Using such nanoantennas we demonstrate, on the one hand, an electrically switchable metallic polymer metasurface for ultra-high-contrast active beam switching (Fig. 1B). On the other hand, we realize an electro-active metaobjectives comprising two metasurfaces-on-demand [2]. The state of metalenses can be set fully independently. Non-volatile operation is used to set the refractive power of the individual metasurfaces either ON or OFF. Such, four different metaobjectives states become possible. By using gel electrolytes, our metadevices can even be integrated into state-of-the-art on-chip electro-optic components [3,4].

![Fig. 1](image)

**Fig. 1** (A) Concept of electrically switchable nanoantennas made from metallic polymers. Right: Nanoantenna ON-state at applied voltage +1 V, plasmonic resonance observed. Left: Antenna OFF-state at -1 V, no plasmonic resonance observed. Switching is possible with video-rate frequencies of 30 Hz. (B) Metallic polymer plasmonic metasurface for ultra-high-contrast active beam steering. Camera images and intensity profiles in the ON- (left) and OFF-state (right). (C) Multi-focal metaobjectives comprising two stacked metasurfaces-on-demand. The state of each metalens can be set individually in a non-volatile operation.

**Scalable Classical and Quantum Light Sources**

Boubacar Kante; UC Berkeley, United States

The scaling of lasers and in-particular of surface emitting lasers is a multi-decade long question that has been investigated since the invention of lasers in 1958. It is an important question with numerous applications. In this talk, I will propose and discuss an intriguing solution to this question that we named the Berkeley Surface Emitting Laser (BerkSEL) and it is the world’s first scale-invariant laser. In the second part of the talk, I will discuss our demonstration of the first deterministic quantum light source in silicon that emits single photons in the telecom band. The work opens unique perspectives for scalable quantum networks.

**Multiplexed Immunoassays Enabled by Pixelated High-Quality Factor Metasurfaces and Acoustic Bioprinting**

Sajjad Abdollahramezani, Parivash Moradifar, Fareeha Safir, Sahl Dagli, Varun Dolia, Jack Hu, Hamish M. Carr Delgado, Kai Chang, Butrus T. Khuri-Yakub and Jennifer A. Dionne; Stanford University, United States

Nanophotonic biosensors hold the promise of early disease identification and continuous treatment monitoring due to their high sensitivity, fast response time, and possibility for label-free detection. Here, we leverage ultra-densely-pixelated high-quality factor (high-Q) metasurfaces in conjunction with acoustic bioprinting surface chemistry to enable scalable multiplexed immunoassays. Our platform capitalizes on a 2D array of finite-size all-dielectric metalenses supporting quasi-bound state in the continuum (qBIC) resonances to significantly enhance light-matter interaction with high spatial resolution. Unlike conventional metalenses, where sharp resonances are generally generated via the interference of sub- and super-radiant modes in a large 2D arrangement of metamirrors, our high-Q metalenses exploits photonic mirrors to highly confine the collective qBIC mode of a 2D array of broken-symmetry resonators. Without comprising the optical performance, such small-scale (i.e., 15×3 μm²) metalenses provide high Q-factors (~3000) with a mode volume below (λ/100)³. We demonstrate an ultradense array of pixelated biorecognition elements by introducing an acoustic bioprinting approach for the local functionalization of each qBIC resonator. In contrast to conventional surface functionalization approaches, which expose all sensing elements at once, our approach facilitates the realization of multiplexed biodetection by addressing individual elements at KHz rate. In combination with hyperspectral imaging, this sensitive label-free sensing platform allows for the simultaneous quantitative detection and kinetic analysis of multiple antibodies (e.g., SARS-CoV, influenza A, and influenza B) on a single chip. Further, we demonstrate how a single chip can also allow simultaneous detection of proteins and the associated gene fragments. Our AI-enhanced technique can capture two-dimensional spatially resolved images across contiguous spectral bands revealing subtle differentiation of spectral signatures associated with each linked bioanalyte, without relying on bulky and expensive spectrometers. The capability of our multiplexed immunoassay platform for parallel measurement of several biological targets of interest opens the door for easy-to-use and portable diagnostics.

**A Simple Route for Generating Iridescent Retrorreflective Color Filter**

Jioun Yeo, Joo Hwan Ko and Young Min Song; GIST, Korea (the Republic of)

Iridescent colors found in the body of various animals and insects, such as tails of birds or wings of butterflies, exhibit eye-catching visual information, enabling camouflage, predation, courtship, and communication in various environmental changes. In particular, certain living, *Papilio palinurus*, which has multilayer photonic structures on the concave structure of the wing surface, exhibits conspicuous light-matter interaction with both iridescent color reflection and retroreflection, which delivers vibrant visible information in the direction of light input¹. Conventionally, retroreflectors employ geometric structures, such as corner-cube shapes, to redirect incident light back toward its source. However, these structures typically yield non-iridescent colors and are challenging to apply in various applications due to these limitations. Moreover, the use of organic materials such as dyes and pigment for colorization compromises the color purity and durability of retroreflective materials. Based on a lesson from natural photonic structure, specific examples have been introduced to make an iridescent retroreflector inducing gap interference within biologically inspired microsphere structures or distributed Bragg reflector (DBR)². However, these methods still suffer from limitations such as intricate structures and time-consuming manufacturing processes. In this study, inspired by the structural properties of butterflies, we present a conspicuous iridescent retroreflective color filter that dynamically changes in response to the incident angle. The filter aims to overcome limitations in dynamic coloration and durability by utilizing an ultra-thin resonant layer (UTRL) on a metal film.

To implement the iridescent retroreflector filter, a metal film is deposited on a micro-concave array (MCA) designed to implement retroreflective behavior to form a UTRL. The round curvature of the MCA possesses different deposition angles at various locations, which consequently allows the UTRL to deposit with a gradual change in porosity, resulting in sequential color changes under modulated resonance conditions [4]. The fabricated UTRL converts white light into iridescent light that gradually changes with the curvature of MCA by turning the direction of light to the original light source. The resonance conditions were regulated by controlling the porosity of the absorption medium in the metal reflector, which means that when resonance occurs in the visible wavelength range, the change in porosity causes a color change³. The dynamic angle-sensitive color changes resulting from the difference
between this porosity and the effective index are experimentally confirmed by the measurement of the reflection spectrum and its spectral color at a wide angle. Additionally, the retroreflective filter can analyze using a rotational linear polarizer. When the polarizer was located in front of the light source and the image sensor, the retroreflective light was detected in four segments of the concavity. As a result, we implemented a sustainable retroreflective structural color filter that is constructed using a self-graded porous medium comprising concave structures. The iridescent color filters can be used in various visual applications such as load signals or optical devices.

Plasmonic Metasurfaces for Taste Visualization Juhyeong Lee, Doeun Kim, Gyurin Kim, Juhwon Kim, Hyun Min Kim, Jang-Hwan Han and Hyeon-Ho Jeong; Gwangju Institute of Science and Technology, Korea (the Republic of)

Discriminating taste information before food consumption is vital for mitigating health risks associated with factors such as virus infection, radioactive pollutants, and drug abuse. Plasmonic nanosensors based on refractive index sensing have emerged as a promising platform for taste molecular sensing due to their facile and modular sensing capabilities with low detection thresholds. However, a challenge for the plasmonic nanosensors lies in the lack of qualitative analysis of multiple target species.

Here, we present a breakthrough in plasmonic nanosensors that addresses the challenge of taste-sensing through a wafer-level plasmonic metasurface. This plasmonic metasurface is constructed in a scalable manner by coating metallic nanoparticles onto a metallic mirror, which are separated with a uniform solid nanogap. This design ensures an identical plasmonic cavity resonance (i.e., color) with enhanced sensitivity (> 100 nm/RIU) and uniform surface-wetting properties across the entire wafer. Leveraging this plasmonic metasurface, we introduce the concept of 'binding-free' multiple molecular sensing by simply capturing 2D projection images of molecular droplets on the single plasmonic metasurface using a conventional optical microscope. We are then able to extract two essential physical properties: the molecular refractive index and surface tension, obtained from the droplet's color and size, respectively. The combinatorial analysis of these two properties offers a scalable and intuitive means of detecting and visualizing the five basic tastes, otherwise impossible from either physical property alone. To showcase the utility of our surface-sensitive sensing platform, we successfully identify the tastes of various commercially available liquids. This breakthrough holds significant potential in establishing an end-user-friendly potable taste-sensing platform.

In this presentation, the fabrication method of the plasmonic metasurfaces will be discussed along with their theoretical and experimental optical features and sensing performance. Furthermore, we will demonstrate how to qualitatively model and mathematically analyze the colors and sizes of molecular droplets as a function of the molecular concentrations for taste visualization and discrimination.

Procedural Metamaterials: A Unified Procedural Graph for Metamaterial Design Liane Makatura1, Bohan Wang1, Yi-Lu Chen2, Bolei Deng1, Chris Wojtan2, Bernd Bickel1 and Wojciech Matusik1; 1MIT, United States; 2IST Austria, Austria

Metamaterials have been architected to achieve a wide range of incredible material properties, from optical to acoustic, mechanical and beyond. These highly-performant metamaterials generally exhibit an equally wide range of structural “architectures”, including diverse elements such as straight trusses, curved beams, thin shells, and solid bulks. Although this breadth is powerful -- as each architectural class offers a unique set of strengths -- it also complicates the process of metamaterial design, because no existing representation is well-suited for all classes. Generic representations like voxel grids can express any structure, but the specification is cumbersome and difficult to edit. Class-specific representations are often more practical, as each structure’s description is compact and editable. However, the underlying specifications are as varied as the structures themselves, and they are generally incompatible with one another. These issues make it difficult to explore over the full space of interesting metamaterial architectures, which limits the set of structures that are easily accessible to engineers.

To alleviate these challenges, we propose a unified procedural graph representation that can succinctly represent the construction process for any structure using a simple thickness-annotated skeleton. Our high-level approach is intuitive and accessible: the designer builds a skeleton that describes a small fundamental piece of the desired structure; applies a sequence of mirror or rotation operations; and then thickens this skeleton to obtain the final volumetric object. Our low-level skeleton representation preserves this powerful simplicity, by leveraging intuitive, easy-to-specify elements like lines and surfaces. Each skeletal element is constructed from a small set of simple, high-level specifications comprised of vertices and edges, a bounding volume, and the type of skeletal element (e.g. line, surface) to be instantiated. Ultimately, the spatially-varying thickness function associated with each element determines how it should be thickened into a physically realizable volume (e.g., beam, shell, or solid bulk).

Despite its simplicity, our representation is expressive enough to capture a wide range of established structures, including those based on the complex triply periodic minimal surfaces (TPMS), which have traditionally been challenging to explore. Our representation can also seamlessly combine elements from various architectural classes. Moreover, our representation is compact, intuitive, and easily-editable, such that it is amenable to manual or automated design space exploration. As such, our approach streamlines the process of metamaterial design and greatly expands our capacity for exploration. To demonstrate the expressiveness, accuracy and efficiency of our representation, we recreate a wide range of established structures with diverse architectures. We also conduct a user study to verify our representation’s intuitiveness and ease-of-use. Finally, we demonstrate the potential of our approach by showing that random searches over our representation can efficiently produce large collections of novel structures with promising material properties.

Development of Spiropyran Immobilization and Characterization Protocols for Reversible Photo-Patterning of SiO2 Surfaces Bokun Zhou and Vincent Remcho; Oregon State University, United States

Spiropyran, a type of photochromic compound, is distinguished by its reversible transformation between its colorless, hydrophobic spiropyran (SP) form and the purple, hydrophilic merocyanine (MC) form. This transformation can be triggered by UV light and reversed by either visible light or heat. Spiropyran functionalized surface, therefore, present reversible contrast in properties such as color, fluorescence, and reactivity, rendering it optimal for a range of applications in chemical sensor, biosensor, drug delivery, and heavy metal extraction.

Despite the successful application of spiropyran attachment in various substrates: non-covalently in metal organic frameworks (MOFs), poly (ethylene glycol) (PEG) lipids, polydimethylsiloxane (PDMS), and covalently in poly (methyl methacrylate) (PMMA), polystyrene microbeads, silica microbeads,
Inverse-Designed Contact Lenses for Precise Correction of Color Vision Deficiency promise for cooling heat-sensitive electronic and optoelectronic devices and serves aesthetic purposes as well. Developed through deep learning, achieves a maximum cooling power of 329.47 W/m² while offering customizable color generation. This CDRC holds applications.

Diverse severity of color vision deficiency patients, the wavelength shift (Δλ) of patient’s abnormal photoreceptors was measured to inversely design the best blocking wavelength and blocking rate of our contact lenses. The customized contact lenses were then fabricated by adding silica-coated gold nanoparticles to our contact lenses.

Here we demonstrated the new inverse-designed contact lenses based on nanoparticles for precise correction of color vision deficiency. Firstly, due to the classification and severity, none of current glasses/lenses provides customized correction for various color vision deficiency patients, resulting in undesirable correction effects. We also discussed the intrinsic limitations of immobilizing spiropyran onto a plain and rigid substrate, such as steric hindrance and effective activated surface sites, which greatly reduced the number of spiropyran immobilized. To address these challenges and expand the potential applications of our protocol, we propose several innovative directions for future research. One approach involves immobilizing spiropyran to a porous media that provides a larger surface area or finding a type of surface with more effective activated sites. Another strategy is to further modify the MC form to enhance the contrast between SP and MC forms.

In conclusion, our study highlights the potential of spiropyran in surface patterning applications and offers a comprehensive protocol for its immobilization on SiO₂ surfaces, which should also be applicable to other surfaces. These findings pave the way for the development of on-chip sensing and other applications.

SESSION EL06.07: Poster Session: Metamaterials Innovation in Photonics, Acoustics, Fluidics and Thermal Sciences

Ductile Mode Machining Process of Piezoelectric Single Crystal for the Broad-Bandwidth Ultrasonic Transducer Applications Jun Sae Han, Dong-Hyun Seo, Eun-Ji Gwak, Tae-Jin Je and Doo-Sun Choi; Korea Institute of Machinery and Materials, Korea (the Republic of)

Ductile mode machining process was investigated with piezoelectric single crystal material based on laser assisted mechanical cutting process. For the fabrication of acoustic/ultrasonic metamaterials, micro/nano patterning of functional material have been widely researched. Especially for therapeutic ultrasound transducer, focusing and enlarging of ultrasonic wave have special interest to achieve high intensity. As a promising candidates for micro/nano hybrid patterning process of function piezoelectric single crystal, ductile mode machining process was established and optimized. In this research, machinability of the relaxer based PMN-PT single crystal was investigated to achieve crack free cutting surface. Especially, effects of laser assisted cutting parameters were systematically investigated in the aspects of mechanical, chemical, crystallographic, and piezoelectric perspective. Based on the optimized process, crack-free high quality machined surface can be obtained with the roughness of 2.1 nm. Also, lens like curved structure was smoothly machined without any brittle crack defects. Fabricated structural PMN-PT single crystal was assembled as ultrasonic transducer and validated its ultrasonic transducer performance. Fabricated curved shape structure showed enhanced bandwidth properties which enable to achieve broad-bandwidth ultrasonic gas flow meter application. Based on established material processing technology, multi-scale patterning results will be presented for the advanced manipulation of ultrasonic wave.

8:00 PM EL06.07.02
Utilizing Deep Neural Networks for the Inverse Design of Multilayered Daytime Radiative Coolers with Customizable Colors Jungeun Park¹, Dongwoo Chae², Heon Lee³, Junsuk Rho⁴, Harit Keawmuang⁵, Trevon Badloe⁶ and Chihun Lee⁷; ¹Pohang University of Science and Technology, Korea (the Republic of); ²Korea University, Korea (the Republic of)

Passive daytime radiative cooling is an environmentally friendly and cost-effective cooling method achieved by reflecting solar radiation and releasing heat through the Earth's atmosphere at specific infrared wavelengths (atmospheric window; 8 - 13 μm). Traditional daytime radiative coolers are typically grey or white to reflect sunlight effectively. However, we introduce a colored daytime radiative cooler (CDRC) capable of high reflectance in the near-infrared (NIR), high emissivity in the atmospheric window, and the ability to create various colors based on Fabry- Pérot interference using metal-insulator-metal (MIM) structures. By utilizing tandem neural networks for inverse design, the structural parameters of the MIM layers are tailored. This advanced CDRC, developed through deep learning, achieves a maximum cooling power of 329.47 W/m² while offering customizable color generation. This CDRC holds promise for cooling heat-sensitive electronic and optoelectronic devices and serves aesthetic purposes as well.

8:00 PM EL06.07.03
Inverse-Designed Contact Lenses for Precise Correction of Color Vision Deficiency Ye Tian and Jianfeng Zang; Huazhong University of Science and Technology, China

Color vision deficiency affects more than 300 million people on the earth. Although no radical cure for the disorder exists now, some specialized color filtering glasses/lenses have been used on color vision deficiency management. However, as color vision deficiency patients usually diversify on their classification and severity, none of current glasses/lenses provides customized correction for various color vision deficiency patients, resulting in undesirable correction effects. Here we demonstrated the new inverse-designed contact lenses based on nanoparticles for precise correction of color vision deficiency. Firstly, due to the diverse severity of color vision deficiency patients, the wavelength shift (Δλ) of patient’s abnormal photoreceptors was measured to inversely design the best blocking wavelength and blocking rate of our contact lenses. The customized contact lenses were then fabricated by adding silica-coated gold nanoparticles to our contact lenses.
nanoparticles (Au@SiO2 nanoparticles) with appropriate sizes and concentrations to hydrogels or Polydimethylsiloxane (PDMS). Thus, contact lenses obtained by conformal optical absorption band due to the surface plasmonic resonance effect of the added Au@SiO2 nanoparticles. The effect of customized inverse-designed contact lenses was then verified by the simulated color vision and practical human tests.

In summary, inverse-designed contact lenses for color vision deficiency correction were developed and testified in this work. The proposed concept of this work may open avenues to precise color vision correction, optical metamaterials in the wearable device and medical field, thereby addressing the challenge and unmet needs for color vision deficiency management.

8:00 PM EL06.07.04
Polarimetric Study of an Embeddable, Flexible, Textile-Compatible Ferromagnetic Microfiber Platform Seokkee Min1, Joseph Plumittalio1, Petr Moroshkinia, Zheng Chen2, Richard M. Osgood3, Ihsan Uluturk3 and Jimmy Xu1; 1Brown University, United States; 2Howletech, China; 3U.S. Army DEVCOM SC, United States

In the information age, much effort and attention remain focused on the processing and transmission of information. Of equal importance is data acquisition and execution, which is made even greater with today’s big data and AI. In this work, we present an embeddable, flexible, wearable, and scalable sensing and actuation platform for monitoring, communicating physical and chemical conditionals, as well as extracting/delivering molecular substances. The platform is based on a novel ferromagnetic microfiber and can be configured into various embedded structures such as 2D arrays and 3D stacked sheets.

It offers many degrees of freedom to exploit, such as electrical, magnetic, and optical activities. The microfiber itself consists of a 30 μm diameter conductive ferromagnetic alloy (CoFeSiB) core, encased in a 10 μm thick borosilicate glass (Schott Duran) shell. This choice of materials and feature sizes allows us to exploit magnetic and electrical degrees of freedom, and strong polarization dependent electromagnetic activity that can be embedded in coating layers, fabrics and textiles and then read-out and/or activated from remote, over a broad spectral band from RF to visible to deep infrared while maintaining flexibility, chemical stability, cost effectiveness, and manufacturing lengths up to kilometers. In addition to individual fibers or their random ensembles, we can also structure them into 2-3-dimensional arrays of these fibers (e.g. photonic band-gap engineering) to exploit their collective optical activities or functionalities, which are therefore variable via their spacings, fillings, and externally applied electric and/or magnetic fields.

Applications of these tunable degrees of freedom include but are not limited to sensing, actuation, remote-tracking, and thermal property management. Some configurations would also allow for delivering payloads (e.g., drug) via inductive heating of the conductive ferromagnetic core combined with thermal expansion and the Laplace force.

As an example, we report on a polarimetric study of a 1-D array of parallel microfibers, embedded between two PET double-sided acrylic adhesive layers, that are invisible to human eyes and indiscernible by touch. A polarimetric reflectance spectra, however, can read out this array and determine its structure features (e.g. optical thickness, orientation, and effective spacing). The experiment was conducted over the 600–1750 nm spectral range with a polarized broadband (Halogen) light source. To isolate the optical activity of the fibers from their ‘concealing cover’ (PET), the normalized reflectance spectra was subtracted from a control spectra of the PET films. The resulting spectra revealed a polarization-dependent cavity effect. When the polarization was both parallel and rotated 45° clockwise from the longitudinal axis of the fibers, we observed a free spectral range of 7.14 THz (optical thickness ~21 μm).

When the polarization was both orthogonal and rotated 45° clockwise from the longitudinal axis of the fibers, we observed a free spectral range of 7.89 THz (optical thickness ~19 μm). The measured effective optical thickness of the array is consistent to the ~200 μm periodic spacing of the array. But the polarization preference off of the principal axes is curious. One contributor is the anisotropy of the PET films, resulting from a residual strain from the rolling and pressing process during manufacturing. Since the fiber spectrum was isolated from the control, the measurements also suggest an additional and likely mesoscopic physical origin (e.g. the ferromagnetic alloy grain/domain). However, the current 1D ferromagnetic array at a layer thickness of 50 μm already shows promise for a wide range of sensing and photonic management applications.

8:00 PM EL06.07.05
Anisotropic Metamaterials for Elastic Wave Mode Conversion Over a Wide Incidence Angle Range Jeseung Lee, Gihyun Kim and Yoon Young Kim; Seoul National University, Korea (the Republic of)

The constitutive relation of an elastic medium requires a fourth-order elasticity tensor, leading to multi-modal characteristics in the elastic wave regime. As a result, elastic waves in solids carry not only longitudinal (pressure) but also transverse (shear) waves. This multi-modal characteristic complicates but enriches elastic wave phenomena, the most unique of which is the mode conversion between longitudinal and transverse waves. Early studies demonstrated that full-mode conversion between longitudinal and transverse waves could be realized by using anisotropic metamaterials with the non-zero mode coupling component in the elasticity tensor. However, the previously suggested anisotropic metamaterials for the mode conversion phenomenon operate only at normal incidence or oblique incidence with a specific incidence angle. Here, we present a novel anisotropic metamaterial with a spatially dispersive anisotropic tensor that converts longitudinal waves into transverse waves with high mode conversion efficiency over a wide range of incidence angles. The proposed anisotropic metamaterial was fabricated by drilling aperiodic holes with different sizes and angles in an isotropic base material. The mode conversion performance of the proposed anisotropic metamaterial was verified using ultrasonic-guided waves in aluminum plates.

8:00 PM EL06.07.06
Development, Fabrication and Characterization of Hyperbolic Flat Lensing in the X-Band using 3D Printing and Quasi-Conformal Transformation Optics Alexandros Cooke-Politis, Andrew Rittenberg, Daniel Martin and Brian M. Wells; University of Hartford, United States

Transformation optics is a well-established technique that can be used to design many novel electromagnetic and optical devices; some include cloaking, integrated optical components, focusing devices, and antennas. The method relies on the form-invariance of Maxwell's equations under a spatial coordinate transformation. Consequently, this approach can be difficult to implement in fabrication due to the complex material properties imposed, often requiring anisotropic lossy metamaterials. In this work, we restrict the transformation to a quasi-conformal mapping, requiring only dielectric isotropic materials. This allows for flat lens designs with varying focal lengths and thicknesses to be fabricated through 3D printing, experimentally tested, and compared with FEM numerical simulations.

Various flat hyperbolic lenses with controlled thicknesses and focal lengths have been designed for fabrication and experimental characterization in the X-band microwave regime. Standard Polymaker PLA 3D-printer filament has been optically characterized, allowing the refractive index to be modeled as a function of infill percentage. Quasi-Conformal transformation optics is used to transform modeled hyperbolic canonical lenses of various focal lengths into a planar lens of controlled thickness with variable refractive index. The varying refractive index regions of the flat lens are controlled through the 3D-printed infill percentage. After FEM numerical simulations verify the desired optical properties of this transformation, the lenses are fabricated using 3D printing. Both the flat lens and hyperbolic lens are created for experimental comparison. It is verified through this process that these flat lens variants are in excellent agreement with the FEM simulations and the experimental results from their hyperbolic canonical lens counterparts.

8:00 PM EL06.07.07
High-Performance Confocal Piezoelectric Energy Harvesting using the Achromatic Elastic Lens Geon Lee1, Jeonghoon Park1, Wonjae Choi2,
In this study, we present a novel and high-performance confocal piezoelectric energy harvesting system that overcomes limitations observed in previous energy harvesting platforms. These limitations include changes in coal position with operating frequencies and impedance mismatch caused by inclusions or holes. To address these challenges, we developed a Mikaelian lens-based piezoelectric energy harvesting platform with a gradually distributed refractive index profile. This platform leverages the self-focusing ability based on conformal mapping theory and the achromatic ability based on the Kirchhoff-Love thin plate theory. The proposed platform demonstrates exceptional elastic wave focusing capabilities. Through the experimental validation, we achieved highly amplified output electrical power up to 1.44 mW within the frequency range of 40 kHz to 60 kHz, originating from confined elastic wave energy. Notably, the output electrical power extracted at the confocal position was up to 3.76 times higher than that extracted at the lens’s input position. This highlights the effectiveness of our broadband achromatic piezoelectric energy harvesting platform. The remarkable performance and broad applicability of our platform lay a solid foundation for potential applications in wireless sensing, structural health monitoring, and biomedical devices.

8:00 PM EL06.07.08
Near-Infrared Signal-Based Sensor Platform with Wireless Data Transmission System for Accurate Detection of Infectious Disease Virus Sungwon Kim, Eunyoung Jeon, Sunghyun Park and Jooneok Lee; Hanyang University, Korea (the Republic of)

Luminescent nanomaterial-based layer flow immunoassay (LFA) is widely used in on-site detection of infectious virus. Foot-and-mouth disease virus (FMDV) is a highly contagious infectious disease virus that can be spread over long distances in the air. The keys for reducing the risk of infectious disease spread and economic damage are: 1) rapid and sensitive on-site detection, and 2) real-time surveillance and remote monitoring in the field. However, on-site saliva samples from livestock are considerably opaque due to the high levels of contaminants and biological components such as food, feces, soil, and blood. These interfering agents in clinical saliva samples interfere with the detection of colorimetric signals of LFA by the naked eye. Commercial gold nanoparticle-based LFA, whose excitation and emission are located in the visible region, is limited in their low sensitivity affected by the background interference in the opaque sample. Here, we report a high sensitive detection of FMDVs in clinical samples and the wireless monitoring system of FMD's outbreak. We introduced near-infrared (NIR)-to-NIR upconversion nanoparticles (UCNPs) as a nanoprobe of the LFA platform for background-free sensitive detection of FMDV. The NIR-to-NIR UCNPs are effective in minimizing the interference noise of opaque biological samples because the interfering agents in the samples have low autofluorescence, scattering, and absorption within the NIR window. This NIR-to-NIR nanoprobe shows stable emission intensity at 800 nm without being disturbed by interfering agents under 980 nm excitation. The sensitivity of LFA assembled with NIR-to-NIR nanoprobe (denoted as NIR signal LFA) was improved in opaque clinical samples. The NIR signal LFA has 32-fold lower limit of detection (LOD) compared to a commercial gold nanoparticle-based FMDV LFA for assay using live FMDVs for all 7 serotypes. 148 clinical samples including saliva and vesicular fluid samples were used to validate the sensing performance of NIR signal LFA for FMDVs. The NIR signal LFA successfully detected FMDVs in clinical samples with a high sensitivity of 96.9%, and a specificity of 100.0%. In addition, information such as virus-detection results and infection location were successfully stored and transmitted in real-time through an online server. The developed platform is promising for establishing a quarantine linkage system that can effectively prevent and control the spread of FMDV at an early stage.

8:00 PM EL06.07.09

1.0 μm near-infrared (NIR) is considered unsuitable as an imaging and analytical signal in biological environments owing to the strong absorption of water at around the regions. However, the 1.0 μm NIR can be converted to heat and used as a local water-molecular heating strategy for photothermal therapy of biological tissues. Herein, we designed a novel Nd-sensitized 1.0 μm emissive core@shell NPs (NaYF4:50%Yb@NaYF4:40%Nd,20%Yb, denoted as water-heating NPs) as a local water-molecular heating material as a strong 1.0 μm emissive NP to target the absorption band of water. Especially, the strong energy absorption coefficient derived from the overtones and the stretching vibrations of H-O-H oscillators matches the emission spectrum of water-heating NPs. Furthermore, introducing Tm ions into the water-heating NPs enabled the NIR lifetime, and it was developed as an NIR imaging-guided water-heating probe (water-heating NIR NPs). In the glioblastoma multiforme (GBM) mouse model, tumor-targeted water-heating NIR NPs reduced the tumor volume by 78.9% in the presence of high-resolution intracranial NIR long-lifetime imaging. Hence, water-heating NIR NPs can be used as a novel nanomaterial for imaging and photothermal ablation in deep-tissue-bearing tumor therapy.

8:00 PM EL06.07.10
Enhanced Thermoelectric Properties of Bi4Sb3Te5 Through the Decoration of SnO2 Nanoparticles SungWook Ye1, Jeongmin Kim2, Sehoon Seo1, Dae-Hwang Yoo1 and JongWook Roh1; 1Kyungpook National University, Korea (the Republic of); 2Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

Thermoelectric energy harvesting has emerged as a promising solution to mitigate global climate change by enabling the conversion of waste heat into electricity. The efficiency of thermoelectric devices relies heavily on the performance of thermoelectric materials, evaluated through the thermoelectric figure of merit (ZT). ZT is defined as ZT = σS/κT, where S, σ, T, and κ represent the Seebeck coefficient, electrical conductivity, absolute temperature, and thermal conductivity, respectively. To achieve high ZT values, thermoelectric materials must exhibit high σ and S values while minimizing κ, particularly κv, and κs. However, independently controlling these parameters is challenging, making simultaneous optimization of these thermoelectric properties difficult. Numerous studies over the past few decades have focused on enhancing the power factor (σS) through nanostructuring or maximizing phonon scattering has been explored to achieve low thermal conductivity. Among various thermoelectric materials, Bi4Sb3Te5 (BST) stands out as a material capable of converting temperature differences into electricity. Consequently, BST-based alloys have been investigated to improve thermoelectric performance by incorporating other materials as nanoparticles, aiming to increase the power factor and decrease thermal conductivity. However, the trade-off relationship between electrical and thermal properties presents challenges in simultaneous control.

To overcome this trade-off, we propose a novel approach called the metallization of surface reduction nanoparticle method. This method enables independent control of electrical and thermal properties, offering enhanced stability in the interface between the base material and the surface. SnO2, a typical n-type semiconducting oxide, exhibits unconventional behavior due to disruptions in the stoichiometric ratio of tin and oxygen caused by interstitial Sn atoms or O vacancies. The reduction reaction from the surface allows the existence base material (SnO2) to form crystals without surface amorphousness, facilitating sequential arrangement (SnO2 - SnOx - Sn rich) from SnO2 (in the core) to metallic Sn (on the surface). Based on this principle, we fabricate n-type SnO2-decorated BST alloys using a combination of microwave irradiation, ball milling, and spark plasma sintering processes. These processes prevent the synthesis of SnO2 nanoparticles with other elements from BST, enabling the decoration of pure SnO2 nanoparticles onto the surface of the BST matrix (BST-SnO2). We confirm the presence of approximately 100 nm-sized SnO2 nanoparticles as a secondary phase in the BST matrix, exhibiting excellent dispersion. By decorating the surface with SnO2 nanoparticles, the average thermoelectric figure of merit
Large area highly transmissive colored coatings were fabricated by roll coating of SiO$_2$ nanoparticles on glass substrates and on the photovoltaic cell glass covers. This coating is to maintain an attractive color appearance of the exterior surface for architecturally integrated photovoltaics and can be coated on fabricated photovoltaic panels. These nanoparticles form ordered layers with thickness that can be controlled from one layer of nanoparticles to several layers. The color and optical properties of the nanoparticle coating was investigated for different SiO$_2$ nanoparticles with diameters of 200, 300, and 400 nm, which showed blue, pink, and green colors, respectively. Multilayer coatings of the nanoparticles coated on polycrystalline silicon solar cells provided blue, pink, and green colors with solar cell power loss of 5.47 %, 15.61 %, and 16.73 % for the 200, 300, and 400 nm, respectively. Single-layers act as an antireflection coating enhancing solar cell power without a noticeable change in solar cell appearance. Power gain of 3.39 % and 3.21 % is observed for single-layer of 200 and 400 nm nanoparticles, respectively.

Highly Transmissive Scalable Colored Silica Nanoparticle Coatings for Photovoltaic Panels

Xuanjie Wang$^1$ and Shankar Narayan$^2$; 1Massachusetts Institute of Technology, United States; 2Evergreen Technologies, United States

Materials with dynamically switchable optical properties can modulate their interaction with sunlight, potentially saving significant energy for heating and air-conditioning if used as building exteriors. This study proposes a new technique for solar-thermal regulation using porous polytetrafluoroethylene (PTFE) layers integrated with a spectrally-selective absorber (PTFE-SS). This multilayered structure can provide tunable optical properties by wetting or dewetting the porous PTFE with a refractive-index-matching liquid, allowing a highly reversible change in solar transmittance of 0.62. This variation allows the multilayered structure to switch between highly reflecting and absorbing states that is tunable using different PTFE thicknesses. With this multilayered structure as building exteriors, sunlight can be reflected or absorbed to reduce dependence on conventional heating and cooling systems driven by non-renewable primary energy sources. When exposed to 1 sun illumination under ideal conditions, this variation allows a 51 °C change in PTFE-SS steady temperatures. When applied to buildings as roofing materials, the PTFE-SS promises significant energy reduction with annual cooling and heating savings of around 77% and 27%, respectively. Hence, the proposed PTFE-SS structure presents a new paradigm for passive thermal management of buildings by controlling their interaction with sunlight and decreasing our dependence on fossil fuels.

Ultrafast Energy Transfer from Plasmonic Hot Carriers: Disentangling Injection Mechanisms in Pulsed Photocatalysis

Andrea Schirato\textsuperscript{1,2,3}, Stephen K. Sanders\textsuperscript{1}, Remo Proietti Zaccaria\textsuperscript{1,4}, Peter Nordlander\textsuperscript{1,5}, Giuseppe Della Valle\textsuperscript{1,5} and Alessandro Alabastri\textsuperscript{1,1}; 1Politecnico di Milano, Italy; 2Istituto Italiano di Tecnologia, Italy; 3Rice University, United States; 4Chinese Academy of Science, China; 5Consiglio Nazionale delle Ricerche, Italy

Photocatalysis involves capturing energy from light to initiate and promote chemical reactions of industrial and environmental relevance. In the process, the photocatalyst absorbs and converts photons into charge carriers, driving thermodynamically favourable and non-spontaneous reactions. Since, as for natural photosynthesis, sunlight can be used, photocatalysis represents an attractive sustainable alternative to current chemical industrial processes, which often require intensive energy input, are fed by non-renewable sources and operate at high temperatures and pressures. In this framework, increasing attention has been drawn to plasmonic photocatalytic systems, offering opportunities for light-driven reactions under substantially milder conditions. At the interface between chemistry, nanophotonics and thermodynamics, this approach relies on plasmonic nanostructures and their peculiar optical properties. These nanostructured metallic materials couple strongly to light and support resonant oscillations of their free electrons, known as Localized Surface Plasmons. Their ability to concentrate electromagnetically visible radiation, excite highly energetic (hot) carriers, and locally convert their excess energy into heat via ultrafast non-radiative relaxation processes has made them crucial in various applications. In the context of catalysis, strong interaction between light and plasmonic nano-metasurfaces (especially metasurfaces) provides the energy needed for photocatalytic conversion, and photoexcited nanoparticles can alter chemical reactions through both thermal and non-thermal pathways, close to the thermodynamic limit.

Among the mechanisms involved in photocatalysis, the hot carrier contribution is at the same time the most intriguing, as it leads to unique phenomena (e.g., changes in energy barriers for certain reactions) and the most challenging to control, mainly due to the carrier internal relaxation (which, on ultrafast timescales, brings them back to equilibrium). While promising advances have been reported on the carrier generation and ultrafast dynamics, a comprehensive theoretical description of their behaviour when interacting with nearby chemical species is missing. This is pivotal towards the accurate modelling of the energy harvesting from light to catalyse chemical transformations. Here, we propose a novol approach to model the ultrafast dynamics and ensuing effects of hot carriers across extended plasmonic nanostructures in the presence of adsorbed molecules resonantly accepting energy from the photoexcited electrons. For that, we develop a numerical platform based on a rate-equation model of the excitation/relaxation of nonequilibrium carriers, where the injection of electrons to the molecule acts as an extra decay channel. Our approach combines the well-established quantum description of inelastic electron scattering with ‘hot’ adsorbate (generating transient negative ions) with a thermodynamics-like formalism (approximating the Boltzmann equation) for nonequilibrium electrons in metals. This results in a compact model enabling us to track over time and space, with a resolution of less than 1 fs and a few nm across nanostructures/meta-atoms of hundreds of nm, the evolution of the...

Designing Chemical Reactivity in Plasmonic Nanogaps Regina Ragan; University of California, Irvine, United States

I will present data on vibrational spectroscopy alongside state-of-the-art computational methods to ‘visualize’ chemical reactions in plasmonic nanogaps in order to understand physical and chemical cues governing reactions between functional groups on molecules. An experimental platform, using electrohydrodynamic (EHD) flow, which produces flow fields in solution with components parallel to an electrode surface in the presence of a perturbation, is used to facilitate interactions between plasmonic nanoparticles (NP). Au NP from colloid are first deposited using electrophoresis to seed EHD flow on a working electrode patterned with polystyrene-block-poly(methyl methacrylate) (PS-b-PMMA) copolymer. Au NP with ligands having carboxylic acid functional groups attach to ethylenediamine functionalized PMMA domains using carbodiimide coupling chemistry. After, an AC potential with a bias of 10 Vp-p is applied resulting in EHD flow around Au NP seeds. Electron microscopy analysis of clusters chemically crosslinked during assembly shows deposition with a potential having an amplitude of 5 V and frequency of 500 Hz produces surfaces with a high density of Au NP trimers with 1 nm gap spacings controlled by crosslinking chemistry.

We have monitored crosslinking reactions between Au seeds and Au NPs deposited using EHD flow using surface-enhanced Raman scattering (SERS) in situ. An NP functionalized with either lipic acid, 4-mercaptoanilinic acid and 4-mercaptobenzoic acid ligands may form anhydride bridges using carbodiimide crosslinking chemistry and reactivity appears governed by the proximity between the reactive carbon atom in the O-acylisooxirane intermediate and the deprotonated oxygen atom from molecular dynamics simulations. Comparing experimental spectra with that simulated using density functional theory simulations indicate that chemical reactions within nanogaps are promoted by the confined geometry, i.e., entropically driven sampling of molecular conformations in nanogaps leads to reactions. Reactions do not occur in the absence of EHD flow; the long range EHD driving force allows chemical reactions with high activation energy barriers to proceed in observable time frames. The temporal evolution of an acetylene reaction between analytes and anhydride bonds in plasmonic nanogaps will also be presented. Control of nanogap spacing and surface chemistry in plasmonic hotspots has numerous applications including molecular sensors, non-linear optics, and photocatalysis.

9:30 AM EL06.08.04
3D Interconnected Nanowire Scaffolds that Increase the Thermoelectric Efficiency in Comparison to Similar Diameter 1D Nanowires Mariisol Martin-Gonzalez1, Alejandra Ruiz de Clavijo2, Nicolas Perez2, Olga Caballeri1, Kornelia Nielsch1, Francesca Peiri1 and Segi Plan2; 1Inst de Micro y Nanotecnologia, Spain; 2Ifw Dresden, Germany; 3Universidad de Barcelona, Spain

We will present how 3D interconnected nanowire scaffolds can increase the thermoelectric efficiency in comparison to similar diameter 1D nanowires and films grown under similar electrodeposition conditions. Bi2Te3 3D nanonetworks offer a reduction in thermal conductivity (κT) while preserving the high electrical conductivity of the films. The reduction in κT is modeled using the hydrodynamic heat transport equation, and it can be understood as a heat viscosity effect due to the 3D nanostructuration or to additional scattering centers. The Seebeck coefficient is twice that of nanowires and films, and up to 50% higher than in a single crystal. This increase is interpreted as a nonequilibrium effect that the geometry of the structure induces on the distribution function of the phonons, producing an enhanced phonon drag. These thermoelectric metamaterials have higher performance and are fabricated with large areas by a cost-effective method, which makes them suitable for up-scale production. Other studies have also explored the transport properties of Bi2Te3 nanowires, including low temperature magnetoresistance measurements and local magnetic suppression of topological surface states. The crystalline structure and composition of the 3D Bi2Te3 nanowire network can be finely tuned by controlling the applied voltage and the relaxation. These findings have important implications for the development of macroscopic nanostructured thermoelectric materials based on scalable fabrication processes that could be directly integrated into devices. The study of the localization and directionality of electron transport in Bi2Te3 ordered 3D nano-networks is a fascinating area of research. In this study, the resistance of an ordered 3D-Bi2Te3 nanowire nano-networks were analyzed at low temperatures, and the increase in resistance below 50 K was found to be compatible with the Anderson model for localization. The angle-dependent magnetoresistance measurements showed a unique weak anti-localization characteristic with a double feature, which could be associated with transport along two perpendicular directions dictated by the spatial arrangement of the nanowires. The coherence length obtained from the HLN model was about 700 nm across transversal nanowires, corresponding to approximately 10 nanowire junctions. The observed localization effects could be the reason for the enhancement of the Seebeck coefficient observed in the 3D-Bi2Te3 nano-network compared to individual nanowires. This research has important implications for the development of macroscopic nanostructured thermoelectric materials based on scalable fabrication processes that could be directly integrated into devices.

Acoustic Metamaterials at the Microwave Rachel Sun, Yun Kai and Carlos M. Portela; Massachusetts Institute of Technology, United States

Micro-architected materials allow for tunability of extreme static mechanical properties such as stiffness, Poisson’s ratio, or strength. However, dynamic and acoustic properties of micro-architected materials remain largely unexplored, partially because it is challenging to measure their response at these scales. Dispersion resulting from Bragg scattering occurs at wavelengths which are dictated by the characteristic dimensions of the metamaterials, while local resonance remains wavelength-independent. Therefore, micro-architected materials have the potential to allow control of mechanical waves both at high (MHz) and medium-range (kHz) frequencies.

Here, we design, fabricate, and characterize micro-architected materials with tunable mechanical and acoustic properties in the megahertz regime. Using a two-photon lithography prototyping method, we explore the response of a class of architected material morphologies with varied mass distribution, features down to ~1.5 µm, and unit cell sizes of 15 µm. We demonstrate that decoupling mass and stiffness by strategically placing micro-inertia affects the effective stiffness scaling of this class of acoustic metamaterials at the microwave. We present novel measurement techniques for wave velocity of three-dimensional architected materials that employ laser-ultrasonic principles, demonstrating a tunable range of wave velocities around 1000 m/s for different designs in a wide range of relative densities. We then validate their acoustic response numerically with Bloch wave analysis to determine their dispersion relation and rod-wave velocities. Our results provide a baseline to map the tunable acoustic metamaterial design space at the microwave and megahertz regime. These materials could have important implications in acoustic devices in microelectromechanical systems, biomedical imaging, and microwave waveguides.
Mechanical Metamaterials Enabling Knudsen-Pump-Based Propulsion for Novel Sensor-Based Mesosphere Exploration

Thomas CeLENza, Andy Eskenazi, Zhipeng Lu, Lorenzo Yao-Bate and Igor Bargatin; University of Pennsylvania, United States

We propose a novel flight mechanism powered solely by light, with no moving parts, capable of photophoretically levitating metamaterials with kilogram-scale payloads. The ability to study certain atmospheric regions, such as the mesosphere, is hindered by current propulsion methods. The urgency to address climate change makes learning about all layers of the atmosphere imperative. For example, carbon dioxide in the mesosphere is critical due to its cooling effect, a crucial factor in climate prediction models [1]. Unfortunately, recording atmospheric data in the mesosphere is challenging due to air pressures that are too low for aerodynamic plane or balloon flight and too high for satellites. Developing an airborne platform operating in a low-density, low-pressure atmosphere on Earth for gathering atmospheric data related to wind patterns, temperature, pressure variations, and gas concentrations would be tremendous. Our proposed solution leverages the mesosphere environment through architected metamaterials to generate a high-speed gas jet due to Knudsen pumping [2], allowing controllable lift.

Nanocardboard, the metamaterial that achieved photophoretic flight, was created for tuning material properties such as increased bending stiffness and strength, shape recovery capabilities, and weight reduction [3]. Nanocardboard is a microfabricated analog of sandwich composites (like cardboard), made of Al2O3. The structure consists of 0.1-micron face sheets on top and bottom, connected by several micron tall hollow rectangular channels, giving an area density of approximately 1 g/m^2. For our purposes, we coated 1-cm wide nanocardboard plates with carbon nanotubes (CNTs). Due to the Al2O3 being an exceptional thermal insulator, a temperature difference between the top and bottom of the plates is introduced, given that CNTs absorb light and heat up. This temperature difference drives air through the channels and creates a lift force due to the Knudsen-pumping effect. Optimal at mesosphere air pressures, this phenomenon is known as photophoretic levitation. However, with such small plates, the experimentally recorded lift force is only a few milligrams [4]. Photophoretic levitation is not new for macroscale objects, but increasing payloads becomes more interesting.

Hence, we created a MATLAB model to scale the photophoretic force, employing nanocardboard on a large scale, simulating 3D structures with dimensions of tens of meters. The geometries included spheres, rockets, and cones, made of nanocardboard, with CNTs on the inner walls. When illuminated, CNTs heat up to Knudsen-pump air into the hollow inner chamber and out of a nozzle to create jet velocities, increasing lift. The model considers flight altitudes from sea level to 80 km in the atmosphere. We analytically solved a heat transfer system to calculate the temperature inside the structure. When the CNTs heat up, they heat the surrounding air in the inner chamber, decreasing its density and creating a buoyancy force. This solar buoyancy regime loses significance as the photophoretic regime starts dominating around 40 km, where balloons can no longer fly. We calculate the overall lift force from a characteristic equation discovered in our previous work [5] combined with the solar buoyant force. The results show a several-kg payload for a 30-meter radius spherical structure, which is comfortably sufficient to carry atmospheric data sensors like GPS and thermocouples from sea level to 80 km. These structures present brand-new flight mechanisms in the mesosphere, enabled by the unique mechanical and thermal properties of the nanocardboard metamaterial.

Frequency Responsive Metamaterials for Contactless Acoustic Manipulation

Yun Kai, Thomas Pezeril and Carlos M. Portela; Massachusetts Institute of Technology, United States

Mechanical metamaterials, possessing custom-designed 3D structures at the nano- to microscale, exhibit exceptional properties that surpass those of their constituent materials. These structures unveil a diverse mechanical property landscape. Previous studies relied primarily on contact-based methods for mechanical characterization, such as nanoindentation, extracting static properties like stiffness and strength. These techniques often necessitate laborious sample preparation or specialized sample designs. There is a need for time-resolved characterization techniques to accelerate the process of characterizing the mechanical behavior of metamaterials and broaden our understanding of their dynamic response.

We present a characterization method for metamaterials that allows us to capture their effective dynamic elastic constants and linear dynamic response in a reliable and iterative manner. We fabricate architected materials using two-photon lithography with feature sizes on the order of ~1 µm and unit cells on the order of 10 µm. We employ a laser ultrasonic scheme to determine their effective elastic properties to excite elastic waves within the materials. We utilize a common-path interferometric setup to register the sample eigen vibrations. We experimentally reconstruct partial dispersion relations and attenuation properties of the 3D micro-architected materials, present their fully experimental dynamic elastic surfaces, and demonstrate the potential to use dynamic responses to identify defects in these materials. We validate this technique using a variety of 3D architectures along various crystallographic orientations.

The field of mechanical metamaterials is in need of novel characterization techniques since, at this point, the design of new metamaterials has significantly outpaced efforts to construct structure-property relations. Our work addresses this need and provides a route for the accelerated data-driven discovery of materials and microdevices for dynamic applications such as protective structures, medical ultrasound, or vibration isolation.

Frequency Responsive Metamaterials for Contactless Acoustic Manipulation

Sam Keller, Matthew Stein, Yujie Luo and Ognjen Ilic; University of Minnesota-Twin Cities, United States

The radiation pressure of waves—such as acoustic waves or electromagnetic waves—enables mechanisms for entirely contactless actuation of objects with relevance spanning materials assembly, bioengineering and biomedicine, and imaging and sensing. However, the ability to control such motions is substantially limited by the way conventional objects scatter waves. For instance, acoustic actuation is often restricted to small (subwavelength) objects or objects with specific symmetries where actuating energy potentials are easy to create. Additionally, this form of contactless manipulation often features single-task devices that can only produce a single dynamic response. Here, we show how such wave force limitations can be overcome by embedding subwavelength metasurface patterns to alter the acoustic momentum of inaudible ultrasonic fields locally. Consequently, these metasurfaces can facilitate precise control of local acoustic forces independent of the size or shape of the object. We present the theory, modeling, and experiments to support the development of metasurfaces exhibiting novel dynamical behaviors, such as self-guiding metasurfaces and frequency-responsive metasurfaces. We survey several families of metasurface topologies and compare their advantages and limitations for contactless actuation. Additionally, we discuss the benefits and tradeoffs associated with ultralightweight acoustic metasurfaces. Our findings present a new approach to controlling radiation pressure forces and achieving dynamic behaviors that go beyond the limitations of traditional wave-matter interactions.

Enhanced Piezoelectric Energy Harvesting Through Multiband Elastic Wave Localization using Trampoline Metamaterials

Justus C. Ndukaife, Sen Yang, Guodong Zhu and Iljun Hong; Vanderbilt University, United States

Recently, the concept of bound states in the continuum (BICs) has emerged as a promising approach to achieve sharp spectral resonances and strong electromagnetic field enhancements in plasmonic and dielectric metasurfaces. BICs represent eigenmodes that exist above the light cone but remain decoupled from the radiation continuum of free space. While true BICs are completely invisible in the radiation spectrum and inaccessible, perturbations can lead to quasi-BIC modes characterized by a sharp spectrum peak and a finite quality factor (Q). In the first part of my talk, I will discuss the utilization of quasi-BIC modes to enable optofluidic control in all-dielectric metasurfaces. By exciting BIC modes, we can significantly enhance the speed of particle transport and assembly. The high-Q nature of quasi-BICs allows for precise tuning of particle assembly by adjusting the wavelength within a narrow spectral range. This enhanced optofluiddic control enabled by quasi-BICs holds great potential for lab-on-chip applications, including analytic enrichment for sensing, on-chip mixing, and reconfigurable optically-active colloidal assembly. Moving on to the second part of my talk, I will introduce the use of plasmonic quasi-BICs for engineering thermal emission. Additionally, I will present a slotted quasi-BIC metasurface design that further enhances the quality factor of thermal quasi-BIC metasurfaces. Our numerical simulations demonstrate an ultra-narrowband emission peak with a Q factor of approximately 64 and near-absorbance overlap across a broad band spanning more than 10 μm. By symmetrically introducing air slots, the Q factor can be further increased to around 100. Importantly, our experimental measurements confirm the remarkable stability of the resonance frequency in the face of temperature fluctuations. This research showcases the potential of plasmonic quasi-BICs in the design of ultra-narrowband thermal emitters that remain insensitive to temperature changes in the mid-infrared range. Furthermore, this concept can be readily adapted to other frequency ranges, such as near-infrared, Terahertz, and Gigahertz.

2:00 PM EL06.10.02

Enhanced Piezoelectric Energy Harvesting Through Multiband Elastic Wave Localization using Trampoline Metamaterials

Geon Lee1, Jeonghoon Park1, Wonjae Cho2, Bonggyu Ji1, Miso Kim1 and Junsuk Rho1; 1Pohang University of Science and Technology, Korea (the Republic of); 2Korea Research Institute of Standards and Science, Korea (the Republic of)

In this study, we investigate the efficient piezoelectric energy harvesting at both low and high frequency bands. Traditional energy harvesting platforms were limited to a narrow or high frequency range and showed insufficient electrical performances. To address this, we propose a novel piezoelectric energy harvesting platform based on a periodically arranged trampoline metamaterial with a defect. Our platform demonstrates exceptional electrical output at both low and high frequencies. By utilizing Bragg scattering, our platform expands the bandgap in the high frequency range, while the local resonance enables a wide bandgap in the low frequency range. Through the introduction of periodically broken structures, we create defect states that facilitate the trapping of flexural wave, capitalizing on fundamental physical phenomena. Through experimental validations, we confirm the localization of flexural waves within the defect cavity, which are efficiently converted into electrical energy using piezoelectric elements. Our measurements reveal an output voltage of 1.37 V and 4.05 V, as well as an output power of 24.4 μW and 1.28 mW at the 1st and 2nd defect modes, respectively. These results represent a significant improvement of 188% and 400% compared to the bare plate configuration. The high-power energy harvesting platform we present holds promising potential as a renewable and sustainable energy source in various applications, including structural health monitoring, signal processing, and sensors.

2:15 PM EL06.10.03

Glass Materials for Emission Stabilization Under High Temperatures

Janet A. Elias1, Luis A. Diaz-Torres2, Gemma Perez-Cuellar3, Pablo Reyes-Hernandez3, Eduard Montes1 and Miguel Angel Vallejo Hernandez4; 1Universidad de Guanajuato, Mexico; 2Centro de Investigaciones en Optica, Mexico, 3Centro de Investigaciones en Optica, Mexico, 4Universidad de Guanajuato, Mexico

By melt-quenching technique, sixteen samples of lithium diborate glass doped with Er3+, Yb3+, Dy3+ and containing Ag and Cu nanoparticles were synthesized. SEM micrograph is presented. X-ray diffraction patterns of all samples reveal their amorphous structure. Physical properties such as density, molar volume and boron-boron separation of amorphous materials are shown. UV–Vis–IR absorption spectrum of all samples was recorded and display the characteristic bands of the used rare earths; all absorption bands present an enhancement with increasing metallic nanoparticles concentration. The estimated optical energy band gap of the samples was obtained using the Tauc plot method. Emission spectra of doped samples were collected in the temperature range from 30 to 180 °C. The results of emission under temperature indicates that the addition of metallic nanoparticles (Ag and Cu) in glass matrices are responsible for emission stabilization in samples when the temperature is increased creating a glass material for photonics and thermal sciences.

3:30 PM *EL06.10.04

High-Temperature Thermal Energy Transport and Conversion using Photonic Nanostructures and Metamaterials

Renkun Chen; University of California, San Diego, United States

High-temperature thermal energy transport, conversion, and management is fundamentally important for a multitude of energy processes, such as thermochemical, solar-thermal, thermophotovoltaic, thermal energy storage, and industrial heating, etc. Heat transfer physics at high temperature is also markedly different from its counterpart at room- and low- temperatures, including stronger phonon-phonon scattering leading to lower phonon thermal conductivity and the more prominent or even dominant role of radiation heat transfer. On the other hand, high temperature poses tremendous challenges on materials, especially on their thermal and chemical stability. Here we present two recent examples from our studies on photonic thermal energy transport and conversion at high temperature. First, we experimentally probed the more prominent role of surface phonon polariton (SPhP) in polar dielectric (e.g., SiO2) nanostructures and studied their contribution to thermal radiation and conduction from room to high temperature. We show that the geometry of the polar dielectric nanostructures can be manipulated to engineer the SPhP-mediated thermal radiation and conduction. In particular, we observe photon-like heat conduction contributed by SPhP in SiO2 nanoribbons. Second, we developed high-temperature selective emitters based on metamaterials. While metamaterial emitters have been widely explored, they are often not stable at high temperature due to the presence of nanoscale interfaces. We use novel material and structural designs to attain high temperature stability. These selective emitters could be used to more efficiently converting optical and electrical energy into thermal energy within a desirable spectrum that are useful for systems such as thermophotovoltaic and infrared heating.
The blackbody spectrum for room temperature peaks at mid-infrared (IR) frequencies, making this spectral range of prominent importance for both fundamental science and technology. Examples include mid-IR thermal energy harvesting and radiative cooling, spectroscopy, molecular sensing and detection, thermal camouflage, and mid-IR free-space communications. Despite the relevance of mid-IR photonics, however, phase retardation, the process of rotating light's polarization and converting linear to circularly polarized light is limited to wavelengths up to approximately ten micrometers. Beyond this wavelength, due to the lack of strongly birefringent crystals and the prominent resonances in all polar media due to lattice vibrations (phonons), there exists no commercial phase retarder. In this talk, I will discuss how, by leveraging the strong frequency dispersion of a low-dimensional van der Waals crystal, amolybdenum trioxide (a-MoO3), we built the first deeply subwavelength phase retarders at mid-IR frequencies, achieving 90 degrees polarization rotation within a micrometer of material.

Using the strong frequency dispersion due to optical phonons in crystals, I will also discuss how once can built fully pattern-free heterostructures that can achieve direction control of thermal emission and absorption at mid-IR frequencies. By considering hexagonal boron nitride (hBN) as a thermal emitter, we theoretically predict thermal emission lobes there are comparable to those achievable with conventional gratings, yet without any lithography.

Furthermore, I will discuss approaches to leverage the strong anisotropy of several low-dimensional crystals to achieve deep-subwavelength control of optical chirality, without any nanopatterning. Chirality up to 0.8 is estimated with a-MoO3 at mid-IR frequencies. I will discuss our current efforts to measure mid-IR chirality in the laboratory.

Furthermore, mid-IR-relevant low-dimensional materials, such as a-MoO3 or hBN, are typically exfoliated in the laboratory, rather than grown in large scale. Exfoliated flakes are typically too small for mid-IR far-field optical experiments, due to the size mismatch between an IR beam and a flake. This introduces a major challenge: rather than being directly measured experimentally, for example via spectroscopic ellipsometry, the dielectric function of most low-dimensional materials is approximated by numerical fitting in experiments performed in the near-field, via scanning microscopy. I will introduce a robust method for retrieving the mid-IR dielectric properties of exfoliated flakes using far-field optics.

Single crystalline pure titanium nitride (TiN) and partially oxidized titanium nitride (TiNO) thin films have been grown in a rock-salt structure using high vacuum conditions with and without intention oxygen ambience by a pulsed laser deposition (PLD) method. The films were grown under different vacuum conditions on different single-crystal substrates such as sapphire, silicon, and doped/undoped TiO2. X-ray photoelectron spectroscopy (XPS) and Rutherford Backscattering spectroscopy analysis have shown that the oxygen content of the titanium oxynitride (TiNO) films increases with film thickness (or deposition time) and also with an increase in oxygen pressure during film deposition. The lattice constant of the TiNO films, measured using XRD, is found to increase with the oxygen content in the film. The lattice constant increase is explained using enhanced electrostatic repulsion between O2- orbitals in the absence of vacant Ti3+ sites; in order to maintain charge neutrality within the lattice, one Ti4+ cation vacancy is created for every three substitutions of N2+ ions by O2- ions. Despite the oxygen content, all films show metallic behavior, with a resistivity around 70-100 mW-cm and a carrier concentration of the order of \( n_e \sim 10^{23} \) cm\(^{-3}\). Further support of this result is confirmed by (determined from) electrical transport, Hall effect and infrared spectroscopy measurements.

A spectroscopic ellipsometer was used to measure TiN/TiNO's spectroscopic optical properties and structural parameters. The reflection coefficient of TiN/TiNO films was measured within the electromagnetic range of 193 nm to 1690 nm by taking the ratio of perpendicular and parallel polarized light. The optical constants (refractive index, extinction coefficient, and film thickness) of the TiN/TiNO films were determined by analyzing the amplitude and phase difference components of the reflection coefficient where a line-shape analysis a point-by-point fit, or a parametrized function model were applied. A maximum in refractive index curves appears at a wavelength in the region of ~300 nm and a minimum at a wavelength range of 500-650 nm. The extinction coefficient plots of the films showed a minimum in the wavelength range of 300-400 nm. This result suggests that nitrogen present in the sample contributes to the additional critical point around 400 nm when compared to a pure TiO2 layer in the literature. Widening of the absorption spectrum was seen, which indicates a narrowing of the bandgap when compared to TiO2. We have observed a variation in the optical bandgap of the TiNO films as a function of film thickness. The bandgap values obtained are suitable for the absorption of solar light in the full spectrum range, which indicates that the TiNO thin films can be used for converting solar light into electrical energy.
Three-Dimensional Colloidal Nanocrystal Metamaterials CHERIE R. KAGAN; University of Pennsylvania, United States

Colloidal nanocrystals (NCs) have inorganic cores and organic or inorganic ligand shells. They are prized for their size- and shape-dependent properties and serve as building blocks of artificial materials and unconventional devices. Here, we describe NC-based, three-dimensional optical metamaterials constructed using imprinting techniques from single- and multiple-types of metal and metal oxide NCs. We focus on the chemical and thermal addressability of NCs, i.e., the ability to select, exchange, strip, or add atoms, ions, and molecules during or post-deposition, that is not accessible in bulk materials, and allows the control of metatransfer structure and properties. Through ligand engineering we tailor the dielectric function of metal NC assemblies through an insulator-to-metal transition. 1. By juxtaposing NC assemblies and bulk thin films to make bilayer heterostructures, we exploit ligand exchange to trigger folding of two- into three-dimensional structures, 2 which we use to achieve broadband 3, 4 and reconfigurable 3D chiral optical metamaterials. These structures can also be released from the surface to create and study active matter and its interface with microscale robotics. 5

8:45 AM *EL06.11.02 Nonlinear Optics via Multiple Linear Scattering Demetri Psaltis; EPFL, Switzerland

9:15 AM BREAK

9:45 AM EL06.11.03 From Electrophononics to Photophononics—Controlling Heat Flux with External Fields Claudio Cazorla1, Sebastian Bichelmaier2, Carlos Escorihuela Sayalero1, Jorge Carrete3 and Riccardo Rurali2; 1Universitat Politècnica de Catalunya, Spain; 2Technische Universität Wien, Austria; 3Institut de Ciència de Materials de Barcelona, Spain

Dynamical tuning of the thermal conductivity in crystals, k, is critical for developing novel phononic devices able to perform logic operations with phonons, as well as for solid-state refrigeration, energy harvesting, and thermoelectrics. Such a desired k control can be achieved in functional materials that experience large structural and phonon variations as a result of field-induced phase transformations. 1

Current strategies to design materials with tailored thermal properties typically rely on the creation of structural inhomogeneities that scatter phonons and reduce the thermal conductivity (e.g., lattice defects, grain boundaries and nanostructure surfaces) and the engineering of periodic heterostructures (superlattices) in which wave interference induces the appearance of phonon frequency gaps. These approaches, however, yield changes in the thermal properties of materials that are static and irreversible. The design of phononic devices 1, capable of performing logic operations with phonons similarly to what their electronic counterparts do with charge carriers, on the other hand, relies on the possibility of dynamically tuning the thermal conductivity of materials, k.

A promising dynamical k tuning approach consists in using electric or magnetic fields to manipulate the lattice of polar and magnetic materials, respectively, ideally exploiting the operation conditions need to be close to zero-bias transition points, since otherwise the required driving fields may grow unfeasibly large and the materials performances be seriously compromised owing to the presence of leakage/eddy currents and dielectric/magnetic losses. On the other hand, the possibility of manipulating k with light thus far has received very little attention. Light-driven control of the thermal conductivity could bypass some of the issues posed by the schemes described above (e.g., application of large driving fields) as well as simplify the design of logic devices (i.e., lack of electrical contacts) 8.

In this talk we will discuss our predictions, based on first-principles calculations, of each of these three effects: electro-, magneto-, and photophononic couplings as effective way to dynamically manipulate the thermal conductivity of materials with external fields.

10:00 AM *EL06.11.04 Scalable 2D Material-Based Plasmonic Phototransistors Yu-Jung Lu1,2; 1Academia Sinica, Taiwan; 2National Taiwan University, Taiwan

Monolayer transition metal dichalcogenides (TMDs) are promising materials for electronics and photonics at highly scaled lateral dimensions. However, their low photon absorption poses a challenge for high-performance optoelectronic devices. We present plasmonic phototransistors (photoFETs) that integrate monolayer molybdenum disulfide (MoS2) with plasmonic metasurfaces [1-2], such as Ag, Bi, HfN, and TiN. These plasmonic photoFETs exhibit a significant enhancement in photocurrent compared to pristine 2D photoFETs, enabling high-performance devices with ultrahigh photoresponsivity. The enhancement is achieved through plasmonic nanostructures that enhance light absorption [1-4], photo-carrier generation, photo-gating, and hot-carrier...
transfer rates. We also discuss the design of 2D material-based plasmonic photodetectors that can be extended to other 2D materials, facilitating the development of ultrathin, high-performance optoelectronic devices. Lastly, we explore the prospects for new-generation optoelectronic devices in the trans-Moore era, where traditional silicon-based electronics face limitations. The integration of monolayer 2D materials with plasmonic metasurfaces offers an avenue for enhancing optoelectronic device performance, while the design flexibility enables the utilization of various 2D materials. These advancements hold promise for developing ultrathin, high-performance optoelectronic devices for applications in telecommunications, sensing, and data processing.

Creating Superlattices for Interlayer Excitons with Metasurface Nanoelectrodes Qitong Li, Sze Cheung Lau, Tony F. Heinz and Mark L. Brongersma; Stanford University, United States

Atomically-thin transition metal dichalcogenide (TMDC) monolayers have attracted significant and broad interest in the last decade. They serve as a promising material platform for future low-dimensional electronics and optoelectronics because of their exceptional charge-carrier mobility and quantum yield, and provide a clean 2D system for fundamental physics study because of the enhanced quantum effects and correlations due to the reduction of the available states in the system. As compared with intralayer excitons in monolayers, interlayer excitons in TMDC heterostructures display longer lifetimes as their recombination rate is limited by the tunneling effect, resulting in a diffusion length of up to a few micrometers and creating an exciting playground for quantum many-body physics study.

Here, we propose that with state-of-the-art nanofabrication techniques, we can spatially control the energy level of interlayer excitons down to the nanometer scale via the DC Stack effect with the carefully designed metasurface nanoelectrodes. For instance, an electrode with patterned nano-holes (diameter ~ 30 nm) can trap interlayer excitons in quantum wells. The depth of the quantum wells can be scaled with the applied external vertical electric field up to ~ 100 meV. A superlattice can therefore be achieved with a periodically nanopatterned hole array (period ~ 50 nm), where its Hamiltonian can be described using a Bose-Hubbard model. By gradually tuning the depth of the quantum wells, a material phase transition (from insulating to conducting) is expected. What’s more, a more complicated material phase (i.e., Hamiltonian), including but not limited to defect states, quasi-crystal, as well as general quantum metasurfaces, can all be simulated by engineering the geometry of the metasurface electrodes and associated DC electric field distribution.

Electromechanically Reconfigurable Optical Vortex Array Sanghyeok Park, Dongha Kim and Min-Kyo Seo; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

An optical vortex (OV), which is a topological texture of the electromagnetic field with the intensity singularity and spiral phase rotation, has been garnering significant interest due to the supported orbital angular momentum [1]. The generation and modulation of OVs are important for applications that utilize the orbital angular momentum of light, such as multiplexing and multi-valued logic systems that aim to increase data capacity [2]. To date, active pixel arrays, including spatial light modulators or digital micromirror devices, have been typically employed to create and control a reconfigurable array of OVs [3]. However, these systems suffer from the modulation speed limited by the intrinsic response time of the materials used and the requirement to control each pixel individually. Moreover, the size of the pixel unit imposes constraints on achieving a compact OV array and increasing the number of OVs. Recently, the gradient thickness optical cavity (GTOC) has been proposed as an innovative platform for creating and controlling an array of reconfigurable OVs, capable of exhibiting quasiparticle-like behaviors [4]. The GTOC platform projects the parametrized space defined by the thicknesses of the employed dielectric spacers onto the real space through thickness gradients. The GTOC enables to spontaneously generate OVs and actively change their positions by engineering the optical thickness of the interlayer separating the dielectric spacers.

In this study, we demonstrate the creation and high-speed manipulation of a reconfigurable OV array using an electromagnetic GTOC (EM-GTOC). Employing a piezo-actor to rapidly control the thickness gradients of the dielectric spacers, the EM-GTOC can control the position and periodicity of the generated OV array with a speed exceeding tens of kHz. The EM-GTOC is a multi-layered structure that includes a glass layer combined with a piezo-actor, an air spacer, an 8-nm-thick Ni layer, a polymer layer (Norland Optical Adhesive), and an Al bottom mirror. The thickness of the air spacer between the glass and Ni layers changes with position, and the piezo-actor electromechanically controls the thickness gradient. Phase distributions measured by a holographic interferometer reveal that the period of the OV array varies depending on the voltage applied to the piezo-actor. Furthermore, the OVs can actively move in one dimension over distances of approximately 1.92 times of the period of the OV array. The high-speed piezo-actor allows the rapid reconfiguration of the OV array at the region of interest. We assessed the reconfiguration speed of the EM-GTOC employing the orbital angular momentum dependent diffraction by a fork-grating. We observed that the EM-GTOC encodes the orbital angular momentum into the reflected light at a speed of 10 kHz, equivalent to the typical speed limit of the spatial light modulator, or potentially even faster. We also demonstrated a reconfigurable OV array of which the OVs move in two-dimensional space. Another piezo-actor combined with a Ni-coated cover glass, which replaces the Ni/polymer/Al structure, provides the second OV driving axis. By applying voltage to the two piezo-actors connected to the cover glass and the slide glass, we successfully maneuvered the vortex and anti-vortex within a space of 1.33 period 2.19 period. We expect that the EM-GTOC platform, which can rapidly reconfigure an array of OVs, can find applications in orbital angular momentum-based multi-level logic networks. We also anticipate that the use of Micro-Electro-Mechanical Systems (MEMS) techniques could potentially control OV arrays at sub-GHZ speeds.

Novel and efficient renewable energy sources, solar cells or water splitting devices are hot topics within the society. The emphasis is put on the usage of solar energy, e.g. light-driven water splitting as well as its transformation into electrical energy by applying photovoltaic cells. Those devices require photoelectrode materials exhibiting wide absorption range overlapping solar spectrum, low recombination rate of photogenerated charges and photocorrosion resistance. Among different materials TiO₂ has been widely studied, in particular titania nanotubes (TiO₂ NTs) that provide unique set of geometrical and electrical properties as well as low production costs via anodization, chemical inertness and non-toxicity [1]. Though, it should be taken into account that it is a wide-bandgap semiconductor and some strategies should be undertaken to increase its absorption in visible range [2].

In this studies, we propose semi-transparent nanostructure fabricated via combined electrochemical and laser processing. In the first step the formation of flat metallic (pure Ti or Ti-Ni) layers onto the transparent conducting oxide substrate was realized via DC and RF magnetron sputtering. In order to obtain highly ordered metal oxide architecture anodization process was performed for applied voltage in the range of 30 - 60 V. SEM inspection confirmed the presence of nanotubes for both types of layers, i.e. Ti and Ti-Ni. Moreover, the outer NTs diameter increases with the anodization voltage, from 90 to 120 nm and 50 to 70 nm, for NTs formed out of Ti and Ti-Ni films, respectively. Interestingly, with the increase of the voltage value the length of NTs decreases from 1050 to 770 nm for the NTs obtained from Ti layers, while increases from 970 to 1100 nm for the ones obtained from Ti-Ni layers. The optical band-gap values estimated for pure TiO₂ NTs vary in the range of 3.11-3.25 eV for different anodization voltage which is consistent with changes in geometrical features. Meanwhile, the band-gap values decrease for oxide nanotubes prepared out of Ti-Ni films confirming the correctness of undertaken strategy. Additionally, the presence of nickel in the anodizing layer led to the appearance of highly pronounced fringes in the UV-vis spectra of oxide NTs that were not observed for pure titania material. This phenomenon can be described by surface plasmon resonance, photonic behavior of the material and constructive and destructive interference of partially reflected light [3].

After calcination ensuring phase transition to anatase, the samples underwent laser processing (355 nm wavelength, 2 Hz repletion rate, 6 ns pulse duration) with varying fluence of 20-100 mJ/cm². Such processing resulted in the partial melting of the NTs tops with preservation of the tubular scaffold. The electrochemical measurements, such as cyclic voltammetry and linear sweep voltammetry, were performed for all the laser-treated and non-treated samples. All the samples show good electrochemical stability while the material treated with 40 mJ/cm² fluence exhibits 14.5 times higher photoactivity than the non-annealed one. Overall, these findings suggest that the elaborated synthesis route can be successfully employed to form the systems exhibiting nature of the photonic crystal and plasmonic effect. Therefore, proposed material can be regarded as a promising electrode for utilization in optoelectronic devices, particularly solar cells and water photosplitting reactor.

the vast majority of sunlight as a heat source for desalination.

Heating and evaporating water is only one stage of the desalination process. Water vapor needs to be collected through condensation and latent heat recovered to make the process energy efficient. We have been developing desalination modules based on the concept of Resonant Heat Transfer (RHT), where a combination of conductive and convective heat transfer mechanisms allow the desalination process to be described as an oscillating thermal system where heat is re-utilized, thermal energy is stored, and losses are minimized [5,6]. Such an energy recovery method makes compact modules robust, performing and scalable.

We successfully demonstrated an RHT-based solar desalination module capable of delivering up to 20 L/m²/day [7], paving the way to realizing scalable and sustainable light-driven water purification systems. I will provide a perspective on the future opportunities and challenges of modular thermal desalination systems [8].

9:00 AM *EL06.15.03 Non-Linear and Non-Local Light-Matter Interaction in Quantum Materials Guru V. Naik and Ding Zhang, Rice University, United States

The optical response of quantum materials under illumination is interesting. The fine balance between many microscopic processes in quantum materials can be tipped by low-intensity light leading to a nonlinear response. Further, tipping such equilibrium also leads to an incommensuracy of the quantum order resulting in domains with different electronic properties. This coexistence of multiple quantum many-body phases or electronic inhomogeneity is fundamental to quantum materials and gives rise to a nonlocal optical response. This optical nonlocality in quantum materials captures the competition between different electronic phases and serves as a useful material parameter. Here, we present a model to describe the optical non-linearity and nonlocality in quantum materials and validate it by optical experiments carried out on a charge density wave (CDW) material, 1T-TaS2. 1T-TaS2, a quasi-2D material, supports nearly commensurate CDWs at room temperature. CDW domain walls exist in every layer of 1T-TaS2. Each CDW domain can now stack on top of the others in neighboring layers differently giving rise to a stacking order. This stacking order is sensitive to low-intensity incoherent light. Light tips the competition between center-to-corner and center-to-corner stacking types. As a result, the reflectance of TM polarized light changes with illumination intensity manifesting in an optical nonlinearity.

Apart from nonlinearity arising from the underlying competition between different orders, the optical response of quantum materials is also nonlocal. The nonlocality arises from spatial inhomogeneity. The existence of domains of different orders results in optical nonlocality. In 1T-TaS2, the CDW domains in each layer corresponding to a particular stacking type are about 50 nm wide in any layer at room temperature. This level of spatial inhomogeneity at visible frequencies would result in appreciable nonlocality. Employing a single-shot energy-momentum microscopy, we capture the non-linear and non-local optical response of 1T-TaS2 and infer the quantum order in this material. This work not only sheds light on light-matter interaction at low illumination intensities in quantum materials, but also demonstrates a quick and non-invasive technique to design, discover, and optimize quantum materials.

9:30 AM *EL06.15.04 Explorations into the Dynamics of Maxwell Lattices Nicholas Boechler; University of California, San Diego, United States

In this invited talk, I will describe our recent collaborative studies into the dynamics of a class of mechanical metamaterial referred to as Maxwell lattices. Maxwell lattices are mechanical structures on the verge of instability, and they have drawn interest due to their capacity to support topologically protected, zero-energy modes of quasi-static deformation. Within this scope, I will show new phenomena observed in Maxwell lattices including: synthetically non-Hermitian deformation fields, the time evolution of said fields; backscattering free edge wave transport; and the interplay of finite energy thresholds with topologically protected localized modes, and their implications for active, and dynamic material phase transformation.
microscopy (SEM). Using angle-resolved cathodoluminescence spectroscopy we analyse the spatial modulation of Smith-Purcell radiation that results from the coherent interplay of free-electron driven optical excitations in a chirped metagrating. We embed cylindrically-shaped metagrating patterns onto the input facet of a multi-mode optical fiber to experimentally demonstrate the coupling of free electrons and guided fiber-optic modes via the Smith-Purcell effect.

In the last part of the talk I will introduce an integrated near field/far-field multiple scattering formalism to control the absorption of light in solar cells. We design and fabricate a metallodielectric metasurface back contact for an ultra-high efficiency InGaAs/InGaAsP/Si multi-junction solar cell and enhance the light trapping inside the silicon bottom cell by multiple scattering, creating a record photovoltaic energy conversion efficiency for silicon-based tandem solar cells of 36.1%.

**Tunable and Dynamic Photonics with Tailorable Conducting Oxides and Metal Nitrides**
Alexandra Boltasseva; Purdue University, United States

Transparent Conducting Oxides (TCOs) and Transition Metal Nitrides (TMNs) are emerging material platforms for applications in tunable and nonlinear optics such as tailorable/tunable flat optics, all-optical switches and modulators, high harmonic generation as well as novel photonic time crystal concepts and beyond. We report on various approaches to both statically tailor the materials’ properties and dynamically tune the optical response at the ultrafast time scales. We demonstrate remarkable control of the epsilon-near-zero response of TCOs such as aluminum-doped zinc oxide (AZO) and yttrium doped cadmium oxide. We also investigate the strong thickness dependence of the TCOs and TMNs optical properties. Employing the Berreman modes of TiN and AZO films on the same platform, we demonstrate variable switching speeds of an optically-pumped metasurface. We also demonstrate the nonlinear capabilities of undoped ZrO for optical switching and third harmonic generation. To explore the realization of photonic time crystals, we investigate the fastest material response to an optical pump in AZO, showing sub-10 femtosecond rise time. Our approach paves the way to novel phenomena and device generation, in both passive and active metasurface designs. I will also describe active metasurfaces with both spatial and temporal phase gradients, and an active metasurface as a lens-less imaging system, and compare the characteristics to conventional lens-coupled image sensors.

**Making Waves: Acoustic and Nanophotonic Platforms for Amplification-Free Cellular and Molecular Detection**
Jennifer A. Dionne1, Mark Lawrence2, Fareeha Safir2, Jack Hu1, Varun Dolia1, Halleh Balch1, Sajjad Abdollahrmezani1 and Parivash Moradifar1; 1Stanford University, United States; 2Washington University in St. Louis, United States

Infectious diseases are one of the leading causes of death in the 21st century, claiming the lives of over 16 million individuals each year. These staggering numbers highlight the need for rapid, sensitive, and multiplexed diagnostics to minimize the spread of infectious disease and guide appropriate treatment. Existing diagnostic methods often suffer from a need for sample culturing or molecular amplification, leading to long diagnostic times or high limits of detection when amplification is not possible. Here, we combine acoustic bioprinting with nanophotonics towards 1) culture-free detection and identification of bacteria in blood, sputum, and wastewater samples using surface enhanced Raman Spectroscopy and 2) enrichment-free detection of proteins using high-Q metasurfaces. While acoustic bioprinting allows for rapid, picoliter volume sample handling for isolation of analytes of interest from clinical samples, nanophotonics enables control of light at molecular scales and optical concentration that minimizes the need for sample enrichment or amplification. First, I describe how acoustic bioprinting combined with surface enhanced Raman spectroscopy (SERS) can be used to rapidly detect and identify pathogens from complex multicellular samples. Acoustic droplet ejection allows for nozzle-free, kHz-rate printing of biological samples in ~2pL droplets while maintaining cell viability. We use our home-built 150 MHz acoustic bioprinter to rapidly digitize droplets from solutions of blood, sputum, or wastewater. When the sample is infused with plasmonic gold nanorods, SERS enhancements of up to 1500x are achieved. We train a machine learning (ML) model on droplets consisting of either pure cells or mixed, multicellular species. We achieve ≥99% classification accuracy of droplets printed from cellularity-pure samples, and ≥87% accuracy in droplets printed from cellularity-mixed samples. Our combined acoustic droplet ejection, SERS and ML platform could enable clinical and industrial translation of SERS-based cellular identification for rapid pathogen detection.

Next, I describe a high quality-factor ("high-Q") dielectric metasurface assay that, when coupled with our acoustic bioprinter for site-specific surface chemistry, allows for detection of multiple gene fragments and proteins. Our high-Q resonators produce a strong concentration of the electromagnetic field intensity within sub-wavelength-scale volumes. This platform can enable simultaneous read-out of the ~5 million independent sensor elements patterned per square cm. Unlike existing assays that rely on secondary tagging, our high-Q surfaces generate resonant scattering intensities that are proportional to minute refractive index changes from target protein load. We use hyperspectral imaging to demonstrate binding of Inf. A, Inf. B, and SARS-CoV2 gene fragments, as well as the associated IgG antibodies, with sub-femtomolar sensitivity and over 96% specificity. Together, this work provides a foundation for faster, higher-throughput, and more sensitive cellular and molecular diagnostics.

**4:50 PM CLOSING REMARKS**
Plasmons can serve as efficient generators of hot electrons and holes that can be exploited in light harvesting applications. The physical mechanism for plasmon-induced hot carrier generation is plasmon decay. Plasmons can decay either radiatively or non-radiatively with a branching ratio that can be controlled by tuning the radiance of the plasmon mode. Non-radiative plasmon decay is a quantum mechanical process in which one plasmon quantum is transferred to the conduction electrons of the nanostructure by creating an electron-hole pair, i.e., excitation of an electron below the Fermi level of the metal into a state above the Fermi level but below the vacuum level. These hot carriers interact with all charge carriers in the system and eventually transfer their energy into phonons (heat). In my talk, I will discuss the time-dependent relaxation of plasmon-induced hot carriers including electron-electron scattering, fluorescence, and electron-phonon coupling [1] and show that the hot carrier lifetimes can exceed several picoseconds. I will also discuss recent applications of plasmon-induced hot carrier generation such as plasmon-enhanced photocatalysis, and how photocatalytic efficiencies can be enhanced and quantified by placing catalytic reactors in the nearfield of a plasmonic antenna in Antenna/Reactor geometries [2-6].

The large-scale assembly of nanowires (NWs) with controlled orientation on surfaces remains one challenge toward their integration into practical devices. During the last decade, we have reported the growth of perfectly aligned, multi-meter-long, horizontal NWs of Ge, ZnO, ZnSe, ZnTe, CdSe, CdS, ZnS, CuPbBr3 and other materials, with controlled crystallographic orientations on different planes of sapphire, SiC, quartz, and spinel. The growth directions and crystallographic orientation of the NWs are controlled by their epitaxial relationship with the substrate, as well as by a graphoepitaxial effect that guides their growth along surface steps and grooves. We demonstrated the massively parallel self-integration of NWs into circuits via guided growth and the production of optoelectronic nanosystems, including photodetectors, photodiodes and photovoltaic cells. This talk will present systematic studies to map the crystallographic orientations and polarity of epitaxially guided NWs based on their nonlinear optical response under external electric fields [1]. Studies about epitaxially guided ZnO NWs on sapphire by Au-catalyzed vapor-liquid-solid (VLS) growth reveal intriguing details about their formation mechanism and the role of the substrate and the catalyst in determining the polarity and morphology of the guided NWs. Studies done with epitaxial CsPbBr3 perovskite NWs on sapphire by non-catalytic vapor-solid (VS) growth reveal an intriguing memory effect and a strong modulation of their photoluminescence under electric field [2]. These studies reveal the important interplay between epitaxy, polarity and optoelectronic behavior of guided NWs.

Short-Range Atomic Ordering and Unintentional Doping of Ge/Ge-Sn Semiconductor Alloy Core/Shell Nanowires
John Lentz1, Joe Woicik2, Matthew Bergerschnieder3, Ryan Davis4, Apurva Mehta4, Kyoungjae Cho1 and Paul McIntyre4,5; 1Stanford University, USA; 2National Institute of Standards and Technology, USA; 3The University of Texas at Dallas, USA; 4SLAC National Accelerator Laboratory, USA

Ge-Sn alloys exhibit a tunable direct gap in the mid-infrared in an all-Group IV semiconductor system compatible with Si complementary metal-oxide semiconductor (CMOS) technologies, presenting interesting possibilities for detectors and on-chip photonics. Ge-Sn films grown epitaxially around Ge nanowires result in core/shell structures with a strain-free Ge-Sn shell. In recent work, extended x-ray absorption fine structure (EXAFS) measurements detected short range order (SRO) in such structures, wherein Sn atoms are ~40% less likely to be nearest neighbors relative to a random alloy film. SRO has been shown to produce interesting physical properties in metals, but is not well-studied in semiconductors and has been predicted to substantially alter the electronic structure of Ge-Sn. EXAFS data are also consistent with a vacancy concentration in the Ge-Sn shells less than the detection limit. Vacancies produce acceptor levels in Ge and, therefore, are thought to be the origin of the high as-grown carrier concentrations in Ge-Sn films, often in the 1018 cm-3 range. By lithographically patterning metal contacts onto single nanowires and performing four-point probe measurements, we have obtained electrical resistances corresponding to much lower carrier concentrations of about 1015 cm-3. This also suggests that the Ge core/Ge-Sn shell nanowire geometry promotes atypically small vacancy incorporation, reducing the unintentional hole doping compared to conventional, planar Ge-Sn films.

Condensation-Driven Growth of Tellurene Nanosheets for Memristive Applications
Sara Ghomi1,2, Carlo Grazianetti1, Alessio Lamperti2, Christian Martella1 and Alessandro Molle2; 1Consiglio Nazionale delle Ricerche, Italy; 2Politecnico di Milano, Italy

The increasing demand for the development of memories with low operating voltage, compatible with CMOS technologies and simple structure, has recently targeted the class of two-dimensional (2D) materials [1]. Novel 2D materials such as transition metal dichalcogenides like MoS2 and MoTe2 have inspired ultra-scaled layouts of non-volatile random-access memory (RAM) devices based on a resistive switching or phase change mechanism [2,3]. In this respect, mono- or elemental 2D crystals, termed Xenes [4], may lead to a structural simplification with benefits in terms of energy consumption and performance. In this work, we report on the low temperature synthesis of tellurium nanosheets, known as tellurene, by condensation-driven vapor transport growth processing inside a chemical vapour deposition reactor towards the development of a tellurium-based memristive cell layout. First, we show that the process microscale tellurium structures like hexagonal pillars and nanotubes is scaled down to the 2D level by mastering the growth of tellurene sheet on SiO2/Si substrates with lateral coverage on the order of tens of microns with a process temperature below 100°C, namely within BEOL compatible thermal regime. On the same line, we applied the same process to (111)-terminated metal templates like Au(111) and Ag(111) epitaxial on Si substrate as metallic substrate, thus enabling the manufacturing of different tellurene nanosheets with high chemical and electronic integration on top and bottom electrodes, respectively. A resistive switch behavior of tellurene was revealed by local C-AFM probing, i.e. by applying a linearly ramped voltage and measuring the current passing from the sample to the tip. A trapped assisted space charge limited conduction (SCLC) in the tellurene nanosheets was found to be consistent with the observed I-V behavior thus paving the way to store, read, and write a non-volatile information through tellurene. As such, the configuration details of the growth are accordingly developed for tellurene to be integrated as active layer in a memristor device, and thus transferred to a memristive computing architecture.

The work has been financially supported by the European Commission under the H2020 ERC-COG grant n. 772261 “XFab”.

