystallographic planes, as observed by STEM analysis. High index planes contain lower density of kinks, which optimize the adsorption/desorption energies to be neither too weak nor too strong. Pt-nanoparticles under accelerated durability testing (ADT) outperform their state of the art commercial catalyst counterparts, surviving 81% of electrochemical active surface area (ECSA) after 10,000 testing cycles.

Using a catalyst coated membrane (CCM) technique membrane electro assembly (MEA) was prepared to test Pt nanoparticles under actual PEMFC operation conditions (i.e. temperature and humidity). MEA prepared using the synthesized Pt-nanoparticles outperformed their counterparts prepared by Pt-XC/72R state of the art commercial catalyst with 27% enhancement factor. The reported Pt-based nanoparticles propose a competitive and more efficient synthesis route to prepare large scale commercial catalyst without the need of sophisticated apparatus or special heating conditions.
Li-ion batteries are complex systems whose electrochemical performance depends on properties and design of many components that are combined to make a cell. Manufacturing of these components involves complicated processing, from slurry preparation, to casting and drying, to electrode calendaring. Each step depends on several variables, for example drying rate or calendaring pressure. Relationships between these variables and the resulting performance of the electrochemical cell has not been completely established. This talk reports on efforts towards establishing such relationships through characterization and mathematical modeling. Methods for computing elastic and inelastic properties of battery electrodes from their microstructure will be presented and the results will be correlated with degree of electrode compression during calendaring. Predictive capabilities of the models in terms of electrochemical performance will be discussed.

This research at Oak Ridge National Laboratory, managed by UT Battelle, LLC, for the U.S. Department of Energy under contract DE-AC05-00OR22725, was sponsored by the Vehicle Technologies Program for the Office of Energy Efficiency and Renewable Energy.

Light-Directed BiVO4–C Fuel Cell with Simultaneous Production of H2O2 Xinjian Shi and Xiaolin Zheng; Stanford University, Stanford, California, United States.

Photoelectrochemical (PEC) systems have been researched for decades for their great promise to convert sunlight to fuels. Majority of the research on PEC has been focusing on using light to split water to hydrogen and oxygen, and its performance is limited due to the need of additional bias. Another research direction on PEC focuses on using light to decompose organic materials while producing electricity. In this work, we report a new type of unassisted PEC system that uses light, water and oxygen to simultaneously produce electricity and valuable hydrogen peroxide (H2O2) on both electrodes, with each consisting of BiVO4 photoanode where water is oxidized to H2O2 and carbon cathode where O2 is reduced to H2O2. In addition to producing H2O2, this PEC system also generates electricity, achieving a maximum power density of 0.194mW/cm2, an open circuit voltage of 0.61V, and a short circuit current density of 1.09mA/cm2. The electricity output can be further used as a sign for cell function when accompanied by a detector such as a LED light or a multimeter. This is the first work that shows H2O2 two-side generation with strict key factors study on such system, with clear demonstration on electricity output ability for it using low-cost earth abundant materials on both sides, which represents an exciting new direction for PEC systems.

Light-Driven BiVO4–C Fuel Cell with Simultaneous Production of H2O2 Xinjian Shi and Xiaolin Zheng; Stanford University, Stanford, California, United States.

Frequency stable, high permittivity nanocomposite capacitors produced under mild processing conditions offer an attractive replacement to MLCCs derived from conventional ceramic firing. Here, 0–3 nanocomposites were prepared using gel-collection derived barium titanate (BTO) nanocrystals, suspended in a poly(furfuryl alcohol) matrix, resulting in a stable, high effective permittivity, low loss dielectric. The nanocrystals are produced at 60 °C, emerging as fully crystalized cubic BTO, 8 nm, with a highly functional surface that enables both suspension and chemical reaction in organic solvents. The nanocrystals were suspended in furfuryl alcohol where volume fraction of nanocrystal filler (νf) could be varied. Polymerization of the matrix in situ at 70–90 °C resulted in a nanocomposite with a higher than anticipated effective permittivity (up to 50, with νf only 0.41, from 0.5–2000 kHz), exceptional stability as a function of frequency, and very favorable dissipation factors (tan δ < 0.01, νf < 0.41; tan δ < 0.05, νf < 0.5). The increased permittivity is attributed to the covalent attachment of the poly(furfuryl alcohol) matrix to the surface of the nanocrystals, homogenizing the particle−matrix interface, limiting undercoordinated surface sites and reducing void space. XPS and FTIR confirmed strong interfacial interaction between matrix and nanocrystal surface. Effective medium approximations were used to compare this with similar nanocomposite systems. It was found that the high effective permittivity could not be attributed to the combination of two components alone, rather the creation of a hybrid nanocomposite possessing its own dielectric behavior. A nondispersive medium was selected to focus on the frequency dependent permittivity of the 8 nm barium titanate nanocrystals. Experimental corroboration with known effective medium approximations is evident until a specific volume fraction (νf ≈ 0.3) where, due to a sharp increase in the effective permittivity, approximations fail to adequately describe the nanocomposite medium.

Simple Process for Preparing Core–Shell Type Hybridized Nanoparticles for Polymer Electrolyte Membrane Akiko Masubara1,3, Keiji Shito1, Yuki Takahashi1, Satoshi Sekine1, Kazuki Koseki1, Keisuke Tabata1, Tomohiro Nohara1 and Toshihiko Arita1; 1Yamagata University, Yonezawa, Japan; 2IMRAM, Tohoku University, Sendai, Japan; 3Roel, Yamagata University, Yonezawa, Japan.

We designed a novel polymer electrolyte membrane (PEM) for PEFC using inexpensive materials and fabricating precise nanostructures. Hence, we have focused on general inorganic filler filling method, which has advantage on improvement of heat resistance and gas barrier properties of the membrane. Novel model PEM consists of silica nanoparticles (NPs) with proton conductive polymer layer prepared by Reversible Addition-Fragmentation chain Transfer Polymerization with Particles (RAFT PwP) on its surface. RAFT PwP can prepare precisely adsorbed hydrophilic polymer layer on particles surface. Effective medium approximations were used to compare this with similar nanocomposite systems. It was found that the high effective permittivity could not be attributed to the combination of two components alone, rather the creation of a hybrid nanocomposite possessing its own dielectric behavior. A nondispersive medium was selected to focus on the frequency dependent permittivity of the 8 nm barium titanate nanocrystals. Experimental corroboration with known effective medium approximations is evident until a specific volume fraction (νf ≈ 0.3) where, due to a sharp increase in the effective permittivity, approximations fail to adequately describe the nanocomposite medium.
Radio frequency (RF) dielectric barrier discharge plasma was used to exfoliate graphite oxide (GO) into graphene. The GO was synthesized from a modified Hummers method. The exfoliation occurred swiftly once the RF power and gas pressure reached a level that enabled sufficient energy transfer from the plasma to the GO. X-ray diffraction (XRD) and transmission electron microscopy (TEM) confirmed that graphene or carbon nanosheets were successfully prepared. The plasma exfoliation mechanism was revealed based on the microstructure characterization and optical emission spectroscopy, which indicated that oxygen was released at the moment of exfoliation. Inspired by the success of GO exfoliation, N-doping was realized by treating pyrrole-modified GO with plasmas. The N concentration in the resulted graphene depended strongly on the plasma gas. Of the gases studied, CH4 treated pyrrole-modified GO (GO-PPY-CH4) contained considerable concentration of N that was beneficial to electrical double layer capacitors (EDLCs).

Supercapacitors made of the N-doped graphene exhibited promising capacitive characteristics. Electrochemical measurements showed that the GO-PPY-CH4 presented an initial specific capacitance of ~312 F g⁻¹ under 0.1 A g⁻¹ charge/discharge current and ~100% retention after 1000 consecutive cycles under currents ranging from 0.1 to 10.0 A g⁻¹ in 6 mol L⁻¹ KOH electrolyte. This study demonstrated that the plasma exfoliation was an efficient approach to fabricating graphene and N-doped graphene that had promising potential to be high-performance electrode materials for EDLCs.

Furthermore, flexible solid-state supercapacitors featuring lightweight and large capacitance have many attractive applications in portable and wearable electronics. The study demonstrates a magnetically enhanced dielectric barrier discharge that has the potential to efficiently exfoliate polyaniline-modified graphene at low input power. The plasma exfoliated N-doped graphene is subsequently used to fabricate flexible solid-state supercapacitors, which exhibit large specific capacitance of 45 mF cm⁻² at 0.2 A cm⁻² charging rate, ~100% capacitance retention after 1000 charge/discharge cycles at different current densities, and outstanding mechanical flexibility. The magnetically enhanced plasma exfoliation of graphite oxide offers a potentially cost-effective approach to producing high-quality carbon nanomaterials for energy storage.
component. We characterized our films using Scanning Electron Microscopy, X-ray Diffraction, and Raman Spectroscopy. Electrochemical characterization, i.e., cyclic voltammetry and charge-discharge cycling, were carried out in three-electrode cell configuration (where Hg/HgO, Pt, and our sample are the reference, counter and working electrodes respectively) with 1 M KOH as the electrolyte. The presence of redox peaks in cyclic voltammetry curves confirms the pseudocapacitive behavior of the sample while identical CV curves even at higher scan rates further suggest excellent rate capability and ideal supercapacitor behavior. The galvanostatic charge-discharge measurements (GCD) performed at 0.25 mA current resulted in specific capacitance as high as 12 mF/cm² for the electrode prepared with 2-pulses of irradiation. After performing GCD measurements for 5000 cycles, we found that the electrode retains as high as 80% capacitance, which shows that as prepared electrode possesses excellent stability and long cycle-life. Next steps will be the work on other mixed oxides electrodes, such as Ni-Mn oxides, Mn-Fe oxide and thicknesses and different fluence values during irradiation.

CNT Flexible Membranes for Energy Conversion and Fuel Cells

We have successfully employed charge transfer mechanism to nanosegregate the surface of CNT powder and converted into CNT flexible membranes. The processing protocol has limited or no impact on the intrinsic properties of the CNTs. The CNT membranes have bulk mass density greater than that of water (1.0 g/cc). We have demonstrated the use of the CNT membranes as electrode in a pristine and oxidized single/stacked solid-state capacitor as well as pristine interdigitated microcapacitor that show time constant of ~32 ms with no degradation in performance even after 10,000 cycles. The capacitors maintained very excellent performance even at temperature up to 90°C. We will present these results including the specific capacitance, leakage current, energy and power densities, as well the effects of flexing on these properties.

ET07.03.04

Stretchable Wire-Shaped Supercapacitor Based on Biodegradable Metal and Polymer

Hanchan Lee, Geumbee Lee and Jeong Sook Ha. Korea University, Seoul, Korea (the Republic of).

Recently, there has been extensive interest in transient devices which experience the complete biodegradation after use for certain desired time since they can contribute to the realization of environmentally friendly electronic devices, wearable/implantable devices, or various transient systems for internet of things. In this study, we report on a facile fabrication of stretchable wire-shaped supercapacitor (WSC), in which all components are completely resorbable in water or biofluid; water-soluble molybdenum (Mo) wire as a current collector, molybdenum oxide as a pseudocapacitive electrode, polyvinyl alcohol containing sodium chloride as an electrolyte, and poly (1,8-octanediol-co-citrate) (POC) film as an encapsulant as well as a deformable substrate. Mo oxide film is grown on the Mo wire surface via electrochemical oxidation by application of constant voltage of 0.8 V to Mo wire in electrolyte. Along with the duration time for applied bias voltage, the thickness of the oxide layer increases. Such fabricated WSC exhibits areal capacitance of 4.15 mF/cm² at a current density of 0.05 mA/cm² and a total cell capacitance increases in proportion to a cell length. Compared to the bare Mo, the capacitance increases dramatically by 47 times with electrochemically grown Mo oxide owing to the pseudocapacitance. A free-standing WSC maintains stable electrochemical properties under various deformation of bending, knotting, and a wavy WSC embedded in the stretchable POC films also maintains initial capacitance after repetitive stretching cycles. Finally, electrochemical performances of the WCS decreases with time in phosphate-buffered saline (0.01 M, pH 7.4) at body temperature, confirming the biodegradable WSC. This work suggests a facile way to fabricate a high performance transient WSC with a stretchability.

Vertically Aligned Insulating Nanotubes as a Structural Separator for Multifunctional Energy Storing Composites

Luiz Acauan, Yue Zhou and Brian L. Wardle. Aeronautics and Astronautics, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

The use of carbon fiber reinforced polymers (CFRP) as multifunctional structural supercapacitors has been limited by the low ionic conductivity and/or mechanical properties of the insulator separator. Here we propose a novel type of “structural separator” based on aligned insulating nanowires “nanostitched” between carbon microfibre laminates. Proof-of-concept composites were fabricated using aligned alumina nanotubes (ANTs) as well as standard commercial separators between carbon CF prepregs. ANTs nanostitched-composite laminates showed similar mechanical properties as the structural composite with no separator, while the commercial separator exhibited reduced strength due to interface failure. ANTs embedded in polymer electrolyte revealed 2X higher ionic conductivity than the pure electroactive polymer due to the nanowires disrupting the polymer semi-crystallinity. This new structural separator architecture allows standard CFRP structural composites to act as a multifunctional energy storage device, with the potential to enhance energy storage capabilities due to the process-structure coupling in ionically-conductive polymer.

ET07.03.06

Microstructure Engineering to Improve Wettability of Thick, Porous Electrodes for Energy Storage

Katherine Stoll, Thomas Carney and Fikile Brushett, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Rechargeable batteries are well suited for energy storage due to their high energy density and efficiency. However, these devices are limited to the use of electrodes less than 300 µm thick to avoid diffusion limitations. Thin electrodes significantly increase the number of inactive components needed for the battery to function, leading to high costs as well as low energy and power densities. Transitioning to thicker electrodes requires novel electrode and cell architecture design to simultaneously enable sufficient ion transport through the flooded pores of the electrode and electron transport through the solid-phase material. Here, we investigate the permeability and wettability of different engineered electrodes as well as the compatibility of various electrode-electrolyte combinations with an overarching goal of enabling low-resistance thick electrodes. Specifically, we examine the electrolyte surface tension and viscosity as well as the electrode microstructure (e.g., porosity, pore size, pore geometry, and topology) in accordance with the Lucas-Washburn equation, to determine the effect on battery performance.

We employ two methods, varying the particle size and altering the binder material, to fabricate electrodes with tailored microstructure. Theoretical models indicate that electrodes with graded porosity decrease resistance and improve capacity retention. Inks of varying particle size will be systematically utilized to optimize the pore size distribution and total porosity, while contact angle goniometry will be used to quantify the electrolyte-electrode interactions as a function of pore geometry, surface chemistry, and applied voltage. The electrode permeabilities will be characterized using pressure drop testing in accordance with Darcy’s law. The methods developed in this work are portable and can be applied to a wide range of materials and energy storage systems.
storage devices.

Effect of Rheological Properties on Microstructure and Electrochemical Performance of Si Composite Electrodes [Hanzhi Hu] and Yang-Tse Cheng; University of Kentucky, Lexington, Kentucky, United States.

Silicon has been intensively studied as one of the high capacity negative electrode materials for lithium-ion batteries (LIBs). Typically, a silicon electrode is prepared by a wet coating process during which a slurry is made by mixing the components in a solvent and then casted onto a current collector, followed by a drying process. Thus, the rheological properties and stability against sedimentation may affect the microstructure and the electrochemical performance of the electrode. In this work, slurries consisting of Si nano-particles, carbon black (CB), and Na-carboxymethyl cellulose (Na-CMC) with various solid loading were prepared in an aqueous medium, and their rheological properties were compared. The effects of rheological properties on the microstructure and electrochemical performance of electrodes were investigated as well. The results show that, due to the formation of an internal network of solid particles bridged by polymer chains, slurries with higher than 6% solid loading are solid-like. With decreasing solid loading, the slurries become more liquid-like. The Si/CB/Na-CMC electrodes prepared using slurries with high solid loading are more uniform in microstructure than that prepared using low viscosity slurries. The propensity to aggregation, porosity, and the adhesion of the electrode laminate are also influenced by the rheological properties of the slurries. This work demonstrates the importance of slurry property on the microstructure and electrochemical performance of silicon electrodes.

ET07.03.08
Aluminum–Air batteries with Ultrahigh Energy Density [Sangjin Choi] and Wooyoung Shim; Yonsei University, Seoul, Korea (the Republic of).

There is growing interest in high-performance energy storage systems to meet the strong needs for high-energy-density and high-power devices. Metal-air battery systems could offer a low cost, environmental friendliness, and outstanding energy-storage capability. In particular, aluminum-air batteries are attractive systems due to their safe and energy-density property. However, actual performances of them are far below the theoretical performances. Here, we show aluminum-air batteries adopting a sparkled graphene oxide/silver nanoparticle cathode. The spark reaction makes the graphene oxide very porous structure that can provide a wide oxygen diffusion path. Moreover, silver nitrate is reduced by the reaction and becomes a silver nanoparticle which acts as a catalyst for the oxygen reduction reaction. The resultant aluminum-air cell shows very remarkable electrochemical performance close to the theoretical value, and showed enough power to turn on a smart watch when connected in series. This work represents an advancement in aluminum-air batteries using a facile one-step spark reaction concept, showing a practical applicability of aluminum-air batteries.

ET07.03.09
Fabrication of All-Solid-State Lithium-Ion Batteries [Simon E. Hafner]1, 3, Lei Cao1, Hyukkeun Oh1, Harvey Guthrey2, Sehee Lee1 and Chunmei Bao2; 1National Renewable Energy Laboratory, Golden, Colorado, United States; 2Mechanical Engineering, University of Colorado, Boulder, Colorado, United States.

The complexity and expense of manufacturing all-solid-state batteries has long hindered the development of large-scale solid-state batteries for transportation and grid storage applications. Electrolyte-electrode interfacial resistance, air stability, and mass production capabilities pose particular challenges. In our work, we demonstrate a new battery manufacturing method that overcomes the challenges of scaling and interfacial resistance by depositing very dense cathode, solid-state electrolyte, and anode layers directly on top of one another. This method enables using a variety of battery and solid-state electrolyte materials and manufacturing all-solid-state batteries in an ambient environment. Furthermore, the approach could ensure a straightforward transition to a roll-to-roll process and incorporate a wide range of materials for future large-scale manufacturing. This presentation will discuss the manufacturing process and electrochemical cycling performance of the as-fabricated all-solid-state batteries.

Photofuel Cells Consisting of a Particulate TiO2 Photoanode with Using Cellulose as a Direct Fuel [Takumi Yoshimura, Youseke Kageshima and Hiromasa Nishikiori; Department of Engineering, Graduate School of Science and Technology, Shinshu University, Nagano, Japan.

Recent population growth and the resultant increase of energy consumption have caused the serious energy and environmental issues, that is, global warming and depletion of fossil resources. Renewable energy sources, such as solar energy and biomass, have been regarded as one of the promising alternatives to supply reliable electricity. Fuel cells have been intensively studied as clean energy systems with less environmental load. However, since H2 utilized as the fuel is typically produced by steam reforming of the fossil fuels, the conventional fuel cells are not truly environmentally friendly. The alternative direct fuel cells with using biomass-derived fuels, such as methanol1, glucose2 and cellulose3 have also been developed. Above all, cellulose can be expected as one of the most attractive biomass-derived fuels, since a tremendous amount of cellulose is disposed without effective reuse or recycle and is free from worry about competition against biological resources for edible use. It should be noted that the reports of the direct fuel cells with using cellulose as a fuel are still limited due to rigid crystalline structure of cellulose and its resulting insolvency in solvents. Most of the cellulose-based fuel cells are designated to use a large amount of expensive enzyme.3 Y. Sugano et al. reported a novel method for direct electrochemical oxidation of cellulose dissolved in strong alkaline aqueous electrolyte on the inorganic metal electrode.4 In the present study, we demonstrated a photofuel cell consisting of a particulate TiO2 photoanode, where cellulose is oxidized on the photoanode to generate electricity in an external circuit. The TiO2 particles (P25, Nippon Aerosil) were coated on an FTO/glass substrate and evaluated as a photoanode. Cellulose was fed to the photofuel cells as a direct fuel by several methods: 1) with covering the photoanode surface by cellulose thin film or 2) by dissolving cellulose in a strong alkaline electrolyte. In the presentation, (photo)electrochemical investigations for cellulose oxidation, influence of methods for cellulose supply, effects of photoelectrode preparation conditions, and performances of the photofuel cells will be discussed in detail.

ET07.03.11 Mussel-Inspired Polydopamine Treated Reinforced Membranes with Self-Supported CeO₂ Radical Scavengers for Highly Stable PEMFC Ki Ro Youn¹, Kyung-Ah Lee¹, Sun-Hee Choi¹, Seung-Ho Yook³, Il Doo Kim¹ and Jim Young Kim¹; ¹Fuel Cell Research Center, Korea Institute of Science and Technology (KIST), Seoul, Korea (the Republic of); ²Materials Science and Engineering, Korea Advanced Institute of Science and Technology (KAIST), Daejeon, Korea (the Republic of).

The physical and chemical degradations of proton exchange membranes (PEMs) in fuel cells induced by the harsh operation environments such as high humidity, high pressure, and repeatable wet/dry conditions and the free-radical attacks are critical factors limiting long-term operation of the PEMFCs. Mussel-inspired polydopamine (PD) with defective ceria nanoparticles (CeO₂ NPs) is introduced into porous polytetrafluoroethylene (PTFE) substrates for highly durable and chemically stable composite membranes in proton exchange membrane fuel cells (PEMFCs). The hydrophilic functionalities of PD coated PTFE (PD@PTFE) films enable uniform coating of Nafion ionomer dispersion during blade casting and allow strong mechanical adhesion between PTFE and Nafion layers in PD@PTFE membrane (m-PD@PTFE). Furthermore, the redox properties of catechol at PD surface render the cerium salts to be self-supported CeO₂ NPs as sustainable radical scavengers. Improved properties of prepared CeO₂ and PD coated PTFE membrane (m-CePD@PTFE) were characterized via water uptake, dimensional stability, proton conductivity, elongation test, Fenton’s test, and ex-situ observation. Finally, it was found that m-CePD@PTFE shows superior mechanical stability and long-term cell performance during repeated wet/dry cycling tests (6,000 cycles) via suppressed physical fracture and radical attacks on PFSA ionomer.

ET07.03.12 “Nanoscale Nucleation” In Situ Polymerization Method for Preparing Dielectric Nanocomposites with High Energy Density Tao Zhang, Yang Shen and Ce-Wen Nan; Tsinghua University, Beijing, China.

Polymer nanocomposite dielectrics, composed of polymer matrix with high breakdown strength and nanofillers with high dielectric constant, can achieve outstanding energy density. However, the large electrical mismatch between polymer and nanofillers will lead to poor compatibility and thus damage dielectric properties of the composites. Introducing a transition layer to the filler surface can significantly reduce the degree of mismatch. In this work, a “nanoscale nucleation” in-situ polymerization method was developed to successfully synthesize a series of BaTiO₃-based nanofillers with core-shell structure. Due to the “nucleation” role of the nano-BT particles, the polymerized monomers tend to form a stable coating layer on their surfaces. Nano-BT particles coated with three different monomers (TFEMA, HFPMA, DFHMA) were fabricated, respectively. The results demonstrate that the core-shell structures are all successfully achieved and the thickness of shell can be controlled between 2 to 7 nm. With great interfacial compatibility and thus alleviating electrical mismatch, BT@PDFHMA-P(VDF-HFP) nanocomposite with 1 wt.% BT@PDFHMA fillers showed higher energy density of ~18 J cm⁻³ compared with the conventional solution blended BT nanocomposites BT-P(VDF-HFP) (~12 J cm⁻³). We consider that this novel and versatile method can be widely used in the preparation of core-shell structures in dielectric nanocomposites.

ET07.03.13 MXene/Carbon Nanotube Yarn Supercapacitor Jong Woo Park and Seon Jeong Kim; Hanyang University, Seoul, Korea (the Republic of).

Development of wearable electronics and flexible energy harvesters such as piezoelectric or triboelectric energy harvesters largely demand flexible and wearable energy storage devices especially, supercapacitors. Yarn type supercapacitors which are flexible, knittable, and stretchable are receiving large interests. However, the energy density of the yarn supercapacitors should be increased when their limited footprints are considered. The asymmetric configuration of yarn electrodes is one of the strategies to increase the energy storing performance, the low capacitance of conventional carbon materials such as activated carbon, graphene, and carbon nanotube (CNT) hinders the overall performance of the asymmetric supercapacitor. To accomplish high capacitance of the negative electrode, there have been reported some other materials such as PPy, VN, MoS₂, recently. MXene, especially Ti₃C₂Tx, denotes surface functional groups is an emerging material for its high volumetric capacitance in aqueous electrolyte and high electrical conductivity. The high volumetric capacitance makes this material great candidate for the active material of yarn structured supercapacitors. Also, MXene could be utilized for the negative electrode in asymmetric supercapacitors owing to its potential range. In this work, MXene was biscalculated with CNT sheets to form a high-performance yarn electrode. The biscalculated MXene/CNT yarn exhibited high areal and volumetric capacitance in 1 M sulfuric acid electrolyte. Using the MXene/CNT yarn as the negative electrode, MnO₂/CNT yarn as the positive electrode, and PVA/LiCl gel as a solid electrolyte, resulted yarn-type asymmetric supercapacitor could operate up to 2 V and store high energy density. The all-solid-state yarn supercapacitor could be woven into commercial cotton textile and perform without degradation under mechanical deformations.

ET07.03.14 Direct Urea Fuel Cells Based on CuNi Plated Polymer Cloth as Anode Catalyst Keiichi Kaneto¹, Mao Nishikawa¹, Sadahito Uto¹ and Toshiyuki Osawa²; ¹Department of Biomedical Engineering, Osaka Institute of Technology, Osaka, Japan; ²Department of Environmental Engineering, Osaka Institute of Technology, Osaka, Japan.

Direct and passive type urea fuel cells were studied based on CuNi plated polymer cloth for the anode catalyst and current collector. Pt-black and cation exchange membrane were used as the cathode catalyst and polymer electrolyte, respectively. The output power was significantly enhanced by coating the CuNi cloth with a conducting polymer of poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS). The cell exhibited the open circuit voltage (Eₒ), 0.68V and the maximum output power (Pmax), 1.88 mWcm⁻² for 0.5 M urea solution. Similar results of Eₒ = 0.65V and Pmax = 1.74 mWcm⁻² were obtained for 0.5 M ammonia solution. The cell performances and mechanisms of anode reactions were discussed taking the results of various biofuel cells using the other conducting polymers and polymer electrolytes into consideration.

ET07.03.15 Direct Observation of Dehydrogenation of Mg₂FeH₆ by Using In Situ Transmission Electron Microscopy Hyunmin Kimp¹, Joseph Song¹, Julien Fadonougbo¹, Jee-Hwan Bae¹, Jaeyoung Hong², Soongju Oh², Younghwan Choi², Jaeyoung Ahn², Wooyoung Shim³, Dongwon Chun³ and Jinyoo Suh¹; ¹High Temperature Energy Materials Research Center, Korea Institute of Science and Technology, Seoul, Korea (the Republic of); ²Korea University, Seoul, Korea (the Republic of); ³Yonsei University, Seoul, Korea (the Republic of); ⁴Advanced Analysis Center, Korea Institute of Science and Technology, Seoul, Korea (the Republic of); ⁵Electronic Materials Research Center, Korea Institute of Science and Technology, Seoul, Korea (the Republic of).

Magnesium-based ternary hydrides have been considered as a promising candidates in fuel cell and hydrogen transport in light of their high hydrogen capacity and cycling ability. Understanding hydrogenation /dehydrogenation mechanism is, however, hampered by difficulties in the in-situ observation.
of nanostructured ternary hydrides. For example, rapid dehydrogenation process at high temperature hinders proving the decomposition mechanism of ternary hydrides through electron microscopy. Currently, developed equipment such as in-situ electron microscopy (EM) holder, high resolution/fast image acquisition (One-view charge-coupled device (CCD) camera, Gatan) and fast energy-dispersive X-ray spectroscopy (Super-EDS) have enabled studies of fast reaction phenomena through electron microscopy.

Here, we investigated the dehydrogenation process of Mg2FeH6. The nanostructured Mg2FeH6 sample was loaded on the in-situ TEM holder (Fusion, Protochips) and heated the sample with temperature of 250 degrees - 400 degrees for 1 hour to trigger the decomposition of Mg2FeH6 by hydrogen desorption. We imaged dynamics and diffraction patterns of Mg2FeH6 on dehydrogenation by one-view camera, attached on the Titan (G2, FEI) 25 pictures were acquired every second. In addition, high-speed EDS analysis was performed by super-EDS embedded TEM (Talos F200X, FEI) before and after the dehydrogenation. We utilized profile analysis of the SAD pattern (PASAD) program for the quantitative analysis of diffraction patterns. Upon heating, intensities of Mg2FeH6 diffraction spots were decreased and eventually disappeared within a couple of minutes. Sequentially, diffraction spots of Fe and Mg were appeared and its intensity increased through the dehydrogenation process. This is because the phase segregation in immiscible elements of Fe and Mg by the hydrogen desorption from Mg2FeH6. It is noteworthy that MgO diffraction spots were observed simultaneously after the extinction of Mg2FeH6 diffraction spots, which might be possibly due to the oxidation of segregated Mg in TEM column. Super-EDS results reveal that nanosized Mg and Fe were produced after the dehydrogenation of Mg2FeH6 which was not observed in the sample before dehydrogenation at a temperature below 300 degrees. On the contrary, at a temperature above 300 degrees, size of segregated Mg and Fe increased much. Also, chemical composition of Mg was decreased appreciably. This suggests induced Mg was evaporated even below its melting points, indicating high energy electron beam promotes Mg evaporation.