Low-Dimensional Neuromorphic Electronic Materials and Applications
Mark C. Hersam; Northwestern University, United States

The exponentially improving performance of digital computers has recently slowed due to the speed and power consumption issues resulting from the von Neumann bottleneck. In contrast, neuromorphic computing aims to circumvent these limitations by spatially co-locating logic and memory in a manner analogous to biological neuronal networks [1]. Beyond reducing power consumption, neuromorphic devices provide efficient architectures for image processing

recognition, machine learning, and artificial intelligence [2]. This talk will explore how low-dimensional nanoelectronic materials enable gate-tunable neuromorphic devices [3]. For example, by utilizing self-aligned, atomically thin heterojunctions, dual-gated Gaussian transistors have been realized, which show tunable anti-ambipolar for artificial neurons, competitive spiking circuits, and mixed-kernel support vector machines [4]. In addition, field-driven defect motion in polycrystalline monolayer MoS2 enables gate-tunable memristive phenomena that serve as the basis of hybrid memristor/transistor devices (i.e., ‘memtransistors’) that concurrently provide logic and data storage functions [5]. The planar geometry of memtransistors further allows multiple contacts and dual gating that mimic the behavior of biological systems such as heterosynaptic responses [6]. Moreover, control over polycrystalline grain structure enhances the tunability of potentiation and depression, which enables unsupervised continuous learning in spiking neural networks [7]. Overall, this work introduces foundational circuit elements for neuromorphic computing by utilizing the unique quantum characteristics of low-dimensional nanoelectronic materials [8].

Nanoscale Heterogeneities at Transition Metal Dichalcogenide-Au Interfaces Taisuke Ohta; Sandia National Laboratories, United States

Two-dimensional geometry renders unique screening properties in transition metal dichalcogenides (TMDs). Consequently, the electronic properties of TMDs are susceptible to extrinsic factors (e.g., substrate interactions, mechanical strains, and charge transfer), and display spatial nonuniformities as evidenced in recent reports. Thus, material combinations (i.e., TMD, dielectrics, and metals) and their nuanced interactions need to be considered when designing TMD-based devices. Of particular importance are the interfaces with metallic contacts. Uncovering the origin of heterogeneities at TMD-metal interfaces and establishing strategies to control TMD-metal interfaces could enable engineering pathways for future applications. In this presentation, we show that the electronic structures of mechanically exfoliated TMD-Au interfaces exhibit pronounced heterogeneity arising from the microstructure of the supporting metal. These electronic structure variations indicate spatially nonuniform doping levels and Schottky barrier height across the junction, which are pertinent for device applications. Through examination of the electronic structures of WS2 and WSe2 at 10s of nanometers spatial resolution via photoelectron emission microscopy (PEEM) we reveal key differences in work function and binding energies of the occupied states. Complemented with ab-initio calculation, electron backscatter diffraction, and scanning tunneling microscopy, our measurements show distinct variations in excess of 100meV due to the crystal facets of Au [namely (111), (112), and (110)]. Additionally, when multilayer WS2 and Au(111) facets are azimuthally aligned, strong interactions induce mechanical slippage of the interfacing WS2 layer, with respect to the rest of the WS2 layers, resulting in local stacking variations with an occupied state energy shift of 20-50meV. Finally, we employed oxygen plasma treatment of Au to fabricate homogenous TMD-Au interfaces while also tuning the electronic properties of the TMDs. Our findings illustrate that the electronic properties of TMDs are greatly impacted by the interface interactions at energy and length scales pertinent to the operation of TMD-based electronics and optoelectronics.

Cryogenic Nano-Imaging of Second-Order Moire Superlattices Petr Stepanov; University of Notre Dame, United States

Magic angle twisted bilayer graphene has been realized as a new platform to study strongly correlated quantum states of matter such as superconductors, correlated insulators and topological orders hosted by its native flat bands. Recent observations of anomalous Hall effect in MATBG revealed a non-zero Berry-curvature-induced orbital ferromagnetism and has been followed by extensive experimental and theoretical studies of its origin. Initial electronic transport studies demonstrated anomalous Hall effect at $v = +3$ electrons per moire unit cell in the samples aligned with the adjacent insulating hBN layer, which breaks MATBG moire inversion symmetry thus assisting in opening non-trivial insulating gaps with finite Chern numbers. Here we report on photovoltage scanning near-field imaging at cryogenic temperatures (10 K) of a MATBG device structurally aligned with hBN layer. We reveal a complex pattern of quasi-local photovoltage fringes attributed to the second-order superlattice (supermoire) potential modulated through the sample bulk. We assume that predominantly the photocurrent originates from PV generation mechanisms induced by the proximity of a hot spot formed on the metallic atomic force microscopy tip radiated by mid-infrared photons. Strikingly, we find a clear change of the PTE fringes’ real-space orientation when the sample doping changes between the valence and conductance flat bands which may signal a nematic ordered state in a highly doping-dependent low-energy spectrum of MATBG. Our observation sheds a new light on the microscopic mechanisms of the inversion symmetry breaking on a mesoscopic lengthscale.

Raman Spectroscopy on 1D Graphene Nanoribbons: From Structure to Electron-Phonon Interactions Angel Labordet Alvarez1, Mickael Perrin1,2, Klaus Müller3, Roman Fasel4, Michel Calame5, Gabriela Borin Barin1 and Mirjana Dimitrijevska1; 1Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; 2ETH Zürich, Switzerland; 3Max Planck Institute for Polymer Research, Germany; 4University of Bern, Switzerland; 5University of Bern, Switzerland;
The intercalation of graphene nanoribbons (GNRs) in ultra-high vacuum towards optimized dry-transfer into devices. Dominik Lüthi, Lin Yang, Ji Ma, Akimitsu Narita, Xinliang Feng, Pascal Ruffieux, Roman Fasel, and Gabriela Borin Barin. Empa Swiss Federal Laboratories for Materials Science and Technology, Switzerland; University of Bern, Switzerland; Technische Universität Dresden, Germany; Max Planck Institute for Polymer Research (MPIP), Germany; Okinawa Institute of Science and Technology, Japan.

Atmosically precise graphene nanoribbons (GNRs) show exciting properties deriving from electron confinement and related band gap tunability. The ability to tune GNRs’ electronic and magnetic properties at the single atom level makes them an ideal platform for a wide range of device applications, from classical transistors to spintronics. To achieve such control, atomic precision in the fabrication of the GNRs is indispensable. On-surface synthesis, based on covalent coupling of specific precursors on a metallic surface, allows access to various types of GNRs including armchair-GNRs, zig-zag-GNRs, and GNRs with specific edge-extensions. Such edge topologies can give rise to intriguing physical properties such as spin-polarized edges with a long spin lifetime and topological quantum states.

In this work, we explore GNR-intercalation to achieve their decoupling (and decreased interaction) with the underneath metal, as a viable path to allow GNRs’ dry-transfer in ultra-high-vacuum. Such method would allow better access to GNRs electronic characterization decoupled from the metal substrate as well as their direct integration into different device architectures without any air exposure, therefore preserving GNRs intrinsic properties.

Our first approach was to explore the intercalation of GNRs with barbenes (BIM) [4], as it has been shown to strongly interact with Au(111) by forming covalent bonds. The intercalation occurs due to the formation of a dense self-assembled monolayer (SAM) on the surface, causing stochastic intercalation of GNRs. We attribute a sterical argument to the intercalation, as the high excess of barbenes on the surface leads to some GNRs migrating to the top layer.

Scanning tunneling microscopy and spectroscopy characterization of intercalated GNRs will be discussed.

Another exciting approach is the intercalation to open a pathway to study the interaction of GNRs with other surfaces. A promising template in this regard is the growth of transition metal halides with tuneable electronic and magnetic properties [5]. Intercalation of GNRs with transition metal halides allows to probe their interaction with magnetic layers by scanning tunneling spectroscopy (STS), while potentially keeping the advantage of decoupling GNRs for device integration via dry-transfer.

has been reported. Here, the spin originates from unpaired electrons present in nanophosphores with controlled substrate imbalance or topological frustration. The corresponding magnetic moments live in orbitals and are hence largely delocalized, which allows for chemical control over their exchange interaction when covalently linking several molecular building blocks. Here, I will present synthesis of various prototypical magnetic nanophosphores and the possibility to covalently link them to form coupled spin systems where exchange coupling can exceed 100 meV. Using halogen-substituted precursors, we achieve the on-surface synthesis-based deterministic bottom-up fabrication of various spin chains including a triangulene spin-1 chain revealing the predicted Haldane gap and fractional excitations at the chain termini or a strictly alternating spin-½ chain with chemically engineered coupling strengths $J_1$ and $J_2$. Scanning tunneling microscopy and spectroscopy is used to determine the length- and site-dependent magnetic excitations. Furthermore, we apply hydrogenation to achieve spin site passivation and controlled tip-based local reactivation to fabricate and characterize specific spin patterns in one-dimensional spin chains and spin clusters.

Next, we show that atomically thin Cs$_3$Bi$_2$I$_9$, an all-inorganic lead-free perovskite derivative with strong optical activity can be successfully synthesized by vapor growth method. Reducing the dimensionality of such perovskites could utilize the materials advantages for solid-state information devices like valleytronics. By breaking the inversion symmetry, 2D Cs$_3$Bi$_2$I$_9$ flakes with odd-layer number exhibited persistent, optically addressable valley polarization. This study potentially opens generalizable CVD method for growing a broad range of 2D perovskites towards cost-effective and energy-efficient integrated device applications. Finally, we report a two-step vapor phase growth process for the creation of high-quality vdW heterostructures based on perovskites and TMDs, such as 2D Cs$_3$Bi$_2$I$_9$/MoSe$_2$, with a large lattice mismatch. Supported by experimental and theoretical investigations, we discover that the Cs$_3$Bi$_2$I$_9$/MoSe$_2$ vdW heterostructure possesses hybrid band alignments of type-I and type-II heterojunctions because of the existence of defect energy levels in Cs$_3$Bi$_2$I$_9$. More importantly, we demonstrate that the type-II heterojunction in the Cs$_3$Bi$_2$I$_9$/MoSe$_2$ vdW heterostructure not only shows a higher interlayer exciton density, but also exhibits a longer interlayer exciton lifetime than traditional 2D TMDCs based type-II heterostructures. Such vdW heterostructures provide promising platforms for exploring novel physics and cutting-edge optoelectronics and valleytronics applications.

Two-dimensional (2D) materials, such as Graphene, h-BN and MoS$_2$, are promising candidates in a number of advanced device applications, owing to their exceptional electrical, optical and mechanical properties. Scalable growth of high quality 2D materials is crucial for their adoption in technological applications the same way the arrival of high-quality silicon single crystals was to the semiconductor industry. While CVD growth of wafer-scale monolayer graphene and TMDs has been demonstrated, considerable challenges still remain. In this talk, we first report a CVD method to grow fluorine rich 2D polymer (2D-F) on various substrates for low-k dielectrics in 2D TMDs based devices. Using precursors with low vaporize temperature, a uniform and ultra-flat 2D-F film with controlled thickness can be deposited on silicon oxide wafer, glass, sapphire and mica substrates. Dielectric properties and relevant mechanical properties were carefully characterized. These 2D-F films were then used as the substrate for transition metal dichalcogenides (TMDs) based devices, and significant improvements in device performances were found, possibly owing to the ultra-smooth and dangling bond free surface of 2D-F that can significantly reduce the interfacial scattering of carriers.

Two-dimensional ferroelectric nanomaterials have gained increasing attention due to their promising potential in new memory device applications, such as ferroelectric field effect transistors (FeFETs) and non-volatile memory (NVM). The In$_2$Se$_3$ family represents a promising system for 2D ferroelectrics that can be deposited at temperatures compatible with back-end-of-line processing and can enable an ultra-thin body due to the 2D layer structure. However, it is a complex material system with many combinations of polymorphs (α, β, γ, and θ) and polytypes. In the current scientific literature, phase assignment and phase characterization are still controversial. The phases are determined by the stacking sequence of the quintuple layers. The α-In$_2$Se$_3$ has two polytypes (2H and 3R), and β-In$_2$Se$_3$ has three polytypes (1T, 2H, and 3R). γ-In$_2$Se$_3$ is not a 2D material, but has a distorted wurtzite structure leaving room for polarization in the tetrahedra. While existing reports suggest in-plane or out-of-plane polarization in In$_2$Se$_3$, many existing publications fail to discuss the specific phase or polytype when reporting the synthesis and ferroelectric properties. A deeper understanding of the In$_2$Se$_3$ phases and polytypes is crucial as ferroelectricity is directly coupled to the crystal structure. On the other hand, not all of the phases and polytypes are noncentrosymmetric. Detailed studies are therefore needed to explore the synthesis and structural properties of specific phases and polytypes of In$_2$Se$_3$ to unambiguously connect to their respective ferroelectric properties.

This talk presents our findings on the growth and characterization of 3R-β’-In$_2$Se$_3$ films grown on c-plane sapphire and Si(111) substrates by molecular beam epitaxy (MBE). Single phase b-In$_2$Se$_3$ films were obtained on sapphire at 600°C and on Si(111) at 350°C. High Se/In flux ratio was required to suppress the formation of other indium selenide phases. In and Se atomic fluxes were calibrated with a quartz crystal microbalance (QCM) at the film growth position. The tooling factors of the QCM flux calibration were previously determined from physical thickness measurements on calibration samples using X-ray reflectivity (XRR) and scanning electron microscopy (SEM). An infrared (IR) camera was installed to serve as an additional substrate temperature meter along with the system’s thermocouple installed behind the substrate. In-situ reflective high energy electron diffraction (RHEED) was used to monitor the structural formation of the films. Phase examination of the samples was determined by ex-situ X-ray diffraction (XRD) and Raman spectroscopy. Scanning transmission electron microscopy (STEM) carried out on the sample cross-sections revealed the films on sapphire and Si(111) to be the 3R polytype with small polytype impurities at the film/substrate interface. Furthermore, analysis of the STEM images indicated that the central Se atoms in the Se-In-Se-In-Se quintuple layer structure were slightly displaced in the in-plane direction, resulting in in-plane polarization and the phase assignment of the β phase. The results were further supported by second harmonic generation (SHG) polar plots which were consistent with the observation of in-plane Se atoms displacement. I-V measurements and piezoresistance force microscopy (PFM) are being applied to capture the hysteresis behavior of 3R-β’-In$_2$Se$_3$ grown by MBE.

The atomically thin nature of two-dimensional (2D) transition metal dichalcogenides (TMDs) makes them susceptible to the dielectric environment. Efforts on dielectrics for 2D semiconductors have been focussed on gaining better gate control using high k dielectric STO or thin HfO$_2$ [1, 2]. While SiO$_2$, HfO$_2$, and ZrO$_2$ are widely employed as dielectrics, our understanding of how they influence the electronic properties of atomically thin semiconductors remains limited [3]. In this study, we investigated interfaces between monolayer MoS$_2$ and various dielectrics (SiO$_2$, HfO$_2$, ZrO$_2$ and hBN) using photoluminescence (PL), synchrotron X-ray photoelectron spectroscopy (XPS), and electrical transport measurements. PL results show that MoS$_2$ on SiO$_2$ gives the highest exciton peak energy at 1.91 eV and MoS$_2$ on ZrO$_2$ gives the lowest at 1.89 eV. Through XPS, we find that the Mo 3d$_{5/2}$ core level binding energies are 231.05 eV, 230.60 eV, and 230.22 eV, when MoS$_2$ is in contact with SiO$_2$, HfO$_2$, and ZrO$_2$, respectively. The results indicate monolayer
MoS₂ has the highest electron doping when in contact with Si₅O₂ and the lowest when in contact with ZrO₂. Furthermore, we determined the band alignments at the interfaces between monolayer MoS₂ and the dielectric materials through angle-dependent XPS, elucidating the depth profile of elemental core-level binding energy and thus providing insights into the charge-transfer behaviour when atomically thin MoS₂ interacts with different dielectrics.

Replacing Hydrogen Sulfide with Di-tert-butyl Disulfide as an Atomic Layer Deposition Precursor for Synthesizing Transition Metal Dichalcogenides

Sulfur-containing transition metal dichalcogenides (TMDs), like molybdenum sulfide, have proven to be promising materials for electrocatalysis, energy storage, and microelectronics applications that are demanding increasingly thinner films and smaller particles over large areas. Useful films of TMDs can be prepared via the process of exfoliating layers within TMDs, which suffers from poor scalability, or through approaches like chemical vapor deposition and atomic layer deposition (ALD). ALD is capable of depositing atomically thin layers of material by using self-limiting, surface-saturating reactions that make it uniquely capable of synthesizing subnanometer-scale layers and particles over large areas with variable topography. Currently, the dominant method for preparing sulfide TMDs via ALD is to alternately expose a substrate to a metalorganic precursor and a sulfur source, which is often hydrogen sulfide (H₂S) or a plasma containing H₂S. H₂S is a corrosive, toxic, and flammable gas that is heavier than air, which makes it hazardous and expensive to store, install, and transport. Additionally, the odor of H₂S is imperceptible at life-threatening concentrations, making it even more dangerous. Alternative sulfur precursors in the solid or liquid phase would be beneficial in terms of cost and safety and would require the installation of no additional hardware for most ALD reactors. In this contribution, the widely researched ALD process using bis(tert-butylimido)bis(dimethylamino)molybdenum(IV) [(Bu₂N)₂(NMe₂)₂Mo] and H₂S plasma is compared to a novel ALD process using (Bu₂N)₂(NMe₂)₂Mo, hydrogen plasma, and di-tert-butyl disulfide (TBDS), which is an inexpensive, liquid-phase sulfur precursor. The growth behavior of both ALD processes is characterized via continuous in-situ spectroscopic ellipsometry, which reveals saturating reactions for H₂S-plasma and TBDS exposures. The composition and stoichiometry of the deposited films are determined using X-ray photoelectron spectroscopy, Rutherford backscattering, and elastic recoil detection. The crystallographic structures of the films are assessed using Raman spectroscopy and selected-area electron diffraction in conjunction with transmission electron microscopy. Molybdenum sulfide films prepared using both sulfur precursors are compared for their abilities to catalyze the hydrogen evolution reaction and for their electronic resistivities and charge carrier mobilities as determined by van der Pauw measurements. Finally, it is demonstrated that the TBDS-based ALD process is transferable to the synthesis of other TMDs like niobium sulfide.
mobility reached high values, peaking at approximately 100 cm²/Vs. Furthermore, we systematically analyzed the transport behavior of the oxygen-doped WSe₂-FET using density functional theory simulations and photoexcited charge collection spectroscopy measurements.

Charge Transport Characteristics in Non-Van Der Waals 2D Transition Metal Nitrides Synthesized via Atomic Substitution Approach Hongze Gao¹, Da Zhou², Zifan Wang¹, Lu Ping¹, Jun Cao¹, Mauricio Terrones³ and Xi Ling¹; ¹Boston University, United States; ²The Pennsylvania State University, United States

Two-dimensional (2D) materials have been extensively explored in the past decade to advance the development of nanoelectronic devices by virtue of their exciting properties emerging at the reduced dimension. Numerous 2D crystals have been synthesized and studied, including graphene, transition metal dichalcogenides (TMDs), and h-BN, which are van der Waals (vdW) layered materials with vdW gaps between two adjacent atomic layers. Such vdW gaps result in an anisotropic bonding in the crystal and hence a weak interlayer interaction, which facilitates the separation of ultra-thin layers of these crystals. However, technological gaps in vdW 2D materials (e.g., absence of high-K dielectrics), exploring the non-vdW 2D crystals plays a vital role in advancing the development of 2D electronics. In contrast to vdW crystals, the isotropic strong bonding in non-vdW crystals imposes great challenges in downsizing these materials. Targeting on this technological challenge, our group developed an atomic substitution approach to prepare ultra-thin non-vdW 2D crystals, where vdW 2D crystals (e.g., MoS₂ and WSe₂) are used as precursors and converted into non-vdW materials through a chemical reaction. Non-vdW 2D metal nitrides (MNₓ) (e.g., MoN₁ₓ and WN₁ₓ) with high crystallinity, smooth surface, and well controlled thicknesses have been successfully synthesized. Hereby, we further investigated the charge transport characteristics in these 2D MN, prepared by the atomic substitution approach. A wide range of electrical conductivities of different MN, were measured using four probe electrical measurements, and we also found high 2D carrier concentrations of the MN₄ from Hall measurements. Temperature-dependent resistance (R-T) measurements further revealed the thermal excitation and weak localization effect in the charge transport behaviors of the 2D MN₄. We comprehensively investigated the charge transport characteristics in MN₄ and demonstrated their potential applications in nanoelectronic devices.

Unusual Properties of TiO₂ Nanotube Arrays Formed Anodically in Alkanamide-Based Electrolytes Navneet Kumar, Kazi M. Alam, Damini Vrushabendrakumar, Harshitha Rajashkekar, John Garcia and Karthik Shankar; University of Alberta, Canada

The formation of highly ordered transition metal oxide nanotube arrays through electrochemical anodization of valve metals (Ti, V, Hf, Zr, Ta, Nb, etc) in fluoride-containing electrolytes is relatively well-established. Titanium dioxide nanotube arrays (TNTAs) have shown immense potential as photocatalysts, photoanodes, photodetectors and electron layer transducers for photovoltaics. In the overwhelming majority of journal and conference papers on this topic, the TNTAs are grown in ethylene glycol-based organic electrolytes (eg-TNTAs) containing water and fluoride salt. Ethylene glycol is a polar protic solvent with a dense network of hydrogen bonds resulting in a high viscosity and a moderate dielectric constant of 37. On the other hand, alkanamides whilst polar protic solvents, have a polymer-like structure due to the availability of merely two hydrogen bonding sites in a trans-configuration. Furthermore, alkanamides exhibit large values of the dielectric constant resulting in significantly higher than water e.g. formamide has εᵣ of 111 while n-methylformamide has εᵣ of 171 at room temperature. Herein, we present some unusual properties of TNTAs grown in formamide-based electrolytes (fa-TNTAs). Unlike eg-TNTAs which are self-organized into a closed honeycomb structure with a triangular lattice ordering, fa-TNTAs are non-periodic and have a more open structure with ready access to both the inner and outer nanotube walls. The fa-TNTAs absorb more visible light compared to eg-TNTAs, exhibit much lower lattice strain, differ in surface composition, possess a lower work function and demonstrate superior performance (3-fold improvement) in sunlight-driven transformation of carbon dioxide into carbon monoxide. Infrared spectroscopy indicated the dramatically different nature of adsorbates on fa-TNTAs compared to eg-TNTAs following CO₂ chemisorption. These differences in electronic properties and electronic device performance will be elaborated upon, and explained in the context of the different anodization electrolytes producing changes in morphology, composition, lattice strain and electronic band-structure.

Chemical Vapor Etching of Silicon Wafer for the Synthesis of Highly Dense and Aligned Sub-5 nm Silicon Nanowires Arrays Juyeon Seo¹, Sen Gao¹, Sanghyun Hong¹, Jinlin Li¹, Peiyun Feng¹, Ji Young Byun² and Yung Joon Jung¹; ¹Northeastern University, United States; ²Korea Institute of Science and Technology, Korea (the Republic of)

Silicon nanowires (SiNWs) have attracted great interest for applications in high-performance miniaturized devices and energy harvest and storage systems. Vapor-solid growth and metal-assisted chemical etching methods are the most commonly used approaches for synthesizing silicon nanowires. Still, using these catalyst-assisted methods, producing a large quantity of silicon nanowires with diameters below 10 nm is elusive, and the removal of catalysts is a challenge for their practical applications. Recently, we reported the synthesis of highly dense and vertically aligned sub-5 nm silicon nanowires with a high aspect ratio of over 10,000 by a catalyst-free chemical vapor etching of silicon. In this paper, we systematically investigated the effect of key chemical vapor etching parameters that govern the morphology of silicon nanowires. We achieved highly aligned nanowires arrays with sub-5 nm diameter and a length of up to 52.1 µm by controlling the oxidant gas concentration, reaction temperature, and hydrogen concentration. The results demonstrate that ppm level of oxidant gases is crucial for silicon's steady-state etching into nanowires by passivating their surface with a silicon oxide suboxide layer. Furthermore, the thermodynamic analysis combined with the experimental result suggests that anisotropic etching of silicon is also facilitated by increasing the reaction temperature and hydrogen concentration due to the increased ratio between two primary etchants (HCl/SiCl₄), suggesting an optimum range of the etchant ratio (0.131–0.216) for the nanowire formation. Our results can help us understand the chemical vapor Si etching process and guide a scalable synthesis of ultra-narrow silicon nanowires for future scientific research and practical applications.

8:00 PM EL07.03.08
Multi-Ion Sensor Based on Carbon Nanotube Fibers for Wearable Electronic Tongue Hocheed Gwang and Seon Jeong Kim; Hanyang University, Korea (the Republic of)

Wearable electronic tongue (e-tongue) sensors have garnered significant attention for their potential in enabling taste sensing in robotic systems and monitoring aberrant conditions, such as poor water quality, food spoilage (or freshness), and microbial contamination. Despite notable advancements in wearable multi-ion sensors, challenges persist in achieving stretchability and miniaturization of ion-selective sensors capable of detecting a wide range of ions for practical applications. In this study, we present a wearable multi-ion sensor based on ion-selective coiled fiber (iSCF) integrated with Carbon nanotubes (CNTs). The iSCFs were fabricated by coating CNT fibers with ion-selective membranes that include ionophores (valinomycin, sodium ionophore X, and Hydrogen ionophore I) corresponding to the target ions. In addition, the iSCF was fabricated in a coiled configuration to achieve stretchability without employing elastomers. Furthermore, they demonstrated selectivity for each target ion. Importantly, this sensitivity and selectivity were sustained even under mechanical deformations, such as a 25% strain, bending, and knotting. Furthermore, we endeavored to downscale the sensor into a single fiber (about 250 µm) by plying three types of iSCFs and an all-solid-state reference electrode. This multi-ion potentiometric sensor was successfully woven into fabrics, such as clothing or gloves, demonstrating functional sensing performance in various solutions (sea, river, distilled waters,

Final Program 1/25/24
labeled, coconut, and grape juices) as practical applications. Collectively, these findings underscore the high potential of our potentiometric sensor as a taste sensor and monitoring device within the realm of e-tongues.

An Electrostatic Force Microscopy-Based Analysis for Metallic and Semiconducting Carbon Nanotubes
Indra Mendi Khalori1, Yuki Kuwahara1, Fahmida Nasrin2, Ryota Yuge3 and Takeshi Saito4; 1National Institute Advanced Industrial Science and Technology, Japan; 2NEC Corporation, Japan

Carbon nanotubes (CNTs) have been known as a promising material for developing high-performance electronic devices. Depending on its chirality, CNTs can be semiconducting (s-type) and metallic (m-type). S-type CNTs have bandgaps, and high carrier mobility which is suitable as transistor, sensor, and logic nano-devices. On the other hand, m-type CNTs have near-ballistic conductance and high current density which is excellent as electrodes and interconnecting component in electrical circuits.[1,2] In general, as-grown CNTs are composed of the mixture of m-type and s-type. So, there is a need to quantify their m/s ratio. Optical methods, such as Raman spectroscopy and absorption spectroscopy, are widely used to characterize the m/s ratio and structure of CNTs.[3,4] It is suitable for macroscopic analysis of multiple nanotubes in the bulk sample, but it is not easy for the optical methods to evaluate the microscopic analysis of individual CNTs. The direct observation of individual CNTs is a promising approach for visualizing and characterizing an individual CNT on the area of interest. Electrostatic Force Microscopy (EFM) has been reported to determine the metallicity of CNTs individually based on the line-shape of profile.[5] Another work demonstrated the primary use of EFM to analyze the m/s fraction based on the counted number of CNTs.[6] In this work, we demonstrated the determination of the m/s ratio of CNTs through the analysis of the topographic and EFM images, expressed as value of phase shift (ΔΦ).

The sample in this work was prepared by drop-casting as-grown CNTs on the APTES-functionalized Si wafer. Then, PTFE-coated cantilever were used to obtain the topographic images and EFM images. Then, the topographic image was analyzed to obtain the selections of all CNTs. The selection lines representing CNTs are drawn based on nearest end-to-end point selection of CNTs. Next, the selected lines were transferred to the EFM images to obtain the corresponding data of ΔΦ from each of the selected CNTs. The ratio of the m-type and s-type CNTs were determined by two methods, direct contrast observation of the EFM images and the ΔΦ average calculation. Based on the value of the phase shift, the height, and length of CNTs, we obtained the ratio of m/s-type, the diameter and the length distribution of the as-grown CNTs.

By analyzing three data sets of topographic and EFM images, the developed EFM-based analysis showed the fraction of s-type CNTs in the as-grown sample around 67% ± 1%. The threshold of the sampling is determined to be around 600 units (line selection) to obtain 1% deviation. This result agrees to theoretical ratio of m/s-type CNTs for as-grown samples. In addition, m-type and s-type CNTs showed asymmetric length distributions with mean length of 396.36 ± 10.93 nm and 232.85 ± 4.99 nm, respectively.

Further analysis and more experimental would be conducted to address characterization of CNTs’ bundling, the non-straight CNTs analysis, and a simple quantification with precision down to 0.1% change of composition in the mixture of CNTs.

Performance Improvement of Thread Transistor using Carbon Nanotube Composite Thread with Ionic Gel
Hiroki Kodaira and Takahide Oya; Yokohama National University, Japan

We propose a unique transistor based on carbon nanotube (CNT) composite threads with ionic gel. It is known that the CNTs have many excellent properties such as highly electrical conductivity, highly chemical stability, electrical properties that can be metallic or semiconducting depending on their structure. Because of these properties, CNTs are expected to have a wide variety of applications. However, since the CNTs exist on a nanoscale, it is difficult to handle them on their own. For this reason, many approaches such as combining with other materials have been proposed. We have succeeded in developing “CNT composite threads” (CNTCTs), which combines CNTs with threads, a familiar material of our daily life. This material had good properties based on CNTs. In addition, we have also succeeded in producing metallic CNTCTs with a metallic property and semiconducting CNTCTs with a semiconducting property. Furthermore, by combining these, we succeeded in developing the “thread transistor” in our previous work. However, several problems have remained, including low performance.

In this study, we are aiming to develop ionic-gated thread transistors using CNTCTs. Recently, ionic-gated transistors attracted attention because of its large capacitance and low operating voltage. Ionic liquids are suitable for gate dielectrics, but liquid state is not suitable for practical devices. Therefore, ionic gels are used as dielectrics, which is produced by combining ionic liquids and polymers. Because ionic gels have high mechanical ruggedness, we considered flexible transistors can be fabricated by combining them with CNTCTs.

The production method of our CNTCTs is based on the traditional dyeing method for threads. It is suitable for macroscopic analysis of multiple nanotubes in the bulk sample, but it is not easy for the optical methods to evaluate the microscopic analysis of individual CNTs. The direct observation of individual CNTs is a promising approach for visualizing and characterizing an individual CNT on the area of interest. Electrostatic Force Microscopy (EFM) has been reported to determine the metallicity of CNTs individually based on the line-shape of profile.[5] Further work demonstrated the primary use of EFM to analyze the m/s fraction based on the counted number of CNTs.[6] In this work, we demonstrated the determination of the m/s ratio of CNTs through the analysis of the topographic and EFM images, expressed as value of phase shift (ΔΦ).

As results of measurements, the current-voltage characteristics of the thread transistor were p-type, and gate voltage dependency was improved compared to previous studies. Although the problem of high off-state current due to impurities in the CNTCTs still remains, we believe this approach is effective for performance improvement of our thread transistors.

By further developing this approach, we believe that our CNT composite thread will be used as a transistor in the near future.

Development of "Transpiration-Type Thermoelectric Power Generating Paper" using Carbon-Nanotube-Composite Papers Without Need for Heat Source
Yudai Kanesaka1, Koya Arai1 and Takahide Oya2; 1Yokohama National University, Japan; 2Mitsubishi Materials Corporation, Japan

Indra Mendi Khalori1, Yuki Kuwahara1, Fahmida Nasrin2, Ryota Yuge3 and Takeshi Saito4; 1National Institute Advanced Industrial Science and Technology, Japan; 2NEC Corporation, Japan

It is known that the CNTs have many excellent properties such as highly electrical conductivity, highly chemical stability, electrical properties that can be metallic or semiconducting depending on their structure. Because of these properties, CNTs are expected to have a wide variety of applications. However, since the CNTs exist on a nanoscale, it is difficult to handle them on their own. For this reason, many approaches such as combining with other materials have been proposed. We have succeeded in developing “CNT composite threads” (CNTCTs), which combines CNTs with threads, a familiar material of our daily life. This material had good properties based on CNTs. In addition, we have also succeeded in producing metallic CNTCTs with a metallic property and semiconducting CNTCTs with a semiconducting property. Furthermore, by combining these, we succeeded in developing the “thread transistor” in our previous work. However, several problems have remained, including low performance.

In this study, we are aiming to develop ionic-gated thread transistors using CNTCTs. Recently, ionic-gated transistors attracted attention because of its large capacitance and low operating voltage. Ionic liquids are suitable for gate dielectrics, but liquid state is not suitable for practical devices. Therefore, ionic gels are used as dielectrics, which is produced by combining ionic liquids and polymers. Because ionic gels have high mechanical ruggedness, we considered flexible transistors can be fabricated by combining them with CNTCTs.

The production method of our CNTCTs is based on the traditional dyeing method for threads. It is so simple method of dipping a thread in the CNT dispersion and drying in oven. Here we chose (6,5)-chirality CNT as the semiconducting CNT and multiwalled CNT (NC7000) as the metallic CNT. The method of preparing CNT dispersions was a typical one. Ionic gels are prepared by combing ionic liquids (EMI-TFSI), polymers (PVDF-HFP), and solvents (acetone). The solution is agitated until homogeneous. By combining the semiconducting CNTCT as a channel and the metallic CNTCT as a gate electrode, the thread transistor can be easily constructed. Here, a drop of the ionic gel is inserted between both CNTCTs to construct our ionic-gated thread transistor.

As results of measurements, the current-voltage characteristics of the thread transistor were p-type, and gate voltage dependency was improved compared to previous studies. Although the problem of high off-state current due to impurities in the CNTCTs still remains, we believe this approach is effective for performance improvement of our thread transistors.

By further developing this approach, we believe that our CNT composite thread will be used as a transistor in the near future.
We propose a unique thermoelectric power generating device using carbon nanotube (CNT) composite paper, “transpiration-type thermoelectric power generating paper.”

In recent years, thermoelectric power generation has been attracting attention because of its ability to effectively utilize heat that tends to be disposed of. However, the problem is that many of the thermoelectric materials currently in use are rare metals. Therefore, we focused on CNT, which has been shown to have high electrical conductivity and a high Seebeck coefficient. However, CNT is difficult to handle because they exist in powder form. For this, we have solved by developing CNT composite paper by combining paper and CNT. In this study, we are developing thermoelectric power generating devices based on the CNT composite papers.

Conventional thermoelectric power generating devices require a heat source to generate electricity. This research focuses on the capillary phenomenon of paper and aims to develop a new type of thermoelectric power generating paper that does not require a heat source and generates a temperature difference using the heat of vaporization when liquid evaporates from the CNT composite paper containing liquid.

The CNT composite paper is made using the modified Japanese washi paper making process. Specifically, a CNT dispersion consisting of single-walled CNT and SDS (sodium dodecyl sulfate) as dispersant dispersed ultrasonically in pure water is mixed with a pulp dispersion consisting of pulp, the raw material of paper, dispersed in pure water. Next, the water is removed from this mixed dispersion with a fine mesh. Finally, it is dried and molded to complete the process.

To conduct thermoelectric power generation without a heat source, one end of this transpiration-type thermoelectric power generating paper is dipped in pure water filled in a container, and the other end is fixed from the top. At the top, the temperature is lower than at the bottom, which is immersed in water, due to the heat of vaporization caused by the evaporation of water lifted by capillary action. The difference in temperature causes the Seebeck effect. In the fabricated paper, a temperature difference of 0.9K was spontaneously generated, resulting in an electromotive force of 22μV.

As the next step in this research, we aim to further improve the output by changing the amount of material and the structure of the paper. Since our transpiration-type thermoelectric power generating paper obtained in this study does not require a heat source, we believe that it can be used as an environmental power generator in rivers and oceans in the near future.

CNFs/CNT-Prussian Blue/Chitosan Modified Thread Electrode for Non-Invasive Sensor of Glucose and Lactate

Naditnan Promphret1, Chusak Thanawattano2, Chatthai Buekban3, Thidarat Laochai1, Praneet Rattanawaleedroj1, Krisana Siralertmukk1, Pranut Potiyaraj5, Juan Hinestroza6 and Nadmutt Rodhongkum1; 1Chulalongkorn University, Thailand; 2National Science and Technology Development Agency, Thailand; 3Cornell University, United States

Non-invasive diagnosis is an alternative approach to monitor health status without the patient painfulness. Among the flexible substrate materials, thread textile has become a promising substrate format for non-invasive wearable sensor fabrication owing to its small size, high flexibility, non-skin irritation, low-cost, and easy-to-use as an auto-microfluidic device. Herein, thread based non-invasive electrochemical sensor for sweat glucose and lactate was engineered. The cotton thread surfaces were modified by cellulose nanofibers (CNFs)/carbon nanotube (CNT) ink-Prussian blue/chitosan to enhance liquid adsorption, increase bioreceptor immobilization and improve sensor performance. The CNFs/CNT-prussian blue/chitosan modified cotton thread was characterized by laser scanning confocal microscopy, scanning electron microscopy, and fourier transform raman spectroscopy. Amperometric measurements using a hydrogen peroxide (H2O2) were applied for electrochemical characterization of the modified thread electrodes. A portable potentiostat was designed as a wristwatch and integrated with the modified thread electrode to provide a real-time detection of glucose and lactate. This sensor provides a linear range of 0.1–3 mM with the detection limit of 0.1 mM for glucose and a linear range of 1–35 mM with the detection limit of 1 mM for lactate which can distinguish the cut-off level of both glucose (0.3 mM) and lactate (25 mM) between the normal and high-risk people.

Enhancing Learning Accuracy with Floating-Gate Memristors in a Multi-Terminal Spiking Neurosynaptic Network

Hosung Choi and Woojong Yu, Sungkyunkwan University, Korea (the Republic of)

Spiking neural networks (SNNs) are regarded as a more natural representation of artificial neural networks, distinguishing them from other types of networks. While several studies have been conducted to model SNNs, incorporating multiple connections between neurons has proven challenging due to the limited number of terminals in memristors. In this research, we propose a novel spiking neurosynaptic network that utilizes a multi-terminal floating-gate memristor.

Our memristor, named TRAM (Tunneling Random Access Memory), leverages the change in the Fermi energy level (Ef) of graphene, exhibiting desirable memory characteristics such as a high on/off ratio (>10^5), excellent retention (>10,000 times), strong endurance (>100,000 times), and low energy consumption (120pJ). To emulate synapses and neurons, we adjusted the thickness of the insulating film layer (Al2O3). A thin layer (3nm) was used for neurons to demonstrate the Leaky Integrate-and-Fire (LIF) characteristic, while a thicker layer (7.5nm) was employed for synapses to exhibit Spike-timing-dependent Plasticity (STDP).

When voltage inputs are applied to multiple synapses, all inputs are transmitted to the neurons. If the cumulative input from the synapses fails to surpass the threshold voltage of a neuron, the neuron slowly discharges its voltage in accordance with its leaky properties. However, if the threshold voltage is exceeded, the neuron fires and generates an output signal to update the weight (conductance) of the synapse. The threshold and feedback voltage of the neuron are created using a comparator.

Through our multi-terminal spiking neurosynaptic network, we achieved a high learning accuracy of up to 83.08% on the unlabeled MNIST handwritten dataset.

Tuning of Ultrastart Carrier Dynamics in 2D GeS and GeSe by Cu Intercalation

Sepideh Khanmohammadi1, Kateryna Kushnir1, Catherine Tran2, Kristie Koski2 and Lyubov V. Titova1; 1Worcester Polytechnic Institute, United States; 2University of California, Davis, United States

Germanium sulfide (GeS) and germanium selenide (GeSe) are 2D layered van der Waals semiconductors. These semiconductors have high carrier mobilities and moderate band gaps in the near-infrared (1.55-1.65 eV for GeS and 1.1 eV for GeSe, in the bulk)4. Previously, we demonstrated that photoexcitation with either above or below the bandgap energy results in long-lived transient conductivity. Plus, photoexcitation above the bandgap results in emission of THz pulses in both materials due to shift current generation5. We found that 800 nm (1.55 eV) excitation results in longer-lived free photoexcitons, lasting for hundreds of picoseconds to several nanoseconds. While it was in the order of hundreds of picoseconds for 400nm (3.1 eV) excitation6. Here, we focus on photoexcited carrier lifetimes by intercalation of zero-valent Cu into the van der Waals gaps of GeS or GeSe nanoribbons. We find that intercalation of copper drastically decreases carrier lifetime and introduces a much faster decay time. This behavior can be observed in both GeS and GeSe which can be promising for engineering optical properties of these materials for high-speed optoelectronic devices.

We propose paper transistors using CNT composite papers. It is known that CNTs have many properties such as high electrical conductivity, light weight, high strength, and flexibility. Because of these properties, CNTs are expected to be applied in various fields. However, since CNTs exist in nanoscale and powder form, it is necessary to devise ways to apply them to devices. Therefore, we focus on paper, which is inexpensive, easy to process, and a familiar material. By combining CNTs and paper, we are applying CNTs to devices as the CNT composite paper, which has the properties of both CNTs and paper. The method of making our CNT composite paper is described below. Our CNT composite paper is produced by using modified Japanese washi papermaking method. Specifically, CNT and Sodium Dodecyl Sulfate (SDS) are dispersed in pure water by ultrasonication to prepare CNT dispersion. Next, the pulp is placed in pure water and stirred to prepare pulp dispersion. The CNT dispersion and pulp dispersion are mixed, and then dehydrated on a fine mesh. After dehydration, the paper is formed in a heat press to complete the paper. By selecting metallic or semiconducting type CNTs when making the paper, it is possible to make the composite paper with each characteristic. Next, the paper transistor fabrication method is described below.

Paper transistors can be made by cutting each part to the size used, moistening it with pure water, and then heat pressing it so that the paper fibers intertwine and adhere to each other.

Since CNTs exhibit p-type semiconducting characteristics in air, it is known that fabricated paper transistors exhibit p-type characteristics. Therefore, p-type doping for CNTs should be used to prepare n-type semiconducting CNTs. By using the n-type doping to our paper transistors, they should show a n-type property. In previous research, our composite paper was dipped in a n-type doping solution and dried in an oven, was used. However, it failed to develop a desired n-type transistor because the dependence of the gate voltage could not be confirmed even after doping. One possible cause was that soaking the paper in the solution led to degradation of the paper fibers and the CNT network. Therefore, we adopted a new doping method, vapor deposition, to develop a desired n-type transistor. In this method, we do not immerse the paper in the solution, but instead uses the doping solution as a vapor to attach the dopant to the CNT composite paper. As a result of this deposition method, we obtained an on/off ratio of 1.82 with the deposition method compared to 1.51 with the previous deposition method at a drain voltage of 2 V, confirming a significant performance improvement. We were also able to confirm the gate voltage dependence and succeeded in developing a paper transistor with desired n-type characteristics, which could not be obtained in previous studies.

In the future, we will aim to realize paper logic circuits by combining p-type and n-type paper transistors. If this technology is realized, it will be possible to make every paper product have information processing functions, we believe.
We present an ultralow-power, highly sensitive, and miniaturized X-ray sensor with micropatterned single-walled carbon nanotube (SWCNT) interdigitated networks inspired by the Geiger-Mueller counter design. Due to the unique nanostructured surface and superb electronic transport nature of assembled SWCNTs, a strong electric field is formed between and within highly organized SWCNT interdigitated electrodes, which effectively separates electrons and ionized ions created by incident X-rays into electrodes, facilitating electron detection. As a result, the device can detect a low X-ray dose rate (9.97 μGy s⁻¹) with an extremely low power consumption of 80–90 fW, demonstrating a sensitivity of up to 203.96 μC Gy⁻¹ cm⁻². Furthermore, the interdigitated SWCNT electrode design produces a low noise level in the picoampere range, permitting exceptional real-time signal detection during X-ray exposure. These unique features of our SWCNT X-ray sensing device enable various low SwaP (size, weight, and power) radiation detectors in the fields of medicine, homeland security, and defense.

Quantitative Comparison of Conductivity and Piezoresistance in Networks of Graphene Nanosheets with Different Aspect Ratios
Jose Munuera, Luke Doolan, Kevin Synnatschke, Cian Gabbett, Oran Cassidy, Tian Carey, Joseph Neilson, Adam G. Kelly and Jonathan N. Coleman; Trinity College Dublin, Ireland

Solution processed 2D nanosheet networks have found applications in printed transistors, batteries, photodetectors, catalysts and strain sensors. These networks are assembled from nanosheets in a liquid phase through a range of deposition techniques, yielding notably different structures. In this work, we prepared graphene inks by liquid phase (LPE) and electrochemical (EE) exfoliation with very different nanosheet aspect ratios (~30 vs ~1000) and processed them into networks via spray coating and liquid-liquid interfacial assembly techniques. Top-down SEM and FIB SEM 3D imaging of the networks show clear differences in morphologies due to both nanosheet aspect ratio and deposition technique. Small, rigid LPE nanosheets form highly porous networks with point-like junctions, displaying different degrees of alignment depending on the deposition technique, while large, flexible EE nanosheets yield compact networks with large conformal junctions for every deposition technique. The electrical conductivities of these networks show a similar dependence on morphology, with a tenfold increase (~10⁴ to ~10⁵ S/m) for spray-coated LPE and EE nanosheets. Piezoresistance measurements show a strong dependence on the network morphology on gauge factor, as predicted by the percolation based model developed in previous work. Gauge factors of nanosheet networks were found to range between 0.4 and 350 depending on the network structure. This study casts light on the key tuning parameters to modify the network structure of nanosheet networks and the effect different structures have on the conductivity and piezoresistive response of the networks. Understanding these key electronic properties will pave pathways towards device applications using 2D materials, including strain sensors and printed flexible electronics.

Optical Blocking Layer and Field-Induced Junction on Silicon Nanowire Multispectral Photodetectors Toward High Quantum Efficiency
Deokjae Choi, Junseok Lee and Kwanyong Seo; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Crystalline silicon nanowires (c-SiNWs) have unique optical characteristics that enable tuning of their spectral response depending on their diameter. However, real-world applications of c-SiNWs multispectral photodetectors are still hampered by their low selectivity and low quantum efficiency (< 30%). The primary obstacles include the broad-spectrum light absorption of the bottom crystalline silicon (c-Si) substrate underneath the c-SiNWs. In addition, it is difficult to form appropriate p-n junctions on c-SiNWs and it leads to severe recombination which makes low external quantum efficiency (EQE). In this study, a thin metal film was applied as an optical blocking layer to block light absorption in the bottom c-Si substrate, and atomic layer deposition (ALD)-based AlOₓ was employed to form a dopant-free p-n junction on diameter-controlled c-SiNWs. Consequently, the maximum EQE of the fabricated photodetector was 77.4% at 620 nm with remarkable wavelength selectivity. This work removes major stumbling blocks for the use of c-SiNW as selective light bandpass photodetectors.

SAW-Induced Spin Wave Excitation in Ferromagnetic Epitaxial Thin Films
Alfons G. Schuck, Sebastian Kölsch, Swarnasree Banik and Michael Huth; Institute of Physics, Goethe-University, Germany

Surface acoustic wave (SAW) excitation of spin waves in ferromagnetic thin films has recently gained significance due to the potential for the realization of novel microwave devices and applications in magnonics. So far, SAW excitation has commonly been accomplished by use of piezoelectric substrate materials, such as LiNbO₃, on top of which the ferromagnetic thin film is deposited. This approach has severe limitations with regard to studying SAW-spin wave coupling effects in epitaxial magnetic thin films. For epitaxy to occur, selected substrate materials and crystal orientations have to be used; and these substrate materials tend not to be piezoelectric. Here we show how textured piezoelectric AlN thin film transducer structures can be fabricated on different substrate materials by means of reactive RF sputtering. By proper selection of the material for the interdigital transducer electrode structures and standard UV lithography, the frequency range up to about 3 GHz becomes available for spin wave excitation. Selected examples of SAW-induced spin wave excitation in epitaxial magnetic thin films are presented and compared to results obtained on Nickel thin films as commonly used reference material.

Demonstration of Controlled Doping and Complementary Inverter Operation in Transition Metal Dichalcogenide Transistors using Self-Assembled Monolayers
Dong Hyun Lee, Youngmin Han and Hocheon Yoo; Gachon University, Korea (the Republic of)

Transition metal dichalcogenides (TMDs) are attracting attention as next-generation semiconductor materials due to their theoretically high carrier mobility and excellent optical properties [1-3]. In addition, the TMDs are extensively researched as an alternative that can overcome the limitations of integration in conventional silicon-based electronic devices. However, a method for controlling the electrical properties of TMD-based electronic devices...
Development of Graphene Oxide with a Single Oxygen Functional Group and Applications for the Gas Barrier Membrane

Tatsuki Tsugawa, Kazuto Hatakeyama, Michio Koimuma and Shintaro Ida; Kumamoto University, Japan

Graphene oxide (GO) has a variety of functional groups on the surface, making it highly dispersible in various solvents such as water and N,N-dimethylformamide. This makes it possible to easily fabricate laminated membrane on the substrates of various shapes by using GO dispersion solution. Furthermore, GO has excellent potential for gas barrier applications due to high aspect ratio and flexibility. Therefore, GO has been investigated as gas separation membranes that can achieve both high flow rate and high selectivity, but in general, the many defects (nanopores) located in the nanosheet cause reduction in gas barrier performance. As a result, the electron mobility and on/off ratio of n-type MoTe2 transitor doped with PCFETES has increased by 4.6 times and 79 times, respectively. On the other hand, MoTe2 doped with PCFETES present p-type behavior had increased 18.4 times of the hole mobility and 159 times of on/off ratio. Finally, we demonstrated a complementary inverter using SAM-doped n-type and p-type MoTe2 transistors, presenting a clearer full-swing operation compared to before SAM doping.

Advancements in Precise Atom Manipulation for Tailored One-Dimensional Molecular Arrays: Synthesis, Characterization and DFT calculations
Orlando J. Silveira1, Kewei Sun2, Lauri Kurki1, Jose Lado1, Ondrej Krejci1, Keisuke Sugasaka3, Shohei Saito4, Shigehiro Yamaguchi3, Oscar Custance2, Takashi Kubo5, Tomohiko Nishia1, Takuya Kodama1, Yuan Zhangyu2, Adam Foster1,6 and Shigeki Kawar1; 1Aalto University, Finland; 2University of Tsukuba, Japan; 3Kyoto University, Japan; 4Nagoya University, Japan; 5Osaka University, Japan; 6Kanazawa University, Japan

The synthesis of one-dimensional molecular arrays with tailored stereoisomers presents a challenging yet highly promising avenue for molecular opto-, electronic-, and magnetic-devices, where the local array structure critically influences functional properties. This research showcases significant advancements in the synthesis and characterization of one-dimensional materials through precise atom manipulation. Utilising scanning tunnelling microscopy (STM) and spectroscopy (STS) with functionalized tips, coupled with density functional theory (DFT) calculations, we comprehensively characterised the materials. Firstly, we show that the magnetic states of a Boron substituted graphene nano ribbon (GNR) on an AuSi4 intercalation layer are suppressed by Si atoms adsorbed into the substituted areas, but can be recovered and controlled by tip-induced removal of the embedded Si atoms, as a clear Kondo resonance peak appears [1]. The successful control of such spin polarised states in an extended π carbon system holds great potential for spintronics application. Next, we describe the sequential tip-induced removal of bromine atoms on a linear array of 3D moieties with C-Br bonds protruding from the molecular plane [2]. Subsequently, an open-shell singlet diradical is observed, which undergoes an inelastic spin transition of 91 meV to a triplet state. Furthermore, we show the synthesis and characterization of one-and two-dimensional covalent orbital frameworks whose backbones contain 1,4-disilabenzenes [3]. Substituting carbon with silicon in organic molecules and materials has long been an attractive way to modify their electronic structure and properties. Silicon-doped graphene-based materials are known to exhibit exotic properties, yet conjugated organic materials with atomically precise Si substitution have remained difficult to prepare. For our results this part demonstrated the high generality of the C–Si on-surface coupling by depositing Si atoms and subsequent polyaromatic hydrocarbons on Au[111]. These remarkable advancements pave the way for novel functional materials with vast scientific and technological implications.

Selective Passivation of 2D TMD Surface Defects by Atomic Layer Deposited Al2O3 for Enhancement of Recovery Properties of Gas Sensor
Lee Raeyoung1, Sohn Inkyu1, Wi Sungjoo1, Kim Youngjun1, Kim Myoungsub1,2, Yoon Hwi1, Shin Dain2, Kim Jaehyeok1, Seo Jeongwoo1, Seungmin Chung1 and Kim Hyungjun1; 1Yonsei University, Korea (the Republic of); 2SK Hynix, Korea (the Republic of)

Two-dimensional (2D) transition metal dichalcogenides (TMDs) which possess large surface-to-volume ratio have been widely used for room temperature gas sensing applications. [1] However, due to its intrinsic defect or vacancies on TMD surface, incomplete recovery of TMD gas sensors hinder the realization of reliable and repeatable use of 2D TMD gas sensors. [2] Here, we demonstrate improvement of recovery rate of TMD gas sensors by selectively passivating TMD surfaces’ defect or vacancies with Al2O3 using atomic layer deposition. SEM analysis confirms that nucleation and growth of atomic layer deposited Al2O3 occurs along the grain boundaries and defects of 2D MoS2 and WS2, not covering inert basal plane. Also, Raman, Photoluminescence and XPS spectra shows the slight n-doping effect of Al2O3, which attributes to improvement of gas sensor response as well as recovery rate. Our unique and unreported defect passivated TMD gas sensors show 400% response toward 1 ppm of NO2, and the recovery rate rises up from 74% to 96% as the number of ALD cycle increases even at room temperature. Also, the recovery rate toward NH3, which is the reducing gas, shows an increase of more than 30% implying that our proposed method is a promising strategy for improving the recovery rate of 2D TMD gas sensors.

Low Temperature Magneteto-Transport Properties of ALD Grown TiN0.87O0.97 Films
Filipe Baron; SAAM Micro Inc., United States

We report results of the magneto resistivity and R(T) measurements of TiN0.87O0.97 films with different N/O-content grown by ALD in magnetic fields up to 11 Tesla. Our results indicate that the films are amorphous metals, which follow the Mooij rule, they demonstrate both positive and negative magnetoresistance, and some of them undergo superconductive transition below 4.2K. The technology for obtaining a compact temperature sensor for wide temperature range (liquid helium to +260deg C) based on 40 nm thick TiN0.87O0.97 is presented. This technology is fully compatible with standard CMOS.

Development of Graphene Oxide with a Single Oxygen Functional Group and Applications for the Gas Barrier Membrane
Tatsuki Tsugawa, Kazuto Hatakeyama, Michio Koimuma and Shintaro Ida; Kumamoto University, Japan

Graphene oxide (GO) has a variety of functional groups on the surface, making it highly dispersible in various solvents such as water and N,N-dimethylformamide. On the other hand, GO has been studied as gas separation membranes that can achieve both high flow rate and high selectivity, but in general, the many defects (nanopores) located in the nanosheet causes reduction in gas barrier performance. As a result, the gas barrier performance is significantly lower than that of graphene. Because of the uncontrolled introduction of these defects during GO synthesis, its use as a barrier membrane has been limited to large molecules or ions. In particular, the barrier performance for small molecules and ions such as H+ has only been achieved by graphitization using strong reducing agents, which was impractical given the damage and hazards to the substrate. In this report, we describe the GO with low defect density that sweep away this perception and barrier
membranes based on it. The nanopores on the GO surface are formed by introducing COOH and C=O groups and breaking the C=C bonds of the graphene backbone through oxidation treatment. In other words, GO without nanopores theoretically be obtained by introducing oxygen functional groups in-plane while maintaining the C=C bond. Oxygen functional groups that achieve these results include C-O-C (epoxy group) and C-OH (hydroxy group). It has been reported that graphite oxide treated with fuming HNO3 and KClO3 has almost only epoxy groups, and such GOs are considered to be free of nanopores. In this study, we succeeded in obtaining highly efficient monolayer nanosheets from this graphite oxide using a weakly basic solvent with the addition of ammonia, and clarified the detailed structure. It was found that the barrier performance against specific gases of GO without nanopores was found to be 10^3 times higher than that of conventional GO and superior to Kapton and PET films in terms of gas permeability coefficient considering the film thickness. Furthermore, it was found that GO without nanopores exhibits 10^5 times higher proton barrier performance than conventional GO.

Observation of Topological-Hubbard Phase Diagram in Twisted Homo-Bilayer MoTe2-Moire Superlattice Kai-Fei Kang1, Ye Chen Qiu2, Kenji Watanabe3, Takashi Taniguchi4, Jie Shan4,5 and Kin Fai Mak4,5,6,7; Cornell University, United States; 8:00 PM

At half-filling of a honeycomb lattice, competition between the onsite Coulomb repulsion and spin-orbit interaction leads to the Kane-Mele-Hubbard phase diagram, consisting mainly of a topological band insulating phase and an antiferromagnetic Mott insulating phase. Despite decades of theoretical efforts, experimental evidence is yet to be observed. Here we present the first demonstration of such a phase diagram in a honeycomb moiré superlattice formed by small angle twisted MoTe2 monolayers. A quantum phase transition from a quantum spin Hall insulator (QSHI) to an antiferromagnetic Mott insulator (AFMI) is realized by tuning the vertical electric field. In the QSHI state, we observe a resistance plateau of −h/2e^2 for temperatures below 10 K. In the AFMI state, we observe a zero Hall plateau and sharp magnetic transitions up to a Neel temperature of TN ~ 30 K. At high magnetic fields of B > 10 T, both QSHI and AFMI are driven into Chern insulators with the quantized Hall resistance R_{xy} = h/e^2. A spin density wave state is further observed when the AFMI is electron doped. Our observation paves the way for realization of exotic phases of matter such as quantum spin liquid and heavy fermion superconductivities in moiré materials.

Charge Transport in Charge Transfer Co-crystal Nanoribbons Yuri Chung, Satwik R, Scott Melis and Edward Van Keuren; Georgetown University, United States

Charge transfer co-crystals have interesting applications in the field of organic electronics due to their unique optical and electronic properties, and have potential advantages over inorganic materials, such as being flexible and biodegradable. Controlled evaporative self-assembly (CESA) is a technique that produces long, ordered ribbons of material on a substrate from an evaporating solvent, a more convenient method of fabrication than for many inorganic material devices. Charge transfer co-crystals were successfully grown using this method to form a neat arrangement of ribbons that were readily integrated with metal electrodes to create organic field-effect (OFET) transistors for electronic measurements. We show that the temperature dependence of device mobility can be described by a hopping mechanism for the charge transport in co-crystals such as phenothiazine and 7,7',8,8' tetracyanoquinodimethane (PTZ-TCNQ) and phenoxazine and TCNQ (PXZ-TCNQ). Ongoing work involves studying the semiconductor potential of other cocrystal pairs and superexchange modeling.

Ink-jet Printed Graphene-Silicon Schottky Diodes Alessandro Grillo1, Zixing Peng1, Aniello Pelella2, Antonio Di Bartolomeo2 and Cinzia Casiraghi1; 1University of Manchester, United Kingdom; 2University of Salerno, Italy

Integration of graphene (Gr) in silicon-based technology is of crucial importance for enabling the next generation electronics, photonics and sensors [1]. Although numerous works have reported devices based on Gr-Si junctions, the integration process relies on the use of high quality Gr produced by Chemical Vapour Deposition (CVD), making the fabrication steps expensive, time consuming and by limiting the large scale devices’ reproducibility. In this work we show that inkjet-printing enables simple and scalable integration of Gr into Si-technology [2]. We developed a simple fabrication procedure, based on the mechanical or chemical etching of the SiO2 layer from a standard Si wafer, followed by the inkjet printing of water-based printable Gr inks [3] on the exposed area, leading to Schottky diodes with excellent rectifying behaviour and figures of merit, comparable to those produced with CVD graphene. We fully characterized the devices and applied several theoretical models achieving deep understanding of the underlying physics of the devices. We also investigated the optical response of the diodes by demonstrating a spatially selective photodetector. Our results demonstrate that inkjet printing is a cost-effective and scalable method, which is also compatible with back-end-of-line fabrication processes for the integration of graphene in the modern Si-technology.

Visualizing the Electrochemical Microenvironment in Engineered Electrode Structures Yiming Wang, Mingxuan Zhu, Zhifei Yan, Sam Veroneau and Daniel Nocera; Harvard University, United States

The activity and selectivity of an electrocatalyst are intricately tied to the micro-environment at the electrochemical interface. While several factors influence the micro-environment, the impact of mesoscale electrode geometry remains relatively unexplored. Most electrocatalysis employs three dimensional structures to increase the electrochemical surface area. However, due to mass transport, local diffusional gradient emerges inside the pores or trenches of the catalyst layer, which creates the micro-environment distinct from that of the bulk. To fully understand the effect of electrode geometry, operando study is essential. Experimentally probing micro-environment in operating condition is challenging not only because it requires high spatial and temporal resolution but also because of the difficulty in systematically varying the mesoscale electrode geometry. Researchers have been using a variety of methods to elucidate the interplay between electrode structures and its micro-environment. However, most of the studies only provided qualitative insights, lacking the quantitative descriptors vital for the rational design of electrode architectures and the corresponding local environment. To address the above-mentioned challenges, we use fabricated micro-wire arrays to systematically study the effect of electrode architecture on local pH near the electrocatalyst. By varying the shape, size and spacing of the micro-wires we aim to attain a quantitative understanding of the influence of diverse geometric descriptors. We use confocal fluorescence microscopy to map pH near the micro-wire arrays in operando conditions. Our findings hold potential applications across numerous proton-coupled electron transfer reactions. The experimental design could also be easily adapted to study other elements within the micro-environment.
Study of the multiwall WS2 nanotubes (NTs) behaviour for numerous applications has been demonstrated that rolling of the WS2 molecular layers into nanocylinders promotes modifications in their structure. This results in unusual mechanical, chemical and electrical properties, which appear not only due to size reduction and quantum confinement, but mainly due to strain in the lattice, curvature and chirality of the layers, inherent to the tubular structure. Thus, rare bulk photovoltaic effect (BPVE) was recently discovered in WS2 NTs and exhibited the photocurrent in the nanotube-based devices orders of magnitude larger than in other BPVE materials. BPVE appears due to the intrinsic properties of NTs: the small band gap (1.4-2.1 eV), broken inversion symmetry and polar structure[1]. An exponential increase of the NTs’ resistivity with tensile strain up to a recorded elastic elongation of 12% was revealed, thereby making WS2 NTs suitable for piezoresistive sensor applications[2]. Bandgap engineering via size and number of layers control was recently demonstrated via cathodoluminescence measurements of these NTs[3]. Moreover, a fully operated artificial vision system was built based on the memory ability, produced by discovered programable photoeffect and sliding ferroelectricity in multiwalled WS2 NTs[4]. Such a wide investigation of this nanomaterial, became possible due to the breakthrough in their vapor-gas-solid (VGS) synthesis, which result in a pure phase and macroscopic amounts[5]. Special efforts were applied to complete extremely complicated synthesis of MoS2 NTs from molybdenum trioxide (MoO3) nanowhiskers in three-step high-temperature reaction with H2/H2S gases[6]. The availability of MoS2 semiconductor NTs will enable their wide investigation in the future.

Emerging Functionalities of Carbon-Based 1D and 2D Nanoarchitectures Aran Garcia-Lekue1,2; 1Donostia International Physics Center (DIPC), Ikerbasque, Basque Foundation for Science, Spain; 2Ikerbasque, Basque Foundation for Science, Spain

Nanostructuring graphene at the atomic scale is now possible by on-surface synthesis methods, which unite the sturdiness of covalently bonded networks with the easy tunability of molecular materials[1,2]. These experimental advances have boosted the research attempts to create novel 1D and 2D carbon-based structures aimed at the development of new nanoelectronic, spintronic or optoelectronic devices. However, before graphene nanostructures can be used in practical applications, an atomic level understanding and control of their properties is required. As such, ab-initio simulation has developed as an essential partner in the search of optimal carbon-based low dimensional materials.

In this talk, I will present some studies of prototype graphene nanostructures, such as graphene nanoribbons (GNRs) and nanoporous graphene (NPG), that we have recently performed in our group. Using mainly density functional theory (DFT), and in collaboration with our experimental colleagues, we have investigated their structural, electronic, magnetic and transport properties. On the one hand, we have explored the emergence of localized spins in metallic GNRs realized by substitutionally doping a narrow band gap GNR with boron atoms in its interior.[3] We have also reported on a novel NPG structure, which can be envisioned as GNRs laterally fused by phenylene bridges. Interestingly, electron transport simulations demonstrate the capability of modulating the interribbon coupling by different degrees of freedom provided by the phenylene bridges.[4] Our results thus show that chemical doping offers the perspective of electronically controlling spins in 1D carbon nanoarchitectures, while molecular bridges emerge as an efficient tool to engineer quantum transport in 2D networks.

From a purely theoretical perspective, we have investigated prototypical hybrid GNRs formed using two existing carbon-based precursor molecules and a porphyrin center[5]. Our results reveal that narrow band gap hybrid GNRs might be achieved, and that embedding an iron atom in the porphyrin center gives rise to a spin-polarized ground state. Besides, our electron transmission calculations demonstrate how strain or chemical adsorption on the Fe atom gives rise to spin-crossover. This work highlights the potential of porphyrin-based hybrid GNRs as a highly tunable and flexible platform for spintronics and sensing applications.

Topological Radical Pairs Produce Ultrahigh Conductance in Long Molecular Wires Liang Li, Shayan Louie, Austin Evans, Elena Meirizadeh, Colin Nuckolls and Latha Venkataraman; Columbia University, United States

In the field of molecular electronics, it has been a challenge to make highly conductive long molecular wires. Typically, the conductive wires made to date are mostly designed and built from conjugated units, which conduct through a coherent and off-resonant mechanism. Within this mechanism, the conductance decays exponentially with increasing length. Therefore the conductance becomes low when more units are added to lengthen the wires. To overcome this problem, a new class of molecular wires with topological radical states at the edge sites (so-called edge states) can be created following the
Su-Schrieffer-Heeger (SSH) model. These wires are one-dimensional topological insulators (1D TIs) and conduct through the energetically low-lying edge states that are localized to the wire ends. As a result, such 1D TI wires feature a reversed conductance decay, that is, the conductance increases exponentially with increasing wire length \( \text{(Nat. Chem. 2022, 14, 1061-1067.)} \). However, the reversed conductance decay only appears for short wires, as when the wire length increases beyond a threshold, the localized edge states become decoupled and no longer support electron transport. To extend the wire length at which these properties can be observed, we designed topological oligo[n]emeraldine wires, using short 1D TIs as building blocks \( \text{(J. Am. Chem. Soc. 2023, 145, 2492-2498.)} \). As the wire length increases, so does the number of topological states, resulting in an enhanced electronic transmission along the wire with increasing length. In our experiments, we successfully drove a current of over a microampere through a single ~5 nm molecular wire, significantly surpassing the performance reported long wires. With DFT calculations, we demonstrated that the longest topological oligo[n]emeraldine exhibits over \( 10^6 \) enhancements in the transmission compared to its isostructural non-topological molecular wire. Furthermore, there is no theoretical limit to the number of 1D SSH TI repeat units that can be incorporated with a single chain. Therefore, it is reasonable to expect that longer analogues of topological oligo[n]emeraldine \( (n > 7) \) will achieve higher currents and conductances. This discovery represents a significant breakthrough in implementing molecules in complex, nanoscale circuitry, as it overcomes a fundamental hurdle that their structures become too insulating at practical lengths for designing nanoscale circuits.

Leveraging Density Functional Theory in the Design of Novel Metal Organic Chalcogenide Assemblies (MOChAs) Adriana Laderer, Aria Mansouri Tehrani and Tess Smidt; Massachusetts Institute of Technology, United States

In this work, we use density functional theory (DFT) and geometric algorithms to propose hypothetical low-energy metal organic chalcogenide assemblies (MOChAs) to aid synthesis efforts. MOChAs are hybrid organic-inorganic, self-assembled Van der Waals crystals where low-dimensional transition-metal chalcogenide (TMC) inorganic structures are scaffolded by organic ligands, which insulate the TMC structures from one another. Despite being bulk crystals, MOChAs, like other low-dimensional TMC materials, host excitonic properties relevant to optoelectronic applications. The choice of organic ligand can control the geometry of the inorganic structure which drives the optoelectronic properties of the MOChAs. This tunability and ease of synthesizability makes MOChAs a compelling material class for exploring structure-property relationships.

We propose hypothetical MOChA structures by systematically generating hypothetical combinations of inorganic structures, organic ligands, and corresponding stacking patterns and evaluating their energetics with DFT. We benchmark our methods on experimentally synthesized MOChAs. In this talk we (i) discuss the efficacy of using DFT as a computational aid to evaluate MOChA structure feasibility, (ii) relate changes in MOChA geometry to electronic properties, and (iii) present a library of energetically favorable hypothetical MOChAs.

Quantum Theory of Sputtering Rates in 2D Materials by Transmission Electron Microscopy Vincent Meunier; Penn State University, United States

Many computational models have been developed to predict the rates of atomic displacements in two-dimensional (2D) materials under electron beam irradiation. However, these models often drastically underestimate the displacement rates in 2D insulators, in which beam-induced electronic excitations can reduce the binding energies of the irradiated atoms. This bond softening leads to a qualitative disagreement between theory and experiment, in that substantial sputtering is experimentally observed at beam energies deemed far too small to drive atomic dislocation by many current models. To address these theoretical shortcomings, this paper develops a first-principles method to calculate the probability of beam-induced electronic excitations by coupling quantum electrodynamics (QED) scattering amplitudes to density functional theory (DFT) single-particle orbitals. The presented theory then explicitly considers the effect of these electronic excitations on the sputtering cross section. Applying this method to 2D hexagonal BN and MoS\(_2\), significantly increases their calculated sputtering cross sections and correctly yields appreciable sputtering rates at beam energies previously predicted to leave the crystals intact. The proposed QED-DFT approach can be easily extended to describe a rich variety of beam-driven phenomena in any crystalline material.

Nonlinear Probing of Structural and Electronic Phase Transition in 2D Quantum Materials Xiaofeng Qian; Texas A&M University, United States

2D quantum materials have demonstrated a plethora of novel physical properties with complex structural and electronic phase transition and potential applications. It is thus highly desirable to understand the underlying mechanism associated with those phase transitions. In this talk, I will report our recent theoretical effort on predicting nonlinear responses in 2D quantum materials, demonstrating nonlinear probe for structural and electronic phase transition, and showing the promise for quantum nonlinear electronics. Specifically, I will present microscopic theory of ferroelectric nonlinear Hall effect in time-reversal invariant layered topological materials and discuss the complex interplay of symmetry, electronic structure, and Berry curvature, and briefly report the experimental demonstration of Berry curvature memory effect as a high-order multiferroicity. Second, I will also present our recent theoretical work on magnetic shift photocurrent and magnetic injection photocurrent as the counterparts of normal shift current and normal injection current in time-reversal symmetry and inversion symmetry broken systems, and demonstrate how these nonlinear photocurrent responses can help decipher magnetic structures and interactions which could be particularly fruitful for probing and understanding magnetic topological quantum materials and phase transition.

10:30 AM EL07.04.06
Giant Rectification in Strongly-Interacting Driven Tilted Systems Juan J. Mendoza-Arenas\(^1\)\(^2\) and Stephen Clark\(^2\); \(^1\)University of Pittsburgh, United States; \(^2\)University of Bristol, United Kingdom

Correlated quantum systems feature a wide range of nontrivial effects emerging from interactions between their constituting particles. In nonequilibrium scenarios, these manifest such as many-body insulating states and anomalous scaling laws of currents of conserved quantities, crucial for applications in quantum circuit technologies. In this work \([1]\) we propose a giant rectification scheme in one-dimensional systems based on the asymmetric interplay between strong particle interactions and a tilted potential, each of which induces an insulating state on their own. While for reverse bias both cooperate and induce a strengthened insulator with an exponentially suppressed current, for forward bias they compete generating conduction resonances; this leads to a rectification coefficient of many orders of magnitude. Based on numerical and analytical calculations, we uncover the mechanism underlying these resonances as enhanced coherences between energy eigenstates occurring at avoided crossings in the system’s bulk energy spectrum. Furthermore, we demonstrate the complexity of the many-body nonequilibrium conducting state through the emergence of enhanced density matrix impurity and operator space entanglement entropy close to the resonances. Our proposal paves the way for implementing a perfect diode in currently-available electronic and quantum simulation platforms.

10:45 AM EL07.04.07

A Many-Body Diffusion Monte Carlo and DFT+U Study of Monolayer VSe2, Daniel Wines1, Kayahan Saritas1, Jaron T. Krogel2, Nishanth Gudibanda1, Ramal Choudhary1, Francesca Tavares1 and Can Ataca1; 1National Institute of Standards and Technology, United States; 2Oak Ridge National Laboratory, United States; 3University of Maryland Baltimore County, United States

Previous works have controversially claimed near-room temperature ferromagnetism in two-dimensional (2D) VSe2, with conflicting results throughout the literature. For T-phase VSe2, competing magnetic and non-magnetic states are predicted to exist, which can drive charge density wave (CDW) formation. Although density functional theory (DFT) calculations can capture the differences in chemical composition and polymorphism, strong coupling between the magnetic and structural properties in this material makes it difficult to trust the results from approximate density functionals. For example, T and H-VSe2 have a close lattice match and similar total energies, which makes it difficult to determine which phase is being observed experimentally. In this study, we used a combination of density functional theory (DFT), highly accurate diffusion Monte Carlo (DMC) and a surrogate Hessian line-search optimization technique to resolve the previously reported discrepancy in structural parameters and relative phase stability. With DMC accuracy, we determined the pseudoferromagnetic geometry of both phases and constructed a phase diagram. In addition, we studied the energy differences between the pseudoferromagnetic, antiferromagnetic and CDW phases through a many-body lens to resolve these discrepancies for T-VSe2. Going one step further, we also studied the effect of strain and Se vacancies on the electronic and magnetic properties of these competing magnetic states. Our findings demonstrate the successes of the DMC method when applied to a correlated 2D magnetic system such as VSe2.

A New Strategy to Develop p-Type Semiconductivity in Transition Metal Dichalcogenides: A First-Principles Study Nikhil Sivadas, Mahdi Amachraa and Yongwoo Shin; Advanced Materials Lab, United States

Over the years, silicon has been the preferred choice of channel material in transistors due to its simplicity and scalability. However, the performance of Si-based transistors degrades significantly as the channel thickness is reduced below 4 nm [1]. TMDs with group formula MX2, where M = Mo, W and X = S, Se are a class of two-dimensional (2D) semiconductors that can replace Si in the next-generation transistors. Recently, it was shown that the mobility of monolayer TMDs are comparable with 4 nm thick Si channels [1]. Therefore, integrating TMDs into existing hyper-scaler geometries has the potential to leapfrogging decades on Moore's law time scale [2]. However, strategies to p-dope TMDs have been largely unsuccessful. Conventional approaches like substitution doping creates inhomogeneity such as charged defects within the channel layer that limits the transistor mobility [3].

In this talk, we propose a new strategy to p-dope TMDs via a surface charge transfer mechanism (SCTM) using inorganic oxides. Using physics based HT screening we identify 11 element that when doped into the high-k dielectric oxide layer (e.g. HfO2) can p-dope TMDs without creating channel defects. To validate these finding, we demonstrate p-doping of WS2 using Ni-doped HfO2 using first-principles density functional theory (DFT) calculation. We also discuss practical device geometries for implementing this SCTM induced doping and strategies to control the concentration of dopants. Thus our holistic approach proves the feasibility of p-doping TMDs while retaining the advantages of having a high-k gate-dielectric layer. Demonstrating p-doping in atomically-thin TMDs can allow us to save decades in Moore’s law scaling, and can usher in the post-Si era for transistors. This approach can be easily generalized to tackle a broad array of materials design challenges. Our results provide a new strategy for p-doping TMDs.

11:15 AM EL07.04.09
Tunability of Doping in 2D Material Heterostructures using High Work Function RuCl3: A First Principles Study Dakotah M. Kirk and Marcelo Kuroda; Auburn University, United States

The facile formation of heterostructures based on two-dimensional (2D) materials permits controlling the electronic properties of the resulting systems [1,2,3,4]. In particular, charge transfer between adjacent layers may be exploited to dope layers that improve charge carrier injection and engineer band alignments [3,4,5,6,7]. Here we quantify how large work function RuCl3 alters the electronic properties of heterostructures formed with various 2D materials: semiconducting transition metal dichalcogenides (TMDs), and few layer graphene structures. To this end we produce first principles calculations within the density functional theory (DFT) accounting for the on-site Coulomb interaction and spin-orbit. In the proximity of RuCl3, TMD and graphene layer(s) become heavily p-doped with carrier densities of ~ 5 × 10^13 cm^-2, in agreement with prior experiments on RuCl3 on graphene and WSe2 [7]. We successfully rationalize our first principles results employing an analytical model based on properties of individual constituents. Study of the structural and electronic properties of the heterostructure upon application of vertical strain on these systems reveals that strain barely alters charge transfer but yields a stronger hybridization between layers. Additionally, accounting for the magnetic order in the RuCl3 also results in similar doping when adjacent to semiconducting TMDs or graphene layers. The results of this work show that 2D material heterostructures may improve charge injection efficiency and band engineering in these systems.

The authors gratefully acknowledge the support from the National Science Foundation (NSF) through Grant No. NSF-1848344.

11:30 AM EL07.04.10
First Principles Study of Nernst Effect in 2D Materials Emadi S. Rezaei and Peter Schindler; Northeastern University, United States

The rapidly growing demand for replacing fossil fuels with clean energy harvesting methods necessitates research in renewable energy generation and management. Two-dimensional materials have attracted much attention in energy conversion applications due to their unique transport properties, more enticingly, when a thermoelectric power factor greater than 5 was reported in Fe2V0.8W0.2Al thin films[1]. Similar to the Seebeck effect, the ratio of the developed voltage to the temperature gradient in the presence of a magnetic field is called the Nernst effect[2] which has been utilized in cryogenic
cooling[3], thermopile systems[4], and radiation detector applications[5]. The Nernst effect was observed in Bismuth for the first time and then further studied in semiconductors such as silicon, germanium, and indium antimonide. The Nernst effect in topological semimetals has been of focused interest, more recently. However, data of the Nernst coefficient of 2D materials has been very limited. Here, we present on large-scale screening of 2D structures using high-throughput density functional theory (DFT) calculations to discover promising new materials candidates with high Nernst coefficients. Our preliminary theoretical results show that some 2D materials could exhibit relatively considerable Nernst coefficients. The discovery of new ultra-high Nernst coefficient 2D materials (larger than Bismuth) could pave the way towards more efficient radiation detectors and more productive cryogenic cooling designs.

Graphene Nanoribbon-Based Field-Effect Transistors for High-Performance Logic Technology Zafer Mutlu; University of Arizona, United States

Silicon has powered computing for decades through miniaturization, facilitated by innovations such as strained silicon, high-k dielectrics, fin field-effect transistor (FinFET), and the latest industry trend: gate-all-around FET (GAAFET) architectures. However, silicon is reaching its limits as miniaturization yields diminishing benefits. This necessitates a new ‘wonder’ material that can potentially take some pressure off silicon’s shoulders and meet the increasing demands of computationally intensive technologies such as AI. Bottom-up synthesized, atomically precise graphene nanoribbons (GNRs) feature extremely high theoretical charge carrier mobility and on-state drive current capability at the atomic scale, making them highly promising transistor channel materials for high-performance logic applications. In this invited talk, I will begin with an introduction to GNRs, explaining the features that make them promising for FETs, detailing the bottom-up synthesis, discussing techniques used for their characterization and device fabrication, presenting the current state of the art with transistors made from them, and addressing the remaining key issues. In the next part, I will detail our recent studies, involving enhancing electrostatic control of the GNR channel through the deposition of an ultrathin high-k top HfO2 dielectric layer, ultimately scaling transistors with GNRs, and optimizing the channel-contact interface through contact engineering to reduce contact resistance. Finally, I will address the remaining challenges and potential enhancements in materials, processes, device integration, and related areas that could enable GNRs to approach outstanding theoretical predictions and explore future opportunities in the field.

2:00 PM *EL07.05.02
Self-Assembly of Dense, Aligned, Semicontinuous Carbon Nanotube Arrays for High Performance Transistors Michael S. Arnold; University of Wisconsin--Madison, United States

Carbon nanotubes conduct more electricity per width than silicon and more rapidly switch between on and off states with less voltage, making them ideal for next-generation fast, low-energy logic and high-speed, linear RF devices. However, despite carbon nanotubes’ promise, no one has yet been able create a process for employing nanotubes in high-performance electronics commercially. Since their discovery more than 25 years ago, nanotubes’ commercialization has been delayed by manufacturing challenges in purifying, aligning, and uniformly assembling them with precision over large areas. For nanotubes to be most useful, they must be purified by their electronic type (semiconducting versus metallic) and then lined up in the same direction in a dense layer with the thickness of a single nanotube, so that electricity can rapidly and efficiently travel through them. This talk will present recent discoveries on (1) purifying and aligning semiconducting nanotubes into massively parallel arrays and (2) the research and development of semiconducting carbon nanotube logic and radio frequency devices. We have pioneered nanotube array fabrication technologies that enable the (a) partial alignment of nanotubes (±30°) via shear (demonstrated 100 mm wafer-scale); (b) finer alignment (±6°) at liquid-liquid interfaces (demonstrated 100 mm size-scale); and, (c) the selected-area deposition of nanotube arrays (±7°) in lithographically-defined patterns combining topographical and chemical features (demonstrated 25 mm size-scale). Most recently, we have discovered a powerful new mechanism for driving the self-assembly of nanotubes into aligned arrays, by coaxing them to form two-dimensional liquid-crystals. We have uncovered that when nanotubes are segregated to liquid-liquid interfaces, mesogenic interactions cause them to self-align (within ±5.7 degrees so far) and self-assemble into dense arrays (> 100 per micron) like those needed for microelectronics. The assembled nanotubes are easily integrated on silicon substrates at room-temperature and integrated into high-performance devices. Work on the development of novel multifunctional polymer wrappers and the removal of these wrappers will also be presented.

2:30 PM *EL07.05.03
Anchoring to Prevent Bundling in Dense CNT Array Device Process Shengman Li; Stanford University, United States
Carbon nanotubes (CNTs) are highly promising candidates for replacing silicon (Si) in digital devices due to their remarkable characteristics, including a 1-nm thick body, high mobility/velocity, and low capacitance. To achieve high-performance devices, there is a demand for high-density aligned CNT arrays with a pitch size of 2-4 nm. Significant progress has been made recently in CNT array assembly through the dimension-limited self-alignment method, along with the use of small molecule additives to suppress CNT bundling.

However, the various processing steps involved in fabricating CNT field-effect transistors (CNTFETs) introduce extrinsic defects, such as lateral aggregation and vertical stacking, into the as-prepared CNT arrays. The presence of such CNT bundles can severely impact the ability of the transistor gate to effectively control the flow of charge carriers in the CNT channel, leading to considerable device-to-device variability.

In response to these challenges, this study proposes the incorporation of dielectric anchors to prevent CNT bundling. Through the use of Atomic Force Microscopy (AFM) and Transmission Electron Microscopy (TEM), we investigate the CNT bundling conditions after essential processing steps, including post-evaporation, post-Atomic Layer Deposition (ALD), post-resist spin-coating, post-developing with the anchor layer, and without the anchor layer. By implementing the anchoring-first approach, we demonstrate reduced subthreshold slope variation (SS) and higher drain current (I_on) in CNTFETs.

These findings presents a promising process flow to construct high-performance CNTFETs, thereby advancing CNTFET fabrication towards practical applications in digital devices. The elimination of CNT bundling and improved device characteristics achieved through this study are crucial steps towards the realization of high-performance CNT-based electronics.

One-Dimensional Graphene Devices Herre S. van der Zant; TU Delft, Netherlands

One-dimensional devices made of graphene are of great interest to study mesoscopic quantum transport phenomena. On one hand, one can define one dimensional channels by electrostatic gating with the advantage that the edges do not play a significant role in the transport characteristics. On the other hand, atomically precise graphene nanoribbons (GNRs) are predicted to exhibit exceptional edge-related properties, such as localized edge states, spin polarization, and half-metallicity. However, creating a good contact between electrodes and GNRs has been a longstanding challenge as it requires the controlled fabrication of sub-20 nm metallic gaps, a clean GNR transfer minimizing damage and organic contamination during the device fabrication, as well as work function matching to minimize the contact resistance. Here, I will discuss examples of both approaches: electron focusing and collimation experiments in bi-layer graphene channels defined by electrostatic gating and our progress in contacting 9-atom-wide armchair-edged GNRs with Pt, MoRe and Pd contacts. The two latter metals are known to provide low-contact resistance to carbon nanotubes. Density functional theory (DFT) calculations combined with the non-equilibrium Green’s function method (NEGF) explain the observed p-type electrical characteristics using Pt electrodes and demonstrate that Pt gives a strong coupling and higher transmission in comparison to other materials such as graphene. Detailed electrical characterizations of the MoRe and Pd nanogaps, at various bias/gate voltages and temperatures allow us to investigate the formation of Schottky barriers at metal-GNR interface and extract the activation energies.

4:00 PM EL07.05.05
Non-Volatile Doping of Graphene Transistors using a Solid Polymer Electrolyte Crosslinked by Field Effect for Polymorphic Electronics Dynavesh Deepak Sarawate1, Priscilla Prem1, Ke Xu2, Eric Beckman1 and Susan Fullerton1,1; 1University of Pittsburgh, United States; 2Rochester Institute of Technology, United States

Hardware security comes at a high price in the U.S. at $200 billion annually. Polymorphic electronics provide a potential solution to hardware security threats by preventing unauthorized parties from accessing circuitry information through reverse engineering. The goal of this work is to obscure a device’s function by taking advantage of electric double layer (EDL) gating to reconfigure NAND gates to/from NOR gates on-demand. The key innovation is a custom-synthesized polymer electrolyte that reacts under an electric field created by the EDL (~V/nm), retaining charges in the channel by crosslinking the polymer electrolyte. Ion mobility is confirmed in a lateral, parallel-plate capacitor geometry, and graphene field effect transistors (GFETs) are used to test non-volatile doping. Preliminary evidence of non-volatile doping is observed by programming GFETs at positive gate voltages (V_G > +2 V), and then sensing the Dirac point shift and ON/OFF ratio change. Positive programming voltages less than +2 V showed no effect on the doping; however, the device becomes more n-type, and ON/OFF increases as V_G increases from +2 to +5 V. Note that in the absence of a non-volatile doping mechanism, grounding the gate would dissipate the EDL and reverse the doping effect; however, in the case of our custom synthesized electrolyte, the doping effect persists even after the gate bias is grounded, confirming non-volatile doping at the graphene channel. Applying a negative V_G demonstrates a semi-permanent - but reversible - doping effect. Specifically, as V_G increases from -1 to -5 V, the Dirac point shifts less n-type and ON/OFF decreases, implying that the doping effect is reversible but non-volatile. We will also report on the sheet carrier densities measured by Hall effect to quantify the formation of Schottky barriers at metal-GNR interface and extract the activation energies.

4:15 PM EL07.05.06
Electronic Transport in Twisted Nanoporous Graphene/Graphene Van Der Waals Heterostructures Xabier Diaz de Cerio1, Aleksander Bach Lorenzen2, Mads Brandbyge2 and Aran Garcia-Lekue1,3; 1Donostia International Physics Center (DIPC), Spain; 2Technical University of Denmark, Denmark; 3Ikerbasque, Basque Foundation for Science, Spain

Nanoporous graphene (NPG) is a promising candidate for the development of next generation electronic devices [1]. Recent advances in bottom-up nano-chemistry have allowed the fabrication of increasingly large atomically precise samples of various NPG geometries, which can be thought as lateral arrays of weakly coupled semiconducting graphene nanoribbons [1,2]. Besides, the highly anisotropic electronic structure of NPG causes injected currents to flow according to the so-called Talbot effect interference pattern [3]. Such phase coherent phenomenon can be tuned by the introduction of structural and chemical modifications, making this 2D material appealing to control currents at the nanoscale [2,4]. On the other hand, van der Waals heterostructures have attracted great interest in the last decade due to their unconventional electronic properties and the high level of control achieved in the stacking of 2D materials. In this regard, the stacking of NPG over graphene has emerged as a noteworthy strategy to tune the electronic and transport properties of the latter [5,6]. However, the potential control of nanoscale currents in such heterostructure remains largely unexplored.

In this work, we theoretically study the electronic anisotropy and transport properties of twisted NPG/graphene van der Waals heterostructures. Combining Non-Equilibrium Green’s Functions with a tight-binding approach, we model devices comprising ~200,000 atoms and lengths over 50nm. In particular, we simulate the current flow in various commensurate and incommensurate geometries corresponding to different interlayer twist angles. The response of currents to the twist angle parameter is rationalized by means of the evolving interlayer coupling. Our findings showcase the versatility of NPG/graphene heterostructures for electronic applications and open new prospects for the realization of carbon nanocircuitry.

Sensor has potential applications in a wide range of fields, including civil engineering, agriculture, and industrial processes. The sensor is highly sensitive, reversible, and inexpensive. It is also easy to fabricate and can be scaled up for mass production. The montmorillonite/graphene composite is a promising candidate for highly efficient humidity sensor with plenty of advantages over traditional sensors.

The results showed that the sensor had a linear response to humidity, with a sensitivity of 10% per RH. Moreover, we find out the sensor was reversible and stable over time.

The incorporation of graphene into montmorillonite, at the point where graphene’s concentration exceeds electrical percolation threshold, forms a cost-effective composite material compared to carbon materials like GO or rGO that exhibits enhanced electrical resistance changes for humidity sensing. Additionally, the hydrophilic nature of montmorillonite facilitates the absorption of water molecules into the composite, whereas the hydrophobic nature of pristine graphene facilitates the desorption of water molecules. This combination of properties can contribute to the reduction of both response and recovery time in the composite.

The montmorillonite/graphene composite was fabricated using a simple solution-based method. The composite was then coated on an electrode deposited substrate. The best ratio of montmorillonite/graphene of composite sensor was confirmed through observation of distinct electrical resistance change in the composite.

The montmorillonite/graphene composite was fabricated using a simple solution-based method. The composite was then coated on an electrode deposited substrate. The montmorillonite/graphene composite facilitates the desorption of water molecules. This combination of properties can contribute to the reduction of both response and recovery time in the composite.

The needs about precise humidity sensor are getting higher gradually in numerous major industries for insuring optimal performance of electrical devices and safety in diverse environments. Graphene, the two-dimensional material, has extraordinary electrical properties due to its π-bonding of sp² hybrid orbital. Recent study has shown possibility of graphene-based material as the humidity sensing material because of its ultrahigh surface area. However, the results reported thus far are limited in recovery time and long-term stability due to irreversible adsorption of water molecules on graphene’s surface during humidity sensing. Its high price also can be challenge for the practical application. Although doping other sensitive material to graphene is one of the possible ways that can improve recovery property, but it not that effective way to improve sensor’s sensitivity.

In this study, we propose a stable humidity sensor based on a montmorillonite/graphene composite to overcome these recovery, stability, and price problem. As a natural clay mineral, montmorillonite has attracted interest because of its abundance and unique ability to absorb large amounts of water by an increase in the c-axis of the layer lattice structure.

The specific problems of graphene-based humidity sensors are limited in recovery time and long-term stability due to irreversible adsorption of water molecules on graphene’s surface during humidity sensing. Its high price also can be challenge for the practical application. Although doping other sensitive material to graphene is one of the possible ways that can improve recovery property, but it not that effective way to improve sensor’s sensitivity.

The needs about precise humidity sensor are getting higher gradually in numerous major industries for insuring optimal performance of electrical devices and safety in diverse environments.

Colloidal inorganic nanocrystals are an attractive class of nanomaterials for both fundamental research and technical applications thanks to their size- and shape-dependent properties, but also because of their excellent chemical processability. In particular, colloidal CdSe nanocrystals (NPLs) are fascinating nanocrystals to explore the potential of two-dimensional (2D) materials for next generation optoelectronic devices. The strong quantum confinement in the vertical direction leads to peculiar optical properties that depend on their thickness, such as, narrow emission, high exciton binding energy, relatively small dielectric constant, giant oscillator strength, large linear/nonlinear absorption cross sections and short radiative fluorescence lifetime. In addition, the large volume of NPLs makes Auger recombination less efficient. All of these advantages make NPLs promising for application in Light-Emitting Diodes (LEDs).

However, application of CdSe NPLs in the ultraviolet/ blue region remains an open challenge due to charge trapping leading to limited photoluminescence quantum yield (PLQY) and sub-bandgap emission in core-only NPLs. Furthermore, for LEDs based on II-VI semiconductor quantum dots (QDs), the efficiency and stability of red and green QD based devices is close to standards for commercial applications, while blue QLEDs (Quantum dots-LEDs) lag behind in terms of device efficiency and stability. The specific problems of blue QLEDs are as follows: surface defects and lattice mismatch of blue QDs, carrier injection imbalances, high absorption coefficient of charge injection layers, fluorescence quenching caused by exciton dissociation induced by an electric field, instability of the organic transport layer, and the loss of light caused by plane-laminated structures.

We recently focused on the synthesis of 3,5 ML CdSe/CdS core/crown blue emitting nanoplatelets developed in 2023. After a significant improvement in
core-only synthesis\textsuperscript{\textcopyright} with a precise control over the aspect ratio (length/width), we raised the PLQY of core/crown NPLs up to 60\% with complete emission in the visible range and without any observable second phase. More specifically, our crowning procedure increases the quantum efficiency of 4 times with respect to the core-only using much less material than a core/shell structure. Using CdSe/CdS core/crown NPLs emitting in the pure blue region of electromagnetic spectrum (2.7 eV = Eg, λ = 460 nm), we then obtained the highest EQE (2.8\%) existing for blue core/crown structured CdSe-based material in Light Emitting Diodes fabrication. We take advantage of some important strategies to improve EQE in our proposed LED. In contrast to the majority of works present in the literature, we avoid using ZnO film as ETL due to its absorption in the same region of NPLs emission and in order to reduce self-absorption in NPLs, we use a very low thickness of NPLs as emissive layer. The electroluminescence measurement shows a 460 nm peak with a turn-on voltage of 3.3 V.

Our results show an effective way for the PLQY improvement of core-crown CdSe/CdS NPLs and good performances in hybrid organic-inorganic Light Emitting Diodes application.

8:00 PM EL07.06.03
Various Frequency Band Electromagnetic Shielding Film by Internal Multi-Reflection Between ITO Nano-Branches Younho Kim\textsuperscript{1} and Hakki Yu\textsuperscript{2}; \textsuperscript{1}Korea University, Korea (the Republic of); \textsuperscript{2}Ajou University, Korea (the Republic of)

Electromagnetic wave interference (EMI) means that electromagnetic waves generated from the outside interfere with the operation of some device. As various industries develop, the contamination by electromagnetic waves increases and the risk also increases day by day. In particular, such interference in communication equipment or the space industry can lead to failure of huge capital projects from causing inconvenience in daily life. Shielding this interference is called electromagnetic wave interference shielding (EMI shielding), and various materials or processes are being studied. Representative materials studied so far include carbon, ferrite, perovskite, silicon carbide, and conducting polymer series. It is usually in the form of a composite composed of two or more materials without using a single material. What these composites have in common is that they basically use reflection by electron conductivity or absorption by dielectric or magnetic property. In addition, the effect of dielectric properties occurring at interfaces or internal scattering occurring between surface can be expected. For application to various fields, the thickness of the EMI shielding film should be thin, but considering only absorption by dielectric properties, it cannot be thinner than the skin depth, so the aforementioned additional effects are inevitable. In this study, ITO nano branches were used, and a film capable of EMI shielding on various regions was produced by increasing the density of the rods constituting the nano branches. Consequently, 22.31 dB (X band), 21.88 dB (Ku band), 21.09 dB (K band), and 17.81 dB (Ka band) shielding effect were shown for each region at a thickness of around 6 mm. It has a very high shielding efficiency compared to a very low thickness. Therefore, it is expected that it can be used in various fields.

2D Materials-Based Ink to Develop Meta-Structures for Electromagnetic Interference (EMI) Shielding Suwarna Datar; Defence Institute of Advanced Technology, India

2-D transition metal-chalcogenides which are semiconductor materials of the type MX\textsubscript{2}, where M is a transition metal atom (like Ni, Fe, or Co) and X is a chalcogen atom (such as S or Se) are emerging class of materials which have excellent properties like atomic scale thickness, strong spin-orbit coupling, ability to form 2D nanosheets, direct band gap which 2D carbon based materials lack and many other mechanical and electronic properties. They are actively used in the fields like flexible electronics, opto-electronics, energy harvesting spintronics, personalised medicines etc. These properties make 2D materials lucrative for EMI shielding applications because of strong electronic polarization and enhanced dielectric loss. Research on hybrid materials like magnetic metal chalcogenides with transition metal-chalcogenides like magnetic core-shell nanomaterials, Fe doped MoS\textsubscript{2}, doped MoS\textsubscript{2}-rGO composite, MoS\textsubscript{2}/CoSe\textsubscript{2} hybrids, among several others suggests, these materials have high reflection loss. Further, magnetic transition metal dichalcogenides such as NiSe\textsubscript{2}, CoSe\textsubscript{2} and their heterostructures, expedites multiple reflections and scattering of the incident wave, thereby elongating the course of transmission of the incident microwave, and thereby increasing dissipation efficiency, along with large specific surface area, which caters to EM absorption. In the present work inks have been developed base on these materials to make them versatile for several applications where it can be coated or screen printed.

The second part of this work involves development of meta structures using these paints as Radar absorbing materials. The tunability of material properties occurs between surface can be expected. For application to various fields, the thickness of the EMI shielding film should be thin, but considering only absorption by dielectric properties, it cannot be thinner than the skin depth, so the aforementioned additional effects are inevitable. In this study, ITO nano branches were used, and a film capable of EMI shielding on various regions was produced by increasing the density of the rods constituting the nano branches. Consequently, 22.31 dB (X band), 21.88 dB (Ku band), 21.09 dB (K band), and 17.81 dB (Ka band) shielding effect were shown for each region at a thickness of around 6 mm. It has a very high shielding efficiency compared to a very low thickness. Therefore, it is expected that it can be used in various fields.

Morphological Characterisation of Printed Networks of Nanomaterials using FIB-SEM Nanotomography Luke Doolan, Cian Gabbett, Kevin Symmatschke, Emmet Coleman, Adam G. Kelly, Shixin Liu, Eoin Caffrey, Jose Munuera, Catriona Murphy, Lewys Jones and Jonathan N. Coleman; Trinity College Dublin, Ireland

Networks of nanomaterials find applications in a wide variety of fields such as printed electronics, sensors, and energy storage\textsuperscript{[1]} While it is known that the morphology of the network plays a dominant role in determining their physical properties, quantitative measurements of morphology have proven difficult\textsuperscript{[2]}. It has been demonstrated that changing nanomaterial size changes the network’s electronic properties, however, its effect on network morphology is not well understood\textsuperscript{[3]}. Utilizing FIB-SEM nanotomography we characterize the morphology of networks of nanomaterials. 3D-images with a voxel size of 5 x 5 x 15 nm were obtained from printed networks of graphene with different nanosheet length. Using machine learning, 3D images were segmented into nanosheet and pore components and a wide range of morphological properties of the networks, including porosity, pore shape, nanosheet alignment, nanosheet aggregation and pore and nanosheet tortuosity were calculated. These properties were used to distinguish between the effect of network morphology and nanosheet size on the electrical properties of the networks, allowing calculation of the resistance of the junctions between the nanosheets. The same methodology was applied to printed networks composed of silver nanoplatelets, silver nanowires and tungsten disulphide with varying nanomaterial length. The technique was then extended to investigate the interfaces within vertical printed hetrostacks, allowing
measurement of the interfacial roughness and material penetration into subsequent layers, demonstrating the ability of this technique to characterize printed hetrostacks devices.[4]

Oxidative Chemical Vapor Deposition of Highly Conductive and Transparent Polymer Layers for Contact Fabrication in 2D-MoS2-Based FET Structures Jinmei Zhu, Florian Meierhofer and Tobias Voss; Braunschweig University of Technology, Germany

For 2D MoS2 field-effect transistors (FETs), contact fabrication easily results in damaging the MoS2 channel due to the fragility of the atomically thin structure, making it difficult to reliably achieve high-performance devices. To overcome this challenge, the deposition of highly conductive and transparent polymer layers from the gas phase (oxidative chemical vapor deposition (oCVD) [1]), is a promising approach that can lead to low-resistivity Ohmic contacts. In this work, we demonstrate a method for fabricating 2D MoS2 bottom-gated FETs with poly (3,4- ethylenedioxythiophene) (PEDOT) electrodes. PEDOT is a conductive polymer widely used as transparent electrode material. We used lithography to pattern oCVD-grown PEDOT layers and transferred them onto MoS2 channels without aggressive chemical and physical treatments. This method allowed us to achieve a damage-free MoS2 channel with a clean and smooth interface of the PEDOT electrodes, significantly decreasing the charged impurity and interface-roughness scattering processes. This universal approach could be applied to different 2D materials, thus enabling the fabrication low-resistivity Ohmic contacts in high-performance FETs without damaging the atomically thin crystals.

Designing Natural Hyperbolic Materials: Expanding the Possibilities of Two-Dimensional Systems Mingwen Zhao; Shandong University, China

Hyperbolic materials (HMs) have garnered significant interest for their unique electromagnetic response characteristics, including optical nanoscale cavities, spontaneous emission enhancement, nanoscale imaging, and full-angle negative refraction. While initially achieved in metamaterials, the development of meta hyperbolic surfaces through intricate substrate patterning has enabled the support of highly-directional hyperbolic surface plasmons, crucial for optoelectronic devices. In this study, we introduce the concept of hyperbolicity into natural two-dimensional (2D) materials exhibiting highly-anisotropic electronic band structures. We demonstrate that these materials present intriguing scenarios similar to those observed in meta hyperbolic surfaces. Notably, natural hyperbolic 2D materials possess advantages over meta-surfaces, leveraging their small atomic-scale periodicity to yield large wavevectors and easy predictability without the need for complicated surface patterning. Based on orbital anisotropy, we propose a design principle for 2D hyperbolic materials and predict a family of candidate materials using first-principles calculations. Our computational results showcase the broadband hyperbolic regimes exhibited by these natural 2D-HMs across the near-infrared to ultraviolet spectrum, enabling the propagation of highly directional hyperbolic surface plasmons. By simulating the directional propagation of surface waves with hyperbolic dispersion relations through the solution of Maxwell’s equations, we establish a correlation between the fascinating plasmonic properties and the unique electronic structures of these highly-anisotropic 2D materials. The findings presented in this study offer a promising strategy for the design of 2D hyperbolic materials, paving the way for advancements in optoelectronic devices and expanding the possibilities of utilizing natural materials with remarkable electromagnetic characteristics.

The Effect of 2D Nanosheet Size on the Performance of Printed Devices Anthony Dawson, Jose Munuera, Kevin Synnatschke, Joseph Neilson and Jonathan N. Coleman; Trinity College Dublin, Ireland

Printed networks of materials such as few layer MoS2 enable the production of low-cost but poorer performance devices. This poor performance is due to low nanosheet network mobility of about 0.1 cm2/Vs, this is in part due to inter-nanosheet junctions. To improve network mobility of printed networks, we must better understand these junctions. To achieve this, this project sees the development of size-controlled networks by separating nanosheets into discrete size selected samples.

Recently developed Electrochemical Pellet Intercalation (ECPI) methods enable the scalable exfoliation of nanosheets from cheap, widely available powders. The development of size-controlled networks from commercially available powders via ECPI could transform access to the development of 2D material-based device development. [1,2]

The electrical performance of these networks is characterised, and these measurements are used to refine printing parameters to optimise network morphology, toward reducing junction resistance and thus improving mobility. Applying this knowledge, transistors are developed using these optimised networks and their performance assessed. [3]

The Borophene and Silicene-Based Humidity Sensors using Quartz Crystal Microbalance Ahmet Gulsaran1,1, Bersu Bastug Azet1,1, Nevin Tasaltin2,3, Cihat Tasaltin4 and Mustafa Yavuz2,4; 1University of Waterloo, Canada; 2Maltepe University, Turkey; 3Consens Inc., Turkey; 4Tubitak Marmara Research Center, Turkey

Humidity sensors, fundamental to a wide array of applications ranging from environmental monitoring to healthcare, have seen innovative advancements with the advent of two-dimensional (2D) materials. This study explores the promising potentials of borophene and silicene, two emergent 2D materials, as effective elements in humidity sensing when integrated into a Quartz Crystal Microbalance (QCM) platform.

These sensors, fabricated by transposing atomically thin layers onto a QCM surface, operate based on the detection of mass variations as a consequence of water molecule adsorption or desorption, thereby causing a resonant frequency shift in the quartz crystal. Leveraging the exceptional surface-to-volume ratio and ultrathin attributes of borophene and silicene, these sensors exhibit a marked sensitivity to ambient humidity levels.

Our rigorous examination of the borophene and silicene sensors’ humidity sensing performance showed significant shifts in the QCM's resonant frequency in relation to humidity changes, demonstrating their high moisture sensitivity.

We have also analyzed the borophene and silicene's surface structure and morphology for their applications in humidity sensing. We employed Scanning Electron Microscopy (SEM) and Brunauer-Emmett-Teller (BET) analysis to determine atomic arrangements, topographical features, specific surface areas, and pore size distributions. The integrative use of SEM and BET has provided an in-depth characterization of these 2D materials, expanding our understanding of their potential applicability.
In conclusion, our research emphasises borophene and silicene as potent candidates for humidity sensing applications, with their great sensitivity and atomically thin composition demonstrating a new era in sensor development. This study's insights could guide the design and optimization of advanced 2D material-based humidity sensors.

8:00 PM EL07.06.10
First Demonstration of VGA Format Microbolometer FPAs using Semi-Conducting SWCNT Networks for Uncooled LWIR Image Sensor
Tomo Tanaka1,2, Masahiko Sano1, Masataka Noguchi1,2, Takashi Miyazaki1,2, Megumi Kanaori1,2, Toshihito Miyamoto1,2, Naoki Oda1 and Ryota Yuge1,2; 1NEC Corporation, Japan; 2AIST, Japan

Uncooled infrared sensors of bolometer type have a wide range of applications such as security, military, food inspection, health care, and automotive night vision system. Currently, the highly sensitive device development is the key issue for further expansion of demand. The bolometer is an infrared detector of long wave infrared (LWIR) region for radiate heat by means of an infrared absorber having a temperature sensitive electrical resistance material. Infrared radiation strikes the absorber material heating it and thus changing resistor material resistance. Therefore, bolometer’s performance is strongly limited by temperature coefficient of resistance (TCR) of the resistor. The conventional resistor is generally based on vanadium oxide (VOx) with TCR of about -2%/K [1] and an outstanding resistor is essential to achieve highly sensitive infrared detectors. Recently, single-walled carbon nanotubes (SWCNTs) have been expected as promising materials with high TCR and high chemical stability. We have reported that semi-conducting SWCNT networks extracted by the “Electric-field inducing Layer Formation (ELF)” method [2] show high TCR which is close to -6%/K [3]. The pristine SWCNTs are fundamentally a mixture of both semi-conducting and metallic SWCNTs. The ELF method is the remarkable promising technique to extract semi-conducting SWCNTs with high purity, which show stable device performance and excellent electrical transportation property.

In this study, we fabricated the Video Graphics Array (VGA) format focal plane allays (FPAs) with semiconducting SWCNTs for the first time and characterized them. Previously, we have developed a VOx microbolometer with a suspended structure for thermally separation between the infrared absorber and the substrate by micro electro mechanical system (MEMS) process [4]. By utilizing this technology and constructing a new MEMS structure suitable for the CNT networks, we have successfully developed a SWCNT microbolometer FPAs. Device chip which was mounted on the ceramic carrier was installed in a vacuum dewar. For responsivity measurement, infrared radiation from cavity type blackbody was irradiated onto the microbolometer through the ZnSe optical window. This radiation was chopped by an optical chopper and the response signal of microbolometer was measured by lock-in amplifier.

The responsivity of LWIR region was estimated to be around 106 V/W in our FPAs with semi-conducting SWCNTs. This is about three times higher than that in FPAs with VOx. TCR of our semi-conducting SWCNT networks was above -6%/K, which is approximately three times higher than that of VOx. Therefore, it means high TCR of semi-conducting SWCNT network was responsible for the increased sensitivity.

In conclusion, we showed the high-purity semi-conducting SWCNT networks extracted by ELF method effectively work for higher responsivity of microbolometer FPAs. In the future, we will evaluate the performance in more detail and obtain infrared images by combining a microbolometer and a readout circuit.

Acknowledgments: Part of this study was supported by Innovative Science and Technology Initiative for Security Grant No. JPJ004596, ATLA, Japan.

Spatially Heterogeneous Optical Emission from MoSe2 Nanoribbons: Nanoambrozaite1, Zhe Zhang1, Sarah Hiestand2, Leo Sun3, Atac Imamoglu2, Adam Friedman2, Aubrey Hanbicki2 and Thomas J. Kempa1; 1Johns Hopkins University, United States; 2ETH Zürich, Switzerland; 3Laboratory for Physical Sciences, United States

In order to fully exploit the unique physical properties of 2D materials, one must precisely control their dimensionality, composition, strain state, and edge structure. Achieving these goals through a rational chemical synthesis strategy is a compelling but challenging prospect. Here we present detailed optoelectronic characterization of atomically-thin MoSe2 nanoribbons synthesized through a directed growth strategy on phosphine treated Si surfaces. Temperature-dependent photoluminescence studies reveal both simultaneous shifts in the emission energy of the MoSe2 nanoribbons relative to their 2D monolayer counterparts, and previously unobserved regular spatial variations in the photoluminescence intensity across the nanoribbon crystals. Transport measurements on a MoSe2 nanoribbon field-effect transistor device are used to examine how edge effects manifest in changes of the channel and Hall conductance. This study pushes the boundaries of 2D materials synthesis by revealing that precise control over the structural attributes (dimensionality and edge states) of these crystals gives rise to unprecedented physical properties, and thereby paves the way for harnessing their novel phenomena to advance optics, electronics, and quantum sensing.

Transition-Metal Doped Ceria Nanoparticles Loaded Metal Oxide Nanofibers: Heightened Surface Activity for Chemiresistors
Jong Won Baek and Il-Deo Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Oxide semiconductor chemiresistors have shown promise as powerful gas sensors. However, their low surface reactivity limits sensitivity and selectivity. To address this issue, the functionalization of noble metal catalysts on oxide supports has been proposed, but challenges such as scarcity, agglomeration, and poisoning effects hinder practical application. In this study, we present a solution by introducing the highly promising physical and chemical properties of transition metal-doped cerium oxide (CeO2) as an alternative catalyst. To achieve uniform functionalization, we propose an elaborate design principle that employs an electrosprinning technique to integrate CeO2 catalysts onto nanostructured metal oxide nanofibers. Through a single-step liquid-phase reaction involving organic solvents, we have developed sub-2 nm-sized Co-doped CeO2 nanoparticle colloids, which can be conveniently and efficiently used for functionalizing the SnO2 surface through solution-based electrosprinning. The synthesized particles possess distinct physicochemical properties and exhibit active catalytic behavior, characterized by high purity and crystallinity. The resulting composite exhibits superior gas sensing characteristics, specifically for isoprene (C6H8), with low detection limit and excellent long-cycling stability. Notably, the high catalytic activities of Co-CoO2 facilitate the spillover process of chemisorbed oxygen species, resulting in a 27.4-fold higher response towards the target analyte with exceptional selectivity. Furthermore, to gain further insights into the mechanisms behind the chemisorption of oxygen species and selective gas adsorption facilitated by the Co-CoO2 sensitizers, we employed density functional theory (DFT) calculations and X-ray photoelectron spectroscopy (XPS) analyses. Altogether,
our findings demonstrate the potential of transition metal-doped CeO$_2$ functionalization for highly sensitive chemiresistive gas sensors.

Imprinted 2D/3D Perovskite Film with Gradient Phase Distribution Toward High-Performance Polarization-Sensitive Photodetector Dustin Liu, Qi Wei, Lyuchao Zhuang and Shu Ping Lau; The Hong Kong Polytechnic University, Hong Kong

Polarization-sensitive perovskite photodetectors (PSPPDs) are attracting wide attention due to their potential application in remote sensing, optical radar, astronomy detection, and military. The current mainstream of PSPPDs is forming perovskites into anisotropic structures, especially nanowires (NWs). However, synthesizing high-quality perovskite NWs can be a challenging process. Two-dimensional (2D) Ruddlesden–Popper perovskites with the multilayered structure have emerged as promising candidates in optoelectronic devices for their higher oxygen and moist resistance than their three-dimensional (3D) counterparts. Previous research suggested that the spontaneously formed multiple phases of 2D perovskite films are always inhomogeneously distributed, hindering radiative recombination. It is an effective method to modulate perovskite phase distribution to facilitate the separation of charge carriers and improve carrier lifetime. This work reports a PSPPD with high optoelectronic performance based on a 2D/3D perovskite heterojunction with a facile preparation process. The vertical gradient phase distribution of synthesized (PEA)$_2$(MA)$_n$PbnI$_{3n+1}$ film was determined by transient absorption (TA). This ordered phase distribution causes a progressive band energy alignment, which promotes the separation of photogenerated carriers, thereby enhancing the photodetector responsivity. Furthermore, the imprinting method was adopted to form NW-like nanoscale linear patterns on the film surface, realizing polarized light detection. The responsivity of the PSPPD reaches almost 90 A/W, and the detectivity reaches the order of 10$^{12}$ Jones. The photoluminescence intensity of the perovskite film with nanoscale linear patterns presents an anisotropy ratio of 2.2, and the photocurrent of the PSPPD exhibits an anisotropy ratio of 1.6.

8:00 PM EL07.06.14

Investigation of Structural Regularity of Graphene Oxide by Experimental and Computational Methods Kazuto Hatakeyama, Takashi Taniguchi, Tatsuki Tsugawa and Shintaro Ida; Kamamoto University, Japan; ‘National Institute for Materials Science, Japan

Graphene oxide (GO) is a well-known multifunctional 2D material. Owing to its highly useful properties, GO and reduced GO (rGO) are applied to a wide range of applications such as batteries, catalysts, and functional membranes. Furthermore, GO is easily produced via a liquid process from inexpensive natural graphite, and normally obtained as monolayer nanosheet well-dispersed in many kinds of solvents; thus, it is recognized that GO is a 2D material that is closest to practical use. However, the complex structure, which contains many types of functional groups and defects (nano-pores), has become a major impediment to studying GO. For example, its complex structure has prevented the elucidation of GO’s useful properties and research using theoretical calculations. In addition, lack of repeatability, accuracy, and controllability is induced by its complex structure, which causes differences in results and discussions between papers. Moreover, rGO with the same characteristics as graphene has not been achieved because graphene structure cannot be restored perfectly using any reduction process. Recently, we developed a monolayer GO with low defect density and one type of oxygen functional group identified in MXenes, addressing a longstanding challenge that has perplexed researchers in the field. Furthermore, our findings shed light on the potential applications in various fields [1,2,3,4]. Understanding the transport behavior in these materials is crucial to elucidating their underlying physics and developing advanced electronic devices. In this study, we focus on developing a method to calculate the Hall scattering factor, a key parameter in magnetotransport studies, using Rodes’ iterative approach. Our goal is to enable the calculation of this factor as part of ab initio calculations, thus providing a valuable tool for studying the transport properties of 2D materials. We formulate the Hall scattering factor in the context of the ab initio method [5] and present it in the calculation of Hall scattering factors of semiconducting Mxenes such as Sc$_2$CF$_2$, Sc$_2$CO$_2$ and Sc$_2$C(OH)$_2$. By including elastic (acoustic and piezoelectric) and inelastic (polar optical phonon) scattering mechanisms, we model the electrical transport in these Mxenes [6]. In particular, we find that polar optical phonon scattering is the most important mechanism in these materials. Interestingly, we observe a clear behavior of the Hall factor over a range of carrier concentrations. Specifically, Sc$_2$CF$_2$ exhibits an exceptionally high Hall factor of 2.49, while Sc$_2$CO$_2$ displays a relatively small value of approximately 0.5. In contrast, Sc$_2$C(OH)$_2$ achieves the ideal value of 1. This fascinating behavior of the Hall factor holds significant promise for surface group identification in Mxenes, addressing a longstanding challenge that has perplexed researchers in the field. Furthermore, our findings shed light on the role of various scattering mechanisms and highlight the intriguing behavior of the Hall factor in different materials. This work contributes to the understanding of magnetotransport phenomena in 2D materials and offers a pathway towards harnessing their unique properties for future electronic applications.
Humidity sensors hold an imperative role due to increased demand to control the indoor ambient environment, food and medicine storage, agriculture, health, industry, textile, and even space environments. There has been a rapid increase in developing humidity sensors with enhanced sensitivity at low and high relative humidity (RH) ranges for monitoring moisture, temperature, and chemical gases in various application fields. Zeo-type Titanosilicate ETS-10 is a microporous material that shows competitive sensitivity to TiO₂. However similar to TiO₂ at low humidity range it needs some modifications. To achieve this, vanadium (V) incorporated titanosilicate microporous thin films were successfully fabricated to investigate their performances as humidity sensors. A structure with both vanadium and titanium atoms of differing coordinations in the quantum wire of ETS-10 was used to better understand the sensing mechanism. The results indicated that vanadium incorporation led to structural changes in ETS-10, resulting in the formation of Ti²⁺ centers along with Ti⁴⁺ states with a more significant amount of V⁵⁺ as the incorporated vanadium level increased. Vanadium incorporation also resulted in the decreased bandgap, suggesting the introduction of disorders created along the -Ti-O-Ti- chains. The developed sensors showed full range sensitivity at an optimized amount of vanadium into the -Ti-O-Ti- quantum wires in ETS-10. It was observed that V-incorporated samples with an optimized amount of V/Ti=V ratio of 0.2 showed enhanced sensitivity at particularly low relative humidity (RH) levels for the first time. These results demonstrated that titanosilicate ETS-10 has potential application in fabricating humidity sensors, and the sensing performance is enhanced, particularly at an optimized vanadium amount.

Keywords: Humidity Sensor, Titanosilicates, V-incorporated ETS-10, Impedance Spectroscopy

8:00 PM EL07.06.20 Thermal Conductivity and Dielectric Behavior of Nanobrick Wall Thin Films: A New Generation of High-Performance Insulation Ethan T. Iverson1, Hudson Legendre1, Shubham Vasant Chavan2, Anil Aryan3, Maninderjeet Singh4, Sourav Chakravarty5, Kendra Schmieg1, Hsu-Cheng Chiang1, Patrick Shamberger1, Alangir Karim6 and Jaime Grunlan7; 1Texas A&M University, United States; 2University of Houston, United States

Various high voltage electronics for aerospace, defense, and energy storage and conversion have experienced a significant increase in their miniaturization, complexity, power draw, and heat generation. Current insulation systems are inadequate to meet the demands of these rapidly evolving electronics due to subpar thermal conductivities, dielectric properties, and conformability to complex part geometries. Little research has focused on creating novel insulation systems that excel at both dissipating heat and withstanding high voltages (i.e., have both high thermal conductivity and superior dielectric breakdown strength) due to the inverse relationship between the material’s thermal conductivity and insulating dielectric properties. Electronics often require specific combinations of thermal and dielectric properties that are difficult to obtain with one material. Layer-by-layer (LBL) deposition of polyelectrolytes and inorganic nanoplatelets, yields nanocomposite coatings with a high degree of conformity and ordered structures, with unique properties which rival Kapton. Properties can be controlled by adjusting solution concentration, chemistry, and pH, which directly alters the system’s nanostructure. Thermal conductivity as high as 1.87 W/m*K and impressive dielectric constant, losses, and breakdown strength (3, 0.05, and 140 kV/mm, respectively) have been achieved. These novel insulation systems also demonstrate impressive dielectric properties at elevated temperatures, with breakdown strengths ranging from 180-270 kV/mm and low dielectric losses (<0.1). This unique application of LBL assembly provides a practical route for the precise production of high performance, thermally conductive insulation systems for high voltage electronics.

8:00 PM EL07.06.21 Structural and Electronic Properties of α-Borophene Scrolls Guilherme Fabrini1, Douglas S. Galvao2 and Ricardo Paupit2; 1Federal University of Pelotas, Brazil; 2State University of Campinas, Brazil; 3University of São Paulo State—UNESP, Brazil

Since the advent of graphene, there is a renewed interest in low-dimensional materials. Among the structures related to graphene, it is worth mentioning the carbon nanoscrolls (CNS). CNS can be topologically described as graphene sheets rolled up into a spiral shape (papyrus-like) [1]. CNS and scrolls of other elements have already been obtained. Recently, borophenes (single-layer boron structures) were predicted and experimentally realized [2,3]. A natural question is whether stable borophene scrolls can exist.

In the present work [4], we proposed and investigated the structural and electronic properties of boron-based nanoscrolls (armchair and zigzag) using the DFTB+ method. The electroactuation process (injecting and removing charges) was also investigated. Our results showed a giant electroactuation, similar to what was reported for carbon nanoscrolls [5]. Our results also show that the borophene scrolls are thermally and structurally stable for a large range of temperatures (up to 600K), and the electroactuation process can be easily tuned and can be entirely reversible for some configurations.

8:00 PM EL07.06.22 New Paradigm of Label-Free Biosensor Enabled by Two-Dimensional Hexagonal Titanium Oxide Yange Luan, Bao Yue Zhang and Jianzhen Ou; RMIT University, Australia

Biosensors with high sensitivity and selectivity are increasingly in demand, especially in the fields of medical devices, health monitoring, and treatment, etc. Two-dimensional (2D) materials-enabled nanotechnology has brought promising pathways in rapid, highly sensitive, and selective cancer biomarker sensors. The recently developed 2D planar hexagonal titanium oxide (h-TiO₂) monolayer derived from the metal-gas interface exhibited a unique narrowed bandgap and extraordinary carrier transport performance up to 950 cm²V⁻¹s⁻¹ at room temperature, compared to that of conventional bulk phased ones. The findings show exciting opportunities in realizing high-performance electronic biosensors.

Herein, we demonstrated the sensing capability of 2D h-TiO₂ by FET-based biosensor for carcinoembryonic antigen (CEA) detection-a representative broad-spectrum tumor marker. The h-TiO₂ nanosheets FET devices were functionalized with monoclonal CEA antibody using the probe linker of J-aminopropyltriethoxysilane. The dissociation constant between anti-CEA and CEA protein was estimated to be approximately 1.03 × 10⁻⁹ M by hill model, showing high affinity between CEA protein and anti-CEA. Multiple techniques including XPS, and KPFM were carried out to investigate the surface condition at each of the functionalization stages. The real-time measurement of 2D h-TiO₂ FET biosensor showed a high specificity of and an ultralow limit of detection (LOD) down to 0.23 pg ml⁻¹, exceeding the performance enabled by conventional 2D systems including graphene, black phosphorus (BP), transition metal dichalcogenides (TMDs), etc. The outcome of this work demonstrates the significant potential of 2D hexagonal metal oxide in biological sensing applications.

8:00 PM EL07.06.24
Role of Carbon-Based Nanocomposites for Energy Storage

Jake Irvin, Day Pham, Mason Cox and Ashish Aplehe; Kennesaw State University, United States

Certain allotropes of carbon have unique properties that have the potential for clean energy storage systems, healthcare, aerospace, and energy conversion applications. In this work, graphene-based nanocomposites (GNCs) were synthesized and investigated for their use in an ultracapacitor device. GNCs were selected for use as an electrode material for the supercapacitor due to their superior electrochemical properties and high surface area which is promising to provide superior energy storage performance. GNCs will be synthesized using an electrochemical deposition technique and the performance will be evaluated using various electrochemical studies in the presence of various different aqueous electrolytes. Distinct Faradaic and non-Faradaic charge transfer mechanisms will be investigated using cyclic voltammetry (CV), electrochemical impedance spectroscopy (EIS), and galvanostatic charge-discharge (GCD) studies. Results of different percentages of dopants in the nanocomposite during synthesis and their effect on ultracapacitor performance will be presented. Lifecycle testing of the ultracapacitor device will be discussed and its post-test analysis will be presented. The role of different substrates, electrolytes, and their effect on the device performance will be discussed. Mechanisms of charge storage and transfer between the electrolyte and GNC surface will be presented.

Mist CVD Modulated High-k a-AlxTiOy Films for p-WxSe1−x-Channel Metal Oxide Field Effect Transistors (MOSFETs) Abdul Kuddus1, Kojun Yokoyama2, Shinnichiro Mouri1,2, Keiji Ueno3 and Hajime Shiraishi1; Ritsumeikan University, Japan; 2Saitama University, Japan

Introduction: High-k amorphous (a-Al2O3, and a-TiO2) thin films from Al(aca)3, and Ti(aca)4;OIPr3 precursors dissolved in alcohol solvent investigated by mist CVD method in our previous reports [1,2]. In addition, the Al2O3, and TiO2 alloy of a-AlxTiOy (ATO) films revealed an adjustable dielectric constant of 6.23-25.12 and band gap of 4.25-6.38 eV studied. Further, an exfoliated MoSe2-channel MOSFET on Al2O3/TiO2 layer, thin film as gate insulator with Au as the source and drain electrodes showed a mobility of 85 cm2/Vs, the threshold voltage of 0.92 V, and an on/off current ratio greater than 10^6 [3]. However, a consistent fabrication of TMDCs such as MoSe2, MoS2, and WS2; WSe2 or their alloys such as WS2-xSex film and the high-k dielectric is highly promising toward large-scale device fabrication. To date, the synthesis of high-quality defect-free large-area TMDCs films and transfer-free device fabrication are major hindrances to further advancing in TMDCs-based devices technology. In this study, we investigated a consistent fabrication technique of metal oxide and TMDCs films as high-k dielectric and channel layers in MOSFETs toward transfer-free large-scale TMDCs device fabrications.

Experiment: A 0.015 M Al(aca)3, and Ti(aca)4;OIPr3 solution with CH3OH dilution was placed directly above a 3 MHz atomizer, N2 was used as a generator, and dilution gas (500 and 2400 sccm) was used to transport the mist. A cleaned Si substrate was placed 16 cm inside the tube furnace in the open air. On the other hand, ammonium tetathiotungstate (NH4)2WS3 dissolved in N-methyl-2-pyrrolidone (NMP) solvent was used as a precursor of WS2-xSex. The WS2-xSex films were synthesized by mist CVD with Ar gas containing H2 (25%) at a T of 400-600 °C at atmospheric pressure. Subsequent selenization of mist CVD WS2-xSex was executed to further improve the film's quality at T of 600 °C for 20 min. The p-WxSe1-xy-channel MOSFETs on ATO dielectric were fabricated with Pt source and drain electrodes [4].

Results and Discussion: The deposition rates were found of 11 nm/min for Al2O3/TiO2 layer, with an adjustable dielectric constant of 6.23-25.12 and band gap of 4.25-6.38 eV. While, an average flake size of over 700-800 µm on ATO substrate, the mobility over 40 cm2/Vs, the threshold voltage around 0.30 V, and an on/off current ratio in the range of 10^6 were obtained in p-WxSe1-xy-channel MOSFETs on ATO dielectric retaining reduced leakage current. Thus, a strong potential is revealed by the mist CVD to be used as a consistent manufacturing process for the fabrication of metal oxides and TMDCs films as high-k dielectric and channel layers in MOSFETs toward transfer-free, large-scale TMDCs device technology.

Atomic Layer Etch of Tungsten Disulfide Semiconductor using Downstream Plasma Treatment and Wet Etch Removal Young-Hyun You, Joonyn Baek and Jihyun Kim; Seoul National University, Korea (the Republic of)

Silicon has been used as a channel material for field-effect transistor (FET), driving the growth of the semiconductor industry. However, in modern technology where the channel size has been reduced to several nanometers, silicon has shown limitations such as short channel effects. Since numerous defects such as dangling bonds exist on the surface of silicon, the movement of carriers is hindered by the defects in channel with atomic-scale thickness. High-performance transistors with smaller form factor require the next-generation semiconductors to replace silicon. Recently, two-dimensional (2D) materials have drawn considerable attention due to their unique layered structure. Since layer-to-layer bonding is achieved through van der Waals (vdW) interaction, layer-to-layer separation can be easily achieved with relatively weak force. The separated monolayer has a complete structure and no defects on surface compared to silicon. Several semiconductor chip manufacturers have reported results of applying 2D materials as channels in various structures of next-generation transistors.

Transition-metal dichalcogenides (TMDCs) are one of the most actively studied 2D materials. Among them, WS2 has a very high electron mobility of ~234 cm2V−1s−1 and generally exhibits n-type behavior due to its sulfur vacancy. WS2 can also be used as a p-channel through p-doping and it is possible to implement a single semiconductor-based complementary metal–oxide–semiconductor (CMOS). Thickness-dependent energy band gap and excellent mechanical properties of WS2 enable multiple device applications such as photo detectors and wearable devices. However, various problems exist in the fabrication process of electrical devices with TMDCs. In general, the mechanical exfoliation is used for interlayer separation of TMDCs and it is difficult to obtain the materials with accurate thickness due to its randomness. Photore sistors or contaminants may also remain on the surface of TMDCs, which can cause interface defects and reduce device reliability. WS2 can be oxidized in atmosphere and the oxide layer gives an unwanted doping effect. The fabricated devices exhibit different electrical properties from those originally designed because of the above problems.

In this study, we propose a method to accurately control the thickness and restore the contaminated surface to the pristine state through atomic layer etching of WS2. Only the outermost layer of WS2 can be oxidized by self-limiting reaction using downstream O2 plasma. Subsequent KOH solution treatment selectively removes only the oxide layer (WOx) for layer-by-layer control of thickness. A back-gate FET using WS2 as a channel material was fabricated to confirm the changes of physical and electrical properties by atomic layer etching. The etch rate of WS2 channel measured with atomic force microscope (AFM) was approximately 0.65 nm/cycle, equivalent to the thickness of WS2 monolayer. Micro-Raman spectroscopy and high-resolution transmission electron microscopy (HR-TEM) showed that atomic layer etching had a minor effect on the crystallinity of WS2. Finally, the n-type behavior was recovered through the surface cleaning effect and the recessed-channel WS2 FET with improved output current on/off ratio higher than 10^6 was realized. This method, which provides a facile approach to thickness control and surface cleaning, allows TMDCs to be precisely engineered, increasing their potential as channel materials for next-generation transistors.
Electrochemical Sculpting of Phosphorene Nanoribbons: Unleashing the Anisotropy of Black Phosphorous

Jacek B. Jasinski, Usman Aba, Sharmin Akter, Bimal Nepal, Gamini Sumanasekera, Badrit Narayanan and Hui Wang; University of Louisville, United States

In recent years, phosphorene, a two-dimensional (2D) form of black phosphorus (BP), has garnered significant research attention due to its exceptional properties, including high carrier mobility (2,000 cm² V⁻¹s⁻¹), thickness-dependent bandgap (0.3 – 2.0 eV), and strong in-plane anisotropy. Moreover, phosphorene nanoribbons (PNRs) exhibit even more impressive characteristics owing to their one-dimensional (1D) nanostructure, which gives rise to additional quantum confinement effects, density of states redesign, and a high density of active edge sites. While several methods for producing PNRs have been explored, scalable synthesis with narrow widths remains challenging.

Here, we present our recently developed method termed "electrochemical sculpting" to synthesize PNRs through an electrochemical process utilizing the highly anisotropic ion diffusion in BP along the [001] (zigzag) direction. In this method, BP flakes are nanostructured via an electrochemical process into bundles of parallel PNRs separated by narrow amorphous phosphorus channels running along the zigzag direction, as confirmed by transmission electron microscopy (TEM) and in-situ Raman spectroscopy. A subsequent ultrasonic treatment in a solvent can be used to separate the PNR bundles into individual, well-defined PNRs. Using this low-cost and scalable electrochemical method, we were able to fabricate PNRs with confined widths (< 10 nm) that are significantly narrower than those produced by most previous methods. Our fabricated PNRs exhibit a highly confined structure with a suppressed B2g vibrational mode. Notably, when employed in field-effect transistors (FETs), the PNR bundles demonstrate n-type behavior, which differs from that of BP flakes.

In our ongoing study, we focus on understanding this process and extending it to other anisotropic 2D layered materials. So far, the obtained results indicate that electrochemical sculpting and the fabrication of nanoribbons can also be achieved in black arsenic-phosphorus (b-AsP) alloys, i.e., 2D layered materials where some of the phosphorus atoms in the BP structure are substituted by arsenic atoms. This is significant because b-AsP alloys are promising materials where some of the phosphorus atoms in the BP structure are substituted by arsenic atoms. This is significant because b-AsP alloys are promising.

The Seebeck coefficient is an important indicator of the thermoelectric (TE) properties of a material, so accurately measuring the Seebeck coefficient is essential. However, it is challenging to measure the Seebeck coefficient of a 2D film having extremely high resistance. Here, we propose a simple method to measure the intrinsic Seebeck coefficient of a 2D PtSe₂ thin films with high electrical resistance over 2 MΩ by two-step thermal annealing process. After two-step annealing process, the electrical resistance of the film was decreased from ~2 MΩ to ~400 kΩ and the intrinsic Seebeck coefficient could be measured, and the value is exceeding 159 μVK⁻¹, which is approximately 400% higher than that of single crystalline PtSe₂ bulk. Furthermore, the power factor of the sample was calculated up to 44 µWm⁻¹K⁻². Additionally, it was observed that the measured intrinsic Seebeck coefficient was independent of the top metal electrode. We discuss the role of thermal annealing process in high resistance 2D semiconducting films based on the atomic crystallographic characteristics and contact resistance between the film and electrode. Our findings demonstrate significant achievements in measuring and understanding the Seebeck effect of 2D transition metal dichalcogenide (TMDC) materials.

Preparation of 2D MoS₂ Atomic Layers from Precursor Solution Formulation and Simple Thermal Annealing for Patterned MoS₂ TFT Thi Thu Thuy Can and Woon-Steep Choi; Hoseo University, Korea (the Republic of)

Due to unique properties such as high carrier mobility and innate band gap, two-dimensional (2D) transition metal dichalcogenides (TMDs) have attracted great attention in optoelectronic and nanoelectronic fields as well. Among those atomically thin materials, molybdenum disulfide (MoS₂) has become an emerging candidate because of the indirect to direct band gap transition in monolayer limit. Chemical vapor deposition (CVD) with sulfur gas is the most popular method for synthesizing large-scale 2D materials with high quality. Various MoS₂ can be obtained from this method using various precursors with different properties, process temperatures, and substrate materials. Solution process methods show advantages for preparing films with large size, high throughput, low cost, thickness control, and an environmentally friendly process.

We developed a Mo-based solution formulation for solution-processed synthesis of MoS₂ with large-scale and uniformity. The precursor solution can be converted to atomic layer films using simple thermal annealing without using chemical vapour process. A MoS₂ thin film was prepared by a simple jet printing and one-step annealing method. Three atomic layers of MoS₂ were obtained with 0.0125 M of precursor solution, which was confirmed by STEM. The atomic layers of the synthesized MoS₂ were identified as 2 layers for 0.0070 M, 3 layers for 0.0125 M, and 5 layers for 0.0250 M of MoS₂ solution by STEM-FIB. A printed MoS₂ TFT shows a high current ratio of approximately 10⁶, a good mobility of 27.5 cm²V⁻¹s⁻¹, a threshold voltage of 1.76 V, and a subthreshold slope of 1.32 Vdec⁻¹.

8:00 PM EL07.06.29
Observation of Intrinsic Seebeck Coefficient of 2D PtSe₂ Semiconducting Films Through Two-Step Annealing Process Minjeong Kim, Yunho Kim, Jae Won Choi, Jungmin Cho, Hyeyoung Kwon, Gil-Sung Kim, Sangkwan Lee and No-Won Park; Chung-Ang University, Korea (the Republic of)

The Seebeck coefficient is an important indicator of the thermoelectric (TE) properties of a material, so accurately measuring the Seebeck coefficient is essential. However, it is challenging to evaluate the Seebeck coefficient of a 2D film having extremely high resistance. Here, we propose a simple method to measure the intrinsic Seebeck coefficient of a 2D PtSe₂ thin films with high electrical resistance over 2 MΩ by two-step thermal annealing process. After two-step annealing process, the electrical resistance of the film was decreased from ~2 MΩ to ~400 kΩ and the intrinsic Seebeck coefficient could be measured, and the value is exceeding 159 μVK⁻¹, which is approximately 400% higher than that of single crystalline PtSe₂ bulk. Furthermore, the power factor of the sample was calculated up to 44 µWm⁻¹K⁻². Additionally, it was observed that the measured intrinsic Seebeck coefficient was independent of the top metal electrode. We discuss the role of thermal annealing process in high resistance 2D semiconducting films based on the atomic crystallographic characteristics and contact resistance between the film and electrode. Our findings demonstrate significant achievements in measuring and understanding the Seebeck effect of 2D transition metal dichalcogenide (TMDC) materials.

1D Topological Systems for Next-Generation Electronics Judy Cha; Cornell University, United States

Topological nanowires, topological materials confined in one dimension (1D) at the nanoscale, hold great promise for robust and scalable quantum
computing and low-dissipation interconnect applications, which will transform current computing technologies. To do so, research in topological nanowires must continue to improve their synthesis and properties.

In this talk, I will discuss my group’s efforts to develop a synthesis method that is high throughput, scalable, and well controlled to fabricate 1D topological systems with precision in crystalline phase, morphology, and dimensions [1]. I will highlight our results on topological semimetal nanowires that can rival current state-of-the-art Cu interconnects for low-resistance interconnect applications. Specifically, we experimentally demonstrate that the resistivity scaling of MoP nanowires is superior to those of the latest Cu interconnect technologies and Cu alternative metals [2], presenting MoP as a breakthrough metal for the low-resistance interconnect applications.

Unconventional Resistivity Scaling in Nanocrystalline NbP and TaP sub-5 nm Thin Film Asir Intisar Khan1, Emily Lindgren1, Xiangjun Wu1, Hyun-Mi Kim2, Akash Ramdas1, Byoungjun Won1, Felipe Jornada1, Il-Kwon Oh1, H.S. Philip Wong1, Yuri Suzuki2 and Eric Pop1; 1Stanford University, United States; 2Korea Electronics Technology Institute (KETI), Korea (the Republic of); 3Ajou University, Korea (the Republic of)

The electrical resistivity of ultrathin metal films typically increases with decreasing film thickness due to electron scattering from the film surfaces. This behavior limits the performance of metal-based interconnects in all modern nanoelectronics [1]. To overcome this bottleneck, novel quantum materials like topological semimetals with disorder-tolerant conductive surface states have been suggested in the ultrathin film limit [2, 3].

Here we uncover the reduction of electrical resistivity with decreasing film thickness of ultrathin nanocrystalline NbP and TaP films, probed by detailed transport measurements, material characterization, and modeling. These materials have been demonstrated to be topological Weyl semimetals in the bulk [2], a class of materials wherein surface conduction is predicted to dominate thin-film transport even in the presence of disorder [3].

NbP and TaP thin films are sputtered on both r-plane sapphire and MgO substrates at 400 °C, a process compatible with back-end-of-the-line (BEOL) semiconductor fabrication. A thin seed layer of Nb (or Ta) is used to reduce lattice mismatch between the substrate and sputtered NbP (or TaP) thin films. High-angle annular dark-field (HAADF) scanning transmission electron microscope (STEM) imaging reveals nano-crystallinity of the ultrathin NbP films with short-range ordering at the NbP surface, irrespective of the film thickness. The compositional homogeneity of the NbP thin films is further confirmed by energy-dispersive X-ray analysis.

Our measured resistivity of NbP at room temperature decreases from 207 to 149 μΩ-cm (from ~18 nm down to ~2.3 nm film thickness), unlike conventional metals. We further confirm the decreasing resistivity trend with decreasing thicknesses of NbP film irrespective of the thickness of the seed layer. For example, with a 4 nm Nb (Ta) seed layer, we find that the resistivity of NbP thin films decreases from 135 μΩ-cm (18 nm thick film) to ~34 μΩ-cm (~1.5 nm thin film). On the other hand, the measured resistivity for ~1 nm thin TaP film is ~12 μΩ-cm. For both cases, the resistivity is significantly lower than the bulk single-crystal resistivity. We also note that the resistivity of NbP (TaP) thin films with a 4 nm seed layer is lower compared to their thinner seed layer counterparts due to possible charge transfers from the thicker metal seed layer to the NbP (TaP) thin films.

Temperature-dependent electrical resistivity measurements of NbP show a significantly weaker temperature dependence of resistivity in the thin NbP compared to control metal Nb. This behavior suggests a disorder-driven localization of conduction instead of phonon-dominated transport. To understand our measurements, we present a transport model in terms of a surface channel and bulk conduction in all films with surface-dominated conduction in the thinner NbP films leading to a decrease in effective electrical resistivity. Our measured Hall resistance is nearly linear with the magnetic field. This is a signature of transport dominated by single carriers (holes for NbP).

In summary, we demonstrated an unconventional resistivity scaling trend with the film thickness in sub-5 nm NbP and TaP thin films. Our transport measurements suggest surface-dominated conduction in such materials even at room temperature, which is promising for next-generation nanoelectronics.

8:45 AM EL.07.07.03
Synthesis of Thin Film Weyl Semimetal TaP Arka Chatterjee and Shengxi Huang; Rice University, United States

Topological Weyl semimetals (WSMs) have opened up a new horizon in physics and materials science due to their unique electronic, optical, and thermal properties. So far, experimental studies of WSMs have mainly focused on bulk samples. However, it has been predicted that thin films of WSMs could generate unique phenomena unachievable by bulk crystals, such as the unusual twisting of the Fermi surface, a metal-insulator transition upon thickness confinement, and the emergence of Floquet topological insulator phase modes. Furthermore, the synthesis of WSM thin films could potentially open up opportunities for creating heterostructures and functional interfaces with other materials, such as superconductors, ferromagnetic or antiferromagnetic materials, and ferroelectric materials. These interfacial interactions have been found to be promising for applications in spintronics and superconducting devices. Thus, the synthesis of thin film WSMs would be impactful from both fundamental and practical standpoints.

TaP, a type of WSM, has attracted significant attention due to its cleanest carrier pockets close to the Weyl fermions dominated Fermi energy and unsaturated negative magnetoresistance (MR), highlighting its potential for electronic applications. Here, we report the successful synthesis of thin films of TaP using a fast thermal process. State-of-the-art characterization techniques were employed to confirm the high quality of the synthesized TaP thin films. The electronic and optical properties were also obtained. Our synthesis method also offers the potential for wafer-scale manufacturing of thin film TaP. In summary, our synthesized TaP thin films hold great promise in both fundamental topological physics and novel electronic applications.

Transport and Electron-Phonon Coupling of 2D Electrons in Layered Electrides

Vahid Askarpour and Jesse Maassen; Dalhousie University, Canada

Layered electrides are ionic solids comprised of weakly-interacting atomic layers in which the conducting 2D electrons are confined to the interstitial region between the atomic planes, or on their surfaces when exfoliated to form 2D electrides. Because the conducting electrons are physically separated from the lattice, layered electrides display high conductivity, low electron-phonon (el-ph) coupling, and low work function. As a result, they are promising material candidates for applications in transparent conductors, electron emitters, ohmic contacts to 2D semiconductors, and interconnects.

In this talk, we present our first-principles study exploring the transport and electron-phonon scattering characteristics of seven layered electrides of the form M2X, where M is an alkaline earth metal (M = Ca, Sr, Ba) and X is a pnictogen (X = N, P, As, Sb). Our density functional theory calculations reveal that Sr2N and Ca2N have the lowest electrical resistivity and el-ph scattering rates among this group of electrides. To better understand what controls these properties, we analyze and compare their scattering phase space, average el-ph coupling, distribution of modes, average velocity, and mean-free-path for backscattering. Interestingly, while Ca2N shows some of the lowest el-ph collision rates, resulting from its small scattering phase space, it has the largest el-ph interaction strength. Repeating these calculations for the metals Al, Au, and Cu reveals that their el-ph coupling can be an order of magnitude greater than the electrides. The decoupling of the conducting 2D electrons from the lattice in layered electrides, leading to weak el-ph interaction, suggests that these materials may be promising interconnects in nanoelectronic circuits.

10:15 AM EL07.07.07
Monte Carlo Simulation of Joule Heating in Monolayer MoS2 Devices

Maritha A. Wang and Eric Pop; Stanford University, United States

Two-dimensional (2D) transition metal dichalcogenides (TMDs) like monolayer MoS2 have emerged as promising semiconductors for nanoscale transistors and electronics due to their good charge mobilities at small thicknesses compared to ultrathin silicon [1]. However, to engineer high-performance 2D transistors, a detailed understanding of charge scattering and heat generation in TMDs is needed. When electrical current passes through a transistor, heat is generated due to electron-phonon scattering, an effect known as Joule heating. This effect occurs even in nanoscale transistors, where charge transport is partially ballistic [2]. Joule heating leads to increased phonon occupation, causing additional electron-phonon scattering, and thus a degradation of electrical transport; it also causes reliability concerns [2].

Here, we employ Monte Carlo simulations to investigate charge transport in monolayer MoS2 transistors with Joule heating, inspired by earlier approaches with silicon [3]. We consider intravalley and intervalley electron-phonon scattering using the deformation potentials from [4]. To incorporate Joule heating, we consider the back-gated transistors frequently used in experimental transport studies on 2D semiconductors. The thermal resistance Rth of such a device is estimated as the sum of 1) the thermal boundary resistance of the MoS2-SiO2 interface, 2) the thermal resistance of the underlying oxide (SiOx), and 3) the thermal resistance of the back-gate (Si) [5]. Such a thermal model can be easily modified to include heat loss through a top-gate or gate-all-around geometry for more general device structures [6].

The Monte Carlo approach is advantageous because it provides rich details about the contributions of different phonon modes to heating. With this approach, we simulate electron drift along the MoS2 channel as the transistor heats up due to Joule heating. At steady-state, the average temperature rise is ΔT = P/Rth, where P is the power generated in the MoS2 channel. This P is computed by summing the heat generated from electron-phonon scattering events and agrees with the expected P = IV, where I is the current and V is the potential across the channel. At 300 K ambient temperature, carrier density of 10¹³ cm⁻², and lateral electric fields in the velocity saturation regime (~4-5 V/µm), our simulations show that Joule heating leads to a transistor temperature rise of ΔT ≈ 200-250 K during steady-state operation. This heating decreases the electron saturation velocity by >50% compared to when heating is not considered, indicating that high-field measurements of transistor operation must consider self-heating during analysis [7].

Overall, this work highlights the important consequences of Joule heating on charge transport in monolayer MoS2 transistors. These simulations can further be extended to other TMDs and transient (i.e. digital) operation to identify design parameters for high-performance TMD devices that minimize Joule heating. This work was in part supported by the NSF Graduate Research Fellowship and Shoucheng Zhang Fellowship (M.A.W.) and by the SRC ASCENT JUMP Center (E.P.).

10:30 AM EL07.07.08
Intact Electrical Contact to Air-Sensitive Atomically Thin Semiconductors and Their Optoelectronic Applications

HaeYeon Lee, Zhiying Wang, Yang Liu and James Hone; Columbia University, United States

Two-dimensional semiconductors have been extensively explored with remarkable potential for applications in electronics and optoelectronics, however, high contact resistance and disorders in the monolayer still constrain harnessing their novel optoelectronic properties. There have been a lot of efforts to overcome these challenges such as using semimetal or low temperature metal deposition. Unfortunately, these approaches are not applicable for air-sensitive materials such as MoTe2 or NbSe2, as they require exposing the materials to deposit metal on top. Therefore, degradation is unavoidable unless the materials are completely encapsulated throughout the entire fabrication process. In the monolayer limit, this degradation issue becomes more critical. While the introduction of a protection layer between metal and the monolayer can prevent exposure of the monolayer to the air, it can inadvertently impede charge transfer, resulting in deteriorated performance.

Here, we present a novel technique that enables intact electrical contact to air-sensitive monolayer semiconductors while simultaneously achieving high performance by tackling both two issues. Our approach involves the perfect sealing of the air-sensitive monolayer MoTe2 throughout the process by

\[ P = IV \]

where \( P \) is the power generated in the channel, \( I \) is the current, and \( V \) is the potential across the channel. At 300 K ambient temperature, carrier density of 10¹³ cm⁻², and lateral electric fields in the velocity saturation regime (~4-5 V/µm), our simulations show that Joule heating leads to a transistor temperature rise of ΔT ≈ 200-250 K during steady-state operation. This heating decreases the electron saturation velocity by >50% compared to when heating is not considered, indicating that high-field measurements of transistor operation must consider self-heating during analysis [7].

\[ R_{th} = R_{1} + R_{2} + R_{3} \]

where \( R_{1} \) is the thermal boundary resistance of the MoS2-SiO2 interface, \( R_{2} \) is the thermal resistance of the underlying oxide (SiOx), and \( R_{3} \) is the thermal resistance of the back-gate (Si) [5]. Such a thermal model can be easily modified to include heat loss through a top-gate or gate-all-around geometry for more general device structures [6].

\[ P = IV \]

indicating that high-field measurements of transistor operation must consider self-heating during analysis [7].

Overall, this work highlights the important consequences of Joule heating on charge transport in monolayer MoS2 transistors. These simulations can further be extended to other TMDs and transient (i.e. digital) operation to identify design parameters for high-performance TMD devices that minimize Joule heating. This work was in part supported by the NSF Graduate Research Fellowship and Shoucheng Zhang Fellowship (M.A.W.) and by the SRC ASCENT JUMP Center (E.P.).
In addition to their utility in guiding transistor design and optimization, predicting temperatures, estimating transient heating and cooling rates, and (4) top gates can lower temperatures by as much as 30% and 50% for wide and narrow (~50 nm width) devices, respectively.

While promising candidates for next-generation transistors, two-dimensional (2D) semiconductors like MoS2 suffer from unique challenges due to the van der Waals gaps at their interfaces. These have made it difficult to achieve good electrical contacts, and they also result in relatively high thermal boundary resistances (TBR) to adjacent materials [1, 2]. In much the same way the electrical contact resistance is a key limiter of performance for nanoscale 2D transistors, the TBR is a major bottleneck for the cooling of these devices [2]. Coupled with their atomically thin channel which has limited capability of in-plane heat transport, this results in elevated temperatures during operation, reducing mobility [3] and posing thermal degradation and reliability concerns [4].

Here, we present fast analytical thermal models for common 2D transistors, carefully taking into account their thermally-resistive interfaces, contact geometry and other non-idealities. We first develop a steady-state thermal model for simple back-gated transistors, which quantifies the device temperature for a given power input. This model elucidates the cooling mechanisms for a wide range of device geometries and material combinations, highlighting in particular the crucial role of the contacts. Notably, scaling down the channel length does not necessarily lead to improved cooling performance as commonly assumed, because metal contacts are not ideal heat sinks for typical 2D material TBR and thermal conductivity values. Next, we extend this work into frequency-dependent models that can estimate the complex-valued device thermal impedance, which characterizes the amplitude and phase of temperature oscillations for sinusoidally-varying power. These models can be used to predict device thermal time constants, as well as to compute the temperature response to arbitrary power pulses, through an inverse Fourier transform. Finally, we generalize our models to top-gate and dual-gate FETs by accounting for the heat transferred to the contacts via the top gate. We validate our models against finite-element method simulations, with a worst-case temperature error of <1% across typical device geometries and material/interface properties.

Key insights gained from this work include: (1) the thermal resistance of 2D transistors is relatively insensitive to channel length for sub-100 nm devices, which are dominated by their contact thermal resistance, (2) the short-channel transistor thermal resistance is influenced equally by the 2D material TBRs and the in-plane thermal conductivity, while also depending on contact geometry, (3) due to their ultrathin channel, thermal time constants of 2D transistors are often sub-nano-second, making it difficult to probe intrinsic device performance (i.e. not limited by self-heating) with pulsed electrical measurements, and (4) top gates can lower temperatures by as much as 30% and 50% for wide and narrow (~50 nm width) devices, respectively.

In addition to their utility in guiding transistor design and optimization, predicting temperatures, estimating transient heating and cooling rates, and detailing pathways for heat flow, our fast analytical thermal models for 2D transistors can also be packaged into direct-current (DC), alternating-current (AC) and transient electrical compact models which incorporate self-heating. This work was supported in part by the Stanford SystemX Alliance, by the Semiconductor Research Corporation (SRC) and DARPA JUMP Centers, and by the National Science Foundation (NSF) Engineering Research Center for Power Optimization for Electro-Thermal Systems (POETS).

Observing Aharonov-Bohm Oscillations in CVD-Grown, Parallel Graphene Nanoribbons at 4K

11:00 AM  EL07.07.10

The Aharonov-Bohm (AB) effect demonstrates that the orbital wave function of a charged particle picks up a different phase when it moves along two different paths in the presence of an external magnetic field, which is proportional to the magnetic flux of the enclosed area divided by Planck's constant. While the AB effect has been studied in various semiconductors, including GaAs, InP, InAs, AlGaSb, phosphorene, and Bi2Se3 [1–3], graphene is an ideal material for studying the AB effect owing to its long coherence length of electrons: The electron coherence length in graphene is stated as 3-5 µm at 260 K, and 765 nm-1.25 µm at 4 K [4] For this reason, several studies have been conducted on the AB effect in mechanically exfoliated graphene rings to examine the fundamental mode given by the sample geometry ranging from 155 to 242 1/T, and the interval of the AB from 4.14 mT to 6.46 mT, as expected for two GNRs conjoined at the start and the end, with the spacing between the GNRs of 800 nm and the arm width of 200 nm. The fast-Fourier transform (FFT) data showed a broad band of AB oscillation frequencies that constitute the interval of 1/T. This work shows the AB oscillations in the lower mobility, non-suspended monolayer GNRs at a significantly high temperature (4K). We are currently working on modifying and improving the GNR design based on modeling inputs, including fabricating cascaded-parallel GNRs to seek amplifying oscillation signals.

Heat Dissipation in 2D Material Transistors: The Role of Interfaces and Contacts

Semiconductor Research Corporation (SRC) and DARPA JUMP Centers, and by the National Science Foundation (NSF) Engineering Research Center for Power Optimization for Electro-Thermal Systems (POETS).

Fluorinated graphene layer. At the same time, fluorine atoms improve the charge transmission between metal and MoTe2 by reducing the interatomic spacing. As a result, monolayer MoTe2 field effect transistor exhibits more than two orders of magnitude improvement in contact performance with excellent ambipolar behavior. By taking advantage of low contact resistance, intrinsic electrical properties of monolayer MoTe2 are comprehensively elucidated. Furthermore, efficient charge transfer of both electrons and holes enables fabricating lateral p-n homojunction. The small band gap (1.1 eV) of monolayer MoTe2 coupled with its compatibility with silicon holds promising potential for optoelectronic application including photodetector. Moreover, the electrical contact technique introduced in this study can be extended to offer air sensitive materials, broadening its applicability.
Due to our life style changes, data created exponentially and continuously increases. To respond to the huge data created, conventional Si device scaling down for angstrom era, and 3D stacking device and introduction of disruptive device should be considered [1]. However, the process technology and material performance of Si devices are gradually reaching their limits, and the development of new materials, processes and device architectures is required to overcome these limitations. Graphene and 2D Materials have an ultra-thin crystal structure with a stable surface state. For example, among diverse 2D materials, MoS2 has a great potential in logic transistor because of its high mobility, and no short channel effect [2]. In this talk, we will introduce 2D material and integration designs via interface property control to realize the Angstrom-scale multi-stack device: (i) adhesion pattern [3] and (ii) Interconnect with a low thermal contact metal barrier [4] and ultralow dielectric material [5].

multiple processes of thermal annealing and diffusion doping. Ambipolar materials such as WS₂ can be expected to reduce process complexity with a single-channel CMOS device structure. Therefore, the proposed p-doping methods in this study enable the fabrication of complementary metal-oxide semiconductor (CMOS) devices with down-scaled architectures.

What Are 2D Materials Good For? Eric Pop, Stanford University, United States

This talk will present my (biased!) perspective of what two-dimensional (2D) materials could be good for. For example, they could be good for applications where their ultrathin nature gives them distinct advantages, such as flexible electronics [1] or light-weight solar cells [2]. They may not be good where conventional materials work sufficiently well, like transistors thicker than a few nanometers. I will focus on 2D materials for 3D heterogeneous integration of electronics, which presents major advantages for energy-efficient computing [3]. Here, 2D materials could be monolayer transistors with ultralow leakage [4] (due to larger band gaps than silicon), used to access high-density memory [5]. Recent results from our group [6,7] and others [8] have shown monolayer transistors with good performance, which cannot be achieved with sub-nanometer thin conventional semiconductors, and the 2D performance could be further boosted by strain [9]. I will also describe some unconventional applications, using 2D materials as thermal insulators [10], heat spreaders [11], and thermal transistors [12]. These could enable control of heat in “thermal circuits” analogous with electrical circuits. Combined, these studies reveal fundamental limits and some unusual applications of 2D materials, which take advantage of their unique properties.

High-Mobility Flexible Transistors with Low-Temperature Solution-Processed Tungsten Dichalcogenides Tian Carey, Oran Cassidy, Kevin Synnatschke, Eoin Coffrey, James Garcia, Shixin Liu, Harneet Kaur, Adam G. Kelly, Jose Munuera, Gian Gabbett, Domhull O’Suilleabhaín and Jonathan N. Coleman, Trinity College Dublin, Ireland

Solution-processed electronic inks with two-dimensional (2D) materials have the potential to enable the next generation of low-cost printed digital electronics. [1] Here we will present the advances in fabricating printed complementary inverters achieving a voltage gain |ΔV| ≈ 0.1 with liquid phase exfoliated (LPE) flakes and discuss the limitations of the technology. [2] The electrochemical exfoliation of large-aspect-ratio (>100) semiconducting flakes of tungsten diselenide (WSe₂) and tungsten disulfide (WS₂) as well as molybdenum disulfide (MoS₂) will be necessary to create a library of high-mobility solution-processed networks that conform to substrates, remain functional over thousands of bending cycles and can be utilised in complementary solution-processed circuits.

We will present the use of Langmuir–Schaefer coating to achieve highly aligned and conformal flake networks of flakes, with minimal mesoporosity (~2–5%), at low processing temperatures (120 °C) and without acid treatments. [3] Our processing enables the fabrication of state-of-the-art flexible transistors in ambient air, achieving average mobilities μ > 10 cm²V⁻¹s⁻¹, with a current on/off ratio of L₅₀/L₉₀ ≈ 10⁵–10⁶. [3] We will also demonstrate subthreshold slopes as low as 182 mV/dec, essential for maintaining power efficiency and examine the performance of our WSe₂ transistors after 1000 bending cycles at 1% strain.[3] Additionally, we will demonstrate air-stable, low voltage (~5 V) operation of inkjet-printed CMOS with MoS₂, with a voltage gain above unity |ΔV| ≈ 1.4. [4] The results represent a critical enabling step towards ubiquitous long-term stable, low-cost solution-processed digital integrated circuits.[4]

Bi-MoS₆C Contacts in the Ultra-clean Limit: Closing the Theory Experiment Loop Zhivine Wang¹, Yang Liu¹, Song Liu¹, Amirali Zangiabadi² and James Hone¹; ¹Columbia University, United States; ²University at Buffalo, The State University of New York, United States

Achieving robust electrical contacts has emerged as a key challenge to realizing the promise of monolayer two-dimensional (2D) semiconductors, such as semiconducting transition metal dichalcogenides (s-TMDs) in next-generation electronic technologies. While recent work has reported breakthroughs in achieving low contact resistance using defective s-TMDs, there still exists a lack of fundamental understanding of the contact interfaces, especially, the role of defects within the s-TMD and external disorder in achieving the reported low contact resistance is not well understood.

In this work, we study bismuth (Bi) semimetal contacts to monolayer molybdenum diselenide (MoSe₂), utilizing a device platform that combines ultrahigh-purity MoSe₂, damage-and strain-free interfaces, and encapsulation of the channel within hexagonal boron nitride (hBN). The ultrahigh-purity MoSe₂ crystal is characterized through dedicated STM imaging. Gaps etched in the hBN define the contact regions and stabilize the structure. We characterize the damage-free and strain-free metal-semiconductor junction with atomically sharp interface by cross-sectional STEM imaging. We quantify the contact characteristics using contact-frontend and contact-end measurements that go beyond the basic transfer length method. These measurements reveal large differences between sheet resistance inside the channel (Rₐ) and underneath the contacts (Rᵥ), which are assumed to be equal in the standard transfer length method. We employ a charge transfer model to gain further insight into the microscopic mechanism of vertical transport across the van der Waals metal-s-TMDs interface. In deeply scaled contacts, we directly observed a steep increase in end resistance when the contact length downscaled to around 40 nm, in agreement with the experimental and theoretical model derived characteristic length. This integrated approach can be readily expanded to other clean semiconductors to allow better comparison between theory and experiment.
Transition metal dichalcogenides (TMDCs) have emerged as alternative 2D materials for field effect transistor fabrication. Molybdenum disulfide (MoS2) is a TMDC with semiconducting properties with monolayer (1ML) MoS2 having a 1.8 eV direct bandgap and multilayer (~2ML) MoS2 a 1.2 eV indirect bandgap [1]. Sulphur vacancies tend to form on the top sulphur layer which gives MoS2 a natural n-type doping. However, exposure to ambient oxygen and humidity oxidizes the surface of MoS2 and, along with increased number of defects from the sulphur vacancies, MoS2-based devices can lose performance. Therefore, encapsulation with different materials has been suggested as a solution for improving the device performance [2]. Hexagonal boron nitride (h-BN) is a 2D material with a 6.1 eV band gap [3] which can be utilised as an encapsulation material and also an insulator. The weak basal plane van der Waals forces of h-BN will not modify the surface of MoS2 and hence improve the device performance.

One of challenges of 2D materials is the lack of scalable and reproducible large area 2D material growth. We propose to utilise pulsed laser deposition (PLD) as an alternative to high-quality, large-area growth of 2D materials capable of depositing uniform, large-area, thin-films with good control of the deposition parameters. High quality MoS2 thin films can be grown with PLD [4], on the other hand, h-BN is difficult to grow with PLD because it needs temperatures above 1000°C. Therefore, amorphous boron nitride (a-BN) is grown as encapsulation, featuring large dielectric strength and low refractive index [5].

In this work, PLD was used to deposit a-BN thin-films on SiO2/Si substrates. Subsequently, PLD was used to deposit the MoS2/a-BN heterostructure on SiO2+Si substrates with optimized deposition parameters for MoS2 [4] and a-BN, varying the thickness of MoS2: (1ML, 2ML, 4ML, 10ML, 15 ML). Back-gated field effect transistors (FETs) were fabricated on the MoS2/a-BN heterostructure samples using standard lithography techniques, followed by e-beam evaporation of Ti/N/Au contacts and rapid thermal annealing to reduce the contact resistance. The MoS2/a-BN back-gated FETs were electrically characterized, resulting in mobilities increasing one order of magnitude when compared to back-gated MoS2 FETs without encapsulation. The devices can turn on and off, although their leakage current is still significant (~10² - 10³ nA), which can be attributed to the large voltages needed to control the gate (~50 V).

Density functional theory (DFT) studies to understand the metal interface will also be conducted and the results will be presented. DFT simulations of MoS2-based back-to-back Schottky devices will be shown to compare the measured output characteristics with the calculated ones. The effect of h-BN encapsulation on the back-to-back Schottky devices was also calculated.

An Investigation of Lithium and Cobalt Intercalation Method in 2D Transition Metal Dichalcogenides Yongha Shin and Woojong Yu; Sungkyunkwan University, United States

In recent studies, it has been confirmed that 2D van der Waals (vdW) materials, including magnetic elements such as CrI₃, Fe₂GeTe₂, Cr₇Ge₃Te₆, V₅S₆, and VO₃₅ exhibit long-range ferromagnetic order. In addition, the previous studies have explored improving electrical properties by injecting magnetic dopants into 2D transition metal dichalcogenide (TMD) materials with semiconductor properties or chalcogen defects. However, the intercalation method of inserting a magnetic element between the van der Waals planes of 2D TMDs has rarely been explored. This study proposes implementing ferromagnetism by inserting Cobalt (Co) between layers of Molybdenum ditelluride (MoTe₂) using a wet chemical method that sequentially proceeds with Li intercalation and Co intercalation. n-Butyllithium diluted in hexane is widely used as a reagent for Li intercalated complexes because Li has a small atomic radius, high reactivity, and can react at room temperature. 2D TMD materials can exist in a 2H (semiconducting) or 1T (metallic) phase. MoTe₂ typically exists in a 2H phase under atmospheric conditions and has the lowest equilibrium energy difference between 2H-1T among TMD materials. Pristine 2H-MoTe₂ undergoes a phase transition to 1T-MoTe₂ by Li intercalation for 48 hours. This phase transition is confirmed by the 1T peak observed in the Raman spectrum and the change in gap distance from 6.97 to 6.95 Å measured by X-ray diffraction (XRD) analysis. Li-intercalated 1T-MoTe₂ induces ionic exchange during secondary Co intercalation due to its strong reducing ability, effectively allowing zero-valent Co to settle within the vdW gap instead of Li ion. Dicobalt octacarbonyl, Co₃(CO)₁₂, is used as a precursor to provide Co.

Effect of Hot-Wire Oxidation and Sulfur Annealing on Layered p-MoS2 for TFT Application Kousaku Shimizu; Nihon University, Japan

High-quality p-type Thin Film Transistors have drawn considerable attention for switching elements in active matrix displays such as OLEDs and LCDs. We are investigating sputtered amorphous p-MoS₂ thin films for one of the good candidates. Hot-wire oxidation and sulfur annealing have been done to improve TFT performances. Raman spectroscopy and XPS were employed to characterize the film structure and compared with Id-Vg characteristics. The sputtered amorphous MoS₂ is generally p-type[1], and the film consists of a stack of small two-dimensional MoS₂ pieces. To reduce the valence mismatch between metals and MoS₂, Cr/Cu double-layered electrode was employed. According to the TFT simulations, ATLAS, the mobility of TFT with Cr/Cu source-drain electrodes was the highest performance, around 9.95 cm²/Vs. After annealing at 200°C for one hour in air, it increased by 51.42 cm²/Vs. It has found that the sputtered film had many sulfur defects according to the TFT simulation and XPS study. To compensate for the defects, we have tried oxidation by the Hot-Wire method. As a result, the mobility increased to 62.73 cm²/Vs. The effect of oxygen introduction has been investigated by first-principles calculations [2]. Furthermore, it was found that the sulfur defects exist between the layers must be reduced in order to reduce the off-current. It was annealed at 200°C for 1 hour in a metal-sealed container containing S powder. We have succeeded in suppressing the off-current less than 10⁻¹⁰ A.

Photoelectrochemical Polymerization (PEP) of EDOT for Formation of Pattered PEDOT at Specific Arbitrary Regions on Hematite (α-Fe₂O₃) Misol Hwang, Taeyoon Kim and Joohoon Kim; Kyung Hee University, Korea (the Republic of)

We performed photoelectrochemical polymerization (PEP) on hematite (α-Fe₂O₃) to synthesize PEDOT (poly(3,4-ethylenedioxythiophene)) in specific arbitrary regions with a high 2D flexibility. PEDOT is a conductive polymer that is highly attractive due to its ability to enhance conductivity and stability of electrical activity when used as crosslinkers or fillers. Hematite, as a semiconductor material with a bandgap of 1.9-2.2 eV, generates minority charge carriers (holes) with a short diffusion length when exposed to visible light. we confirmed the synthesis of PEDOT on hematite using cyclic voltammetry, CO₂RR, Nitrogen Reduction Reaction (NRR),Iodide oxidation reaction (IOR).However, the topological correlation with electrochemical reactivity is relatively less reported due to a lack of high spatial resolution electrochemical measurement techniques. In this work, an advanced scanning electrochemical cell microscope (SECCM) is used to probe the microscale electrochemical reactivity of 2D materials for HER. With minute electrolyte droplets and surface feedback signals to adjust the surface-to-probe height, a highly spatial resolved topological correlation with electrochemical reactivity for 2D materials is revealed.

We have previously used SECCM to evaluate the activity of MoS₂, identifying the HER activity differences between edge areas and basal areas. Besides the defect related active sites, some processes were also applied to manipulate the surface properties of 2D materials for enhanced reaction activity, such as light modulation, strain, or surface polarization. The morphological and topological properties that correlated to the water splitting performance of 2D materials were visually revealed through the measurements of Kelvin probe (KPFM), piezo response force microscopy (PFM), and SECCM. This work fills the gap between electrocatalytic HER and topological properties of 2D materials, and provides a microscopic understanding to further improve water splitting performance for clean energy.

8:00 PM EL07.09.09
Spatially Resolved and In Situ Electrochemical Imaging on Two-Dimensional Materials using Scanning ElectroChemical Cell Microscopy (SECCM) Lu Yang-Sheng¹, Yu Chun-Hung¹, Cheng Yu-Chieh⁵, Chen Chun-Wei² and Li Shao-Shian¹; ¹Institute of Materials Science and Engineering, National Taipei University of Technology, Taiwan, Taiwan; ²Department of Materials Science and Engineering, National Taiwan University, Taiwan, Taiwan; ³Department of Electro-Optical Engineering, Taipei Tech, Taiwan

In recent years scientists have used microelectrode technology to probe the electrochemical properties of a surface of interest through position feedback, allowing direct topographic and electrochemical imaging. It is especially important to determine the topological information correlated to the electroactivity of atomically thin 2D materials. Many researches have revealed that two-dimensional materials possess a promising potential for electrochemical catalytic reactions, such as Hydrogen Evolution Reaction (HER), Oxygen Evolution Reaction (OER), Carbon Dioxide Reduction (CO₂RR), Nitrogen Reduction Reaction (NRR),iodide oxidation reaction (IOR).However, the topological correlation with electrochemical reactivity is relatively less reported due to a lack of high spatial resolution electrochemical measurement techniques. In this work, an advanced scanning electrochemical cell microscope (SECCM) is used to probe the microscale electrochemical reactivity of 2D materials for HER. With minute electrolyte droplets and surface feedback signals to adjust the surface-to-probe height, a highly spatial resolved topological correlation with electrochemical reactivity for 2D materials is revealed.

We have previously used SECCM to evaluate the activity of MoS₂, identifying the HER activity differences between edge areas and basal areas. Besides the defect related active sites, some processes were also applied to manipulate the surface properties of 2D materials for enhanced reaction activity, such as light modulation, strain, or surface polarization. The morphological and topological properties that correlated to the water splitting performance of 2D materials were visually revealed through the measurements of Kelvin probe (KPFM), piezo response force microscopy (PFM), and SECCM. This work fills the gap between electrocatalytic HER and topological properties of 2D materials, and provides a microscopic understanding to further improve water splitting performance for clean energy.
Nanowire-Based Sensor Platform for Breath Analysis

Marios Constantinous, Sotirios Christodoulou, Agapios Agapiou and Chrysafis Andreou; University of Cyprus, Cyprus

Nanomaterials, such as nanowires (NWs), are enabling new directions in nanotechnology with significant applications in the biomedical sector. With the use of Surface-Enhanced Raman Spectroscopy (SERS) as an analytical technique for rapid biomarker identification, nanomaterials can play a pivotal role in shaping the next generation of non-invasive, rapid, and pain-free diagnostic devices. Potential applications include breath analysis for cancer screening. SERS is an ultra-sensitive vibrational spectroscopic technique used as a tool to detect volatile organic compounds (VOCs) near the surface of plasmonic metal nanoparticles with sharp features (‘hot spots’). Conventional bottom-up approaches for sensing applications are based on the self-assembly of nanoparticles, which offers a simplistic, quick, and low-cost SERS substrate preparation. However, this approach demonstrates low reproducibility, hampering the sensor’s performance. Top-down approaches use micro- and nano-fabrication techniques with better uniformity and reproducibility, but with higher manufacturing costs.

We present a hybrid approach using NWs as the backbone of the SERS sensor – decorated with nanoparticles (NPs) – acting as 3D ‘hot-spot’ network for maximizing the available SERS-active surface of the device while achieving signal reliability and reproducibility. We employed this new architecture for SERS-based gas sensing. The NWs are derived from fast and cost-effective solution processing, and form higher-order structures via dielectrophoresis (DEP)-based self-assembly. DEP offers unique features, including NW alignment on predefined locations, preferential orientation, and most importantly, controllable deposition and NW densities for precise ‘hot-spot’ distribution. The self-assembly technique will be discussed and compared to conventional SERS-sensor approaches. Our solution-based technique for the rapid gold (Au) nanoparticle decoration of the 1D titanium oxide (TiO2) NWs will be described. This novel architecture further increases the overall ‘hot-spot’ availability, and combines strong SERS signal amplification with increased sample capture, allowing the detection of analytes at low concentrations.

The performance of the developed sensor was assessed by investigating the SERS signal of 4-aminothiophenol (4-ATP) in gas phase, at concentrations as low as 10 parts-per-billion (ppbv), and in liquid phase down to 24 picomolar (pM). Additionally, the SERS signals successfully separated - using the principal components analysis (PCA) - samples of exhaled breath from healthy volunteers. These findings demonstrate the applicability and potential of 1D nanomaterials in conjunction with state-of-the-art solution-processed techniques for the development of breath analysis platforms for cancer screening. The developed non-invasive NW-based breath sensor platform can provide mobile, low-cost, miniaturized, and rapid breath analysis, making it suitable for clinical deployment. The sensor is suitable for real-time point-of-care (PoC) diagnosis and can significantly improve the understanding of the complex relationship between the exhaled VOC profile and disease, and lead the way to a new clinical breath-based diagnostic tests.

Sensitive Microwave Spectroscopy of Van der Waals Materials with Coplanar Waveguides

Vincent Stenzke, Christian Elsässer, Isabell Grand-Ionita, Jan Stelzner, Lars Tiemann and Robert Blick; Universität Hamburg, Germany

Strongly correlated states in graphene and transition metal dichalcogenides give rise to electrically tunable insulating, metallic and superconducting phases, making them of great interest for fundamental research and potential applications. Probing the electronic structure of such correlated systems is essential to understand their phase transitions and isospin order. Microwave spectroscopy has proven to be a powerful technique for resolving low energy gaps and studying spin interactions in large area graphene. However, implementing exfoliated van der Waals (vdW) materials into sensitive microwave measurements presents several technological challenges, including optimizing contact resistances, impedance matching, and the small area of exfoliated flakes. Microstructured transmission line models, such as the planar waveguide (CPW), allow to efficiently couple microwaves to a two-dimensional material that rests nearby. Graphene Josephson junctions embedded in such a planar microwave circuit are commonly utilized as microwave bolometer devices, enabling detection of microwaves at the single-photon level due to graphene's broadband absorption and low heat capacity. Generally, CPWs have been designed and optimized for a specific purpose to minimize the attenuation (losses) in the desired frequency range. Here, we discuss design choices of CPWs that are optimized for sensitive microwave spectroscopy in two-dimensional vdW materials. We highlight different approaches and their associated technological challenges in coupling microwaves to vdW materials via CPWs. Simulations and fabrication approaches are presented along with the characterization of the finalized CPW. Our designs can be applied in various applications ranging from the investigation of strongly correlated phases and isospin physics in vDW materials to bolometric applications.

Ultratrace PFAS Detection using Amplifying Fluorescent Polymers

Alberto Concellón, Jesus Castro Esteban and Timothy M. Swager; MIT, Department of Chemistry, United States

Per- and polyfluoroalkyl) substances (PFAS) are environmentally persistent pollutants that are of growing concern due to their detrimental effects at ultratrace concentrations (ng/L) in human and environmental health. Suitable technologies for on-site ultratrace detection of PFAS do not exist and current methods require complex and specialized equipment, making the monitoring of PFAS in distributed water infrastructures extremely challenging. Herein, we describe amplifying fluorescent polymers (AFPs) that can selectively detect perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS) at concentrations of ng/L. The AFPs are highly fluorinated and have poly(p-phenylene ethynylene) and polyfluorene backbones bearing pyridine-based selectors that react with acidic PFAS via a proton-transfer reaction. The fluorinated regions within the polymers partition PFAS into polymers, whereas the protonated pyridine units create lower-energy traps for the excitons, and emission from these pyridinium sites results in red-shifting of the fluorescence spectra. The AFPs are evaluated in thin-film and nanoparticle forms and can selectively detect PFAS concentrations of ~1 ppb and ~100 ppt, respectively. Both polymer films and nanoparticles are not affected by the type of water, and similar responses to PFAS were found in milliQ water, DI water, and well water. These results demonstrate a promising sensing approach for on-site detection of aqueous PFAS in the ng/L range.