SESSION ET07.04: Electrode Manufacturing
Session Chairs: Wilhelm Pfleging and Pu Zhang
Tuesday Morning, November 27, 2018
Hynes, Level 3, Room 312

8:30 AM *ET07.04.01
Towards High Energy Density Electrodes—Ultrathick Cathodes and Prelithiation Lukas Ibinger1, Florian Holstiege2, Tobias Gallasch2, Tobias Placke2, Falko Schappacher2 and Martin Winter2; 1 Helmholtz Institute Münster HI MS, Forschungszentrum Jueltich GmbH, Münster, Germany; 2MEET Battery Research Center, University of Münster, Münster, Germany.

The production of cost effective, high energy and environmentally friendly electrodes is key for the success of lithium ion batteries (LIBs) to be used in electro-mobility or grid storage. To overcome the remaining drawbacks new ways towards cost effective processing of LIB electrodes and higher energy density battery cells are main topics of nowadays research. One way to combine both requirements is the preparation of ultra-thick electrodes using aqueous processing: Thick dry film thicknesses (large active mass loadings) allow an increase in energy density, while the relative reduction of copper and aluminum current collectors reduces the costs. However, compared to conventional processing, aqueous electrode formulation also goes along with disadvantages like surface crack formation and basic pH values accelerating active material degradation, especially in case of cathode materials like NMC (LiNi0.5Mn0.25Co0.2O2 with x ≥0.33 and y,z ≤ 0.33). Our approach to successfully overcome mechanical electrode instability is to develop a suitable “binder package” combining the water soluble components polyacrylic acid (PAA), polyethylene oxide (PEO) and sodium-carboxymethylcellulose (CMC). This mixture combines high flexibility (PEO) with low viscosity (PAA) and sufficient adhesion (CMC) resulting in a superior water compatible binder system to manufacture ultra-thick cathode sheets. Using this binder composition it was possible to achieve NMC based cathodes free from cracks with high amounts of active material and active mass loadings up to 50 mg cm-2 delivering discharge capacities of 120 mAh g-1 at 0.2 C.

A further issue, which decreases the gravimetric energy and volumetric energy density of LIBs is active lithium loss, caused by solid electrolyte interphase formation on the surface of the anode, occurring mainly in the first cycle of operation. In order to compensate the loss of active lithium, various pre-lithiation methods have been developed that result in an increased reversible capacity and, consequently, in a higher gravimetric energy and volumetric energy density. Thereby, the term “prelithiation”, describes the addition of lithium to the active lithium content (= reversibly transferable lithium ions between positive and negative electrode) of a LIB prior to battery cell operation. Therefore, with help of prelithiation it is possible to use novel active materials inside LIB full cells which otherwise could not be utilized due to high active lithium losses.

9:00 AM *ET07.04.02
New Approaches to Cathode Manufacturing to Meet Emerging Environmental Restrictions Stuart D. Hellring; PPG, Allison Park, Pennsylvania, United States.

NMP remains the most commonly used solvent in the lithium ion battery cathode manufacturing process. However, NMP faces mounting global regulatory pressure, and recently issued EU directives could effectively eliminate NMP usage by 2021. These new restrictions will place enormous challenges on the industry’s ability to locally manufacture lithium ion batteries for electric vehicles. Novel solutions will be needed to manufacture cathodes without NMP. PPG is actively engaged in developing innovative solutions to the challenges presented by this historic transition. These solutions address eco-friendly battery manufacturing as well as providing other performance improvements in energy storage. Applying these unique approaches for NMP-free cathode production enables the manufacturing of lithium ion batteries within this new regulatory environment to support the predicted growth in EV production.

9:30 AM ET07.04.03
An Advanced Dry-Powder Manufacturing of Lithium-Ion Batteries Applicable to Various Electrode Designs Yangtao Liu1, Jin Liu1, Brandon Ludwig2, Heng Pan* and Yan Wang1; 1 Worcester Polytechnic Institute, Worcester, Massachusetts, United States; 2 Mechanical Engineering, Missouri University of Science and Technology, Rolla, Missouri, United States.

The slurry casting method currently dominates the manufacturing of electrodes for lithium-ion batteries. There exists a recognized shortcoming of this conventional method that the liquid solvent, mostly as the organic (N-methyl-2-pyrrolidone), is indispensable to fluidize the electrode material during casting, which is toxic and high cost during the entire processing. To overcome this restriction, an advanced power-based technology was developed by us to fabricate electrodes of the lithium-ion batteries through additive manufacturing. Gas-driven spraying guns are chosen to address a direct dry-powder printing of electrode structures onto the current collectors without involving solvents. Therefore, the removal of solvents shortened the production time. 
from days to seconds, analyzed to reduce 20% of production cost, and enabled a more precise control of electrode microstructure during manufacturing. We have demonstrated this technology with a wide range of compatibility on different electrodes design, including cathodes (LCO, LMO, NCM), anodes (Graphite), advanced architecture designs (Ultra-low binder recipe (<1%), High-energy thick electrodes (~280um), Layered structured). Based on our current study, the dry printed electrodes outperformed the reference slurry cast electrodes at a few performance parameters (80% capacity retained in 500 cycles), high bonding strength, high structural integrity, high materials homogeneity Integrality. Along with better electrochemical and physical properties, this dry-powder manufacturing method could be attractive and competitive for nowadays production of electrodes and has the potential for further design.

9:45 AM ET07.04.04
Dry Process for Fabricating Low Cost and High Performance Electrodes for Energy Storage Devices Qiang Wu1, Jim Zheng1, M. Hendrickson2 and E.J. Plichta3; 1Florida State University, Tallahassee, Florida, United States; 2U.S. Army Research Laboratory, Aberdeen Proving Ground, Maryland, United States.

We report a roll-to-roll dry processing for making low cost and high performance electrodes for lithium-ion batteries (LIBs) and lithium-ion capacitors (LICs). Currently, the electrodes for LIBs and LICs are made with a coating or slurry casting procedure (wet method). The dry electrode fabrication is a three-step process including: step 1 of uniformly mixing electrode materials powders comprising an active material, a carbonaceous conductor and the soft polymer binder; step 2 of forming a free-standing, continuous electrode film by pressing the uniformly mixed powders together through the gap between two rolls of a roll-null; and step 3 of roll-to-roll laminating the electrode film onto a substrate such as a current collector. A prototype hybrid lithium ion capacitor cell with lithium iron phosphate (LFP)/activated carbon (AC) composite cathode and Li doped hard carbon (HC) anode has been made by our dry method, which has a breakthrough energy density of ~30 Wh kg\(^{-1}\), high power density of 2,000 W kg\(^{-1}\), as well as long cycle life over 30,000 cycles (90% retention). LIBs of LiNi\(_{0.6}\)Mn\(_{0.2}\)Co\(_{0.2}\)O\(_2\) (NMC622)/graphite and LiNi\(_{0.6}\)Mn\(_{0.2}\)Co\(_{0.2}\)O\(_2\) (NMC622)/graphite-silicon also has 250 Wh kg\(^{-1}\) and 300 Wh kg\(^{-1}\) energy density, respectively.

Compared with the conventional wet slurry electrode manufacturing method, the dry manufacturing procedure and infrastructure are simpler, the production cost is lower, and the process eliminates volatile organic compound emission and is more environmentally friendly, and the ability of making thick (~120um) electrodes with high tap density results high energy density of final energy storage device.

10:00 AM BREAK

10:30 AM *ET07.04.05
Reduce Electrode Manufacturing Cost—Transition from Batch to Continuous Production David Ventola; B&W MEGTEC LLC, De Pere, Wisconsin, United States.

The basics of Li-ion battery electrode manufacturing have not changed much in the last twenty years. Ten years ago, B&W MEGTEC developed a method to utilize their extensive knowledge and experience in flotation drying to enable simultaneous 2-side coating of Li-ion electrodes. This development included a unique slot die coating arrangement along with proprietary technology to stabilize the thin foil current collector substrate. These advancements enabled world class battery manufacturers to reduce costs of manufacturing and increase productivity. Simultaneous 2-side coating allows for a simplified factory layout which reduces total floorspace required and reduces material moves. Additionally, when compared to a more typical sequential coating process the 2-side coating and flotation dryer only requires roughly half of the utilities which greatly reduces the operating expenses.

The focus of this talk will be to leverage the benefits of 2-side coating and flotation drying; linking other unit operations to streamline the electrode manufacturing process. Specifically, the following technologies are usually separate and distinct unit operations each with varying levels of materials in que, WIP and material transfers between operations.

- Slurry Mixing
- Electrode Coating & Drying
- Calendering / Roll Pressing
- Secondary Drying

These unit operations can be linked to create a streamlined continuous processing plant with a focus on increasing productivity, improving quality and reducing manufacturing costs.

Continuous mixing leads directly into simultaneous 2-side coating and flotation drying. Traditionally after drying the coated electrode rolls are removed, stored and put in queue to move on to the calendaring/pressing operation. This movement and storage is wasted effort and floorspace. Linking calendaring/pressing directly after drying in the processing line eliminates this waste. The new process methodology allows for the dried electrode to move directly to the inline calendner/press, bypassing the intermediate rewind and unwind steps.

In many electrode manufacturing processes, a secondary drying step is required to achieve the final level of drying or residual solvent retained on a percent or parts per million scale. Typically, this is done by loading full rolls of coated electrodes into a drying chamber and essentially “baking” the electrode for an extended period. The period could be as short as 8 hours or as long as 24 hours. The mechanics of extracting solvent and/or water out of a coated electrode wound into several hundred if not a thousand layers are very difficult. A new approach exists to employ continuous secondary drying inline with the other unit operations presented. Inline secondary drying provides more consistent drying of the entire electrode surface area, which leads to a more consistent and higher quality electrode.

Present and Future Methods of Li-Ion Battery Electrode Slurry Preparation Bernhard Stalder; Buhler AG, Uzwil, Switzerland.

An overview over present and near future preparation methods of electrode slurries will be presented:

1. The traditional methods with batch mixers (usually planetary type mixers) which have been used from the very first of the Li-ion battery history. The method is well known and has advantages in R&D use but shows low hanging limitations as soon as mass production is considered: The scalability via the mixer size has reached its upper end. The only way for a further scale up has to be performed via the number of mixers which is very expensive. Further, the reproducibility of the slurry quality shows some challenges due to the batch operation method.

2. An advanced semi-continuous thin film method in combination with simple batch mixers or existing planetary mixers for increased throughput rates and improved reproducibility of the slurry quality. Mainly the reproducibility of the viscosity as a key property of a slurry is on a high level and allows an easy electrode coating process. The method can be used in R&D scale (some 10 milliliters) but can be scaled up to manufacturing size with throughput rates of more than 1000 liters per hour.
Coating technologies for functional materials by solution based (“wet”) processing methods are a highly promising approach for production upscaling towards industrial scales. The use of flexible polymer substrates not only allows the preparation of ultrathin bendable devices, but also enables roll-to-roll (R2R) manufacturing, with all its associated benefits such as high volume, large area and high throughput production. Whereas for certain sectors like the packaging and paper industries, R2R printing and wet coating have been the established standard already for decades, its use in more demanding application areas like printed electronics has only recently started to emerge. Within this branch of industry, energy conversion and storage devices are a core application area with intense research activity going on to introduce R2R production technologies. This contribution presents technical approaches for solution based R2R manufacturing methods which can be applied in the large scale fabrication of flexible printed electronics devices for energy conversion and harvesting. The development of a R2R line with two slot-die coating stations is presented which can deposit two functional layers consecutively in a single run (“tandem coating”) at web speeds up to 30 m/min. Whereas slot die coating typically is a technology for the uniform deposition of continuous functional thin films, additional adjustments to the equipment also allow patterning both in the web transport direction (stripe coating) and perpendicular to it (intertmittent coating). These patterning options are a crucial prerequisite for the manufacturing of properly encapsulated devices with high stabilities and long lifetimes. Particularly for functional inks with low viscosities, well controlled intermittent slot die coating with proper edge definition of the resulting patches is far from trivial. It requires specially designed ink supply systems able to actively remove (suck back) fluid from the die opening in a precisely timed manner to achieve a uniform and sudden start and stop of the coating process. It will be demonstrated how, employing this approach in combination with stripe coating, patterns can be produced at high R2R speeds with definitions in the millimetre range using inks relevant for the manufacturing of energy conversion and harvesting devices.

Advantages and challenges of each method will be discussed and compared. Remarks concerning the interaction of slurry preparation and the subsequent coating process will be shared.
Recent progress in developing three-dimensional graphene macro-structure has resulted in a diverse array of bulk graphene aerogels for a plethora of applications. However, these aerogels generally exhibit compromised electrochemical performance compared to their two-dimensional counterparts, particularly when engineering into supercapacitor electrodes. This drawback is due mainly to their highly tortuous and stochastic pore networks that retard ion diffusion throughout the entire electrode. These structural limitations can be well addressed by developing graphene-based architectures with ordered macro pores to provide ions with straightforward diffusion "expressways". Our recently pioneering work developed a direct ink writing, one of the 3D printing techniques that manufactured the first group of 3D graphene aerogels with periodic macropores as supercapacitor electrodes. These aerogels, though possess thickness 10-100 times thicker than most other reported carbon-based supercapacitor electrodes, display exceptional capacitance retention of ~90% from 0.5 to 10 A/g, a performance that is comparable or even outperforms those of conventional thin film supercapacitor electrodes. This talk will first present the key factors in developing an extrudable graphene oxide-based ink for electrode printing. Another emphasis will be given to the electrochemical analyses elucidating the links between the 3D printed structure and the excellent rate capability performance. This presentation is expected to highlight the power of direct ink writing (or generally, 3D printing) as an advanced manufacturing technique to revolutionize the production of electrochemical energy storage devices.