Radiation Synthesis of Multimetallic Nanoparticles on 1-D Metal Oxide Nanotubes via Carbothermal Shock of Carbon Nanofibers for Highly Sensitive Acetone Gas Sensors

Jae Hyun Ko and II-Doo Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Multi-metallic nanoparticles (MMNPs) have generated significant interest in various fields such as catalysis, bioimaging, and gas sensors due to their improved catalytic performance. Therefore, it is crucial to develop an efficient, cost-effective, and straightforward synthesis method for MMNPs, as the synthetic approach directly affects their applicability, stability, and performance. Traditional methods often involve intricate and expensive experimental procedures. In the various approaches to synthesizing MMNPs, the carbothermal shock (CTS) synthesis has gained attention for its simple yet sophisticated mechanism. However, the CTS synthesis has a limitation, as it requires oxygenated, conductive carbon as a supporting material. To broaden the range of suitable substrates, we propose a novel and uncomplicated method that utilizes carbon support solely as a heat generator for the direct synthesis of MMNPs on SnO2 nanotubes. The experimental procedure involves synthesizing SnO2 nanotubes using the conventional electrosprinning method, followed by loading Pt, Pd, and Ni precursors onto the synthesized SnO2 nanotubes through immersion of SnO2 powders in Pt, Pd, and Ni precursor solutions. The precursor-loaded SnO2 nanotubes are then covered with a carbon nanofiber (CNF) film, and electrically-triggered Joule heating of the CNF film in a vacuum induces carbothermal shock. The successful deposition of Pt, Pd mono-metallic, PdP, PdNi bimetallic, and PdPNi tri-metallic...
The fabrication of free-shaped 3D objects with very high accuracy using focused electron beam-and focused ion beam-induced deposition (FEBID and FIBID) has been demonstrated in recent years.[1] For instance, we demonstrate the formation of free-form ferromagnetic 3D nanostructures and nanowires that can be used as functional devices and at the same time can emulate different morphologies in terms of magnetic properties.[2] Moreover, the direct writing also enables the growth of core-shell heterostructures by combination of 3D-nanowire FEBID scaffolds and the successive site-selective chemical vapor deposition (CVD). In particular, conductive 3D nanowire-based bridges are printed by FEBID and used as resistors allowing deposition induced by Joule heating. This hybrid-approach allows tailoring the cross section, shape and material combination for specific purposes. The applicability of the nano-CVD onto FEBID-nanowires has been demonstrated for two material systems of specific physical properties.[3] The fabrication of complex 3D core-shell heterostructures promises to add new functionalities by combining free-shaped 3D nanostructure writing with thin film deposition of different functional materials.

Tuning Electromigration Forces on Adsorbates on Low-Dimensional Materials Anshul Saxena1,2 and Narayana Aluru1,2; 1University of Texas at Austin, United States; 2The University of Texas at Austin, United States

Electromigration, the movement of atoms induced by electrical currents, is a phenomenon of significant importance in various nanoscale applications. This study focuses on analyzing and optimizing electromigration forces on adsorbates, by considering the direct force resulting from the electric field and the electron wind force due to interactions with current-carrying electrons. Recent research has highlighted the influence of energy level alignment of adsorbates with the fermi level of the current carrying system on the nature of electromigration forces. By altering the electronic structure of current carrying membranes, fine-tuning and optimization of electromigration forces becomes possible, facilitating migration of adsorbates on membrane surfaces. This property finds diverse applications in nanofluidic systems, including mass transport and ionic current generation. Using Density Functional Theory and Non-equilibrium Green’s function calculations, we investigate the nature of electromigration forces on adsorbates across a range of low-dimensional systems such as Graphene, MoS2, MXenes, etc. This study explores the impact of membrane characteristics, including semiconducting, metallic, or insulating properties, on electromigration forces. The results provide valuable insights into the underlying mechanisms and offer guidelines for designing and optimizing nanofluidic systems with tailored electromigration properties.

Reveal Atomic Phase Transition via Nanomechanical Resonator Yulu Mao, Fan Fei, Meijue Zhang, Dajun Zhang, Yangchen He, Daniel A. Rhodes, Chu Ma, Jiamian Hu, Jun Xiao and Ying Wang; University of Wisconsin Madison, United States

The diverse interactions between lattice symmetry and layer stacking orders make transition metal dichalcogenides (TMDs) especially potentially effective to detect for investigating novel topological states and quantum phase transitions. A case in point is transition metal dichalcogenides, notable for its diverse phases: hexagonal (2H, α-phase), monoclinic (1T, β-phase), and orthorhombic (Td, γ-phase). The 2H phase exhibits semiconductors behavior while the 1T' and Td phases are semimetal. Current approaches to reveal the phase transition between those phases are limited to electrical and optical approaches, in which the contrast is low [1]. For example, the 1T' and Td phases are structurally commensurate[2]-[4], in which the structural difference refers to layer-to-layer stacking orders. In this paper, the phase transition in transition metal dichalcogenides is studied by nanomechanical resonators. Phase transition is revealed by the frequency shift of the resonators. Modeling has been established to qualitatively correlate the frequency of the nanomechanical resonator with the phase change. Accompanied by a high-quality factor exceeding 1000, the high sensitivity of the resonator shows small sliding transition,providing the possibility of the new application degree for 2D resonators combining with materials’ phase diagram investigation and the potentiality to extract the thermodynamics information during the phase transition.

Investigations of WSe2/Graphene Heterostructures with Raman Spectroscopy Ariane Marchese1, Yang Liu2, Thiago Seniuk3, Ariete Righi3, James Hone1 and Marcos Pimenta3; 1Columbia University, United States; 2Peking University, China; 3Universidade Federal de Minas Gerais, Brazil

Recent work has highlighted the potential for using tungsten diselenide (WSe2) to modify the properties of graphene, including spin-orbit coupling (Island et al., 2019), superconductivity (Su et al., 2022), and electron-phonon scattering (Banszerus et al., 2019). Here we study interaction between WSe2 and graphene using Raman spectroscopy. We observe blue-shifting of the 2D mode of 1.6 cm-1 for heterostructures of graphene and few-layer WSe2. The shift doubles with top and bottom WSe2 coverage. The G mode for these measurements remains consistent at 1588 cm-1, indicating the shifts were not due to strain. Further investigations will study the renormalization of the Fermi velocity in these heterostructures.

8:00 PM EL07.09.18
Electrical Behavior of Thin Film Devices Exposed to a Magnetic Field
Guinevere Strack, Jin Ho Kim, Alkim Akyurtlu and Richard M. Osgood
University of Massachusetts Lowell, United States; US Army Combat Capabilities Development Command Soldier Center, United States

The exploration of novel, magnetically controlled thin film devices can enable a range of technologies. For example, we demonstrated that the incorporation of ferromagnetic materials into a diode-type device can enable changes in electrical behavior in the presence of a weak, permanent magnet. The diode, when combined with an antenna array, could serve as a rectification device. Magnetic control of the rectenna was referred to as memory rectification, which would not increase the electrical burden given that the permanent magnet did not require an external power source. Another application is the generation or storage of code in a series of magnetic thin film devices. An applied magnetic field could write or erase an electrical message that is stored in the thin film devices. The materials properties of an array of devices could be varied to store a code that could be decrypted or erased via the application of a magnetic field.

Moving forward, the study of the device behavior in a stronger magnetic field in different configurations with respect to the direction of the applied field (in-plane vs. out-of-plane) would enable a better understanding of how the magnetic field influences the average electronic motion through the device. We will use a dipole electromagnet with adjustable pole gap and coil spacing to apply the field, which can be at least 1T, depending on the pole gap spacing. This builds upon our prior work in which the relatively weak magnetic field (~690 Oe) was roughly perpendicular to the film stack and therefore roughly parallel to the electronic transport across the layers. For this MRS presentation, we will measure and understand the transport when the magnetic field lies roughly in the plane of the sample, roughly perpendicular to the electronic flow between layers in the Metal-Insulator-Metal (MIM) diode stack. We will also report the impact of the fabrication techniques on device quality and performance. Dielectric layer (niobium oxide (NbOx)) deposition using atomic layer deposition (ALD) can enable single layer deposition and the deposition of a few layers. Preliminary characterization of the ALD-deposited NbOx using x-ray photon spectroscopy (XPS) revealed that the deposited layer was in the Nb2O5 oxidation state, with peaks found at 208.4 eV and atomic percentages of 29% niobium and 71% oxygen.

Polyvinylpyrrolidone/CNTs Electrosprun Composites for Advanced Applications
Fatima Toz Zahra1, Adeolu Ajayi2, Quincy Quick1 and Richard Mu1;
1Tennessee State University, United States; 2Columbia University in the City of New York, United States

Electrosprinning has attracted the attention of the scientific community since it is a simple yet effective technique to prepare fibers and their composites for various applications. Moreover, it provides a variety of choices in materials as compared to other methods that are used for fiber fabrication. The composites of interest in this study are CNT-based composites, as they hold a great significance in various applications due to their superior physical properties. There are various studies that confirm the potential of CNTs for enhanced properties such as superconductors, microwave absorbers, and biomedical field. In the presented study, polyvinylpyrrolidone (PVP) and CNTs have been utilized to prepare composites using electrosprinning technique. The purpose of this study is to prepare wire-like fibers which have good thermal and electrical conductivity and for that, the alignment of CNTs encapsulated in the fibers is one of the main features that was aimed. PVP and CNTs composites are believed to have high thermal and electrical conductivity along with good mechanical strength. Moreover, PVP has proven to be a good source of dispersion for CNTs. Generally, the PAN based CNTs are utilized during electrosprinning, however, in the presented study we propose the simplified way to encapsulate CNTs directly in PVP nanofibers by using electrosprinning technique. PVP with lower molecular weight (10,000mol/gm) is utilized to attain fine nanofibers by optimizing the molarity, flow rate, voltage and needle to collector distance. The CNTs of length range 5-20μm and diameters 15±5nm, 30±10nm were dispersed ultrasonically in the PVP and ethanol solution. The optimized process parameters were used for electrosprinning. Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) were utilized to study the morphology and structural properties of the prepared composites. The thermal and electrical conductivities of the samples were also analyzed. The CNTs tend to align along the length of the fibers, which led to enhanced thermal and electrical conductivities. Furthermore, considering the good dielectric properties of PVP, increasing the PVP content can lead to high potential of the study in microwave absorption applications.

8:00 PM EL07.09.22
Graphene-Enabled Selective Wetting of Liquid Metal on Polyamide Substrate for the Fabrication of Soft Wearable Electronics
Wedyan Babatani, Orgun Kilic Afsar and Hiroshi Ishii; Massachusetts Institute of Technology, United States

The development of soft wearable electronics has gained significant attention due to their potential for seamless integration with the human body. This study presents a novel approach for fabricating soft wearable electronics using a graphene-enabled selective wetting of liquid metal on a polyamide substrate. Specifically, we leverage the growth of laser-induced graphene (LIG) on polyamide substrate as a surface modification functional material to allow precise patterning of liquid metal, offering control over the deposition process. The patterned liquid metal devices can be subsequently transferred from polyamide to various flexible and stretchable substrates, making them suitable for wearable applications. In order to study the interfacial behavior of LM on top of the LIG substrate, scanning electron microscopy images of the patterned traces were reported, Raman spectrum of the grown LIG layer was obtained and scratching angles of the LIG/LM interfaces was measured. Through a series of experiments and characterization, we demonstrate the successful fabrication of soft wearable electronics, including sensors using the proposed method. The selective wetting behavior of liquid metal on the polyamide substrate allows for the creation of intricate and functional patterns with excellent resolution producing LM traces up to 200 μm. The resulting devices exhibit remarkable mechanical robustness, enabling them to withstand bending, stretching, and other mechanical deformations for 1000 cycles without compromising their performance, allowing them to stretch up to 40% and bend with radii as small as 5 mm. The combination of graphene-enabled selective wetting and soft polymeric substrates offers several advantages for fabricating soft wearable electronics such as pressure sensors and touchpads. It provides a versatile and accessible approach that can be scaled up for mass production.

8:00 PM EL07.09.25
2D InGaOx Transistors Printed by Cabrera-Mott Oxidation of Liquid In-Ga Alloys
Simon A. Agnew, Anand P. Tiwari and William J. Scheideler; Dartmouth College, United States

Next-generation flexible electronics will require low-temperature fabrication of high-mobility 2D semiconductors. Continuous liquid metal printing (CLMP) powered by Cabrera-Mott oxidation can support this goal by offering rapid (< 3 s) processing of large-area (~20 cm²) 3 nm thick ‘2D’ layers of conducting oxides with high mobility. However, their high intrinsic carrier density demands new mechanisms of electrostatic control. We present a strategy for controlling transport in 2D In2O3 via doping with trace Ga inclusions (0.1–0.001 wt.%) in precursor metal alloys. We use these alloys to print indium gallium oxide (IGO) transistors at < 200 °C with enhanced subthreshold slope and near 0 V turn on by replacing the electron concentrations 10-1000X with Ga-doping in the resultant channels (<70 at.%). Printed 2D IGO transistors exhibit exceptional field effect mobility, with champion devices...
achieving up to 17 cm²/Vs and \( I_{on}/I_{off} \) up to 10⁶, with enhanced bias-stress stability over pure \( \text{In}_2\text{O}_3 \). Moreover, through a combination of experiments and finite element simulation, we demonstrate the synergy between 2D IGO and ultrathin high-k \( \text{Al}_2\text{O}_3 \) dielectrics for achieving low-voltage transistors with steep switching.

We apply detailed materials characterization including XPS to quantify Ga doping and oxygen stoichiometry in the 2D IGO channels and EDS to analyze the Ga-rich surface oxide of the liquid precursor alloys. IGO films were investigated by XRD to evaluate the doping threshold for amorphization and by UV-Vis to analyze modulation of the optical bandgap and effects of quantum confinement. Collectively, these results illustrate the power of liquid metal alloy printing to control 2D semiconductor electrostatics and crystallinity for developing high performance flexible electronics and next-generation display technologies.

8:00 PM EL07.09.26

Van der Waals SbSeI Quasi-1D Nano-Columns for Advanced Photonic Applications

Ivan Caño Prades, Alejandro Navarro Güell, Edouard Maggi, Joaquim Puigdollers, Sergio Giraldo, Zacharie Jehl, Marcel Placidi and Edgardo Saucedo; Universitat Politècnica de Catalunya, Spain

There is an increasing interest in van der Waals materials such as \( \text{Sb}_x(\text{S},\text{Se}) \) and \( \text{(Sb,Bi)}(\text{S,Se})(\text{Br,I}) \) systems, thanks to their natural ability to form low dimensional structures with exotic properties. This strong is related to their highly anisotropic transport characteristics, which results in unique electrical and optical properties when the materials are correctly oriented. In addition, these semiconductors can cover a plethora of different possible technological applications including sensors, supercapacitors, piezoelectric generators, and solar cells. Amongst this family of largely overlooked materials, \( \text{(Sb,Bi)}(\text{S,Se})(\text{Br,I}) \) pnictogen chalcogenides are highly attractive due to their wide range of possible bandgaps between 1.2 eV up to 2.2 eV, customizable optical properties by using different halides or chalcogenides while retaining their quasi-1D structure, defect-tolerance, and ferroelectric properties. Nevertheless, the progresses in the development of these pnictogen chalcogenide semiconductors are being limited by the complexity to synthesize compounds containing halogens and chalcogenides in the same structure, due to the very different elemental vapor pressure.

The first attempts to synthesize these materials have been essentially focused on low temperature (<300 C) and atmospheric pressure solution-based chemical routes, resulting in columnar films with poor crystalline quality and very limited morphology tunability. Aiming towards a more controlled, reproducible and versatile system, in this work SbSeI, one of the most relevant materials amongst this family, has been synthesized by a novel procedure based on the selective iodination of co-evaporated \( \text{Sb}_x\text{Se}_y \) films at high pressures (between 2 atm up to 20 atm), developing extremely uniform, single-crystal nano-columnar structures. We will show how the thickness, height, and density of these 1D nano-columns can be tuned by finely varying annealing temperature and pressure. The resulting nano-columns were characterized using microscopy imaging techniques, Raman spectroscopy and X-ray diffraction, demonstrating the formation of SbSeI single phase with orthorhombic structure (space group Pnma), and with excellent crystalline quality and compositional homogeneity. To study the potential of this material for different photonic applications, electrical and optoelectronic measurements have been performed on micro-scale devices, connecting nano-columnar crystals to Pt and Au contacts on a SiO\textsubscript{2}/Si wafer. Interestingly, a clear diode response has been observed with Au-Au and Au-Pt, which is greatly enhanced under illumination. Memory effect, capacitance-voltage and ferroelectric measurements have also been performed. Kelvin probe microscope analysis has been used to determine its work function, observing that different facets of the crystals yield distinct surface potential, supporting our hypothesis that the quasi-1D growth of the material gives rise to anisotropic transport properties.

Overall, this work presents to the best of our knowledge, the first study of the physical vapor deposition synthesis and characterization of novel SbSeI chalcogen-halide compound, demonstrating the tunability of the SbSeI nano-columns morphology by varying synthesis pressure and temperature, as well as the potential of low dimensional chalcogenides to be implemented into innovative architectures and advanced functionalities (such as for enhanced carrier collection and light trapping), pointing the way to develop defect-tolerant and ferroelectric absorbers with anisotropic electrical properties for advanced photonic applications.

8:00 PM EL07.09.29

Enhancement of p-type Behavior of Inkjet-Printed Single-Walled Carbon Nanotube Transistors from Phenylphosphonic acid Coating

Dong Hwan Lee¹, Siwon Hwang², Bongjun Kim² and Hocheon Yoo¹; ¹Gachon University, Korea (the Republic of); ²Sookmyung Women’s University, Korea (the Republic of)

Single-walled carbon nanotube (SWCNT) had interest over the past decade as a high potential material due to their thermal stability and high conductivity [1-2]. In particular, SWCNTs had high carrier mobility and advantages of solution processing lead to their development for applications in electronic devices such as transistors and logic circuits [3-4]. However, the doping technology for controlling the charge carrier transport of SWCNT is still
immature. The chemical doping method is a process that modulates the Schottky barrier without damaging SWCNT. In this paper, we present p-type doping to enhance SWCNT transistors by patterning semiconductors and electrodes using inkjet printing technology and depositing them with the self-assembled monolayer (SAM) material phenylphosphonic acid (PPA). The benzene rings of PPA coated on the SWCNTs have been annealed without removing the voids in the channels by π-stacking as an interaction. As a result, SWCNTs connected through PPA form additional pathway for charge carrier transport. The p-type current of the SWCNT transistor is enhanced 4.3 times due to the improved hole injection resulting from PPA doping effect. In addition, the PPA-doped SWCNT transistors increased the hole mobility by an average of 8.25 cm2 V−1 s−1. Finally, the positive-shifted threshold voltage of 0.55 V indicates the potential for application in depletion mode of PPA-doped SWCNT transistor.

8:00 PM EL07.09.31
The Influence of ZnO Thin Film Thickness on Anion Exchange Membrane Fuel Cell Performance
Rohan Suri1, Samuel Chen2, Kriste An3, Haoyan Fang4, Md Farabi Rahman5 and Miriam Rafailovich6; 1Ladue Horton Watkins High School, United States; 2Ed W. Clark High School, United States; 3Harvard-Westlake School, United States; 4Stony Brook University, The State University of New York, United States

In response to the global challenge to find a clean and sustainable power source, scientists have turned their attention to anion exchange membrane fuel cells (AEMFCs). Though significant progress has been made in the development of AEMFCs, several obstacles impede their application. Poor water management in AEMFCs, for example, leads to anode flooding and cathode dehydrogenation, causing cell deterioration to occur over time. Additionally, platinum will ionize and migrate during operation, causing the AEM to degrade, leading to eventual cell failure. Left unmitigated, these problems could easily render a possible solution to the energy crisis useless. Herein, we report that depositing ZnO thin films on an AEM using Atomic Layer Deposition (ALD) can lead to increased maximum power outputs for AEMFCs. For testing, ALD was used to deposit 5, 10, 15, 20, and 30 layers of ZnO onto anion exchange membranes (Sustainion grade T). Atomic Force Microscopy (AFM) was used to verify that a uniform layer formed a flat tomography, proving that ZnO was successfully coated on the surface. Our results demonstrated that there appears to be an optimal thickness of the ZnO thin film layer, with 10 cycles yielding the highest observed maximum power density of 0.430 W/cm² (a 28.7% increase from the control cell). Further addition of ZnO began to reduce maximum power densities, with 30 layers of ZnO causing a maximum power density of 0.274 W/cm² (an 18.0% decrease). Afterward, XRD measurements were performed, demonstrating the amorphous nature of the ZnO deposited, giving further insights into how the nanostructure could affect possible results. A possible explanation for our observations could be that ZnO improves the electrochemical durability of the AEM, allowing it to function for longer periods of time and become more resistant to the osmotic gradient created within the cell during operation. Future research should include further spectroscopic and microscopic characterization of the membrane and electrodes before and after the performance tests to gain a deeper understanding of our results. Regardless, the scientific community must continue to work with ZnO as a possible solution to many of the problems that plague AEMFCs, furthering humanity’s goal to find sustainable energy sources.

Support from the Office of Naval Research [N00014-29-1-2858] is gratefully acknowledged.

understanding of the spin and phonon characteristics in this emerging topological magnetic material, promising for quantum computing and spintronics applications.

8:30 AM EL07.10.02
Quantum-Coherent Electron Transport in Carbon Nanotube Fibers and Bundles with Ultrahigh Conductivity Shengjie Yu, Natsumi Konatsu, Liyang Chen, Nicolas M. Peraca, Xinwei Li, Renjie Luo, Oliver Dewey, Lauren Taylor, Ali Mojtabpour, Geoffrey Wehmyer, Matteo Pasquali, Matthew Foster, Douglas Natelson and Junichiro Kono; Rice University, United States

Macroscopic fibers of aligned carbon nanotubes (CNTs) with exceptional electrical conductivity (>10 MS/m) have emerged as potential alternatives to conventional metal-based electrical cables. However, to optimize their conductivity, a comprehensive understanding of the microscopic electronic transport processes within these CNT fibers is important, encompassing considerations of disorder, doping, and electron-electron interactions. This study presents the outcomes of temperature- and magnetic field-dependent conductivity measurements performed on solution-span aligned CNT fibers and bundles. At high temperatures, all examined fiber and bundle samples exhibited metallic behavior, with conductivity increasing monotonically as the temperature was reduced from room temperature to a sample-specific temperature between 30 and 100 K. Below this characteristic temperature, the conductivity exhibited a gradual decrease with further decreases in temperature. Additionally, pronounced negative magnetoresistance manifested at low temperatures, signifying the presence of weak localization—a hallmark of quantum coherence in electron transport. Furthermore, investigations on individual bundles exfoliated from the fibers revealed fluctuations in conductivity as a function of magnetic field at temperatures below 50 K. These fluctuations, recognized as universal conductance fluctuations, provide further substantiation of the quantum-coherent nature of electron transport in the examined CNT bundles. By unraveling the interdependencies between temperature, magnetic field, and conductivity in CNT fibers and bundles, this study enhances our understanding of quantum-coherent electron transport phenomena, thereby contributing to the advancement of ultrahighly conductive materials for prospective applications.

9:00 AM EL07.10.06
A Novel Approach for Achieving Highly Clean Interfaces in 2D Material Spin Valves Ting-Chun Huang and Mario Hofmann; National Taiwan University, Taiwan

Spintronics is expected to revolutionize traditional electronics by harnessing the intrinsic spin property of electrons, but the spin manipulation requires high quality junctions between materials with different magnetic properties. 2D materials hold great promise for such junctions due to their atomically sharp interfaces. However, the current experimental results still fall short of meeting the theoretical expectations. This observed difference is primarily attributed to undesirable oxidation of the interfaces during the fabrication process. We here demonstrate a novel approach, called the asymmetrical deposition, to fabricate FM/graphene/FM spin valves (as-GSV) with unprecedented quality. This method achieves all necessary fabrication steps in-vacuo and thus eliminates any possibility for oxidation at the interface. The resulting spin-valve structure exhibits excellent layer conformity and low contamination. This advance yields a current density of the as-GSV that is four orders of magnitude higher than conventional spin valves. Parallel and antiparallel magnetic measurements confirm the high quality of the interface and highlight the importance of lattice-induced effects on spin transport. Furthermore, nearly identical amplitudes of magnetoresistance along two mutually perpendicular magnetic fields demonstrate a novel transport regime. Our results open up new routes for the integration of 2D materials in spintronics and provide inspiration for unprecedented device functionality.

9:30 AM BREAK

10:15 AM EL07.10.07
Stimuli-Controlled Magnetism in Molecular 2D Magnets Zhongxuan Wang, Shengqiang Ren and Yulong Huang; University of Maryland - College Park, United States; 2The State University of New York at Buffalo, United States

Two-dimensional (2D) magnets provoke a surge of interest in large anisotropy and long-range magnetic ordering, and are promising for next-generation information technology where dynamic magnetic tuning is essential. Here, the controllable transformation of low-temperature magnetic order into room-temperature hard magnetism and pressure-controlled magnetism in LCPC is reported. The chemical tuning via electrochemical lithiation and solvation/desolvation exhibits continuously variable magnetic features from cryogenic magnetism to the room-temperature optimum performance of coercivity (Hc) of 8500 Oe and energy product of 0.6 MGOe. Due to the interlayer coupling of these two-dimensional magnets, interlayer magnetic coupling of molecular layered compounds also can be tuned by applied pressure via chromium-pyrazine coordination. Room-temperature long-range magnetic ordering exhibits pressure tuning coercivity coefficient, while pressure-controlled interlayer magnetism also presents a strong dependence on alkali metal stoichiometry and composition. Chemical tuning and pressure-controlled magnetism pave a pathway toward the understanding of room-temperature 2D magnetism in molecule-based systems.

10:30 AM EL07.10.08
Long-Lived Electronic Spin Qubits in Single-Walled Carbon Nanotubes Jia-Shiang Chen, Kasidet Jing Trerayapiwat, Lei Sun, Matthew D. Krzyaniak, Michael R. Wasielewski, Tijana Rajh and Xuedan Ma; 1Argonne National Laboratory, United States; 2Northwestern University, United States; 3Arizona State University, United States; 4The University of Chicago, United States

Electron spins in solid-state systems offer the promise of spin-based information processing devices for quantum communication and computing. The key to preserving the encoding information is realized by the robust coherent spin state which acts against decoherence from losing the phase information. Single-walled carbon nanotubes (SWCNTs), an all-carbon one-dimensional material whose spin-free environment and weak spin-orbit coupling promise long spin coherence times, offer diverse freedom for extended functionality not available to bulk systems. Here, we report the creation of highly confined electron spins in SWCNTs by chemical functionalization through a bottom-up approach. The record long coherence time of 8.2 µs and spin-lattice relaxation time of 13 ms of these electronic spin qubits allow demonstration of quantum control operation manifested as Rabi oscillation. Investigation of the decoherence mechanism reveals an intrinsic coherence time of tens of milliseconds. These findings show that combining molecular approaches with one-dimensional crystalline systems provides a powerful route for reproducible and scalable quantum materials suitable for qubit applications.
Atomic Layer Smoothing for Quantum Materials: An Initial Investigation
Haozhe Wang; Duke University, United States

In the realm of quantum devices such as qubits and microwave kinetic inductance detectors, surface imperfections in metallic and dielectric films have been identified as a root cause of non-ideal behaviors. Despite significant investigations into surface-induced decoherence and low-frequency fluctuations, current nanofabrication techniques remain inadequate in addressing these issues. We introduce a novel surface smoothing technique utilizing a ‘reversal’ mechanism in atomic layer deposition (ALD), specifically isotropic plasma atomic layer etching (ALE), to mitigate Angstrom-level defects in quantum materials. Our approach focuses on minimizing surface roughness and native oxides, thereby enhancing device performance. This talk provides insights into the application of atomic layer smoothing in the processing of aluminum nitride, with observed smoothing effects at the Angstrom scale, offering potential improvements to AlN-based quantum optical devices. Further discussion will cover advancements in ALE for metallic aluminum, a material frequently used in superconducting circuits. We propose an integrated ALE-ALD approach to achieve smoother and oxygen-free surfaces.

Charge and Magnetotransport in Hybrid Molecule/Quantum Material Van der Waals Heterostructures
Emanuele Orgiu; Université du Québec/Institut National de la Recherche Scientifique, Canada

2D Quantum Materials are held together by weak interplanar van der Waals (vdW) interactions. The incorporation of molecules in such materials holds an immense potential to understand and modify the fundamental physical properties of the pristine materials while creating new artificial materials. Whilst nature offers a finite number of 2D materials, an almost unlimited variety of molecules can be designed and synthesized with predictable functionalities. The possibilities offered by systems in which continuous molecular layers are interfaced with inorganic 2D materials to form hybrid organic/inorganic van der Waals heterostructures (H-vdWH) are emphasized. Similar to their inorganic counterpart, the hybrid structures have been exploited to suggest novel device architectures. Moreover, specific molecular groups can be employed to modify intrinsic properties and confer new capabilities to 2D materials. In particular, I will highlight how molecular self-assembly at the surface of 2D materials can be mastered to achieve precise control over position and density of (molecular) functional groups, paving the way for a new class of hybrid functional materials.

Monolayer Electrolyte for an All-Solid-State Non-Volatile Memory: Local Switching and Speed
spetrler1, Dilara Abdel2, Zhan.song Geng1, Frank Schwierz1, Patricio Farrel1 and Martin Ziegler1,1; 1Ilmenau University of Technology, Germany; 2Weierstrass Institute, Germany

Two-dimensional (2D) layered transition metal dichalcogenides (TMDCs) are promising materials for memristive devices and have gained significant attention because of their potential use in neuromorphic computing systems. However, despite extensive experimental work (e.g., [1,2]), the underlying resistive switching mechanisms in 2D TMDCs are still not understood, impeding progress in material and device functionality. This study discusses the contributions of various mechanisms to the current-voltage hysteresis and switching dynamics in 2D TMDC materials in detail and reveals the dominant
role of mobile point defects [3]. Here, the switching process is governed by the formation and annihilation dynamics of a local vacancy depletion zone. Moreover, minor changes in the interface potential barriers surface fundamentally different device behaviors, and these changes are thought to originate from multiple mechanisms. The key mechanisms are identified with a numerical charge transport model for electrons, holes, and ionic point defects, including image-charge-induced Schottky barrier lowering, Joule heating, and charge trapping dynamics. The model is validated by comparing simulations with measurements for various 2D MoS2-based and HfS2-based lateral devices, which also allows us to identify the characteristic dynamic behavior as a fingerprint of the underlying physical mechanism. Our results strongly corroborate the relevance of vacancies in lateral TMDC devices and offer a new perspective on the switching mechanisms and the influence of Joule heating. The insights gained from this work can be used to extend the functional behavior of 2D TMDC memristive devices in future neuromorphic computing applications.

Funding by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation)-Project-ID 434434223-SFB 1461, the Carl-Zeiss Foundation via the Project MemWerk, and the Leibniz competition 2020 (NUMSEMIC, J89/2019) is gratefully acknowledged.

1. Bessonov, A.A.; Kirikova, M.N.; Petukhov, D.I.; Allen, M.; Rybänen, T.; Bailey, M.J.A. Layered memristive and memcapacitive switches for printable circuit design and reduce overall production costs. Memristors play a crucial role in realizing the in-memory computing. Versatile memristors, which can realize various functions without changing the layout. We developed non-volatile reconfigurable transistors based on 2D CuInP2S6/MoTe2 heterostructures [1]. The polarity (n-type or p-type) of these logic transistors can be dynamically programmed, while the configuration is non-volatile in nature. Utilizing these ferroelectric devices, we demonstrate reconfigurable logic gates with NAND/NOR dual functions, whose input-output mapping can be transformed in real-time without changing the layout. These reconfigurable circuits will serve as important building blocks for high-density data-stream processors and reconfigurable Application-Specific Integrated Circuits.

Content addressable memory (CAM) is one of the promising in-memory computing circuits widely used in high-speed search applications. However, traditional SRAM-based CAM needs ten transistors (10T) per bit, which imposes severe limits on the area and energy efficiency. We developed a novel 1-transistor-per-bit CAM based on the ferroelectric reconfigurable transistor. By exploiting the switchable polarity of the ferroelectric reconfigurable transistor, XOR/XNOR-like matching operation in CAM can be realized in a single transistor. By eliminating the need for the complementary circuit, these non-volatile CAMs based on reconfigurable transistors can offer a significant improvement in area and energy efficiency compared to conventional CAMs.

Furthermore, we developed multifunctional devices based on semiconducting ferroelectrics (In2Se3), which can concurrently serve as an electronic memory, photonic memory, logic gate, and photodetector [2]. This dual electrical and optical operation of the memories can simplify the device architecture and offer additional functionalities, such as ultrafast optical erasing of large memory arrays. We also demonstrated reconfigurable Schottky diodes based on In2Se3/graphene heterostructures, where the diode polarity is reversible via switching the In2Se3 polarization. The current ratio between ON and OFF states at a given read voltage can be as high as 100. These results indicate that ferroelectric In2Se3 and other semiconducting ferroelectric materials have great potential for multifunctional devices.

into a single device enables their applications in more complex scenarios while maintaining low power consumption. In simple graphene/CIPS/Au device configuration, the migration of Cu⁺ ions under electrical stimuli and persistent photoconductivity under optical stimuli were leveraged to demonstrate the simultaneous realization of electronic and optoelectronic synapse functionalities. Taking advantage of optical-electrical cooperative effect, information perception, processing, memorizing and light adaption behavior were efficiently demonstrated in such simple-structure electronic/optoelectronic synapse, paving a prospective way towards achieving artificial visual system. The findings presented contribute to the advancement of CIPS-based devices and their potential for various applications in the field of multifunctional electronic devices.

4:30 PM EL07.12.05
Monolayer Electrolytes for Nonvolatile Memory: Impact of Salt Identity on Electrical Characteristics Hairan Wang, Shubham S. Awate and Susan Fullerton; University of Pittsburgh, United States

A solid-state, non-volatile memory based on electric-double-layer (EDL) gating using a monolayer electrolyte (ME) has been developed in our lab. This ME comprises cobalt crown ether phthalocyanine (CoCrPc), with four, 15-crown-5 ethers (15C5) attached, and a lithium salt that forms an ordered array on the two-dimensional (2D) semiconductor surface. The monolayer electrolyte is capped with h-BN. Each crown solvates one metal cation that is stable in two distinct states in the crown: one near the 2D semiconductor, creating a low-resistance state, and the other near h-BN, creating a high-resistance state. The switching mechanism is triggered by an electric field via a back-gated field-effect transistor (FET). Prior work focused exclusively on LiClO₄ deposited with ethanol. Here, we report on additional salt/solvent systems and their impact on switching, including LiCl, LiI, NaClO₄, and Ca(ClO₄)₂. The surface roughness (Rₛ) of bare WSe₂ flakes before electrolyte deposition is typically 0.2 ± 0.01 nm, and after 15C5-CoCrPc/LiClO₄ deposition, the Rₛ increases by a factor of 2 to 3. Therefore, for electrical characterization, we select salts for which the Rₛ remains within this range: LiCl, NaClO₄, Ca(ClO₄)₂ in ethanol. Non-volatile subthreshold voltage shifts (ΔVₛ) in the range of 9 – 15 V are observed for all three salts measured, indicating that all three are bistable in 15C5-CoCrPc. Specifically, ΔVₛ of 9.1 ± 1.4, 14 ± 2.1, and 9.2 ± 0.3 V for LiCl, NaClO₄, and Ca(ClO₄)₂, respectively, correspond to sheet carrier densities (Δnₛ) of 1.4 × 10¹¹, 1.2 × 10¹², 1.0 × 10¹¹ cm⁻². Thus, the best performing salts are those containing perchlorate anions with doping densities on the order of 10¹² cm⁻², suggesting that the anion may play an important role in the switching mechanism. ON/OFF ratios of ~ 10⁴, ~ 10³, and ~ 10 are measured for LiCl, NaClO₄, and Ca(ClO₄)₂, respectively. These ratios are similar to what we observe in LiClO₄, indicating two distinguishable resistance states in MERAM. Retention measurements will be reported. These findings advance our goal of developing a high-speed, non-volatile memory at the limit of scaling. This work is supported by the NSF under Grant # NSF-DMR-EPM CAREER: 1847808.

Highly Nonlinear Memory Selectors with Ultrathin MoS₂/WSe₂/MoS₂ Heterojunction Hongye Chen¹, Tianqing Wan¹, Yue Zou¹, Jianmin Yan¹, Hongyu Yu¹ and Yang Chui²; ¹The Hong Kong Polytechnic University, Hong Kong; ²Southern University of Science and Technology, China

Two-terminal (2D) resistive random access memory (RRAM) crossbar arrays require the highly nonlinear selector with high current density to address a specific memory cell and suppress leakage current through the unselected cell. Three-dimensional (3D) monolithic integration of RRAM array requires selector devices with a small footprint and low-temperature processing for ultrahigh-density data storage. Here, we design an ultrathin two-terminal n-p-n selector below 10 nm with 2D transition metal dichalcogenides (TMDs) by a low-temperature transfer method. The van der Waals (vdW) contact between transferred Au electrodes and 2D TMDs reduces the Fermi level pinning and retains the intrinsic transport behavior of TMD. The selector with single type of TMD exhibits a trade-off between the current density and nonlinearity depending on the barrier height. By controlling the thickness of p-type WSe₂ and high current density (2×10⁵ A/cm²) simultaneously. We further integrate the n-p-n selectors with a bipolar hexagonal boron nitride (h-BN) resistive switching memory and calculate the maximum crossbar size of the 2D material-based 1SI1 according to a 10% read margin, which offers the possible realization of future 3D monolithic integration.
applications of the low temperature MoS2 material will be presented, including FEOL single and multi-channel MoS2 transistors, BEOL memory circuits, and high performance RF harvesting devices.

Chip-Less Wireless Electronic Skin Sensors Enabled by Epitaxial Freestanding Compound Semiconductors Junmin Suh1, Yeongin Kim1,2, Jiho Shin1, Yunpeng Liu1, Jyeewon Han1 and Jeewhan Kim1; 1Massachusetts Institute of Technology, United States; 2University of Cincinnati, United States; 3Amorepacific R&D Center, Korea (the Republic of)

Electronic skin (e-skin) has been developed with a goal to obtain a non-invasive human health monitoring electronic system with its imperceptibility. So far, one of the major shortcomings in this field is the bulky wireless communication system that severely affects its wearability. In this work, we introduce a single-crystalline non-Si-based e-skin system where fully conformable, ultrathin, piezoelectric, compound semiconductor membranes are incorporated as power-efficient wireless communication modules and extremely high sensitivity sensors without needing for bulky chips and batteries. The developed GaN surface acoustic wave-based device successfully measured wirelessly three different inputs including strain, ultraviolet light, and ion concentrations. The consistency and accuracy of the measured heart rate and pulse waveforms over a 7-day period, during which the e-skin was re-attached 7 times, strongly demonstrate the reusability and long-term wearability of our device. This study will change the paradigm of e-skins by providing versatile wireless platforms for fully imperceptible e-skins with very high sensitivity and low power consumption.

Large-Scale Integrated Vector-Matrix Multiplication Processor Based on Monolayer MoS2 Mukesh Tripathi, Aleksandra Radenovic and Andras Kis; Ecole Polytechnique Federale de Lausanne, Switzerland

In recent years, data-driven algorithms took the spotlight promising new and efficient ways for processing and extracting meaningful information from ever-growing amounts of generated data. Although the von-Neuman architecture was the backbone of the data revolution, the separation of the memory and processing units makes the current processors spend a significant amount of energy moving data compared to the energy spent in computing [1]. This motivated the research in emerging computer architectures which could provide energy benefits while performing data-driven algorithms, such as artificial neural networks or signal and image processing. Among the different proposals, in-memory computing has been systematically shown to be beneficial for the previously mentioned applications [2]. Despite the intense research efforts put into the types of memory devices used in this architecture, no technology has been able to satisfy all the requirements [3]. The lack of a universal memory platform for performing computation has led to the investigation using two-dimensional materials as a promising material system for this emerging architecture [4]. In this light, here, we fabricated a 32x32 vector-matrix multiplier with 1024 floating-gate field-effect transistors (FGFET) that use atomically thin MoS2, as the semiconducting channel material. This large-scale integration device is developed in a wafer-scale fabrication process, achieving high yield and low device-to-device variation. Due to the low device variability, an open-loop programming scheme can be employed while obtaining multi-level memory behavior. Finally, our in-memory processor is used to demonstrate discrete signal processing based on vector-matrix multiplications. Our findings lay the foundations for creating complex in-memory processors that can harvest all the advantages of 2D materials.

Van der Waals Integration beyond the Limits of Van der Waals Forces Farnaz Niroui; Massachusetts Institute of Technology, United States

Heterostructures of dissimilar materials are core building blocks of nanoscale devices. Their growth through common chemical epitaxy or physical vapor deposition often poses strict chemical and physical compatibility constraints, limiting accessible heterostructures due to potential disorder and damage. Physical stacking provides an alternative approach to hetero-integration. This has been the foundation of the growing discipline of van der Waals (vdW) physical stacking provides an alternative approach to hetero-integration. This has been the foundation of the growing discipline of van der Waals (vdW) physical stacking provides an alternative approach to hetero-integration. This has been the foundation of the growing discipline of van der Waals (vdW) deposition often poses strict chemical and physical compatibility constraints, limiting accessible heterostructures due to potential disorder and damage. Here, we introduce the adhesive matrix transfer approach to overcome this fundamental limit to enable direct fabrication of conventionally-forbidden vdW heterostructures and single-step 2D material-to-device integration. As no solvents, high-temperatures or sacrificial layers are involved, our platform yields pristine surfaces and interfaces uniquely suited for studying the intrinsic properties of 2D materials and leveraging them in device applications which will be discussed.

NIL, Nanopatterning and Etching of Nanopillars for GaN-Based microLEDs Nabil Labchir1, Saber Hammami2, Kilian Baril1, Maya Webhe1, Sébastien Labau1, Camille Petit-Étienne1, Blandine Alloing1, Matthew Charles2, Jesus Zuniga Perez2 and Cécile Gourgoujon1; 1LTM/CEA, France; 2CEA Leti, France; 3CRHEA-CNRS, France

NIL, Nanopatterning and Etching of Nanopillars for GaN-Based microLEDs Nabil Labchir1, Saber Hammami2, Kilian Baril1, Maya Webhe1, Sébastien Labau1, Camille Petit-Étienne1, Blandine Alloing1, Matthew Charles2, Jesus Zuniga Perez2 and Cécile Gourgoujon1; 1LTM/CEA, France; 2CEA Leti, France; 3CRHEA-CNRS, France
At present, GaN-based µLED optoelectronic devices are progressing beyond solid-state lighting, inspiring a fascinating new category of applications. Indeed, the µdisplay sector has reached a highly dynamic expansion phase. Unlike conventional displays, µdisplays require image magnification to be seen by the human eye. However, they must be able to display an image of similar quality to that of standard in terms of definition, i.e. number of pixels. To display as many pixels on a smaller surface, we need to reduce the pixel pitch, i.e. the distance between two pixels, from a few hundred micrometers to only a few micrometers. At present, controlling the internal crystal quality of the GaN substrate permits the development of smaller, more efficient µLEDs. However, the µLED lifetime is highly dependent on the density of dislocations inside GaN which behave as non-emissive zones on the µLED surface. In this context, nanoimprint lithography (NIL) will be deployed to nanotexture silicon-on-insulator (SOI) substrates in order to achieve a high density of GaN growth sites. The regrowth on these SiO2-based sites enhances the GaN quality and therefore the µLEDs performance. The innovation in our strategy is selectivity to VOCs.

Enhancing Electrochemical Sensing via Hybridization of 2-D Mxene and Transition Metal Dichalcogenides

Lia Stanciu, Winston Y. Chen and Dimitrios Stanciu; Purdue University, United States

The exceptional conductive properties, flexibility, and surface functionality of two-dimensional (2D) transition-metal carbides/nitrides (MXenes) position them as prospective electronic materials for electrochemical sensing specifically. Nonetheless, strategies to amplify MXene's sensitivity to volatile organic compounds (VOCs) in particular remain relatively uncharted. In this study, we elucidate a novel methodology involving surface treatment and exfoliation to fabricate a hybrid material of 2D WSe2 and Ti3C2Tx. By employing scanning electron microscopy, transmission electron microscopy, X-ray diffractionmetry, and dynamic light scattering, we characterised the microstructure, size, and surface charge states (zeta potential) of WSe2 and Ti3C2Tx nanosheets. This extensive analysis facilitated the optimal processing of the WSe2 and Ti3C2Tx hybrid, enabling its use as an ink for ink-jet printing of flexible Ti3C2Tx/WSe2 electrochemical sensors, which are integrated into wireless systems. VOCs were selected as the test subject to elucidate the functional properties of these 2D nanohybrids for electrochemical sensing. Within this configuration, the Ti3C2Tx scaffold contributes high electrical conductivity while the WSe2 nanoflakes impart remarkable sensitivity and enhanced selectivity to VOCs.
As the aging society emerges, the market for point-of-care (POC) biosensing platforms capable of rapidly and efficiently diagnosing diseases like cancer and diabetes is expanding rapidly. This shift in the biosensing paradigm from reactive to preventive healthcare has increased the demand for advanced detection of biomarkers, such as autoantibodies related to proteins in the endoplasmic reticulum (ER) stress pathway. This is crucial for the diagnosis, prognosis, and therapeutic monitoring of chronic diseases, transforming biomedical research. Solution-processed electrochemical biosensors offer advantages in rapid and large-area fabrication, facilitating prompt personalized medical treatments compared to traditional laboratory or hospital-based disease detection. Utilizing 2D nanomaterials, such as reduced graphene oxide (rGO), in biosensors is common due to properties like high conductivity, large surface area, easy functionalization, solution-processability, cost-effectiveness, and environmental friendliness. These properties are enhanced by the formation of nanometer-scale wrinkles in the rGO films, increasing their geometric surface area and improving electron and mass transfer, as well as the loading capacity of bioreceptors. In case of solution-processed biosensors, analyzing fluid behaviors and rheological properties of the solution is crucial as it directly influences thin-film properties and sensing performances. In particular, rGO molecules can be assembled into a rational nanostructure with wrinkles. However, there is a lack of investigation into the engineering aspects of wrinkled rGO during coating when elucidating the mechanism and causes of wrinkled film formation. To address this gap, we conducted the correlation between the wrinkled film and fluid behavior during solution shearing through numerical simulation and fabricated the cross-linked rGO-chitosan-based thin film. This ultrathin film (thickness of 45 nm) exhibited high wrinkling (BET surface area of 234.78 ± 0.54 m²/g). From this optimized film, we successfully developed a multiplex enzyme electrochemical sensor capable of detecting three different autoantibodies (anti-GRP78, antiPERK, and anti-PDIA6) specific to GRP78, PERK, and PDIA6, respectively. Each sensor demonstrated a dynamic range of 0.1 to 100 ng/ml and piconewton level limit of detection values, correlating with clinical data of autoantibodies circulating in serum. In conclusion, by controlling the degree of wrinkles in the rGO-chitosan-based film through solution shearing, we have successfully developed a sensor capable of detecting three different ER stress-induced antibodies. This outcome highlights the potential applicability of our sensor for the early detection of ER stress, understanding cellular health, and monitoring the progress of chronic diseases and the effectiveness of their treatment.

The demand for power-efficient, high-performance gas sensors operating at room temperature has promoted research into light-activated gas sensors for Internet of Things (IoT) applications. While semiconducting metal oxides have been extensively employed due to their suitable electronic band structure for light absorption, their low gas response with light-activation mechanism still requires improvement with effective strategies such as catalyst decoration for enhancing light absorption. Recently, graphene quantum dots (GQDs) have newly proven their catalytic ability for room temperature gas sensing with their tunable electronic band structure and surface functional groups. Herein, wedecorated high-quality GQDs on In2O3 nanofibers with varying the size of GQDs (2 nm to 20 nm) for enhancing light-absorption of In2O3 nanofiber. The electronic band gap of GQDs was tuned from –2 eV to 3.5 eV to facilitate optimized light absorption and electronic transfer. The gas sensing performance of GQDs decorated In2O3 nanofiber was investigated with NO2 gas under different light illumination (UV, violet, blue, green) at room temperature. Regardless of the QD size, the QD decoration improves NO2 gas responses compared to bare In2O3. Notably, pristine In2O3 nanofibers exhibited their highest gas response under violet light. However, upon decoration with graphene quantum dots (GQDs), a notable shift in the activation wavelength toward a longer wavelength, specifically blue light. The most significant enhancement was observed with 5 nm-sized QD under blue light, resulting in a remarkable 5-fold improvement in NO2 gas response. This improvement can be attributed to the modulation of QD electronic band gap, enabling enhanced light absorption and suitable band alignment. In addition, the oxygen functional groups in GQDs can lower the adsorption energy of NO2 gases, realizing selective gas responses to NO2 gas. Our findings offer fundamental insights into the potential of graphene quantum dots as catalysts for high-performance light-activated gas sensors, paving the way for advancements in IoT applications with their low-power consumption and room-temperature operation.

Layered 2D materials are increasingly investigated for their often highly anisotropic properties, such as thermoelectricity. Such a property is useful in electronics, such as transistors and sensors, where wasted heat is not only economically and environmentally unsustainable, but can also be detrimental to device performance. It is repeatedly assumed that planar defects, such as stacking faults, affect the thermoelectric properties of these materials [1-2]. However, to date, no comprehensive study into establishing this relationship has been performed. In this work, the ternary chalcogenide TlGaSe2 serves as a prototypical example of this type of analysis. TlGaSe2 is characterized via (scanning) transmission electron microscopy (STEM) and density functional theory (DFT) simulations. Streaking in selected area diffraction patterns are correlated to simulations which indicate the presence of stacking faults in the growth direction [3]. High resolution STEM confirms these stacking faults and indicates a lack of long-range order to the stacking. DFT calculations reveal a high preference for the system to include these faults. This is then coupled with phonon dispersion and electron transmission simulations to confirm their relationship to the thermoelectric properties of the material.

Diverse nanotechnologies have been widely applied for efficient energy generation in low-power consuming and self-powering devices. Herein, we explore the origin of bending-driven power generation in carbon nanotube (CNT)/halide/poly(ylidene fluoride-trifluoroethylene) (P(VDF-TrFE)) nanofiber and their versatile applications in piezoelectric energy harvester, tactile sensor, and pressure sensor. Two effective fillers of inorganic halide perovskite CsPbBr3 nanocrystals and CNT were incorporated in P(VDF-TrFE) matrix to demonstrate bending-driven energy harvesting performances and their ability to sense physiological signals from the human motions. Owing to the synergetic piezoelectric coupling between the fillers and the matrix, impressive harvesting outputs of ~15.9 V and 1.128 nA were achieved for the 0.3 wt.% CNT and 5 wt.% halide-incorporated samples, which are ~17.6 and 10.5 times better than the results achieved for the pure P(VDF-TrFE) nanofiber harvester. The values are also the best values reported using bending-driven operations. The origin of substantial enhancements in electromechanical energy generation under the bending motions is attributed to the extra dipolar polarization by embedded CsPbBr3 and space-charge polarization by dispersed CNTs in contact with the piezoelectric polymer matrix. Wearable physiological and pressure sensors were successfully demonstrated to effectively sense the motions and convert them into electric signals. The optimal nanofiber-based sensors demonstrated a wide force detection range from 0.002N to 600 N, and superior reliability and repeatability for 20,000 cycles under the periodic mechanical deformation. Nanofiber composites-based pressure sensor was further applied in the pressure signal-mapping system, demonstrating its promising possibility in the self-powered health monitoring system.

Conductive 2D Metal-Organic Frameworks for Chemical Sensor Applications Seon-Jin Choi; Hanyang University, Korea (the Republic of)

Metal-organic frameworks (MOFs) are materials formed by the combination of metal nodes and organic linkers. They possess a large surface area and high porosity, making them promising materials for chemical sensing applications. Several MOFs have been synthesized and utilized as chemical sensing layers in combination with other sensing materials such as metal oxides, as demonstrated in our previous studies [1–4] However, intrinsic 3D MOF's typically exhibit insulating properties, which limits their application in electrochemical sensing materials. In contrast, electrically conductive 2D MOFs have recently gained attention for chemiresistive-type gas sensor applications. These materials possess intrinsic electrical conductivity and show redox-reactive properties with gaseous analytes. The presentation will highlight recent progress in the development of conductive 2D MOFs and their application in chemiresistive-type gas sensors. Various electrically conductive 2D MOFs were prepared by combining metal nodes (CuII, NiII, and CoII) with an organic linker (hexahydroxytriphenylene, HHTP). The result showed that the 2D CuII(HHTP) MOF film exhibited high sensitivity toward hydrogen sulfide and toluene at room temperature. To gain insights into the fundamental sensing mechanism, an in-situ spectroscopy analysis technique was established. This technique involved monitoring surface adsorbed species and by-products after chemical reactions using Raman spectroscopy and gas chromatography-mass spectroscopy (GC-MS), respectively. Through these investigations, a better understanding of the fundamental sensing mechanisms of 2D MOFs was obtained, paving the way for the development of high-performance chemical sensors for environmental monitoring and healthcare applications.

Magnetic Phase Transition and Magneto-Mechanical Coupling in Layered CrSrBr Probed by Nano-Optomechanical Resonators Fan Fei1, Yulu Mao1, Wenhai Liu1, Bing Lv2, Ying Wang1 and Jun Xiao1; 1University of Wisconsin–Madison, United States; 2The University of Texas at Dallas, United States

Recent progress in 2D magnetic materials represents an emerging research frontier. For example, various types of novel magnetic orderings at 2D limit have been discovered, including collinear ferromagnets/antiferromagnets, noncollinear spin textures, quantum spin liquid and magnetic topological insulators [1]. In addition, their spin excitations and the coupling with other quasiparticles are expected to be substantially enhanced due to the weak dielectric screening at the 2D limit [2,3]. In contrast to the abundant optical and electrical studies, the thermodynamic and mechanical properties for these rich quantum phases and unique coupling physics are important yet missing. In this talk, I will present our study of the thermodynamic and mechanical properties in van der Waals magnets using nano-optomechanical resonators. In particular we have successfully developed nanoscale resonators based on target ultrathin magnetic membranes CrSrBr, in which mechanical properties of the membrane can be electrically driven and sensed by precise optical interferometry. The nanomechanical response contains critical thermodynamic and information in magnetostriiction in different spin orderings. Our work advances the understanding of magneto-mechanical coupling in 2D magnetic materials and enables new opportunities for coupling light, magnetism, and mechanics at the nanoscale.

Impact of Precursor Material on the Structural, Chemical and Gas Chemoresistive Properties of β-Ga2O3 Nanowires Marina Rojano-Mateos1,4, Anna Estany-Macià1,2,3, Guillem Doménech-Gil1, Elena Lopez-Aymerich1, Paolo Pellegrino2, Christophe Serre1,3, Mauricio Moreno-Sereno1,3, Jan Romano-deGea4, Isabel Gracia5, Carles Cané5 and Albert Romano-Rodriguez1,1; 1Universitat de Barcelona, Spain; 2Danmark Technical University, Denmark; 3:45 PM EL07.15.08-Universitat de Barcelona, Spain; 4Linköping University, Sweden; 5Ecole Polytechnique Federale de Lausanne, Switzerland; 1Consejo Superior de Investigaciones Científicas (CSIC), Spain

Gallium oxide (β-Ga2O3) is a wide band gap semiconductor material used in the fabrication of high power, high temperature and gas sensing devices. For its use as gas sensor, Ga2O3 has been formed in thin films by well characterized methods, such as towards oxygen or reducing gases at temperatures above 600°C. To decrease the working temperature to bring sensors based on this material towards their compatibility with the Internet of Things (IoT), different innovations have been proposed, mainly based on surface functionalization, material doping or the increase of the surface-to-volume ratio using the nanowire (NW) morphology.
In this work we report the synthesis, characterisation and gas sensing behaviour of β-Ga2O3 NWs. These nanowires are fabricated via a metal-assisted vapour liquid solid (VLS) mechanism using either gallium metal evaporation or carbothermal reduction of Ga2O3 nanopowders and employing Au as seed for the growth. The NWs have been grown on oxidised silicon or on fused silica substrates. For their use as gas sensors, the NWs have been removed from the substrates where they grew and were transferred to substrates containing microelectrodes. In some cases, these are on placed on suspended microhotplates containing a buried heater. In this way, individual NWs have been contacted using Focused Electron (FEB) and Focused Ion Beam (FIB) Induced Deposition techniques, giving rise to resistors whose value changes in the presence of different gases, i.e., they are chemiresistors. The grown NWs are monocrystalline and almost defect free, with a diameter of few tens of nm and lengths in the range of several tens of micrometres, which increases with evaporation time. The NWs grow by carbothermal reduction present, in addition, a carbon-containing shell, which is the result of the use of graphite. From the electrical point of view, this shell gives raise to an important reduction of the resistance of the resistor. The electrical properties of these chemoresistive gas sensors have been measured in the presence of different gases, which will be described. The structural and chemical properties of gas materials, their sensing behaviour and the differences among them will be discussed as a function of the fabrication routes employed.

4:00 PM EL07.15.10
Interfacial Engineering of Reduced Graphene Oxide Sensing Layer for Remote Floating-Gate FET Sensors Wen Zhuang1,2, Hyun June Jang1,2, Xiaoyu Sui1,2, Byung hoon Ryu1, Yuqin Wang1,2, Haihui Pu1,2 and Junhong Chen1,2; 1University of Chicago, United States; 2Argonne National Laboratory, United States

With the increasing demand for field-deployable, sensitive, and low-cost sensors, nanomaterial-based field-effect transistor (FET) sensors have been widely studied over the past decades, due to the advantages in rapid response, lower detection limit, miniaturized sensor chip and direct digital readout. Two-dimensional (2D) materials such as reduced graphene oxide have gained the attention for FET sensors due to excellent mechanical, electrical and physicochemical properties, which enables extremely higher sensitivity and stronger selectivity to analytes compared to bulk counterparts. Despite numerous demonstrations of high sensitivity given by 2D reduced graphene oxide (rGO) FET sensors, there is a lack of fundamental understanding of rGO interfaces, especially to improve sensing performance by engineering the rGO interfaces. In rGO-based sensors, it has been challenging to characterize the intrinsic properties of solution interfaces due to a lack of reliable analytical tool. In our previous work, a remote floating-gate (RFG) structure proposed for a 2D rGO layer eliminates non-reliable behaviours of solution interfacial properties while remaining in a high surface-to-volume ratio at the sensing zone. To be specific, the RFG structure enables to avoid any undesirable effects from interface traps, defects, and redox reactions of 2D rGO sensing membrane, which produces a high yield of signal reproducibility and could serve as a potential analytical platform to study the rGO interfaces.

In this work, we investigated properties of rGO-based sensors that are prepared with self-assembled layers such as (3-Aminopropyl) trimethoxysilane (APTMSTM) and hexamethyldisilazane (HMDS) through measurements of pH sensitivity of such APTMS- and HMDS-treated rGO layers. For this analysis, we adopted the remote floating-gate FET (RFGFET) configuration which enables the characterization of intrinsic properties of solution-rGO interfaces only. The HMDS-treated surface induces more hydrophobicity on the interface and lowers pH sensitivity of rGO layers by reducing the number of oxygen functional groups. On the other hand, the APTMS-treated surface contains more rGO layers with enriched oxygen functional groups, which leads to higher pH sensitivity and hydrophilicity. Finally, we also characterized interfacial potentials of rGO layers modified by 1-pyrenebutyric acid N-hydroxysuccinimide ester (PBASE) linker molecules during functionalization process and monitored the surface charge density of the solution-rGO interface brought by PBASE functionalization. These results suggest useful interface-engineering strategies to tailor the sensing performance and functionalities of FET-based sensing devices, which holds great promise for developing advanced chemical and biological sensors.

SESSION EL07.16: Virtual Session

8:00 AM EL07.16.03
High Thermal-Conductive Packaging Composites Based on Uniform Dispersion of 2D Materials Chia-Lien Chang1, Yu-Chiao Chang1, Rong-Teng Lin1, Yun-Hong Yang1, Bi-Xian Wu1, Kuan-Yun Chi1 and Tzu-Hsuan Chang1,2; 1Graduate Institute of Electronics Engineering, National Taiwan University, Taipei, Taiwan, R. O. C., Taiwan; 2Graduate School of Advanced Technology, National Taiwan University, Taipei, Taiwan, R. O. C., Taiwan

The scaling of integrated circuits (IC) has posed significant challenges, particularly when aiming for nanometer-level scales capable of accommodating billions of transistors. To keep up with Moore's Law, IC industry has shifted towards developing three-dimensional integration (3DICs). The use of 3D packaging technology has allowed chips to incorporate numerous additional functionalities. While the calculation capability increased substantially by dielet stacking, power density per area increased as well. In this way, the design of 3DIC has intensified the research focus on thermal management. While heat dissipation is managed through metals in the TSV design of 3DIC, the additional supporting approaches of thermal dissipation capability by IC packaging remain unsolved. Conventional packaging materials have shown poor thermal conductivity, typically ranging from only 1 to 2 W/mK for decades, despite having maximum contact area with the stacked dielets. Consequently, it is crucial to develop innovative strategies to tackle these problems, potentially utilizing packaging materials with high thermal conductivity. While commercially available packaging materials like polymer and epoxy are lightweight, inexpensive, and easy to process, they suffer from low thermal conductivity properties. This is primarily because conventional techniques are unable to address the issue of percolation, where the stuffed and isolated ceramic particles blended that were used to enhance the thermal conductivity can not form the continuous phonon heat conductive path. In this study, we have successfully tackled this issue by dispensing 2D materials as the filler of packaging materials to develop novel composites with high thermal conductivity. The filler incorporates graphene, which exhibits excellent thermal conductivity, weaves continuous networks inside the epoxy, and forms thermal conductive network. To maintain the structural integrity and successful dispersion of the graphene, cellulose nanofibers (CNF) with 1D structures were used. The resulting graphene/CNF structures can form continuous heat dissipation network. Through the blending of the graphene/CNF filler, the thermal conductivity of the polymer, polypropylene, can be increased by 270 times, rising from 0.2 W/mK to 54 W/mK, and epoxy can be increased by 66 times, rising from 0.14 W/mK to 9.35 W/mK. While keeping the superior high thermal conductivity, our composite still maintains low leakage that shows a promising candidate for the next generation packaging materials.

8:05 AM EL07.16.04
Insights from Ab-Initio Simulations on the Working Mechanism of Single-Layer MoS3 Memristors Gabriele Boschetto1, Stefania Carapezzi1 and Aida Todri-Sanial1,2; 1LIRMM, France; 2Silvaco Europe, France; 3Eindhoven University of Technology, Netherlands
Memristors are promising building blocks for important technological applications such as high-density memory, data encryption and neuromorphic computing. In this context, 2D memristors based on atomically thin single-layer molybdenum disulfide (MoS\textsubscript{2}) are particularly interesting due to their extremely compact size and low-power operation [1,2].

Although few notable examples of working devices based on monolayer MoS\textsubscript{2} have been already reported in the literature, their working mechanism is still far from being understood, the main challenge being the great variability in terms of device architecture and quality of MoS\textsubscript{2} film. Nevertheless, regardless of the device architecture, intrinsic defects in MoS\textsubscript{2} are thought to be crucial for the functionality of memristors; for instance, S vacancies are highly abundant in CVD-MoS\textsubscript{2} and may impact non-trivially the properties at the interface with the metal contact, such as the contact resistance [3]. Moreover, in vertical Au/MoS\textsubscript{2}/Au memristors it has been argued that the resistive switching mechanism may be due to the migration of metal atoms from the electrode to fill such S vacancies in MoS\textsubscript{2} [4].

Here, we focus on such a device architecture and we carry out atomistic computer simulations in the framework of density functional theory (DFT). We employ surface calculations based on the Green’s function formalism [5] to construct realistic interfaces and to compute relevant properties at the interface between MoS\textsubscript{2} and Au electrode. To elucidate the working mechanism of MoS\textsubscript{2} memristors, we consider defective MoS\textsubscript{2} either with S vacancies or with Au substitution (adatoms). Then, we investigate the effect of defect concentration and defect clustering on the physics and chemistry of MoS\textsubscript{2} interfaces. By exploring several possible case scenarios, we were able not only to better understand the pivotal role of the extra Au atoms for the resistive switch mechanism of MoS\textsubscript{2} memristors, but also to provide the theoretical justification on experimental findings.

8:20 AM EL07.16.05
A Preliminary Study on Implementation of Five-Qubit Quantum Information Processing in Silicon Devices
Junghee Ryu and Hoon Ryu; Korea Institute of Science and Technology Information, Korea (the Republic of)

INTRODUCTION
An electrode-driven Silicon (Si) quantum dot (QD) system can be adopted to design scalable quantum processors with well-established industrial fabrication technologies [Nat. Electron. 5, 184 (2022)]. Recently, there have been experimental efforts to understand the physics of electron-spin qubits in Si QD systems whose confinement is manipulated with human controls, including a successful implementation of entangling logic operations up to six qubits [Nature 609, 919 (2022)]. Device designs & control engineering of physical systems consisting of many QDs, however, are still critical issues that must be uncovered with computational modeling to secure the scalability of quantum processors. Here we study the control engineering needed to initialize the linear five QD (FQD) system in Si and show the initialized spin states can be controlled to produce the magic state, one of quantum resource for realization of fault-tolerant quantum computing [Nature 510, 351 (2014)].

METHODS
Device simulations are conducted for the realistically sized Si FQD system with our multi-scale modeling approach integrating the bulk physics & the parabolic effective mass approximation. Qubits are encoded to electron spins that are created with quantum confinement driven by gate biases imposed on top electrodes. A static magnetic field is applied with a lateral gradient to make the Zeeman-splitting energies of electron ground states distinguishable. Once a set of five Zeeman-splitting energies and exchange interactions between nearest QDs is obtained from device simulations, the time-response of spin qubits is obtained from solutions of a time-dependent Schrödinger equation that is described with the Heisenberg spin Hamiltonian.

RESULTS AND DISCUSSION
We rigorously explored appropriate sets of biases imposed on the top electrodes, with which the FQD can be stably created satisfying the symmetric-biasing condition. Figuring out the bias condition that fills a single electron to each QD (qubit initialization), we engineered the sizes of nine electrodes to calibrate the distance between nearest electron spins to ~100nm. When the system is initialized, the five Zeeman-splitting energies come clearly distinguishable, and the four exchange interactions between nearest electron spins turn out to be weak enough to guarantee the individual address of five qubits. Then, as an application example, we show how a specific type of 5-qubit magic states can be prepared in the Si FQD platform, where we also present the detailed guideline of controls required to implement the non-Clifford Z-gate and the Hadamard gate that are essential to generate the magic state. Robustness of the secured 5-qubit circuit (and so the magic state) to charge noise is also confirmed by simulation results that are obtained with unintentional random fluctuations in exchange energies.

8:25 AM EL07.16.06
Theoretical Exploration of Two-Dimensional Electrenes for Low-Resistance Metal-2D Semiconductor Contacts
Mohammad Rafiiee Diznab, Erin R. Johnson and Jesse Maassen; Dalhousie University, Canada

Transition-metal dichalcogenides (TMDCs), including MoS\textsubscript{2}, have great potential in electronic applications. However, achieving low-resistance metal contacts is a challenge that impacts their performance in nanodevices, due to strong Fermi level pinning and the presence of a tunnelling barrier. As a solution, we explore a strategy utilizing two-dimensional (2D) alkaline-earth sub-pnictide electrenes with a general formula of M\textsubscript{2}X (M = Ca, Sr, Ba; X = N, P, As, Sb) as an intermediate material between the 2D TMDC and metal. Electrenes possess one excess electron per formula unit resulting in the formation of 2D sheets of charge on their surfaces. This charge can be readily donated when interfaced with a TMDC semiconductor, thereby lowering its conduction band below the Fermi level and eliminating Schottky and tunnelling barriers. Density-functional theory calculations were performed on metal-electrone-MoS\textsubscript{2} heterojunctions for all stable M\textsubscript{2}X electrenes, and both Cu and Au metals. To identify the material combinations that provide the most effective Ohmic contact the charge transfer, band structure and electrostatic potential, among other quantities, were analyzed. In all cases, a linear correlation was found between the charge donated to the MoS\textsubscript{2} and the electrone surface charge. The electrone Ca\textsubscript{2}N is found to be most promising for achieving an Ohmic metal-MoS\textsubscript{2} contact, due to its high surface charge density.

Integrating 2D Materials in Silicon Microchips
Mario Lanza; King Abdullah University of Science and Technology, Saudi Arabia
Two-dimensional layered materials (2D-LMs) materials have outstanding physical, chemical and thermal properties that make them attractive for the fabrication of solid-state micro/nano-electronic devices and circuits. However, synthesizing high-quality 2D-LMs at the wafer scale is difficult, and integrating them in semiconductor production lines brings associated multiple challenges. Nevertheless, in the past few years substantial progress has been achieved and leading companies like TSMC, Samsung and IMEC have started to work more intensively on the fabrication of devices using 2D-LMs. In this talk, I will discuss the state-of-the-art on micro/nano-electronic devices made (entirely or partially) of 2D-LMs, the most sophisticated circuits ever constructed, and the fabrication of CMOS/2D hybrid microchips. I will put special emphasis on devices that employ hexagonal boron nitride, the only 2D-LM with an enough high band gap to be employed as dielectric. I will also discuss the main technological challenges to face in the next years and provide some recommendations on how to solve them.

Enhancement of Electrochromic Performance of W18O49 NWs Through Instantaneous Acceleration of Ion and Electron Transport via Ti3C2Tx (MXene) Addition Muhammad Hassan and Kenji Celebi, Zhejiang University, China

The field of flexible electrochromic materials has garnered considerable attention due to their potential applications in emerging technologies like smart windows, wearable displays, and electronic paper. Transition metal oxides (TMOs) show promise as electrochromic materials for smart windows and displays. However, the challenge remains to achieve simultaneous improvements in flexibility, coloration efficiency, and response time. Effective strategy to simultaneously boost the transport kinetics of electrons and ions in TMOs thin films is critical. One effective approach is the utilization of nanostructured materials in the form of 2D nanosheets, which significantly enhance electrical and ionic transport due to their increased surface-to-volume ratio. The high contact area between adjacent nanosheets facilitates even redistribution of induced strain, leading to improved mechanical strength and film flexibility.

In this regard, we present advancements in the development of a promising material, the MXene-W18O49 nanowires (NWs) composite, and its interface assembly for flexible electrochromic applications. These assembled nanometer-thick heterostructures exhibit well-balanced alignment and connectivity, enabling fast and efficient transport of ions and electrons, as well as superior mechanical and electrochemical stability. Furthermore, we demonstrate the feasibility of large-area flexible devices that can be seamlessly integrated onto curved and flexible surfaces, paving the way for future global electronics.

Room Temperature Photoluminescence Mediated by Sulfur Vacancies in 2D Molybdenum Disulfide Manish Chhowalla; University of Cambridge, United Kingdom

Atomic defects in monolayer transition metal dichalcogenides (TMDs) such as chalcogen vacancies significantly affect their properties. In this work, we provide a reproducible and facile strategy to rationally induce chalcogen vacancies in monolayer MoS2 by annealing at 600 °C in argon/hydrogen (95%/5%) atmosphere. Synchrotron X-ray photoemission spectroscopy shows that a Mo 3d5/2 core peak at 230.1 eV emerges in the annealed MoS2 associated with non-stoichiometric MoSx (0<x<2), and Raman spectroscopy shows an enhancement of the ~380 cm−1 peak that is attributed to sulfur vacancies. At sulfur vacancy densities of ~2.4×1014 cm−2, we observe a defect peak at ~1.72 eV (referred to as LX0) at room temperature in the photoluminescence (PL) spectra. The LX0 peak is attributed to excitons trapped at defect-induced in-gap states and is typically observed only at low temperatures (~77 K). Time-resolved PL measurements reveal that the lifetime of defect-mediated LX0 emission is longer than band edge excitons, both at room and low temperatures (~2.77 ns at 8 K). The LX0 peak can be suppressed by annealing the defective MoS2 in sulfur vapor, which indicates that it is possible to passivate the vacancies. Our results provide insights into how excitonic and defect-mediated PL emission in MoS2 are influenced by sulfur vacancies at room and low temperatures.

Attractively Thin SnO-Based p-Channel Thin-Film Transistor and Low-Power Complementary Inverter Chi-Hsin Huang1, Yalun Tang2, Tzu-Yi Yang1, Yu-Lun Chueh1 and Kenji Nomura2,2; 1University of California, San Diego, United States; 2University of California San Diego, United States; 3National Tsing Hua University, Taiwan

Atmospherically thin oxide semiconductors play a crucial role in the development of next-generation, cost-effective, and energy-efficient electronics. In this study, we successfully developed a high-performance, fully depleted-type p-channel oxide thin-film transistor (TFT) utilizing an atmospherically thin p-type tin monoxide (SnO) channel with a thickness of approximately 1 nm. The SnO channel was grown using a vacuum-free, solvent-free, metal-liquid printing process at a remarkably low temperature of 250°C in an ambient atmosphere. To enhance the performance of the p-channel SnO TFTs, we employed oxygen vacancy defect terminations for both the bulk-channel and back-channel of the SnO channel. As a result, the presented p-channel SnO TFTs exhibited favorable characteristics, including a reasonable TFT mobility of ~0.47 cm2V−1s−1, a high on/off current ratio of ~102, a low-off current (~3×10−4A), and a subthreshold swing of ~2.5 V decade−1, which was improved compared to the conventional p-channel SnO TFTs. Furthermore, we successfully developed a low-power oxide-TFT-based complementary metal-oxide-semiconductor (CMOS) inverter using the ultrathin p-SnO and n-In2O3 TFTs. The CMOS inverter demonstrated a high voltage gain of approximately 120 and achieved low-power operation, consuming less than 58 nW, for the p-SnO/n-In2O3-TFT-based CMOS inverter.

This work highlights the significant potential of oxide-TFT-based CMOS logic development by leveraging atmospherically thin oxide material channels. It offers new opportunities for next-generation, energy-efficient, and cost-effective oxide TFT technology, with the added benefits of vacuum-free, solvent-free, and low-temperature processing technologies.

SYMPOSIUM EL08
Emerging Material Platforms and Fundamental Approaches for Plasmonics, Nanophotonics and Metasurfaces
November 26 - December 5, 2023
In our design, the upconverting material is a 100-nm thick bulk heterojunction comprising organic molecules Y6 (sensitizer) and rubrene (emitter; here, with the ultimate goal of enabling a wearable, all-passive, NIR-to-visible imaging system.

To enhance light extraction while operating in transmission mode, we developed a dichroic substrate that reflects visible light while transmitting NIR light, which allows us to recover visible light otherwise emitted backwards towards the source. To further improve the efficiency of the upconverter, we designed triplet annihilation [1], enabling solid-state upconverting thin films [2]. However, the previously demonstrated efficiency of this upconversion process is limited by the relatively slow response of the cantilever. Although improved mechanical designs of the scanner have enabled a high-speed atomic force microscope (Hs-AFM) that can reach up to 1300 frames per second, a single image -frame still takes hundreds of microseconds, significantly longer than the thermal relaxation time of nanoparticles, which is in the nanosecond regime.

In this talk, I will introduce an ultrafast visualization of dynamic heat transfer in the nanosecond temporal regime with a spatial resolution of around 10 nm. We show the heating and cooling stages of a single gold nanoparticle using nearfield optical force imaging, termed decoupled optical force nanoscopy (Dofn). Our technique, different from conventional near-field scanning optical microscopy, probes optical forces originating from the interactions between the illuminated nanoparticle and the probe.

10:30 AM EL08.01.02
Boosting the Efficiency of Passive Upconversion Imaging using Engineered Nanostructures Rabeeya Hamid1, Demeng Feng1, Emma Belliveau2, Manchen Hu2, Pournima Narayanan2, Chenghao Wan2, Justin Edwards1, Daniel Congreve2 and Mikhail Kats1; 1University of Wisconsin-Madison, United States; 2Stanford University, United States

Most existing technologies to enable vision in the near infrared (NIR) region rely on cameras, displays, and other powered optoelectronics. These devices capture NIR images and convert them to the visible. In contrast, we are working on a passive frequency-upconversion imaging system that directly converts NIR light to visible light, thereby eliminating the need for external power sources or electronic components. We use a photon upconversion process that involves a sequential transfer of energy from two low-energy incident photons, resulting in the emission of a higher-energy photon via triplet-triplet annihilation [1], enabling solid-state upconverting thin films [2]. However, the previously demonstrated efficiency of this upconversion process is not sufficient for passive near-sight imaging systems.

We designed and demonstrated several types of nanostructures that enhance the absorption, emission, and collection efficiencies of upconverting films, with the ultimate goal of enabling a wearable, all-passive, NIR-to-visible imaging system.

In our design, the upconverting material is a 100-nm thick bulk heterojunction comprising organic molecules Y6 (sensitizer) and rubrene (emitter; here, doped with DBP [2]), similar to the materials in the bilayer structure in ref. [3]. Our bulk heterojunction passively converts incident NIR light to orange light with peak emission at ~600 nm; however, the emission is incoherent and isotropic. To enable imaging, the directionality of rays needs to be preserved through the upconversion process. We address this issue by positioning the upconverter at the focal plane of a Keplerian telescope system, a strategy that we previously demonstrated for a down-conversion imaging system [4].

To enhance light extraction while operating in transmission mode, we developed a dichroic substrate that reflects visible light while transmitting NIR light, which allows us to recover visible light otherwise emitted backwards towards the source. To further improve the efficiency of the upconverter, we designed...
a superstrate that is transparent in the visible range but reflects in the NIR, enabling the recycling of unabsorbed NIR light back into the upconverting film, thereby enhancing the absorption and the subsequent emission. We designed the multilayer substrates and superstrates such that they provide a consistent spectral response across a broad range of viewing angles (here, up to 30 degrees) for the desired wavelengths (500 – 650 nm in the visible, and 750 – 900 nm in the NIR). This functionality was implemented using niobium pentoxide (Nb2O5) and silicon dioxide (SiO2) layers. To maintain our imaging resolution, we limited the total thickness of the combined structure to 2 microns, thus ensuring that we remain within the depth of focus of our imaging system.

Our approach has yielded an approximately 2.5-fold enhancement in collection efficiency as a result of increased absorption. As of this writing, we have verified the collection-efficiency enhancement in experiments using both a laser source (at 852 nm) and a broadband NIR source. We anticipate presenting the absorption-enhancement data at the conference.

In addition to power measurements, we have demonstrated imaging through the upconverter with the engineered substrate, observing an approximate doubling in brightness without compromising spatial resolution. We anticipate that our approach will be useful for a variety of incoherent upconverting schemes beyond the all-organic chemistry presented here (e.g., those based on inorganic nanocrystals [2, 4]) and can enable all-passive vision even under low-power NIR illumination and longer wavelengths.

We acknowledge funding from DARPA under Grant No. HR00112220010

**Optical Loss Measurements of Silicon-Nitride Membranes using Photothermal Common-Path Interferometry**

Using graphene-referenced PCI, we found the absorption coefficient of stoichiometric Si3N4 to be ~1.3 x 10^{-2} cm^{-1} and that of non-stoichiometric SiNx membranes has not been directly measured. We used photothermal commonpath interferometry (PCI)4, a sensitive pump-probe technique, to measure the absorption of Si3N4 membranes in the near infrared. We characterized membranes because they are the closest form factor to laser sails, and conventional techniques such as variable-angle spectroscopic ellipsometry are not sensitive enough to measure optical absorption in such thin low-loss membranes. PCI characterizes optical loss in a material by measuring the effect of the sample's absorption of a chopped pump beam on a probe beam via the thermo-optic effect. The amount of modulation in the probe beam carries information about the sample’s absorptivity at the pump wavelength.

Translation of the PCI signal to the actual absorption value depends on the sample geometry and material properties, including the thermo-optic coefficient and thermal conductance of the sample. The translation is most-easily done using a reference similar to the sample in terms of optical and thermal properties, except with a higher, known absorbance. Here, we transferred a monolayer of graphene onto the SiN membranes we want to measure. Because it is thin and grown by chemical vapor deposition, the graphene does not significantly affect the overall thermal conductance of the sample; however, the presence of graphene increases the optical absorption from the ppm level to the ~1% level (the latter easily measurable using ellipsometry or reflection/transmission spectroscopy), and thus the resulting graphene/SiN structure can be used as a reference for PCI measurements of the SiN alone. To verify the collection-efficiency enhancement in experiments using both a laser source (at 852 nm) and a broadband NIR source. We anticipate presenting the absorption-enhancement data at the conference.

**Materials that feature low optical loss and relatively high refractive index are important for applications such as on-chip photonics1, free-space optics for sensitive experiments like LIGO2,3 and, more recently, laser-driven light sails comprising thin membrane-like structures that efficiently reflect a high-power drive laser4. We have been investigating stoichiometric silicon nitride (Si3N4) membranes as a candidate material for such laser-light sails, due to its [a] low loss in the near infrared, [b] a moderately high refractive index (~2), [c] a large bandgap (~4.5 eV) that prevents two-photon absorption5,6, and [d] vibrational resonances in the mid infrared that can enable radiative cooling7. To our knowledge, the optical absorption of Si3N4 membranes has not been directly measured.**

Paradigms for Realizing Symmetry-Guaranteed Pairs of Bound States in the Continuum and Identifying Super-Mossian Materials

Chloe F. Doiron; Sandia National Laboratories, United States

Over the last decade, all-dielectric metasurfaces have emerged as a powerful platform for enhancing light-matter interactions, enabling device performance improvements across a range of applications. To increase light-matter interactions, photonic states with long lifetimes (high-quality factors) are desirable, requiring improvements in photonic designs, material quality, and fabrication tolerances. In this talk, I will present one structural design paradigm and one material search heuristic for improving all-dielectric metasurfaces.

Bound states in the continuum are states that are completely decoupled from a continuum leading to infinitely long lifetimes. In practice, while states with infinitely long lifetimes are undesirable, they enable a design paradigm that solves the photonic design component leaving material quality and fabrication tolerances as the primary means to achieve arbitrary lifetimes. Demonstrations using bound states in the continuum have enabled improvements for lasers, sensors, and frequency mixers. However, many applications require degenerate or nearly degenerate high-quality factor (Q) states, such as spontaneous parametric down conversion, non-linear four-wave mixing, and intra-cavity difference frequency mixing for terahertz generation. I will present a group theory approach based on lattices with six-fold rotational symmetry for creating symmetry-guaranteed pairs of bound states in the continuum. Using this design paradigm, the splitting and Q-factors can be independently and robustly controlled creating new pathways for improving metasurfaces for frequency conversion, heralded single-photon production, and sensing.

Finally, I will discuss a search heuristic for materials with refractive indices that surpass the common form of the Moss rule (n^4Eg ≈ 95 eV) leading to the creation of super-Mossian materials. With this heuristic, I will present an experimental realization of a super-Mossian metasurface using iron pyrite (FeS2), with refractive index greater than 4.37 and a bandgap of 1.03 eV, surpassing the common form of the Moss rule by nearly 40%.

Understanding the Origins of Low-Frequency Instability in Thin-Film Lithium Niobate Nanophotonic Devices

David R. Barton1, Matthew Yeh1, Gavin Smith2, Evelyn Hu1 and Marko Loncar1; 1Harvard University, United States; 2University of New Hampshire, United States

Thin-film lithium niobate on insulator (TFLN) is a promising platform for integrated classical and quantum photonics due to its intrinsically large electro-optic effect and wafer-scale availability. The direct connection between driving electric fields and refractive index in this platform has enabled new schemes for creating pulsed lasers on chip, high-bandwidth and energy-efficient modulators, and devices for integrated nonlinear photonics. However, it is generally recognized that the reliability of thin-film lithium niobate modulators is subject to unstable electro-optic response at low frequencies, and undesired photorefractive index changes due to defect absorption at high optical powers. Post-processing methods such as annealing have been developed to reduce these deleterious effects, but their microscopic origins remain unclear. It is also not known if these effects relate to fundamental materials issues, might be exacerbated for materials in thin-film form with possible strain inhomogeneities, and indeed might arise from thin-film preparation, which involves ion implantation, and chemical-mechanical polishing.

Here, we use a combination of materials characterization (XPS, Atom Probe Tomography, and electronic transport) and optical device characterization to explore the structure-device-processing parameter space in integrated lithium niobate devices and attempt to identify a mechanistic insight for low-frequency instability in our devices. All our devices are fabricated on 600 nm thick ×-cut Lithium Niobate on insulator wafers, and we explore fabrication processes that impact both the bulk and interfaces in our devices. First, we show through XPS that the etch conditions and standard acid cleans used in our thin-film processing dramatically impact the surface by removing lithium from the surface, locally reducing Nb5+ to Nb3+, and creating a damaged amorphous Lithium Niobate layer. Specific chemical cleans remove the damaged layer, while annealing at moderate temperatures in an oxygen environment restores the surface Li:Nb ratio to its unprocessed status. We gained additional insight by using APT to map out the material composition in 3D with ~nm-scale resolution. Surprisingly, we find that the lithium composition within the unprocessed material varies substantially over length scales on the order of 10 nanometers, suggesting that local defect structures such as the small polaron may exist in appreciable concentrations that could give rise to photorefractive. Annealing our samples temporarily increases quality factors and reduces photorefractive, indicating that diffusion of mobile species such as Lithium or Hydrogen may indeed play a role in long-term stability of our devices.

Finally, we find that the metal-Lithium Niobate interface is important for the low-frequency response of our devices. Etching through the oxide cladding in our structures dramatically improves the electro-optic response but leaves behind an amorphous lithium niobate interface for the electrical contacts. Surprisingly, any attempts to remove redeposition or clean the surface semiconductor-metal interface reduces the low-frequency response and degrades the response flatness. Together, these results point to the important role of surface and bulk conductivity within our electro-optic devices for stable low-frequency tuning, a requirement for deployable devices and systems in thin-film Lithium Niobate.

The Origins of Low-Frequency Instability in Thin-Film Lithium Niobate Nanophotonic Devices

David R. Barton, Matthew Yeh, Gavin Smith, Evelyn Hu, Marko Loncar; 1Harvard University, United States; 2University of New Hampshire, United States

Understanding the origins of low-frequency instability in thin-film lithium niobate is critical for the development of high-performance photonic devices. In this talk, we will explore the fundamental mechanisms underlying the low-frequency response of thin-film lithium niobate devices. We will present evidence for the role of surface and bulk defects, as well as the importance of interface effects, in determining the low-frequency properties of these materials. Additionally, we will discuss the implications of these findings for the design and optimization of future photonic devices.
spectroscopy for biosensing can be pushed further in its resolution by demonstrating ~98% accurate classification of presence of anti-TB drug resistance using spontaneous Raman to its expansion in its sample volume reach by demonstrating rapid magnetic isolation and detection of hand full of pathogenic bacteria from water and food contaminants using polymer coated magnetic beads as Raman reporters. We also demonstrate detection on home built hand Raman systems for ease of deployment to clinical end users. Lastly, I will cover new territories Raman spectroscopy can serve in next generation disease therapeutics. Clinical and field translation of Raman based cell detection calls for careful analysis of the application at hand as either labeled or label free alternatives would best serve the target.

Plasmonic Ammonia Synthesis with a AuRu Bimetallic Alloy
Lin Yuan, Briley Bourgeois, Alan X. Dai, Peiwen Ren, Felipe Jornada and Jennifer A. Dionne; Stanford University, United States

The Haber-Bosch process has had a significant impact on global food production, enabling ammonia synthesis for nearly all agricultural fertilizers. However, ammonia production generally requires high operating temperatures (exceeding 300 °C) and high pressures (100 atm), leading to over 3% of annual global greenhouse gas emissions. To promote sustainable chemistry, ammonia synthesis must be accomplished under milder conditions while also eliminating the greenhouse gas footprint. In this presentation, we describe bimetallic plasmonic nanoparticles that enable high-efficiency and sustainable nitrogen fixation at room temperature and pressure. We utilize AuRu metallic nanoparticles, where Au serves as the plasmonic optical absorber, and Ru acts as the catalyst for nitrogen bond-breaking. We develop a colloidal synthesis to create AuRu nanoparticles with controlled phases, including the fcc phase and hcp phase. We vary the Au and Ru composition from 1:0.1 to 1:0.3. We then load the nanoparticles onto a commercial MgO substrate at 5% mass-loading. Using UV-Vis spectroscopy, the nanoparticles show strong optical absorption at wavelengths of 520 nm. We use our bench-scale photocatalyst to characterize the ammonia synthesis(N_2+3H_2→2NH_3), using nitrogen and hydrogen as a feeding gas, at various temperatures, pressures, and under various illumination conditions. Our observations indicate an ammonia rate of 60 mmol/g/h under 100 mW/cm^2 visible light irradiation, and a 0.12% external quantum efficiency on our AuRu catalyst. By correlating the wavelength-dependent reactivity and electromagnetic hot carrier calculations, we have identified the potential contributions from phonon-assisted intraband and interband transitions in driving the photochemical transformation. Our study provides a solution for designing photocatalysts to drive nitrogen fixation under mild conditions and an understanding of the mechanisms that can inform future applications.

3:45 PM EL08.02.06
Single Particle Plasmonic Nanocavity-Based Strong Coupling with Intrananogap Nanostucture
Kyunghwa Chung1,2, Soohyun Lee1, Nathan Grain1, Subin Yu1, Seokhyoung Kim3, Sung Ho Park2 and Luke Lee3,2; 1Harvard University, United States; 2Sungkyunkwan University, Korea (the Republic of); 3Michigan State University, United States

Achieving strong coupling in practical applications of cavity quantum electrodynamics (CQED) often poses significant challenges due to the delicate conditions required. In particular, the realization of strong coupling with single nanoparticles has been predominantly demonstrated using J-aggregate dye molecules. In this work, we present a novel CQED probe capable of transforming a nanocavity within a single nanoparticle. Our approach utilizes a plasmonic CQED structure based on a gold double nanoring (Au DNR) that incorporates an intraparticle nanogap. Through dark-field measurements on individual particles, we observe the emergence of exciton-plasmon polaritons, known as plexcitons, evidenced by the bifurcation of the scattering peak into two distinct resonances. Finite-element modeling is employed to elucidate the correlation between the Au DNR morphology and the cavity resonance wavelength relative to the exciton absorption, while temporal coupled-mode theory quantifies the strength of coupling. Verification of plexciton states is accomplished through photoluminescence measurements, which demonstrate light emission from the lower plexciton state. The proposed CQED nanocavity serves as a promising nanoprobe for the detection of small molecules within cells and offers a platform for groundbreaking biomolecular studies.

Crystalline AuNP with Strain-Controlled Morphologies and Optical Properties
Qiaomu Yao and Peter K. Petrov; Imperial College London, United Kingdom

Metallic nanoparticles (NP) decorated with thin films have been extensively studied and exhibit promising performance in a wide range of applications, including biosensing, electrical devices, photocatalysis, and solar cells. For perovskite thin films, the decoration can produce an enhanced plasmonic response, which indicates a promising future in nanowaveguides, energy harvesting, and chemical sensing applications. The morphologies and chemistries of NPs strongly govern plasmonic performance. The size and density of AuNPs dramatically influence the absorption, surface plasmonic resonance peak intensity, and the second harmonic generation responses. It also alters the so-called epsilon-near-zero (ENZ) effects, where the interplay between real and imaginary parts of permittivity results in the strong enhancement and local confinement of the normal field inside ENZ materials. Here we present a study of the formation of gold nanoparticles (AuNP) grown by PLD onto perovskite strontium niobate (SNO) thin films deposited on both MgO and SrTiO3 substrates. The strain-free SNO (a = 4.023 Å) has a -3% lattice mismatch with the STO (a = 3.905 Å) and 4.5% with MgO (a = 4.212 Å) which leads to compressive and tensile in-plane residual strains, respectively. We observed that the formation of Au NPs and their morphology depends on the structure of the underlying SNO film. It conveys the surface structure and controls nanoparticle formation. The morphologies of AuNPs were measured using SEM and AFM. The residual strain in the SNO thin films and AuNPs was evaluated by X-ray diffraction (XRD). Finally, the complex permittivity of AuNP-decorated SNO films was measured using Variable Angle Spectroscopic Ellipsometry (VASE). In summary, AuNP-decorated SNO/MgO and SNO/STO thin films exhibit different optical properties with only gold-decorated SNO/MgO samples showing nanostructures’ size-dependent epsilon-near-zero behaviour. These results provide an additional route to control the structure of AuNPs. They can be used for the design and development of strain-engineered gold nanoparticle decorated devices for surface-enhanced Raman spectroscopy (SERS) and photocatalysis.

Scalable Plasmonic Superstructures for Colorful Dichroism
Jang-Hwan Han, Juwhan Kim, Gyun Min Kim, Hyun Min Kim and Hyeon-Ho Jeong; Gwangju Institute of Science and Technology (GIST), Korea (the Republic of)

Flat optics based on metasurfaces has emerged as a promising approach to achieve compact and efficient optical systems. However, the development of optical color filters using single or multilayered thin film resonators or reflectors has received less attention, although their structural thickness still needs to exceed at least a quarter of a wavelength, resulting in bulky optical systems. Herein, we present scalable plasmonic superstructures comprising randomly but uniformly distributed metallic nanoparticles embedded within a glass matrix. These superstructures are fabricated using a metal-dielectric co-deposition method with substrate cooling, allowing for precise control over the sizes, densities, and materials of the plasmonic nanoparticles in the form of wafer-scale nanocomposite film. Crucially, we introduce ‘scattering-free’ plasmonic resonators with diameters below 10 nm, so the reflected colors from these superstructures can be engineered primarily based on the film thickness, covering a wide range from ultraviolet to near-infrared regions, analogous to the conventional dielectric thin film reflectors. In contrast, the
transmitted colors through the same structures exhibit weak dependence on the film thickness, but give rise to the vibrant colors due to strong plasmonic absorptions. This unique property of the plasmonic superstructure films enables independent engineering of reflected and transmitted colors by controlling their thickness and materials, thus demonstrating applications such as dichroic imaging and encryption systems.

In this presentation, the design rule, fabrication method, and optical features of the plasmonic superstructures will be discussed. Especially, we will demonstrate how to achieve full colors in both the reflection and transmission modes, featuring their potential for colorful imaging applications.

4:30 PM EL08.02.09
Simulation and Fabrication of Tunable Metal-Insulator-Metal Bow-Tie Antenna Arrays for Surface Enhanced Raman Scattering Sümevra Vural Kaymaz1,2, Hasan Sarigül1, Caner Soylukan1, Selim Tanriseven1, Hasan Kurt1 and Meral Yuce1; 1Sabanci University, Turkey; 2SUNUM Nanotechnology Research and Application Center, Sabanci University, Turkey; 3Imperial College London, United Kingdom

Surface plasmons in metal/dielectric interfaces provide significant field enhancement in the subwavelength resolution, enabling a wide range of applications. One such application is surface-enhanced Raman scattering (SERS), a powerful analytical method for label-free molecular fingerprinting of various analytes. A careful design and nano-fabrication of SERS substrates with a considerable Raman enhancement factor (EF) at the wavelength of interest are imperative for SERS applications. SERS substrates based on noble metal colloids, roughened nanosurfaces, nanospheres, and nanotips have been previously reported. Nevertheless, the low reproducibility of electric field hot spots has limited the utilization of these inherently random structures with high EF. The period arrays of plasmonic nanostructures offer the potential for generating reproducible SERS substrates.

Specifically, metal-insulator-metal (MIM) based nanostructures exhibit substantial gap resonance due to the coupling of localized fields between two metal layers underlying the dielectric layer. By adjusting the geometric parameters of metal nanostructures and dielectric layer thickness, gap resonance can be tuned for application-specific requirements. In this work, we investigated the performance of gold (Au) bow-tie antenna arrays on insulator-metal substrates for SERS applications. The Finite-difference time-domain (FDTD) method was used to simulate the effects of parameters such as bow-tie apex angle, gap size, length, and dielectric layer thickness. We achieved an electric field enhancement of up to 630 times the incoming electric field intensity, corresponding to a SERS EF factor improvement of ~3.9 × 10^5 in our final optimized design at an excitation wavelength of 785 nm. Later, we fabricated Au MIM bow-tie antenna arrays using beam lithography and investigated their optical characteristics with an in-house modular reflection/transmission-based Microscopy system.

SESSION EL08.03: Advanced Nanophotonic Materials and Devices

Low-Cost and Scalable Manufacturing of Optical Metasurfaces in the Visible using Engineered Optical Materials (PER, Low-Loss a-Si:H, and Hybrid ALD Structural Resin) Junsuk Rho and Joohoon Kim; Pohang University of Science and Technology, Korea (the Republic of)

Here, we demonstrate low-cost, scalable manufacturing of optical metasurfaces with three approaches: 1) increasing a refractive index of resin with dielectric particle embedding for single-step nanoimprinting, 2) suppressing optical losses of hydrogenated amorphous silicon (a-Si:H) to apply complementary-metal-oxide-semiconductor technologies, and 3) high-index atomic layer deposited (ALD) structural resin. We demonstrate the effectiveness of these materials in creating optical metasurfaces operating at different wavelengths in the infrared, visible, and ultraviolet spectra. Firstly, we achieve high efficiencies of up to 90.6%, 47%, and 60% with a-Si, TiO2, and ZrO2 PER at wavelengths of 940, 532, and 325 nm, respectively. Furthermore, we obtain a measured efficiency of 30% at a wavelength of 248 nm using ZrO2 PER metasurfaces. Secondly, by adjusting the deposition conditions of plasma-enhanced chemical vapor deposition, we engineer the bandgap of a-Si:H to enable low-loss operation, with minimum extinction coefficients as low as 0.082 at 450 nm. Using low-loss a-Si:H, we demonstrate efficient beam-steering metasurfaces with measured efficiencies of 42%, 65%, and 75% at 450, 532, and 635 nm, respectively, marking the first Si-typed metasurfaces working at the full visible. Finally, we manufacture highly efficient metalenses using hybrid ALD ALD structural resin with deep-ultraviolet lithography at visible wavelengths. Their measured efficiencies approach 60.9%, 77.8%, and 68.4% at 450, 532 and 635 nm, making them suitable for ultrathin virtual reality devices. Our approaches using PER, low-loss a-Si:H, and hybrid ALD structural resin enables the low-cost, large-area manufacturing of efficient optical metasurfaces across different wavelengths, facilitating the commercialization of metasurface-based photonic devices.

11:00 AM EL08.03.02
3D Interior Plasmonic Nanocavities for Sensitive and Selective Recognition of Hazardous Substances in Plastic Products Seung-Gyu Park; Korea Institute of Materials Science, Korea (the Republic of)

Surface-enhanced Raman scattering (SERS) utilizing plasmonic nanomaterials and nanostructured substrates has been extensively investigated to directly recognize substances because the energy differences between the incident and scattered lights correspond to the molecular vibrational energy states of the substances. SERS performance is dominantly derived from electric fields confined in dielectric media, called hotspots, between adjacent plasmonic nanostructures. Recently, the 3D interior hotspots templated with dielectric media surrounding by plasmonic materials have attracted great attention [1]. Various electrochemical techniques such as catalytic reaction, electrodeposition, and galvanic reaction (GR) have been exploited to realize the 3D interior hotspots. Particularly, a GR process spontaneously originates from energy differences in the reduction potential of two or more materials [2]. An imbalanced atomic exchange strategically defines narrow hollow regions which have dual functions of electric field confinement domains and molecular diffusion paths. For deeper comprehension of interior hotspots, the Ag nanocavities galvanically replaced by Au (Au/AgNC) on the silicon substrates were prepared. The proposed Au/AgNC platforms were used to trace hazardous substances such as phthalates. The activation of interior hotspots with superior density in a unit volume enabled reliable sensing operations at ppb levels. From the collected dataset, a machine-learning model was designed to predict various combinations (i.e., single, binary, ternary, and quaternary) of four major phthalates. Subtle differences in the phthalates’ spectral characteristics were successfully classified using a machine learning algorithm based on a principal component analysis–linear discriminant analysis model.

11:15 AM EL08.03.03 Multifractal Photonic Membranes for Random Lasing Devices Tornike Shubitidze, Yilin Zhu and Luca Dal Negro; Boston University, United States

Random lasers are at the center of an intense research activity due to their ease of fabrication and robustness combined with small-size (micron-scale) of the order of the lasing wavelength as well as their unique characteristics that include low-spatial coherence, lack of directionality, and bio-compatibility. In particular, non-resonant random laser devices rely on uncorrelated random fluctuations of the dielectric environment that give rise to traditional photon diffusion. On the other hand, anomalous light transport phenomena with significantly slower dynamics, or sub-diffusive transport, occur in engineered random media with correlated disorder, providing opportunities to further enhance optical amplification and reduce device footprints. In this talk, we present our work on the design and fabrication of active photonic membranes with multifractal structural correlations and we characterize their optical emission properties using leaky-mode and photoluminescence spectroscopy.

Photonic multifractals are heterogeneous with complex spatial fluctuations at multiple length scales characterized by a rich spectrum of local scaling exponents, i.e., a multifractal spectrum. Differently from well-known fractal structures, which possess only one global scaling quantified by a single fractal dimension, multifractals feature a continuous distribution of generalized fractal dimensions and can be considered as “intertwined sets” of self-similar structures. While the optical properties of fractal structures are well-understood, photon transport and light emission in multifractals remain fundamentally open problems. Here, we discuss photonic structures with tailored multi-scale correlations generated by iterative and multiplicative cascades of random fields. Localization and transport properties are explored and optimized using rigorous multi-particle MC theory in combination with efficient tight-binding models. Based on this approach, using electron beam lithography and high-quality deep reactive ion etching, we demonstrate multifractal nano-hole arrays in both passive (a-Si:H, Si3N4) and active (ZrO) photonic membrane geometries. We report on the characterization of the optical and structural properties of each membrane structure with variable angle spectroscopic ellipsometry (VASe), photoluminescence spectroscopy, x-ray diffraction measurements, scanning electron microscope imaging(SEM) and atomic force microscopy.

11:30 AM EL08.03.04 EuO-Codoped GaN-Based High-Q Two-Dimensional Photonic Crystal Cavities in the Red Region Takanori Iwaya1, Shuhei Ichikawa2, Dolf Timmerman1, J. T. Tatebayashi1 and Yasufumi Fujiwara3; 1Osaka University, Japan; 2Research Center for Ultra-High Voltage Electron Microscopy, Osaka University, Japan

EuO-codoped GaN (Ga{N,Eu,O}) is an efficient red light emitting material based on the GaN platform. We have demonstrated red light-emitting diodes using Ga{N,Eu,O} grown by organometallic vapor phase epitaxy method and reported a high light output power of 1.25 mW at 20 mA operation with a maximum external quantum efficiency over 9% [1,2]. Furthermore, we have shown that Ga{N,Eu,O} has a moderate value of gain of 6.6 cm−1 [3]. This observation suggests the possibility to develop a novel Ga{N,Eu,O}-based red laser diodes (LDs). The emission wavelength from Eu3+ ions is highly stable with respect to the surroundings, thus Ga{N,Eu,O}-based red LDs have a large potential applications including high-resolution laser displays and optical communications. In this contribution, we designed an optical cavity with a high Q-factor in the red region, which is required for the realization of a laser based on this material [4].

Although two-dimensional photonic crystal (2D-PhC) cavities are prominent candidates to achieve high Q-factors, they typically show relatively low Q-factors (< 5000) due to structural disorder that is inevitably introduced during the fabrication stages [5]. From an extensive analysis of the influence of such disorder for various cavity designs, we have shown that especially H3-type cavities are much less sensitive to optical losses, when compared to linear (LN) cavities [6]. We have fabricated H3-type cavities and demonstrated a highest value of Q of 7900. This value is much higher than previously reported Q-factors (~5500) of III-nitride-based 2D-PhC cavities in the visible range, and approaches the theoretical Q-factor of this cavity design. These results demonstrate that H3-type cavities can indeed effectively suppress the disorder-induced optical losses, and that a further improvement of the design is required with a higher theoretical Q-factor, in order to achieve higher experimental values.

We propose a 2D-heterostructure with core, transit and clad region. By designing the radii as $r_{core} > r_{trans} > r_{clad}$, the photonic band structure is modified and light at the photonic band-edge is well confined in the core region. For the optimal design parameters, a theoretical value of the Q-factor of 1.1×10^5 was obtained. The fabricated structure of this design shows a few resonant modes, with the mode with the largest Q-factor reaching a value of Q = 10500 [6], which is almost twice that of previously reported values. Thus, we conclude that this type of III-nitride-based 2D-PhC cavity is effective for confining light, and has a great potential for achieving high Q-factors in the visible region. This study shows the guideline to achieve high Q-factors with III-nitride-based 2D-PhC cavities in the red region, which would open up a large potential application.

11:45 AM EL08.03.05 Gate-Tunable Optical Anisotropy in Wafer-Scale, Aligned Carbon Nanotube Films Jason Lynch1, Evan Smith Smith2, Adam Alfieri1, Baokun Song3, Cindy Yuwei Chen1, Chavez Lawrence1, Cherie R. Kagani1, Honggang Gui1, Shiyuan Liu1, Lian-Miao Peng1, Shivashankar Vangala1, Joshua Hendrickson1 and Deep M. Jariwala4; 1University of Pennsylvania, United States; 2Air Force Research Laboratory, United States; 3Huazhong University of Science & Technology, China; 4Peking University, China

Modern telecommunications and polarimetry systems require active control of the polarization of light. This is currently done by either combining an intrinsically anisotropic material with a tunable isotropic one in a heterostructure or by nano-patterning a tunable material to give it optical anisotropy. Both of these processes complicate the fabrication process of real-world devices. Although materials that are both highly anisotropic and highly tunable can actively control the polarization of light on their own, materials that possess both properties are scarce and rarely available in high-quality thin films over wafer scales. Here, we present optical anisotropy and gate-tunability in semiconducting, highly-aligned, single-walled carbon nanotubes (SWCNTs) over 4" wafers in the visible and near-infrared (IR) regimes. SWCNTs were found to have a normalized birefringence value of up to 0.09 in the near IR which is larger than common anisotropic crystals such as liquid crystals (0.06), calcite (0.05), and LiNbO3 (0.02). The optical selection rules of SWCNTs result in a large optical band gap difference in the ordinary and extraordinary directions of 210 meV enabling its normalized dichroism to reach 0.58 which is only exceeded bulky, unstable crystals. SWCNTs were found to have record normalized birefringence and dichroism values for thin films (< 4 nm thick).
Additionally, the optical properties of SWCNTs can be modulated using carrier injection to induce the plasma dispersion effect. The real and imaginary parts of the extraordinary refractive index were tuned by 5.9% and 14.3% in the near infrared at 2200 nm and 1660 nm, respectively. This outperforms popular semiconductors for near IR telecommunications systems such as Si, LiNbO3, and graphene. Highly-aligned SWCNTs are among the most optically anisotropic and tunable materials and promise to open new avenues for their application in integrated photonics and telecommunications.

SESSION EL08.05: Poster Session I: Nanostructure Design, Fabrication and Characterization

8:00 PM EL08.05.01 Characterization of Iridium Films for Emerging Optical Applications Zachary Kranefeld, Pan Menasuta, Kevin Grossklars, John McElearney and Thomas Vandervelde; Tufts University, United States

Iridium (Ir) is a refractory metal with optical properties that make it an excellent candidate for a wide range of optical applications, including metamaterials; such as, selective-emitters for thermophotovoltaic (TPV) cells. Metamaterial applications require patterning with nanofabrication techniques, but these processes are still relatively unexplored for Ir films. In this work, various density Ir films were characterized throughout wet and dry etch fabrication processes. Electrical properties were measured as a function of film thickness via 4-point probe. Complex refractive index (n and k) was measured with variable angle spectroscopic ellipsometry (VASE) and reported as a function of film thickness and density. Surface morphology was determined by AFM and SEM, as a function of etch depth. Additionally, well-defined etch rates as well as etchant selectivity are reported for each etch recipe.

8:00 PM EL08.05.03 Omni-Directional Improvement for Organic Solar Cells by Quasi-Random Nanostructures Devin Krystek, Seokhun Lee and Hui Zhao; University of Nevada, Las Vegas, United States

Organic solar cells provide many hopes for the future: potential for mass manufacturing, cheap materials, flexible substrates. However, they also pose many problems that have yet to be solved, namely relatively low efficiency and instability. This work attempts to improve the efficiency of organic solar cells by using a quasi-random nanostructured active layer. While many methods exist for manufacturing nanostructures, we utilize a soft lithography approach using Digital Video Disks (DVDs) as molds. DVDs provide a low cost, programmable alternative to conventional manufacturing methods, which aligns with the goals and prospects of organic solar cells. Previous papers have explored this DVD soft lithography method, but we propose further improvements by using the optimized quasi-random sequence into the DVD before the soft lithography process. The optimized quasi-random structure increases the local surface randomness thus increasing the light trapping properties of the active layer. Additionally, the tiered structures generated by DVD nanomPRINTING reduce reflectance at higher angles of incidence, leading to improved performance at all angles.

8:00 PM EL08.05.05 Improvement of Light Extraction Efficiency and Viewing Angle Characteristics of Organic and Quantum Dot Light Emitting Diodes with Spontaneously Formed Buckling Patterns of Soft Materials Yoon-Jeong Choi, Jeong-Yeol Yoo and Byung Doon Chin; Dankook University, Korea (the Republic of)

There exist a lot of technologies for a light extraction (LE) of organic light emitting diodes (OLEDs). However, for the successful commercial application, the restriction on the cost of manufacturing, directionality of color, and the requirement to maintain a high-quality image are severe for devices with LE. Insertion of scattering medium in the OLED with microcavity (mostly popular for commercial panels) can be generally effective but reduces the function of polarization, which blocks the reflection from the external light. Recovering of the lost power from surface plasmon (SP) is also effective for an enhancement of LE, and a method of grating coupling by a generation of corrugate the organic/metal interface causes Bragg scattering. Several kinds of periodically corrugated or “buckled” patterns were proposed, showing a reduction of light loss (LE effect) by a scattering of SPs [1,2]. In this work, simple fabrication processes for the micro-scale LE pattern formation is introduced. For a top-emitting OLED (TOLED), a useful platform of commercial panels for high-resolution mobile on the non-transparent polymeric substrates, colors and spectra are significantly sensitive to those specific LE structures and intrinsic micro-cavity effects of TOLED having translucent electrodes. Here, a quasi-periodic and controllable buckling patterns with broad size/scale distribution are described in detail [3,4]. The formation of buckling patterns is spontaneously driven by the mismatch of thermal expansion coefficient of the stacked organic and polymeric layers, which are easily deposited by a simple deposition process in the vacuum or solution coating environment on top of the translucent cathode of TOLED structure. Further experimental studies on the effect of molecular weight, glass transition temperature with segmental softness/rigidity, and phase separation behavior of material combination will be presented for the understanding of the mechanism of quasi-periodic 3-dimensional buckling structure formation. As for OLED and QD-LED performance with buckling LE structure, luminous efficiency of device with buckling patterns in a various position of device was characterized. The results on the microcavity-driven, top-emitting type OLED showed the improvement of the luminous efficiency of phosphorescent device (68 cd/A) more than 40% of the pattern-less control devices (47 cd/A). Such a result, observed in case of optimum buckling structure formed on top of the translucent electrode of device, can be explained by the suppression of light loss by the SP mode at semi-transparent metal/air interface without losing the control of polarization of light. Moreover, the shift of the maximum peak of electroluminescence for buckling patterned device was less than 4nm with the viewing angle range of 0 to 75 degree (>20nm shift for control device), securing a negligible change of the spectral characteristics and color stability (robust viewing angle behavior) [5]. Our corrugated pattern structure was also successfully applied to the electroluminescent quantum dot (QD) device, where the intrinsic pure and saturated emission colors and narrow FWHM (full width at half maximum) could be further improved.

8:00 PM EL08.05.06
Flexible Route to AuNP-Cluster Arrays for Plasmonic Sensing  
Pooria Golvari1, Tyrone Morales1, Stephen M. Kuebler1,1,1 and Jimmy Touma1;  
1University of Central Florida, United States; 2Air Force Research Laboratory, United States

Periodic assemblies of gold-nanoparticle (AuNP) clusters are attractive as tunable substrates for surface-enhanced Raman spectroscopy (SERS), as well as analyte sensors based on coupled localized surface plasmon resonance (LSPR) and diffractively-coupled plasmonic surface lattice resonances (SLRs). We report an approach for fabricating two-dimensional lattices selectively filled with mono- or multi-layers of AuNP films. The lattices are prepared using e-beam lithography and then transferring the pattern into fused silica by reactive ion etching. Centrifuge-sided deposition assisted by a protein binder is then used to load dense mono- and multi-layers of AuNPs into the silica arrays, in one tenth of the time required for immersion methods. Post-assembly cross-linking of the binder prior to drying the AuNP film is used to control the spacing between the deposited layers and to tune the LSPR coupling. Masking and lift-off can be used to selectively deposit AuNP-clusters inside the prepatterned arrays. The AuNP-filled arrays are optically characterized in reflection and transmission modes in the visible and near-infrared. The method provides a means for independently controlling properties of the AuNP-clusters (e.g., size and interparticle spacing) and properties of the lattice (e.g., symmetry, the size, the depth, and periodicity). As such, the method should be useful for preparing sensors based on hybrid-SERS with controlled coupling between AuNPs and SLR modes.

Hot-Carrier Multi-Junction Solar Cells: The Best of Both Worlds  
Maxime Giteau1,2, Samy Almosni1,3, Jean-François Guillemoles1,4 and Daniel Suchet1,4;  
1NextPV, The University of Tokyo, Japan; 2ICFO, Spain; 3Saule Technologies, Poland; 4CNRS, Ecole Polytechnique, ENSCP, Institut Photovoltaïque d’Ile de France (IPVF), UMR, France

Conventional single-junction solar cells are limited in power conversion efficiency at around 33% (Shockley-Qeisser limit) due to the mismatch between the broadband solar spectrum and the fixed bandgap of the cell. Multijunction solar cells (MJSCs) can overcome this limitation by combining multiple subcells with decreasing bandgaps, allowing them to extract more energy per photon. These are the most efficient cells manufactured today, but they remain expensive and offer limited material combinations. An alternative approach is the hot-carrier solar cell (HCSC), which converts the extra kinetic energy of the (hot) carriers into electricity before it is dissipated by interaction with the lattice, in a process called thermalization. However, despite significant progress, thermalization rates remain too fast for hot-carrier devices to operate efficiently as solar cells. In essence, the main issue is that HCSCs should be ultrathin to significantly reduce thermalization, while nonetheless absorbing most of the incident illumination (optically thick). To alleviate this issue, we introduce the hot-carrier multi-junction solar cell (HCMJSC) concept [1,2], a 2-junction MJSC in which the top subcell is an HCSC. With this configuration, photons not absorbed in the ultrathin hot-carrier subcell can be harvested by the bottom subcell, thereby not sacrificing absorption. As a result, HCMJSCs make it much easier to benefit from hot-carrier effects than HCSCs, leading to large efficiency gains for realistic thermalization rates. HCMJSCs also offer a significant advantage over MJSCs: the efficiency shows little dependence on the bandgap of the subcells. As a result, HCMJSCs can be designed for whatever bandgap combination is most practically achievable, which is especially relevant for lattice-matched III-V multi-junction devices. We will highlight some promising material combinations, including double homojunction configurations, in which both subcells use the same material. After illustrating the advantages of HCMJSCs over both MJSCs and HCSCs, we will look at their resilience under operation conditions, focusing on the influence of the cell temperature and variations in the illumination spectra [3].

Engineering Exciton Emission in Monolayer MoS2 by using Electroplated Gold Plasmonic Nanodiscs  
Abhay A. V S1, Mihir K. Sahoo1, Faiha Mujesh1, Albin Varghese1, Subhabrata Dhar2, Saurabh Lodha1, Sandip Ghosh2 and Anshuman Kumar1;  
1Indian Institute of Technology Bombay, India; 2Tata Institute of Fundamental Research, India

Transition metal dichalcogenides (TMDCs), such as MoS2, hold great promise as 2D semiconductors, making them suitable for various applications in optics and novel electrical devices. However, their atomic thinness and low quantum yield have hindered their practical application due to limited light absorption. Integrating subwavelength plasmonic nanostructures with monolayer TMDCs is a promising method to address these challenges effectively and manipulate the optical properties. In this study, we utilized electron beam lithography and electroplating techniques to fabricate an array of gold nanodiscs (AuNDs) capable of significantly enhancing the photoluminescence (PL) of monolayer MoS2. The monolayer MoS2 on the gold nanodisc array resulted in an impressive photoluminescence enhancement compared to as-grown MoS2 on sapphire and a monolayer MoS2 on a plane gold film. To gain insights into the underlying mechanism behind this enhancement, we conducted Finite-Difference Time-Domain (FDTD) simulations.

8:00 PM EL08.05.10  
Highly Efficient Near-Infrared Light-Emitting Diode Based on CdHgSe/ZnCdS Core/Shell Nanoplatelets  
Hossein Roshani1, Anatol Prudnikau2, Fabian Paulus2, Beatriz Martin-Garcia3, René Hübner4, Houman Bahmani Jalali1,1,1,1, Manuela De Franco1, Mirko Prato1, Francesco Di Stasio1 and Vladimir Lesnyak1;  
1Istituto Italiano di Tecnologia, Italy; 2ICFO, Spain; 3Saule Technologies, Poland; 4CNRS, Ecole Polytechnique, ENSCP, Institut Photovoltaïque d’Ile de France (IPVF), UMR, France

Luminescent quantum dots (QDs) have gathered significant attention over the past decade. Their distinct chemical and optical properties, including size-adjustable light emission, remarkable photostability, and a range of fluorescence colors, have motivated extensive investigations. In recent years, near-infrared (NIR) quantum dots have emerged as a promising avenue for a new generation of optoelectronic devices including infrared detectors and light sources. This study presents the fabrication of NIR-LEDs operating at the o-band optical telecommunication wavelength (1300 nm) using novel CdHgSe/ZnCdS core/shell nanoplatelets with a photoluminescence quantum yield of 70%. The nanoplatelets achieve a remarkable external quantum
efficiency (EQE) of 7% in the final device. Notably, the resulting EQE of the fabricated NIR-LED sets a new benchmark for mercury-based QD LEDs.

Utilizing Short-Pulsed Laser Ablation to Create Plasmonic Colloidal Nitride Nanoparticles for Biomedical Applications Nikolaos Pliatsikas, Spyridon Kassavetis, Stavros Panos, Tamara Oduotola, Ilias Fekas, Chrysanthi Papoula, John Arvanitidis, Dimitris Christofilos, Maria Gioti and Panos Patsalas; Aristotle University of Thessaloniki, Greece

The field of plasmonics is currently witnessing rapid growth and advancement, offering exciting prospects for various scientific and technological applications. In particular, metal nanoparticles (NPs) exhibiting plasmonic behavior in the Near-Infrared (NIR) spectral range have gained significant attention for their potential in biological applications. These NPs possess exceptional abilities to efficiently absorb and generate heat within a highly confined volume surrounding them. However, conventional plasmonic metal NPs like gold (Au) and silver (Ag) face limitations when exposed to the high temperatures and intense electric fields required for biomedical applications involving NIR concentrated light [1]. To overcome these challenges and unlock new possibilities in plasmonic bio-applications, the fabrication of refractory transition metal nitride NPs has emerged as a promising avenue. Among them, Titanium Nitride (TiN) stands out, as it offers plasmonic performance that extends into the NIR spectral range through stoichiometry variations and/or doping [2]. Pulsed laser ablation in liquids (LAL) has emerged as the most favorable method for producing plasmonic TiN NPs, offering advantages in terms of reproducibility and scalability. LAL ensures that the ablated NPs maintain the elemental composition of the solid target, a crucial factor considering the sensitivity of plasmonics to the stoichiometry and doping of TiN. By leveraging LAL, researchers can explore and optimize the plasmonic properties of TiN NPs, paving the way for groundbreaking advancements in the field of plasmonic biomedical applications.

In this study, we demonstrate the fabrication of refractory and stable plasmonic TiN NPs with absorption characteristics within the NIR biological window using LAL. To achieve this, we initially developed target materials through reactive Magnetron Sputtering at room temperature. Subsequently, the colloidal TiN NPs were shaped using a nanosecond Nd:YAG pulsed laser system at different wavelengths (1064, 532, and 355 nm) via the LAL. To assess the structure, morphology, and material quality of the TiN NPs, we conducted comprehensive analyses employing Raman spectroscopy, scanning electron microscopy (SEM), atomic force microscopy (AFM), and X-ray photoelectron spectroscopy (XPS). Additionally, the optical properties of the TiN target materials were evaluated using NIR-Vis-UV spectroscopic ellipsometry, while optical absorbance characterization was performed on the colloidal TiN NPs. Furthermore, we investigated the photothermal properties of these colloidal TiN NPs and conducted preliminary biocompatibility tests using proteins such as albumin and fibrinogen in a PBS solvent.

We gratefully acknowledge support of the Hellenic Foundation for Research and Innovation (H.F.R.I.) under the “2nd Call for H.F.R.I. Research Projects for supporting Post-Doctoral Researchers” (Project Number: 1099).

8:00 PM EL08.05.12
Novel Synthesis and Characterization of Magneto-Plasmonic Core-Shell Nanoparticles Carlos A. Marquez Barra1, Natasha Engel1, Gesuri Morales-Luna2, Nicolas Large1, Nancy Ornelas-Soto1 and Kathryn Mayer1; 1The University of Texas at San Antonio, United States; 2 Universidad Iberoamericana, Mexico; 3Tecnológico de Monterrey, Mexico

Advancements in numerous technologies including chemical sensing are spurting progress in the development of novel composite nanostructures that integrate magnetic and plasmonic materials. These nanostructures exhibit a unique amalgamation of plasmonic and magnetic properties, positioning them at the forefront of scientific research. The magnetic properties facilitate precise control and manipulation of the nanoparticles in the presence of magnetic fields. Furthermore, materials with plasmonic activity, such as gold, offer outstanding biocompatibility, along with exceptional optical features that include enhanced scattering and high sensitivity to changes in refractive index. The aim of this research is to analyze and describe core-shell nanoparticles (CS-NPs) comprising a magnetite core enveloped by a gold shell (Fe3O4/Au CS-NPs). These nanoparticles are synthesized through a novel method that integrates established wet lab synthesis techniques under ambient conditions. A comprehensive characterization approach was employed. Electron microscopy techniques including Scanning Electron Microscopy (SEM) and Transmission Electron Microscopy (TEM) were utilized to examine and analyze the structure and surface morphology of the investigated materials. Additionally, analytical techniques including Energy-Dispersive X-ray Spectroscopy (EDS) and Fourier Transform Infrared Spectroscopy (FTIR) were employed to investigate the chemical composition of the samples and the presence of surface ligands. Furthermore, computational methods including finite difference time domain (FDTD) and finite element method (FEM) modeling were applied to confirm the plasmonic properties of the composite materials. Calculated optical properties of light absorption and scattering cross-sections were compared with experimental characterization data obtained via techniques including UV–vis absorbance spectroscopy and dark-field scattering microspectroscopy. By employing these extensive characterization methods, the research aims to obtain valuable insights into the composition and properties of the materials under investigation. These insights will serve as a foundation for the development of sensing technology for water quality monitoring.

Simulating the Co-Assembly of Cellulose Nanocrystals and Gold Nanorods - Effect of Size Distribution and Density Jiaxin Hou, Yuchen Zhu, William Sampson and Ahu Gumrah Dumanli; University of Manchester, United Kingdom

The self-assembly of anisotropic materials holds great potential in fabricating multifunctional optical materials through cholesteric structures. Specifically, cholesteric structures formed by these particles can exhibit unique optical properties, making them ideal for various applications for sensing and fabrication of optical security features. In particular, integrating plasmonic materials into cholesteric phases that can interact with the visible spectrum can be used in building metasurfaces that can alter the interaction of the light completely. While there have been efforts to validate this hypothesis, the experimental work on combining the self-assembly of gold nanorods (Au-NRs) with cellulose nanocrystals (CNCs) had limited success as the plasmonic particle loading was minimal and didn’t allow coupling between the plasmonic states of the Au-NPs possible without disrupting the cholesteric order. To understand the physical and theoretical limitations of this co-assembly system, we used molecular dynamic coarse-grained methods with Gay-Berne potential with anisotropic particle systems of different aspect ratios and densities to complement our experimental work. Our experimental and modeling work demonstrated good agreement with regard to identifying the surface charge and the density of Au-NRs as the main driving force on the co-assembly. Negatively charged AuNRs can distribute uniformly and align in the same direction with CNCs and the particle systems with higher aspect ratio distributions would have successfully co-assembled, as AuNRs would prefer to fill the vacancy between the cholesteric structures formed by CNC particles. Our further studies explain the limit of maximum concentration from density, as lighter particles (CNCs) would reach assembly conditions compared to the AuNRs. Our work sheds new light on the understanding of the self-assembly of multi-component systems with polydispersity and charge variations and takes our understanding one step further in developing optical materials.

Phosphorinduced Electric Effects in Magnetic Metasurfaces of Various Geometry MD Afzalur Rah, Sean Nesbit and Natalia Noginova; Norfolk State University, United States

Permalloy metasurfaces with design-controlled magnetic uniaxial anisotropy have been fabricated and studied for plasmonic behavior and photoinduced electric effects. Significant photovoltages are observed as the response to the pulsed laser illumination, and are maximized at the plasmon resonance conditions. The voltage sharply changes its polarity at different fields which are different for systems of different geometry. The switching fields are found to be in good correlation with the magnetic anisotropy fields determined by the ferromagnetic resonance method. The effects are discussed taking into account non-equilibrium heating of the electron subsystem by the laser pulse and the Nernst effect.

Optical Characteristics of Superconducting Plasmonic Transition Metal Nitrides Li-Chung Yang1,2, Jingwei Wang1,3, Jing-Yuan Chen1, Tzu-Ya Peng1,2, Shang-Tung Ke1 and Yu-Jung Lu1,2; 1Academia Sinica, Taiwan; 2National Taiwan University, Taiwan; 3National Taiwan University of Science and Technology, Taiwan

Transition metal nitrides (TMNs) exhibit exceptional promise due to their elevated melting points, metallic optical characteristics, and superconductivity at cryogenic temperatures. Recent attention has turned toward TMNs as potential substitutes for conventional plasmonic materials like gold and silver due to their unique plasmonic properties. However, the optical properties of plasmonic TMN films in the superconducting state have remained uncharted territory. In the past, we have demonstrated the utility of plasmonic TMN films (including TiN, ZnN, HfN, and NbN) as alternative plasmonic materials for various applications [1-3]. Here, we sputtered a thin film of NbN onto a MgO (100) substrate at 800°C, revealing a measured critical temperature (Tc) of 10.5 K. Employing temperature-dependent spectroscopic ellipsometry, we systematically characterized the optical behavior of NbN films from 4 K to 300 K within a wavelength range spanning 300 nm to 2 μm. As the temperature decreased, we observed a remarkable reduction in the magnitude of the imaginary part of the permittivity, the magnitude dropped by 13.8 times at 1550 nm. Subsequently, we applied the Drude-Lorentz model for parameter fitting, elucidating that the substantial reduction in the imaginary component primarily resulted from a sharp increase in the relaxation time. These findings underscore NbN's potential as a highly promising material for the development of low-loss superconducting plasmonic devices.

Light Extraction and Stability of Fluorescent and Phosphorescent Organic Light-Emitting Diodes Incorporating Plasmonic Ag Nanoparticles Sneha Sreedhar1 and Deirdre O'Carroll1,2; 1Rutgers University, United States; 2Rutgers, The State University of New Jersey, United States

In recent years, organic light-emitting diodes (OLEDs) have gained great popularity in the display industry due to their thin form factor, high color quality and the ability to be fabricated onto flexible substrates. However, OLED stability and efficiency, particularly at blue wavelengths, need significant improvement for future, more demanding display applications, such as micro displays. Several methods have been employed to increase the light-extraction efficiency (LEE) and stability in OLEDs, including the development of new active-layer materials, interfacial layer modifications, addition of nanoparticles into various layers of the devices, optimization of the structural design and the application of microlens arrays. The LEE in an OLED is typically ~20% with the rest of the 80% of photon energy being lost to substrate, surface plasmon and thin-film waveguide modes. While these approaches are effective for improving LEE of red and green OLEDs, very few of these approaches have significantly improved the efficiency of blue OLEDs. We have shown in previous studies that plasmonic Ag enhances the quantum yield in fluorescent materials through the Purcell effect and improves the photostability of phosphorescent OLED materials by a factor of 3.6 by reducing the triplet emission lifetime. Here, we present a study of the use of silver nanoparticles introduced at different device interfaces and within different layers from the anode to the cathode to combat the various optical losses that reduce LEE. The results show improvements in blue OLED stability and luminescence lifetime in addition to improved LEE. We have chosen a blend of PFO: F8BT to study fluorescent OLEDs and a blend of PVK:Flrpic to study blue phosphorescent OLEDs as a function of different nanoparticle additions. The devices are built on ITO on glass substrates with different formulations of PEDOT:PSS to get the highest conductivity. We vary the Ag nanoparticle size from 15-50 nm and introduce them into different layers of the OLED including: (i) on ITO directly, through spin coating or de-wetting methods, (ii) doped into the PEDOT:PSS layer; (iii) grown on the PEDOT:PSS layer; (iv) within and on top of active layer; and finally (v) deposited on top of the active layer before depositing the Ca/Al cathode. We present current-density measurements, luminescence, electroluminescence measurements, external quantum efficiency and stability measurements in addition to lifetime and quantum yield measurements to investigate how positioning of the plasmonic structures effects the stability and lifetime of the OLEDs. We are hoping to contribute to solving the issue of low efficient blue OLEDs by improving the lifetime and stability of the devices as well as achieving the required “true blue” color that is required by the display industry by manipulating the interactions between the plasmonic Ag particles and the emissive layers.

8:00 PM EL08.05.18
Ultra Short Pulse Laser Ablation of Titanium Nitride Nanoparticles in Solvent for Biomedical Applications Ilias Fekas, Nikolaos Platissikas, Spyridon Kassavetis, Stavros Panos, Tamara Oudotula, Evi Rampota, Chrysanthi Papoulia, Chrisitos Kapnopoulos, Maria Gioti, Stergios Logothetidis and Panos Patsalas; AUTH, Greece

Titanium Nitride (TiN) has emerged as a promising alternative plasmonic material that may outperform the traditional plasmonic metals, such as Au and Ag in terms of durability to high temperatures and/or to the high electric fields of concentrated light present in most realistic plasmonic applications. TiN is a well-known conductor of high mobility, widely used in the mainstream microelectronics industry, and it owes its electronic conductivity to the partially filled valence d orbitals that are not completely hybridized with the N 2p electrons and presents high optical response similar to that of Au, hence its golden optical appearance, when in stoichiometric form; non-stoichiometric TiNx films are also reported and are predicted to exhibit Localized Surface Plasmon...
Resonance (LSPR) in red and Near-Infrared (NIR) ranges. TiN is usually grown in thin film form by sputter deposition, its bottom-up nanostructuration was not successful so far, and the formation of colloidal TiN is exceptionally rare, both due to the refractory character of TiN, which is a major obstacle for its wide range implementation [1, 2].

The scope of this work is the fabrication of colloidal TiN nanoparticles with tunable LSPR from the visible to the NIR spectral ranges, thus covering the biological window, a property that can find use in many different biomedical applications. The TiN nanoparticles were fabricated by Ultra Short Pulse Laser ablation (USPL) of TiN in liquid media irradiated at 532nm laser wavelength [1, 3]. USPL corresponding to a shorter thermal relaxation time and would be expected to more effective than nanosecond. USP lasers can reach a higher peak intensity and induce a stronger photoacoustic effect than nanosecond lasers, they can be used with reduced laser fluence compared to that utilized for nanosecond lasers for the TiN nanoparticles fabrication.

The TiN films were grown by reactive magnetron sputtering at room temperature. The chemistry, crystallinity, optical properties, and the point defects of the target materials were evaluated by X-Ray Diffraction, X-Ray Photoelectron Spectroscopy and Scanning Electron Microscopy, respectively. Then, the major laser ablation parameters were investigated, in particular, low power (up to 2 W) and solvent (water, aceton, and isopropanol). The optical properties, the size, and the structure/defects of the produced nanoparticles were assessed by optical transmission spectroscopy, Scanning Electron Microscopy and atomic force microscopy, respectively.

IGZO Based Oxide Heterostructured Phototransistor for Widening The Detection Limit up to 1000 nm Wavelength Jun Hyung Jeong and Seong Jun Kang
KyungHee University, Korea (the Republic of)

On the rapidly developing technologies for light communication, night vision system, invisible security system, and health care system industries, detecting near infrared (NIR) wavelength light is becoming a crucial component for electronic devices. Among various structures of photodetectors, such as phototransistors, photodiodes, and photoreceivers, phototransistors possess much higher potential compared to other structures photodetectors, such as ultra-low dark current, facile tunable photocurrent by modulating gate and drain bias, which leads to the much higher photodetection characteristics. Numerous materials, such as organic semiconductors (OSCs), quantum dots (QDs), or perovskite materials have widely investigated for transparent NIR detection owing to their adequate photon-electron conversion efficiency maintaining relatively high transparency. However, these materials are intrinsically suffered from environmental moisture or oxygen. The device exhibited high photoresponsivity and photodetection characteristics of 9.9 A/W and 5.55×10^14 Jones, respectively. Our results suggest a useful method for fabricating metal-oxide hetero-structured NIR phototransistors.

Plasmonic Tip-Enhanced Probing of Excitonic Materials and Heterostructures Deep M. Jariwala
University of Pennsylvania, United States

Two-Dimensional (2D) chalcogenides of Mo and W are semiconductors that show strong excitonic responses due to their highly quantum-confined character. This talk will discuss our recent work on optical phenomena and electronic phenomena in 2D semiconductors when they are placed in close proximity on plasmonic substrates such as Au, Ag and Al.

For a bulk of this talk, I will be presenting our work on near-field optical spectroscopy using a plasmonic tip. I will also show how using a plasmonic tip can be used to probe buried metal-semiconductor interfaces in 2D MoS2. Specifically, I will focus on how scanning potential probe and scanning conductance probe can be correlated with near-field photoluminescence (PL) to understand the nature of contact character. This talk will discuss our recent work on optical phenomena and electronic phenomena in 2D semiconductors when they are placed in close proximity on plasmonic substrates such as Au, Ag and Al.

Multi-State Control Of Spectral Response In Coupled 2d Material Systems

Reconfigurable optical systems capable of reproducing complex spectral profiles have broad relevance across optics and photonics. Here, we present a

framework for designing reconfigurable metamaterials using active cells that incorporate gate-tunable two-dimensional (2D) materials. Due to their

reduced dimensionality, 2D materials exhibit high sensitivity to electric fields, allowing for the tuning of their optical properties through the application of

external voltage. By assembling nanopatterned 2D materials into coupled arrays, a single solid-state device can be used to synthesize a wide range of

spectral responses. However, the design of such multi-state devices is challenging due to the inherently high-dimensional parameter space involved.

To address this challenge, we present a coupled-mode analytical framework to model the relationship between system control inputs (e.g., voltage) and the

manifold of optical outputs embodying multiple spectral resonances. Using graphene as a model 2D material, we investigate the potential for synthesizing

complex thermal-infrared spectral absorption profiles within the spectral range where graphene supports surface plasmon polaritons. By employing this

coupled framework, we demonstrate that a single judiciously designed array of graphene resonators can dynamically switch between distinct absorption

spectra of multiple gases, mimicking both narrow spectral features and broad spectral envelopes. We validate our model by comparing it to full numerical

EM simulations, demonstrating a high level of agreement with orders of magnitude speed up in computation time. In addition, through the integration of

auto-differentiation algorithms, our model enables efficient gradient-based optimization over the multi-state, multi-spectral design space. We elucidate the

tradeoffs between the device complexity, number of resonators and their spectral performance, in both planar and stratified configurations. This approach

has potential for various applications in sensing, energy harvesting, and signature management.

Photonic Properties of Thin Film BaTiO3 Grown via Molecular Beam Epitaxy

Electro-optic modulators form the backbone of efficient data transfer necessary for modern optical communications. These modulators directly connect a

driving electric field with optical properties of a material, efficiently converting an electrical signal to an optical signal. Modern data centers and high speed

internet, as well as sensing systems, heavily rely on these devices. The electro-optic modulators are often bulk crystals of lithium niobate with indiffused

waveguides, limiting their size, speed, and efficiency. Although thin film lithium niobate offers improved scalability and higher bandwidth over its bulk counterpart, lithium oxides are not CMOS compatible and there is a growing need for higher bandwidth modulators with lower voltage requirements. Barium titanate (BaTiO3) is an alternative material platform which exhibits an extremely high electro-optic coefficient (r23 ~ 900 pm/V), a reasonably high band gap (> 3eV), a relatively high refractive index (n ~ 2.4), and is compatible with traditional CMOS processing. Scalable methods for creating high quality, single ferroelectric domain films of barium titanate are therefore extremely attractive for highly efficient modulators and integrated optical devices.

In this work, we use molecular beam epitaxy to grow high quality BaTiO3 films on a variety of substrates and use electron microscopy, electronic measurements, and confocal optical measurements to evaluate the optical and electro-optic properties.

Novel Tunable Low-Index Materials for Metaphotonics Applications

Low refractive index and epsilon-near-zero (ENZ) materials give rise to many fascinating optical properties driven by strongly enhanced nonlinear optical

processes such as harmonic generation, frequency mixing and conversion, electro-optical modulation, and order-unity light-induced refractive index

changes. These effects are important requirements to enable reconfigurable optical devices and metamaterials with ultrafast (sub-picosecond) response

times for active device in the photonics and metaphotonics domains. However, ENZ materials operating in the near- and mid-infrared spectral ranges often rely on metallic components with limited tunability of the optical permittivity and high absorption losses. Likewise, they traditional platforms are not compatible with the widespread silicon technology, severely limiting their scalability and device integration. Here we report on a novel and largely tunable Si-compatible low-index material platform based on zirconium silicon oxynitride (ZrSiON). In particular, using co-deposition RF magnetron sputtering with Nitrogen gas, we have developed ZrSiON thin films and investigated their structural and optical properties using X-ray diffraction (XRD) and variable angle spectroscopic ellipsometry (VASE) in a broad spectral range. We find that resistivity decreases as SiO2 incorporation is increased, becoming a dispersionless dielectric material with a approx. 2.5 and negligible dispersion losses in the infrared spectral ranges. On the other hand, when SiO2
incorporation is comparable to Zr, we found the material becomes metallic with an ENZ transition in the near-infrared spectrum around 830 nm. We found that upon post-deposition annealing at 500°C these materials exhibit a transition to the metallic regime that can be controlled with the sputtering and annealing conditions. In addition, we measure the optical bandgaps and resistivity and the nonlinear optical responses of the fabricated materials via Z-scan technique. Finally, we identify optimal etching conditions for achieving resonant nanostructures for integration into nonlinear optical devices and metasurfaces.

Full-Colored, Large-Area, Electrically Reconfigurable Photonic Resonator with Low-Power Consumption [Hyo Eun Jeong, Joo Hwan Ko, Se Rim Kim, Hyeon-Ho Jeong and Young Min Song; Gwangju Institute of Science and Technology, Korea (the Republic of)]

Display technology plays an essential role in effectively delivering visual information in contemporary daily life. Reflective display, which uses external ambient light as a source, can operate without a backlight panel electronic paper, enabling low energy consumption. In the past few years, there have been various approaches implemented to improve the performance of electronic paper (e-paper), particularly in terms of switching time and on/off ratio. As a result, leading electronics companies (e.g., Amazon Kindle) have introduced e-papers with enhanced capabilities. While e-papers serve as excellent display devices, they have certain limitations, such as the necessity of high operating voltages and monochromatic image operation, restricting colorful output. Recently, a new strategy has emerged focusing on the active modulation of plasmonic structural colors based on optically active materials, including phase change materials and conducting polymers, which modulate its complex refractive index by external energy [2]. Especially, conducting polymer, which controls the optical property by an electrochemical redox reaction, has attracted great attention due to its low power consumption. However, the limited complex refractive index and minimal variation levels impede strong interaction between light and matter on plasmonic structures, leading to a diminished ability to express vibrant colors [3].

In this study, we present the milliwatt-level controllable electrochromic thin-film resonator capable of full-color generation based on polyaniline (PANI). To overcome the low complex refractive index variation level of PANI (Δn ~ 0.6), we designed a highly resonant planar photonic structure based on a refractive index engineered layer on the metal film, resulting in diverse coloration over an entire visible wavelength range. In particular, the electrochemical redox reaction is enabled by the exchange of proton, which controls the doping level of PANI, leading to the fast/efficient modulation of optical properties. The protonation process is achieved in the narrow voltage range from -0.2 V to 0.8 V. The voltage level significantly contributes to low power consumption (~1.32 mW cm²), which is 20 times lower than commercial displays such as OLED, and even half the power consumption of e-paper. In addition, the active resonant structure based on PANI demonstrates stable reversibility without any degradation over 200 cycles. Moreover, this device achieves a fast-switching time (~34 ms), and also, shows operation capability compared to a commercial video rate of 30 Hz. In conclusion, we present an electrochemically switchable reflective display based on PANI, enabling remarkably efficient and dynamic coloration. We also suggested a passive matrix display module; thus, the pixel-by-pixel control of potential enables diverse pattern generation. We believe that our suggested platform will be utilized as a promising display application including smart windows, electronic wallpapers, attachable displays, and many types of electronics based on its ultra-thin scale, large color space, and low power consumption.

Colloidal Crystal Engineering for Programmable and Stimuli-Responsive Optical Metasurfaces and Metamaterials [Koray Aydin; Northwestern University, United States]

Metasurfaces and metamaterials emerged as promising nanophotonic material and device platforms to control light-matter interactions at the nanoscale. In such materials, the collective and effective optical response is dictated by individual building blocks and controlled by the geometrical parameters forming the crystal structure. I will introduce DNA-assembly of gold nanoparticles as a fabrication method to realize bottom-up, programmable, and stimuli-responsive nanophotonic hybrid metamaterials and metasurfaces. The ability to control the distance, size, shape, architecture of nanoparticles and overall crystal structure enables access to optical properties that are not accessible readily in nature. I will highlight wide range of functional nanophotonic device architectures including epsilon-near-zero metasurfaces, negative index metamaterials and broadband absorber meta-films. The synthesis of plasmonic nanoparticle architectures with structures and stimuli-responsive behavior that are not accessible in lithographically defined plasmonic nanostructures provides an opportunity to design materials with emergent optical properties that offer new fundamental insights and previously inaccessible functionalities.

High Quality Ordered Titanium Nitride Nanotriangles and Nanowires for Plasmonic Applications [Spyridon Kassavetis, Evi Rampota, Stavros Panos, Nikolaos Platsikas, Despina Tsielesidou and Panos Pataras; Aristotle University of Thessaloniki, Greece]

Novel and cost-efficient fabrication techniques of alternative plasmonic nanostructures pave the pathway for practical applications in various fields such as energy harvesting, microelectronics and medicine. Transition metals nitrides (TMNs) emerge as alternative plasmonic nanomaterials suitable for a wide range of applications.
range of applications from photovoltaics to photonics and medicine. The TMNs are conductive ceramics that combine exceptional properties such as substantial electronic conductivity, high melting point (>3000 K) and tunable work function, while the TMNs are particularly useful in photochemical environments, high temperature, and strong electric fields, such as in lasers. Among them, Titanium Nitride (TiN) is emerging as significant candidate material for practical plasmonic applications (biosensors, catalysis and photochemistry, solar energy harvesting, photo-detection, and optical storage of information).

In this work, we focus on the low-cost fabrication of TiN nanotriangles with controlled spacing and tunable dimensions (thickness and lateral dimensions) using a combination of Nanosphere Lithography (NSL) and several reactive magnetron sputtering (MS) deposition techniques such as DC, Closed-Field Unbalanced MS or Highly Power Impulse MS (HIPMS) on rigid and flexible substrates and with the aim to study the fundamentals that will unlock the fabrication of high quality TMNs nanotriangles and nanowires for plasmonic applications.

NSL appears as a very promising approach, due to its rapid implementation and compatibility with wafer-scale processes, combines the advantages of both top-down and bottom-up approaches and includes: (a) development of the nanospheres monolayer colloidal mask, (b) deposition of the desired material in the empty space between the nanospheres and (c) removal/lift-off of the nanosphere colloidal mask to “reveal” the deposited material that keeps the ordered patterning of the mask interstices. Specifically, a suspension of monodisperse polystyrene nanospheres (diameter, d=552 nm or d=175 nm) was spin coated on a substrate (such as Si (001), glass, flexible PET) to form the colloidal mask. A UV ozone process was used to confine the triple-junction vias of the polystyrene mask. Subsequently, the selective growth of TiN was made by the above mentioned MS in Ar/N atmosphere by varying the TiN thickness from 10 to 30 nm, while the MS process parameters were also fine-tuned to increase the directionality of deposited species, and the TiN crystal quality (low concentration of point defects). In particular, the substrate-to-target distance was maximized to improve geometrical directionality, and a negative bias voltage during the growth of the TiN was used to “guide” the ionic species deep into the vias between the nanospheres.

The arrays of ordered TiN nanostructures and nanowires appear after the lift-off of the mask. Atomic Force Microscopy characterization of the samples showed the fabrication of TiN nanotriangles, with low concentration of point defects, similar structure with the continuous TiN films of high electrical conductivity and plasmonic performance, and durability at least up to 400º C.

To assess the optical performance of the fabricated TiN nanotriangles, the arrays were placed inside a vacuum chamber and illuminated with a tunable laser operating near the surface plasmon resonance of the nanotriangles. The optical response was measured using a spectrometer and a high-speed photodetector. The results showed a strong enhancement of the optical absorption and emission, indicating the presence of plasmonic modes within the nanotriangles. The enhancement was found to be dependent on the spacing between the nanotriangles, with the highest enhancement observed for arrays with the smallest spacing.

2:30 PM DISCUSSION TIME

2:30 PM *EL08.08.05

Moiré Nanoplasmonics Teri W. Odom; Northwestern University, United States

Moiré patterns can be described as the superposition of two or more periodic structures rotated by a relative twist angle. These patterns can be formed either from the vertical stacking of periodic lattices or the projection of two periodic lattices into the same horizontal plane. Photonic moiré lattices have exhibited broadband light trapping, optical chirality, and spatially-confined as well as long-range lasing. This talk will describe optical moiré phenomena in different plasmonic architectures. First, we will discuss how to design moiré nanostructures using scalable nanofabrication tools. Next, we will characterize and model their optical properties at different twist angles. Finally, we will integrate the plasmonic moiré nanopatterns with emissive materials and discuss potential applications of their short-range and long-range responses.

3:00 PM EL08.08.06

Reaching a Strong Coupling Regime between Quantum Emitters and Plasmonic Resonators using DNA Jeanne Heintz and Sebastien Bidault; ESPCI Paris, France

Light-matter interactions in condensed media at room-temperature are fundamentally limited by electron-phonon coupling. For instance, while the excitation cross-section of an isolated atom, or of a single quantum emitter at cryogenic temperatures, can reach one half of the wavelength of light squared (the so-called unitary limit), this value is reduced by 6 orders of magnitude for a fluorescent molecule or for a colloidal quantum dot at room temperature because of homogeneous phonon broadening. In order to render the exceptional optical properties of single quantum systems (such as single-photon emission and noninertias) efficiently accessible at room temperature and in condensed media, it is essential to enhance and optimize these interaction cross-sections.

Over the last decade, gold nanostructures have shown amazing promise towards this goal thanks to their ability to enhance optical fields by several orders of magnitude in deeply sub-wavelength volumes. However, the nanoscale dimensions of these field enhancements mean that it is extremely difficult to address them in a controlled and reproducible way. To this end, we exploit DNA molecules to create plasmonic resonators with a control over both their nanoscale dimensions and their chemical environment. Using this strategy, we were able to enhance single-photon emission from fluorescent molecules by more than two orders of magnitude in a weak-coupling regime (ACS Nano 10, 4806 (2016)) and to reach a strong-coupling regime between a plasmonic resonator and 5 organic molecules, albeit with low reproducibility (ACS Nano 15, 14732 (2021)). We propose the DNA-based assembly of dimers of plasmonic nanocubes in order to provide reproducible single-molecule strong coupling and to make the coherent interaction of light with single quantum emitters feasible at room temperature (J. Phys. Chem. Lett. 13, 11996 (2022)).

3:15 PM EL08.08.07

Photon Avalanches in Nanoparticles Bruce E. Cohen; Lawrence Berkeley National Laboratory, United States

While the original applications of nanoscience to bioimaging used luminescent nanocrystals whose properties largely mirrored those of traditional probes, newer nanocrystals have been engineered with optical properties unlike anything found in organics or proteins. These include perfect photosensitivity, multiphoton emission a billion-fold more efficient than standard multiphoton techniques, and most recently, photon avalanches hosted within nanomaterials. In two recent studies,1,2 we describe the engineering and imaging of avalanching nanoparticles (ANPs), which are Tm3+ doped NaYF4 uponcoating nanoparticles that efficiently convert near infrared excitation to higher energy emission. Avalanches are steeply nonlinear events in which outsized responses arise from a series of minute inputs and, with light, photon avalanching had been observed only in bulk materials, often at cryogenic temperatures. The extreme nonlinearity of ANP emission enables sub-70 nm spatial resolution using only simple scanning confocal microscopy and before any computational analysis. Two-way NIR photoswitching of ANPs enables full optical control of photodarkening and photobrightening, and we find indefinite photoswitching of individual nanoparticles in ambient or aqueous conditions without measurable photodegradation. This enables unlimited photon collection for calculation of sub-Angstrom localization accuracies, and we can distinguish individual ANPs within tightly packed clusters.

3:30 PM EL08.08.08
Strong Emission Enhancement of Rare Earth Quantum Emitters in an Integrated Waveguide Nano De-Focusing Platform Nicholas A. Gusken1, Ming Fu2, Maximilian Zapf3, Michael Nielsen4, Robert Röder1, Stefan Maier4–6, Mark L. Brongersma1, Carsten Ronning1, Rupert Oulton7 and Alex Clark8; 1Stanford University, United States; 2Imperial College London, United Kingdom; 3Friedrich-Schiller-Universität Jena, Germany; 4University of New South Wales, Australia; 5Monash University, Australia; 6University of Bristol, United Kingdom

As demonstrated in our recent publication, we present a novel reverse nanofocusing platform which allows to boost, extract and guide quantum emission at and from the nanoscale efficiently.

Enhancing fluorescence of quantum emitters while allowing for efficient extraction of emission in an integrated fashion is of great interest for future photonic quantum networks. Optical and electrical control at the emitter level is important in different fields of research and applications ranging from sensing and quantum networks to active metasurfaces. Dielectric as well as metallic cavities can accelerate radiative transitions of emitters by orders of magnitude based on the Purcell effect. For dielectric cavities, emission enhancement can be achieved by efficient modal coupling to high quality cavities. One drawback of this approach however is the fundamental limit in bandwidth and mode size. Plasmonic metal structures in contrast, are not diffraction limited and allow for the creation of cavities with mode volumes far below the wavelength scale and electrical control for direct emitter manipulation. One emitter which has raised significant interest is erbium, due to its C-band emission which is of strong technological significance for optical communications.

Here we demonstrate a strong radiative emission enhancement of Er3+ ions based on efficient coupling to and de-focusing from a hybrid plasmonic waveguide platform. Our results show acceleration of quantum emission over several orders of magnitude across the entire C-band based on a single hybrid plasmonic waveguide. Additionally, efficient coupling to a highly confined waveguide mode allows to resolve single electric dipole transitions which can be attributed to Stark-split energy levels of Er3+.

Computational characterization of optical response in noble metals and plasmonic ceramics Xiao Zhang and Emmanouil Kioupakis; University of Michigan at Ann Arbor, United States

Understanding the optical response of plasmonic materials is essential for understanding the physics and functionality of plasmonic devices. While traditional plasmonic materials such as noble metals have shown great success, the search of alternative materials for high-temperature applications remains open in the community. In recent years, several transition-metal nitrides and carbides have emerged as a promising new family of plasmonic materials. Benefiting from their high thermal stability, these materials are expected to be promising for easy processing and for high-temperature applications. To better understand and guide the discovery of new plasmonic materials, a reliable computational first-principles framework to characterize optical properties of metallic systems is important. These characterizations require a predictive treatment of free-carrier absorption considering both inter- and intra-band single particle excitation, and the collective oscillation of electrons (Drude contribution) on the same footing.

In this work, we present a computational framework that combines density functional theory, density functional perturbation theory, many-body perturbation theory, the maximally localized Wannier function approach, and the special displacement method to capture the direct and phonon-assisted single-particle process, as well as the Drude contribution, to provide a consistent, predictive description of the optical response of metallic systems. We show that with our framework, we can characterize the optical response both of noble metals (Ag, Au, and Cu) and of TiN, a promising plasmonic ceramic material. We achieve excellent agreement with experimentally measured dielectric functions, and we successfully characterize the temperature dependence of the optical response of TiN. We show that in the IR to visible region, both single-particle phonon-assisted indirect transitions and the Drude contribution are important to understand optical response of metals. Our framework is general and is available as a community tool implemented in the open source EPW code. It can be extended to other metallic materials, thus provides a general platform to accurately model the optical properties of metallic materials. Our platform creates an excellent opportunity to enable rational design of new plasmonic materials for nonconventional applications.

Low-Powered, Electrically Controllable Tamm Plasmons for High On/Off Ratio Optical Switch Joo Hwan Ko1, Dong Hyun Seo1, Sejeong Kim2 and Young Min Song1; 1Gwangju Institute of Science and Engineering, Korea (the Republic of), 2The University of Melbourne, Australia

Recent advances in reconfigurable photonics have attracted attention for enabling the active manipulation of light, facilitating rapid information transfer and high-density multi-spectral operations. The fundamental requirements of active photonics are the photonic structure, which confines a specific wavelength range at the target resonance, and the active material that modifies the condition of light-matter interaction using external stimuli or control mechanisms [1]. To confine and propagate electromagnetic waves effectively, these resonators rely on photonic structures. Specifically, in metasurfaces-driven reconfigurable photonics, photonic structures have emerged as highly promising, leveraging resonant properties to interact with light and enable localized manipulation, detection, or confinement at subwavelength scales. However, the intricate design and complexity of fabrication processes have posed challenges. Alternatively, thin-film-based optical modulators have shown significant potential for strong light-matter interaction, even with simplified configurations. Tamm plasmon (TP) structures, as powerful planar plasmonics, offer efficient light absorption. Optical TPs can occur at the interface between distributed Bragg reflectors (DBRs) and an absorbing layer with layers of optical thickness half the light wavelength [2]. While the lossy layer efficiently absorbs the confined electric field density at the interface in the Tamm plasmon state, complete elimination of the lossy property is necessary to deactivate the absorption. To unlock their active functionality, the ability to perform optical mode conversion between lossless and absorption states is essential.
In this study, we introduce the active Tamm resonator, which utilizes poly(3,4-ethylenedioxythiophene)-polystyrene sulfonate (PEDOT:PSS) as the active material for optical modulation. By applying a voltage range of ±1 V, the resonator transition to a Tamm resonant state (complete absorption) to a mirror state (total reflection). PEDOT:PSS possesses optical characteristics that enable efficient and rapid conversion of the optical mode between a lossless state (dielectric) and an absorption state (metallic) through a redox electrochemical reaction [3]. This conversion is achieved through an electrochemical redox reaction involving proton exchange, facilitated by self-alignment Au nanocolumns acting as a membrane between TPs and electrode for fast proton permeability. The active Tamm resonator exhibits reversible and fast response, characterized by triggered stimulation. Notably, cyclical electron is transferred from the diamond to the metal nanoparticles, enabling the development of a non-volatile memory device. By sequentially programming the input electrical signal, the fabricated device demonstrates optically readable information with excellent retention. Moreover, by designing a circuit that can address each pixel, we have developed an information storage system that uses square pulsed potentials for optical recording and reading. Overall, this research emphasizes the design of optical structures and material selection for the active Tamm resonator as a powerful tool in reconfigurable photonics.

Combining Plasmonic Nanostructures and Diamond for Emission of Electrons using Visible Light

Daniele Catone1, Giuseppe Ammirati2, Alessandro Bellucci, Valerio Campanari1, Faustino Martelli2, Matteo Mastellone1, Patrick O’Keefe1, Silvia Orlanducci2, Alessandra Paladini1, Riccardo Polini2, Francesco Toschi1, Daniele Trucchi1, Stefano Turchini1 and Veronica Valentini1; 1Istituto di Struttura della Materia - CNR, Italy; 2CNR, Italy; 3Università di Roma "Tor Vergata", Italy

Combining plasmonic metal nanoparticles with wide bandgap semiconductor materials has been demonstrated to be an effective way to sensitize these materials to sub bandgap light. This is often used as a strategy to improve the photocatalytic properties of these materials. In this work we focus our efforts on diamond as it has the very interesting property of having a negative electron affinity at its surface when it is hydrogenated. The result is that when electrons are excited into the conduction band in the vicinity of a diamond/vacuum or, indeed, a diamond/water interface they are ejected from the diamond into the vacuum or water. This property can lead to numerous useful applications such as a cold cathode or as a clean source of solvated electrons. The problem is that diamond has a band gap of 5.5 eV and therefore this process only works with VUV light.

We have fabricated two separate systems based on the combination of plasmonic nanoparticles with diamond which show that the exciting the plasmonic resonance of the metal nanoparticles can lead to a strong enhancement of the emission of electrons from the diamond surface. The process is demonstrated using an array of nanoparticles embedded below the surface of a thin film of diamond for the emission of electrons into vacuum using visible light. The increased electron emission efficiency was verified by photoemission and photoconduction measurements. Initial attempts with Aluminum as the plasmonic material were not successful while successive fabrication using silver showed the required properties. Furthermore, a second system involving detonation nanodiamonds coupled with gold nanoparticles in aqueous solution has been shown to be source of solvated electrons following interaction with visible light. In this case the presence of solvated electrons was verified by using an ultrastable pump-probe experiment in which a visible light pump was used to excite the plasmonic resonance of the gold nanoparticles while the white light probe was used to optically detect the formation of the solvated electron in the first picoseconds after the excitation.

Based on the details of the above measurements we propose slightly different mechanisms to explain the photoemission in the AgNP@Diamond system with respect to the formation of hydrated electrons in the AuNP@Nanodiamond system.

Thermal Radiation Around a Nanobubble Generated by a Heated Gold Nanoparticle

Sreyash Sarkar, Jerôme Sarr, Olivier Merchiers and Pierre-Olivier Chapuis; University Lyon, CNRS, INSA Lyon, Université Claude Bernard Lyon 1, France

By injecting metallic nanoparticles into a liquid, localized heating without physical contact is achieved, facilitated by steady-state or pulsed illumination that generates nanobubbles around the particles. This technique has applications [1] in optical hyperthermia for local therapy, microbiology, and solar thermal water heating. The complex dynamics of bubble formation involve vaporization, heat transfer by vapor molecules, and multiple scattering [1]. However, the thermal radiation between nanoparticles and the liquid has not been adequately studied due to the size of the nanoparticles being below the characteristic wavelength (Wien’s wavelength). To accurately assess the sub-wavelength thermal radiation emission, fluctuational electrodynamics calculations are necessary. These calculations reveal that the effective emissivity of small objects can exceed unity [2]. Furthermore, due to the small distance between the nanoparticle and the fluid, the radiative transfer occurs through photon tunneling, in the near field. Fluctuational electrodynamics provides also a suitable approach for considering this phenomenon. This work focuses on evaluating these radiative contributions. The analysis considers the dipole approximation, encompassing both electric and magnetic dipole cases within a cavity immersed in a dissipative medium. Multireflection scattering solutions account for wave-related effects in the vacuum cavity. The results obtained in spherical geometry, using the Mie theory, demonstrate the significance of both wave effects. The volumetric near-field absorption in water varies as almost a sixth power of the distance from the origin and as a third power of the cavity radius, exhibiting observable interferences when approaching the far-field regime. Spectral signature resonances of water dominate the radiative exchange in this scenario. This work will contribute to a more comprehensive understanding of radiative exchange in nanoparticle-liquid systems ultimately aiding the development of thermal engineering, bioengineering, and biomedical applications.

Keywords: near-field thermal radiation, nanobubbles, nanoparticles.

Acknowledgments: The authors acknowledge the support of ANR research funding in the frame of the CASTEX project and valuable discussions with Dr. Samy Merabia.

Bioinspired Colorimetric Metasurfaces for Next Generation, On-Chip Imaging of Tissue Microstructure

Lisa V. Poulikakos, Zaid Haddadin, Paula Kirya, Shahrose Khan, Dev Shah and Loren Phillips; University of California, San Diego, United States

The origin and progression of a variety of leading health challenges, encompassing Alzheimer’s disease, heart disease, fibrosis and cancer, are directly linked to changes in the presence and orientation of fibrous matter in biological tissue. Fibrous biological tissue exhibits distinct anisotropic optical properties, which can be leveraged for selective imaging. However, these naturally occurring light-matter interactions are inherently weak, posing barriers to their visualization in a clinically translatable manner. Existing imaging techniques which visualize the fibrous properties of biological matter face challenges in complexity, cost, destructiveness, or precision. Thus, innovation in imaging technology of fibrous tissue with facile clinical implementation is urgently needed.

To address this challenge, we develop a new class of anisotropic, colorimetric metasurfaces to selectively visualize disease-relevant fiber density and orientation in biological tissue. We draw inspiration from iridescent structural color which is abundant in nature, arising in the saturated blues of the Morpho butterfly wing or the greens of jeweled beetle shells. At the micrometer scale and smaller, these naturally occurring, three-dimensionally (3D)-architected photonic crystals are composed of ordered, geometrically anisotropic features which exhibit distinct interactions with light at varying angles of incidence or polarization state. Due to their 3D hierarchical architecture, these nature-derived systems are unique sources of polarization-sensitive structural color with high color purity and brightness. Based on these principles, our colorimetric metasurfaces are designed to exhibit a high sensitivity to varying polarization states of light. We implement our colorimetric metasurfaces as a next-generation tissue microstructure imaging technology. Starting with the example of breast cancer diagnostics, we then expand our view to the rich palette of fiber-affecting diseases where metasurfaces hold great potential to achieve rapid, precise and low-cost tissue diagnostics with facile clinical implementation.

Active Metal-Dielectric Photonic Crystals

David Allemeier; Boston University, United States

Metal-dielectric photonic crystals (MDPCs) are periodic structures realized by vertically stacked metallic microcavities, resulting in alternating layers of semi-transparent metals and relatively thick dielectrics. Unlike plasmonic metamaterials, MDPCs rely on the hybridization of the underlying microcavity states rather than the coupling of surface plasmons, which produces multiple optical Bloch states arranged in photonic bands. This hybridization can be accurately described using coupled-mode theory, exactly analogous to the formation of molecular orbitals and the electronic energy bands in atomic crystals.

The high conductivity and carrier density of the metallic layers makes MDPCs ideal for active photonic devices and enables a significant reduction in physical thickness due to the high reflectivity at the metal-dielectric interfaces. We have recently exploited this to develop organic light-emitting diodes (OLEDs) that directly express the photonic band structure in their electroluminescence spectrum in the weak coupling regime. In this presentation, we discuss the theoretical foundations of MDPCs using quasi-normal mode formalism and coupled-mode theory. We apply this theory to demonstrate control over the emission spectrum of electrically-driven MDPC OLEDs in both simple and binary crystal configurations by varying the density-of-states and introducing a photonic band gap.

Plasmonic Optomechanical Switch

Irene Castro Fernández1, Daniel R. Vega1, Antonio García-Martín2 and Manuel Marques3; 1Materials Science Institute of Madrid (Spanish National Research Council), Spain; 2Instituto de Micro y Nanotecnología (CSIC), Spain; 3Universidad Autónoma de Madrid, Spain

In this work we theoretically demonstrate the use of a two-level optomechanical system actuated by plasmon-mediated optical forces as a reconfigurable nanophotonic switch. We have simulated a nanostructured suspended gold membrane allowing the normal excitation of a Surface Plasmon Polariton by patterning an air nanohole array. By placing the membrane in a close proximity of a reflecting substrate, we observe a mode splitting which provides two stable mechanical states accessible by tuning the illuminating wavelength.

In recent years the active control of optical forces is attracting more and more attention from the scientific community ranging from the fundamental physics [1] to diverse applications such as optical (and plasmonic) tweezers [2], optically reconfigurable nanophotonic devices and cooling and/or
amplification of the mechanical modes to reach the fundamental ground state [3] or to increase the sensitivity of inertial sensors [4]. In this work, we present a two level optomechanical system that can be stably or dynamically manipulated to act as an optical bit in photonic nanophotonic devices or as an optical switch. The accomplish of the optical force modulation is theoretically demonstrated by means of the mechanical excitation of a suspended membrane consisting of an array of air nanoholes in a gold layer supporting surface plasmon polaron modes [5]. The nanostructured membrane is suspended on a silicon substrate assembling a Fabry-Perot microcavity that enables strong coupling between cavity and plasmonic modes [6]. We simulate the whole optomechanical device through finite element simulations, including the coupled Fabry-Perot cavity. The optical force is calculated by the asymmetries in the integral of the Maxwell stress tensor over a closed surface around the suspended membrane. The Surface Plasmon Polariton and its influence on the optical force is calculated as a function of the cavity length. From the force calculation at a fixed wavelength a double potential well is obtained, showing two stable states with a central energy barrier. It is possible to dynamically actuate on the length of the cavity by introducing a mechanical actuation on the membrane by means of a harmonic displacement. The oscillatory movement of the suspended membrane can be modeled by a Duffing non-linear mechanical oscillator whose amplitude can be manipulated via optomechanical amplitude modulation (cooling or amplification).

Therefore, the final state (stable) of the dynamical system can then be actively chosen, opening the door for the development of an optomechanical switch.

Controlling Spontaneous Emission from Semiconductor Metasurfaces: From Reconfigurability to Single Photon Sources Prasad Iyer; Sandia National Labs, United States

The ability to achieve spatiotemporal control of incoherent (thermal and quantum) light emission has been a critical challenge in the field of optics with far ranging applications from remote sensing, holographic displays and quantum information processing. Here we present our results on two light emitting metasurfaces systems: 1) Ultrastiff dynamic steering of spontaneous light emission from high-density InAs quantum dots (QDs) embedded inside GaAs resonators under structured optical pumping and 2) Enhancement of single-photon emission from single GaAs local-droplet epitaxial QDs from within AlGaAs Huygens’ metasurfaces.

Spatially varying refractive index profiles are the key to steer incoherent light, since reconfigurable metasurfaces operating as phased-antenna arrays can only steer coherent (laser) light. We discover spatial refractive index profiles beyond human intuition that enable high efficiency (77%) steering of incoherent emission from reconfigurable dielectric metasurfaces over an 80° field of view, using generative models and active learning. We developed a machine learning framework where an active learning agent drives a generative model (variational autoencoder- VAE) to predict a spatially structured optical pump pattern which, when imaged onto the metasurface, generates a highly directional emission of incoherent light. This was achieved by creating a dynamic spatially varying resonant phase gradients across the metasurface using an ultrastiff (80fs, 1 KHz rep rate, 3mJ/cm²) 800nm pump which images the pattern from a spatial light modulator (SLM) onto the metasurface. The photoluminescence (beam) steering is initially demonstrated using a periodic blaze (saw-tooth) grating pattern, which created a periodic refractive index profile using Drude free-carrier refraction, resulting in a spatial phase gradient on the metasurface and ultimately directing the momentum of the light emission. We find that Al-generated pump patterns are 10x more efficient in beam steering compared to the initial periodic blaze grating pump pattern designed using human intuition. Our work provides a novel machine learning driven closed-loop platform to understand and discover the physics of incoherent emission steering from metasurfaces with potential applications for augmented and virtual reality displays.

Epitaxially grown III-V QDs are promising sources for single photons with some of the highest metrics in purity, emission efficiency, brightness and indistinguishability reported to date. Here, we explore Al₀.₃Ga₀.₇As Huygens’ resonators with spectrally overlapping the electric and magnetic dipole modes at the emission wavelength of a GaAs local droplet etching quantum dot for enhancing the emission of single photons. We enhance the emission rate of a single QD by an order of magnitude in comparison to an unstructured layer. We simulate the whole optomechanical device through finite element simulations, including the coupled Fabry-Perot cavity. The optical force is calculated by the asymmetries in the integral of the Maxwell stress tensor over a closed surface around the suspended membrane. The Surface Plasmon Polariton and its influence on the optical force is calculated as a function of the cavity length. From the force calculation at a fixed wavelength a double potential well is obtained, showing two stable states with a central energy barrier. It is possible to dynamically actuate on the length of the cavity by introducing a mechanical actuation on the membrane by means of a harmonic displacement. The oscillatory movement of the suspended membrane can be modeled by a Duffing non-linear mechanical oscillator whose amplitude can be manipulated via optomechanical amplitude modulation (cooling or amplification).

Therefore, the final state (stable) of the dynamical system can then be actively chosen, opening the door for the development of an optomechanical switch.

Nanoimprinted PEDOT:PSS Polymer Metasurfaces with Metal-Like Infrared Optical Properties Haydee Pacheco and Deirdre O’Carroll, Rutgers, The State University of New Jersey, United States

Polymer plasmonics offer exciting opportunities for the development of infrared nanophotonic devices. Notably, the high conductivity of heavily doped polymers allows for plasmonic properties and local electric field enhancement, resulting in enhanced infrared absorption and antenna effects. Understanding and controlling the shift in the plasma frequency of doped conductive polymers is crucial for designing and optimizing plasmonic devices and metasurfaces with tailored optical properties in various spectral ranges, including the infrared region.

Here, we report the fabrication and characterization of a nanoimprinted poly(3,4ethylenedioxythiophene) polystyrene sulfonate (PEDOT: PSS) polymer metasurfaces with metal-like optical properties in the infrared and high electrical conductivity. We focus on investigating the shift in the plasma frequency of nanoimprinted PEDOT:PSS polymer metasurfaces relative to planar-doped and undoped PEDOT:PSS surfaces. By adding dopants, such as DMSO, aniline, and ethanolamine, during film fabrication, we significantly enhance the film conductivity while inducing a corresponding shift in the plasma
frequency. The heavily doped PEDOT:PSS films exhibit high electrical conductivities ranging from 10 to 1000 S/cm, making them suitable for plasmonic applications. Doped PEDOT:PSS metasurfaces were fabricated by spin-coating dopant-PEDOT:PSS solutions into films onto glass substrates and nanoimprinting the film using a custom-designed mold with a periodic array of nanostrips. We find that the resulting metasurface exhibits infrared absorption peaks in the 1.5 μm to 15 μm wavelength range, which we attribute to the excitation of surface plasmon resonances. We also characterize the metasurfaces using scanning electron microscopy (SEM) to confirm the morphology of the nanostrips, and Fourier-transform infrared (FTIR) spectroscopy to identify the chemical composition of the various doped PEDOT:PSS films. Our results show metasurface-induced significant changes in the reflection spectrum, with a pronounced dip at the resonance wavelengths, demonstrating efficient manipulation of infrared light by the metasurface structure.

11:00 AM EL08.11.07  
**Optical and Structural Characterization of ScOxNy and ScSizOxNy Thin Films as Dispersion Engineered Optical Materials**  
Smntihidi Chawla1, Kristian W. Munnikhuis1, Tomike Shubitidze1, Wesley Britton1, David Woolf1 and Luca Dal Negro1; 1Boston University, United States; 2Physical Sciences, Inc., United States

The development of compact diffractive optical elements with tailored optical phases has revolutionized the field of photonics, enabling the creation of high-efficiency photonic components with unprecedented functionalities. This research contributes to developing novel ScOxNy and ScSizOxNy thin films, providing valuable insights into their optical properties, structural characteristics, and patterning potential. We studied the optical and structural properties of ScOxNy and ScSizOxNy thin films, synthesized using reactive RF magnetron sputtering. By modulating the growth conditions and incorporating SiO2 components through co-deposition and post-deposition annealing, we achieve tunability in the optical constants of the materials with refractive indices ranging from 1.7 to 3 with negligible absorption losses across the visible spectral range. Variable angle spectroscopic ellipsometry (VASE) is employed to determine the dielectric function of each sample in a broad spectral range extended from the ultraviolet to the mid infrared wavelengths. Furthermore, the structural properties of the thin films are investigated using atomic force microscopy (AFM), X-ray diffraction (XRD), and scanning electron microscopy (SEM). These characterization techniques provide insights into the surface morphology, crystal structure, and composition of the films, essential for understanding their optical performances. In addition, our study explores the suitability of different reactive ion etching (RIE) processes for the fabrication of nanodopants in these materials. The etching behaviour and selectivity of the thin films is investigated with an aim to identify optimal etching conditions for achieving precise patterning and integration into functional photonic devices such as ultracompact imaging components and broadband dielectric metasurfaces.
This approach gives us the possibility to access quantitatively to the performances of the structure, in terms of efficiency or total emitted power. The latter for instance can be maximized by maximizing the local absorptivity of the structure within the active layer, and making it as close as possible to unity.

In a second part, we will present devices consisting of a 2D metallic (silver) grating covered with a thin layer of nanoplatelets deposited by spin coating on the metasurface. The samples were designed following the Kirchhoff’s approach, then fabricated in a clean room environment. Our samples provide highly directional photoluminescence at 605 nm, both in s and p polarizations, with an emission cone around 13.4° half angle.

This work paves the way towards new paradigms in metasurface designs and to a new generation of ultra-thin photoluminescent sources providing highly-controlled wavefront all in a device incorporating both the active medium and the electromagnetic environment that shapes the emission.

Adaptive Photonic Platforms for Radiative Thermal Management in Near-Space and Space Environments

Materials with tunable optical properties offer exciting opportunities for dynamic control of thermal emission and radiative heat transfer. Among such materials, solid-state chalcogenide glasses are characterized by a reversible amorphous-crystalline phase change process with benefits such as substantial refractive index contrast, stability of both phases over a broad range of temperatures, and the ability to maintain state without the use of energy. In this work, we discuss how these desirable properties can be implemented into photonic platforms for near-space and space environments where the radiative contribution to heat transfer is dominant.

We present a systematic approach for modeling and optimizing multi-state thermal emissivity spectral profiles that are relevant in this radiative environment. Using this model, we explore viable candidate metamaterial and metasurface platforms capable of minimizing or maximizing their temperature profiles, depending on the desired target behavior. Our analysis further elucidates the appropriate experimental parameters governing the thermal behavior of these photonic structures in near-space and space environments. This enables reliable prediction of temperature profiles of different adaptive photonic platforms under various heat transfer modes. The proposed approach has promise in realizing efficient and dynamic thermal management of satellites and spacecraft.

Advances in Strong Coupling Between CdSe Nanoplatelets and Fabry-Pérot Microcavities

Fabry-Pérot (FP) cavities containing CdSe nanoplatelets (NPLs) were fabricated by three methods. In the first method, NPLs were dispersed in a polymer film on top of a distributed Bragg reflector (DBR), and overcoated with silver. The resulting cavity exhibited strong coupling, with a Rabi splitting of 50 meV and a Q-factor of 270. However, the presence of the polymer and resulting phase segregation between polymer and NPLs limited the concentration of NPLs within the cavities, thereby limiting the strength of the coupling between the NPLs and the cavity photon.

In the second method, the NPL/polymer layer was replaced with a single layer of neat NPLs. These cavities exhibited larger Rabi splittings, up to 80 meV, but with Q-factors around 50, lower than the Q of the NPL/polymer cavity, which we attribute to the increased absorption and scattering losses of the concentrated NPL films, and to the roughness of silver mirror deposited onto the neat NPL film.