Co-Extrusion (CoEx) is a high speed, scalable deposition process for creating finely patterned, interdigitated thick films. Our CoEx printhead is designed to be a drop-in replacement for slot-die heads on web coaters, enabling novel geometric structuring of electrodes with minor changes to existing battery electrode processing lines. Here, we present the use of CoEx to prepare thick (~120 µm) NMC cathode electrodes consisting of alternating regions of high lithium-ion transport and high lithium-ion storage capacity. By structuring the cathode electrode, we enable full lithium utilization at C/2, despite near doubling of the electrode thickness compared to conventional baseline electrodes. CoEx cathode electrodes are paired with thick, graded graphite anode electrodes and assembled into 1 Ah pouch cells for electrochemical testing. CoEx pouch cells demonstrate 10 – 20% improved energy density with respect to conventional electrodes and >30% improved power density with respect to thick conventional (unstructured) electrodes at high discharge rates.

Battery electrodes are nearly universally formed via tape casting of a slurry containing a mixture of active material, binder, and conductive carbon. However, the electrochemical and mechanical properties of slurry cast electrodes are often limited by weak interconnections between particles and between the particles and the substrate. We suggest conformal electrodeposition of high-quality electrode materials would provide opportunities to enhance battery performance (energy density, power density, and flexibility) and broaden the scope of available electrode form factors (size, shape, porosity, and 3D integration). We have now made considerable advances in the direct electrodeposition at modest temperatures of high performance tin-based Na and Li-ion anodes and LiCoO2, NaCoO2, LiMn2O4, and Al-doped LiCoO2-based Na and Li-ion cathodes. The electrolytically active materials were formed either as solid films, or where significant volume changes upon cycling are present, via a templating process, as a 3D mesostructured film. The capacities are near-theoretical, and in the case of the electroplated oxides, the crystallinities and electrochemical capacities of the oxides are comparable to powders synthesized at much higher temperatures (700 ~ 1000 °C). The electrodeposition method significantly broadens the scope of battery form factors and functionalities, enabling a variety of highly desirable battery properties including microbatteries, and high energy, high power, and flexible designs.

A new concept for making battery electrodes to simultaneously control macro-/micro-structures of electrodes is developed to address present energy storage technology gaps and meet future energy storage requirements. This new fabrication process fully utilizes the benefits of additive manufacturing, which provides a pathway for inexpensive and flexible production of specialized products. Furthermore, the process allows a simultaneous control of the microstructure and macrostructure of electrodes which cannot be achieved via conventional manufacturing techniques. Modern batteries are fabricated in a form of laminated structures that are composed of randomly mixed constituent materials. Due to this randomness, there is an ample room in the conventional method to enhance performance by developing viable processing techniques to construct well-organized structures. The synergistic control of micro-/macro-structures is a novel concept in energy material processing that has considerable potential for providing unprecedented control of electrode structures and enhancing performance. Electrochemical tests show that the new electrodes exhibit superior performance in their specific capacity, areal capacity, and cycle life. It is concluded that the macro-micro-controlled structure showed 21%, 16%, and 7% more areal capacity than a structure with no control, a macro-controlled structure, and a micro-controlled structure, respectively. The proposed control of 3D structures, with a well-organized distribution of energy materials, demonstrated more superior properties and advantages than structures with randomly distributed materials.

Silicon as high-energy anode material for next generation lithium-ion batteries has recently become of great interest. Graphite active material mixed with silicon nanoparticles is under development in order to increase significantly the practical capacity of commercial anodes and to overcome the drawbacks of silicon due to large volume changes during electrochemical cycling. However, it is well known that pure silicon will form a native oxide layer during exposure in ambient air. During battery operation, this native oxide layer will restrain the lithiation process and a drop in silicon capacity will be achieved. Therefore, carbon-coated silicon nanoparticles were applied in order to maintain a high specific capacity of 3579 mAh/g. In order to reduce the intrinsic...
mechanical stress of silicon/graphite electrodes and to improve the lithium-ion transport kinetic, free-standing electrode structures were generated by applying ultrashort laser ablation. For comparison, a thin alumina layer (thickness ~5 nm), which acts as an artificial solid electrolyte interphase, was coated on structured silicon/graphite electrodes by applying atomic layer deposition. Cyclic voltammetry measurements were performed to investigate the fundamental properties of carbon- and alumina-coated silicon/graphite electrodes. Galvanostatic measurements reveal that the cells with structured electrodes exhibit excellent electrochemical properties and improved lithium-ion diffusion kinetics compared to cells with unstructured electrodes.

3D Architectured Pyrolytic Carbon as Efficient Battery Electrode Kai Narita, Michael Citrin, Heng Yang and Julia R. Greer; California Institute of Technology, Pasadena, California, United States.

Engineering optimal electrode architecture in rechargeable batteries can improve volumetric power and energy density by controlling factors such as diffusion path of ions in electrode and electrolyte, mass loading of active materials, thickness of electrodes and migration path of electrons. Electrode engineering has been incorporated into batteries, for example, by utilizing 3D current collectors, by aligning active materials by an external field and by employing sacrificial template methods. These efforts are still being developed because powder electrodes require having a binder and methods that involve sacrificial templates offer limited flexibility in local geometry. Aiming at greater flexibility in electrode structure without such limitations, we developed a facile and scalable fabrication method of 3D architectured carbon anodes using direct light processing (DLP) 3D printing with UV-curable resin and a subsequent pyrolysis process in an inert atmosphere. The architectured pyrolytic carbon electrode is free-standing and binder-free enabled by the monolithic structure and electrical conductivity of carbon. The specific architecture of these electrodes is fully controllable over every length scale: from local geometry (micrometer-scale) to control tortuosity and mass loading, as well as global geometry (centimeter-scale), to intergrade into any device geometries. We fabricated 1mm-thick 3D periodically architectured carbon electrodes with simple cubic-like geometry and 12% relative density composed of ~30 micron-diameter beams. We characterized its electrochemical performance by constructing a half-cell against a lithium metal counter electrode. X-ray diffraction (XRD), energy dispersed spectroscopy (EDS), Raman spectroscopy and transmitted electron microscope (TEM) showed that the pyrolytic 3D lattice was mainly amorphous, with a few interdispersed sp²-hybridized regions. Battery cycling of these electrodes using a coin cell showed reversible capacity of ~230 mAh/g, which corresponds to 7 mAh/cm² at a current density of 16 mA/g or 0.6 mA/cm². Varying cycling rate from 0.6 to 10.1 mA/cm² revealed that the 3D carbon electrodes are capable of good performance enabled by low tortuosity of the periodic structure, for instance, ~3.5 mAh/cm² at 3.4 mA/cm². These electrodes showed stable capacity over 50 cycles at 16 mA/g.

This methodology offers a facile and scalable fabrication method of 3D architectured carbon that can serve as an efficient approach to create high energy density battery electrodes that can potentially be integrated into 3D interdigitated batteries.

4:30 PM ET07.05.09
Additive Manufacturing of Three-Dimensional (3D) Micro-Supercapacitors Based on MXenes Jafar Orangi and Majid Beidaghi; Materials Engineering, Auburn University, Auburn, Alabama, United States.

Energy storage devices are crucial for the future development of portable/wearable electronic devices, wireless sensors, and self-power microsystems. The first requirement for fabrication of energy storage devices with high energy and power densities is using electrode materials and electrolyte with superior electrochemical properties. Another critical requirement is to develop manufacturing methods that enable the assembly of the electrode material and electrolytes in structures that promote high electrical and ionic conductivities. Recently, a family of two-dimensional (2D) materials, referred to as MXenes, has been introduced as high performance electrode materials for electrochemical capacitors (ECs, also called supercapacitors). It is demonstrated that a MXene with the composition of Ti3C2Tx can deliver specific volumetric capacitances as high as ~1500 F/cm³, which has set a new record for the electrochemical performance of EC electrodes. In this talk, we present our recent research on using 2D MXenes as building blocks for the fabrication of three-dimensional (3D) supercapacitors using an additive manufacturing process. In this process, a water-based ink of MXene with viscoelastic properties was developed and directly used for extrusion-based 3D printing of supercapacitors. The fabrication process follows a layer-by-layer deposition of the MXene ink using a programmable printing machine. This process allows rapid fabrication of supercapacitors on a variety of substrates, while the thickness of the electrodes can be controlled by the number of deposited layers. The evaluation of the electrochemical performance of the printed devices shows their excellent electrochemical properties. For example, a flexible device fabricated using Ti3C2Tx electrodes and a gel polymer electrolyte delivered an extremely high areal capacitance of ~1100 mF/cm². Our study suggests that due to its high electrical conductivity and electrochemical properties, MXene is an excellent choice as the building block for the fabrication of 3D energy storage devices.

4:45 PM ET07.05.10

Flow batteries are a promising technology for large scale energy storage and load balancing from intermittent power sources, but their viability hinges on our ability to attain high-power outputs while minimizing costs and meeting performance constraints. Effective engineering of these systems is further complicated both by limitations on the control of the electrochemical cell component morphologies across scales and accurate modeling of the multiple, simultaneous physical processes. At Lawrence Livermore National Lab, we have pioneered a potential solution to this problem using additive manufacturing techniques which enable hierarchical structures controlled from the sub-micron through the centimeter length scales. Yet, even with this expanded design space, the complexity and tight coupling of the underlying physical processes remains as an obstacle to effective design. Apparently obvious choices can nevertheless lead to an unexpected adverse performance impact. To address this challenge, we present an automatic design methodology to optimize flow-through electrode topologies over precisely defined performance criteria. We combine forward physics solvers for the full, multidisciplinary electrochemical problem, including fluid flow, electrochemistry and mass transfer, with adjoint solvers to determine topological sensitivities. Our algorithms compute optimal electrochemical cell architectures which are then physically created using additive manufacturing techniques and post-processed to create carbon electrodes. We compare the predicted performance of computationally optimized designs against standard, bulk electrodes and focus on the tradeoff between high surface areas and pressure drop. Our work provides a systematic path toward rational design of cost-effective, high-power flow batteries and other porous electrode systems.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.
Recently, many inorganic metal chalcogenides based on earth abundant elements such as copper zinc tin selenide (CZTS), lead sulfide (PbS), copper(I) sulfide (Cu2S), tin sulfide (SnS) and antimony sulfide (Sb2S3) have been investigated as an absorber material for solar cell. Among them, Sb2S3 has received intense attention as a light absorbing material due to its suitable band gap (~ 1.7 eV), high absorption coefficient (~106 cm⁻¹), low cost, less toxicity, and high air stability.\(^1,3\)

In this study, Sb2S3 was deposited through a simple spin-coating process previously reported by Wang et al. using an antimony-complex precursor solution prepared by dissolving antimony oxide (Sb2O3), carbon disulfide (CS2), and n-butylamine in an ethanol solvent.\(^4\) In order to enhance the performance of Sb2S3 solar cells, we applied surface treatment on TiO2 layer by Cs2CO3 solution to adjust the work function of TiO2 to the conduction band of Sb2S3 light absorption layer. Figure 1(a) shows a scheme of the device architecture. The bottom layer is composed of compact TiO2 layers acting as electron transporting. Light is absorbed by the Sb2S3 while holes are transported by the P3HT, and collected at the Au counter electrode.

As can be seen in figure 1(b), the power conversion efficiency (PCE) of 3.51% was obtained under AM1.5G illumination in a planar type device consisting of FTO/Cs2CO3 treated TiO2/Sb2S3/P3HT/Au, which is significantly higher than that of the control device without Cs2CO3 treatment (2.48%). The higher PCE of planar type Sb2S3 solar cell based on Cs2CO3 treated TiO2 is attributed to uniform surface formation, suitable energy level alignment, and efficient electron transport properties. We believe that this solution processable surface treatment can provide simple and effective way of device performance improvement in planar type inorganic metal chalcogenide solar cells.

The Washington Clean Energy Testbeds opened at the University of Washington in February of 2016. The Testbeds are a group of facilities that allow researchers from academia and industry to collaborate on clean energy solutions at low cost, representing an open-access model reducing risk and capital outlays for developing commercial-scale, clean energy systems that get to market faster. Specifically, the Testbeds provide best-in-class fabrication and characterization for photovoltaic and energy storage material processing, device prototyping, pilot commercial scale manufacturing, performance verification, and systems integration. Fabrication of current state-of-the-art and next-generation photovoltaics and battery architectures is enabled through variety of advanced and additive manufacturing techniques, such as roll-to-roll printing, sheet coating, and 3D printing with options for processing in controlled environments. A full suite of material analysis instrumentation allows for rapid iteration of novel material formulations and manufacturing processes. Finished devices can be tested on industry-best solar simulators with NREL traceability, battery test channels, and/or integrated into simulated grid environments. The Testbeds serve as an innovation hub, providing access to key resources, including capital funding to startups, a relevant talent base, and new innovation programs for established companies. The presence of private companies and investors in the Testbeds represents a higher level of public-private coordination necessary to harvest the fruits of research and bring them to market faster than we see today. The Testbeds’ first year of operation provided early successes with UW spin-out companies, Battery Informatics and Membrion, achieving proof of concept, gaining early customers, and raising funds. Now in the second year of operation, the Testbeds management has evaluated a number of successful elements that will be key to helping researchers developing energy products. Facilities like the Testbeds are essential to ensuring that new materials and processing techniques make significant impact on the energy market.

**Industry Scale Additive Manufacturing of Photovoltaic Devices Using Advanced Roll-to-Roll Processing**  

The Washington Clean Energy Testbeds provide researchers with a cost-effective solution for accelerating product development by offering pay-per-use open access to state-of-the-art R&D instrumentation. Our staff scientists have pioneered large-scale printing of both organic and perovskite photovoltaic materials using state-of-the-art additive manufacturing techniques. This expertise is essential to driving the development of scalable next-generation photovoltaic devices and systems. This know-how is passed on to Testbeds users from around the world through related proprietary work with industry partners and hands-on workshops designed to train researchers on ink preparation and analysis, slot-die coating, screen printing, and film characterization. Using cutting-edge process-scalable solar materials such as PCE-11 polymer and methylammonium lead halide perovskites, users learn the latest techniques to scale up solar cell manufacturing. Workshops are fully customizable to accommodate specific interests and applications. Our unique industrial-scale roll-to-roll printer is specially designed to fabricate printed, flexible solar modules and is used to develop advanced methods for manufacturing the next generation of low-cost solar materials. By fine-tuning crystal growth kinetics through innovative ink formulations and film drying methods, we demonstrate fast and effective conversion of methylammonium lead halide perovskite inks, yielding flexible perovskite films on meter length scales in just minutes. Furthermore, implementation of in-line characterization methods (e.g. light-scattering, photoluminescence and Raman spectroscopy) is underway for assessing film quality during printing. In addition to active solar material coatings, we demonstrate greater than 20 meter per minute flexographic printing of thin and smooth patterned silver electrodes on 12-inch-wide plastic substrates. High precision web guiding and registration offers the ability to print and coat full solar cell device stacks. Fabrication activities at the Testbeds are supplemented with industry-leading characterization equipment. A large suite of rapid-scan materials analysis equipment provides immediate, comprehensive feedback on formulations and fabrication processes. Completed devices can be thoroughly tested on world-class equipment against NREL traceable reference devices.