To improve the Q factor of the cavities, a third iteration of cavities were made having thinner layers of neat NPLs enclosed between two SiO2 spacer layers. This arrangement reduced the average absorption and scattering losses of the film stack and planarized the Ag top mirror. A Rabi splitting of up to 60 meV and a Q of 360 was achieved.

These results demonstrate the importance of concentration and uniformity in the assembly of FP microcavities with colloidal semiconductor nanoplatelets, and how these factors meaningfully affect the degree of strong coupling.

Fundamental Limits of Optical Materials and Metamaterials

In this talk, I discuss our recent research efforts on determining fundamental and practical limits to various properties of optical materials and metamaterials, including upper bounds on the refractive index of transparent media, universal bounds on reflection, and challenges and opportunities of time-varying metamaterials. Our findings provide insight into the physical constraints of natural and engineered materials and suggest ways to achieve significant improvements over the current state of the art.
Quantum technologies are widely expected to bring a revolution in communications and information technologies in the coming decade allowing, for example, un-parallelled levels of secure communications. For quantum communication, photonic quantum effects have played a central role, but most photonic solutions and systems based on light-matter interaction also require cryogenic environments. Strong coupling of light and matter at the single emitter level is a fundamental quantum resource offering deterministic energy exchange between single photons and a two-level system, and the possibility to achieve single-photon nonlinearities via the anharmonicity of the Jaynes-Cummings ladder. Until recently, however, the conditions for achieving strong light-matter coupling were most commonly met at cryogenic temperatures such that de-coherence processes are suppressed. As a major step forward, we have recently demonstrated room-temperature strong coupling of single molecules [1] and single quantum dots [2] to ultra-confined light fields in plasmonic resonators at ambient conditions. The fact that strong-coupling conditions may be reached at room temperature is of immense interest because it represents a clear route to a practical implementation and use of quantum behaviour in nanophotonic systems and its application in bi-sensing [3].

The talk will discuss how nanophotonics can be an enabler of ultrafast quantum nanophotonic networks via strong coupling and ultrafast quantum dynamics [4]. We will highlight the physics associated with recently demonstrated room-temperature strong coupling of single molecules in a plasmonic nano-cavity [1] and near-field generated strong coupling of single quantum dots [2] and single quantum emitter Dicke enhancement [5] paving the road towards single-photon quantum nonlinearities. The presentation will also explain near-field enhanced single-photon emission in near-zero index materials [6] and ultrafast multi-partite quantum entanglement [7]. This provides the foundation for unprecedented control over photon number, single photon dynamics, and dynamic multi-photon coherence. These properties are all imperative for the development of next-generation, nanoscale building blocks in ambient-temperature quantum communication technologies.

Design of Different Leaky MoS2 Nanoresonators Focusing on Biosensing Application Dipanjan Nandi and Manisha Gupta; University of Alberta, Canada

Novel atomically thin layered two-dimensional transition metal-dichalcogenides (TMDCs) such as MoS2 are a promising material for different for optoelectronic applications [1] as well as biosensing [2,3]. In recent reported works, MoS2-based field-effect transistor platform was demonstrated for sensing of protein and DNA molecules [4]. Stacked heterostructure of MoS2 and graphene were also explored for detecting Rhodamine 6G (R6G) molecules [5] and DNA hybridization [6].

In this work, we propose different metasurface designs with MoS2 for biosensing applications. The reason of using MoS2 is due to its high refractive index (n > 4 [8]) contrast with air and low absorption (k < 1 [8]) in the visible wavelength range both at monolayer and bulk thicknesses. Also, MoS2 surface favours bonding with carboxyl (-COOH) group, which makes it compatible for biofunctionalization. We have explored designs with MoS2 split-nanorings and nanoantennas. Finite difference time domain (FDTD) simulations were performed to optimize the different design parameters such as, inner and outer diameter, pitch, and split gaps of nanorings and side length and gap between nanoantennas, height of MoS2 to study the leaky resonances for biosensing applications. Simulations have been performed with polystyrene particles (100 nm diameter) distributed (Gaussian distribution) over the device surface and the resonance wavelength shift was calculated with respect to the number of particles. The size of polystyrene particles was chosen as 100 nm because, because it matches with the size of small virus such as, SARS-CoV-2 and Influenza (H1N1). Here, we have considered polystyrene particles as most of the bioanalytes have similar refractive index to the polystyrene [9].

One of the best design parameters for split-nanorings resonators are: diameter: nanoring’s outer diameter- 200 nm, inner diameter- 100 nm, height of MoS2 nanoring- 150 nm, split gap- 50 nm with gap between two adjacent nanorings- 200 nm, and sensitivity achieved 59.49 nm/decade. The best sensitivity achieved with MoS2: nanoantennas array is 305.31 nm/decade with 100 nm side length of 100 nm of equilateral triangle. In this study our primary goal is to introduce a symmetry breaking structure to leak out the resonance field to attain high detection sensitivity for small size bioanalytes detection. Attachment of target bioanalytes on the MoS2 nanoresonators surface disturbs the resonance field and induces a red-shift at the resonance wavelength and detection sensitivity is obtained by calculating the slope of resonance shift curve with respect to the bioanalytes concentrations. We will present the design optimization and comparison between different MoS2 nanoresonators detection performances.

8:00 PM EL08.14.03

We will present the design optimization and comparison between different MoS2 nanoresonators detection performances.
In the quest for efficient and sustainable energy sources, a photovoltaic technique has emerged as a promising solution for harnessing solar energy. The primary strategy for facilitating this technique is to achieve efficient light absorption and/or manipulation of light propagation inside the media. This study presents a novel design to remarkably improve the efficiency of photovoltaic devices by incorporating the concept of optical asymmetry. The proposed structure features multidimensional and hierarchical geometry that differ hundreds of times, allowing anomalous light propagation within the media. It phenomenologically shows the notable light-trapping effect at a wide wavelength regime, thereby enhancing the short-circuit current by up to 46.19%. Taking a step forward, we explored the leverage of this structural design for the wavelength-converting material. Targeting the photon excitation regime of the photovoltaic layers, we observed a significant improvement of short-circuit current density up to 25.97% in the semi-transparent photovoltaic system at indoor light illumination. We believe this research opens up new avenues to externally optimize such photovoltaic systems, paving the way for more efficient and sustainable solar energy utilization.

**Au@Ag Nanostructures for the Sensitive Detection of Hydrogen Peroxide**

I-Hsiu Yeh1, Sirimuvva Tadepalli2 and Keng-Ku Liu1; 1National Tsing Hua University, Taiwan; 2Stanford University, United States

Hydrogen peroxide (H2O2) is an important molecule in biological and environmental systems. In living systems, H2O2 plays essential functions in physical signaling pathways, cell growth, differentiation, and proliferation. Plasmonic nanostructures have attracted significant research attention in the fields of catalysis, imaging, and sensing applications because of their unique properties. Owing to the difference in the redaction potential, silver nanostructures have been proposed for the detection of H2O2. In this work, we demonstrate the Au@Ag nanocubes for the label- and enzyme-free detection of H2O2. Seed-mediated synthesis method was employed to realize the Au@Ag nanocubes with high uniformity. The Au@Ag nanocubes were demonstrated to exhibit the ability to monitor the H2O2 in the range of concentration from 0 µM to 200 µM with r2=0.904 of the calibration curve and the limit of detection (LOD) of 1.11 µM. In the relatively narrow range of the H2O2 concentration from 0 µM to 40 µM, the LOD was calculated to be 0.60 µM with r2=0.941 of the calibration curve of the H2O2 sensor. This facile fabrication strategy of the Au@Ag nanocubes would provide inspiring insights for the label- and enzyme-free detection of H2O2.

8:00 PM EL08.14.05

**Plasmonic Nanomaterials-Based Flexible Strip for the SERS Detection of Gouty Arthritis**

Mei-Chin Lien, I-Hsiu Yeh, Yin-Cheng Lu and Keng-Ku Liu; National Tsing Hua University, Taiwan

Flexible biochips that enable sensitive detection and simultaneous quantification of biomarkers are of great importance in the field of point-of-care testing. Cellulose paper-based biochips have been employed for the diagnostics and biosensing owing to their unique advantages such as high specific surface area, flexibility, and abundance. Recently, surface-enhanced Raman scattering (SERS)-based flexible biochips have attracted a great deal of research attention for disease detection due to their rapid, sensitive, and noninvasive sensing abilities. Phenomenal progress in the synthesis of structure-controlled plasmonic nanomaterials has made SERS a powerful sensing platform for disease diagnosis and trace detection. Owing to their outstanding optical properties, noble metal nanomaterials are excellent candidates for chemical and biological sensing applications. Yolk-shell structured plasmonic nanomaterials, which consist of solid nanomaterials as the core and nanocage as the shell, have been demonstrated to exhibit extraordinary optical properties due to their high surface to volume ratio and the high density of the electromagnetic fields compared to their solid counterparts. Here, we demonstrate the flexible plasmonic biochips for the SERS-based detection of uric acid (UA). Flexible strips exhibited excellent sensing performance with a detection limit of around 10 µM of UA, which is lower than the average level of UA in tears. This rapid and sensitive detection method enables the noninvasive diagnosis of gouty arthritis.

8:00 PM EL08.14.06

**Comprehensive Development of Reactive Sputtering Parameters for High-Performing Zirconium Nitride Thin Films for Earth-Abundant Plasmonics**

Kyle Hue1 and Vivek Subramanian1,2; 1École Polytechnique Fédérale de Lausanne, Switzerland; 2Institute of Electrical and Microengineering, Switzerland

Zirconium Nitride (ZrN) is a highly promising earth-abundant alternative for plasmonic materials due to its lower cost, high electrochemical stability, and greater mechanical durability than traditional metals like Au and Ag. While epitaxial films enable longer plasmonic propagation lengths than their polycrystalline counterparts, epitaxial ZrN has so far only been achieved with expensive, MgO substrates via unbalanced magnetron reactive sputtering. Therefore, research efforts have been focused on developing ZrN films on Si/SiO2 substrates to achieve low-cost films with optical performance suitable for commercial plasmonic applications such as on-chip waveguiding and catalysis enhancement. However, a comprehensive understanding of the reactive sputtering deposition conditions necessary for high-performing ZrN thin films on Si/SiO2 substrates is lacking; most research has relied on high-deposition temperatures and the tuning of N2 flow rates to produce films of acceptable quality. Most notably, the influence of large substrate biases (>100V) on ZrN film formation and its corresponding optical properties has been largely unexplored; given the strong impact of the increased kinetic energy that results from bias, this is a shortcoming of the existing studies.

Herein, for the first time, we explore the systematic tuning and effect of deposition temperature, nitrogen flow rate, and substrate bias, on the optoelectronic properties of ZrN thin films via XRD, XPS, and spectroscopic ellipsometry. First, to optimize the nitrogen concentration and generate stoichiometric ZrN, the ideal gas flow rate was found to be 2.0:30sccm N2:Ar at a plasma power of 150W. Next, we demonstrate that a large, applied RF bias of 400V to the Si substrate enables optimum film formation conditions, likely arising from increased film densification, as evidenced by improved optical properties and higher surface plasmon polarization figures of merit (Qpp). Lastly, we show the effect of moderate, elevated temperatures of 400C, on improved film performance likely from decreased microstrain as evidenced similarly.

As a result, our highest performing ZrN films demonstrate a Qpp over 50 in the VIS-IR spectrum rivaling the best silicon-based ZrN films across literature. Without relying on expensive MgO substrates or extremely high deposition temperatures, we demonstrate the comprehensive effective of sputtering conditions on film formation and plasmonic performance. Given the significant performance achievements, this work can open the door for widely accessible, earth-abundant plasmonic materials suitable for electrochemical and optoelectronic systems and devices operating within the VIS-IR spectrum.

8:00 PM EL08.14.07

**Engineering Photonic Nanodevice by Prescribed Particles Organization and DNA-Based Self-Assembly**

Alexia Yun1, Brian Minevich1, Huajian Ji1, Jiahao Wu1, Katerina DeOlivares1, Daniel Redeker1, Gloria Lee1, Nanfang Yu1 and Oleg Gang1,2; 1Columbia University, United States; 2Brookhaven National Laboratory, United States

Engineering novel optical properties via self-assembly is a promising approach for the fabrication of complex photonic devices with light harvesting, light manipulation, and optical communication capacities. The ability to organize nanoparticles with precise spacing at different scales can enable the structured
nanomaterial with emergent optical properties. However, the realization of such materials remains a challenge. We use a DNA-based self-assembly platform to fabricate three-dimensional (3D) optical materials with ordered nanoparticles. DNA origami frames with DNA complementary bonds can capture sub-10 nm nano-carbon in prescribed spatial positions with nano-scale precision. Programmed bonds enable DNA origami to serve as building blocks that can self-assemble into 3D lattices with repeating and highly organized nanoparticle motifs. By designing an organized structure that couples plasmonic and light-emitting nanoparticles, we investigated the light-emitting properties of the assembled 3D arrays. The optical properties were strengthened by the site-specific growing of the plasmonic particles within the lattice. To enhance stability, the assembled materials were silicatized prior to advanced material characterization and optical measurements. To characterize the assembled materials and to achieve the desired optical response, we used electron microscopy and small-angle X-ray scattering (SAXS) to optimize the assembly process, particle sizes, and particle organization. We further investigated the optical properties by optical microscopy and spectroscopy.

8:00 PM EL08.14.08 Integration of Nanophotonic Structures with a Metallic Nanoporous Air Filter for Particulate Matter Monitoring Seongjae Kim1, Gaabhin Ryu1, Jihee Chang1, Yongtaek Im1, Jesse Sungyun Jeon1, Hana Lim2, Hyun-Jong Kim2 and Sanha Kim1; 1Korea Advanced Institute of Science and Technology, Korea (the Republic of); 2Korea Institute of Industrial Technology, Korea (the Republic of)

The filtration and analysis of airborne particles have received substantial attention since the COVID-19 pandemic. Previous methods of analyzing airborne particles were conducted independently using a sampler, which requires a lengthy and complicated preparation process. In this research, we introduce a new concept of filter-type surface-enhanced Raman spectroscopy (SERS) substrate that allows the simultaneous collection and analysis of ultrafine nanoparticles in the air. SERS is an analytical technique that investigates small amounts of molecules without labeling, which predominantly utilizes the localization effect of an electric field on the nanophotonic surface. Such an analysis method is advantageous over conventional chemical sensors, as a wide range of analyte molecules are detectable. Furthermore, with the recent advance in the miniaturization of spectroscopic devices, there is an increasing potential for integration with Internet of Things (IoT) applications. The proposed substrate in this study is fabricated using the scalable electrochemical deposition of copper nano-dendritic followed by appropriate post-engineering processes to create a nanoporous metal membrane. The thin porous media is suitable for the physical filtration of small particulate matter in the air, and the excellent electrical conductivity of copper allows the capture of particles via electrostatic attraction. In addition, the SERS activation capability is achieved via electron beam deposition of gold. The gold-copper nanoporous membrane demonstrates a particle capture efficiency of ~96% for 300 nm particles under a charging condition of 5 kV with a differential pressure of 121 Pa. The captured particulates on the substrate can be monitored via Raman spectroscopy. We evaluate the performance of the substrate by measuring the Raman spectra of a 1 μM Rhodamine 6G solution and a bacterium sample (P. aeruginosa). Characteristic peaks are observed in both cases, which indicates successful detection. Additionally, we measure the Raman spectra from aerosolized Rhodamine 6G particles as small as 150 nm. The substrate exhibits excellent mechanical properties due to the roll pressing process, which simultaneously allows it to be reused via liquid phase rinsing. Even after undergoing repeated compression tests of ~22,000 cycles at 177 kPa, the substrate maintains functionality along with its filtering and sensing properties. We further conduct numerical simulations to elucidate the localized enhancement of the Raman signal from the nanoporous metal membrane. Finite-difference time-domain (FDTD) simulations of Maxwell's equations reveal amplification of the near field between the nanopores. Moreover, by analyzing the electrostatic potential using the finite element method (FEM), we confirm that the particles can be spontaneously transported toward the electromagnetic hotspot.

8:00 PM EL08.14.09 Plasmonic External Nanogap Dumbbells for On-Particle Direct Raman Assays Kyungjin Choi and Jwa-Min Nam; Seoul National University, Korea (the Republic of)

Metal nanostructures with a plasmonic nanogap are useful for surface-enhanced spectroscopy, and many bio-applications like biosensing and bioimaging. The use of these structures as chemical and biological sensing/imaging probes typically requires an ultra-precise synthesis of the targeted nanostructure and skill in complex nano-assembly techniques are required. Here, we designed and synthesized a plasmonic nanostructure based on Au nanorod cores with two types of external nanogap particles with different gap positions. Au dual-gap nanodumbbells (AuDGNs) were synthesized via the anisotropic adsorption of polyethyleneimine (PEI) on Au nanorods to facilitate tip-selective Au growths on nanorod tips for forming mushroom-shaped dumbbell-head structures at both tips. The dual gaps (intra-head and inter-head gaps) were formed within a single particle. Au tip-intragap nanodumbbells (AuTIDs) were synthesized based on co-reduction and dealloying process of Ag and Au on the tip of Au nanorods. Two heads with closed intra-head gap were grown on the tips of Au nanorod and inter-head gap exposed to outer environment were formed within a single particle. Importantly, these particles enabled facile on-particle SERS detection assays in a short period of time through the diffusion of target molecules into the gap exposed to outer environment.

8:00 PM EL08.14.10 Phase Modulator Ellipsometry Based Biosensor for Detection of E. coli K12 Soraya Zangenehzadeh1, Fenja Schröder, Svenja Herdan1, Enni Agoes1, Nassima Amroun1, Rebekka Biedendieck2, Bernhard W Roth1, Hans-Hermann Johannes1, Dieter Jahn2 and Wolfgang Kowalsky1; 1Institute of High Frequency Technology, Germany; 2Braunschweig Center for Systems Biology, Germany; 3Hanover Center for Optical Technologies, Germany

In recent years, rapid detection of pathogenic microorganisms in human food and water resources has been widely investigated to reduce the number of deaths as well as economic loss. Surface plasmon resonance (SPR) sensors as an optical method is used for detection of biological and chemical targets. These biosensors are extensively applied for detection of microorganisms such as bacteria. While most strains of E. coli are harmless, there are certain pathogenic strains that can cause illnesses in humans. Due to the size of E.coli bacteria (~1 micron), detection of these microorganisms brings challenges in experimental measurement. In this study, we aim to apply phase-modulator based ellipsometer to enhance the performance of conventional SPR sensors for E. coli detection.

Surface plasmons as an surface charge density waves of free electrons at a metal surface propagate at metal-dielectric interface. In specific angle, the p-polarized incident light is strongly absorbed in consequence of coupling the evanescent wave generated at metal-dielectric interface and surface plasmon waves. Hence, the resonance can be observed as an sharp dip in reflectivity profile. Conventional SPR sensors monitor the changes in the intensity of reflected light according to the changes of refractive index of target sample. In resonance condition, not only the intensity of the incoming light changes, but also the phase change is strongly modulated. Due to the significant phase jump, this sharp shifter can be studied to improve the performance of SPR sensors. Spectroscopic ellipsometry provides this opportunity to study both reflectance ratio and phase changes in reflected light from the sample of interest.

Spectroscopic ellipsometry analyzes the changes in the polarization state of light after reflection or transmission from a surface and determines the optical properties and thickness of thin films. These changes in polarization states are studied by the amplitude ratio (Ψ) and the phase difference (Δ) between p- and s-polarized light, respectively. There are different measurement methods of ellipsometry based on the optical elements configuration and arrangement. Barium borate crystal based phase-modulator has been used in our optical setup to induce phase changes in the incoming light beam. Using a phase-modulator in optical design of ellipsometer makes it a faster measurement tool compared to the conventional ellipsometric measurement methods. Using this method each measurement takes around one second. Therefore, this method can be used for detection of microorganisms with high time resolution.

This project has been focused on using conventional Kretschmann configuration including quartz prism and ~45 nm of homogeneous gold film to support
propagation of surface plasmon waves. Gold film is functionalized with porphyrin molecules as a linker with specific peptide group to bind with outer membrane of Gram-negative bacterium. This configuration has been used upon phase-modulator ellipsometer to monitor E. coli K12.

8:00 PM EL08.14.11 Abnormal In-Plan Epitaxy and Formation Mechanism of Vertically Aligned Au Nanopillars in Self-Assembled CeO2–Au Metamaterial System Junjuan Lu1, Di Zhang2, Rolyynne L. Paldi3, Zhihao He4, Ping Lu5, Julia Deitz6, Ahmad Ahmad7, Hongyi Dou8, Xuejing Wang1, Juncheng Liu1, Zedong Hu1, Bo Yang1, Xingxing Zhang1, Anter A. El-Arab1 and Haiyan Wang1; 1Purdue University, United States; 2Los Alamos National Laboratory, United States; 3Sanda National Laboratories, United States

Metamaterials present great potential in the applications of solar cells and nanophotonics, such as super lenses and other meta devices, owing to their superior optical properties. In particular, hyperbolic metamaterials (HMMs) with exceptional optical anisotropy offer improved manipulation of the light-matter interactions as well as a divergence in the density of states and thus have enhanced performances in related fields. Recently, the emerging field of oxide-metal vertically aligned nanocomposites (VANs) suggest a new approach to realize HMMs with flexible microstructural modulations. In this work, a new oxide-metal metamaterial system, CeO2–Au, has been demonstrated with variable Au phase morphologies from nanoparticle-in-matrix (PIM), nanoantenna-in-matrix, to VAN. The effective morphology tuning through deposition background pressure, and the corresponding highly tunable optical performances of three distinctive morphologies, were systematically explored and analyzed. A hyperbolic dispersion at higher wavelength has been confirmed in the nano-antenna CeO2–Au thin film, proving this system as a promising candidate for IIBM applications. More interestingly, a new and abnormal in-plane epitaxy of Au nanopillars following the orientation of CeO2 matrix instead of the SrTiO3 substrate, was discovered. Additionally, the tilting angle of Au nanopillars, α, has been found to be a quantitative measure of the balance between kinematics and thermodynamics during the depositions of VANs. All these findings provide valuable information in the understanding of the VAN formation mechanisms and related morphology tuning.

8:00 PM EL08.14.12 Alternative Platform for COVID-19 Diagnosis Based on AuNPs Modified Lab-On-Paper Pornchanok Punnov, Tatiya Siripongprom, Trairak Pisitkun, Nadnuda Rodthongkum and Pranut Potiyaraj; Chulalongkorn University, Thailand

Since the SARS-CoV-2 virus was first discovered, it has spread over the world. Rapid testing is critical to retard the spread of the virus. Herein, a Lab-on-Paper for diagnosis of COVID-19 is developed applying a colorimetric method for screening test, along with high precision SARS-CoV-2 antigen detection on paper using a laser desorption ionization mass spectrometry (LDI-MS). Gold nanoparticles (AuNPs) were modified on paper for both colorimetric and LDI-MS detection. The colorimetric detection is based on the color change occurring on the paper from pink to purple as a result of AuNP aggregation which can be regulated by antigen–antibody bioconjugation. AuNPs on paper can be used directly as an LDI-MS substrate for direct quantitation of SARS-CoV-2 antigen in saliva without sample preparation for SARS-CoV-2 quantitative detection. In comparison to RT-PCR, LDI-MS provides early diagnosis with high sensitivity, rapidity without sample preparation, as well as a lower cost/test, which is crucial for preventing mortality of patients with underlying conditions. This approach demonstrated linearity between 0.01 and 1 µg mL⁻¹, covering a cut-off value of 0.048 µg mL⁻¹ for COVID-19 indication in saliva. Hence, this platform might be a potential device for applying as non-invasive diagnosis of COVID-19 Omicron BA.2 variant.

8:00 PM EL08.14.13 In Vivo Real-time Multiplex Detection of Plant Signalling Molecules using Surface-Enhanced Raman Scattering Nanosensor Won Ki Son, Seon-Yeong Kwak and Dae Hong Jeong; Seoul National University, Korea (the Republic of)

To understand the biological and chemical dynamics of plants is essential in agriculture, and various sensor technologies have been studied. Plant signalling molecules released against stimuli are drawing attention as a key to understand plant’s status under stressors. Surface-enhanced Raman scattering (SERS)-based nanosensor has shown strong potential for its non-invasiveness and capability of real-time detection from fingerprint spectra. In our research, we fabricated PDDA-capped Ag nanoshell (AgNS@PDDA) and introduced it into plants through stomata. Due to AgNS@PDDA’s optical activity in NIR, it was possible to evade chlorophyll’s autofluorescence and obtain SERS signals with fine quality. Also, PDDA polymer effectively attracted signalling molecules by Coulombic interaction. Then, we studied the plant’s reaction against biotic and abiotic stress with SERS signal monitoring. When plants leaf was under wound stress or cold stress, nasturtolin B, extracellular ATP and glutathione were successfully detected in vivo environment. Meanwhile, biotic stress was studied for the plants infected with fungal disease. F. Graminearum was injected into the plant, and signaling molecules were monitored with biosensors according to the elapsed days after injection. Even only 2 hours after the fungi injection, when no lesion was detectable, SERS signals of eATP and salicylic acid related to systemic acquired resistance were successfully detected.

8:00 PM EL08.14.14 Pulsed Laser Ablation for Flexible Printed Electronics Applications: Harnessing the Power of Colloidal Nitride Nanoparticles Stavros Panos, Nikolaos Platsikas, Spyridon Kassavetis, Maria Gioti and Panos Patsalas; Aristotle University of Thessaloniki, Greece

Nitrides are of the most prominent families of materials dominating nowadays. They can be divided into two distinct sub-categories: i) III-nitride wide-gap semiconductors (GaN, AlN) and ii) Conducting nitrides of IIIb-Vb transition metals (TiN, ZrN, Ti1-xScxN, Ti1-xTaxN) that have recently emerged as important plasmonic materials. Despite the intrinsically superior electrical and optical performance of nitrides compared to conductive oxides, there is a continued and strong prominence of oxides over nitrides in flexible printed electronics due to the compatibility of oxides with solution processing that provide enormous scale up and have allowed oxides to enter the field of printed electronics. The refractory nature of nitrides and the use of high vacuum, introduce industrial costs, reduced scalability and increased power consumption. Therefore, alternative technologies for the fabrication of nitrides are required to be adapted to the needs of printed electronics such as R2R printed sensors and optoelectronic devices. In this study we propose a radical solution to overcome all the aforementioned obstacles by applying laser fabrication processes that promises to produce colloidal nitride nanoparticles with the desired optoelectrical or plasmonic performance compatible with printed technologies. The colloidal nanoparticles were fabricated through laser ablation of Titanium Nitride (TiN), Gallium Nitride (GaN) and Aluminum Nitride (AlN) thick coatings using a nanosecond Nd:YAG pulsed laser at 355, 532 and 1064 nm wavelengths in various liquids. The colloidal NPs’ structure, morphology as well as quality have been analysed by Raman, SEM, AFM. The optical properties of the target materials have been evaluated by NIR-Vis-UV, Spectroscopic Ellipsometry, while an optical absorbance characterization was performed on the colloidal TiN NPs.

8:00 PM EL08.14.15 Color Purity Enhancement Through Effective Index Modulation of GST for Applications in Reconfigurable Displays Youbin Lee, Joo Hwan Ko1, Sung-Hoon Hong2 and Young Min Song3; 1Gwangju Institute of Science and Technology, Korea (the Republic of); 2Electronics and Telecommunications Research Institute Materials and Components Research Division, Korea (the Republic of)
Phase-change materials (PCMs) have been emerging owing to their reconfigurable physical properties such as refractive index, light absorption, electrical conductivity, and Young's modulus by switching between amorphous and crystalline phases [1]. GeSbTe (GST), which consists of germanium, antimony, and tellurium, is one of the representative PCM materials and is widely studied for a dynamic color display or phase change memory by utilizing its great tunability in both optical and electrical properties. Due to the nature of the refractive index variation depending on the phase of GST, there have been tremendous suggestions for reconfigurable photonic structures, including photonic memory, thermal radiation modulator, and tunable structural color [2]. Typically, optical coating of dielectric thin films is based on Fabry-Perot or thin film interference. Recently, high-absorption dielectric films have been studied as optical coatings, and when metals are combined with high-absorption dielectrics, strong optical interference can be obtained with a small phase change of the reflected wave, which can significantly reduce the thickness compared to conventional coating layers. Resonance behavior impacting the structural color can be observed in structures consisting of a metal-coated substrate with an ultra-thin absorbing layer. The high color purity and feasible tuning functions of structural coloration has attracted attention due to its promising applicability as a next generation color display. Despite its great potential application, low chromaticity and limited intermediate step over phase change have been treated as a barrier to the efficient operation as a color display [3].

In this study, we present an ultrathin tunable color filter comprising GST. We modulate the effective index of GST by applying porosity (potential application, low chromaticity and limited intermediate step over phase change have been treated as a barrier to the efficient operation as a color display) with anisotropic geometry, resulting in color purity enhancement and enhanced controllability based on polarization-driven modulation. Specifically, we deposit GST on top of an Au film using glancing angle deposition (GLAD) to manufacture self-aligned porous nanocolumns (PNCs) with varying $P_r$ (0% to 40%, 70%). In the amorphous GST/Au reflection spectrum, dip intensity decreases as $P_r$ increases, and we find that color purity can be enhanced by controlling the $P_r$ and phase. Particularly, the amorphous phase of GST exhibits a higher color purity and a wider color range than the crystalline phase. Additionally, mitigate the risk of surface oxidation and potential damage when depositing GST on an Au film exposed to ambient air, we conducted simulations to explore the effect of incorporating an oxide layer as a film passivation strategy. This additional dielectric layer serves noticeable shift in the dip position of the reflectance spectrum and changes in the phase condition, the color response can be dynamically adjusted, offering a wide range of color variations depending on the thickness of the oxide layer. Furthermore, GLAD technique induces atomic shadowing and creates inclined columnar structures on the substrate, resulting in an increased porosity. Due to the shadowing effect, the slanting plane direction of the PNCs has a higher $P_r$ and varies with the polarization angle, causing a structural color change. We confirm that the color purity can be improved with the $P_r$, phase, thickness of GST, and polarization angle. And the incorporation of the additional dielectric layer provides both protective benefits and enhanced control over color presentations, presenting exciting possibilities for diverse applications. Our suggestions can be used as a way to improve optical properties in applications such as optical coating, optoelectronic displays, and optical storage devices.

Infrared Thermal Management with Graphene-Ag Nanocubes Heterostructures
Ihsan Uluturk1, Michael Leuenberger2, Peter Capuzzi3, Margaret Peters2, Jin Ho Kim1, Michael J. Manser1 and Richard M. Osgood1; 1U.S. Army, United States; 2University of Central Florida, United States; 3University of Massachusetts Lowell, United States

The main purpose of textiles throughout history is to regulate heat flow and provide warmth or decrease excessive heat for the wearer. In recent times, the textile industry has developed new materials that can ensure the wearer stays dry in hot environments and that repel moisture. The main downside of these new textiles, however, is that their electromagnetic response has not been fully optimized, allowing too much radiation to be absorbed and radiated back to the skin, causing the wearer to overheat. Our work is composed of two parts: simulation and experimentation. Simulations will first be conducted to better understand graphene chemistry, as graphene ink with Ag nanocubes, FeCl3, and SU-8 are spin coated onto silicon wafers.

In this work, heterostructures made of Ag nanocubes-Graphene-FeCl3-SU-8-Si wafer-Al mirror are considered. This system is a representative of a Fabry-Perot type of cavity, where incident infrared light interacts strongly with graphene and the Ag nanocubes. FeCl3 is used to dope graphene to a Fermi energy of $E_F=-0.6$ eV. The thickness of SU-8 will be chosen to be a quarter of the infrared wavelength in order for the amplitude of the infrared light to be maximal at the position of the graphene sheet.

Finite-difference time domain (FDTD) simulations show narrow resonance peaks in the absorbance (=emittance) due to localized acoustic surface plasmons (AGPs) in the dielectric between graphene and the Ag nanocubes. The positions of the resonance peaks can be tuned in the range between 3 mm and 12 mm by means of a gate voltage. When the number of graphene layers is increased, the conductivity is multiplied by the number of layers, which results in a blueshift of the AGP peaks. By increasing the size of the Ag nanocubes and the period of the square lattice of Ag nanocubes, the AGP peaks are redshifted. For highly doped graphene layers with a small layer of FeCl3 of around 50 nm between graphene and the Ag mirror, the absorbance (emittance) between 3 mm and 12 mm is around 2%, independent of the number of graphene layers. Such heterostructures could be useful for thermal management systems. Based on the simulation results, we will be fine tuning the graphene chemistry. Resultant graphene ink with Ag nanocubes will be spin coated onto Si wafers. The fabricated heterostructures made of Ag nanocubes-Graphene-FeCl3-SU-8-Si wafer-Al mirror will be characterized using in-house developed Delta T measurement system. In this system, anodized Aluminum with an emissivity of 0.77 is used, which is smaller than the emissivity of human skin (95% to 98%). The anodized aluminum is placed on a hot plate and a thermocouple. The hot plate is heated up to 38 C to simulate the body temperature and standoff is created between heterostructures and the hot plate. Thermocouples will be used to measure the temperature difference between the heterostructures and plain Al mirrors to see if the heterostructures have a significant effect on the thermal management property.

Genetic Algorithm Optimization of Mid-Infrared Nonreciprocity in Weyl Semimetal Planar Photonic Structures
Hannah Gold, Simo Pajovic, Abhishek Mukherjee and Svetlana V. Boriskina; Massachusetts Institute of Technology, United States

Engineering thermal radiation from surfaces is usually limited by the constraints of Kirchhoff’s law of radiation, which states that the spectral directional emissivity of a surface equals its spectral directional absorptivity at thermal equilibrium; This imposes fundamental limits on the efficiency of radiative-energy harvesting, as any absorber also acts as a thermal emitter in the same spectral and angular range. In turn, breaking this reciprocity enables breaking the barriers in thermal efficiency engineering [1,2]. In this work, we develop an algorithm to optimize the non-reciprocal infrared response and to enable breaking of the Kirchhoff’s law in a one-dimensional (1D) planar photonic multi-layer stack composed of thin films of Weyl semimetals and dielectrics. The design space and parameters of this structure were traversed using a genetic algorithm to find a global optimal solution, and then the design was further refined with numerical gradient descent to find the local minimum thereafter. The resulting design achieves a large non-reciprocal absorption contrast in the near infrared wavelength range at positive and negative angles of incidence (55 and -55 degrees were used during the optimization). Differently from prior studies, our optimized design accounts for both s- and p-polarized reflection coefficients when calculating the non-reciprocal Figure of Merit (FOM),
which is vital for applications in harnessing the thermal radiation from the structure. Because the non-reciprocity is governed by the excitation of the surface plasmon-polariton modes at the interfaces between Weyl semimetal and dielectric layers, it is limited to the p-polarized optical response engineering. Thermal emission in the allowed s-polarized modes is still reciprocal and may degrade the overall figure of merit in the design of a non-reciprocal thermal emitter. Furthermore, our optimally designed 1D planar non-reciprocal absorber avoids the technical challenges of fabricating grating-based structures that require lithographic techniques. Finally, our optimum design offers the largest FOM while using much fewer layers in the heterostructure, which should significantly simplify its experimental realization. The use of the Weyl semimetals instead of the conventional magneto-optical materials in our design eliminates the need for an external magnetic field bias, thus allowing for a compact form factor and integrability. Applications of our work range from thermophotovoltaic cells to optical switches, circulators, and isolators.

Ellipsometric Detection of Bacteria using Dielectrophoresis Fenja Schröder, Soraya Zangenehzadeh, Emil Agocs, Marten Musiol, Nassima Amrouni, Rebekka Biedendieck, Dieter Jahn, Hans-Hermann Johannes and Wolfgang Kowalsky; Technische Universität Braunschweig, Germany; Leibniz Universität Hannover, Germany

The aim of this research is to detect bacteria by ellipsometry and evaluate if dielectrophoresis (DEP) can be useful to improve the limit of detection of optical biosensors.

Spectroscopic ellipsometry allows the non-destructive and contactless analysis of thin films or biological samples in a time range of seconds. Ellipsometry is based on the investigation of the polarization state of reflected or transmitted light. The measured parameters are the amplitude ratio (Ψ) and the phase difference (Δ) of s- and p-polarized light. Our measurement set-up consists of a flow cell that guides bacteria in liquid environment to a sensing surface, which consists of a glass substrate coated with thin film gold electrodes. Measurements were performed in Kretschmann configuration utilizing a quartz prism and gold electrode substrates. The bacteria studied in our experiments is the well-known, Gram-negative E. coli K12 strain.

The irradiation of the electrodes under a certain angle of incidence at a certain wavelength of light allows the excitation of surface plasmons resonance (SPR). Under this condition p-polarized light is coupled to the mode of surface plasmons at the metal-liquid-interface. This phenomenon can be monitored in the spectra of the ellipsometric parameters Ψ and Δ in form of a sharp dip, that correlates to the intensity minimum of the reflected p-polarized light. The excitation of SPR is highly dependent on the refractive index at the metal-liquid-interface. The presence of bacteria in a liquid changes the refractive index near the gold surface and therefore also changes the excitation condition of the SPR. Due to the penetration depth (~300nm) of the evanescent wave associated with the excitation of SPR, SPR-based sensors can only provide information on the refractive index very close to the metal interface. Therefore, it is of high importance to increase the number of bacteria at the metal-liquid-interface. To reach our goal of a highly sensitive SPR sensor we utilize the effect of dielectrophoresis.

Dielectrophoresis (DEP) describes the movement of dielectric particles in suspension due to the presence of inhomogeneous electric fields. DEP is divided into positive and negative DEP, depending on the different movement of particles due to the outer electric field. For positive DEP (pDEP) particles, such as bacteria, are accelerated to regions of high field inhomogeneity, which occur at the electrode edges. Hence bacteria are collected directly on the electrodes, the change in the spectra of Ψ and Δ magnified.

To explore the efficiency of bacteria collection by pDEP and the behavior of different electrode geometries in ellipsometry, a variety of electrode structures were designed. The structures vary in complexity and symmetry. Furthermore, the dependence of dielectrophoretic bacteria collection and SPR excitation on the gold film thickness was investigated. The designed electrodes and measurement set-up were able to visualize the influence of DEP on an ellipsometry based biosensor.

8:00 PM EL08.14.20
Hardware and Sensor Optimization of a Nanotechnology Enabled Implantable Sensor for Hormones in Marine Animals Xiaojia Jin, Volodymyr Koman, Manki Son and Michael S Strano; Massachusetts Institute of Technology, United States

Biologging has yielded tremendous insights in ecological biology by enabling the collection of data in animals free-roaming in their environments. However, measurements have largely been limited to temperature, pressure, and movement. Physiological data of animals’ biomarkers would create valuable observational datasets and produce more nuanced understanding of organisms in the context of their environments and behaviors. Nevertheless, successes in collecting such biochemical information remain absent. In this work, we explore hardware and sensor optimization of nanotechnology-enabled implantable sensor for tracking hormone levels in marine animals. We have extensively studied the performance of nanosensors based on polymer-wrapped single-wall carbon nanotubes (SWNT) embedded within a biocompatible poly (ethylene glycol) diacrylate (PEGDA) hydrogel under various temperatures, illumination conditions, and sensor concentrations. We have further prototyped a miniaturized fluorescent system integrated into commercially available acoustic tags used in marine biology. An integrated nanosensor hydrogel reached 100 nM limit of progesterone detection as an example of important hormone in marine animals. The developed form-factor will complement the presently collected data by providing insights into the physiological state of the animals in the context of their behavior and environments. With these new data, biologging studies will reach a new level of sophistication and nuanced understanding.

Using Cell Lensing and Nanosensor Chemical Cytometry to Characterize the Efflux Heterogeneity of Immune Cell Populations Xiaojia Jin, Xun Gong, Volodymyr Koman, Soo- Yeon Cho and Michael S Strano; Massachusetts Institute of Technology, United States; Sungkyunkwan University, Korea (the Republic of)

Cellular immune heterogeneities play a critical role in the progression and prevention of cardiovascular or neurodegenerative diseases. Thus, a tool that can profile the dynamic antigenic responses of different immune cell populations in terms of their chemical efflux and biophysical properties can enhance our understanding of past and future unknown microorganisms and diseases. Herein, we have developed a technique called Nanosensor Chemical Cytometry (NCC), that utilizes an optical nanosensor array embedded within microfluidics to interrogate chemical species efflux from individual cells in real-time. The NCC technique takes advantage of the cell itself as an informative Gaussian lens, projecting both the nIR emission of the single-walled carbon
nanotube sensors as well as various cellular physical properties. Different nanosensor integration methods were investigated to optimize the signal readout.

Using the NCC technique, we have profiled both the heterogeneity of nitric oxide (NO) efflux from macrophage populations and hydrogen peroxide (H₂O₂) efflux from monocyte populations. The technique was able to profile immune heterogeneities at attomolar sensitivity in a completely non-destructive and real-time manner with a throughput rate of ~600 cells/hr. In addition, new phenotype correlations between real-time extracellular immune responses and multiple biophysical properties (cell size, eccentricity, RI) of cell populations were investigated with exact numerical values and distribution statistics. This work provides an efficient strategy for the chemical analysis of cell populations in manufacturing and biopharmaceutical engineering.

8:00 PM EL08.14.22
Core-Shell and Yolk-Shell Plasmonic Nanocrystals for Hydrogen Production Yung-Jung Hsu, National Yang Ming Chiao Tung University, Taiwan

With the inherently high degree of complexity, heterostructures composed of two or more materials joined in unique architectures may exhibit superior synergetic properties that are difficult or impossible to acquire from their individual constituents. For semiconductor heterostructures, the relative band alignment of the constituents promotes effective charge separation to bring them desirable properties for photocatalysis applications. Among the different types of heterostructures, core-shell and yolk-shell nanocrystals have received particular interest due to their fascinating properties. Several representative works from our lab will be introduced to demonstrate the promising potentials of core-shell and yolk-shell nanocrystals for hydrogen production applications, especially those involving localized surface plasmon resonance.

Nanoscale Imaging of Surface Plasmon Polaritons at Interface of Metal/Dielectric by UEM Haihua Liu, Thomas E. Gage and Ilke Arslan; Argonne National Laboratory, United States

Haihua Liu1,*, Thomas E. Gage1, Ilke Arslan1
1 Center for Nanoscale Materials, Argonne National Laboratory, Lemont, IL, USA
*Corresponding email: haihua.liu@anl.gov

Surface plasmon polaritons (SPPs) are collective oscillation of surface charge-density waves at the interface between a metal and a dielectric material. The SPPs that propagate along the interface and exhibits exponential decays perpendicular to the interface into an adjacent dielectric medium. With the unique properties of evanescent and surface localization, SPPs are non-radiative and can be transversely localized and guided into subwavelength metallic nanostructures as small as a few nanometers. A new branch of photonoics called plasmonics, based on control and manipulation of light using SPPs at the nanoscale, has the potential to break diffraction limit of light and exhibit significant advantages in nanophotonics device development by replacing electronic signals with light as information carriers. Their prime motivation behind research on photonic circuits. Therefore, it is of great importance to image the SPPs at the nanometer scale to give one deeper understanding of the guide and localization of light below the diffraction limit for nanophotonics applications.

Ultrafast Electron Microscopy (UEM) has been used to study the ultrafast dynamics of light-matter interactions in physics, chemistry and materials science with temporal resolution of hundreds of femtoseconds, which is 10 orders better than that of conventional electron microscopy limited by the camera readout rate. Other than light-matter interaction observed in UEM, the investigation of photon-electron interaction has been enabled by a unique technique called Photon-Induced Near Field Electron Microscopy (PINEM) developed in UEM to capture the evanescent electromagnetic field on its intrinsic time scale and nanometer scale. We recently established one state-of-art UEM scientific platform at the Center for Nanoscale Materials (CNM), Argonne National Laboratory. Besides the capabilities of imaging and diffraction, the UEM at the CNM is equipped with one GIF spectrometer, which enables it to work in energy filtering mode and record the PISEM image. Here, we investigated the excitation and localization of extended two-dimensional surface plasmon polaritons waves at the interface of metal and dielectric material including metal/dielectric interface with simple irregular nano holes or nano slots, and metal/dielectric interface with nanofabrication of nano holes array under excitation by ultrashort laser pulses using PINEM. The interference of the SPPs on surface roughness, propagation distance, laser wavelength, fluence, and polarization was studied at the nanometer spatial scale and femtoseconds time scale. The results reveal that UEM is one powerful tool to study the SPPs at high spatiotemporal resolution of nanometer scale and femtoseconds time scale for the development and applications of SPPs-based photonic circuits such as waveguides, near-field optics, date storage, solar cells biosensing and optical communication.

Work performed at the Center for Nanoscale Materials, a U.S. Department of Energy Office of Science User Facility, was supported by the U.S. DOE, Office of Basic Energy Sciences, under Contract No. DE-AC02-06CH11357.

Nonlocality and Loss in Nonreciprocal Photonics Enabled by Weyl Semimetals Morgan Blevins and Svetlana V. Boriskina; Massachusetts Institute of Technology, United States

Engineering new nonreciprocal optical devices is an important initiative in current photonics research. There is a desire to engineer new, nonreciprocal integrated photonic devices to replace the current standard of magneto-optic materials, which require bulky external magnets incompatible with many chip-scale device architectures [1]. Much research has been dedicated to modeling and designing nonreciprocal devices made from Weyl semimetals (WSMs)
for next generation isolators and enhanced near-field radiative heat transfer devices [2]. However, as has been recently discussed [3], the impacts of nonlocality and loss on the proposed nonreciprocal Weyl devices close the window of opportunity to transport and render the realistic structures less useful than those initially proposed in the lossless, local regime. While loss and nonlocality are inherent to plasmonic devices, nonreciprocal Weyl devices with large figures of merit can be engineered by judicious combinations of external symmetry-breaking stimuli. To date, the qualitative impacts of loss and nonlocality have been mostly investigated in intrinsic time-reversal-breaking WSM [4]. Here, we expand this analysis to time reversal- and inversion symmetry-breaking WSMs under a variety of *in situ* and *ex situ* stimuli, which either induce or enhance nonreciprocity. These stimuli include inhomogeneous strain and Fizeau drag via DC current bias. By evaluating the effect of various external stimuli that induce nonreciprocity in WSMs – as well as their combinations – we aim to identify a breadth of useful regimes for nonreciprocal and tunable WSM devices operation when realistic loss and nonlocality are accounted for.

This research has been supported by the Army Research Office (W911NF-13-D-0001), Lincoln Laboratory, Massachusetts Institute of Technology (ACC-777), and a Draper Fellowship to M.B.

10:15 AM EL08.15.04
An Active Metasurface Single-Pixel Lensless Imaging Device Julie Belleville, Prachi Thureja and Harry A. Atwater, California Institute of Technology, United States

We present a computational model that evaluates the performance of active metasurfaces as platforms for lensless imaging and find that an active metasurface with a 0.3 mm aperture size could capture images at >2 pixel/degree resolution across a wide field of view (FOV) of 120°. Our model optimizes the metasurface array configuration to obtain angular Hadamard and Fourier bases, and the results address the performance of an experimentally realized indium tin oxide (ITO)-based metasurface operating at telecom wavelengths.

Lens-coupled detector arrays are the basis for most of today’s imaging systems but are not well suited to realized low-weight or small-footprint systems due to the weight and focal lengths of lenses. Lensless imaging—in which a modulator is coupled to a detector and modifies the detected light to enable computational image retrieval—offers an attractive alternative to lens-coupled detectors in applications requiring low SWaP (size, weight and power) devices or wide FOVs [1].

We investigate active metasurface elements to modulate light in a single-pixel imaging configuration. In contrast to passive metasurfaces that have set optical properties, the phases and amplitudes of active metasurface elements can be dynamically controlled via external stimuli which modulate their dielectric properties. In this study, we use the experimentally demonstrated performance of a field-effect tunable ITO-based metasurface at an operating wavelength of 1510 nm, with a phase tunability of 271°, covarying reflectance and phase, and modulation speeds exceeding 10 MHz [2][3]. The model and analysis, however, can be applied to various active metasurface platforms.

To determine the attainable performance of active metasurfaces in imaging, we use array-level inverse design, which was previously used to enhance beam steering performance [4]. We simulate the 1D far-field intensity of the metasurface using an array factor calculation and control the acceptance of light by optimizing the voltages applied at each element. Using a simulated aperture size of 0.3 mm (768 elements), we demonstrate a peak resolution of 4 pixel/degree and of 2 pixel/degree across a 120° FOV. We also show the suitability of active metasurfaces for compressed sensing, in which sparse images are recovered in fewer measurements than there are pixels. For this, we optimize the metasurface array configuration to obtain angular Hadamard and Fourier bases. In preliminary tests, our optimized Hadamard basis retrieves images with good agreement to the ground truth, with a power signal-to-noise ratio of 40 dB across 512 pixels. Additionally, we demonstrate the convolution of image processing filters across the FOV, which is desirable in classification applications. Our ability to produce grayscale filters distinguishes our platform from digital micromirror devices, which are often used in single-pixel imaging and support modulation speeds of ~20 kHz only for binary bases [5]. As resolution and FOV improve with metasurface size, we note that our current results are not an upper bound on performance.

As a next step, we will explore algorithms for 2D imaging and increase the realism of our model by modeling amplitude/phase errors, voltage discretization, and component reaction times. We will also report on an analysis of which imaging bases are best suited to active metasurfaces, and on the use of machine learning to correct for imperfections in basis construction. Finally, we will discuss the potential of active metasurfaces in multi-pixel lensless imaging applications.

10:30 AM EL08.15.05
Biomineral-Based Optical Metasurfaces and Cavities - Analysis and Sensing Richard M. Osgood, Jin Ho Kim, Peter Capuzzi, Margaret Peters, Ihsan Uluturk and Richard Pang; CCDC-SC, United States

New optical biomaterials such as biopigments and biominerals enable fascinating optical properties, such as bright and structural color and advanced camouflage. Arrays of isoanthopterin nanoparticles in reflectors within shrimp eyes cause significant photonic backscattering, optimizing the sensitivity and spectral coverage of shrimp eyes.[1] Biominerals such as silicate in diatoms, strontium sulfate in radiolarians, goethite in limpets, magnetic in magnetotactic bacteria, and calcium phosphate in bones provide mechanical structure, sense magnetic and gravitational fields, and can store and mobilize iron. Biominerals are primarily non-toxic and environmentally friendly materials, generally with very high indices of refraction, especially for organic compounds. Biominerals are good candidates for optically sensing materials, because of their high index of refraction and non-toxic, scalable, and manufacturable properties. They are expected to be unregulated in the future due to lack of toxicological concern, unlike metal oxide nanoparticles, which are facing increasing amounts of regulation in manufacturing settings, due to concerns about potential carcinogenic nature from chronic exposure to workers in a manufacturing plant. Biominerals should be supply-chain resilient as well because they are straightforward and relatively simple to fabricate.
We have chemically synthesized the biomimetic goethite (α-FeOOH), using a mixture of iron nitrate and tetramethylammonium hydroxide with an initial pH around 13. The reactant has a pure yellowish color, forms spindly rods that have 10-30 nm diameters and lengths in the range of 100-300 nm as determined by Scanning Electron Microscopy (SEM), exhibits the correct elemental composition for goethite in Electron Dispersive Spectroscopy (EDS), and powder x-ray analysis matches reference data from x-ray crystallographic data. 2-D photonic crystals were formed using 508 nm PS beads and were very iridescent, producing different colors at different angles. These photonic crystals had a bandgap in the red and transmitted light therefore had a yellowish-green color. A film of goethite was dipcoated onto this 2-D array and registered an interesting drop in signal intensity when exposed to ethanol vapor, the analysis of which will be reported in this presentation. 1-D photonic crystal arrays consisting of alternating 70 nm PVA and 100 nm goethite layers were fabricated, show the expected multilayer peaks in reflectivity (7 maxima between 800 nm and 2500 nm), and considerable backscattering above 1100 nm. For wavelengths less than 1100 nm, the silicon substrate attenuated the backscattered light. Exposing this multilayer to glucose liquid, ethanol vapor, and humidity all results in an attenuated signal and possibly a peak shift. This peak shift was modeled and the wavelength shift per refractive unit change at the surface estimated, for detecting molecules like ethanol, water, and glucose. Single Fabry–Perot cavity films of goethite were also fabricated, thickness and optical indices measured with profilometry, spectrophotometry, and ellipsometry, and sensing results from these F-P cavities will be reported. We will also explain how, in the future, to make the biomimetal-based sensing more sensitive and selective, using an embedded specific receptor in the photonic crystal and in thin films. Potential optical systems and detection methods using biominerals will be discussed.

Pushing the Limit of Multiplexing Capacity in Photonic Metasurfaces Yongmin Liu; Northeastern University, United States

Over the past decades, we have witnessed tremendous progress and success of photonic metasurfaces. By tailoring the geometry of the building blocks of metasurfaces and engineering their spatial distribution, we can control the amplitude, polarization state, phase and trajectory of light in an almost arbitrary manner. For practical applications such as high-capacity optical display, information encryption, and data storage, it is crucial to encode distinct functionalities into a single meta-device and increase the information channels. In this talk, I will present our recent works that aim to push the multiplexing limit in photonic metasurfaces through both physics-guided and data-driven approaches. In the first part of my talk, I will show that we can break the fundamental limit of polarization multiplexing capacity of metasurfaces by introducing the engineered noise to the precise solution of Jones matrix elements [Science 379, 294 (2023)]. We experimentally demonstrate up to 11 independent holographic images using a single metasurface illuminated by visible light with different polarizations. To the best of our knowledge, it is the highest capacity reported for polarization multiplexing. Combining our noise engineering method with the position multiplexing scheme, we design and demonstrate another metasurface that can generate 36 distinct images, forming a holographic keyboard pattern. In the second part of my talk, I will show that machine learning enables us to accelerate the development of complex metasurfaces (and other photonic structures) with high efficiency, accuracy and fidelity [Nature Photonics 15, 77 (2021)]. The developed machine learning models, after training, can evaluate the optical responses of metasurfaces and inversely design them in less than seconds. We propose to embed machine learning models in both gradient-based and nongradient optimization loops for the automatic implementation of multifunctional metasurfaces [Advanced Materials 34, 2110022 (2022)]. Fundamentally different from the traditional two-step approach that separates phase retrieval and meta-atom structural design, the proposed end-to-end framework facilitates full exploitation of the prescribed design space and pushes the multifunctional design capacity to its physical limit. With a single-layer structure that can be readily fabricated, metasurface focusing lenses and holograms are experimentally demonstrated in the near-infrared region. They show up to eight controllable responses subjected to different combinations of working frequencies and linear polarization states.

11:15 AM EL08.15.07
Undoped Organic Semiconductors as a New SERS Platform Antonio Facchetti; Northwestern University/Flexterra Inc, United States

Nanostructured molecular organic semiconductor films are promising Surface-Enhanced Raman Spectroscopy (SERS) platforms for both fundamental and technological research. In this presentation we report that nanostructured films of oligothiophenes functionalized with different fluorinated alky or aryl groups demonstrate unprecedented Raman enhancement factor (>10^5) and a low limit of detection (10^{-9} M) for the methylene blue probe molecule. This data is comparable to those reported for the best inorganic semiconductors and even intrinsic plasmonic metal-based SERS platforms. Photoluminescence spectroscopy and computational analysis suggest that both charge-transfer energy and effective molecular interactions, leading to a small but non-zero oscillator strength in the charge-transfer state between the organic semiconductor and the analyte molecule, are required to achieve large SERS enhancement factors and low molecular sensitivities in these systems. Our results provide not only a considerable experimental advance in organic SERS figure-of-merits but also guidance for the molecular design of more sensitive SERS platforms based on organic (macro)molecules.
University of Science and Technology, Korea (the Republic of)

Metasurfaces are composed of arrays of subwavelength structures and can provide fine wavefront-shaping platform with a compact form factor, resulting in both capability of diverse functionality and drastic miniaturization of the optical device. However, due to their low information capacity and passive nature, extensive studies focusing on overcoming these limitations have been conducted to achieve high information capacity [Science 379, 294-299 (2023)], spatial (wavefront) tunability [Science 364, 1087-1090 (2019)], and spectral (wavelength) tunability [Nat. Nanotechnol 16, 795-801 (2021)]. However, previous approaches cannot simultaneously achieve all these features. This manuscript provides the first report of simultaneous spatial and spectral tunable metasurface with high information capacity and its applications in dynamic multicolor holography. To this end, we propose unique combination of an inverse designed metasurface and a layer of oblique helicoidal cholesteric liquid crystal (ChOH) layer. The inverse design method enables the single-phase map encoding of 10 independent holographic images at different wavelengths. To the best of our knowledge, this represents the highest capacity reported for a single-cell metasurface. ChOH provides precise and free modulation of the reflected wavelength with a wide spectral range (420 nm – 720 nm) and narrow bandwidth (13 – 32 nm). Therefore, both holographic image and its color can be varied by applying programmed stimuli (electric field and temperature). Further, we believe that it is a simple and generalizable approach for interactive metasurface with high information capacity, spatial and spectral modulation. Moreover, this work can also be applied to a wide range of novel applications, including secret-sharing platform, hyperspectral imaging, and full-color 3D display.

3D Plasmonic Nanoarchitecture on Paper-Based Strip for Deep Learning-Assisted Human Urine Sensing and Cancer Screening
Ho Sang Jung; Korea Institute of Materials Science, Korea (the Republic of)

Practical human biofluid sensing device is required to screen the patient from the normal group with high sensitivity and specificity. Especially, urine metabolite detection of cancer patient provides insights for early diagnosis and finding of new biomarkers. Here, 3D coral-like plasmonic nanoarchitecture (3D-CPN) is fabricated on a paper substrate as a urine test strip via direct one-step gold reduction process, which is available for quick urine absorption and metabolite filtration. The coral-like nanoarchitecture was grown with multiple grain boundaries forming particle-like protrusions (PPs), which were characterized by scanning electron microscopy (SEM), transmission electron microscopy (TEM), X-ray diffraction (XRD) and so on. The coral-like structure formation mechanism can be explained by successive primary particle-to-particle attachment process, such as oriented attachment and coalescence, following atomic diffusion. After preparation of the nano-structural model using conjugated gaussian random particle generation method, the optical characteristics of the 3D-CPN was investigated and compared with the experimental results. For clinical validation, the prepared 3D-CPN urine strip was used for label-free surface-enhanced Raman scattering (SERS) sensor to obtain metabolite signals from normal, prostate and pancreatic cancer urine. Statistical analysis was performed to verify the meaningful Raman peak positions related with cancer metabolites and then matched with metabolite candidates reported in previous literatures. Then, a typical deep learning method of convolutional neural network (CNN) was applied to classify the normal, prostate and pancreatic cancer after oversampling the train, validation and test sets. The confusion matrix showed the 95–97% accuracy for patient classification. This technology is expected to be applied for non-invasive multi-cancer analysis and also for other diseases after training the urinary signal.

2:30 PM EL08.16.04
Optical Fourier Surfaces for Holography
Yannik M. Glauser1, Patrick Benito Eberhard1, Hannah Nies1, Juri G. Crimmann1, Valentina G. De Rosa1, Nolan Lassaline1,3, Daniel Petter1 and David J. Norris1; 1ETH Zürich, Switzerland; 3Technical University of Denmark, Denmark

Controlling light is crucial for modern technologies, such as solar cells, biosensors, and optical communication. A common approach involves the fabrication of nanostructured surfaces with sub-wavelength feature sizes to manipulate electromagnetic fields through diffraction. However, current lithographic methods are typically restricted to “binary” surface profiles with only two depth levels, limiting their optical performance. Here, we overcome this limitation by exploiting thermal scanning-probe lithography to fabricate grayscale diffractive surfaces, known as optical Fourier surfaces (OFSs) [1]. We utilize these OFSs as reflective phase-only holograms in silver to control the amplitude and phase of the diffracted wavefront in the far field. Due to the non-trivial relation between the surface profile and diffraction output [2], an adapted Gerchberg-Saxton algorithm [3] is applied to inversely design the OFS holograms. Furthermore, we extend the concept of OFS holograms to diffract bound electromagnetic modes, such as surface-plasmon polaritons [4] and waveguided photons [5], to free space. This approach may provide expanded possibilities for holography, beam shaping, and optical display technology.

Van der Waals Nanophotonics for Deeply Subwavelength Optics
Arthur Davoyan; University of California, Los Angeles, United States

Van der Waals materials are of great promise for photonics and optoelectronics. In this talk I will discuss use of bulk van der Waals materials for controlling visible and infrared radiation. I will show that strong light matter interaction within excitonic transition metal dichalcogenides, such as MoS2, allows deeply subwavelength light confinement and manipulation. I will demonstrate passive nanophotonic devices that can confine and guide light in structures that are more than 16 times smaller than the wavelength. I will further present a combined near and far field imaging and discuss device efficiency. I will then discuss use of hexagonal boron nitride for controlling mid-infrared radiation. Specifically, manifestations of strong light phonon coupling in hBN will be discussed and their use for creating deeply subwavelength resonators will be shown. I will then present first in a kind measurement of tunable hBN metasurface emitters which can cover over 2 micron band. Our studies suggest that smaller and more efficient devices may be created with the use of van der Waals materials.

Experimental Demonstration of Deep Learning enabled Ultra-Broadband Epsilon-Near-Zero Perfect Absorbers
David Dang; Sudip Gurung, Juan Manuel Raffo Calisto, Xuguo Zhou, Aleksei Anopchenko and Ho Wai (Howard) Lee; University of California, Irvine, United States
Epsilon near zero (ENZ) materials have gained interest in recent years due to their unique optical properties, such as their large optical nonlinearity, non-reciprocal magnetic optical effects, and specifically, perfect absorption of light. Transparent conducting oxides, in particular, hold promise as ideal ENZ material due to their tunable optical properties during the fabrication process. Broad perfect absorption of light can be achieved by creating a thin film stack of ENZ materials. However, the design of multilayer ENZ stacks is challenging due to the many parameters involved, including the number of layers, thicknesses, ENZ wavelength, and optical losses.

Our machine learning-based approach enables us to efficiently search through the vast design space and experimentally verify the performance of the resulting thin film stack. In particular, we use a physics inspired generative neural network to optimize the thickness and optical properties of the thin film stack. Once we obtained the optimized thickness and optical properties, we used atomic layer deposition and spectroscopy techniques to fabricate and measure the meta-material. The resulting 2-layered AZO ENZ thin film stack achieved perfect absorption of light (> 98%) in the near-infrared region from 1500 nm to 2500 nm, highlighting the potential of machine learning techniques in designing ENZ materials for various applications.
concentration profile of the gradient ENZ layer. Furthermore, we demonstrate the directional tunability of plasmonic thin film based gradient ENZ materials by controlling the total thickness of the gradient ENZ layer, where a third structure with the same doping concentration range as structure 2 but larger thickness of 900nm is used as the test sample: the high emission angular range of the 300nm structure was centered at 74, whereas the 900nm structure was centered at 66. This response originates fundamentally from the spatial shift of the optical mode supported by the thicker gradient ENZ photonic structure relative to the thinner one. As the total thickness of the gradient ENZ layer increases, the dispersion curve of the broadband Berreman mode moves to the left and thus will couple to modes from angles of incidence that are closer to normal incidence. We emphasize that in our approach a directional emitter has emissivity that is highly directional to the same set of angles, across an arbitrary bandwidth. By constraining directional emission to particular angular ranges over arbitrary spectral ranges, improved performance may be possible for a range of applications, including thermophotovoltaics, radiative cooling, and waste heat recovery. It is noteworthy that the lithography/patterning free, chip-scale geometry suggests that the plasmonic gradient ENZ structure can be incorporated with conventional scattering structures, opening up exciting possibilities to observe new optical phenomena where the narrowband resonance condition is relaxed. Ultimately, since these plasmonic gradient ENZ materials exhibit extraordinary modulation of their complex refractive indices as their carrier concentrations can be controlled by orders of magnitude by applying external fields, we believe that this configuration provides an avenue for on-demand control of broadband directional thermal emission, beam steering, as well as broadband non-reciprocal thermal emission.

**Dimensional Patternning of CdO Thin Films for Plasma Frequency Tunability in Mid-IR Plasmonic Metamaterials**

Maxwell Tolchin¹, Angela Cleri¹, Mingze He¹, Kevin Wynne¹, Khalid Hatter¹, Bhaveshkumar Kamaliya⁶, Nabil Bassim⁶, Joshua D. Caldwell² and Jon-Paul Maria¹; ¹The Pennsylvania State University, United States; ²Vanderbilt University, United States; ³University at Albany, State University of New York, United States; ⁴The University of Tennessee, Knoxville, United States; ⁵Sandia National Laboratories, United States; ⁶McMaster University, Canada; ⁷Sensorium Technological Laboratories, United States

Dimensionally patterned monolithic cadmium oxide (CdO) thin films are accessible by high-power impulse magnetron sputtering (HIPIMS) coupled with donor defect doping via ion-beam modification. Although compositional platforms exist to dope graded structures in transparent conducting oxides (TCOs), they are conventionally complex and mostly limited in interface and structural competency. However, we demonstrate two ion-beam techniques of high energy ion bombardment (1-3 MeV) across micron-area graded masks and nanometer-scale ion implantation via focused ion beam (FIB) as facile approaches to spatially modulate CdO permittivity and effectively tune CdO plasma frequency in the mid-IR regime. High-energy bombardment generates donor dopant defects with exceptional transport properties: carrier densities of 2.5 x 10¹⁹ cm⁻³ to 2.5 x 10²⁰ cm⁻³ and mobilities of up to 200 cm²/Vs relative to the ion’s displacement damage dose (DDD). Even upon pattern removal, well-defined optical and morphological interfaces are observed by far-field variable-angle reflectance spectroscopic dispersion maps. Near-field and atomic force microscopy supported by transfer matrix method (TMM) simulations. To further reduce grating feature size, preliminary FIB implantation indicates generated local and controllable donor defects thermally activated with nanometer resolution between doped and undoped regions. These are indicated by Raman shifts and peak sharpness as carrier density and simulations. **Deterministic Positioning of Aqueous Quantum Dots for Single-Photon Emission**

Deepshikha Arora¹, Muhammad T. Pambudi², Xiao Liang³, Lu Ding³ and Joel Yang³; ¹Singapore University of Technology and Design, Singapore; ²A*STAR, Singapore; ³Nanyang Technological University, Singapore

Colloidal semiconductor nanocrystals (NCs), commonly referred to as quantum dots (QDs), represent an innovative class of materials distinguished by their unique electrical and optical properties as well as notable antibunching behavior. Consequently, colloidal QDs emerge as indispensable contenders for deployment in single photon devices, a crucial component facilitating various emerging applications in quantum information technology, quantum sensing, and quantum communication. A pivotal advantage lies in their amenability to solution processing, offering substantial versatility and scalability for seamless integration across a diverse spectrum of material platforms and nanocavities.³⁻⁵ A significant aspect of nanophotonics is the coupling of NCs and nanooptics. Realizing their full potential requires that the emitter be deterministically placed in the nanooptical hotspot. Thus, the controlled assembly of nanocrystals is imperative for the incorporation of these materials into solid-state devices. Numerous assembly techniques have been explored, aiming to achieve precise nanocrystal positioning, high process controllability, scalability, and universality. However, most existing methods fall short of simultaneously accomplishing all of these objectives. In this work, we present a facile and universally applicable, high-yield method for depositing core-shell CdSe/CdS/CdZnS/SiO₂ QDs. This method leverages capillary-assisted slow evaporation in a saturated vapor environment induced by Marangoni flow, for deposition. Herein, polymer cavities are fabricated through lithographic techniques on various substrates. Following this, QDs are deposited into these cavities, and a lift-off process is then utilized to attain a clean background. Therefore, this technique can be effortlessly implemented for photonic integration on various substrates, including silicon (Si), gold (Au), and silicon nitride (SiN). Noteworthy advantages of this method encompass minimal sample requirements and the preservation of the QDs’ optical properties through the requisite processes. We demonstrate a high-yield deterministic deposition, with ~60% representing single particles. Furthermore, this approach not only enables precise single nanocrystal patterning but also opens avenues for deposition and optical studies on both individual and small nanocrystal clusters, holding great significance for various applications.

Here, we report an effective strategy, i.e. deterministic assembly of nanoparticle arrays (DANA), to program the assembly of billion oriented nanoparticles at atomic-smooth interface and mesoscale programmable junction geometries, suggesting an alternative approach to conventional top-down lithography. Towards this projected milestone, bottom-up self-assembly of solution-synthesized nanoparticles exhibits unique capabilities in programming the atomic-scale metal gap junctions over wafer-scale substrates. The ability of site-specific programming few atoms-spaced metal gap junctions on wafer enables the volume production of future atomic-scaled high-performance devices. Towards this projected milestone, bottom-up self-assembly of solution-synthesized nanoparticles exhibits unique capabilities in atomic-smooth interface and mesoscale programmable junction geometries, suggesting an alternative approach to conventional top-down lithography.

The ability of site-specific programming few atoms-spaced metal gap junctions on wafer enables the volume production of future atomic-scaled high-performance devices. Towards this projected milestone, bottom-up self-assembly of solution-synthesized nanoparticles exhibits unique capabilities in atomic-smooth interface and mesoscale programmable junction geometries, suggesting an alternative approach to conventional top-down lithography. Here, we report an effective strategy, i.e. deterministic assembly of nanoparticle arrays (DANA), to program the assembly of billion oriented nanoparticles on 2-inch wafer. Different from previous bottom-up approaches, DANA defines the geometries of diverse designer atomic-scale gap junctions and their positionings without using directional molecular linkers.DANA is generalizable to wide material selections and complex asymmetric patterns. Assembled gap junctions exhibit average spacing down to sub-10 atoms, smaller than the 12-nm gap spacing in the projected 2 nm technology node. The atomic-spacing gap junctions facilitate efficient charge transport different from direct tunneling, with performance superior to lithography-defined or thin-film-assembled analogs. Hence, DANA bridges the atomic-smooth solution synthesis/assembly into wafer-scale high-performance devices, and complements to the resolution limit of conventional lithography.

In this talk, I will discuss our recent progress in the area of polaritonics, and its role in advancing the field of metamaterials and metasurfaces. Tailored material resonances, based on excitons, phonons, magnons and electronic transitions, can be strongly coupled to light in engineered metasurfaces, unveiling new degrees of freedom for the control of light-matter interactions and enhancing optical nonlinearities. In particular, I will discuss our recent progress on metasurfaces strongly coupled to vibrational and excitonic modes of van der Waals crystals, and control of magnon-exciton polaritons through the magnetic bias in tailored metasurfaces.

**Active Exciton Resonance Tuning for Ultrathin Free-Space Optical Modulators**

Tom Hoekstra and Jorik van de Groep; University of Amsterdam, Netherlands

Emergent optoelectronic technologies such as augmented reality and free-space optical communications call for ultracompact devices with dynamic control over their optical functionalities. This presents a problem, since conventional optoelectronics require bulky optical elements and filters to operate, thereby limiting the minimal device footprint. In recent years, optically resonant nanostructures and metasurfaces have enabled highly compact devices and optical coatings with tailored spectral, angular, and polarization responses. Nevertheless, active tuning of the optical response remains challenging, owing to the weak electro-absorptive and electro-refractive effects in traditional semiconductors and noble metals.

Here, we leverage highly tunable exciton resonances in 2D quantum materials to realize hybrid metasurfaces for active wavefront manipulation. We greatly enhance the excitonic light-matter interaction through coupling with guided mode resonances in dielectric metasurfaces. More specifically, we embed atomically thin WS2 in an asymmetric Van der Waals heterostructure cavity and integrate it with a subwavelength grating. The resulting hybrid-2D metasurface exhibits highly tunable and near-unity excitonic light absorption at room temperature, which we leverage to realize an ultrathin free-space optical modulator.

We fabricate a heterostructure comprised of atomically thin WS2 encapsulated by hBN on a Au back-reflector using an all-dry deterministic stamping technique. This method enables sequential stacking of the 2D layers onto the back-reflector, which we prepatterned on a SiO2/Si substrate. As such, we circumvent direct lithography on the WS2 flake, thereby largely preserving its pristine optical and electronic properties. Encapsulation of the monolayer with hBN also limits degradation caused by oxidation, environmental adsorbates, and nanofabrication of the grating.

Next, we integrate the heterostructure cavity with a nonlocal dielectric metasurface to maximize the excitonic light-matter interaction. We fabricate a subwavelength grating in the top hBN layer using electron-beam lithography and reactive-ion etching. The grating allows free-space radiation to couple efficiently to a guided mode resonance of the structure. The guided mode confines the field in the structure and therefore interacts strongly with the monolayer. By tailoring the modal dispersion to spectrally overlap with the exciton resonance, we greatly enhance the coupling efficiency at the operation wavelength. In fact, we achieve near-unity excitonic absorption at room temperature through critical coupling to the cavity mode.

Lastly, we employ electrostatic gating to actively manipulate the exciton resonance amplitude. In our device, the WS2 monolayer is connected to ground, while the Au back-reflector is attached to a voltage source. By applying a gate voltage, we actively modulate the carrier density in the WS2 via the field effect. By inducing strong n- or p-type doping in the monolayer, the Coulombic electron-hole interaction is effectively screened, and we observe a 90% reduction in excitonic emission at room temperature. We can actively and reversibly switch the device out of the critically coupled state by suppressing the exciton state, allowing for a large modulation depth in reflection. Altogether, our results demonstrate how exciton resonance tuning combined with strong light-matter interaction in hybrid-2D metasurfaces enables dynamically tunable and ultracompact optoelectronic devices.

Plasmonically Enhancing 2D WSe₂ Light Absorption for Photodetection
Serene Kamal¹, Andrew Bennett-Jackson², Rohit Srivastava³, Robert Bruce³, Ekin G. Ozaktas³, Chris Khoury¹, Ramesh Budhani¹, David Shrekenhamer² and Susanna M. Thom¹; Johns Hopkins University, United States; ¹Johns Hopkins University Applied Physics Laboratory, United States; ²Morgan State University, United States

2D material semiconductors, specifically transition metal dichalcogenides (TMDs), have gained attention in recent years due to their unique and tunable electronic and optical properties at the monolayer and few-layer thicknesses. Because these materials are thin, low loss, and lightweight, TMDs such as WSe₂ are good candidates for flexible photodetector technology. However, unlike traditional semiconductors, TMD films cannot simply be made thicker to increase their absorbivity because their spectral response is a function of their thickness. Surface plasmonics are a nanoscale, size-tunable solution for enhancing light absorption in certain materials. By incorporating a periodic pattern consisting of nanoplasmonic structures on top of WSe₂ and tuning its design parameters, the performance of a WSe₂ photodetector can be greatly improved at targeted wavelengths.

In this work, Finite Element Method (FEM) simulations are first performed in CST Microwave Studio to design gold nanoellipsoid arrays as enhancement structures for 2D WSe₂ photodetectors. We simulate the coupling between the WSe₂ layer and the localized surface plasmon resonances of the patterned metal layer, and we show that the WSe₂ thickness (number of WSe₂ monolayers) strongly affects the behavior of these plasmonic resonances. By varying the Au nanoellipsoid size and lattice spacing in the plasmonic layer, we optimize the WSe₂ absorption enhancement at a targeted wavelength of 690 nm. We demonstrate an absolute theoretical WSe₂ absorption of 26% in a 5-layer WSe₂ film, which is over 3 times greater than the WSe₂ absorption without the plasmonic structures.

In addition to investigating traditional nanoellipsoids in our simulations, we also investigate their inverses, elliptical nanohole arrays. At a wavelength of 690 nm, we show that inverted nanohole arrays achieve a theoretical WSe₂ absorption of 24%, which is comparable to the optical enhancement achieved by the inverse nanoellipsoid design. These designs can be directly incorporated into the interdigitated electrodes of WSe₂ photodetector photodetectors. This multifunctional electrode strategy could allow for more efficient charge extraction due to the generation of hot carriers associated with plasmonic excitation precisely at the charge extraction point, causing increased photocurrent.

We use our simulated designs to fabricate WSe₂ photodetector photodetectors enhanced by plasmonic nanoellipsoid and nanohole arrays, and we investigate the impact of these designs on the light absorption, photoresponsivity and sensitivity in the devices. We fabricate designs consisting of Au nanoplasmonic arrays on epitaxially-grown WSe₂ using electron-beam lithography, and we characterize the photodetectors' photocurrent response and polarization dependence at 690 nm.

We demonstrate designs for plasmonic Au nanoellipsoid and nanohole arrays and calculate theoretical enhancement factors of up to 3 for absorption in 2D WSe₂. We use electron beam lithography to fabricate plasmonically-enhanced 2D WSe₂ photodetector photodetectors and investigate these designs experimentally. These results should advance the field of next-generation sensors for flexible and wearable applications, and could be further applied to optical communications, photovoltaic, and environmental sensing technologies.

Plasmonic SERS Biosensor for Rapid and Accurate Bacterial Identification
Jiwoo Ko and Yeon Sik Jung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

In 2019, an estimated 7.7 million people died from bacterial infections, accounting for 13.6% of all global deaths. This means that more than 1 in 8 deaths were due to bacterial infections, making it the second leading cause of death worldwide. Deaths from pathogenic bacterial infections are predicted to reach 10 million per year by 2050 due to the emergence of superbugs. Identifying the correct type of bacteria is critical for proper prevention and treatment. Bacteria are categorized into cocci, bacilli, vibrio, spirilla, and spirochaetes based on their shape. While most bacilli (rod-shaped) bacteria are harmless, some, like Bacillus anthracis (causing anthrax) and Bacillus cereus (causing food poisoning), are deadly to humans. Identifying Bacillus species accurately is challenging due to their structural and genetic similarities (99.2-99.6%). PCR analysis is the industry standard, but it is accurate yet time-consuming. Rapid and accurate identification is crucial for high-risk pathogens, prompting the need for a faster analysis method.

Surface-enhanced Raman spectroscopy (SERS) is emerging as an alternative to PCR analysis for the detection of biomaterials. SERS is a rapid, highly sensitive, accurate, and selective identification of extremely trace amounts of analytes by significantly enhancing the Raman signal from plasmon resonance on metallic nanostructures. However, because the SERS effect is strongest at the metal nanosurface and decreases with distance, SERS-based measurements of bacteria can only utilize information about limited outer regions such as the cell wall, cell membrane, and membrane proteins. Therefore, SERS is not known to be a suitable method for the analysis of relatively large biomaterials such as cells or bacteria. In this study, we propose a bacterial pretreatment process to apply the high-potential SERS technique to bacterial identification and analyze the obtained Raman spectra to discriminate between structurally and genetically similar bacteria. The proposed pretreatment process suitable for SERS is a hybrid lysis process consisting of a mechanical lysis process and a chemical lysis process.

Bacillus, Gram-positive bacteria, have a relatively thick cell wall layer, so mechanical lysis is primarily used to reduce the size of the macromolecule bacteria while releasing intracellular components. Alkaline lysis is used to further reduce the size of the analyte, including the crushed cell wall and intracellular components, and in particular, to denature the released DNA into single strands, making it suitable for SERS analysis. In parallel, for Raman signal enhancement, we fabricated a 20 nm three-dimensional nanowire network using nanotransfer printing technology to fabricate nanodevices with ultra-high density hotspot regions where electromagnetic fields are enhanced. The presence of numerous factors in the pretreated bacterial samples, including small crushed cell walls and intracellular components, which can be located in the ultra-high density hotspot regions formed on the fabricated nanodevices, resulted in new signal peak shapes or enhanced signal results.

Finally, principal component analysis, which is used to analyze high-dimensional data, was performed to verify that discrimination of five structurally and genetically similar Bacillus bacteria was possible, confirming its applicability as a next-generation biosensor. The proposed mechanical/chemical hybrid lysis process, which is an appropriate pretreatment process for SERS analysis of macromolecules, is applicable to large biological materials such as cells as well as bacteria. In addition, as a rapid analysis method with high accuracy, it can be applied beyond the public health industry to the high-tech biopharmaceutical, and high-tech defense industry and is expected to be used in the medical field, such as early diagnosis of diseases.

Lattice Kerker Effect and Out-Of-Plane Anisotropic Radiation of Photoluminescence from Nanoparticle Array of Titanium Oxide with Tuned Packing Volume
Makoto Hijishimo, Shunsuke Murni, Tien-Yang Lo and Katsuhiro Tanaka; Kyoto University, Japan

Surface lattice resonances (SLRs) are collective resonances induced by radiative coupling between localized resonances in periodically arranged nanoparticles. When the local scattering elements are Mie-resonators such as dielectric nanoparticles, Mie-SLRs are formed by coupling between local Mie resonances mediated via in-plane diffraction [1]. Because of the orthogonality of local magnetic and electric dipoles excited in each Mie resonator, their scattering field extend to the orthogonal direction and couple to the diffraction modes that match the direction of field expansion. Especially, in
rectangular lattice the spectral positions of magnetic and electric SLRs are tunable independently via periodicities along two axes. The multipolarity of Mie resonances can cause an optical response known as the Kerker effect. In this effect, interference between the far fields deriving from electric and magnetic polarizations suppresses either forward or backward scattering. Rectangular lattices of Mie resonators are very suitable platforms for inducing the Kerker effect, i.e., lattice Kerker effect, because of the independent tunability of spectral position of magnetic and electric SLRs. Zero-backscattering has been reported numerically by carefully tuning the periodicity of one axis [2].

In this study, we focused on photoluminescence control by utilizing the Lattice-Kerker effect in the square array of rectangle-shaped TiO2 nanoparticles. We fixed the lattice periodicity while changing the length of one axis of TiO2 nanoparticles in order to achieve mode crossing of electric and magnetic SLRs. We found asymmetric out-of-plane PL radiation from the light-emitting layer deposited on top of the array at the spectral and angular point where the lattice Kerker effect is achieved.

As a precursor of TiO2, titanium nanoparticle array was fabricated on SiO2 substrate by utilizing nanoimprint lithography. Then TiO2 nanoparticle array was obtained by thermal oxidation of titanium nanoparticle array [3]. Excited resonances were attributed by measured and calculated optical extinction. PL enhancement of TiO2 nanoparticle array was obtained by measured PL intensity of these arrays embedded in polymethyl methacrylate (PMMA) containing coumarin 153.

The optical extinction of TiO2 nanoparticle array was measured through optical transmission at various incident angles. By using in-plane diffraction conditions that dominate SLR and calculated extinction through the finite element method, the peaks in the extinction spectra were attributed to electric and magnetic SLRs. In the angle-resolved extinction spectra, we confirmed the intersection of electric and magnetic SLR due to changes in the dispersion relation near \( \theta_\text{m} = 0° \) with increased packing factor of nanoparticles. The PL enhancement in the front and back of the array as a function of the emission angle was evaluated for each thickness of the emitter layer. Significant PL enhancement was observed at the intersection of electrical and magnetic SLR independent of film thickness. In addition, the PL enhancement at the front of the array was greater than at the back, given a certain film thickness. This result suggests a coupling of Lattice-Kerker effect and PL.

constituent materials and geometrical symmetries. The generation, transport, and relaxation of hot carriers also provide a novel route to active and nonlinear optical effects with ultrafast response rates.

Ultrafast optical switching in plasmonic platforms relies on the third-order Kerr nonlinearity, which is tightly linked to the dynamics of hot carriers in nanostructured metals. Although extensively utilized, a fundamental understanding on the dependence of the switching dynamics upon optical resonances has often been overlooked. Here we employ all-optical control of resonance bands in a hybrid photonics-plasmonic crystal as an empowering technique for probing the resonance-dependent switching dynamics upon hot carrier formation. Differential optical spectral measurements reveal an enhanced switching performance near the anti-crossing point arising from strong coupling between local and nonlocal resonance modes. Furthermore, entangled with hot-carrier dynamics, the nonlinear correspondence between optical resonances and refractive index change results in tailorable dispersion of recovery speeds which can notably deviate from the characteristic lifetime of hot carriers.

We further exploit hot-carrier dynamics to facilitate the creation of handedness-selectable transient chirality in achiral optical meta-surfaces. As much as chiral metasurfaces are significant in stereochemistry and polarization control, tunable chiroptical response is important for their dynamic counterparts. A single metasurface device with invertible chiral states can selectively harness or manipulate both handedness of circularly polarized light upon demand, where in fact chiral inversion in molecules is an active research field. Tactics for chirality switching can be classified into geometry modification and refractive index tuning. However, these generally confront slow modulation speed or restrained refractive index tuning effects in the visible regime with forbidden ‘true’ inversion. Here, we reconfigure the ‘optical’ geometry through inhomogeneous spatiotemporal distribution of hot carriers as a breakthrough, transforming a plasmonic achiral metasurface into an ultrafast transient chiral medium with near-perfectly-invertible handedness in the visible. The photoinduced chirality relaxes through the fast spatial diffusion process of electron temperature compared to electron-phonon relaxation, empowering hot-carrier-based devices to be particularly suitable for ultrafast chiroptics.

Our comprehensive understanding provides new protocols for optically characterizing hot-carrier dynamics and optimizing all-optical light modulation and chirality manipulation for operations across the visible spectrum.

Precision Patternning of ZnO using Femtosecond Laser: Opening Doors to Nanophotonic Device Innovations Ajinkya B. Palwe, Sonu K. Singh, Gaurav P. Singh, Soumi Mukherjee, Sweta Rani, Arun Jaiswal, Shobha Shukla and Sumit Saxena; IIT Bombay, India

Patterned nanostructure exhibits interesting optoelectronic characteristics due to light-matter interaction at comparable dimensions. The optical response of the nanostructure-based devices is modulated by the size and the periodicity of the structure. Numerous techniques based on top-down and bottom-up approaches are used to obtain patterned nanostucture. However, top-down methods provide more precise control over the patterning of the surfaces. Recently patterned structures of metal oxide semiconductors are getting attention for various electronic devices like photodetectors, solar cells, etc. The femtosecond laser has shown the capability to precisely pattern the surfaces with regular and smaller structures. In this work, we have fabricated ZnO nanopillars by patterning the ZnO thin film using a femtosecond laser. ZnO film (thickness ~600 nm) is deposited on a glass slide using an organic salt solution of zinc in isopropanol and annealed at 400°C. The ultrafast mode-locked Ti: sapphire-based femtosecond pulsed laser (Coherent made, Chameleon Ultra I) with fixed pulse width (140 fs) and a repetition rate (80 MHz) is used for this patterning. The laser beam of 800 nm with a beam diameter of 1.2 mm at 1/e² tightly is focused onto the ZnO film for the selective patterning (ablation). The patterns are prominent after increasing the laser power beyond 1.5 W. ZnO is patterned in a square mesh with a periodicity of 1 um, which resulted in the formation of ZnO nanopillars with a side of ~500 nm and a height of 600 nm. The fabricated structure exhibits different colors at different angles due to the scattering of the light. These reflected colors are analyzed with the camera by varying the incident angle of the white light. It is observed that the photo emitted light colour changes from colourless to blue, orange, pink, green, red, and finally deep red. Due to the multiple scattering, the overall path length of the light inside the active material increases. Also, the total surface area of the active material in the patterned film is larger as compared to the plane film. The array of semiconductor ZnO nanopillars exhibits unique electronic and optical characteristics for optoelectronic and photonic applications. Similarly, the femtosecond laser can pattern different metal oxide layers and incorporate the fabricated structures in optoelectronic devices to improve their performances.

Large Magneto-Optic Response from Transparent Conducting Oxide Films near Their Epsilon-Near-Zero Frequency Jonathon Schrecengost1, Angela Cleri1, Maxwell Tolchin1, Ramya Mohan2, John P. Murphy1, Sara Adamkovic1, Alex J. Grede1, Mario Imperatore1, Patrick E. Hopkins1, Jon-Paul Maria1 and Noel Giebink1,2; 1The Pennsylvania State University, United States; 2University of Virginia, United States; 3University of Michigan–Ann Arbor, United States

Transparent conducting oxide (TCO) materials are promising for a variety of plasmonic and nanophotonic applications because their plasma frequency can be varied across the near- and mid-infrared spectrum via doping. In this work, cadmium oxide thin films doped with In or Gd ions are demonstrated as a promising magneto-optic (MO) material for integration of MO isolators, circulators, non-reciprocal linear to circular polarizers (“Faraday retarders”), and sensors in NIR-MIR Si photonics. Near the epsilon-near-zero (ENZ) condition, applied magnetic fields induce large differences between the refractive index of right and left-hand circularly polarized light, leading to correspondingly large Faraday rotations. Experimental data supported by theory show that doped CdO films have Verdet constants in the range of 10⁸-10⁹deg T⁻¹ m⁻¹ that increase with wavelength up to the ENZ condition. The high optical mobility of CdO leads to >10x the Verdet constant and >100x MO figure of merit (rotation/loss) compared to other TCOs such as indium tin oxide (ITO). CdO films offer additional advantages over current state-of-the-art materials, such as high saturation fields (~3 T) that are achievable in photonic chip applications, an ENZ condition that is tunable over a broad range of mid-infrared wavelengths (2-10 microns), and the ability to sputter high quality films on Si.