**Optical Manipulation Using Microlens Arrays of Various Sizes in Organic Photovoltaics**  
Dongwook Ko, Hyojin Song, Seobum Chu and Jongbok Kim; Kumoh National Institute of Technology, Gumi, Korea (the Republic of).

Organic photovoltaics (OPV) are attracting much attention because they can be made light and flexible. However, due to low power conversion efficiency (PCE) compared to silicon-based solar cells, much research is underway to improve the PCE. In order to improve the PCE, many researchers have tried to synthesize noble materials with high light absorptivity or to control a complex interface. However low charge carrier mobility of organic materials have not allowed increasing the PCE. As an alternative, researches have been conducted to introduce various physical structures such as microlens, wrinkle into OPV to control the optical path. Here, we fabricated the microlens of various diameter (0.5μm – 20μm) and confirmed that the optical path and PCE can be dramatically increased with microlens array of optimum diameter. To study the optical manipulation with microlens array, we first prepared the microlens of various diameter (0.5μm – 20μm) by rubbing and water transfer printing method and then replicated them with Polydimethylsiloxane (PDMS). The replicated PDMS lens were analyzed by scanning electron microscope (SEM) and AFM to examine their surface morphology and by UV-VIS-NIR spectrometer to examine optical properties. The total transmittance was almost the same regardless of the diameter of microlenses, but the specular transmittance was decreased by increasing diameter of microlens. It indicated that the dispersed light increased with increasing microlens diameter. Specifically, we found that dispersive transmission was similar above 7μm of microlens diameter. The increase of dispersive light resulted in the enhancement of the light extinction in photactive layer. Similar to dispersed light, the light extinction was similar from 7μm or more. Then, we measured J-V characteristic under the condition of AM 1.5G, 100mW / cm2 to confirm the increase of dispersive light improve PCE in OPV. We observed that short circuit-current density (Jsc) increased with increasing microlens size, and it was similar from 7μm diameter or more. We also confirmed that the PCE increased by 12% compared with the OPV without microlens. As a result, we fabricated various diameter of lens (0.5μm – 20μm) through rubbing and water transfer printing method. Then, we confirmed that dispersive light and light extinction was increased with larger diameter of microlens. Similar to these optical properties, we confirmed that Jsc increases with microlens array and the PCE increases by up to 12%.

**The Effect of Substrate Roughness on the Properties of Sputtered AZO Thin Film**  
Kairi Hamada1, Hideyuki Okumura1, Takaya Ogawa1, 2 and Keiichi N. Ishihara1; 1Socio-Environmental Energy Science, Kyoto University, Kyoto, Japan; 2The Hakubi Center for Advanced Research, Kyoto University, Kyoto, Japan.

Transparent conductive oxide (TCO) for thin film solar cells requires special features such as not only transparency and conductivity but also light scattering in order to increase optical path length and promote more photon absorption for its efficiency. Representative TCO material is indium tin oxide (ITO), while it contains scarce metal, indium (In), and is expensive. Workhorse AZO (AZO) thin film, which has many advantages such as low cost, low sheet resistance, and high transmittance, is one of the most promising alternative candidates to replace ITO as transparent electrodes. However, AZO has the problem of low durability, and it is difficult to combine or satisfy dual properties i.e. the stability and light scattering of the film. In order to obtain simultaneously excellent light scattering characteristics and good stability of AZO film, here, we focus on roughness of the substrate as well as roughness of AZO film surface.

We prepared textured substrates and nontextured substrates, and compared them in terms of structural, optical, electrical properties and environmental stability. In addition, we employed different substrates including of quartz plate and various types of glass slides. The roughness of the substrate surface
was formed by abrasive papers on a rotary polishing machine for 2 minutes, and on the roughened substrate AZO film was made with radio frequency magnetron sputtering.

We expected a high haze value of the textured sample, which is one of the widely known parameters to represent the light scattering capability of rough surfaces. The visible haze value of the textured glass slide sample increases from 1.4% which nontextured glass slide sample showed to 39.2% with a sheet resistance of 8.0 Ω/sq and a visible transmission of 81.1%.

The notable result of this study is to change the absorption edges. For the AZO film on the glass slides, the absorption edge showed a red shift and the optical band gap changed from 3.66eV to 3.48eV by roughening. On the other hand, for the AZO on the quartz plate, the absorption edge showed a blue shift and the optical band gap changed from 3.56eV to 3.68eV by roughening. These results suggest a simple method to control a band gap of a material just by grinding surface of substrates.

The possible origin of these shifts can be the difference of thermal expansion coefficients among AZO, glass slides and quartz plate. The difference could cause the thermal stress, which leads to the occurrence of defects inside the film. These defects could change the Al content in the film, which may lead to the shift in the absorption edges due to the Burstein-Moss effect.

We will continue to study an origin of the altered absorption behavior through investigating more details to confirm above hypothesis and will discuss at the conference.

ET07.06.08
Solution-Processed, Shape-Controlled Sb2Se3 Light Absorber for Efficient Photoelectrochemical Water Splitting Wooseok Yang1, Jaemin Park1, Jeiwan Tan1, Hyungsoo Lee1, Yunjung Oh1, Joosun Kim2 and Josho Moon1; 1Yonsei University, Seoul, Korea (the Republic of), 2Korea Institute of Science and Technology, Seoul, Korea (the Republic of).

Sb2Se3 is recently spurred great interest as a promising low-cost light-absorbing material for solar energy conversion applications, such as thin film solar cells and photoelectrochemical (PEC) water splitting. The properties of Sb2Se3 strongly depend on its crystallographic orientation and surface morphology due to the anisotropic crystal structure. In this study, we synthesized Sb2Se3 light absorbers with various morphological variation from thin films to 1-D nanostuctures via a simple solution processing with two different Sb-Se molecular solutions. The first molecular solution is synthesized by using the solvent mixture of thioglycolic acid (TGA) and ethanolamine (EA) and the aspect ratio of 1-D Sb2Se3 nanostuctures can be controlled by adjusting the relative mixing ratio of TGA and EA. In the other Sb-Se molecular solution using the mixture of 2-mercaptoethanol and ethylenediamine, adjusting the relative amount of the Se precursor with respect to the Sb precursor results in the significant morphological change. The growth mechanism of the various structures of Sb2Se3 was elucidated by liquid Raman spectroscopy. In addition, electrical and photoelectrochemical properties of the shape-controlled Sb2Se3 were investigated depending on the structures. After deposition of TiO2 and Pt, an appropriately oriented Sb2Se3-based photocathode exhibits a significantly enhanced PEC performance; the photocurrent reached 12.5 mA cm-2 at 0 V versus reversible hydrogen electrode under AM 1.5 G illumination.

ET07.06.09
Assessing Adhesive Degradation in Photovoltaic Backsheets Using the Single Cantilever Beam Test Scott Julien1, Jae Hyun Kim2, Xiaohong Gu2 and Kai-Tai Wan1; 1Northeastern University, Boston, Massachusetts, United States; 2Engineering Laboratory, National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

The photovoltaic (PV) backsheet, a multilayered polymer sheet that is laminated to the back side of a PV module, is used for protecting the internal components from corrosion and insulating outside users from the internal electrical components. The backsheet is typically comprised of several layers of polymer, adhered or coextruded together. Over prolonged exposure to the elements (extreme temperatures and humidities, and UV radiation), these layers can undergo adhesive degradation, resulting in weakening of the interfaces or delamination, that cause reduced heat dissipation and provide sites for moisture collection. Testing methods are needed in the industry to assess the adhesive durability of new candidate backsheets, and predict their longevity.

In the present work, we assess the interlayer adhesive strength of a polyethylene terephthalate (PET)-based backsheet, using the single cantilever beam (SCB) test. Backsheet samples of PET/PET/ethylene co-vinyl acetate (EVA) were obtained, and exposed to artificial UV radiation in the integrating sphere-based weathering device, located at the National Institute of Standards and Technology (NIST) in Gaithersburg, Maryland, USA. Samples were exposed to between 290-400 nm of light for varying lengths of time, to simulate field-induced UV degradation. SCB tests were then conducted by adhering a titanium beam to the outer layer of the backsheet and pulling the beam at one end, generating delamination at the weakest interface. The applied force, beam end displacement, and location of the “delamination front” were measured, and used to compute the critical adhesion energy of the delaminating interface.

Preliminary results have been obtained for two types of unaged PPE backsheets, of identical model but acquired during different years. The results show a marked difference in adhesion between the two (250-300 J/m2 vs. 1000-3000 J/m2), which illuminates the significant differences in adhesion that can occur with slight changes in manufacture or formulation. These results will be compared to those obtained from the UV-exposed samples, and the results will be used to correlate UV exposure with long-term adhesive durability. Ultimately, this knowledge is of critical need in the community, for developing predictive models of the longevity of PV backsheet samples deployed in the field.

ET07.06.10
Adhesive Durability of Photovoltaic Backsheets as a Function of Indoor Accelerated Weathering Exposure Scott Julien1, Jianfeng Sun1, Yu Wang2, Andrew Fairbrother1, Xiaohong Gu2, Sophie Napoli1, Liang Ji3, Kenneth P. Boyce1, Mike Kempe6, Gregory S. O’Brien1, Adam W. Hauser4 and Kai-Tai Wan1; 1Northeastern University, Boston, Massachusetts, United States; 2Materials Science & Engineering, Case Western Reserve University, Cleveland, Ohio, United States; 3Engineering Laboratory, National Institute of Standards and Technology, Gaithersburg, Maryland, United States; 4Arkema, Inc., King of Prussia, Pennsylvania, United States; 5Renewable Energy, Underwriter’s Laboratories Inc., Northbrook, Illinois, United States; 6Photovoltaics Research, National Renewable Energy Laboratory, Golden, Colorado, United States.

Photovoltaic (PV) backsheets are polymer sheets used to protect the backside of a PV module from moisture and mechanical damage. They typically consist of multiple layers of polymers, adhered or coextruded together. Over prolonged exposure to harsh outdoor elements—extreme temperatures and humidity, and ultraviolet (UV) radiation—delamination between the layers of the backsheet can occur. The resulting interlayer voids diminish heat dissipation, reduce the effective thickness of the backsheet as a physical barrier, and serve as collection sites for moisture. There is a need within the PV community for methods to quantify the adhesive integrity of the backsheet.

In the present work, we apply a wedge test to measure the interlayer adhesion energy of backsheet samples exposed to indoor accelerated weathering. Test
coupons are prepared by laminating a backsheet sample to a glass substrate, then exposing it to an indoor accelerated weathering protocol. Wedge tests were performed by adhering a titanium beam to the outer layer of the backsheet, then pulling the beam at one end, generating delamination at the weakest interface. A wedge subsequently inserted into interface was used to drive delamination in a displacement-controlled manner. The location of the “delamination front” was measured at intermittent points, and used—in conjunction with the known elastic properties of the beam and wedge thickness—to compute the adhesion energy of the interface.

Tests were performed on backsheets of several different polymer types, and exposed to several different accelerated weathering conditions. Backsheet polymer types included polyamide (PA)-, polyvinyl fluoride (PVF)-, polyethylene terephthalate (PET)-, and polyvinylidene fluoride (PVDF)-based backsheets. Exposure conditions included several UV protocols (e.g. 65°C at 20% relative humidity (RH) with an irradiance of 0.8 W/m².nm at 340 nm) as well as “dark” protocols (e.g. 85°C at 85% RH). The results show a clear difference in adhesive strength among the different types of backsheet, as well as an observable decrease in adhesive strength with exposure time, for several backsheet types. Furthermore, they show a change in location of the delamination interface with prolonged exposure duration. The results are useful in developing correlations with adhesive degradation measured in field-deployed modules, and are currently being used as part of a large-scale study to develop predictive models for the long-term reliability of PV modules.

Optical and Electrical Properties of Bulk Heterojunction CISe Films Aida Torabi; Texas A&M-Central Texas, Killeen, Texas, United States.

Bulk heterojunction CISe films are being developed as a new candidate for PV applications. The structures of these films are complex with the fabrication process dictating film properties. Herein we present our study on the optical and electrical properties of these materials deposited via electrodeposition. Cathodoluminescence (CL), Electron beam-induced current (EBIC), and energy dispersive X-ray spectroscopy (EDS) were measured from different films. Photoluminescence (PL) measurements were also taken to study large areas of the film. We observed peaks in the luminescence which may correspond to both the n and p semiconductors as well as trap states. These responses were mapped across the film to determine possible fabrication improvements.

The Voltagemmtric Hysteresis Behavior and Potential Scan Rate Dependence of a Dye Sensitized Solar Cells T. M. W. J. Bandara1, Ajith DeSilva2, K. Vignaroonbanh1 and L. N. Senaviratna1; 1Physics, University of Peradeniya, Peradeniya, Sri Lanka; 2Physics, University of West Georgia, Carrollton, Georgia, United States; 3Physics, University of Jaffna, Jaffna, Sri Lanka.

During last three decades the field of dye sensitized solar cells (DSSCs) gained significant advancement; however, there are some unresolved issues related to characterization of DSSCs. For example, the volumetric photovoltaic hysteresis such as current density versus cell potential (J-V) curves, is a serious concern because it is known that the performance of DSSCs depends on the direction and the rate of cell potential scan. The present work is focused on studying the dependence of solar cell performance on the direction and the rate of cell potential scan in a DSSC prepared with a novel gel polymer electrolyte. For this purpose, the photo electrode was prepared by sensitizing TiO2 double layers with NiTiO dye. The new gel polymer electrolyte used in this work is based on polyacrylonitrile (PAN) (Mw. 150,000) tetrahydroammonium iodide, KI, 4-tertbutylpyridine (4TPB), Butyl-3-methylimidazolium iodide (BMI) and plasticizers, propylene carbonate (PC) and ethylene carbonate. J-V characteristics of the cells were obtained by varying the scan rate (from 0.01 to 0.1 V s⁻¹) and the direction (from forward bias to reverse bias and reverse bias to forward bias). The quasi solid state DSSC prepared in this work exhibited short circuit current density, open circuit voltage and efficiency 13.63 mA cm⁻², 0.76 V and 6.4% respectively under 1000 W m⁻² irradiation. The energy conversion efficiency of the DSSC increased from 5.9 to 6.4% with the increase of the scan rate (from 0.01 to 0.1 V s⁻¹), when the scanning is conducted from forward bias to reverse bias direction. However, when the scanning direction is reversed a drop of the efficiency was observed with increasing rate of potential scan. Therefore, different trends of efficiency variation were exhibited with the change of the direction of potential scan. The properties of the electrolyte and the DSSC were characterized further by analyzing complex spectroscopic data. Present work emphasizes the importance of reporting the rate and direction of potential scan with solar cell performance parameter.
adjusting the mass loading of active materials, the capacitance parameters of various electrodes and devices were investigated. Excessive contents of Mn were discovered to be detrimental to ionic transport and Faradaic charge transfer, and inferior capacitance performance has thereby resulted. Mass overloads of active materials were demonstrated to reduce conductivity, leading to worse capacitor characteristics. After calculation by the CV results, the asymmetric solid-state supercapacitor 3-NGM1/G1 exhibited the highest specific capacitance of 579 Fg\(^{-1}\). Its corresponding energy and power densities were 73.6 Whkg\(^{-1}\) and 4400.0 Wkg\(^{-1}\), respectively, implying the good charge-discharge capacity. After 2000 bending cycles of GCD under the current density of 1 Ag\(^{-1}\), the retention rate of specific capacitance was approximately 86.7 %. The high flexibility, cycling stability, and good capacitance properties could be attributed to the synergistic effect of mixed-phase \(\text{MnO}_2\), and nitrogen-containing graphene. By combining the electric double-layer material with a pseudocapacitive material, two charge storage mechanisms were in conjunction to improve charge transfer, conductivity, and thus capacitor performance.

**Demonstration of a Self-forming Solid State Rechargeable Li\(_2\)I\(_2\) Battery** Alyson Abraham1, Jianping Huang1, Paul Smith1, Amy C. Marschiliok1,2, Kenneth Takeuchi1 and Esther Takeuchi1,2; Stony Brook University, Stony Brook, New York, United States; Brookhaven National Laboratory, Upton, New York, United States.

Lithium-based battery systems are attractive due to their higher energy densities, however, safety issues resulting from use of organic electrolytes and formation of Li dendrites remain major concerns. Solid-state electrolytes provide an alternative to organic electrolyte, but present their own challenges, including limits in ionic conductivity and the lithium-solid-state electrolyte interface. Self-forming batteries, where the anode and cathode are formed upon charge from a single solid electrolyte, can be a promising avenue to address and reduce interfacial resistance. The Li\(_2\)I\(_2\) couple is an attractive target due to its high energy density (1536 Wh/L, 560 Wh/kg) and opportunity to self-heal. Notably, the primary Li\(_2\)I\(_2\) battery has been a successful technology as the power source for pacemakers.

Herein, we describe a fully self-forming solid-state rechargeable battery based on the Li\(_2\)I\(_2\) couple using LiI rich lithium iodide-(3-hydroxyproprionitrile) electrolyte. To our knowledge, this is the first demonstration of a rechargeable fully self-forming solid-state lithium battery with the inclusion of LiI(HPN)\(_2\). Characterization to verify the formation of the self-forming active battery will be discussed. The impact of variables such as LiI and LiI(HPN)\(_2\) ratio and charging condition on the resulting impedance of the battery system will also be described. These results show promise for the future development of high energy density solid state self-forming self-healing batteries.

**3D Interconnected Binder-Free Electrospun MnO@C Nanofibers for Supercapacitor Devices** Najeh K. Allam, American University in Cairo, New Cairo, Egypt.

Rational design of binder-free materials and high cyclic stability are a great need for high-performance supercapacitors. We demonstrate a facile one-step synthesis method of binder-free MnO@C nanofibers as electrodes for supercapacitor applications. The topology of the fabricated nanofibers was investigated using FESEM and HRTEM. The X-ray photoelectron spectroscopy (XPS) and the X-ray diffraction (XRD) analyses confirm the formation of the MnO structure. The electrospun MnO@C electrodes achieve high specific capacitance of 578 Fg\(^{-1}\) at 1 Ag\(^{-1}\) with an outstanding cycling performance. The electrodes also show 127% capacity increasing after 3000 cycles. An asymmetric supercapacitor composed of activated carbon as the negative electrode and MnO@C as the positive electrode shows an ultrahigh energy density of 35.5 Wh/kg with a power density of 10.7 kW/kg. The device shows a superior columbic efficiency, cycle life, and capacity retention.

9:30 AM ET07.07.05
**Electrochemical Supercapacitor Based on a Heterostructure of 1D MoTe\(_2\) Nanowires and Few Layer 2D 1T’-MoTe\(_2\) Sachin A. Pawar1, Dipali Patil1, Donghwan Kim1,2, Tae-Wan Kim1 and Jae Cheol Shin1,2; 1Yeungnam University, Gyeongsan-si, Korea (the Republic of); 2Korea Research Institute of Standards and Science, Daejeon, Korea (the Republic of).

Transition metal dichalcogenides (TMDs) with the layered structures are an analogue of a graphite which consists stacked graphene monolayers. TMDs are having many technologically essential and scientifically amazing properties due to their anisotropy. The layered TMDs demonstrate the most favorable electrochemical properties owing to their better electrical conductivities due to intrinsically layered structure and large surface areas. Among all TMDs viz., S, Se and Te, Te-based TMDs display higher electrical conductivities which are advantageous to enhance the superior performance of electrochemical supercapacitors. The semiconducting nature in S, Se based TMDs and 2H phase largely hinders their electrochemical performance owing to poor electronic conductivity. Moreover, Te-based TMDs as supercapacitors are gaining a lot of attention nowadays with a few reports. Integration of one dimensional (1D) 1T’-MoTe\(_2\) nanowires into few layered two dimensional (2D) 2H MoTe\(_2\) as a multilayer heterostructure can enhance the performance of supercapacitor. Here, we demonstrate the growth of 1D 1T’-MoTe\(_2\) NW/2D 2H MoTe\(_2\) thin film heterostructure through metal organic chemical vapor deposition (MOCVD) on Si/SiO\(_2\) and thereby successful transfer of these heterostructure on flexible nickel (Ni) foam current collector by simple chemical etching protocol for high performance supercapacitor. A layer by layer study of MoTe\(_2\)/MoTe\(_2\) heterostructure is carried out by varying the number of transfer layers on Ni foam. The resultant supercapacitors demonstrate a threefold enhancement in areal capacitance (1412 mFcm\(^{-1}\)) than a single layer transferred electrode with excellent electrochemical stability (96%) and high energy density (140.36 mWcm\(^{-2}\)). These supercapacitors outperform the TMD based (Te-based) supercapacitors presented in the past portraying the abundant potential for energy conversion devices.

**Golden, Grey and White Titanias—Controlled Surface Oxidation Towards Visible Light Assisted Water-Splitting** Larissa S. Chaperman, Fayna Mammeri and Souad Ammar; ITO Dys, Université Paris Diderot, Paris, France.

The search for energy alternatives to reduce our dependency on fossil fuels has been a very pressing topic for the last few decades. Despite significant advances, oil remains the most used fuel worldwide, while also being the fuel that emits the most CO\(_2\) apart from coal. [1] In contrast, hydrogen rises as a carbon-free fuel with the highest known energy content, while producing only water as a byproduct. [2] When comparing different routes for hydrogen production, unfortunately the ones that rely on fossil fuels are still the most economically viable, since the low efficiencies of routes that use renewable raw materials or energy sources result in a high cost. [2] The key to balance this equation is to improve the efficiency of cleaner routes such as photo electrolytic water-splitting to make the hydrogen production cheaper and more widespread as fuel alternative. In this work, we propose a controlled surface oxidation of metallic titanium plates as a mean to enable its use as photo anode in visible light assisted water-splitting systems. The different degrees of oxidation and predominant treatment mechanisms led to different characteristics and photoelectrochemical properties of the treated samples, allowing us to tune the oxidized layer and obtain very promising materials. By varying key parameters, we managed to increase the TiO\(_2\) visible light absorption band while keeping its semiconductor behavior, which is crucial to its application in photo electrolytic water-splitting systems.

We show, then, that the structural defects and composition variations generated during the productive process are an effective way to improve the photo
Electrospinning (ES) is a versatile and straightforward process to fabricate high porous membranes with high surface to volume ratio. It is a relatively simple and efficient technique to create continuous fibers at nanoscale. The electrospun fibers are collected in ranges of micro- and nano-meters. Although the ES has been widely studied and the electrospun membranes have been created for many biomaterial and energy applications, the electrospun separators have specific characteristics to meet with the requirements of lithium-ion battery (LIB) separators. The separators are electrochemically inactive but crucial for providing safety to the battery. The primary commercial separator materials for LIB are polyolefin, which is anisotropic. Because of the anisotropic characteristic, it is easily damaged by puncture force, tension force and dendrite growth in a certain direction (transverse). The damages allow internal short circuits leading to battery fire and explosion. Properties of the electrospun membranes in a form of non-woven mats are independent to the membrane characteristic, it is easily damaged by puncture force, tension force and dendrite growth in a certain direction (transverse). The damages allow internal short circuits leading to battery fire and explosion. The overall mission of the CAMP Facility is to enable the transition of new advanced battery chemistries invented in research laboratories to industrial production through independent validation and analysis in prototype cell formats (xx3450 pouch, xx6395 pouch, and 18650 rigid cells). It is an integrated team designed to support production of prototype cells using semi-automated cell fabrication equipment, and includes activities in materials validation, modeling, and diagnostics - it is ideally suited to address this new field of R&D.

Initial focus here is on coating ceramic-based films onto the negative electrode. Later efforts may include developing methods of coating functional materials and/or polymer films onto negative or positive electrodes. Two ceramic materials (Al2O3 and MgO) were chosen to scope out the techniques needed for coating onto graphite electrodes. These ceramics are relatively benign in a typical lithium-ion battery system, and could thus serve the purpose of functioning as an added safety refractory layer to support a standard polymer separator during thermal abuse, or as a complete replacement of the polymer separator. Other ceramic materials were used later. In the work presented here, a PVDF-based slurry was used to adhere the ceramic particles to the graphite electrode.

Early coating attempts used a hand coating (doctor blade) method. Attempts were made with a roll-to-roll reverse-comma coater, but process issues arose. Other coating technologies are needed to enhance the coating process, which will be discussed in the presentation. Successful coatings were used in various electrochemical tests in prototype cells (coin & pouch), with and without separators, versus cathodes and lithium counter electrodes. The results from these cell tests are promising. In addition, Argonne's state-of-the-art facility in battery failure analysis (Post-Test Facility - PTF) inspected the interface between the anode and ceramic layer. These results will also be discussed in more detail.

Support from Peter Faguy, Steven Boyd, and David Howell of the Department of Energy’s Vehicle Technologies Office is gratefully acknowledged.

Electrospinning Process for Lithium-Ion Battery Electrodes Wisawat Keaswejjareansuk1, Jianyu Liang1 and Xiang Wang2; 1Worcester Polytechnic Institute, Worcester, Massachusetts, United States; 2Department of Material Science and Engineering, Wuhan University of Technology, Wuhan, China.

Electrospinning is a versatile and straightforward process to fabricate high porous membranes with high surface to volume ratio. It is a relatively simple and efficient technique to create continuous fibers at nanoscale. The electrospun fibers are collected in ranges of micro- and nano-meters. Although the ES has been widely studied and the electrospun membranes have been created for many biomaterial and energy applications, the electrospun separators have specific characteristics to meet with the requirements of lithium-ion battery (LIB) separators. The separators are electrochemically inactive but crucial for providing safety to the battery. The primary commercial separator materials for LIB are polyolefin, which is anisotropic. Because of the anisotropic characteristic, it is easily damaged by puncture force, tension force and dendrite growth in a certain direction (transverse). The damages allow internal short circuits leading to battery fire and explosion. Properties of the electrospun membranes in a form of non-woven mats are independent to the membrane directions. The operation principle of the ES is simply a high electric potential is applied to a spinneret, which is connected to a polymer solution syringe. Polymer solution is fed by a syringe pump and spun in the electric field. The charged spun solution is elongated to a fiber-like jet, and then collected on a collector. The characteristics and properties of the electrospun membrane can be customized by simultaneously adjusting the materials parameters and regulating the process parameters. The material parameters are types of polymer, solvent systems and concentration of polymer solution. The process parameters include electric potential, spinneret-to-collector distance, solution feed rate and collector configuration. In this presentation, we will briefly explain the requirements of LIB separators and discuss in detail the effects of material and process parameters, the process control, and characterizations for customized electrospun separators’ characteristics and properties.

Ultra Lightweight, High Power Density Lithium-Ion Batteries Mihai Duduta, Sebastien de Rivaz, David Clarke and Robert Wood; Harvard University, Cambridge, Massachusetts, United States.

Existing fabrication technologies cannot be used to make lightweight, high power density lithium ion batteries (>300mg). The need is increasing for these small, powerful batteries, as advances in fabrication techniques push the limits of miniaturization in robotics, haptics, wearable and biomedical technologies, and mobile computing for the Internet of Things. Unfortunately, current fabrication methods for lithium ion cells force the end user to make a choice between high energy density and lightweight batteries. Supercapacitors can provide even higher power density (>10 kW/kg), but have very short discharge times (0.1 - 5s) which limits the range of potential applications. To push the limits of performance, we have developed a hybrid manufacturing approach which uses commercially available lithium ion materials and a laser micro machining method to build lightweight (10-200 mg) high power...
Conversion of dissipated heat into electricity is the basic principle of thermoelectricity. It has wide variety of applications in the areas such as automobile engineering, refrigerating coolants, satellite etc. These days there is a high demand of materials which are efficient in converting heat in to electricity [1]. In search of such materials thermoelectrics has given wide scope to complex materials like Tellurides, Clatharates, Zintl compounds, Half Heusler alloys, Silicides, Skutterudite etc. The defining factor for thermoelectric materials is ZT, thermoelectric figure of merit. This attributes to the power factor (electrical conductivity S-Seebbeck coefficient enhancement and thermal conductivity reduction). Band gap tailoring, carrier concentration are a few ways to improve power factor where as in parallel, grain size reduction, point defects, dislocations are key ways to thermal conductivity reduction. These can be achieved experimentally through microstructural engineering and processing [2]. The issues existing with available thermoelectric materials are associated with stability of performance for a long range of temperatures. Fine tuning of microstructure is the key factor in overcoming the thermal stability issues.