Fabrication of Multi-Emissive Nanostructures using Two-photon Lithography for Photonics Applications Gaurav P. Singh1, Arun Jaiswal1, Sarika Joshi1,2, Sweta Rani1,2, Ajinkya Palwe1, Sumit Saxena1,2 and Shobha Shukla1,2; 1Indian Institute of Technology Bombay, India; 2IITB-Monash Research Academy, India

Nanoscale structures enable unprecedented opportunities in innovating multifunctional devices, especially in nanophotonics, optoelectronics, and other related fields. It is desirable to tailor electronic and magnetic properties by tuning size and morphology for niche photonic applications. The realization of such nanostructures depends on sophisticated, complex, time-consuming, serial, and conventional nanofabrication techniques like mask-based photolithography, electron beam deposition, and reactive ion etching. Additionally, precise fabrication of 3D nanostructures, especially control over z-axis features with the subwavelength resolution is challenging using above mentioned methods. There is a need to develop a facile three-dimensional fabrication protocol using new material formulations with embedded functionalization capabilities. In this context, we report the fabrication of multi-emissive nanostructures via two-photon lithography of multifunctional resin.
In this work, we present a multi-emissive polymeric resin comprising a commercially available acrylate-based resin and carbon nanomaterial (CNM). The formulated composite resin was exposed using a femtosecond (fs) laser to induce nonlinear absorption at the focal volume, which helps to create nanostructures with three-dimensional characteristics. The CNMs are multi-emissive with its optical activity retained in resin form as well as in polymerized micro/nanostructures under ultraviolet (UV) excitation. The fabricated structures, when examined under a fluorescence microscope at varying depths, exhibit uniform, bright emission, indicating uniform distribution of CNMs present in the composite resin. These multi-emissive micro/nanostructures are potential building blocks for photonics and can be applied in many areas, such as sensing, optoelectronics, and frequency-selective devices. These multi-emissive properties of the micro/nanostructures have a big impact on improving the field of photonics. Further, tailoring the dimensions of the micro/nanostructures pave the way towards the development of optically engineered next-generation photonic devices.

Properties and Control of Excitons in 2D Semiconductor Heterostructures Tony F. Heinz1,2; 1Stanford University, United States; 2SLAC National Accelerator Laboratory, United States

In this paper we will describe some of our recent progress in understanding fundamental aspects of excitons in 2D heterostructures in the transition metal dichalcogenide (TMDC) family. For many of these systems, type II band alignment is obtained in stacked layers, causing the lowest-lying optical excited state to be an interlayer exciton. Because of the static dipole moment of these charge-separated states, they are highly tunable by external electric fields, making them interesting sources with readily tunable photon energy by gating available in the visible and infrared spectral ranges. In addition, for crystallographically aligned samples, the moiré potential leads to distinctive exciton localization effects. We will present recent advances in characterizing these states, both through direct optical absorption measurements and through the use of time-resolved, angle-resolve photoemission spectroscopy (tr-ARPES). These methods give us new insight into the radiative lifetime of these states and the degree and nature of exciton localization in moiré structures. In addition to their intrinsic interest, the ability to transfer...

Layered Materials as a Platform for Quantum Technologies Andrea C. Ferrari; University of Cambridge, United Kingdom

Layered materials are taking centre stage in the ever-increasing research effort to develop material platforms for quantum technologies. We are at the dawn of the era of layered quantum materials. Their optical, electronic, magnetic, thermal and mechanical properties make them attractive for most aspects of this global pursuit. Layered materials have already shown potential as scalable components, including quantum light sources, photon detectors and nanoscale sensors, and have enabled research of new phases of matter within the broader field of quantum simulations. I will discuss opportunities and challenges faced by layered materials within the landscape of material platforms for quantum technologies, with focus on applications that rely on light-matter interfaces[1].

Predicting Signatures of Unconventional Transport in Low Dimensional and Topological Quantum Materials Prineha Narang; University of California, Los Angeles, United States

The re-invigorated field of electron hydrodynamics in quantum matter has recently garnered considerable scientific interest, both due to its technological promise of designing near dissipation-less nanoelectronics, as well as its fundamental importance as an experimental probe of strong electron-electron interactions. Investigating the capacity to which observations of electron hydrodynamic flows can inform the nature of electron-electron interactions is
Engineering robust solid-state quantum systems is amongst the most pressing challenges to realize scalable quantum photonic circuitry. While several 3D systems (such as diamond or silicon carbide) have been thoroughly studied, solid state emitters in two dimensional (2D) materials are still in their infancy. In this presentation I will discuss hexagonal boron nitride (hBN) as an emerging platform for integrated quantum photonics. In particular, I will focus on emerging ways to deterministically engineer quantum emitters in hBN and discuss their photophysical properties. I will also highlight scalable pathways for integration of these emitters with on chip optical and photonic resonators. I will conclude by discussing a new class of spin defects in hBN, that operate as quantum sensors and can be used at room temperature. Hosted by an atomically thin lattice, the new spin defects poised to revolutionise the field of quantum sensing, by enabling true atomic proximity between the sensor and the analyte. I will summarize by outlining challenges and promising directions in the field of quantum nanophotonics with hBN and its integration with other van der Waals structures.
photodetectors. CsPbBr₃ perovskite grows on ReSe₂ forming aligned rectangular nanoplatelets. Despite the highly symmetric cubic structure of the CsPbBr₃ perovskite, the nanoplatelets are elongated in one principal direction due to the broken symmetry of the ReSe₂ substrate. The CsPbBr₃ nanoplatelets on ReSe₂ have highly anisotropic tribological properties: They easily slide along their long axis, but are firmly locked along their short axis. Cross-sectional TEM shows that the CsPbBr₃/ReSe₂ interface is highly mismatched and incommensurate in the long axis direction, as typical of van der Waals epitaxy, but it is highly coherent with very low mismatch in the perpendicular direction. This explains the anisotropic growth and sliding of the CsPbBr₃ nanoplatelets on ReSe₂. The electronic and optoelectronic properties of the mixed-dimensional heterostructure are characterized by a series of methods. Our work underscores the potential and richness of van der Waals epitaxy for the creation of dimensionally hybrid nanostructures and heterostructures with controlled shapes and orientations and their integration into devices.

Enhanced Crystallinity of ZnO Columns Grown on Monolayer MoS₂ via Compliant Substrate and Combinatorial Epitaxy Yeonjoo Lee1,2, Xuejing Wang1, Kyoung Bae Kim1, Benjamin Derby1, Terrence McCrudden1, Gabriel Calderon1, Michael T. Pettes1, Jinwoo Hwang1, Yeonhoo Kim2, Jeongwon Park3, Aiping Chen4, Doo Yoon Lee5, Junyoung Kwon2, Changhyun Kim2, Minsu Seol2, Jin-Hong Park3 and Jeehwan Kim1,2; 1Massachusetts Institute of Technology, United States; 2Samsung Advanced Institute of Science and Technology, Korea (the Republic of); 3Pohang University of Science and Technology, Korea (the Republic of); 4Los Alamos National Laboratory, United States; 5University of Minnesota, United States; 6Ephemerion-Labs, United States; 7The Ohio State University, United States; 8Korea Research Institute of Standards and Science, Korea (the Republic of); 9Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Numerous multi-dimensional architectures have been studied to realize reusable substrates using remote and van der Waals (vdW) epitaxy techniques. In order to prepare high-quality and transferable semiconductor films, it is mandatory to understand behaviors of two-dimensional (2D) and three-dimensional (3D) materials in epitaxy techniques. We investigated growth behavior of a 3D material on a 2D material by growing ZnO on monolayer MoS₂, which is known that this 2D/3D heterogeneous integration is out of scope for remote and van der Waals epitaxy. We performed high-resolution transmission electron microscopy, grazing incidence wide-angle X-ray scattering, electron beam absorbed current microscopy, Raman microscopy, and photoluminescence measurements to correlate the microstructures and functional properties. This study revealed that random in-plane ordering was preserved while ZnO grew across the monolayer MoS₂ layers. By stacking multiple ZnO/MoS₂ layers, it was shown that inversion of crystallinity occurred; the crystallinity of the top ZnO layer was improved compared to that of the middle ZnO layer. This complex heterostructure can be explained by combinatorial epitaxy, grain alignment across atomically sharp interface, and a compliant substrate. The growth study enabled to form ZnO/MoS₂ heterostructure with type-I band alignment as the narrow band gap of monolayer MoS₂ serves as a charge carrier sink. Our findings provide insight to realize the 2D/3D heterostructure for highly functional device applications.

CMOS Compatible Single-Crystal 2D Material Growth by Geometric Confinement Kiseok Kim1, Doo Yoon Lee1, Seungwhan Seo1, Junyoung Kwon2, Changhyun Kim2, Minsu Seol2, Jin-Hong Park3 and Jeehwan Kim1,2; 1Massachusetts Institute of Technology, United States; 2Samsung Advanced Institute of Technology, Korea (the Republic of); 3Pohang University of Science and Technology, Korea (the Republic of)

The innovations in Si-based complementary metal–oxide–semiconductor (CMOS) technology have a fundamental limit, which precludes achieving ultimate scaling and thereby meeting consumers’ demands in the era of data explosion. Thus, for innovation beyond Si-based CMOS scaling, back end of line (BEOL) compatible new materials and the development of next generation transistors are urgently required. Recently, 2D TMD materials are attracting attention as channel materials for next-generation CMOS logic semiconductor devices, as they can outperform Si-based counterparts in terms of the scaling length and carrier mobility. However, despite the excellent performance of 2D TMDs, major obstacles remain in the commercialization of 2D materials; i) Deterioration of channel performance due to polycrystalline growth, ii) Requirement of epitaxial high-temperature growth and transfer process to form single-crystal channels etc.

In this study, we demonstrated the growth of non-epitaxial single-crystal 2D TMD materials at low temperatures by fabricating trenches on amorphous HfO₂-coated Si wafers. This technology enables the direct growth of single-crystal 2D materials on a Si wafer without a separate transfer process. This advancement significantly enhances the potential for integrating 2D materials into commercial CMOS technology.

9:30 AM EL09.02.04
Remote Epitaxy-Assisted Mixed-Dimensional Integration of 3D Complex-Oxides and 2D Materials Sangho Lee1, Jung-El Ryu1, Kiseok Kim1, Xinyuan Zhang1, Celesta S. Chang1, Min-Kyu Song1 and Jeehwan Kim1; Massachusetts Institute of Technology, United States

A new method for growing and releasing three-dimensional (3D) complex-oxide layers in a single crystal form through an atomically thin graphene interlayer, known as remote epitaxy, has revolutionized the heterogeneous integration strategies, which were previously limited due to stringent lattice and processing restrictions. However, the transfer of graphene, which is a typical process for forming graphene on growth substrates, inevitably introduces a significant number of unwanted defects such as wrinkles, holes, process residues, and interfacial contamination. Such defects can disturb the remote interaction between the substrate and epitaxial layer through graphene, reducing the crystal quality and exfoliation yield of membranes. Recently, we developed a direct synthesis method for growing alternative two-dimensional (2D) materials, such as transition metal dichalcogenides (TMDs), on epitaxial substrates, which enables the creation of wafer-scale, defect-free 2D interlayers for reliable remote epitaxy of spinel CoFe₂O₄ (CFO) and garnet Y₃Fe₄O₁₂ (YIG) thin films of high-quality. The atomically clean van der Waals interfaces formed by direct growth of TMDs onto epitaxial substrates offer an ideal platform for high-throughput production of single-crystalline, freestanding complex-oxide membranes that can be released from substrates, but also for facile fabrication of a new class of mixed-dimensional heterogeneous systems that exhibit emergent physical phenomena at well-defined 3D/2D heterointerfaces. Based on this unique approach to integrating mixed-dimensional heterostructures in a scalable and controlled manner, we demonstrate new device concepts that take advantage of unusual physical coupling or decoupling at exotic 3D/2D interfaces, which are both fundamentally intriguing and practically useful.

assembly techniques [1]. One approach to heterogeneous integration employs transfer-based assembly methods, requiring the delamination of epi-layers fabricated through different batches and procedures. This process encountered significant technical obstacles when aiming for high-density integration of high-performance devices. Firstly, traditional epitaxial growth methods produce epi-layer devices strongly bonded to the substrate, making their separation challenging without resorting to high-power laser irradiation or chemical etchants. These separation techniques are known to cause damage to both the substrate and epi-layers, and their strict requirements restrict improved device performance and productivity [2]. Secondly, during the transfer and assembly process, diverse functional devices need to be divided into tiny chips before their precise transfer and assembly onto the target surface (or substrate). Even slight misalignment during chip bonding to backplane circuits can disrupt device interconnects with underlying layouts, thereby increasing the manufacturing costs of micro-LED displays. Additionally, fabricating higher-density vertical stack devices presents a formidable challenge, not only for high-resolution display production (such as augmented reality (AR) and metaverse devices) but also for hetero-integrated electronics. In this presentation, we examine an emerging epitaxy technique that eliminates chemical bonds between the epi-layer and wafer [3-5]. This method offers a potential solution via simple delamination of epi-layers and subsequent stacking of these layers, supplemented with precise photolithographic patterning procedures [4]. We will showcase our recent work on high-density heterogeneously integrated vertical R/G/B micro-LEDs and flexible devices utilizing this innovative epitaxy approach, highlighting potential applications in AR [6]. The remote epitaxy of spatially isolated micro-crystal LEDs has enabled the fabrication of deformable lighting devices [7]. The emerging epitaxy without chemical bonds could be readily employed to broaden the scope of the semiconductor manufacture, potentially leading to a heterogeneous system on a chip for all-in-one electronic and optoelectronics.

Wafer-Free Monolithic 3D Integration Enabled by Mixed Dimensional Heterostructure
Jeehwan Kim; Massachusetts Institute of Technology, United States

Reduction in the size of devices is no longer an option for enhancing the performance of next-generation electronic products. Vertical stacking of wafers containing electronic devices, known as 3D heterogeneous integration, is being considered as the most promising strategy for further performance enhancement. However, this technique requires the following complex processes: i) drilling holes through the wafer (TSV), filling the holes with Cu, and bonding the wafers through bumps. Omitting wafers during such a complicated 3D stacking process would greatly simplify the process and minimize device loss. However, there are almost no options available to transfer active devices detached from the wafer and restack them together. The direct growth of device layers on top of finished circuitry is even more challenging. In this talk, I will discuss the unique strategies to transfer active device layers from the substrate and ultimately direct grow single-crystalline films on BEOL-processed wafer based on our signature 2D material-based layer transfer technique.

Area-Selective Deposition of Germanium on Patterned Graphene/Molybdenum Disulfide Stacks
Jinkyung Yoo1, Towsifi Ahmed2, Xuejing Wang3, Michael T. Pettes4, Yeonhoo Kim5, Yeonwoo Lee1,4, Jeongwon Park1, Woo Seok Yang5, Kibum Kang1 and Young Joon Hong1; 1Los Alamos National Laboratory, United States; 2Pacific Northwest National Laboratory, United States; 3Korea Research Institute of Standards and Science, Korea (the Republic of); University of Minnesota, United States; 4Korea Advanced Institute of Science and Technology, Korea (the Republic of); 5Korea Electronics Technology Institute, Korea (the Republic of); 6Sejong University, Korea (the Republic of)

Advances in multi-dimensional structures via epitaxy techniques have revealed that two-dimensional (2D) materials can be substrates of the conventional semiconductors, called as three-dimensional (3D) materials, for economical manufacturing and delivering novel functionalities. Integration of 2D materials into the existing device architectures is a key approach for ‘More Moore’ and ‘Beyond Moore’. However, transfer of 2D materials onto the device architecture has been hindered by unintentional contamination of the substrate during the transfer process, and the integration of 2D materials and vice versa is a scalable and promising way to integrate 2D and 3D materials in an architecture. Growth of 3D materials on 2D materials has been hindered by low nucleation efficiency due to low density of surface dangling bonds on a 2D material. Here, we present area-selective deposition of germanium (Ge) on patterned graphene/MoS2 stacks. Stacking graphene onto monolayer MoS2 induces out-of-plane dipole moment that can be transferred to 2D materials in a way that does not disrupt the device. We show that the resultant films are smooth with high crystalline quality.

Remote Epitaxial Growth of GaN Thin Films on Graphene Buffer Layer on SiC Substrates using Metalorganic Vapor-Phase Epitaxy
Seokhee Lee1, Han Kim2, Bo-In Park2, Jinkyung Kim2, Hyunseok Kim2, Gyu-Chul Yi1, Kyusang Lee1 and Jeehwan Kim1; 1Seoul National University, Korea (the Republic of); 2Massachusetts Institute of Technology, United States; 3University of Virginia, United States

High-quality inorganic thin films on flexible substrates are crucial for advancing the field of flexible devices such as wearable sensors, flexible displays, and electronic devices. Remote epitaxy on graphene-coated substrates has emerged as a promising methodology for creating these thin films, offering the potential for mass production of superior material platforms. However, the remote epitaxy of GaN thin films using the widely favored metalorganic vapor-phase epitaxy (MOVPE) has been challenging, mainly due to the degradation of the graphene by the harsh MOVPE growth environment and poor quality of GaN on graphene.

In this study, we demonstrate the successful remote epitaxial growth of GaN thin films on graphene buffer layer (GBL) on SiC substrates using MOVPE. The unique properties of GBL, including its strong adhesion to the SiC substrate and the quasi-2D surface that allows for epilayer release, make it a suitable candidate for enhancing the harsh growth conditions of MOVPE and remote epitaxy. Moreover, the step edges of GBL, naturally formed by the SiC substrate during the graphitization process, provide numerous nucleation sites for GaN. To identify the optimum conditions for GaN film growth on GBL, we investigated the nucleation and lateral growth of GaN, with an emphasis on varying growth parameters such as temperature, pressure, and precursor flow rates. Notably, we found that the step edges of GBL served as effective nucleation sites for GaN. The resultant films exhibited smooth surface morphology, and their high crystalline quality was confirmed through XRD and EBSD analyses. Additionally, we successfully exfoliated and transferred these films onto different substrates, fully preserving their properties.

This study opens new horizons for the large-scale production of high-quality, freestanding GaN membranes by overcoming previous challenges related to
11:45 AM EL09.02.09
Engineering Defects in III-V Semiconductors Grown by Remote Epitaxy on Thin Amorphous Carbon

Remote epitaxy has emerged as a facile technique for producing freestanding, wafer-scale membranes of single-crystalline semiconductors. However, it still encounters challenges but also presents other benefits when compared to direct epitaxy. In the case of growing epitaxial layers on the same or lattice-matched substrates, remote epitaxy results in lower material quality and higher defect density due to the attenuated atomic registry from the substrate. To address this issue, we propose the incorporation of thermal cycle annealing (TCA) and strained layer superlattice (SLS) into the growth process, which effectively reduces the threading dislocation density by a few orders of magnitude.

Conversely, when the substrate and epitaxial layer have a high lattice mismatch, remote epitaxy offers an advantage through the van der Waals interface, which provides an additional pathway to relax the strain developed in heteroepitaxial layers. This spontaneous relaxation mechanism significantly reduces the occurrence of misfit dislocations that are commonly observed in direct heteroepitaxy. By directly growing thin amorphous carbon (TAC) on GaAs, bypassing the need for a 2D layer transfer process, we can create an ultra-thin van der Waals interface that enhances the atomic registry of the epilayer to the substrate while facilitating strain relaxation. In this study, we investigate the impact of TAC growth time on the material quality of remote heteroepitaxial InGaAs layers grown on GaAs substrates. The inherent strain relaxation capabilities offered by remote epitaxy enable the heteroepitaxy of high-quality membranes on lattice-mismatched substrates, paving the way for the fabrication of diverse electronic and optoelectronic devices.

Energy and Charge Transfer in Novel Hybrid Transition Metal Dichalcogenides/2D Perovskite Heterostructures

Van der Waals heterostructures are currently the focus of intense investigation, this is essentially due to the unprecedented flexibility offered by the total relaxation of lattice matching requirements, and their new and exotic properties compared to the individual layers. In this study, we present experimental and theoretical findings on hybrid transition metal dichalcogenide (TMD)/2D perovskite heterostructures. Our density functional theory (DFT) calculations reveal distinctive band alignment in these structures. Specifically, we observe that direct electron transfer between layers is hindered by the presence of the organic spacer in the 2D perovskite. However, the valence band forms a cascade from the TMD monolayer through the organic spacer to the PbI4 octahedral layer, facilitating hole transfer. Optical spectroscopy studies further support these predictions, providing compelling evidence for both charge transfer and energy transfer between the layers.

Moreover, we demonstrate the presence of long-lived interlayer excitons in these structures, which inherits unique valley properties of WSe2. By successfully achieving circular polarization of interlayer excitons, we highlight the efficient spin injection from WSe2 into the 2D perovskite layer. These findings underscore the ability of TMD/2D perovskite heterostructures to engineer the band alignment for diverse excitation transfer processes, as well as spin injection and manipulation.

Magnetic Exciton-Polariton with Strongly Coupled Atomic and Photonic Anisotropies

Anisotropy plays a key role in science and engineering. However, the interplay between the material and engineered photonic anisotropies has hardly been explored due to the vastly different length scales. Here we demonstrate a matter-light hybrid system, exciton-polaritons in a 2D antiferromagnet, CrSBr, coupled with an anisotropic photonic crystal (PC), where the spin, atomic lattice, and photonic lattices anisotropies are strongly correlated, giving rise to unusual properties of the hybrid system and new possibilities of tuning. We show exceptionally strong coupling between engineered anisotropic optical modes and anisotropic excitons in CrSBr, which is stable against excitation densities a few orders of magnitude higher than polaritons in isotropic materials. Moreover, the polaritons feature a highly anisotropic polarization tunable by tens of degrees by controlling the matter-light coupling via, for instance, spatial alignment between the material and photonic lattices, magnetic field, temperature, cavity detuning and cavity quality-factors. The demonstrated system provides a prototype where atomic- and photonic-scale orders strongly couple, opening opportunities for photonic engineering of quantum materials and novel photonic devices, such as compact, on-chip polarized light sources and polariton lasers.

Bandgap Tunable Metal Oxynitride Nanosheets and Functions of Oxynitride/Oxide Superlattices-Like Hybrids

Nanosheets have been studied as multi-functional nanomaterials for a wide range of applications. Controlling the bandgap of nanosheets remains a major challenge. Herein, we report bandgap tunable lanthanum niobium oxynitride nanosheets, which was prepared by exfoliation of layered perovskite oxynitride (La,NbO3,N) via ion-exchange and two-step intercalation processes. The resulting (La,NbO3,N) nanosheets had homogeneous thickness (1.6 nm) and exhibited a variety of chromatic colors depend on the nitridation temperature including yellow, orange, and brown. The band gap energy of the nanosheet was tunable from 2.03 to 2.63 eV, and their band structures were determined by UPS, Mott–Schottky and photoelectrochemical measurement. In addition, well-organized superlattices are successfully prepared by a layer-by-layer assembly using two different oxynitride/oxide perovskite nanosheets (La,NbO3,N/Ca,NbO3). Moreover, the superlattices-like restacked Ca,NbO3/La,NbO3 hybrid showed proton conductivity and dielectric properties strongly influenced by the oxynitride nanosheets, and enhanced photocatalytic activity under visible light irradiation.

spectroscopy at cryogenic temperature. We find that hybrid charge transfer excitons (HCTEs) are formed only when WS₂ monolayer is transferred onto the

angle between the monolayer and Rubrene crystal axes. Finally, polarization measurements reveal that HCTEs preserve spin-valley polarization of the WS₂

monolayer.

Van Der Waals Epitaxy and Thin Film Transfer using Sputter-Grown Two-

Dimensional α-MoO₃ layers using sputtering for low cost and large area devices. The films grown at lower temperature and oxygen-

forces, which are weak and do not require lattice match. Therefore, unlike 3D materials, bulks of 2D materials can be easily thinned to atomic thickness by

mechanical exfoliation and atomically thin 2D materials can be arbitrarily stacked to form vertical van der Waals (vdW) heterostructures, which could

inhibit the unique characteristics of the constituent layers and even exhibit new properties not possessed by them. Particularly, when type-II vdW heterostructures are excited, the positive and the negative charges would reside in the different layers after the charge transfer but be limited within a short distance due to the strong quantum confinement effect of 2D materials, leading to strong Coulomb interaction and the formation of interlayer excitons (IXs). IXs are generally equipped with orientated dipole moment and long lifetime. Currently, studies on IXs are mainly focused on the vdW heterostructures formed by monolayers of transition-metal dichalcogenides (TMDs). Here, I will first talk about an alternate system, vdW heterostructures formed by 2D perovskites and TMDs, for studying IXs. Stacking different kinds of 2D perovskites and TMDs, formation of IXs is confirmed by excitation-power-, temperature-, electric-field-dependent and time-resolved photoluminescence (PL) studies. Notably, robust IX emission can be observed regardless of the stacking sequence and geometric alignment of the constituent layers, showing great advantages over the TMD/TMD vdW heterostructures, which require special twist-angle and thermal annealing. Then, I would like to give a brief introduction on widely tuning the IX emission energy by changing the layer number of the 2D perovskite or the TMD, which shed light on the application of 2D perovskite/TMD vdW heterostructures in broad-spectrum optoelectronics. Besides the layer number, I would like to next talk about how the selection of organic chains in 2D perovskites influences the properties of the IXs. By using chiral 2D perovskites, the IX emission shows substantial circular polarization and the polarization direction is only related to the chirality of the molecules regardless of the excitation scheme or any other external field, which could open up new passages for controlling valley- or spin-
polarization of IXs. By introducing molecules with different dielectric constants, the dielectric screening strength in the vdW heterostructure is changed and hence the binding energy of the IXs is also modified, which offers great opportunities for exploiting tunable excitonic devices. Finally, I will also introduce IX as a non-destructive tool for probing the local phase transition at the surface of the 2D perovskite (BA₂)₃PbI₆ flakes. By spatially PL mapping of the (BA₂)₃PbI₆/WSe₂ heterostructure, two different IX species can be observed to distinguish the low-temperature and the high-temperature phase respectively, which offer a new route to regulate the phase transition of (BA₂)₃PbI₆.
thought of as a new material platform to replace and expand existing optically active 2D monolayers such as transition metal dichalcogenides (TMDs). Most organic monolayers are grown out of planar dye molecules that tend to form J-aggregates. In J-aggregates the transition dipole moments of the molecules are aligned resulting in a strong coupling of the molecules, forming a collective state. The photonic excitation of the collective states to higher electronic levels will result in a very narrow and strong emission peak.

Theoretically and experimentally, we show how robust the collective state is against spatial disorder excited state quenching, and inhomogeneous broadening of the molecular transitions. Therefore, we grow monolayers of N,N’-Dimethyl-3,4,9,10-Perylenetetracarboxylic dianide (MePTCDI), a perylene derivative, on two different van der Waals materials, few-layer hexagonal boron nitride and graphene. Both materials have a flat surface promoting the growth of dye monolayers providing a perfect platform to study the fundamental mechanism of collective states. High resolution AFM was used to determine the lattice structure that the molecules form in a monolayer. Showing a dense packed and highly ordered molecular structure. Optical spectroscopy and light scattering were used to characterize the collective state of the grown 2D material. We were able to measure the characteristic fluorescence for closely packed molecules, further we observed the vanishing Stokes shift between absorption and emission spectrum which is another characteristic for the presence of a collective dipole state. These findings make the molecular monolayers exciting platforms to implement designs of quantum optics in scalable devices.

Amorphous 2D Materials – A Novel Platform for Remote Epitaxy and Nanopatterned Epitaxy of III-V Semiconductors with Low Decomposition Temperatures
Kuangyu Liu, Hyunseok Kim, Ne Myo Han, Sangho Lee, Yunpeng Liu and Jeehwan Kim; Massachusetts Institute of Technology, United States

III-V semiconductor materials such as indium phosphate (InP) offer outstanding photonic properties that outperform silicon. However, the cost of InP wafers is considerably higher compared to commonly used semiconductor wafers like gallium arsenide (GaAs). While reusing original wafers can effectively reduce costs, traditional techniques for wafer recycling, such as chemical or mechanical lift-off, introduce significant expenses during fabrication, negating the cost savings achieved through wafer reuse. Besides, unlike other III-V materials such as GaAs, the epitaxial lift-off method for wafer recycling has not been extensively investigated for InP due to the lack of lattice-matched sacrificial layers with sufficient etching selectivity. Consequently, the reuse of InP wafers becomes more challenging.

Remote epitaxy and nanopatterned epitaxy have emerged as novel methods capable of facilitating the growth of III-V semiconductor membranes with single-crystal quality, as well as enabling easy exfoliation of these films. These breakthroughs offer a promising avenue for cost-effective wafer reuse. However, traditional approaches for transferring two-dimensional (2D) materials, utilizing polymethyl methacrylate (PMMA) or metal stressor layers to transfer materials grown on foreign substrates like copper (Cu) or silicon carbide (SiC), have been found to introduce defects and damages to both the 2D layer and the substrates during the transfer process. As a result, remote epitaxial and nanopatterned epitaxial films grown on these damaged 2D layers or substrates exhibit lower crystal quality, thus limiting the potential for high-performance device applications. Additionally, the method of using thin amorphous carbon (TAC) for AlGaAs/GaAs is not suitable for InP, since the decomposition temperature of InP (< 600°C) is significantly lower than the growth temperature of TAC (700°C).

Here we report the MBE growth of amorphous boron nitride (a-BN) on InP wafers at low temperature that enabled improved quality of remote epitaxial and nanopatterned epitaxial films and their perfect exfoliation. We show fully covered a-BN on InP substrates despite their low decomposition temperatures. The surface of a-BN coated InP substrate remains smooth with a RMS roughness of around 3Å. We also demonstrate 100% coverage of single-crystal InP thin films grown on a-BN, with the film’s quality significantly improved compared to the case of transferred 2D materials. In addition, the growth and exfoliation were successfully repeated multiple times, proving the feasibility for InP wafer recycling. Through this low temperature MBE growth approach with remote epitaxy and nanopatterned epitaxy, we successfully demonstrate large-scale flexible thin film exfoliation and recycling of InP substrates, which will lead to new opportunities in InP thin film-based photonics and novel heterostructures with significantly reduced cost.

8:00 PM EL09.04.04
Remote Epitaxy of III-N Membranes on Amorphous Boron Nitride
Yunpeng Liu1, Kuan Qiao2, Wei Kong3, Bo-In Park1, Jekyung Kim1 and Jeehwan Kim1; 1Massachusetts Institute of Technology, United States; 2Intel Corporation, United States; 3Westlake University, China

Gallium Nitride (GaN) is a wide bandgap binary semiconductor material, which can be fabricated by epitaxy crystal growth such as MBE. GaN wafers own physical properties such as wide bandgap and high breakdown electric field. These merits make GaN a promising material for devices such as Light-Emitting Diode (LED) and High-Electron-Mobility Transistor (HEMT). Knowing the merits of GaN compared with other semiconductor materials, remote epitaxy appears as a new way to manufacture free-standing GaN films recently. Compared with other methods of fabricating free-standing film such as Laser Lift Off (LLO), Controlled Spalling and Epitaxial Lift Off (ELO), remote epitaxy has smoother lift-off interface, higher substrate reusability, thinner membranes and faster process.

So far, both graphene and Hexagonal Boron Nitride (hBN) have been shown in previous papers as promising 2D materials for remote epitaxy growth. Graphene can be transferred to the substrate from Copper (Cu) foil or SiC substrate or directly grown on the substrate by Chemical Vapor Deposition (CVD). Graphene transferred by PMMA (wet transfer) always results in polymer residuals on the graphene surface, which leads to bad epitaxial film quality. Although less residuals appear during dry transfer process (transferred by Nickel), the process results in the holes on the graphene, which can finally lead to the spall of the substrate during exfoliation. CVD grown graphene shows better graphene quality compared with transferred graphene. However, contaminations generated during exfoliation process between chambers, and graphene leads to high Carbon doping concentration. Besides graphene, hBN is also reported as the new platform for remote epitaxy. However, unlike graphene, hBN is a polar material, which means epitaxy is guided by the ionic field of the substrate as well as the hBN interlayer. Depending on the thickness of the transferred hBN, the epitaxial layer can be dominated by either of the two phases.

Aiming to solve the problems mentioned above, in situ MBE grown amorphous Boron Nitride (aBN) is developed as the 2D material for remote epitaxy. aBN is grown in MBE chamber with the help of high temperature effusion Boron cell and plasma assisted nitrogen source. aBN is a more transparent 2D material with no ionic field compared with hBN. Epilayer is purely seeded by the substrate in the remote epitaxy process. This MBE in situ grown aBN fully eliminates the contaminations generated during 2D material transferring process and sample reloading process. This technique enables the growth of ultrathin free-standing single crystalline GaN films. This high-quality free-standing film enables the high sensitivity Surface Acoustic Wave (SAW) sensor which can make a conformal contact on human skin. By transferring the GaN on a substrate with higher heat conductivity, GaN based device heat dissipation can be improved. Multiple GaN/aBN layers can be stacked together with single MBE growth to enhance the fabrication rate of the free-standing film.

Furthermore, unlike normal epitaxy methods, the epitaxy of remote epitaxy spontaneously relaxes due to the slippery surface of the 2D material. The Van der Waal force on the 2D material doesn’t limit the relaxation like the covalent bond. Therefore, high quality relaxed InGaN can be obtained with this method.

The synthesis temperature of MBE grown aBN can go as low as 300 °C, which broadens the application field of aBN based remote epitaxy. In the future, this technique has the potential to be applied to more semiconductor materials.
To fabricate universal platforms for electronic and photonic devices with significantly reduced material costs, it is highly essential to realize free-standing membranes with successful separation of active materials from substrates. However, conventional techniques have their own drawbacks considering poor interface quality, difficulty in stack-up, or materials limitations. Recently, remote epitaxy has posed a remarkable potential that can ultimately overcome the existing challenges and produce high crystalline quality even with the simplicity in choosing the materials. 2D material (e.g. graphene) enables remote interaction between two materials and results in the "remote" epitaxial growth of the material (III-N, III-V, or complex oxides). In this study, we demonstrated an ultra-stable and transfer-free 2D platform using pseudo-graphene(pGr)/SiC in remote epitaxy of GaN. Our approach removed the process for fabricating conventional pGr by exfoliation and achieved wafer-scale high-quality free-standing GaN membrane. This can pave the way for realizing multiple wafer-scale GaN free-standing membranes with high-quality using a single SiC.

Synthesis and Characterization of TiO$_2$-GO Hybrid via Femtosecond Laser Irradiation in Liquid for Enhanced Photocatalytic Applications under Visible-Light Berris Bastug Azer, Ahmet Gulsaran, Reza Karimi, Joseph Sanderson, Michael Pope and Mustafa Yavuz; University of Waterloo, Canada

In the pursuit of efficient photocatalytic materials, the integration of titanium dioxide (TiO$_2$) with graphene oxide (GO) has emerged as a promising strategy. Herein, we present a novel and environmentally friendly method for synthesizing a TiO$_2$-GO hybrid through laser irradiation in liquid. This technique offers simplicity, greenness, and remarkable control over the heterostructure's properties depending on the laser parameters.

The TiO$_2$-GO hybrid was fabricated by ultrasonication of TiO$_2$ nanoparticles and GO in a liquid medium, followed by femtosecond laser irradiation. The resulting heterostructure was characterized using various techniques. The structural properties were investigated through X-ray diffraction (XRD), Raman spectroscopy, and BET analysis. The XRD patterns confirmed the successful integration of TiO$_2$ and GO, while Raman spectroscopy revealed a strong interface formation between the two materials. BET analysis demonstrated increased surface area in the hybrid structure. To evaluate the optical properties, UV-Vis spectroscopy was employed. The absorption spectra exhibited enhanced light absorption in the visible range, indicating efficient utilization of visible light for photocatalytic processes. The band gap energy of the TiO$_2$-GO hybrid was estimated using the Kubelka-Munk function, revealing a reduced band gap compared to pure TiO$_2$. This band gap narrowing enables the hybrid to harness a broader spectrum of light, enhancing its photocatalytic activity under visible light illumination. Moreover, the morphology of the TiO$_2$-GO hybrid was examined using scanning electron microscopy (SEM). The SEM images showcased a well-dispersed and interconnected structure with intimate contact between TiO$_2$ nanoparticles and GO sheets.

In summary, our laser irradiation in liquid synthesis approach enables the fabrication of a TiO$_2$-GO hybrid with outstanding properties for photocatalytic applications. This green and straightforward technique results in a heterostructure that exhibits enhanced photocatalytic performance under visible light, surpassing the capabilities of TiO$_2$ and GO individually. The comprehensive characterization of the hybrid's optical, structural, and morphological properties validates its potential for highly efficient photocatalytic applications.

Artificially Intelligent Formaldehyde Sensing using Printed Graphene-Based Aerogels Zhuo Chen, Binghan Zhou, Tynee Bhowmick and Tawfique Hasan; University of Cambridge, United Kingdom

The identification and analysis of formaldehyde as a hazardous air pollutant in indoor environments present an immediate and critical concern. The endeavour to achieve real-time recognition of formaldehyde in the presence of interfering gases represents a formidable challenge, particularly for room temperature sensors that are susceptible to noise and baseline drift. Exploring the unique properties of dimensionally hybrid systems based on graphene and leveraging artificial intelligence (AI) offer promising pathways.

In this study, we tackle these challenges by utilizing the 3D-printed porous structure of graphene-based aerogels as interconnected frameworks for rapid gas diffusion and sensitising the aerogels with tin oxide quantum dots (QDs) for high-performance chemical sensing at room temperature. Through reaction-coupled diffusion modelling of both filament-structured and film-like aerogels, we explain and experimentally demonstrate the superior gas-sensing capabilities of thinner films with higher surface porosity. With optimised morphology and doping of the printed structures, we achieve an outstanding response of 15.23% towards 1 ppm formaldehyde at room temperature.

Furthermore, we explore the versatility of different structures and chemical doping to construct gas sensor arrays capable of distinguishing formaldehyde from ammonia and nitrogen dioxide. To enable real-time gas species classification, we develop gas recognition algorithms based on dynamic response features that are independent of steady-state response or testing sequences. These algorithms demonstrate remarkable accuracies, even in the presence of significant noise and baseline drift. Our findings present a novel artificially intelligent solution for the detection and real-time identification of formaldehyde at room temperature, offering promising prospects of graphene-based aerogels for addressing this pressing environmental issue.

8:00 PM EL09.04.13
Introduction of Low Dimensional Charge-Boosters into Graphene Oxide Nanochannels for Energy Harvesting Ki Hyun Lee, Hyoenhoo Lee, Woojae Jeong and Tae Hee Han; Hanyang University, Korea (the Republic of)

Osmotic energy, a potential source of electricity from salinity differences in water, relies on ion-exchange membranes to convert salt gradient energy into electric power. However, these membranes encounter challenges, including inadequate charge densities and resistance to mass transfer. Recent efforts have focused on enhancing ion-selective membranes using materials like polymers, metal oxides, and frameworks. Two-dimensional (2D) nanosheets, such as graphene and boron nitride, have shown promise, featuring nanochannels with controlled thickness. These structures exhibit an electrical double layer that enhances ion transport. Utilizing reverse electrodialysis (RED), 2D nanochannel membranes demonstrate high ion conductance and osmotic power extraction. However, the challenges also arise from the intrinsic limitations of 2D nanomaterials, including relatively low surface charge densities and mass-transfer resistance, which hinder their effective integration into RED systems. In this study, we used negatively charged graphene quantum dots (GQDs) and polyelectrolyte nanorods to boost the charge density of graphene oxide (GO) nanochannels. Charged GQDs and polyelectrolyte nanorods can be integrated into GO fibers and films to increase the charge density and improve energy harvesting performances. Moreover, by aligning nanoscale charge boosters onto GO nanochannels through a blade-coating technique, the charge density can be precisely directed to optimize ion transport. Our study introduces an innovative and efficient approach to refining ion transport characteristics of 2D GO nanochannels, ultimately enhancing ion selectivity for proficient osmotic energy generation.
Phonon engineering leads to a controlled modification of phonon dispersion, phonon interactions, and transport. However, engineering and probing phonons and phonon transport at the nanoscale is a non-trivial problem. In this talk, we discuss how phononic properties and thermal transport can be engineered and measured in low dimensional systems.

In particular, a fundamental difference in the phononic properties of 2D and 3D polar materials is predicted to be the long-wavelength dispersion of longitudinal (LO) and transverse (TO) optical phonon modes [1]. In 2D systems these modes become degenerate at the zone center, at variance with the well-known splitting they exhibit in bulk 3D materials. Besides the fundamental understanding of how the phonon modes of polar materials change when dimensionality is reduced, we stress two applicative reasons for this investigation: i) the peculiar characteristics of the phonon modes have an impact on thermal and electrical transport and optical coupling of 2D materials; ii) Raman spectroscopy is one of the most important non-destructive tools used to determine the thickness of the flakes [2], and thus it is essential to interpret correctly the experimental measurements by identifying all the observed phonon modes. We provide the experimental proof of the collapse of the TO-LO splitting in polar 2D materials [3], predicted by ref. [1]. We also investigate the effect of the parity of the number of layers and the role of inversion symmetry. Once all the proper theoretical tools required to fully account for all the experimental features of the Raman spectra of 2D materials are assessed, we exploit them to unveil the lattice dynamics of WSe2 [4], which is, among the most diffused transition metal dichalcogenides, the one having the most controversial phononic properties, due to a very small thickness-dependence of the main phonon modes (A1g and E2g). We show that conventional first order Raman spectroscopy has a limited validity in the determination of the number of layers in WSe2 and we propose an alternative, more general approach, based on multi-phonon bands, which enables to distinguish between 1L, 2L, and 3L [4].

Finally, we present a method to investigate thermal transport in two-dimensional systems using multi-terminal suspended SiN membranes with resistive elements. These devices enable us to probe thermal transport along different directions as a function of thermal bias.

9:00 AM *EL09.05.02 Generating and Exploring the Effects of Ultrastrong Electric Field in 2D Material/molecule Heterostructures* Kirill Boletin; Freie University Berlin, Germany

We consider a new type of heterostructure: a 2D material with donor molecules on one side and acceptor molecules on the other. The charge transfer between the molecules generates an electrical field inside the 2D material. We experimentally measure the field produced by this “molecular gating” and show that it reaches ~4V/m, the highest field measured in a solid-state device. We then explore the effect of this intense field. First, we demonstrate that the field suffices to modify and eventually completely close the bandgap in bilayer 2D semiconductors driving a semiconductor-to-metal transition. Second, we show that the field lifts degeneracies between excitons in semiconductor 2D bilayer and brings different excitons into resonance. Finally, we demonstrate new types of excitonic states that arise because of that.

9:30 AM *EL09.05.03 Role of the Anion in an Ionic Liquid-Gated MoS2 Transistor* Anoir Hamdi1, Iréné Bérenger Amiehe Essombba2, Kana Ishisone2, Ramin Karimi2, Tian Lan2, Clara Santat1, Mauro Boero2, Guido Or1 and Emanuele Orgiu1; 1Institut National de la Recherche Scientifique- Centre Énergie, Matériaux et Télécommunications (EMT), Canada; 2Institut de Physique et Chimie des Matériaux de Strasbourg, CNRS, Université de Strasbourg, France; 3Polytechnique Montréal, campus de l’Université de Montréal, Canada

Electrical double layer gating is employed to achieve ultra-high charge carrier accumulation in a semiconductor material operating as the active layer in a transistor. Such strategy allows to overcome the problem of low carrier density and high operating voltage in field-effect transistors (FETs) due to low capacitance and electrical breakdown of the gate dielectric. In the present work, electrical double-layer transistors based on molybdenum disulfide (EDLT-MoS2) and an ionic liquid (IL) were fabricated to achieve a higher carrier density and lower operating voltage than those in the FET-MoS2 transistor. EDLT-MoS2 were obtained by combining a three-terminal back-gated MoS2 FET with an ionic liquid while disabling the back-gate effect and using the ionic liquid as a top-gate dielectric. A heavily p doped silicon layer Si with thermally grown 285 nm thick SiO2 was used as substrate, while gold (Au) with chromism (adhesion layer) were used to fabricate the source and drain electrodes of the EDLT-MoS2. Activated carbon was chosen as the gate electrode. Two different ionic liquids [EMIM][anion1] and [EMIM][anion2] were used as gate dielectrics in order to: obtain high performance transistors, study the IL/MoS2 interface and identify the anion/cation pair most capable of injecting a high density of charge carriers on the surface of the molybdenum disulfide channel. The results of electrical characterizations showed that both [EMIM][anion1] and [EMIM][anion2] allow us to achieve a higher carrier density in the MoS2 channel than what usually achieved by means of conventional gating with insulating oxides such as SiO2. This allows to use our transistors at lower operating voltage. Comparing the results obtained by the two ILs, it was found that although the gating occurs through the [EMIM] cation, [anion1] achieves the highest effective double layer capacitance over [EMIM][anion2]. Surprisingly, we found that the anion plays a role in the gating efficiency of our devices in spite of the fact that it is the cation that actually charges carriers (electrons in this case) within the FET channel. This is in agreement with theoretical predictions and modeling carried out by using classical and first-principles molecular dynamics simulations. Furthermore, the performances of FET gated by [EMIM][anion1] were found to be stable over time. This work explored from a theoretical and an experimental point of view the role of the anion in an ionic liquid. This paves the way for the choice of suitable pairs of ILs for applications in electronics or superconductivity.

9:45 AM *EL09.05.04 Electrostatic Self-Assembly of GO-CNT Nano-Hybrid Structures* Lokesh Soni, Kamendra P Sharma and Ajay Singh Panwar; Indian Institute of Technology Bombay, India

Carbon-based hybrid nanostructures consisting of graphene oxide (GO) and carbon nanotubes (CNT) could potentially provide superior properties relative to their individual components. However, the fabrication of such nanostructures at this length scale is found to be an arduous task, due to restacking of GO sheets and aggregation of CNTs. By using CNTs as anchoring material to prevent restacking of GO sheets and aggregation of CNTs, a hybrid nanostructure can be generated which can show synergistic properties from both materials[1], [2]. In this study, we report a scalable approach to develop highly ordered CNT intercalated GO hybrid nanostructures in an aqueous medium with an electrostatic self-assembly process. The GO-CNT hybrids were synthesized by first modifying the GO and CNT with polyelectrolytes such as Poly(diallyldimethylammonium chloride) (PDDA) and Poly(styrene sulfonate) (PSS) via non-covalent interactions, resulting in highly stable dispersions of mGO, and mCNT respectively. The hybrid nanostructures were synthesized by homogeneous mixing of mGO and mCNT constituents with varying volumetric ratios with ultrasonication. The hybrid nanostructures were characterized by zeta potential, dynamic light scattering, scanning electron microscopy (SEM), and transmission electron microscopy (TEM). From SEM the hybrid nanostructure with
1.05 mGO:mCNT (v/v) ratio was found with highly organised stacking of CNT intercalated GO sheets, owing to the charge neutralization point of the dispersion as studied with zeta potential. TEM micrographs also show homogeneous distribution of CNTs on the exfoliated GO sheets. Strengthened electrostatic interaction on the GO and CNT with adsorbed polyelectrolytes prevents restacking and aggregation of GO sheets and CNTs and further facilitates the self-assembly of oppositely charged nanoparticles into the formation of layered hybrid nanostructures. The mobility of polyelectrolyte chains also facilitates the ordered arrangement of CNTs with their anisotropic shapes and extends the electrostatic interaction to a much greater length scale to produce a compact yet strengthened nanostructure. The proposed process provides a highly cost-effective method against processes such as CVD, and large-scale production of a highly ordered arrangement of CNTs than the conventional Layer-by-layer assembly method to produce GO-CNT hybrid nanostructures for membrane and high surface area application in aqueous media.

Nanoscale Optoelectronic Characterisation of Hybrid Heterostructures via Scattering-Type Scanning-Near-Field Optical Microscopy Jessica L. Boland1, 2 and Tom Vincent1, 2 1University of Manchester, United Kingdom; 2National Physical Laboratory, United Kingdom

Dimensionally hybrid semiconductor heterostructures and 2D heterostructures have enormous promise for a range of functional technologies. Indeed, heterostructures of planar 2D materials have already found applications in photonics, optoelectronics, straintronics, valleytronics and twistorics, where pushing towards 2D/1D and 2D/0D systems have shown exciting optoelectronic phenomena [1,2]. To understand the effect of this hybridisation, characterisation techniques with high spatial resolution, temporal resolution and depth selectivity are required in order to examine the optoelectronic and chemical properties of individual layers and components of the heterostructure.

In this talk, we present scattering-type scanning near-field optical microscopy (s-SNOM) as a powerful tool for non-destructive optoelectronic characterisation of hybrid heterostructures [3,4]. By coupling radiation to the apex of an atomic force tip, we achieve spatial resolutions way beyond the diffraction limit of light down to 10 nm across wavelengths from the visible to the terahertz range. We perform both imaging and spectroscopy to extract the local material dielectric function on nanometre length scales. By oscillating the tip and changing the tapping amplitude, we can also alter the probing depth to perform nanotomography, enabling us to observe differences in optoelectronic properties in different layers of a material. Here, we present s-SNOM on a range of example heterostructures, including: interlayer charge transfer between 2D TMDC heterostructures [5]; identification of surface layer dependent on local structure.1 Direct visualization of atomic-scale structures and interfaces allows the determination of growth mechanisms and routes.

New Optical Features of Designer 2D Materials and Machine-Learning Assisted Characterization Shengxi Huang; Rice University, United States

2D materials offer enormous opportunities to build designer structures with widely tunable properties. The precise atomic engineering and quick characterization approach are critical to advance the application of designer 2D materials. This talk will introduce new optical features of designer 2D materials [1-4] with a focus on atomic substitution in monolayer WS2 [1]. The engineering of 2D materials presents unique opportunities for optoelectronic device and quantum information platform. When designing optoelectronic devices of 2D materials, spectroscopic permittivity of 2D material is a key parameter. While ellipsometry has been used to measure permittivity, it requires simple device structure, non-trivial parameter fitting, and special setup. This talk will also present a new machine-learning assisted approach to measure permittivity of 2D materials embedded in complex device structures without model fitting, which can facilitate a quick, accurate, and in-situ characterization of 2D and other thin film materials [5].

Tailored Epitaxial Growth and Morphology of 1D/2D Heterostructures Kate Reidy1, Noya R. Itzhak2, Maya Levy-Greenberg2, Paul Miller1, Yasen Hoss1, Federico Panciera1, Jagadeesh Moodera1, Ernesto Joselevich2 and Frances M. Ross1; 1Massachusetts Institute of Technology, United States; 2Weizmann Institute of Science, Israel; 3Université Paris-Saclay, France

Controlling emergent phenomena at the nanometer regime requires unprecedented precision, resolution, and uniformity not readily feasible through conventional top-down fabrication techniques. This is particularly true in the growth and design of van der Waals (vdW) bonded ‘mixed dimensional’ heterostructures, where two-dimensional (2D) and nD (where n is 0, 1 or 3) materials adhered primarily through non-covalent interactions are highly dependent on local structure.1 Direct visualization of atomic-scale structures and interfaces allows the determination of growth mechanisms and routes.

References

Here, we explore how vdW-bonded 2D substrates influence complex epitaxial growth modes of 1D tellurium (Te) nanostructures using a combination of in-situ and ex-situ analysis via atomic resolution scanning transmission electron microscopy (STEM). Te is a p-doped semiconductor that can exhibit a chiral atomic structure and is emerging for application in next-generation electronic, optoelectronic, and piezoelectric applications. First, we utilize vdW epitaxy to tailor Te nanostructure growth on a variety of 2D substrates, exhibiting both hexagonal symmetry and zero asymmetric surface structures. We then elucidate the role of temperature in the resulting nanostructure morphology, moving towards faceted islands at higher temperature with well-defined interfaces and morphologies. We compare the growth morphologies of chiral Te with the case of higher symmetry crystal structures, such as Au, Ti, and Hf, examining the role of symmetry on nanostructure morphology. Such understanding of tailored growth mode allows versatile design of heterostructures for next generation nanoscale devices, and we discuss mechanisms by which optimizing this 1D/2D interface is crucial for improving existing devices as well as generating novel mixed-dimensional heterostructures.

**SESSION EL09.06: Functional Properties II**

Controlling Valley-Selective Absorption and Emission from Monolayer Materials with High-Q Metasurfaces **Jennifer A. Dionne**, Feng Pan, Yin Liu, Sze Cheung Lau, Fang Liu, Mark L. Brongersma and Tony F. Heinz; Stanford University, United States

Atmospheric thin two-dimensional (2D) materials, transition metal dichalcogenides (TMDCs), graphene, and hexagonal boron nitride as well as their heterostructures, have recently found wide applications in optoelectronic devices, condensed matter physics, and quantum information science (QIS). Among these 2D materials, excitons in atomically-thin TMDCs have large exciton binding energies (>500 meV) and provide bright and sharp photoluminescence (PL) emission. More importantly, the presence of spin-orbit coupling and broken inversion symmetry renders the spin-valley polarization addressable through optically-circular polarization control. The valley-polarized PL can be observed and characterized by the degree of circular polarization, defined as DOP = (|I(σ+) − I(σ−)|)/(|I(σ+) + I(σ−)|), where |I(σ+)⟩ and |I(σ−)⟩ are right and left circularly polarized PL intensities. Achieving high DOP is important for high-fidelity quantum information processing and generating high-quality chiral light sources. However, their short spin coherence time due to intervalley scattering, i.e. a few ps even at low temperatures (4 K or 100 K), prevents them from being employed as on-chip valley-selective devices for wide applications in valleytronics.

Here, we integrate the TMDC MoS₂ with high-quality-factor silicon metasurfaces to enhance and control valley-specific absorption and emission. By varying the metasurface disk diameter, we tune the frequencies of Mie scattering modes to match the exciton frequency in MoS₂. When the electric and magnetic Mie modes overlap (a Kerker-like condition), the photoluminescence (PL) intensity of MoS₂ is enhanced by over 30 times on the metasurface in contrast to that on flat sapphire substrate. The MoS₂ emission spectra are also markedly modified via the coupling of neutral excitons, trions and defect bound excitonic states with the metasurface Mie modes. At the Kerker condition, we also demonstrate the symmetric enhancement of the degree-of-polarization (DOP) of neutral exciton and trions via valley-resolved PL measurements, and find that the DOP can be as high as 24% for exciton emission and 34% for trion emission at 100K. These results can be understood by analyzing the near-field impact of metasurface resonators on both the chiral absorption of MoS₂ emitters as well as the enhanced emission from the Purcell effect. Combining Si-compatible photonic design with large-scale (micron-scale) 2D materials integration, our work makes an important step towards on-chip valleytronic and QIS applications approaching room-temperature operation.

2:00 PM *EL09.06.02*

Interfacing 2D Transition-Metal Dichalcogenides with III-V Substrates and Nanostructures **Michele Zendrini**, Michele Ponso, Claire Blaga, Jin Jiang, Mitali Banerjee, Valerio Piazza and Anna Fontcuberta i Morral; Ecole Polytechnique Federale de Lausanne (EPFL), Switzerland

Two-dimensional transition metal dichalcogenides (2D-TMDs) figure as promising candidates for new generation optoelectronics, ranging from flexible electronics to single-photon emitters and strain-tunable devices. Their functionalization through the integration with a suitable substrate is a key factor as 2D materials are strongly influenced by both the substrate morphology and the dielectric environment. The heterostructures of 2D-TMDs and III-V materials have shown to induce sharper and more stable emission with respect to their counterparts on oxides [1]. A clear understanding of the band alignment between the 2D material and the specific III-V material is still needed to outline the most suitable material coupling for functional devices. In this context, one must also consider the impact of the strain on the band structure of the 2D-TMDs and thus on the heterojunction. The substrate
morphology is therefore of primary importance as it can be engineered to induce various strain configurations [2]. In our work, we transfer MoS₂ and WSe₂ monolayers (ML) on different III-V substrates such as GaAs and related ternary alloys. We grow the III-V semiconductors by molecular beam epitaxy in form of a thin film or an ordered array of 1D nanostructures such as horizontal nanowires. Selective area epitaxy allows obtaining arrays with precise morphology and size. In the case of thin films, the TMD/III-V stacking is explored to evaluate the effective band alignment. In the latter case of nanostructures, the extent of strain-induced modification is investigated. The heterojunction properties are defined both optically and electrically. On the one hand, micro-photoluminescence and Raman spectroscopy are utilized to evaluate the evolution of emissions and vibrational modes respectively when transitioning from unstrained to strained MLs. On the other hand, conductive atomic force microscopy and electrical contacts patterned by electron-beam lithography provide comprehension of the electrical response of the different heterojunctions.

This research presents a hybrid carbon material foam developed by chemical vapor deposition technique, with acetonitrile as a carbon source and Ni as scaffolds. Carbon poses some interesting allotropes, and this material exhibits some of them. Graphene and graphene oxide are valuables in the sensors field due to their electrical and conductive properties. However, there are essential applications in gas and liquid media that can benefit from the unique properties of graphene but require a 3D structure able to interact thoroughly with the medium. We studied how the structural properties of the graphene hybrids foams depend on the growth parameters, such as temperature, precursor concentration, and Ni foams thickness. This material will be used as an electrode in sensing some enzymes or other biological molecules which are at low concentrations.

The high purity and yield of the material fabrication would enable further applications for research and industrial processes, such as catalysis and environmental remediation.

10:15 AM DISCUSSION TIME

10:30 AM *EL09.07.05 Understanding and Enhancing the Color Center Emission in hBN Coupled to Photonic Circuits Henry Roberts1, Scott Wicker, Jr., apratim Khandelwal1 and Xiuling Li1; 1The University of Texas at Austin, United States; 2University of Illinois at Urbana-Champaign, United States

Defects embedded in solids or thin films function as attractive quantum sensors. For example, negatively charged nitrogen vacancies NV− in diamond films can be used for detecting electric, magnetic, and strain fields with promising sensitivity and resolutions. Here we explore the color center emission in van der Waals (vdW) materials, particularly hexagonal boron nitride (hBN), and in silicon carbide nanostructures, coupled to photonic circuits. We will discuss the design, photonic structure fabrication, deterministic spin defect generation, and characterization.

11:00 AM *EL09.07.06 (Clarifying) A Few Alternative Facts about 2D Materials Eric Pop; Stanford University, United States

Great interest in the science and engineering of two-dimensional (2D) materials has led to a great rush of publications, some stating or propagating a number of “alternative facts” about 2D material and device properties. (with thanks to Kellyanne Conway for coining this term). An “alternative fact” (AF) is a statement, a number, or a belief that is presented as “fact”, despite reasonable uncertainty or evidence to the contrary. Common examples include the 0.65 nm thickness and 1.8 eV band gap of monolayer MoS2, or various exaggerated mobility values. Unfortunately, such AFs have propagated in the 2D literature perhaps by accident, perhaps because some form a compelling story, or perhaps due to convenience. Here we try to address and hopefully clarify a few AFs, especially as they pertain to basic 2D material parameters or simple device applications. The presentation will be incomplete, yet will hopefully provide some useful guidance for researchers working with 2D materials. The audience will be encouraged to participate and contribute their favorite AFs (and corrections), which will be published online for the benefit of new students and others entering the broad and exciting field of 2D materials.

8:00 AM *EL01/EL09/EL12.01 Enhanced Interactions of Interlayer Excitons in Free-Standing Hetero-Bilayers Yuerui Lu; Australian National University, Australia

Strong, long-range dipole-dipole interactions between interlayer excitons (IXs) can lead to novel multi-particle correlation regimes that drive the system into distinct quantum and classical phases including dipolar liquids, crystals, and superfluids. Both repulsive and attractive dipole-dipole interactions have been theoretically predicted between IXs in a semiconductor bilayer2,3, but only repulsive interactions have been experimentally reported so far3,4. This study investigated free-standing, twisted (51°, 53°, 45°), tungsten diselenide/tungsten disulfide (WSe2/WS2) hetero-bilayers, where we observed a transition in the nature of dipolar interactions among IXs from repulsive to attractive. This was caused by quantum-exchange-correlation effects, leading to the appearance of a robust interlayer biexciton (formed by two IXs) phase that was theoretically predicted but never observed in experiments before. The reduced dielectric screening in a free-standing hetero-bilayer not only resulted in a much higher formation efficiency of IXs, but also led to strongly enhanced dipole-dipole interactions, which allowed us to observe the many-body correlations of pristine IXs at the two-dimensional (2D) quantum limit. In addition, we first observed multiple emission peaks from moiré-trapped IXs at room temperature in a well-aligned, free-standing WSe2/WS2 hetero-bilayer. Our findings can open avenues for exploring new quantum phases with potential for application in nonlinear optics.5

8:30 AM EL01/EL09/EL12.03 Correlated KP FM and TERS Imaging to Elucidate Defect-Induced Inhomogeneities in Oxygen Plasma Treated 2D-MoS2 Layers Sanju Gupta; Penn State University, United States

Modulating physical and chemical properties of two-dimensional (2D) transition metal dichalcogenides (TMD) by defect-engineering induced by oxygen plasma is actively pursued. In this work, exfoliated 2D MoS2 layers treated by medium power oxygen plasma for different times (0, 10, 20, 40, and 60 s) are investigated using Kelvin Probe Force microscopy and tip-enhanced Raman spectroscopy (TERS) besides micro-Raman and photoluminescence (PL) spectroscopy. Under oxygen plasma, defects (mono- and di-sulfur vacancies) and chemical oxidation is predominant from 0s (native defects) up to 40s, while etching becomes dominant beyond 40 s, for mono- (1L), bi- (2L), and tri- (3L) layer MoS2 with optimal defect density for four- (4L) and more layers. While Raman spectra exhibited lattice distortion (broadening of phonon bands) and surface oxidation by the presence of sub-stoichiometric molytrioxide MoO3 (i.e., MoO3-x or MoO3.75) the increased spectral weight of trions and quenching in PL spectra are observed with treatment time. The localized nanodomains (~20–40 nm) and aggregated vacancies as nanovoids and intermixed MoS2/MoO3-x alloy are identified in near-field Raman spectra.
The atomic force microscopy also showed defects aggregation and Kelvin probe force microscopy revealed the work function (WF) increase from 4.98 eV to 5.56 eV, corroborating the existence of MoO$_3-x$, phase which enables doping and shift Fermi level. We also highlight the unique interaction between the gold substrate and the formed MoO$_3-x$, facilitating Mo$^+$ cation reduction to lower oxidation (i.e., Mo$^4+$) thereby yielding intermediate oxidation states responsible for lower WF (ca. theoretical 6.3 eV for stoichiometric MoO$_3$). Strong correlations among the work function, vibrational and optical responses are established while exploring the oxygen plasma-induced defects and changing the landscape on oxygen doping at the nanoscale with varying MoS$_2$ layers, which are useful for heterogeneous electrocatalysis and applicable to other 2D TMDs.

8:45 AM *EL01/EL09/EL12.04
Manufacturing of Meta Optics by Nanoimprint Lithography Niklas Hanson; NIL Technology, Denmark

Metalenses have gained significant attention in various fields such as augmented reality (AR), automotive technology, and consumer electronics. Their unique properties, including high thermal stability, fewer lens components, and focal lengths that closely match design values in production. These aspects lead to simplified camera modules, and make meta lenses highly desirable for these applications.

The efficiency of metalenses is crucial, as low-efficiency metalenses result in undesirable diffraction of light. To achieve high efficiency, it is important that the fabricated meta lenses, typically in the form of pillars, closely match the intended design. Even small deviations in the order of a few nanometers can lead to noticeable decreases in efficiency. Nanoimprint lithography (NIL) is a manufacturing technique employed for mass producing metalenses. We have investigated how closely the fabricated pillar diameters align with the design specifications. In the case of a focusing lens designed for 940 nm, the deviations in pillar diameters were found to be within the range of $\pm 10$ nm for repeated fabrication on a single wafer and between consecutive manufactured wafers.

The corresponding focusing efficiencies of these metalenses were measured to be between 85% and 90%. This indicates that NIL is a valid manufacturing method for producing metalenses suitable for the aforementioned applications. The high efficiency of the manufactured metalenses suggests that they effectively mitigate the issue of light diffraction into unwanted orders, making them a promising choice for AR, automotive, and consumer electronics.

9:15 AM EL01.09.12
Defect State Characterization for p-Si-WS$_2$-a Devices using Frequency-Scanned Deep Level Transient Spectroscopy Mohd Samim Reza, Anannya Mathur and Madhusudan Singh; Indian Institute of Technology Delhi, India

Transition metal dichalcogenides (TMDs), such as tungsten disulfide (WS$_2$), exhibit interesting and technologically relevant optoelectronic characteristics owing to the strong dependence of the bandgap on the dimensionality of the growth[1]. Previous scientific investigations have tended to focus on samples grown using chemical vapor deposition (CVD), with well-known limitations such as poor surface coverage, uncontrolled stacking, and device demonstrations have tended to employ electron-beam lithography for patterning, even for reasonably large flake sizes[2]. In practical two-terminal devices with a vertical transport geometry, nearly 100% surface coverage is essential. Usual methods employed for this purpose involve the use of reactively sputtered thin films, or using composite targets, which often results in sulfur-deficient film growth[3], followed by sulfurization. In this work, we have carried out growth of WS$_2$ using a simplified two-step growth process involving sulfurizing a DC-sputtered (Angstrom Engineering Evovac, 10$^{-3}$ Torr) tungsten film (200Å with a growth rate ~ 0.5 Å/s) over a SiO$_2$ substrate (University Wafers). Sulfurization (500 mg, Sigma Aldrich) was carried out in a a custom-designed twelve-zone horizontal split furnace (Quazar Technologies, 750–950 °C) under Ar flow (0–400 sccm). X-ray diffraction (Rigaku Ultima IV, Copper Kα = 1.54Å) scans revealed hexagonal WS$_2$ growth. Raman spectra (Renishaw inVia) revealed an in-plane (E$_{1g}$) and out-of-plane (A$_{1g}$) vibrational modes at ~344.20/cm and ~414.92/cm, confirming the multilayer WS$_2$ growth[4]. Field-emission scanning electron microscope (FESEM, JSM-7800F Prime) scans indicate the growth of a pin-hole-free film. Energy dispersive X-ray (EDX, Oxford) analysis revealed a stoichiometry of W:S ~1:2. Devices were fabricated in an analogous manner by directly sulfurizing pre-deposited tungsten on p-Si (B-doped, 1-10 Ohm-cm, Siegert Wafer), followed by silver contact metallization. A pulsed voltage source (33600A, Agilent) was synchronized with charge measurements (6514 System Electrometer, Keithley) in frequency-scan deep-level transient spectroscopy (DLTS) measurements at various temperatures, 25, 40, and 60 °C. A defect cross-section of ~2.37x10$^{-13}$ cm$^2$ and a defect level of ~0.43 eV below the conduction band was inferred from constant capacitance analysis[5,6].

#### Effect of Ligands on the Structure and Mechanical Properties of Three-Dimensional Nanoparticles Superlattices

Elena Shevchenko1,2; 1Argonne National Laboratory, United States; 2The University of Chicago, United States

Extensive research has been conducted on the self-organization of uniform nanoparticles, leading to the formation of various types of periodic structures. Numerous instances of both single and multicomponent periodic assemblies have been successfully demonstrated. It has been established that the self-assembly process of nanoparticles is highly intricate, involving a wide range of attractive and repulsive interactions between particles and their ligands. In this study, we will explore the influence of nanoparticle purification, ligand solvation, and the type of ligands on the self-assembly of nanoparticles and their impact on the structure and properties of the resulting structures. Furthermore, we will discuss the effect of size distribution on the structure of periodic superlattices. We will present combined quasi-hydrostatic high-pressure small-angle X-ray scattering (SAXS) and X-ray diffraction (XRD) studies on faceted 3D supercrystals self-assembled from colloidal nanoparticles. To investigate the overall mechanical characteristics of the assembled structures, we employed the diamond anvil cell technique, allowing us to examine the contributions of solvated ligands and inorganic ligands. Additionally, we will discuss the role of ligand solvation in the mechanical properties of periodic structures, as well as the structural transformations that occur upon compression for supercrystals obtained using different nonsolvents and ligands.

#### How General are Changes in Excited State Surface Chemistry of Colloidal Quantum Dots for Photocatalysis?

John B. Asbury; Pennsylvania State University, United States

The ligand-nanocrystal boundaries of colloidal quantum dots (QDs) mediate the primary energy and electron transfer processes that underpin photocatalytic and photoluminescent transformations at their surfaces. These boundaries also protect nanocrystal surfaces from photochemical degradation and maintain their colloidal stability. In recent work, we demonstrated using time-resolved infrared (TRIR) spectroscopy that certain types ligand-nanocrystal interactions on PbS QDs exhibit marked reduction in surface bonding strength in the excited states of the nanocrystals, which may provide a pathway to modulate ligand bonding during photocatalytic reactions. In this work, we examined changes in the excited state surface chemistry of CdSe QDs passivated with stearic acid ligands to test the generality of this phenomenon. Transient absorption and photoluminescence spectroscopies were used to characterize the vibrational spectra of the ligands in the excited states of the QDs and to compare their time-dependence to the dynamics of the electronics states. The transient vibrational spectra of the symmetric and antisymmetric stretch modes of the carboxylate anchoring groups of the ligands indicated a net reduction of their higher frequency antisymmetric stretch and an enhancement of the lower frequency symmetric stretch modes. These changes were consistent with the influence that image dipoles created by the polarizable excited excitonic states of the QDs have on the transition dipole moments of the carboxylate anchoring groups. Importantly, a lower frequency transient vibrational feature around 1330 cm⁻¹ appeared in the TRIR spectra that was not present in the ground state infrared absorption (FTIR) spectrum of the QDs. This feature corresponded to the C–O single bond of more weakly bonded carboxylate groups in the monodentate bonding geometry. The shorter excited state lifetime of CdSe in comparison to PbS QDs allowed us to directly observe the reattachment of ligands to their original bonding geometries on much longer time scales. These findings suggest that changes in excited state surface chemistry may be general to metal chalcogenide QDs and motivates continued work to elucidate the origins and means to control the phenomenon for photocatalytic applications.

#### Density Functional Theory Investigation of Trap States in III-V Quantum Dots

Ezra A. Alexander1, Matthias Kick1, Alexandra McIsaac2 and Troy Van Voorhis1; 1Massachusetts Institute of Technology, United States; 2University of California, Berkeley, United States

Cadmium selenide, one of the premier quantum dot (QD) materials for light emission, solar cells, and biomedical imaging, is highly toxic to both humans and the environment. Alternative nontoxic III-V QDs are held back by a high density of surface-localized mid-gap states, which trap photoexcited charge carriers and reduce device efficiency. Despite the prevalence of density functional theory (DFT) in past research on surface trapping in the II-VI family of QDs, very few studies have applied DFT to the substantially different III-V family of QDs. In this work, we survey a broad range of realistic, carefully selected InP and GaP QDs of different sizes, shapes, and surface terminations. By utilizing orbital localization techniques to deconvolute the dense manifold of states at the band edges, we create a framework for understanding the complex surface trapping in these III-V QDs. Not only can trap states form from under-coordinated surface atoms as in II-VI QDs, but we also identify localized midgap states that originate from atomic dimers and distorted four-coordinate surface atoms. We discuss several factors that influence the depth of both electron and hole traps in these materials, including potential avenues for removing such localized states from the band gap. Finally, we identify key differences between the surface reconstruction and electronic structure of InP and GaP QDs.

### 11:30 AM EL10.01.04
#### Surface Chemistry, Optoelectronic Properties and Methods for Enhancing the Photoluminescence Quantum Efficiency of InP-based Core/Shell Quantum Dots

Pieter Schiattacca, Ben Cruyssaeart, Luca Giordano, Hannes Van Avermaet and Zeeger Hens; Ghent University, Belgium

Colloidal quantum dots (QDs) possess spectrally narrow and tunable emission lines, making them highly attractive for applications in displays, light
sources, and energy devices. However, to meet the stringent demands of efficient and sustainable devices, it is essential for QDs to exhibit high photoluminescence quantum efficiencies (PLQY) that are close to unity. In this study, we, therefore, focus on enhancing the PLQY of InP-based core/shell QDs by investigating the relationship between their surface chemistry and their optoelectronic properties.

Our approach involves saturating the surface of InP-based QDs using a zinc acetate complex. This surface passivation step can be carried out either during QD synthesis or after synthesis. We have successfully applied this method to over 25 QD samples with diverse compositions synthesized by different collaborators, demonstrating its robustness and versatility. Additionally, we develop a ligand exchange technique that enables the transfer of InP-based QDs from apolar to polar media while preserving their high PLQY. This method opens up new possibilities for utilizing QDs in both polar and apolar environments without sacrificing their photoluminescence efficiency.

By significantly enhancing the PLQY of InP-based QDs, our findings offer promising prospects for their application in optoelectronics and photonics. These advancements can contribute to the development of more efficient and high-performance devices in different fields.

11:45 AM EL10.01.05
Solid-State Synthesis and Solution-Processable M6 Nanocrystals
Suhar Mutalik, University of Groningen, Netherlands

Metal hexaborides (MB6) are of high technological interest as they show a wide range of bulk physical properties depending on the metal ion in the structure. Boron-rich compounds like CaB6 and LaB6 possess low work functions (2.5–2.7 eV), while CdB6 and SrB6 possess high-temperature thermoelectric properties. 1 The MB6 is reported to have very high hardness (9.5 on the Mohs hardness scale) with nanodentation hardness of 16-18 GPa. 2 The existing literature reports the solid-state synthesis of MB6 nanocrystals below 500 °C, but so far, no studies have been reported on solution-processable MB6 hexaborides. Herein we report a solid-state synthesis of LaB6 and SrB6 nanocrystals performed at 440 °C and a novel post-processing technique of treating the nanopowders obtained from solid-state reaction to form a colloidal stable ink. Through the surface modification of the nanocrystals, we can exchange the surface ligands from inorganic short-chain ligands to organic long-chain ligands, making them solution processable in both polar and non-polar solvents. The colloidal stable MB6 nanocrystals have great potential to be used as thermoelectric devices or ultra-hard protective coatings, which can be fabricated at low cost by solution-based mass production processes.

Ligands on Nanocrystal Surfaces - What Ligand Stripping Can Tell Us
Zeger Hens, Ghent University, Belgium

Colloidal semiconductor nanocrystals are in most cases synthesized as hybrid inorganic/organic objects where organic ligands passivate the surface of the inorganic crystal. This organic ligand shell helps controlling the growth of nanocrystals during synthesis, stabilizes nanocrystal dispersions by steric hindrance, contributes to the electronic passivation of surface-localized electronic states and determines the mobility of charge carries in nanocrystal films. Hence, the importance of understanding the binding and packing of ligands to nanocrystal surfaces in nanocystal science.

In this contribution, we focus on the binding of metal salts such as cadmium oleate, zinc oleate or zinc halides to semiconductor nanocrystal surfaces. We first discuss how the displacement of such Lewis acids through the addition of Lewis bases can be used to probe the binding energy of these metal salts to the nanocrystal surface. By gradually increasing the concentration of the Lewis base, displacement isotherms can be recorded and analyzed using surface-adsorption models. Using this approach on core nanocrystals, such as CdSe, CdS and ZnSe, we show that Z-type ligands can be ranked according to their binding strength. In a second step, we use the method to probe the distribution of binding energies across the nanocrystal surface, where in the case of 2D colloidal nanoplatelets, the weakest ligands could be localized at the nanoplatelet edges. Finally, we extend the method to InP/ZnSe core/shell nanocrystals, where we relate the progressive displacement of zinc halides from the shell outer surface to the creation of a non-radiative recombination channel that can still compete with the radiative recombination of electron-hole pairs to quench the photoluminescence. This result contrasts starkly with colloidal CdSe nanoplatelets, where the passivation of edge states by a CdS crown suffices to eliminate non-radiative recombination related to ligand desorption. We conclude by highlighting the relation between progressive ligand stripping and photoluminescence quenching as a most useful stresstest to evaluate the emission characteristics of colloidal semiconductor nanocrystals.

Designer Zwitterionic Phospholipid Capping Ligands for Structurally Soft Metal Halide Nanocrystals
Viktoriya Morada1,2, Andriy Stelmakh1,2, Mariia Svirydenko1,2, Leon G. Feld1,2, Marcel Aebli1,2, Joel Affolter1, Christop J. Kaul1, Nadine J. Schrenker3, Sara Balz1, Ibor Cherniukh1, Gabrielle Raino1,2, Andriy Baumknet1 and Maksym V. Kovalenko1,2, 1ETH Zurich, Switzerland; 2Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; 3University of Antwerp, Belgium; 4National Academy of Sciences of Ukraine, Ukraine

The success of colloidal semiconductor nanocrystals (NCs) in science and commercial optoelectronic devices is inextricable from their surfaces. A versatile and robust surface functionalization of lead halide perovskite (LHP) NCs and NCs of other structurally soft metal chlorides, bromides, and iodides poses a formidable challenge. Compared to conventional semiconductors, surface capping ligands bind in a non-covalent, rather ionic manner; furthermore, they may readily engage in adverse solubilization equilibria with the ions constituting the labile inorganic cores of these NCs. We posit that the vast and facile molecular engineering of phospholipids as zwitterionic surfactants make for an attractive platform to deliver highly customized surface chemistries for diverse metal halide NCs. Molecular dynamics simulations inferred that ligand-NC surface affinity is primarily governed by the structure of the zwitterionic head group, particularly by the geometric fitness of the anionic and cationic moieties into the surface lattice sites, as corroborated by the solid-state nuclear magnetic resonance (NMR) spectroscopy. Lattice-matched primary ammonium phospholipids enhance the structural and colloidal integrity of hybrid organic-inorganic LHPs – FAPbBr3 and MAPbBr3 (FA-formamidinium; MA-methylammonium), as well as a range of other functional metal halides. The molecular structure of the organic ligand tail instead governs the long-term colloidal stability and compatibility with solvents of diverse
polarity, from hydrocarbons to acetone and alcohols. These NCs exhibit photoluminescence quantum yield (PL QY) above 96% in solution and solids, retained after repetitive purification steps, and minimal PL emission intermittency at the single particle level with an average ON fraction as high as 94%, as well as bright and high-purity (ca. 95%) single-photon emission.

2:15 PM EL10.02.03
Conformational Entropy Mediated Orientation of Ligated Nanocrystals Eliza Price and William Tisdale; Massachusetts Institute of Technology, United States

Colloidal nanocrystals (NCs) are often assembled into ordered superlattices (SLs) for incorporation into optoelectronic devices. For some NCs, self-assembly is dominated by the inorganic core, depending on NC size and shape. However, when NCs are coated in a soft ligand layer, self-assembly behavior can become unpredictable due to the competing interactions of the inorganic and organic components. To address this knowledge gap, we investigated how the conformational entropy of organic ligands mediates the orientation of non-spherical NCs in self-assembled SLs.

With a framework combining numerically derived ligand density distributions and analytical expressions for the freely jointed chain model, we predict NC orientation for several polyhedral shapes, self-assembled structures, and ligand lengths. Additionally, we compare rotationally ordered and disordered NC SLs to estimate the driving force for nanocrystal orientation, finding a strong dependence on both NC shape and ligand length. We test the predictive ability of this framework by comparing model results to the experimentally observed orientation of truncated octahedral PbS NCs in BCC and FCC superlattices. Our work offers a tractable starting point for the thermodynamic understanding of polyhedral NCs with competing core-ligand interactions and may inform experimental efforts to achieve the self-assembly of coherently oriented NCs for high-quality devices.

Selective Agglomeration for 2D-Separation: Insights into the Surface Interaction in Colloids Azita Rezvani, Zhuang Wang and Doris Segets; 1Institute for Energy and Materials Processes (EMPI), Germany; 2Universität Duisburg-Essen, Germany

Small semiconductor nanoparticles (NPs), known as quantum dots (QDs), have a wide range of applications in various fields, including electronics, optoelectronics, photovoltaics, biotechnology, and medicine. The unique properties of QDs, such as size-tunable emission, high photostability, and high quantum yield are intrinsically linked to their size, shape, composition, and surface chemistry [1]. Hence, the dispersity of a sample in all these dimensions becomes one of the most crucial factors to tailor the final product properties. Although the synthesis of colloidal QDs has seen impressive progress in the past two decades, even with sophisticated synthetic techniques, the obtained sample always exhibits a certain dispersity [2]. It can be assumed that this will be even more dominant in large-scale productions which make it essential to narrow down the dispersity in different dimensions by post-processing approaches. However, there is a clear lack of scalable post-synthetic separation strategies for such small colloids, even in terms of size. In recent studies, selective agglomeration has shown promise as an effective approach with the potential to be scaled up in continuous setups for size-classification of ZnS QDs smaller than 5 nm [3, 4]. It is based on the titration of an already existing dispersion by a poor solvent to selectively flocculate one colloidal component.

A highly relevant case in this context is the post-synthetic classification after the larger-scale synthesis of core-shell QDs, where the shell thickness directly influences the final performance of the product. Therefore, we studied a mixture of InP QDs (first colloidal component) and InP/ZnS (core-shell) QDs (second colloidal component), both having oleylamine on the surface [5]. Considering the small size of QDs, the main challenge in such a binary system is the characterization of the coarse and the fine fraction after separation regarding the mixture composition and particle size distribution of each individual component, in each fraction. To achieve this, we developed a combination of UV-Visible spectroscopy, X-ray photoelectron spectroscopy, analytical ultracentrifugation, and inductively coupled plasma optical emission spectroscopy. Their combination resulted in a toolbox for the characterization of such a complex system which is applicable to potential and potentially even more complex multinary colloids. Finally, the toolbox enables a systematic study of important parameters including the type of good and poor solvents and their volume ratios, and to establish a stability map for the binary mixture.

In conclusion, we developed a strategy to characterize binary colloids of ultrasmall QDs during their selective separation. We successfully established a stability map that provides a fundamental understanding of surface interactions and driving forces in binary colloids in solvent mixtures. This is so far not addressed but it is the main step towards the design of multidimensional classification processes reliant on selective agglomeration. Finally, based on these findings we reported the results of the 2D-separation of ultrasmall QDs in terms of size and composition.

Expeditious Nanoparticle Transfer via Combinatorial Electrostatic Engineering Deokun Kim, Ji Yeong Ma, Juhyeong Lee, Gyu rin Kim, Jang-Hwan Han, Hyun Min Kim and Hye-on Ho Jeong; Gwangju Institute of Science and Technology, Korea (the Republic of)

The versatility of solution chemistry offers exceptional flexibility in synthesizing functional nanoparticles with tailored materials, shapes, and surface properties. However, the translation of these colloidal nanoparticles into the industrial domain remains a significant challenge due to the lack of a rapid and uniform transfer technique for achieving 2D-like monolayered coating—an essential requirement for various applications, particularly photonic devices for plasmonics (metals), down- and up-conversion nanomaterials (semiconductors), and Mie resonance (dielecctrics).

We here present a significant advancement in scalable nanoparticle transfer techniques, enabling the efficient transport of nanoparticles from liquid to a 2-inch wafer remarkably within 10 seconds to reach over 40% surface coverage in a 2D monolayered fashion. This transfer rate, to the best of our knowledge, represents the record, reaching 2.03 cm²/s with 30% nanoparticle coverage—an order of magnitude faster than the currently reported results in the literature. Our success lies in the refinement of the well-established electrostatic coating method, where we combinatorially engineer electrostatic features of both the nanoparticles and the surface. This electrostatic engineering leads to enhanced potential differences and thus generates strong electrostatic attraction forces between the nanoparticle and the substrate. Notably, electrostatic repulsion also plays a crucial role, self-limiting the coating process to a single layer due to repulsive interactions between nanoparticles. This charge-sensitive dynamic further offers 'one-shot' nanoparticle patterning when the surface is patterned with two opposite charges, i.e., the nanoparticles are selectively coated only on the oppositely charged area. Furthermore, our approach can be seamlessly extended to various surface materials, including dielectrics, conducting metal oxides and polymers, and 3D-printed polymers, without requiring conventional surface functionalization and treatment processes specific to individual materials.

In this presentation, we will discuss the nanoparticle coating method in which the electrostatic features are engineered, highlighting its key features such as rapid coating speed, large-area uniformity, charge-sensitive selectivity, and flexibility in surface materials and geometries. We will indeed demonstrate how this coating technique enables the realization of novel functional plasmonic metasurfaces, exhibiting consistent resonating colors across diverse material and geometrical platforms.
Ligand Exchange Equilibrium at Quantum Dot Surfaces in Polar and Aqueous Solvent Environments Andrew B. Greytak; University of South Carolina, United States

Our group and many others have contributed to an increasingly detailed understanding of the surface chemistry of representative compound semiconductor quantum dots, including metal chalcofenides, pnictides, and halide perovskites with effective bandgaps spanning much of the visible and infrared spectrum. Such particles are frequently stabilized by organic molecules with nuclophilic or anionic headgroups that coordinate surface atoms. To date, the greatest understanding has been achieved in non-polar or less polar solvents in which charge balance helps to simplify the range of surface reactions that must be considered. Techniques such as NMR and infrared spectroscopy, mass spectrometry, and isotothermal titration calorimetry have helped to reveal the chemistry at such surfaces, including the importance of ligand interactions that can govern the composition and local organization of the surface monolayer.

It is critically important to extend the understanding of such nanocrystal surfaces to polar solvents, including aqueous solution required for biological applications and polar organic mixtures favored for storable nanocrystal inks for electronic devices. However, polar solvents and buffers introduce additional challenges for fundamentals studies due to charge stabilization, acid-base equilibria, proctic buffer components, oxidation, and the need for core/shell structures to achieve good photoluminescence quantum yield.

I will describe our group’s efforts to quantify ligand association and exchange reactions on nanocrystal surfaces in polar and aqueous solutions, including coordination of quantum dots by imidazoles, thiokolates, and polymeric ligands, and prospects for extending these studies to additional classes of materials including magnetic oxides and halide perovskites. I will also emphasize the advantages and limitations of isothermal titration calorimetry as a tool to study the surfaces of colloidal nanostructures and compare the binding of different ligand architectures in polar environments.

Non-Einsteinian Viscosity Reduction in Water-Based Nanofluids of Boron Nitride Nanotubes, Graphene Nanoflakes and Carbon Nanotubes Andre Guerra, Milan Marie, Alejandro D. Rey and Phillip Servio; McGill University, Canada

Introduction: Nanoparticles have multiple applications, including drug delivery systems, biosensing, and carbon capture. Non-Einstein-like viscosity reduction has been reported in nanoparticle-polymer blends at low nanoparticle concentrations. More recently, a similar non-Einsteinian viscosity reduction effect has been observed in aqueous ultra-low concentration carbon-based nanofluids of graphene nanoflakes (GNF) and multi-wall carbon nanotubes (MWCNT)[1,2]. The use of nanoparticles as promoters of the growth of gas hydrates has been an active research field in the past decade[3–6]. This study aimed to explore the viscosity of ultra-low concentration boron nitride nanotube (BNNT) nanofluids in the presence of air and methane.

Methods: We use a boron nitride nanotube functionalized with hydrophilic groups in rheological experiments to investigate the viscosity reduction in ultra-low concentration nanofluids. We measure the dynamic viscosity in an air atmosphere and methane (0-5 MPag) at low temperatures (0-10 °C).

Results: A negligible effect on the temperature dependence of viscosity was found. Ultra-low concentrations of BNNT reduced the viscosity of the nanofluid by up to 29% at 10 ppm in the presence of methane. The results presented here were compared to similar studies on O-GNF and O-MWCNT nanofluids, which also reported significant viscosity reductions. The non-Einsteinian viscosity reduction measured in BNNT nanofluids in the present work was higher than the effect measured for O-GNF and O-MWCNT nanofluids.