Currently we are exploring a program of microstructure-transport properties correlation of newly processed thermoelectric alloys by fine tuning the eutectic microstructure. In this current work, we have synthesized a set of thermoelectric alloys eutectic and off eutectic compositions in Sn-Te alloy system (Sn₄Te₉ (at%)) [3]. These as melted alloys show eutectic microstructure consisting of Sn₅₀Te₅₀ and Te phase with varied volume fraction. Variations of transport properties with respect to secondary phase fraction have also been studied. Eutectic microstructure with different phase boundary will always help in minimizing lattice thermal conductivity by disrupting phononic movement. Hypo and Hyper eutectic composition are (Sn₂₀Te₈₀ (at%)) and (Sn₄₅Te₅₅ (at%))

The elemental distribution mapping and the compositional analysis using electron probe microanalysis (WDS), demonstrates that the matrix is rich in tellurium and the continuous phase has the composition of Sn₅₀Te₅₀ (at%). Transport properties of the current alloy are attractive in terms of standard thermoelectric material(S−133µV/K and P−3µW/cm-K² at 420oK). We are presently calculating Figure of Merit and detailed structural characterization of this alloy. Further attempts are being made for achieving more improved properties by elemental additions and fine tuning the microstructure. The detailed microstructure-transport properties correlation will be presented.

from the surface down to the current collector interface. Furthermore, LIBS provides a great potential for enabling advanced fundamental studies on 3D electrode micro-structures for discovering their impact on performance enhancements regarding battery life-time and capacity as a function of electrochemical cycling parameters. In general, the main objective is to develop an optimized 3D cell design with improved electrochemical properties, which can be correlated to a characteristic lithium distribution along the laser generated 3D architectures. For this purpose, 3D elemental imaging and depth profiling was performed for the entire electrode. The measurements were carried out in ambient air, applying a multivariate calibration technique “Partial Least Squares Regression”. It could be clearly shown that the generation of 3D architectures tremendously influences the electrochemical performance. Results achieved from post-mortem studies will be presented for cells with unstructured and laser-structured electrodes.

Critical Size Scale and Effects of Manufacturing Defects on Plating in Li-Ion Batteries Craig B. Arnold; Princeton University, Princeton, New Jersey, United States.

Lithium plating is an important degradation mechanism in Li-ion batteries that not only reduces battery capacity, but also can lead to catastrophic failures. The plated lithium can turn into dendrites and gradually grow through the separator, leading to a short circuit. In this study, we show that certain types of manufacturing defects can create conditions favorable to enhanced lithium plating in these cells under normal cycling conditions due to transport gradients within the systems. In particular, we explore effects of defect size and distribution within the cell and the corresponding effect on the plating behavior. Below a critical defect size, plating is unlikely to occur and we develop a simple phenomenological approach to guide manufacturing and quality control in assessing this situation for a given battery cell. Such studies help elucidate the fundamentals behind heterogeneous plating and can provide practical insights into battery safety and product control.

Observing the Volume Change Process of Si/C Electrode by In Situ SEM at Elevated Temperature Yuefei Zhang1, Rui Wu1, Hui Feng Shi3 and Yijing Zheng2; 1Institute of Microstructure and Property of Advanced Materials, Beijing University of Technology, Beijing, China; 2Karlsruhe Institute of Technology, Karlsruhe, Germany.

Compared to the conventional graphite electrode, the silicon-carbon electrode has attracted much interest from researchers due to its high theoretical capacity. However, the Si/C composite electrode is still limited by the low rate capability and cyclability induced by the microstructural challenges such as mechanical failure, SEI crack, and low ionics kinetics, et al. Since the volume expansion rate of silicon is about 300% during charging and discharging, while graphite only expands by 10%, the different expansion rate could lead to poor contact of the electrodes and even pulverization. Among all the improved methods, 3D-structured electrode could potentially alleviate the structural damage caused by volume expansion through the empty space formed by the high-energy laser beam. Therefore, understanding the precise evolution mechanisms of 3D electrode under working conditions and its possible failure mode during the charge/discharge process helps researchers to improve the performance of batteries more purposefully.

The in-situ, real-time, dynamical studying of electrode can directly provide the evidence of structure evolution under charge-discharge cycles. Here, we use the self-developed joint SEM-electrochemical system with the temperature controller to observe the morphological evolution of 3D Si/C composites electrodes. According to the experiment results, we found the separation process of active materials from current collectors because of the electrode’s volume expansion, which leads by the insertion of lithium ion, and the separation direction is from edge to center. As temperature rise from 20°C to 60°C, the discharge voltage platform and discharge time also increase due to the more intense ion movement. Besides, the electrode with 3D structured has better cycle performance than the ordinary plane electrode.

4:30 PM ET07.08.05
Geometry and Size Dependence of Transport Non-Uniformities on Localized Plating Xinyi M. Liu, Alta Fang, Mikko Haataja and Craig B. Arnold; Princeton University, Princeton, New Jersey, United States.

Lithium plating, the formation of metallic lithium, is an important degradation mechanism that not only reduces battery capacity but also can lead to catastrophic failures. While most lithium plating can be prevented under normal cycling conditions, it is difficult to avoid localized plating. In previous work, we demonstrated that the heterogeneity of materials or defects in cells can create non-uniform ionic transport, leading to regions with high current densities and therefore induce plating [1]. In this work, we look further into the importance of the size scale and geometry of transport non-uniformity on localized plating, and directly relate the size scale to the capacity fade of a battery.

We create transport non-uniformities by mechanically compressing separators to close all the pores and cutting the compressed separators into different patterns and sizes. The compressed separator defects were then placed inside the coin cell along with a pristine layer of separator. After a number of cycles, cells were disassembled to record the amount of plating on the electrode surface.

In this work, we show that certain geometric features are more vulnerable to plating than others and localization strongly depends on size[2]. A single continuous feature in a separator induces more plating than a collection of smaller features with same total area. By defining a simple IE ratio, which is a characteristic of size and geometry, we relate the ratio to the propensity of plating. A region with a high IE ratio means more concentrated ionic flow and is more vulnerable to plating. A large defect feature induces more capacity fade of a battery than a small feature. We also demonstrate numerically and experimentally that there exists a critical size scale below which localized plating is unlikely to occur, and such critical size depends on the current density. Finally, we look into the interactions between multiple features that are spaced at various distances. This work not only elucidate the fundamentals behind localization, but also provide insights into battery safety and product control.

Laser-Engineering and -Analytics in Electrode Manufacturing for Lithium-Ion Batteries Wilhelm Pfleging1,2, Peter Smyrek1,2, Yijing Zheng1, Jan-Hendric Rakebrandt1, Yangping Sheng1, Marissa Wood1, David Wood1, Jianlin Li3 and Hans J. Seifert1; 1IAM-AWP, Karlsruhe Institute of Technology, Karlsruhe, Germany; 2Karlsruhe Nano Micro Facility, Eggenstein-Leopoldshafen, Germany; 3Energy & Transportation Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.
So far, high production costs, restricted process reliability, small energy and power density, and short operational lifetime are the main issues of lithium-ion batteries (LIBs). Manufacturing of thick film electrodes is one suitable approach for achieving high-energy densities in LIBs. However, thick film electrodes suffer from electrolyte transfer limitations. Therefore, electrodes with film thickness of about 40-50 μm are currently used for high-power operation while thick film electrodes (thickness ≥100 μm) are developed for high-energy applications. LIBs with high-energy and high-power density can be realized by introducing a three-dimensional (3D) battery concept, which offers an improved electrolyte transfer in thick film electrodes and an improved lithium-ion transport kinetic. For developing next generation batteries, the 3D battery concept, originally invented for micro-batteries, will be transferred to LIBs with large footprint areas. For this purpose, laser materials processing was recently introduced in research and industry enabling advanced design rules for new and state-of-the-art electrode materials. A significant increase of active surface area in lithium-ion cells is achieved by direct ultrafast laser-assisted structuring of composite electrodes. 3D micro-structures and capacillary features in thick film anodes and cathodes are formed in order to shorten the electrolyte diffusion distance and consequently for the improvement of rate performance. The electrochemical performance of lithium-ion cells (coin cells, pouch cells) with laser-structured electrodes were analyzed and compared to cells with unstructured electrodes. The 3D micro-structured electrodes demonstrate high rate capability and an improved liquid electrolyte wetting. Laser-induced breakdown spectroscopy was applied as an analytical tool for chemical characterization of entire electrodes. Elemental mappings were performed for the development of coating processes. Additionally, post-mortem studies were carried out for investigating degradation processes related to thick film electrodes.

The low dielectric constant of organic materials and inhomogeneous distribution of molecular dopants in a conductive matrix impose difficulties in populating free charge carriers in organic materials, leading to practical challenges in developing highly conductive organic materials. We designed two different CPs with long side chains and an electron-donating isodindoloindole derivative in a way that the CPs strongly interact with molecular dopant, 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethan (F4-TCNQ), and the doping efficiency was further enhanced through sequential doping to promote the diffusion degree of F4-TCNQ. With these strategies, electrical conductivities of the doped CPs films were significantly improved (over 140 S cm⁻¹), much larger than that obtained from the conventional blending approach (5 S cm⁻¹). Furthermore, the doping level is scalable with the exposure duration in the ET07.09.02 Mustard Seed Based Triboelectric Nanogenerator Sachin K. Singh1, Subas Muduli2, Ramamurthy Boomishankar2 and Satishchandra Ogale2
1Chemistry, Indian Institute of Science Education Research, Pune, India; 2Physics, Indian Institute of Science Education and Research, Pune, India.

Mechanical energy from a local domain is seldom recovered due to its fluctuating amplitude and low frequency and is therefore usually designated as “unsystematic” energy. With several new ideas and device schemes introduced by Z. L. Wang and coworkers as well as others, it has now become feasible to tap such energy systematically. Herein we introduce an idea of using mustard seeds as a vehicle for construction of a green Triboelectric Nano Generator (TENG). There have been only a few attempts to make such devices using natural materials.1,2 Mustard seeds shells charge highly by friction and hence are susceptible to charge separation, a property that we have utilized in our device.

The flexible TENG furnished an impressive output voltage of 50 V and a maximum current of 5.25 μA. The seed-TENG with good adaptability rendered the maximum output power of 45μWcm⁻², which is capable of driving advertising LEDs and commercial electronic temperature sensors.

ET07.09.03 SLIPS-Designed Electrodes in Monolithic PV-Electrolysis Water Splitting System for Membraneless Gas Separation, Transport and Collection Ki Duk Han, Sangkuk Kim, YongJae Jeung, Seunghyeon Bae, HyunSik Moon and Kijung Yong; Pohang University of Science and Technology, Pohang, Korea (the Republic of).

Recently, PV-electrolysis is attracting much attention as a potential method for hydrogen production by water splitting due to high solar to hydrogen conversion (STH) efficiency. Although there are remarkable advances in modular performance and multifunctional design of PV-electrolysis systems, this artificial leaf system still has critical issues associated with product gas separation. In current monolithic PV-electrolysis modules, the H₂ gas product is inevitably mixed with the O₂ gas. Therefore, in order to obtain pure H₂ gas fuel, additional energy is required for gas separation, such as application of high cost, complex membrane system. To overcome this problem, we invented a simple and very compact gas separation system for monolithic PV electrolysis, which is based on biomimetic surface design. The key idea is adopting slippery lubricant-impregnated porous surface (SLIPS) in designing hydrogen evolution reaction (HER) and oxygen evolution reaction (OER) electrodes, which enables gas bubble manipulation, separation and collection. When H₂ and O₂ gases are generated at the respective SLIPS-edged, inclined HER and OER electrodes, buoyancy drives gas bubbles to move up along each slope of the electrode. In this process, SLIPS-tracks deposited on the lateral edges of cathode electrode catch and transport gas bubbles along the inclined electrodes.
surface to the collection port and prevent air bubbles from escaping and cross-over from the electrode surface. Due to this smart design of electrodes, most generated H2 and O2 gases could be successfully collected at each product port without crossing or loss. Our monolithic PV-electrolysis device could capture, transport and collect H2 and O2 gases very efficiently with a separation efficiency of over 90%. Furthermore, we have realized a monolithic PV-electrolysis system with membraneless gas separation by combining the interconnected CuInS2 (CIS) PV cell with inclined HER/OER electrodes consisting of an inverted triangle configuration. This unique membrane-free artificial leaf encapsulates free space inside and can float on the surface of the water, providing additional benefits such as total light utilization and reusability.

Near-Surface Water Currents Based Triboelectric Nanogenerators
Abdelsalam Ahmed1, Islam M. Hassan1, Ali Radhi1 and Jean Zu2; 1University of Toronto, Toronto, Ontario, Canada; 2Stevens Institute of Technology, Hoboken, New Jersey, United States.

This work presents an entirely parallel network of triboelectric nanogenerators (TENGs) for functional hydrokinetic energy harvesting from near-surface water currents. To the best of our knowledge, this is the first report on using the near-surface water current as a potential energy source. The TENG operates with a free-standing mode with low-cost fabrication and high throughput from incidental water currents. The device is designed for a single unit to contain four TENG components operated in parallel for use within the neritic zone of the ocean. The hybridized TENG parallel network within a single underwater TENG unit attained a voltage of 400 V, a current of 0.8 mA and generated power of 0.2 W, approximately. The observed hydrokinetic power harvesting performance is one of the highest achieved with TENG technology, suggesting significant potential for portable coastal and shallow water applications in sustainable and underwater self-powered sensors.

Synthesis and Photocatalytic Properties of Semiconducting Composite Powder
Kensuke Akiyama1,2, Sakiko Nojima1, Ryo Takahashi1, Hiroshi Funakubo2 and Hiroshi Irie1; 1Kanagawa Institute of Industrial Science and Technology, Ebina, Japan; 2Materials Science and Engineering School, Tokyo Institute of Technology, Yokohama, Japan; 3Clean Energy Research Center, University of Yamanashi, Kofu, Japan.

Photocatalytic water-splitting is an ideal method for solar energy harvesting. Some photocatalysts that can split water under UV light have been discovered. However, development of visible-light sensitive photocatalysts is indispensable due to the effective utilization of incoming solar energy. On the other hand, semiconducting iron disilicide (β-FeSi2) has a band gap of approximately 0.80 eV and a very large optical absorption coefficient over 105 cm−1 at 1 eV. Moreover, it has recently been reported that this semiconducting material acts as a hydrogen-evolution photocatalyst. As a hydrogen-evolution photocatalyst, β-FeSi2 is expected to enable the use of infrared light longer than 1300 nm, which is the longest wavelength of light to be utilized. This semiconducting material is composed of the elements which are naturally abundant and less toxic than the elements used in conventional compound semiconductors.

In this paper, we report on the novel fabrication method of β-FeSi2/SiC composite powder by using metal-organic chemical vapor deposition (MOCVD) method which is general in semiconductor process technology. Moreover, we report on the hydrogen evolution over this composite powder under irradiation of not only UV but also visible light and near-infrared light from methyl-alcohol aqueous solution. 10-nm-thick gold (Au) was deposited on the surface of SiC powder, average diameter of 60 nm, at room temperature by rf-sputtering. β-FeSi2 was deposited on the Au-coated SiC powder by using metal organic chemical vapor deposition (MOCVD) method. Iron pentacarbonyl [Fe(CO)5] and monosilane (SiH4) were used as sources, and the substrate temperature was 923K and the deposition rate was 1.6 nm/min, respectively. ARD 8-20 scan profile showed the formation of poly-crystalline β-FeSi2 phase for the powder after MOCVD deposition of 1 hour. From the SEM observation of this composite powder, the inhomogeneous grains with sizes of the order 10 nanometers were confirmed to be formed on the SiC surface. The hydrogen gas was evolved by irradiation of UV light (250-430 nm) from methyl-alcohol aqueous solution. Moreover, similar hydrogen evolution was confirmed under visible light (420-650 nm) and near-infrared light (1050-1600 nm) light irradiation.

Spectroscopic Study for Hydrophilic Surface of TiO2: Photocatalysts Modified with Au Nanoparticles
Hayato Kondo, Yosuke Kageshima and Hiromasa Nishikiori; Department of Engineering, Graduate School of Science and Technology, Shinshu University, Nagano, Japan.

Semiconductor photocatalytic materials have attracted a great attention as a promising approach to solve worldwide energy and environmental issues derived from mass consumption of fossil fuels. Above all, there are tremendous reports about TiO2 photocatalysts. It is well-known that TiO2 exhibits high photochemical activity and durability and is capable of driving decomposition of organic compounds and formation of hydrophilic surface under illumination of UV light. These unique characteristics enable us to utilize TiO2 for various applications of environmental cleanup (i.e., air purification, water purification, and antibacterial self-cleaning), as well as energy conversion (i.e., dye-sensitized solar cells and water splitting). Although hydrophilic surface of TiO2 under UV irradiation should play an important role for its photocatalytic properties, detailed mechanisms and processes for expression of hydrophilic TiO2 surface are still unclear. Therefore, in this report, expression mechanisms of hydrophilic surface of TiO2 photocatalysts modified with Au nanoparticles were studied via the spectroscopic measurements. Here, it should be noted that Au nanoparticles were modified in order to increase the sensitivity for spectroscopic measurements by surface plasmon resonance. TiO2 particles (P25, Nippon Aerosil) were coated by Au nanoparticles via the photodeposition method. The TiO2 particles were suspended in an aqueous solution containing Au salt, such as AuCl3, and irradiated by UV light for various duration, followed by filtration, drying, and annealing in air. The objective Au/TiO2 particles modified with Au were referred to as Au/TiO2 hereafter. IR spectra of the surface hydroxyl group on Au/TiO2 showed the formation of hydrophilic surface on Au/TiO2, expression mechanisms of hydrophilic surface will be discussed.

High-Efficiency Power Conditioning System for Autonomous Triboelectric Nanogenerator Devices
Aravind Ravichandran and Marc Ramaz; EMSE-CMP, Gardanne, France.

With the rapid development of wearable electronics and sensor networks, batteries cannot meet the sustainable energy requirements due to their limited lifetime, size and degradation. With miniaturization leading to high-power and robustness, triboelectric nanogeners (TENGs) have been conceived as a promising technology by harvesting mechanical energy for powering small electronic systems. However, low output power conversion efficiency has
restricted its practical application because of its own extremely high output impedance.

In this work, a state of the art high efficient power conditioning system is proposed which increases the conversion efficiency by 60% but also with lower impedance matching. Our work represents a nomenclature in the process and experimental methods to achieve effective energy harvesting and storage by TENGs.

In order to solve the limited life problem of typical battery power supply, an autonomous device is conceptualized that is based on the environmental energy harvesting has emerged as an amazing power supply approach. In order to match the high output impedance of TENGs and increase the output power, this work presents a highly efficient power conditioning system, which is composed of a diode rectifier bridge, a control circuit, impedance matching circuit and an energy storage device. Experimental results show that, in less than 3 secs, the storage capacitor reached a voltage of 5 V by the proposed conditioning technique. The charging efficiency increased by 60%.

By considering these merits of simple fabrication, outstanding performance, robust characteristic and low-cost technology, we believe that advanced power management of TENGs can open up great opportunities not only for powering small electronics but can contribute to large-scale energy harvesting through engineering design being complementary to existing energy sources allowing clean and uninterrupted energy production.

ET07.09.08 Fabrication of Nanoscale Multilayered Thin Film Based Integrated Triboelectric Devices Alandria Henderson, Joevonte Kimbrough, Kenneth Davis, Zackary Duncan, John Elie, Sam Chance, Brandon Whitaker, Michael Howard, Michael Glenn, TeAndrea Wimbley and Zhigang Xiao; Electrical Engineering and Computer Science, Alabama A&M University, Normal, Alabama, United States.

We report the growth of nanoscale multilayered triboelectric thin films and fabrication of integrated triboelectric devices for high-efficiency energy conversion. Nanoscale multilayered thin films such as $\text{Sb}/\text{Sb}_2\text{Te}_3$ and $\text{Te}/\text{Bi}_2\text{Te}_3$ thin films were grown using the e-beam evaporation. Integrated triboelectric devices were fabricated with the nanoscale multilayered thin films using the clean room-based microfabrication techniques such as UV lithography. X-ray diffraction and reflection and high-resolution tunneling electron micrograph (HR-TEM) were used to analyze the e-beam-grown nanoscale multilayered thin films. SEM was used to image and analyze the fabricated devices. The open-circuit voltage and output power produced from the fabricated devices will be measured and analyzed, and highly-efficient triboelectric thin-film materials and integrated devices will be demonstrated and reported.

ET07.09.09 Triboelectrically Self-Powered, Structural Carbon-Fiber-Reinforced Composites Seonghwan Lee¹, Changyoon Jeong¹, Maria Q. Feng² and Young-Bin Park²; ¹Mechanical Engineering, Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of); ²Columbia University, New York, New York, United States.

As fossil fuel depletion is accelerating and energy saving is becoming increasingly critical, intensive efforts are being made to develop environmentally friendly, ultra-lightweight materials for applications in weight-sensitive structures, such as automobiles, aircraft, ships and civil structures. Carbon-fiber-reinforced plastic (CFRP), which is an ultra-lightweight material with a density only a fraction of steel, is well suited for structural applications, where a high strength-to-weight ratio is demanded. Here, we present a proof-of-concept study and demonstration of multi-functional CFRPs that serve as the “structural electrodes” – owing to the high electrical conductivity of carbon fibers - in a triboelectric generator system. If a dielectric material is deposited on the CFRP electrodes and rubbed against one another, the surfaces of the two dielectrics become oppositely charged, and the change in the gap between the two dielectrics induces electrostatic induction. This leads to the accumulation of negative charges along the carbon fiber electrode, thus, generating the electrical energy. Harvesting energy from friction allows high efficiency at low frequency, affordability and low weight due to relatively simple mechanisms and implementation, and this adds a great value and functionality to lightweight, structural CFRPs. The self-powered CFRPs transform the abandoned mechanical energy into usable electrical energy, which will find numerous applications where repetitive loading-unloading is applied, including power-generating speed bumps, roads, railways, doormats, and vibrating structures.

8:30 AM *ET07.10.01 Challenges and Opportunities in Primary Electrodeposition of Lithium Films for Secondary Batteries Daniel Steingart and Wesley Chang; Princeton University, Princeton, New Jersey, United States.

In theory, a clear pathway to improving the energy density of lithium based electrochemical energy storage is replacing the intercalation or alloy host negative electrode with lithium metal itself. The challenges of realizing a version of this electrode suitable for secondary batteries are manifold and most are well documented. A practical aspect that receives less attention, however, is how one creates a lithium foil in a practical manner thin enough to leverage the energy density advantages without “overbuilding” the negative electrode.

Electrodeposition is a well established industrial process for creating metal films and foils of thicknesses from nanometers to millimeters, but the reactivity of lithium has made it difficult to use electrodeposition to produce lithium from an electro refining setup or a primary electrowinning process. In this presentation we demonstrate an multi-electrolyte system which can electrodeposit function lithium films from 5 nm to 20 nm, and explore the morphologies and electrochemical behaviors of these films.

9:00 AM *ET07.10.02 From Laboratory to Industrial Manufacturing—Scale-Up Production of Advanced Lithium-Ion Batteries Marcus Jahn and Corina E. Täubert;
Austrian Institute of Technology GmbH, Vienna, Austria.

The rising need for advanced energy storage solutions due to the increased electrification of global car brands has not only highlighted the need for more materials research, but also increased innovation to bring such novel materials into production. The often-non-trivial scale-up process has become more important and is bridging the gap along the chain of technology readiness levels that is observed between fundamental research efforts and innovation actions taken by industry. In this work the critical manufacturing steps and scale-up parameters for Lithium-Ion battery manufacturing are analysed. Influencing parameters from materials to process are portrayed with particular focus on advanced, as well as post-lithium ion battery materials. Conventional manufacturing techniques are presented and critical parameters are identified, which are often ignored during the fundamental research stage of materials development. Advanced mixing and coating technologies are presented as well as electrode design work applied in order to increase energy or power density at a cell level. There is a rising need for moving away from conventional manufacturing methods to accommodate novel systems, such as all-solid-state batteries, but also to fulfill the demanding requirements for current storage systems, which push the limits of modern day cell chemistries. The need for increased energy density can not only be addressed on a materials level, but also on a manufacturing and processing level, which is part of the work conducted at the Research Pilot Line at AIT. This work shows how research pilot lines for Lithium-Ion battery manufacturing have become increasingly important, especially in Europe, and are considered a key enabler of the future of electric vehicles and to the success of the research needed to meet tomorrow’s demands in energy storage.

Thin Continuous Films Built Using Electro spray Atomization of Nanoparticle Aggregates Yaqun Zhu and Paul Chiarot; Mechanical Engineering, Binghamton University, Binghamton, New York, United States.

Using electrospray atomization, we have built thin continuous films with controllable nano- and micro-structure from nanoparticle aggregates. The aggregates were assembled in-flight (i.e. after electrospray emission) and delivered to a target substrate in a dry state. Our research provides insights into the nanoparticle aggregation and thin film deposition phenomena for varying aggregate sizes and morphologies. Titanium dioxide nanoparticles (p25, ~21 nm) were used as a model system given their importance in photovoltaic applications. We have discovered the relationship among all the essential operating parameters and the micro-/nano-structure of the aggregates and films. We reveal how properties such as nanoparticle concentration, solvent volatility, Taylor cone pulsation frequency, and substrate electrical properties (among others) govern the size and morphology of an individual aggregate. We then further report how the aggregate size and morphology governs the structure of the continuous film. Aggregates formed using electrospray possess an excess electric charge that can be maintained after deposition on to the target substrate. We found that this charge accumulation and its decay rate play a significant role in the film formation. For example, films on a conducting substrate are thick and exhibit periodic islands. In contrast, films on semiconducting and insulating substrates are thin and tend to be uniform. To further probe the influence of charge accumulation, we used “periodic printing” (i.e. periodically turning the electrospray on-and-off during deposition). The structure of the films was significantly different when printing periodically compared to continuous printing. This further highlights the strong influence of the excess charge on deposit structure.

9:45 AM ET07.10.04
Large-Scale Printing of Micro-Wire Electrodes for Roll-to-Roll Manufacturing of Transparent Electrodynamic Screen (EDS) Films for Self-Cleaning Solar Collectors Malay K. Mazumder, Caroline Ellinger, Kevin O’Connor, Sean Garner, Julius Yellowhair, Ryan Eriksen, Annie Rabi Bernard, Cristian Morales, Mark Horenstein and Ramakrishnan Lakshmanan; 1Boston University, Boston, Massachusetts, United States; 2Eastman Kodak Company, Rochester, New York, United States; 3Corning Research and Development Center, Corning, New York, United States; 4Sandia National Laboratories, Albuquerque, New Mexico, United States.

A Manufacturing process for producing Transparent Electrodynamic Screen (EDS) films by flexographic printing of micro-wire electrodes on optically clear dielectric films is discussed. The EDS film consists of a series of parallel transparent electrodes embedded between two transparent dielectric layers, which can then be retrofitted or integrated onto the optical surfaces of solar collectors, such as CSP mirrors and PV Modules. Activation of the electrodes by phased voltage pulses creates a non-uniform electric field distribution on the EDS film surface, which charges and levitates the dust particles and then removes the dust layer by a sweeping action of the traveling electric field created by the three-phase drive. Application of EDS film provides water-free cleaning as frequently as needed to maintain high optical efficiency of solar mirrors and solar panels minimizing energy-yield losses caused by dust deposition. Silver nanowire (AgNW) and passivated Cu micro-wire (micro-wire) electrodes were used as scalable and durable inks for solar field applications of EDS films. We screen-printed AgNW ink electrode directly on Willow Glass (Corning) film for producing lab-scale EDS films. For commercializing the technology, an existing roll-to-roll production facility at Eastman Kodak was used. EDS films were produced in medium scale (26 cm x 30 cm) with catalyst electrodes using flexographic printing on PET films. After printing, the substrate is conveyed through a touchless plating line where electroless copper is deposited on the printed catalyst pattern. The deposited copper is treated in-line with an environmental passivation and darkening agent, simultaneously protecting the micro-wires from corrosion and minimizing front-side reflection with a neutral color, all without contacting a roller to minimize the risk of conveyance related defect formation. For laminating the film on an optical surface of a solar collector, the following architecture of the EDS film is used: Willow Glass (sun facing)/Optically Clear Adhesive (OCA)/Kodak-printed EDS electrodes on PET substrate/ OCA laminated on a solar panel or a mirror. The electrodes of the EDS film are connected to a compact power supply unit. A single power supply unit may serve several holoists or PV modules. Cleaning operation can be activated automatically or manually from a control room without any interruption of the plant operation or human labor. Laboratory- and field- evaluations show that the EDS films can be operated in a wide range of ambient temperature (range of PV module application), relative humidity (varying from 20 to 70% RH and RH cycling) in an environmental chamber used for simulating conditions of solar fields. Limited field evaluations were carried out at the National Solar Thermal Test Facility located at the Sandia National Lab in New Mexico and at the Atacama Desert solar fields in Chile. Experimental data taken with EDS film laminated solar collectors would be presented showing (1) dust removal efficiency ≥ 90%; for solar mirrors: (2) specular reflection (SR) efficiency ≥ 90%; (3) specular reflection restoration (SRR) efficiency ≥ 90% and for solar panels: (4) the light transmission efficiency (TE) ≥ 90%; and (5) output power restoration (OPR) efficiency ≥ 95%. Each cleaning cycle requires less than two minutes and expends a negligible amount of energy (0.2 Wh/m2/cleaning cycle).