Conclusions: This work identified a non-Einsteinian viscosity reduction in BNNT nanofluids, exacerbated by methane dissolved in the nanofluid. In a previous study, we suggested the role of nanoparticles in viscosity reduction by disrupting hydrogen bond networks and facilitating energy dissipation through enhanced density fluctuations. At ultra-low concentrations, these effects may dominate over conventional drag and viscous forces present higher-concentration nanofluids and colloidal suspensions, which lead to increased viscosity with particle loading (Einsteinian behavior). The effects measured for the three different nanoparticles studied so far indicate the role of nanoparticle geometry and surface chemistry on the disturbance of hydrogen bond networks in water leading to the reduction in dynamic viscosity. We suggest computational modeling to investigate molecular scale interactions to elucidate the non-Einsteinian viscosity reduction.

Multilayer Diffraction: A New Tool for Probing the Interparticle Region in Nanocrystal Superlattices Stefano Toso1, Dmitry Baranov2,1, Umberto Filippi1, Cinzia Giannini3 and Liberato Manna1; 1Istituto Italiano di Tecnologia, Italy; 2Land University, Sweden; 3Consiglio Nazionale delle Ricerche, Italy

Owing to their hybrid nature, the properties of nanocrystals are determined by both their inorganic core and their organic shell. This is particularly true when nanocrystals are packed into superlattices, where the ligands surrounding each particle stop being just a surface coating and become an actual component of a more complex nanostructured material. Thanks to these organic spacers, each nanocrystal can retain its non-bulk characteristics while also interacting with neighbors through a variety of coupling mechanisms.

Since these phenomena take place at short distances (electronic coupling = neighboring particles; optical coupling = dozens of nanometers), quantifying parameters like the interparticle distance and the degree of disorder at very local scales is crucial for understanding the superlattice properties. This, however, is far from trivial: the grazing-incidence diffraction techniques usually employed for such studies provide an average response over a much wider
In our research, we propose a novel approach to answer such questions. Our method is based on Multilayer Diffraction, an intriguing collective interference effect known for epitaxial thin films but never reported for colloidal nanocrystals before. This phenomenon occurs when X-rays are diffracted by nanocrystals stacked vertically: the radiation scattered by each particle interferes with that diffracted by neighbors, creating fringes of constructive interference. Since the interfering radiation comes from nanocrystals, the fringes are convoluted by their Bragg peak profile, thus retaining information on the nanocrystals structure, size, and orientation. However, the position of the fringes depends on the overall stacking periodicity, which includes the inter-nanocrystal spacing, while their broadening provides a direct quantification of the stacking disorder.

We will retrace our journey into the understanding of Multilayer Diffraction, from its serendipitous discovery in CsPbBr₃ nanocubes superlattices,[2] to the development of open-source pattern fitting algorithms,[3] and their application to films of colloidal nanoplatelets,[4] where the unique advantages of Multilayer Diffraction can be appreciated at their best. Finally, with the help of literature and simulations we will show that Multilayer Diffraction is a much more common phenomenon than one might think, and is routinely observed without being recognized in a variety of appealing nanomaterials behind the borders of halide perovskites.

**Combing Organic or Inorganic Dyes with Lanthanide Nanoparticles to Overcome the Weak Absorption of Lanthanide Ions**

*Zhongzheng Yu*

University of Cambridge, United Kingdom

Lanthanide-based nanoconstructs have gained increasing attention in recent decades due to their unique optical and magnetic properties. The design of lanthanide-based nanosystems is expected to contribute to various applications including biomedical applications, data storage, optical communications, remote sensing, super-resolution fluorescence microscopy, and night vision etc., due to their advantageous properties such as excellent photostability, non-photobleaching, low cytotoxicity, large Stokes/anti-Stokes shift, narrow and tunable emission peaks. There are two major limitations for lanthanide ions, including weak absorption and low photon conversion efficiency. Developing novel lanthanide-based nanoconstructs and uncovering new insights of the energy conversion pathways are key to the advancement of the field. Combing organic or inorganic dyes with lanthanide nanoparticles to form nanohybrids is highly possible to overcome the weak absorption of lanthanide ions. In this talk, I will introduce our recent work about a) dye-sensitized lanthanide-doped nanoparticles, b) novel nanocomposites as photothermal agents and their corresponding applications in light-controlled release, light-activated photomedicines, sensing, multiplexing imaging, photoacoustic imaging and photothermal therapy. I hope the strategies and studies presented in this talk could further enhance the attractiveness of lanthanide-based nanoconstructs towards clinical translation and applications influencing our daily life.

**Semiconductor Nanocrystals and Copper Clusters for Radiotherapy: The Importance of the Coating and Composition for the Radio Incorporation of Cu64, Their Photo- and Colloidal Stability**

*Teresa Pellegrino*

Italian Institute of Technology, Italy

Cation exchange (CE) reactions on nanocrystals consists of the replacement of cations in the nanocrystalline structure with different metal ions while maintaining in place the anchoring framework. This technique has been extensively used for the synthesis of nanocrystals at different compositions. Here, we exploit CE reactions to radiolabel cadmium-free semiconductor NCs of ZnS, ZnSe and chalcopyrite (CuFeS₂) NCs with Cu-64 radioisotope. [1] To make it possible a one-step CE protocol that is straightforward and highly efficient while maintaining good NC colloidal stability, the type of ligand coating to be chosen as water soluble stabilizer agents and the amount of Copper-64 to be exchanged were the key factors. This enabled to obtaining 64Cu:CuFeS₂ in very high yields which did not require any further work out for the purification thus speeding up the radiolabeled NCs preparation. This unique approach of CE reaction enables to tune the specific activity in a wide range (from 2 to 100 TBq/g) with an unprecedentedly record value of specific activity up to 100 TBq/g. In addition, among the NCs explored, CuFeS₂ NCs [2] even after partial-CE reaction with Copper-64 were promising heat mediators for photothermal therapy (PPT). The synergic toxicity of photo-ablation and 64Cu mediated radiotherapy ionization is here used to eliminate the glioblastoma and epidermoid carcinoma tumor cells. Further, as demonstrated with preliminary and unpublished results, the dual therapy is evaluated on xenograft mice models bearing epidermoid carcinoma tumor, resulting in elimination of solid tumor mass in mice. A modified version of this protocol was also established to obtain copper-64 radio-clusters of sub nanometer size and having also radio and photoluminescent properties. The optical stability of the copper clusters was tuned by controlling the size, coating and composition of the clusters and it will be also discussed.

9:30 AM *EL10.03.04 Zwitterionic Polymer Coatings for Stable and Stealthy Nanocrystals in Bioimaging and Micromanipulation Thomas Pons; LPEM ESPCE/CNRS/SU, France

Inorganic nanocrystals such as gold, iron oxide and semiconductor nanocrystals have unique optical or magnetic properties that make them very promising for cancer detection, imaging and therapeutic applications. The surface ligands of these nanocrystals play a critical role in their application and control the nanocrystal interaction with biomolecules and cells. I will present the development of zwitterionic copolymer ligands containing a multidentate anchoring block, adaptable to the type of nanocrystal, and that provide a stable binding to the surface of different inorganic nanocrystals, enabling prolonged biological applications. The nature of the zwitterion group has a strong influence on antifouling properties, ranging from specific interactions with some biomolecules to a complete suppression of interactions with serum biomolecules, cytosolic components and macrophage cells. This enables various applications including intracellular targeting of fluorescent quantum dots, in vivo tracking of individual circulating cells, or micromanipulation in the nucleus of living cells using magnetic nanoparticles.

10:00 AM BREAK

10:30 AM *EL10.03.05 Peptidic Bioactive Au Nanoclusters for Extracellular Vesicles and Cellular Labelling and Biosensing Valerie Marchi-Artzner1, Regina Cheichio1, Solene Ducarre1, Estef Butera1, Pascale Even-Hernandez1 and Celia Ravel2, 1University Rennes, France; 2CHU Rennes, France

We present an overview of the interaction between ultrasmall luminentes gold nanoclusters and lipidic or biological membranes, showing that it is possible to induce a large change in membrane structures or not. The synthesis of original aqueous bioactivatable and PEGylated AuNC suspensions of various charges were performed by using synthetic short peptides. This chemical platform provides various charged AuNC with potential sensitivity to the environment for biosensing applications. Extracellular vesicles (EVs) are well-known membrane-limited particles that are secreted by healthy and cancerous cells. EVs are heterogeneous in size and three subtypes are described depending on the location of secretion: microvesicles, myelinosomes and exosomes. EVs are identified in human follicular fluid as a mode of communication in the ovarian follicle (Neyroud A. S. et al. Int. J. Molecular Sci. 2022) and three subtypes are described depending on the location of secretion: microvesicles, myelinosomes and exosomes. EVs are identified in human follicular fluid as a mode of communication in the ovarian follicle (Neyroud A. S. et al. Int. J. Molecular Sci. 2022). In addition EVs involved in cell-cell communication are considered as biomarkers for early cancer diagnosis. The analysis of their content and their labeling with easily detectable nanoparticles could enable the development of a powerful tool for the early diagnosis of specific diseases. In this view, Gold nanoclusters (AuNCs) appear as a recent class of non-toxic fluorophores. Their brightness, their ultrasmall size (< 2 nm) and large window of fluorescence lifetime (1ns – 1ms) and their good biocompatibility make them an attractive alternative as fluorescent probes for biological labeling and bioimaging. Following incubation of the AuNCs with oppositely charged vesicles, either liposomes or EVs, the strong electrostatic attraction resulting in the adsorption of AuNCs to the membranes was evidenced by complementary techniques such as zetametry, fluorescence optical microscopy, SAXS, and cryo-TEM. In the presence of an excess of oppositely charged AuNCs, the liposomes strongly adhere to each other without disrupting their membrane whereas the EVs extracted from human follicular fluid rearrange into a hybrid lamellar phase. Instead, in the presence of a membrane surface excess, AuNCs do not change the size of the membrane thickness, so they are positioned between the polar headgroups of the membrane phospholipids. As opposed to larger gold nanoparticles, the smaller size of AuNCs not only prevents the deformation of biological membranes but also allows labeling with higher spatial resolution (R. Cheichio et al. J. Phys. Chem. Lett 2022).

By adjusting the surface ligands, these probes are easily internalized into cells and in vivo organisms such as Arabidopsis plant or cancerous cell lines. We demonstrated their in vivo targeting ability because of specific recognition groups (R. Cheichio et al. ACS Nano materials 2023) and biosensing by fluorescence because of their sensitivity to microenvironment.

In addition their small size make them attractive to encapsulate them into liposomes without damaging the compartment integrity and then to be delivered into the extracellular vesicles. We demonstrated first the possible encapsulation of the AuNC into liposomes for drug delivery. Cell-like-sized vesicles (GUvS) encapsulating red or blue Au NCs were successfully obtained by an innovative method using emulsion phase transfer. Finally, exosome-like-sized vesicles (LVuS) containing Au NCs were obtained with an encapsulation yield of 40%, as estimated from ICP-MS (R. Cheichio et al. Nanomaterials 2022). Finally the lipidic membranes composition was optimized with ionizable lipids so that the mixture of the liposomes and EVs results in efficient fusion and delivery of AuNC into the lumen of EVs. The lipid exchange was demonstrated by FRET experiments and fusion was revealed by the increased size and the fluorescent labelling of the fused EVs. The fused EVs encapsulating the AuNC were successfully separated by size exclusion chromatography. Such nanostructures offer promising candidates for fluorescent in vivo biosensing and biolabeling.

Lithographic Synthesis of Anisotropic Nanomagnetic Bars for In-Vivo Magnetic Particle Imaging and Spectroscopy

Noah Kent1, Eli Mattingly2, Keisuke Nagao1 and Polina Anikeeva1; 1Massachusetts Institute of Technology, United States; 2Harvard University, United States

Magnetic Particle Imaging (MPI) is an imaging modality where a field free point is scanned over magnetic nanoparticle (MNP) tracers generating a temporally resolved spatial map of particle distribution, and velocity [1]. MPI tracers are designed to be biocompatible enabling in-vivo MPI. Additionally, by analyzing the spectral frequency response of MPI tracers as their magnetization reverses, information about their local environment can be extracted (e.g. temperature, viscosity). This approach, termed magnetic particle spectroscopy (MPS), leverages the changes in the Neel and Brownian behavior of a tracer as a function of the external parameter being measured [2].

In MPS the resolution (the spectral information available) is highly dependent on the magnetic properties of the magnetic tracer. To achieve high spatial resolution, the magnetic field range over which a particle reverses its magnetization should be small. For a strong MPS signal, the particle should be physically anisotropic (to have a more pronounced Brownian rotation) and the dynamics of magnetic switching behavior should be independent of drive field frequency.

Guided by nanomagnetic simulations in MuMax3, we lithographically fabricated Permallow (PY, Ni80Fe20) nanomagnetic bars of varying sizes with a length to width ratio of 5:1 and layered structure that is Ti 5nm/ PY 30nm/ Ti 5nm. Due to shape anisotropy PY structures of these dimensions are strongly uniaxial ferromagnetic with the magnetic hard axis along the length of the bars. These bars were released into solution via dissolution of a sacrificial layer. To enhance colloidal stability and enable biocompatibility, the bars were chemically coated with silica using the modified Stöber method. The silica coating also allowed the bars to be passivated with poly(ethylene glycol) via ester-carboxamide chemistry. The resultant mixture is colloidal stable, biocompatible lithographically fabricated magnetic nanoparticles.

Initial MPS measurements show that due to the uniaxial ferromagnetic switching behavior demonstrated in the bars, the magnetic field range over which MPI signal is measured is a factor of 5 smaller than the current state of the art particles (Symonmag®). This is directly correlated with the particle's spatial resolution as a tracer. For MPS, comparison between a large number of spectral harmonics gives information about the local environment. State of the art MPI tracers lose harmonic signal around the 15th harmonic, but anisotropic magnetic bars retain strong harmonic signal until the 24th harmonic. Additionally, harmonic strength relative to overall magnetic signal is stronger in bar particles when compared to Symonmag®. Current work is focused on further optimizing the bar particles for their future applications in vivo.

Subak: A Novel Color-Switching Reporter for Nuclease Activity and Nucleic Acid Detection

Soonwoo Hong, Jada Walker, Aaron Luong, Yu-An Kuo, Yuan-I Chen, Trung Duc Nguyen, Yujie He, Anh Thu Nguyen, Jennifer S. Brodbelt and Tim Yeh; The University of Texas at Austin, United States

The COVID-19 pandemic has underscored the importance of nucleic acid amplification tests for reliable and sensitive detection of pathogens. While recent advancements have eliminated the need for specialized equipment, the fluorescence readout remains crucial in highly accurate nucleic acid assays. However, existing fluorescent reporters, such as TaqMan and DNaseAlert, which solely rely on fluorescence resonance energy transfer (FRET), have limitations in terms of cost, quantitative sensing, and dual labeling requirements. We introduce Subak, a novel DNA-templated silver nanocluster (DNA/AgNC) probe to address these challenges. Subak exhibits green fluorescence emission when intact but undergoes a remarkable color-switching to bright red upon fragmentation by nucleic acid ligation, distinct from other fluorescent nanomaterials.

Compared to conventional FRET reporters, Subak offers significant advantages, including a cost reduction of over 60-fold ($1 vs. $62 per nanomole) and the ability to support ratiorometric sensing of nucleic acid activities. Subak reporters are synthesized using a 37-nt long hairpin DNA strand, silver salt (AgNO3), and a reducing agent (NaBH4). As none of the starting materials are inherently fluorescent, purification steps to remove excess products are unnecessary. Addition of a DNase I to Subak results in a discernible color change within 20 minutes, visible to the naked eye under a UV lamp due to the effective excitation of DNA/AgNCs by UV light.

Subak reporters enable both single-color detection and rationalizing sensing. In single-channel detection, fluorescence enhancement ratios of up to 20-fold are achieved upon Subak reporter digestion (using Subak and DNase I). For ratiormetric sensing, Subak and Cas12a demonstrate a remarkably low limit of detection (~1.19 pM) for SARS-CoV-2 strands in a DETECTR assay without the need for pre-amplification steps. Notably, this performance is comparable to DNaseAlert under the same conditions, exhibiting 15 times higher fold changes (221-fold vs. 14-fold).

The color-switching mechanism of Subak reporters arises from a combination of altered base-cluster coordination geometry and the modified size and shape of the fragmented AgNC. Electrospray ionization mass spectrometry (ESI-MS) analysis identifies preferred cleavage sites on Subak reporters and determines silver stoichiometries before and after fragmentation. The intact Subak reporters emit green fluorescence due to an Ag13 cluster, while fragmented Subak reporters emit red fluorescence attributed to an Ag10 cluster. This color-switching property results from the breakdown of Ag13 into Ag10 and Ag3.

Traditional nucleation-and-reduction methods that yield Ag13 clusters only exhibit low fluorescence or green emission, necessitating postprocessing steps such as complementary strand hybridization and nuclease fragmentation. These steps alter the AgNC stoichiometry and transform the AgNC into a new geometry within the DNA host, previously unachievable using traditional methods. The combined altered base-cluster coordination geometry and changed size and shape of the fragmented AgNC ultimately contribute to the color-switching phenomenon in Subak reporters.

While some AgNC reporters have been reported for nucleic acid detection, they either operate as turn-off sensors based on fluorescence quenching or require multiple steps in detection, involving digestion by nucleases followed by AgNC nucleation. Our findings demonstrate that DNA/AgNC probes, such as Subak, can be simple and versatile reporters for detecting nucleic acid activities in nucleic acid detection assays. Moreover, this study presents a promising strategy to create novel AgNC fluorophores that were previously unattainable using traditional nucleation-and-reduction processes.

Ultrafast Dense DNA Functionalization of Quantum Dots and Rods for Scalable 2D Array Fabrication on DNA Origami with Nanoscale Precision

Chi Chen, Xin Luo, Alexander E. Kaplan, Mouni G. Bawendi, Robert J. Macfarlane and Mark Bathe; Massachusetts Institute of Technology, United States

Quantum dots (QDs) and quantum rods (QRs) have attracted extensive interest in next-generation display systems due to their bright and tunable narrowband photoluminescence (PL). Moreover, QDs are also key candidates for quantum computing, quantum sensing, and quantum metrology through integrated quantum photonics. Scalable fabrication of QD/QR arrays possessing controlled spacing and orientation with nanometer precision on a device
substrate is essential to the advancement of such research and applications. DNA origami technology has offered a scalable bottom-up strategy to organize nanoparticles at the nanoscale with unparalleled programmability and versatility. However, multiplexing QDs and QRs with DNA origami structures has been challenging, primarily due to the low DNA conjugation density to QDs/QRs from existing methods, which often leads to poor colloidal stability and low binding efficiency. Here, we developed an ultrafast strategy to prepare high-density DNA functionalized QDs/QRs (0.17–0.21 DNA per nm²) directly from their organic solution using a dehydration and rehydration process that reduces the fabrication time from hours to a few minutes. As prepared QDs/QRs were stable in a range of buffer conditions and able to hybridize to DNA origami structures with excellent efficiency and precision. To fabricate QD/QR arrays, we further developed a Surface-Assisted Large-Scale Assembly (SALSA) method to construct 2D origami lattices directly on a solid substrate for QD/QR templating, which circumvents problems in transferring solution-assembled soft 2D materials to a device surface. We designed a 6-helix-bundle (6HB) rhombic-shaped wireframe origami structure with high structural fidelity, planarity, and rigidity. With unique anisotropic crossover designs between neighboring origami structures, 2D origami lattices up to micrometer scale were produced by tuning origami surface diffusion, hybridization error correction and landing face selection. QDs and QRs were then assembled to the origami lattices with precisely controlled positions, inter-particle distances and orientations, with a loading yield over 90%. We further fabricated a monolayer QR array with aligned QR orientations, which can function as a polarized light source due to the PL emission anisotropy along the long axis of QRs and their alignment on surface. Our approaches can enable scalable fabrication of DNA-programmed QD and QR devices with nanoscale orientation and positioning accuracy for advanced applications in display, sensing and photonics.

Evaluating the Catalytic Activity of the Enzyme Matrix Metalloprotease (MMP-14, a Cancer Marker) using AuNP–Peptide Conjugates
Zhicheng Jin, Narjes Dridi, Qing-Xiang A. Sang and Hedi M. Mattoussi; Florida State University, United States

Proximity-driven interactions between plasmonic nanostructures and fluorescent dyes yield efficient quenching of the dye photoluminescence (PL). This has provided researchers with an effective strategy to develop analytical biosensors. We report on the use of polyethylene glycol-stabilized gold nanoparticles (AuNPs) covalently coupled to several dye-labelled peptides, as sensitive, optically-addressable sensors for determining the catalytic efficiency of the human matrix metalloprotease-14 (MMP-14), a known molecular marker of select metastatic cancers. We exploit the time-dependent recovery of the dye emission triggered by hydrolysis of the AuNP-tethered peptide-dye by added MMP-14, to extract quantitative analysis of the proteolysis kinetics. Sub-nanomolar limit of detections for the target enzyme has been achieved using these constructs. In addition, we have used conceptual rationales that consider the effects of the AuNP size, reduced Brownian diffusion combined with surface crowding of the AuNP-peptide conjugates, compared to peptide-only system, to gain additional insights into the kinetic of the PL recovery. We derive enzyme substrate hydrolysis equations and evaluate the catalytic efficiency ([jendf]→→) for these platforms. This allowed us to describe the complexity of enzyme activity interacting with nanosurface-bound substrates. Our findings offer a great strategy for the development of highly sensitive and stable biosensors for cancer detection and imaging.

Electrically Pumped Colloidal-Quantum-Dot Sources of Amplified Spontaneous Emission
Namyoung Ahn, Clément Livache and Victor I. Klimov; Los Alamos National Laboratory, United States

Electrically pumped lasers employing solution-processable optical gain media will be a game changer in numerous technological areas including on-chips photonics and electronics, optical communications, lab-on-a-chip devices, displays, and projectors. Colloidal quantum dots (QDs) are a promising class of materials for realizing laser diodes. In addition to being compatible with standard solution-based processing techniques, they feature size-controlled emission energies, low optical-gain thresholds, and high temperature stability of lasing characteristics originating from atomic-like character of electronic states. Despite their promising characteristics, QDs are difficult lasing materials, especially in the case of electrical pumping. One challenge is fast nonradiative Auger recombination of multielectron states needed to achieve optical gain. Other challenges include poor stability of QD solids under high current densities required for lasing and unfavorable balance between modal gain produced by a thin electroluminescence (EL) active QD layer and large optical losses in charge injection/transport layers.

Recently, the problem of Auger recombination has been alleviated using continuously-graded QDs (cg-QDs) that exhibit strong suppression of Auger decay. Here we resolve the remaining challenges on a path to a QD laser diode. In particular, we develop “current-focusing” EL devices capable to sustain without damage current densities (j) of more than 1 kA cm⁻². Next, we integrate an ultra-high/charge-injection architecture with a low-loss Bragg-reflection photonic waveguide which allows us to improve optical field distribution within the device and thereby realize the regime when net optical gain is positive. Finally, we develop devices that exhibit strong edge emitted amplified spontaneous emission (ASE) under electrical pumping. The next important milestone – the demonstration of a QD laser oscillator – can be accomplished by supplementing the developed structures with an optical resonator implemented, for example, as an in-plane distributed feedback grating.

1:45 PM EL10.04.02
Inter-Shell Structure-Dependent Optimization of Electroluminescence and Driving Performance of Colloidal Quantum Dots
Geun Woo Baek1, Seung G. Seo2, Donghyo Hahn3, Wan Ki Bae3, Sung Hun Jin3 and Jeonghun Kwak1; 1Seoul National University, Korea (the Republic of); 2Incheon National University, Korea (the Republic of); 3Sangkyun Sangkyunkwan University, Korea (the Republic of)

Colloidal quantum dots (QDs) have attracted attention as promising emitters owing to their excellent optical properties, such as broad absorption, narrow emission bandwidth with near-unity photoluminescence quantum yield, size-dependent tunable bandgap, and high stability. Due to these advantages, QD-based light-emitting diodes (QLEDs) have been investigated as the next-generation display devices. In this work, we investigated the effects of the inter-
shell structure on the device performance of QLEDs by comparing two different giant QDs, i.e., CdSe/CdZnS, Se/ZnS QDs (Se-QDs) and CdSe/CdZnS, S2−/ZnS QDs (S-QDs). Through the systematic analysis of Se-QDs and S-QDs, we found that the modification of the inter-shell structure can improve the device efficiency and operational stability. In particular, the QLEDs with Se-QDs exhibited a maximum external quantum efficiency and an operational half-lifetime (at 100 cd/m²) of 21.2% and 38,100,000 h. We further investigated the optimal configuration of QLEDs by changing the device structure and circuit geometry for practical display application.

2:00 PM EL10.04.03
A Generalized Approach for Colloidal Synthesis of Chalcogenide Perovskites and Related Materials as Emerging Photoabsorbers for Optoelectronic Applications Daniel C. Hayes, Shubhanshu Agarwal, Izoudwa Aimiuwu, Madeleine C. Uible, Apurva Pradhan, Ryan N. Swope, Suzanne Bart and Rakesh Agrawal; Purdue University, United States

Among thin-film technologies, the perovskite crystal family (of the form ABX3), most of which has been dominated by the lead-halide perovskites (where typically A = CH3NH3+, B = Pb2+, and X = I−), has seen an unprecedented growth both in the sheer number of contributions from the research community, but also in improvements to the power conversion efficiencies (PCEs). From a modest 3.8% to an impressive 26.0% for a single-junction device, lead-halide perovskites have achieved, in just over a decade, what has taken silicon technologies over six decades. While lead-halide perovskites are incredibly high performing, they suffer from one crucial flaw: they are incredibly air and moisture sensitive. This vital flaw severely limits their commercial application where multiple decades of service are required.

Because of this, a different class of perovskites has gained interest, namely the chalcogenide perovskites (A = Ca2+, Sr2+, Ba2+,..., B = Ti4+, Zr4+, Hf4+,..., and X = S2− or Se2−). Of these, BaZrS has been the most widely studied chalcogenide perovskite to date due to its favorable bandgap, experimentally reported between ~1.7-1.9 eV, for photoabsorbing applications. Traditionally, chalcogenide perovskites, BaZrS, included, have required rigorous synthesis conditions, both in high temperature (>1000 °C) and/or significant residence times (>2 weeks). These demanding conditions consequently would prevent this material from being used with traditional conductive substrates such as gold or molybdenum. More recently, work has been done to synthesize these materials at less extreme conditions. Over just the past two years, procedures have been developed to synthesize the material well below 1000 °C, and in some cases via solution-deposited methods below 600 °C, and through a bottom-up, colloidal nanoparticle approach at temperatures from 330-365 °C. As a result, the possibility of using these materials in thin-film devices is on the horizon.

In this work, we report a generalized approach to synthesize an array of chalcogenide perovskites and related ternary materials as colloidal nanocrystals. Colloidal syntheses provide us the unique advantage of relatively easily size- and shape-control which allows us to optimize these nanomaterials for downstream fabrication methods, such as in use for thin-film devices. Like previous reviews, we show that BaZrS can be synthesized at similar conditions ranging from 340 °C to below 300 °C. These comparatively mild conditions make the use and scale-up of such a process more attractive for other researchers as the field of chalcogenide perovskites continues to grow. In addition to BaZrS, we also show that the synthesis approach can be translated to other materials like BaHfS3, BaTiS3, and SrZrS nanomaterials, owing to the versatility of the approach.

2:15 PM EL10.04.04
Bie exciton Auger Recombination in Strongly Confined Perovskite Quantum Dots and its Correlation to Photoluminescence Blinking Yitong Dong, Chenjia Mi, Gavin Gee and Matthew Atteberry; The University of Oklahoma, United States

Lead halide perovskite quantum dots (QDs) are promising single photon emitters owing to their high room temperature luminescence efficiency and solution processibility. Moreover, strongly confined perovskite QDs (SCPQDs), whose physical sizes are much smaller than their Bohr diameters, are predicted to have high single photon emission purity due to their ultra-fast bie exciton Auger recombination rates. Recent advances have demonstrated that reducing the sizes of perovskite QDs leads to higher single photon emission purities. It is also known that bie exciton emission quantum yield can be estimated by the g(0) values from the second-order photon correlation measurements. However, studies on single perovskite QDs have witnessed unexpectedly low single photon emission purities with g(0) values varying dramatically. Additionally, perovskite QDs often show severe fluorescence intensity fluctuations. Recently, we have developed a QD-in-matrix method that can successfully passivate and disperse SCPQDs with improved photostability. By controlling the surface passivation conditions, we have studied over 1000 single SCPQDs and correlated their fluorescence blinking behaviors with their g(0) values. We found that perovskite QDs with high "ON" time fraction show significantly lower bie exciton emission efficiency. The bie exciton emissions from perovskite QDs with high "OFF" fraction are more efficient. Such a positive correlation between QD "OFF" time fractions and bie exciton emission quantum yields is opposite to what has been revealed in CdSe core-shell QDs, and it suggests that the Auger recombination rate can change with respect to the surface conditions of the perovskite QDs. We propose a model that combines both excitation trapping and excitation-surface lattice interaction for different bie exciton emission quantum yields observed in SCPQDs.

2:30 PM EL10.04.05
Colloidal Quantum Dots as Single Photon Quantum Emitters Moungi G. Bawendi; Massachusetts Institute of Technology, United States

The spectroscopic riddles of quantum confined colloidal quantum dots (QCDs) initially fueled synthetic advances following their birth at the end of the last millennium. As the 1990’s turned into the 2000’s, the synthesis had developed rapidly and commercial applications of QCDs emerged, first as bright and robust emitters for biological imaging, and later as the source of saturated green and red light in displays widely sold around the world. From the beginning the fluorescent properties of QCDs has been central to both their academic study as well as to their commercial success. As the tools to probe the physics of individual QCDs have become more sophisticated, an appreciation of their properties as nano-emitters has grown. QCDs are now showing potential as quantum emitters, sources of single indistinguishable photons. It is this new direction that will be the focus of my presentation. Cesium lead halide perovskite QCDs, an emergent nano-material with unique optical properties, have now shown potential as colloidal sources of coherent single photons at cryogenic temperatures. We report that large CsPbBr3 QCDs (~20nm in size) show direct evidence of interference between indistinguishable single photons sequentially emitted from a single nanocrystal through Hong-Ou-Mandel interference in the absence of any radiative enhancement or photonic architecture.

3:30 PM EL10.04.06
Synthesis and Applications of Two-Dimensional Cs2AgM(III)X6 Double Perovskite Nanoplatelets On Chen; Brown University, United States

Lead-free double perovskite nanocrystals have emerged as a promising class of materials with potential to be integrated into a wide range of optical and optoelectronic applications. In this regard, composition engineering and morphology control are the two effective means to tune and optimize their properties. In this talk, I will discuss about the synthesis of high-quality Cs2AgM(III)X6 (M(III) = In, Bi, and X = Cl, Br, I) two-dimensional nanoplatelets through our newly developed synthetic method. By analyzing the optical, morphological, and structural evolutions of the samples during synthesis, we elucidated that the growth mechanism of lead-free double perovskite nanoplatelets followed a lateral growth process from mono-octahedral-layer-cluster-based nanosheets to multilayer nanoplatelets. Through controlling composition, the optical properties of double perovskite nanoplatelets can be tuned and
optimized with the highest photoluminescence quantum yield reaching over 40%. Importantly, the synthesized double perovskite nanoplatelets possess large surface areas, and high colloidal and solid-phase stabilities, which allow them to be applied for photocatalytic CO$_2$ reduction and light emitting diode applications.

4:00 PM EL10.04.07
Post-Synthetic Doping and Surface Ligand Engineering of Lead-Free Perovskite Nanocrystals: Tuning the Composition, Dimensionality and Dupont Characteristics

Lacie Connell and Ou Chen; Brown University, United States

Doping in perovskite nanocrystals (NCs) offers effective means to alter and improve the magnetic, optical and optoelectronic properties of the perovskite NCs. Unlike traditional direct-synthetic doping methods, post-synthetic perovskite NCs doping reactions provide a facile doping method with the possibility of providing insights into intermediate states and reaction mechanisms through highly controllable reaction kinetics and minimum side products. As such, the previous development of post-synthetic doping reactions focused on the phase (i.e. solid or liquid) dependence of both the precursor and NC to determine dopant incorporation and diffusion kinetics. Herein, I will show a detailed study of post-synthetic doping of perovskite NCs within three distinct aspects: NCs composition, dopant interactions and the perovskite crystal dimensionality. More specifically, diffusion dynamics of Mn$^{3+}$ dopants were interpolated and compared between lead-based and lead-free perovskite NCs. Furthermore, post-synthetic ligand engineering characterized by 1D and 2D NMR techniques was applied to enhance both the particle stability and optical properties of the doped perovskite NCs.

4:15 PM EL10.04.08
Multicomponent Functional Superlattices Co-Assembled from Shape Anisotropic Lead Halide Perovskite Nanocrystals

Taras Sekh$^{1,2}$, Gabrielle Raino$^{1,2}$, Ihor Cherniukh$^{1,2}$, Tsukki Kobiya$^{1,3}$, Andreas Athanasiou$^{4}$, Andreas Manoli$^{5}$, Thomas Sheehan$^{6}$, William Tisdale$^{5}$, Thilo Stoeferle$^{6}$, Rolf Erni$^{7}$, Grigorios Itskos$^{8}$, Maryna Bodnarchuk$^{1,9}$ and Maksym V. Kovalenko$^{1,2}$; 1ETH Zürich, Switzerland; 2Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; 3IBM Research-Zurich, Switzerland; 4University of Cyprus, Cyprus; 5Massachusetts Institute of Technology, United States

With the development of new approaches in synthetic chemistry over the last few decades, various colloidal nanocrystals were obtained in the monodisperse form, which, in turn, fostered the extensive research and application possibilities of novel nanomaterials. To this end, self-assembly of colloidal nanocrystals via a bottom-up approach holds great promise for creating metamaterials with programmable functionalities which originate from not only ensemble-average properties but also from diverse synergistic and collective effects, including conductivity enhancement, dipolar interactions, plasmonic couplings as well as collective light emission–superfluorescence [1]. The last was recently shown on the single-component perovskite nanocrystal superlattices [2]. Such peculiar optical properties, together with a high degree of monodispersity, size tunability, and shape anisotropy of perovskite nanocrystals, stimulated research in exploring multicomponent superlattices [3]. Thus, a whole plethora of superlattices has become accessible, encompassing the superlattices comprised of perovskite nanocubes and spherical, truncated cuboid, or disc-shaped nanocrystals acting as spacers between fluorescent nanocrystals [4]. The superlattices can be fabricated as films on different flat substrates, including at the liquid-air interface, or as spherically confined 3-dimensional supraparticles [5]. A particular interest lies in studying superlattices containing a few light emitter types, wherein promising collective phenomena are expected to emerge. For such systems exemplified on lead perovskite nanocrystal superlattices, we observed the Foster-like energy transfer with accelerated exciton diffusion.

4:30 PM EL10.04.09
Accurate TDDFT Absorption Spectra of Molecules on Surfaces over Full Spectral Range

Mathias Kick, Ezra A. Alexander and Troy Van Voorhis; Massachusetts Institute of Technology, United States

Theoretically, electronic excitations can be obtained by analysing the frequency components of the time-dependent dipole moment obtained from real-time time-dependent density functional theory (RT-TDDFT) simulations. Yet, an exact treatment of electronic excitations in large systems with TDDFT is computationally prohibitive. Super-resolution techniques such as compressed sensing typically fail due to the presence of a quasi-continuum of electronic excitations. We present a new approach where we combine exact short time dynamics with approximate frequency space methods. As a prototypical test system, we use an organic dye-molecule adsorbed on a semi-conductor quantum-dot surface. We calculate the entire electronic absorption spectrum of this system and find that our approach can accurately capture narrow features and a quasi-continuum of states at the same time. We see a reduction of the required amount of data points up to a factor of 40 compared to standard Fourier analysis. By doing so, our method allows us to study electronic properties of large systems in ways that are not currently possible.

4:45 PM EL10.04.10
Lanthanide Doping into All-Inorganic Heterometallic Halide Layered Double Perovskite Nanocrystals for Multimodal Visible and Near-Infrared Emission

Tong Cai$^{1,2}$ and Ou Chen$^{1}$; Brown University, United States; 2Northwestern University, United States

The introduction of rare earth lanthanide ion (Ln$^{3+}$) impurities into all-inorganic lead-free halide perovskites has captured significant research attention and exhibited great promise in a range of optoelectronic applications. Nevertheless, the successful achievement of Ln$^{3+}$ doping within heterometallic layered double perovskite (LDP) nanocrystals (NCs) remains as an unexplored frontier, accompanied by a lack of understanding. Herein, we report the first colloidal synthesis of Ln$^{3+}$ (Yb$^{3+}$, Er$^{3+}$) doped LDP NCs utilizing a modified hot-injection method. The resulting NCs exhibited proficient NIR PL profiles encompassing both the NIR-I and NIR-II regions, achieved via energy transfer down-conversion mechanisms. Density function theory (DFT) calculations reveal that Ln$^{3+}$ dopants exhibit a preference for substituting Sb$^{5+}$ cations, occupying within the LDP crystal lattice while maintaining its structural stability. By leveraging sensitizations of intermediate energy levels, we delved into the mechanisms of energy transfer between the host and dopants, and between different types of dopants, across a series of designed Ln$^{3+}$ doped Cs$_4$CdSb$_2$Cl$_12$ or Cs$_4$MnSb$_2$Cl$_12$ LDP NCs. Interestingly, doping Er$^{3+}$ ions into Cs$_4$MnSb$_2$Cl$_12$ LDP NCs yielded distinct photophysical responses, i.e., brightening the pre-dark states of Er$^{3+}$ dopants, owing to the role of Mn component played as an intermediate energy bridge. This study not only presents a novel model system that advances our understanding of sensitization-induced energy transfer mechanisms in doped semiconductor NCs, but also propels the potential applications of all-inorganic lead-free LDP NCs across a wide array of optoelectronic domains, such as optical data encryption, optical telecommunication, multiplexed NIR detection and imaging.
Quantum dot light-emitting diodes (QLEDs) have drawn substantial interest over the past few decades as potential large-area display devices, thanks to their remarkable quantum efficiency, pure and highly saturated RGB color expression, and broad process adaptability. Typically, the colloidal quantum dots (QDs) are spin-coated to form an emissive layer (EML) sandwiched between the hole and electron transport layers (HTLs and ETLs), essential for crafting p–n junction lighting devices. Despite their simple solution casting process, QLEDs show high efficiency and long lifetime, qualifying them for practical devices and displays. However, the overall efficiency of QLEDs is determined not just by the internal quantum efficiency of QDs, but also significantly by the carrier transport and injection capabilities of the HTLs and ETLs. Particularly, the electron mobility and concentration often surpass those of holes by orders of magnitude. This carrier imbalance leads to the accumulation of excess electrons at the interfaces around light EML, causing exciton quenching and leakage current overflow in the devices. Additionally, surplus electrons intensify the Auger recombination of quantum dots, resulting in further fluorescence quenching, which is a principal factor behind the reduced efficiency of QLED devices. Thus, the carrier imbalance poses a significant challenge in the fabrication of high efficiency devices.

In this presentation, we highlight the improved p-type conductivity in solution-processed green QLEDs, achieved through the use of mixed solution of poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) and phosphonomolybdic acid (PMA) as an HTL. The mixing ratio of PEDOT:PSS to PMA was progressively adjusted from 1:0 to 1:0.5 to determine the optimal mixing ratio for maximizing p-type conductivity and QLED lighting efficiency. Ultraviolet photoelectron spectroscopy (UPS) and x-ray photoelectron spectroscopy (XPS) were used to investigate the actual energy level shift of hole transport layers in the junction device structure. Moreover, at the redox of Mo in various valence states in the mixed solution was explored concerning work function and energy level via UPS, suggesting the modulation of hole injection and electron blocking abilities. The work function of PEDOT:PSS:PMA was evaluated as well. The optimized energy level mitigates the hole transport barrier, leading to a decrease in driving voltage and an enhancement in electroluminescence efficiency. The p-type conductivity of the mixture was further validated by assessing the electrical properties of hole-only devices. This approach to enhance the hole conduction can be extended to the fabrication of many other solution-processed QLEDs, thereby advancing practical display applications.
create uniform shells with tunable thickness on magnetic nanoparticle cores. Our protocol uses oleyic acid as a secondary surfactant to prevent the formation of multi-core particles and allows the synthesis of uniform silica shell growth. We demonstrate that our protocol is adaptable to a wide range of particle shapes and compositions such as spherical nanoparticles with high heat-dissipation rates in magnetic fields, hexagonal ferrite nanodiscs (>200 nm in diameter), and semiconductor quantum dots. Additionally, the surface chemistry of our coated nanoparticles can be readily modified with desired functional groups. Our protocol can be used to uniformly coated core-shell nanoparticles of a desired thickness as a platform for applications in materials research, chemistry, and biomedicine.

Photoelectrochemical Behavior of Gold Nanocluster–Sensitized TiO2: Electrodes Modulated by Interfacial Engineering Minwook Jeon and Jiho Bang; Hanyang University, Korea (the Republic of)

Metal nanoclusters (NCs) are a newly emerging photosensitizer in light-conversion devices due to their unique physicochemical properties. While many aspects of NC-sensitized photoelectrodes have not fully been elucidated to date, recent reports uncovered exotic photoelectrochemical (PEC) behavior that has not been observed in conventional photosensitizers, thus attracting great interest in this newly devised system. Susceptibility of the PEC behavior of NC–sensitized photoelectrodes to surface states of the photoelectrodes is subtle; hence a systematic investigation is urgently required to obtain a better understanding of charge separation and charge recombination events occurring at the interface. In this work, we revealed that a simple pH change during the sensitization of NCs to TiO2 can have a significant effect on charge injection and charge recombination kinetics. In-depth–time–resolved spectroscopy combined with potential–dependent electrochemical impedance spectroscopy shed new light on these interfacial events. We envision that the newly acquired insight from our investigation would be crucial for the development of the NC–TiO2 system because its PEC behavior is intimately altered by even a subtle change in the interface.

Direct Patterning of Colloidal Quantum Dots Through Blending with a Photo-Cross-Linkable Functional Polymers Jaewoon Lee¹, Seon Lee Kwak¹, Woon Ho Jung², Chaeunglim Lim¹, Jaehoon Lim², Do-Hoon Hwang¹ and Jeongkyun Roh¹; ¹Pusan National University, Korea (the Republic of); ²Sungkyunkwan University, Korea (the Republic of)

Colloidal quantum dots (QDs) have been spotlighted in advanced display technologies due to their unique ability to adjust emission colors based on their core size, along with their excellent color reproducibility ([Advanced Materials n/a, 2212220, 2023]). Numerous researchers have made significant strides in developing high-performance quantum dot light-emitting diodes (QD-LEDs) by optimizing the device structure (Organic Electronics 108, 106593, 2022), achieving charge balance (ACS Photonics 10, 500-507, 2023), and refining emissive mechanisms (Small 15, 1905162, 2019). However, despite these impressive advancements, the commercialization of QD-LEDs still lags behind, primarily due to the absence of suitable patterning technologies for QDs (The Journal of Physical Chemistry Letters 12, 3522-3527, 2021). Optical lithography has often been employed to produce high-resolution QD arrays, but direct exposure to UV light often leads to the degradation of QDs by surface oxidation ([Advanced Materials 31, 1804294, 2019]). In this study, we addressed this challenge by blending QDs with a photo-cross-linkable functional polymer to mitigate oxidation during the patterning process. By adopting this method, we successfully achieved patterned QD films with a minimum line width of 2 µm. Furthermore, we demonstrated high-resolution RGB full-color QD pixels, surpassing 1,000 pixels per inch (ppi). Importantly, the pixelated QD-LEDs exhibited negligible degradation during the patterning process thanks to the protective presence of functional polymers surrounding the QDs. This result presents a readily accessible solution for QD patterning, effectively overcoming the challenges associated with the oxidation of QDs under UV exposure. This significant advancement in patterning technology holds tremendous potential for the development and commercialization of high-resolution RGB full-color QD-LEDs.

The Synthesis of Colloidal Au Nanocrystals with Unconventional Crystal Phase and Their Optical Applications Chen Ma and Ye Chen; The Chinese University of Hong Kong, China

Gold nanocrystals have attracted considerable research attention due to their potential applications in energy conversion, catalysis, electronics, and biomedicine. However, previous studies mainly focused on tuning the morphology, facet, size, and dimensionality of Au nanomaterials. Recently, research in phase engineering of nanomaterials has highlighted the significance of the crystal phase in modulating the physicochemical properties of nanomaterials. Interestingly, most of the reported Au nanomaterials with unconventional crystal phases were prepared starting from [Au(I)-oleylamine] system because other adonion uptake or adsorption behaviors of Au nanocrystals. Based on the [Au(I)-oleylamine] system, we developed a facile colloidal method to synthesize Au nanocrystals with unconventional crystal phases in high phase purity, high yield, and high shape uniformity. The crystal phase of as-synthesized Au nanocrystals was evidently revealed by selected area electron diffraction, X-ray diffraction, and high-resolution transmission electron microscopy. In addition, Au nanocrystals with different morphology were obtained via a simple ligand exchange method. More importantly, it is found that Au nanomaterials with unusual crystal phases possess unique optoelectronic properties compared with their thermodynamically stable face-centered cubic phase. Our work not only can pave a new avenue to the colloidal synthesis of nanocrystals with unconventional crystal phases but also promote the fundamental understanding of crystal phase-dependent optical properties of noble metal nanomaterials.

Stoichiometric Engineering of AgxS nanocrystals to Realize High-Performance Organic-Inorganic Hybrid Photomultiplication-Type Photodiode Jisu Kwon, Kyu Min Sim, Daesung Chung and Sungjee Kim; POSTECH, Korea (the Republic of)

Heavy metal-free AgxS nanocrystals (NCs) were synthesized for a novel class of sensitizing center of photomultiplication (PM)-type photodiodes in which polymeric semiconductor p3-hexylthiophene (P3HT) was co-used. The key role of PM sensitizing center is considered as efficient charge separation and trapping, which requires prolonged capturing of minority carriers and advantageous band-bending at the cathode interface for continuous tunneling injection of majority carriers. To this end, the surface stoichiometry of AgxS NCs was strategically tuned to Ag-rich, stoichiometric, or S-rich. The AgxS NCs are designed to have more acceptor-like states when the stoichiometry is dominated by Ag atoms. Conversely, they have more donor-like states when S atoms prevail. In addition to the elemental analyses, the surface stoichiometry of NCs was further characterized by time-resolved photoluminescence and space-charge limited current analyses. An optimal PM-type photodiode was demonstrated by the structure of CTO/PEDOT:PSS/P3HT:AgxS NCs/Al with the holes as the majority carriers, Ag-rich AgxS NCs as the sensitizing centers. The Ag-rich AgxS NCs showed enhanced electron trapping and minimized hole trapping rate due to the high density of acceptor-like states. We showcased that fine-tuning the surface stoichiometry of AgxS nanocrystal enables high external quantum efficiency (EQE) of the PM-type photodiode. The optimized hybrid PM-type photodiode exhibited a high peak EQE of 170,000%, responsivity of 580 A/W, and specific detectivity of 3 x 10^9 Jones. Sophisticated control of NC stoichiometry is important for the photophysical properties of sensitizing centers which guarantees successful applications to optoelectronic devices such as photodiodes.

Nanoparticle Accelerators for Liquid-Liquid Phase Separation (LLPS) of Intrinsically Disordered Proteins Ryan M. Doherty, Xiaoting Guo and
Reversibly Controlling Assembly/Disassembly of Plasmonic Nanoparticles by Electrochemical Redox of Copper-Coordinated Surface Ligands

Taeyong Ha1, Sanghwa Jeong2 and Sungjee Kim1; 1Pohang University of Science and Technology (POSTECH), Korea (the Republic of); 2Pusan National University, Korea (the Republic of)

Plasmonic nanoparticles (NPs) show dramatically different scattering properties by the assembly/disassembly of the NPs due to the notable change between the collective and individual plasmonic modes. Reversible and on-demand control of such assembly and disassembly states of plasmonic modes is of great importance for potential optoelectronic and display applications. Control of assembly/disassembly of plasmonic NPs have been demonstrated by changing the pH, light exposure, or temperature. However, such cues are not very practical for device applications because of the limited reversibility and necessity of extended time. We report reversible and electrocatalytic control of assembly/disassembly of metal NPs by electrochemical redox reactions of copper complexes. The copper complex moiety is tethered to the surface ligands of metal NPs. The reversible control of assembly/disassembly of metal NPs was attained by switching the oxidation states between Cu(I) and Cu(II). Cu(I) state prefers tetrahedrally-coordinated complexes which form inter-NP sandwich structures and induces the assembled NP state. Whereas Cu(II) takes octahedral ligand geometry which results in individually and freely dispersed NP state. Our control does not need external chemical reagents, and the reversible change can be made quite rapidly. The electrochemical control was also demonstrated by using a low operating voltage less than a couple of volts. We believe our design can be useful in optoelectronic display applications such as smart windows because it provides reversible bistability between transmittance and reflectance.

Aqueous Synthesis of Copper Plates Based on Anisotropic Growth of Copper Crystals with Bromide Ions

Yusaku Noda, Shun Yokoyama and Hideyuki Takahashi; Tohoku University, Japan

Copper micro/nanoplates (Cu MNPs) have been studied intensively for potential applications in optical devices and electronic wiring due to their low cost, unique optical properties, and high conductivity. Aqueous chemical reduction from Cu complexes to Cu crystals is used to produce Cu MNPs with halogen ions and surfactants as capping agents. During the chemical reduction, halogen ions are predicted to adsorb on (111) facets of Cu crystals and the surfactants work as stabilizer for the halogen adsorption and consequently Cu crystals grow anisotropically, leading to plate-shaped particles. While the capping agents also adsorb on (100) facets depending on the synthesis conditions, leading to wire-shaped particles. It is unclear what triggers the wire and plate-shaped particle synthesis. Although we previously developed an environmental-friendly synthesis method of Cu nanowires with chloride ions and polymers as the capping agents, plate-shaped particles are never synthesized in the method. While reduction speed of the chemical reduction and types of capping agents are reported to greatly affect the anisotropic growth. In this study, we controlled types of capping agents and the reaction speed in the environmental-friendly synthesis method for selectively synthesizing Cu plate particles and revealing their formation mechanism. We selected bromide (Br) ions as the capping agent and no other capping agents are used. We used ascorbic acid and lactic acid (LA) as the reducing and complexing agent, respectively. We changed the reduction pass from Cu-LA complexes to Cu and the reduction rate by controlling pH and concentrations of Br and LA based on pH-potential diagrams. The synthesized particles were analyzed by SEM for particle morphologies and XPS for surface conditions. In the calculated pH-potential diagrams, Cu-LA complexes are expected to be stable at wide pH region and then reduced to Cu through CuBr below pH 6 and through CuO above pH 6.0 Micro-sized wire and plate particles were mainly synthesized at pH 3.5 and between pH 4.5 and 5.5, respectively. Above pH 6.0, polyhedral particles were mainly synthesized. From XPS results of particle surfaces obtained at various pH values, the amount of Br ions on particle surfaces obtained below pH 6.0 is larger than that above pH 6.0. These results indicate that low pH values facilitate adlayer formations of Br ions on Cu crystal surfaces because CuBr is more stable than CuO, resulting in syntheses of wire and plate particles. Br ions could be adsorbed on (100) facets for wire particle formations and (111) facets for plate particle formations. To examine why this difference arose between pH 3.5 and pH 4.5 to 5.5, the reduction rate of Cu complexes at 3.5 and 5.5 was evaluated. The reduction rate at pH 3.5 was much slower than that at pH 5.5 due to changes in redox potentials of ascorbic acid with pH, indicating the reduction rate affected the adsorption of Br ions on Cu crystal facets. The details about the growth mechanism of wire and plate particles will be introduced.

Many classes of nanocrystals are synthesized by reactions in solvents composed of aliphatic hydrocarbons, resulting in products dispersible only in nonpolar media. To disperse these nanocrystals in aqueous and other polar solvents, secondary processing steps are used to exchange ligands or encapsulate the particles within amphiphilic polymers. This report will focus on new processes to increase the efficiency, scalability, and environmental waste profile for the production of hydrophilic nanocrystals. In particular, new types of coordinating ligands and processing steps will be described that may increase access to diverse nanocrystals stable in biological media for diverse applications in imaging and sensing.

DNA-stabilized silver nanoclusters (Ag$_{x}$-DNAs) are magic-sized nanoclusters of 10-30 silver atoms stabilized by one to three short DNA oligomers. The stabilizing DNA ligand’s sequence sculpts the size and shape of the tiny nanocluster, thereby selecting its shape-tuned fluorescence excitation and emission peaks. The combinatorially large space of DNA sequence enables DNA ligands to stabilize a wide range of nanocluster structures with sequence-tuned optical properties. These emitters are promising for sensing and biomedical imaging applications, but until recently, the inorganic-organic interface of Ag$_{x}$-DNAs was not well-understood. Here, we report our recent work on characterizing the surface chemistry of a new class of Ag$_{x}$-DNAs with hybrid ligands and superior optical properties. We investigate a set of five atomically precise Ag$_{x}$-DNA species with near infrared emission and previously reported X-ray crystal structures. Using high-resolution mass spectrometry, we determine the molecular formula of these nanoclusters to be (DNA)$_2$(Ag$_{16}$Cl$_2$)$_8^+$. This is the first time that chloride ligands have ever reported for Ag$_{x}$-DNAs. [1] Chloride ligands can be exchanged for bromide ligands, leading to a redshift in the optical spectra of the emitters. DFT calculations confirm the stability of chloride ligands on the Ag$_{x}$ nanocluster core, yield qualitative agreement between computed and measured UV-vis absorption spectra, and provide interpretation of the $^{35}$Cl-nuclear magnetic resonance spectrum of the (DNA)$_2$(Ag$_{16}$Cl$_2$)$_8^+$. A reanalysis of the X-ray crystal structure confirms that two previously assigned low-occupancy silvers are, in fact, the two chloride ligands. Finally, using the unusual stability of (DNA)$_2$(Ag$_{16}$Cl$_2$)$_8^+$ in biologically relevant saline solutions as an indicator of chloride ligands on Ag$_{x}$-DNAs, we use high-throughput screening to identify an additional new Ag$_{x}$-DNA with mixed DNA/chloride ligand chemistry. Inclusion of chlorides on Ag$_{x}$-DNAs presents a promising new route to expand the diversity of Ag$_{x}$-DNA structure-property relationships and to imbue these emitters with significantly enhanced stabilities for in vivo biomedical imaging applications. This work also demonstrates the power of combining high-resolution mass spectrometry, optical spectroscopy, nuclear magnetic resonance, and DFT to characterize the ligand interface of metal nanoclusters and to understand how this interface influences optical properties of these novel emitters.

Polypodamine Coated Gold Nanorods: Photothermal and Photocatalytic Mechanism Study Daniel Aguilar Ferrer, Emerson Coy, Mikhail Bechelya, Thomas Vasileiadis, Igor latsunskyi, Marcin Ziolek, Sergio Moya, Claudia Zebrowska, Olena Ivashchenko, Raquel Pazos, Bartosz Grzeskowiak and Paulina Blaszkiewicz, Adam Mickiewicz University, Poland; Université de Montpellier, France; Gulf University for Science and Technology, Kuwait; Soft Matter Nanotechnology, Centre for Cooperative Research in Biomaterials (CIC biomaGUNE), Basque Research and Technology Alliance (BRTA), Spain; Chromatography & Mass Spectrometry Platform, CIC biomaGUNE, Spain; Poznan University of Technology, Poland

The strong photothermal effect made by the combination of localized surface plasmon resonance (LSPR) presented by gold nanorods (AuNRs) with polypodamine (PDA) makes them appeal nanomaterials for biomedical applications. Here, by seed-mediated growth and a further self-polymerization of dopamine (DA), a reproducible hybrid nanoplatform combining these two materials have been synthesized (AuNRs/PDA). PDA shell thickness was controlled as well as LSPR, besides, their effect on temperature and the photocatalytic response was examined towards Rhodamine 6G (Rh6G) degradation showing a final depletion of 51% in 60 minutes of irradiation and a catalyst concentration of 7.4 µg mL$^{-1}$. Moreover, the kinetics of the reaction were studied through the Langmuir-Hinshelwood model which in combination with time-resolved spectroscopy, and finite-element method simulations of plasmons unveiled low thermalization and enhanced charge carrier at the composite resulted from the combination of AuNRs plasmons and low thermal conductivity presented by PDA [1].

Role of the Ligand Structure Around Nanomaterials for Chemical Reactions Wolfgang Parak and Florian Schulz, Universität Hamburg, Germany

Ligands at the surface of nanomaterials can influence chemical reactions, as will be discussed for 3 different examples. 1) In case ion-responsive ligands are attached to nanomaterial surfaces, the binding properties and such working point can shift. As example, when pH-responsive fluorophores are attached with negatively charged ligands to a surface, then there is a local attraction of H$^+$, i.e. the pH at the surface is lower than in bulk. 2) Ligands may restrict the available space for reactions. 3) Ligands may change the adsorption properties of molecules to surfaces. One interesting example here is the formation of a protein corona. With different coating different proteins can be “fished” from the environment.
Surface functionalization of nanocrystals is essential for their practical application in living systems, but introducing biocompatibility can come at the cost of diminished nanoparticle optics, diminished colloidal stability, or massive increases in probe size. In addition, the cell presents a remarkably complex chemical environment, rich in metal ions, amines, thiols, and other compounds that can disrupt nanoparticle complexes that are perfectly stable in vitro. Inorganic nanocrystals such as quantum dots (QDs), 1,2 upconverting nanoparticles (UCNPs), 3 and avalanching nanoparticles (ANPs) 4,5 are uniquely suited for quantitative live-cell imaging and are typically functionalized with ligands to study specific receptors or cellular targets. Antibodies are among the most useful targeting reagents owing to their high affinities and specificities, but common nanocrystal labeling methods may orient antibodies incorrectly, be reversible or denaturing, or lead to antibody-nanoparticle complexes too large for some applications. We have shown that SpyCatcher proteins, which bind and spontaneously form covalent isopeptide bonds with cognate SpyTag peptides, can conjugate engineered antibodies to nanoparticle surfaces with control over stability, orientation, and stoichiometry. 6 Compact SpyCatcher-functionalized QDs and UCNPs may be labeled with short-chain variable fragment antibody (scFv) engineered to bind urokinase-type plasminogen activator receptors (uPAR) that are overexpressed in many human cancers. Confocal imaging of anti-uPAR scFv-QD conjugates shows the antibody mediates specific binding and internalization by breast cancer cells expressing uPAR. Time-lapse imaging of photostable scFv-UCNP conjugates shows that antibody binding causes uPAR internalization with a ~20 min half-life on the cell surface, and uPAR is internalized to endolysosomal compartments distinct from general membrane stains and without significant recycling to the cell surface. With Tm3+-doped upconverting ANPs functionalized with these scFv antibodies, the extreme nonlinearly of ANP emission leads to sub-100 nm cell surface, and uPAR is internalized to endolysosomal compartments distinct from general membrane stains and without significant recycling to the cell surface. Such a high local concentration of indium ions appears to be detrimental to the cells, while the iron mimics that of copper in neutral and chelator-free biological media, but both indium and iron rapidly dissociate from the particles at very early time points upon exposure to the artificial lysosomal fluid containing citric acid, which is prevalent in the lysosomal compartment of cells. When testing the cellular toxicity of these particles on a HepG2 cell line following 24-hour incubation, CIS exhibits severe toxicity with an estimated IC50 of 124.1 mg/mL cation concentration. Cu2-xS shows moderate toxicity with IC50 cation concentration of 401.3 mg/mL, and CuFeS2 demonstrates the least cytotoxicity with over 75% cell viability at 1 mg/mL cation concentration. We hypothesize that the chelation effect of citric acid in the artificial lysosomal fluid rapidly leaches the indium and iron from the particles. This high local concentration of indium ions appears to be detrimental to the cells, while the strong homeostasis mechanisms used to buffer iron bioavailability may prove protective even in the face of burst release. We found that the surface coating (lipid-PEG micelle encapsulation vs polymer wrapping) alters the rate of oxidation of the surface and particle degradation, inspiring further study into the effect of ligand coating on the degradation and toxicity of CIS QDs. We hypothesize that a covalently bonded ligand will slow the rate of CIS degradation in biological environments and will therefore lead to reduced acute nanotoxicity. This study informs the design of biocompatible nanocrystals by elucidating the relationship between nanoparticle surface ligands, particle degradation, and cytotoxicity for copper chalcogenide nanomaterials.

References:
functional molecules are one of promising approaches for resolving such troubles as an increased binding affinity allows for effective ligand exchange with minimal amount of ligands. However, the limited number of multidentate ligands and complex synthesis routes for granting multidentate nature obstruct their pervasive use.

Herein, we propose the facile synthesis of multidentate hybrid composed of zinc thiolate backbone and functional hydrocarbon branches. For demonstration, zinc chloride (ZnCl₂) and 3-mercaptopropionic acid (MPA) were chosen for preparing hydrophilic hybrid ligands. 1H nuclear magnetic resonance spectroscopy and Fourier transformed infrared spectroscopy revealed two different configurations of linear and toroidal structure. Their multidentate binding on QDs was confirmed in two-dimensional 1H nuclear Overhauser effect spectroscopy displaying clear negative cross peaks from propionate branches bound on surface. Titration of CdSe QDs using the hybrid ligands revealed enhanced binding affinity of the hybrid ligands, enabling effective aqueous phase transfer with ~70-fold fewer binding groups compared to MPA. The aqueous QDs using the hybrid ligands featured sustained PLQY and photochemical stability; the hybrid-capped InP/ZnSe/ZnS QDs displayed ~90% of PLQY that is the record efficient to our best knowledge. Prolonged shelf-life and resistance to ultraviolet irradiation were also achieved. We attribute these enhancements to the robust, thick hybrid ligand shell prohibiting invasion of oxygen and water molecules. We believe that our hybrid ligands are expected to serve as useful building blocks for nanocrystal functionalization.

How Giant ZnSe-Alloyed Shell Realizes Nearly Unity Quantum Yield Byong Jae Kim1,2, Hyeongjun Kim1,2, Yeongho Choi1,2, Woon Ho Jung1,2, Hyeonjun Lee1, Jo-Sang Park1 and Jaehoon Lim1,2; 1Sung Kyun Kwan University, Korea (the Republic of); 2Korea Advanced Institute of Science and Technology, Korea (the Republic of)
Core/shell heterostructure has become one of essential formulae in various applications of colloidal quantum dots (QDs). Heteroepitaxy of wide band gap materials passivates mid-gap defects that are surface dangling bonds of cores and confines carrier wavefunctions to the inside, allowing for realizing near unity photoluminescence (PL) quantum yield (QY). In addition, the extended shell thickness (typically, 4–10 nm), so-called giant QDs, enables us to manipulate ultrafast carrier dynamics in QDs such as nonradiative Auger recombination or energy transfer in densely packed QD films. In the early stages of giant QDs, CdSe/CdS heterostructures have been exclusively spotlighted as the only suitable pair capable of extended shell thickness due to their minimal lattice mismatch. However, recent research has successfully demonstrated giant ZnSe or its alloyed shells for CdSe cores despite the large lattice mismatch that generally deteriorates PLQY as a shell thickness increases. Unfortunately, there are no reasonable explanation for how such new giant QDs are possible. Here, we scrutinize the origin of unexpectedly high PL QY observed in giant CdSe QDs with ZnSe-alloyed shells. In the synthesis of QDs growing the graded thick CdZn₁₋ₓSe (average x = 0.3) or ZnSe shell up to ~10 nm, careful heteroepitaxy reaction accomplished nearly unity PL QY at moderate shell thickness (H ~ 4 nm) followed by the gradual reduction, allowed as defect formation by compressive lattice strain of shell. However, it was found that more intense strain provided by ZnSe or ZnS shell recovered the PL QY of giant QDs. To understand such counter-intuitive phenomenon, we investigate the development of strain in the heterostructure and consequent derivation of electronic states. Along the accumulation of compressive strain applied to CdSe core, probed from the CdSe phonon mode shift and altered exciton dynamics, we observed the emergence of low-energy tail in cryo-PL spectra regardless of shell thickness. Retarded decay dynamics at this tail states and Ab-initio calculation suggest that Zn vacancy in ZnSe shell (VZn) introduced during the shell growth forms shallow hole traps that is 0.05–0.1 eV higher than the 1Sh state of CdSe core. The formation of VZn and partial strain relaxation seems to prevent the excessive strain accumulation and consequent misfit dislocation. As long as the catastrophic strain is avoided, additional hydrostatic compressive strain lifts the 1Sh state of CdSe core and the shallow traps in the shell become deactivated. Our study proposes the bright side of defects that they can mitigate the lattice strain in the growth of thick ZnSe-based shells to prevent the destruction of QDs by the excessive stress.

11:45 AM A SHORT PRESENTATION IN THE MEMORY OF MARCEL BRUchez, MAXIME DAHAN AND NIKOCLAI GAPONIK. PRESENTED BY H. MATTOUSSI AND ELENA SHEVChENko

Effect of Surface Chemistry in Cation Exchange of NPLs Sandrine Ithurria; Sorbonne Université, France
II-VI semiconductor nanoplatelets have attracted lot of interest due to their narrow optical properties controlled by the thickness of these 2D particles. Working with Cadmium chalcogenide semiconductor enables to cover the visible range both with homostructures and heterostructures. In order to extend the optical properties, it is required to use semiconductors with narrow band gaps. However, controlling the shape of the nanoplatelets remains challenging and one option that has been explored for a number of years is cation exchange. One more time preserving the anisotropic shape may be challenging in the case one of the dimensions is very small. Here, we will show that ligands in NPLs, not only control the lateral dimensions of NPLs during a growth, but also the shape of the NPLs and the cation exchange rate such that NPLs with narrow band gap semiconductors with optical properties in the NIR may be obtained.

Controlling Electronic Coupling of Acene Chromophores on QD Surfaces Through Variable Concentration Ligand Exchange Marissa Martinez1, Michelle Nolen1,2, Nicholas Pompetti1,2, Lee Richter3, Carrie Farberow1, Justin Johnson4,5, and Matthew C. Beard1,1; 1National Renewable Energy Laboratory, United States; 2Colorado School of Mines, United States; 3University of Colorado Boulder, United States; 4National Institute of Standards and Technology, United States
Controlling the binding of functional organic molecules on quantum dot (QD) surfaces and the resulting ligand/QD interfacial structure determines the resulting organic-inorganic hybrid behavior. In this study, we vary the binding of tetracene di-carboxylate ligands bound to PbS QDs cast in thin films by performing solid-state ligand exchange of as-produced bound oleate ligands. We employ comprehensive FTIR analysis coupled with UV-Vis spectrophotometric measurements, transient absorption and DFT simulations to study the QD ligand surface structure and resulting optoelectronic properties. We find that there are three primary QD-diacid structures, each with a unique binding mode dictated by the QD-ligand and ligand-ligand intermolecular and steric interactions. They can be accessed nearly independently from one another via different input ligand concentrations. Low concentrations produce mixed oleate/tetracene ligand structures where the tetracene carboxylates tilt towards QD surfaces. Intermediate concentrations
produce mixed oleate/tetracene ligand structures with ligand-ligand interactions through intramolecular hydrogen bonding with the ligands perpendicular to the QD surface and weaker QD-ligand electronic interactions. High concentrations of oleate lead to full ligand exchange and the ligand/dye isomerizing the surface while the QD film compacts. When the tetracene ligand is tilted or lies flat on the QD surface the benzene ring pi-system interacts strongly with the p-orbitals at the PbS surface and produces strong QD-ligand interactions evidenced through QD/ligand state mixing, with a coupling energy of ≈ 700 meV.

Charge- and Energy-Transfer Processes in Two-Dimensional Supramolecular Materials Ruggero Emmanuele1, Hiroaki Sai1, Darin Morrow1, Saw Ha1, Samuel I. Stupp2 and Xuedan Ma1,4,2; 1Argonne National Laboratory, United States; 2Northwestern University, United States; 4Ohio University, United States; 2The University of Chicago, United States

Synthetic soft materials could overcome the limitation of biological structures in terms of robustness, making them appealing for practical applications related to photovoltaics and photocatalysis. Understanding of charge- and energy-transfer mechanisms is often required to build efficient devices from such synthetic soft materials. In this work, we self-assemble 2D supramolecular systems into 2D ribbons and investigate both Frenkel and charge-transfer excitons (FEs and CTEs, respectively) using optical spectroscopy. We discover that the presence of defects intentionally inserted into these nanoribbons leads to variations in the CTEs / FEs emission ratio. Moreover, we find that propagations of the CTEs and FEs are closely related to the compositions and lattice structures of the 2D ribbons. These results were well reproduced by our numerical simulations based on a charge-transfer model. Our findings have important implications for utilizing soft materials in photovoltaics and photocatalytic applications.

CdSe Nanoplatelet Sensitized Upconversion—(Lateral) Size Matters Lea Niemhaus; Florida State University, United States

In photon upconversion, the energy of two photons is combined to generate a higher energy state. A popular pathway for upconversion is triplet-triplet annihilation as it can become efficient at low solar-relevant powers. Here, two triplets are combined to form the desired high energy singlet state. However, since triplet states are 'spin-forbidden', sensitizers are required to indirectly populate the triplet state. Here, we investigate the effect of material dimensionality on the triplet generation mechanism at the interface of two-dimensional CdSe nanoplatelet sensitizers and surface-bound anthracene carboxylic acid and the resulting effect on triplet-triplet annihilation in the annihilator diphenylanthracene. We find an unexpected anti-correlation between the upconversion quantum yield and power threshold \( I_{th} \) as the NPL lateral size increases. This result is attributed to differences in the triplet-triplet annihilation mechanism: one is mediated by molecular diffusion and the other by triplet energy diffusion.1,2

Fluorescence Energy Transfer Processes Involving CsPbBr3 PQD-Dye Assemblies Selin Donmez1, Sisi Wang1,2 and Hedi M. Mattoussi1; 1Florida State University, United States; 2ASTM International, United States

Fluorescence resonance energy transfer (FRET) is a well-known technique that exploits the non-radiative transfer of excitation energy from an excited donor fluorophore to a proximal ground-state acceptor molecule. FRET is highly sensitive to small changes in the separation distance between the donor and acceptor molecules which offers the use of FRET as a platform for a range of applications such as protein conformation studies and biological assays. Colloidal lead halide perovskite quantum dots (PQDs) have gained interest, over the past few decades, owing to their unique photophysical properties, including tunable and narrow photoluminescence (PL) profiles, high PL quantum yields (PLQY), high tolerance for structural defects, along with relatively easy to implement synthesis. Energy transfer interactions using these colloidal materials is a highly important, yet underexplored process, for practical applications relying on energy harvesting as well as for addressing fundamental questions. Questions of whether energy resonance transfer interactions relying on the dipole-dipole approximation apply to colloidal QDs (including conventional nanocrystals) have persisted. Another serious challenge that has impeded a better understanding of energy transfer processes with PQDs is the implementation of controlled conjugation of acceptor molecules. We hereby exploit the ionic nature of CsPbBr3 QDs to achieve controlled coupling, through electrostatic interactions, of sulfo-cyanine dyes bearing zwitterionic moieties. This has allowed us to control among others the spectral overlap function between PQD emission. We combined steady-state and time-resolved photoluminescence experiments using these assemblies to measure highly efficient energy transfer interactions. This manifested in pronounced losses in PQD emission along with shortening of the PQD PL lifetime. Energy transfer rates were also strongly dependent on the spectral overlap. We will detail our synthetic approach, compare our findings to available theories on energy transfer process, and address potential contributions from charge transfer-induced quenching.

4:15 PM EL10.07.06
Enhancing SWIR Emission: Gradient Alloying and Auger Recombination Suppression in High-Performance Heavy-Metal-Free Colloidal Quantum Dots Hyunjin Che and DohChang Lee; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The short-wave infrared (SWIR) region, which indicates light in the 1.4 to 3 um wavelength range, is utilized in various fields such as bio-imaging, telecommunication, and surveillance. However, there has been limited research on the light emission characteristics in the SWIR region using heavy-metal-free colloidal quantum dots. Light Detection and Ranging (LiDAR) is a method that utilizes lasers to determine ranges by measuring the time it takes for the reflected light to return to the receiver. The use of colloidal quantum dots as light emitters in LiDAR can significantly reduce costs and enhance detection capabilities by leveraging the long wavelengths in the SWIR region.

Here, we successfully synthesized In(As/In)(Zn/P)ZnSe quantum dots using a one-batch method, suppressing the vulnerability to oxidation, which is a common issue with III-V quantum dots. We controlled various parameters such as initial volume, injection rate, ligand, and temperature to create quantum dots that emit light in the SWIR region. The resulting quantum dots exhibited emission at 1550 nm in the SWIR region. Notably, these quantum dots achieved a photoluminescence quantum yield (PLQY) of 3% at a wavelength of 1400 nm, which represents the highest reported value thus far. To gain insights into the carrier dynamics, we conducted ultrafast time-resolved photoluminescence and transient absorption spectroscopy experiments. These investigations revealed energy variations attributed to the mid-shell gradient alloy and suppressed Auger recombination within the quantum dots. Moreover, the formation of an outer shell on the In(As quantum dots confirmed the passivation of interfacial traps.

Overall, these findings contribute to the development of heavy-metal-free colloidal quantum dots with excellent performance, particularly in the SWIR...
The flow of energy and electron transfer processes in semiconductor nanocrystal based light harvesting assemblies is governed by the nature of the excited state interactions. Surface interaction of chromophore or redox active molecule with semiconductor nanocrystals dictate the efficiency of photoinduced energy/electron transfer processes. Metal halide perovskite nanocrystals are interesting in the sense that they can either transfer singlet or triplet energy, or selectively transfer electrons or holes to the adsorbed molecules. The presentation will show how one can direct the flow of energy to achieve desired results in a semiconductor-molecular hybrid assembly. The presentation will focus on two specific scenarios of the flow of energy and electron processes in CsPbX₃ nanocrystal-molecular hybrids. The energy transfer is probed through three molecular acceptors – rhodamine B (Rhb), Rhodamine isothiocyanate (Rlh-NCS), and rose Bengal (RoseB), which contain an increasing degree of heavy atom pendant groups. When interacting with CsPbX₃, as an energy donor, photoluminescence excitation spectroscopy reveals that singlet energy transfer occurs with all three acceptors. The acceptor functionalization directly influences several key parameters that dictate the excited state interac(CsPbX3) is employed as a sensitizer we observe triplet energy transfer to RoseB and other rhodamine dyes. A basic understanding of the fundamental differences between the two excited deactivation processes (energy and charge transfer) and ways to modulate them should enable design of more efficient light harvesting assemblies with semiconductor and molecular systems.

In this study, we design a precursor-conversion synthetic approaches to homogeneously control the nucleation and growth mechanism of CsPbX₃ PNC (denoted as heat-up PNCs). The heat-up synthetic approaches accelerate the halide conversion rates by promoting the SN2-based heat-up reaction, and thereby lead to the crystallizations of photo-active CsPbX₃ crystal phases, suppressing the undesired production of photo-inactive and halide-deficient Cs₄PbX₆ phases. During the heat-up process, we monitored the production yield of halide reactants and the nucleation and growth mechanism along with the increasing reaction temperature. Through this observation, we found that the nucleation and growth stages could be separated in the heat-up process and the heat-up CsPbX₃ PNCs are size-focused into CsPbX₃ crystal phases, leading to the inseparable and unmanageable nucleation and growth process. Furthermore, the precursor-injection synthetic methods, using highly reactive ionic-salt-type precursor solutions, induce various synthetic approaches, and their high monodispersity and optical features are maintained even in large-scale synthesis.

Heat-Up-Assisted Precursor-Conversion Synthesis of Ultra-Monodisperse Perovskite Colloidal Nanocrystals Jigeon Kim1, Younghoon Kim2 and Min Jae Ko3; 1Hanyang University, Korea (the Republic of); 2Kookmin University, Korea (the Republic of)

Colloidal quantum-confined nanocrystals are extraordinarily unique photo-active materials, with electronic energy structures, such as optical bandgap energy, that can be tailored by altering their size and dimensionality. Among them, lead halide perovskite nanocrystals (PNCs) have exhibited superior light-harvesting and emitting features, owing to their exceptional optical, photophysical, and optoelectronic properties. Therefore, the PNCs have been extensively studied for their optoelectronic applications such as solar cells, photo-detectors, and light-emitting diodes. Traditionally, the PNCs have been easily prepared at laboratory scale through precursor-injection synthetic methods such as hot-injection methods and ligand-assisted reprecipitation methods. However, the precursor-injection synthetic methods, using highly reactive ionic-salt-type precursor solutions, induce various synthetic variables such as temperature and precursor concentration gradients, leading to the inseparsable and unmanageable nucleation and growth process.

In this study, we design a precursor-conversion synthetic approaches to homogeneously control the nucleation and growth mechanism of CsPbX₃ PNC crystallizations by using the heat-up methods. In this approach, the highly monodisperse CsPbX₃ (X = Cl, Br, I) PNCs can be successfully synthesized by supplying halide reactants through SN2 reactions of various haloalkanes in homogeneously blended precursor solutions (denoted as heat-up PNCs). The heat-up synthetic approaches accelerate the halide conversion rates by promoting the SN2 reactions, and thereby lead to the crystallizations of photo-active CsPbX₃ crystal phases, suppressing the undesired production of photo-inactive and halide-deficient Cs₄PbX₆ phases. During the heat-up process, we monitored the production yield of halide reactants and the nucleation and growth mechanism along with the increasing reaction temperature. Through this observation, we found that the nucleation and growth stages could be separated in the heat-up process and the heat-up CsPbX₃ PNCs are size-focused into CsPbX₃ crystal phases, leading to the inseparable and unmanageable nucleation and growth process. Furthermore, the heat-up approaches enable the synthesis of CsPbX₃ PNCs with diverse halide compositions by promoting the SN2 reactions of various haloalkanes. As a result, ultra-monodisperse heat-up CsPbX₃ PNCs are obtained through the SN2-based heat-up synthetic approaches, and their high monodispersity and optical features are maintained even in large-scale synthesis.

Gate Tunable High-Performance Broadband Phototransistor Based on Organic-Inorganic Vertical Heterojunctions Sourabh Pal, Rajinder S. Deol, Reem Alshanbari, Megan Noga, Oliver A. Duran, Vikrant Kumar and Ioannis Kymissis; Columbia University, United States

In recent times broadband photodetectors find widespread applications in environmental surveillance, optical imaging, spectroscopy, and sensing. A remarkable photodetector performance over a broadband spectral range can be successfully achieved through two primary methods. The first approach involves the utilization of semiconductor materials with broad detection ranges. However, the selection of suitable broadband photoabsorbing materials, especially inorganic ones, is often limited. The second commonly adopted method is the development of hybrid systems by combining nanomaterials with distinct photoabsorption bands, thereby achieving a heterostructured system with a broad photodetection range. Amorphous Indium Gallium Zinc Oxide (a-IGZO) is one of the most widely researched oxide semiconductors owing to its high carrier mobility, good uniformity, and facile synthesis process. However, as an active photosensitive material, a-IGZO also has its own limitation such as the large bandgap (~ 3.3 eV) leading to its limited light absorption capability and response to long-wavelength light. On the other hand, organic semiconductor materials have garnered significant attention in the field of optoelectronics due to their favorable intrinsic properties, together with the simple and easy synthesis processes, making them cost-effective for large-scale fabrication. One promising area of exploration involves the utilization of organic-inorganic heterostructures, which combine the optoelectronic attributes of both constituent materials. This novel device structure allows for synergistic advantages, enabling extensive applications in the fields of electronics as well as optoelectronics. Herein, we report a high-performance broadband phototransistor exploiting the concept of organic-inorganic heterostructure, in which conjugated polymer J71:ITIC with narrow band gap is used as a visible photosensitizer, whereas a-IGZO with high mobility acts as conducting channel as well as active UV sensing material. The favourable energy band alignment between J71:ITIC and a-IGZO effectively contributes to the high-efficiency separation of photogenerated carriers across the interface, resulting in ultrahigh photoresponsivity of ~10^8 A/W and specific detectivity of ~10^15 Jones at an applied gate bias of ~ -7.5 V for incident light illumination of ~ 680 nm together with an adequate UV photoresponse owing to the UV light sensitivity of active channel layer. These results validate that the fabricated J71:ITIC/a-IGZO heterostructure based phototransistor can be an ideal prototype for the next-generation broadband photodetection applications.

Triplet Energy Transfer from CdS QDs Enhances Organometallic Eu(III) Emission Tingting Huang¹, Sheng He², Tianquan Lian² and Ming-Lee Tang³; ¹The University of Utah, United States; ²Emory University, United States

Europium (III) complexes are of interest for bioimaging because of their long-lived, narrow emission in the visible and near-IR wavelengths. Since the direct absorption of light by Eu³⁺ ions is intrinsically poor, the photoluminescence (PL) intensity for Europium (III) complexes are usually low. Their PL quantum yield is improved by coordinating ligands that absorb photons. These coordination ligands are usually excited to their singlet state. Intersystem crossing to the triplet state allows for energy transfer to the central Eu³⁺ ions. Therefore, excitation of the ligands requires high-energy photons and only UV light can be used. Here, we show for the first time that quantum dots (QDs) can serve as triplet photosensitizers for Europium (III) complexes. We make use of the high extinction coefficients of CdS QDs for excitation after 400 nm. Energy transfer occurs through a dark triplet state, eliminating the need for high-energy photon excitation. 1-Naphthoic acid (1-NCA) is used to enhance energy transfer because its triplet state is higher than 5D0 state of direct absorption of light by Eu³⁺ ions is intrinsically poor, the photoluminescence (PL) intensity for Europium (III) complexes are usually low. Their PL quantum yield is improved by coordinating ligands that absorb photons. These coordination ligands are usually excited to their singlet state. Intersystem crossing to the triplet state allows for energy transfer to the central Eu³⁺ ions. Therefore, excitation of the ligands requires high-energy photons and only UV light can be used. Here, we show for the first time that quantum dots (QDs) can serve as triplet photosensitizers for Europium (III) complexes. We make use of the high extinction coefficients of CdS QDs for excitation after 400 nm. Energy transfer occurs through a dark triplet state, eliminating the need for high-energy photon excitation. 1-Naphthoic acid (1-NCA) is used to enhance energy transfer because its triplet state is higher than 5D0 state of Eu³⁺(2.16eV) and lower than QDs' band edge. 1-NCA is critical in mediating the energy transfer between QDs and the Europium (III) complex. Transient absorption spectroscopy confirms triplet energy transfer between QDs, mediator, and Eu(III)-facam)³⁺. The Eu(III) photoluminescence quantum yield is enhanced up to 21.4 times, the highest value reported in literature.

Engineered Hybrid Organic-Inorganic Perovskite/Acet Contact for Preventing Ag Diffusion using Buffer Barriers Ji Myeong Yu, Yunhwa Hong, Seokgi Kim, Sungkyu Kim and Kwang Heo; Sejong University, Korea (the Republic of)

CH3NH3PbI3 (MAPbI3), one of the organic-inorganic halide perovskite materials, has attracted strong interest in various optoelectronic devices due to its high absorption coefficient, tunable band gap, and fast charge transport. [1] However, halide perovskite not only causes reliability issues in temperature and humidity environments but also is decomposed into CH3NH3+ and Pbl6 by an electron-induced reduction reaction at the metal/MAPbI3 interface. [2] Although various candidates such as oxide thin films, 2D perovskites, and polymers were proposed as protective layers to prevent the deformation of MAPbI3, [3] the effects of diffused metal ions on structural deformation and phase transition in the metal/MAPbI3 contact have not been clearly understood yet. Here, we directly confirmed the diffusion of metal ions and phase deformation in Ag/MAPbI3 contact using transmission electron microscopy and energy dispersive x-ray spectroscopy. The Pbl6 phase is formed in the MAPbI3 matrix contacted with metal and gradually transformed into Pbi2 and I as due to Gibbs free energy, which is confirmed by diffraction peaks of the Pbi2 phase at 12.6°, 28.2°, and 29.4°. Furthermore, thermodynamically stable Ag-I bonding is generated by energy barrier, forming an AgI interfacial layer at the Ag/MAPbI3. Because non-protective MAPbI3 with the damaged surface shows reduced grain size by 20% and the formation of deep pinholes, we inserted various protective layers to passivate the surface and maintain the MAPbI3 matrix. In order to prevent penetration of Ag, SnO2 thin films with a thickness of 30 nm were deposited on MAPbI3 by atomic layer deposition. Because anions of the SnO2 precursor are bonded with the most reactive MA⁺ at the early stage, only hexagonal and orthorhombic Pbi2 phases were identified in the as-deposited structure. The physically deposited C60 layer with a 30 nm thickness damages the MAPbI3 matrix, resulting in the formation of Pbi2 phases and a 15% reduction in the grain size of MAPbI3. PMMA of the 30 nm thickness was coated on the MAPbI3 layer for surface protection and prevention of diffused Ag ions. The penetrated Ag ions through the PMMA layer generate AgI phase inside the MAPbI3 matrix though the MAPbI3 was effectively protected for 30 days without the formation of Pbi2 phase. Two types of structures composed of C60 and PMMA are suggested for the anti-diffusion barrier and passivation layer, respectively. Although the C60/PMMA bilayer structure effectively prevents the formation of Pbi2 and AgI phases for 50 days, the grain size of MAPbI3 decreased by 5%. Compared to the bilayer structure, MAPbI3 matrix protected by C60/PMMA complex is well maintained in its original structure even after 60 days without phase deformation and grain shrinking. Because the uniform and cohesive hydrophobic PMMA film not only effectively protects the MAPbI3 structure but also the diffusion of Ag ions is controlled by the C60 layer, our findings suggest advanced buffer layers to protect the surface of MAPbI3 and prevent structural deformation caused by metal diffusion in various metal/MAPbI3 contact. [1] A. Babayigit et al., Nat. Mater. 15, 247 (2016) [2] K. Hong et al., J. Mater. Chem. C. 9, 15212 (2021) [3] Abd. Rashid et al., Energy Environ. Sci. 14, 2906 (2021)
was increased, the peak emission wavelength was red-shifted. This shift was due to Förster-type resonant energy transfer. A light emitting device was fabricated by depositing Nb NPs. The EL device showed improved performance on the materials in contact with the nanocrystals; red emission was obtained for the Al/p-Si/Nb NPs/ITO structure and blue emission was obtained for the ITO/PEDOT:PSS/Poly-TPD/Nb NPs/TPBi/Al structure. These results suggest that the EL mechanism and origin can be controlled by the interface conditions between Nb NPs and the electron (hole) transport layer.

Development of Highly Fluorescent Copper and Silver Chalcogenides for SWIR Imaging via Surface Control

Yidan Sun1; Xingjian Zhong1,1 and Allison M. Dennis1; Northeastern University, United States; Boston University, United States

Ag2S nanoparticles are promising candidates as short-wave infrared (SWIR) imaging agents due to their low toxicity, high photostability, small size, and tunable fluorescence properties in the second near infrared biological window (NIR-II). They have been widely studied for preclinical imaging with high resolution and signal-to-noise ratio. However, Ag2S nanoparticles suffer from potential heavy-metal toxicity as well as poor fluorescence efficiency due to surface defects. To overcome these limitations, we are optimizing Ag2S surface treatments while also investigating alternative heavy-metal-free compositions like Cu-based nanocrystals. While copper sulfide nanocrystals are more commonly known for their localized surface plasmon resonance behavior, recent research shows that stoichiometric Cu2S nanocrystals fluoresce with a peak between 900 to 1100 nm; more effort is needed to optimize their fluorescence properties and stability. A common factor influencing the photophysical behavior of nanoparticles is their surface properties, including the presence of surface defects and the ligands at the interface between the nanoparticle and the surrounding media. Energy transition processes are highly correlated with these interfacial interactions, impacting both radiative and non-radiative recombination and thus photoluminescence. By modifying the ligand coating and shelling, nanoparticles can be protected from defect-derived nonradiative relaxation and energy loss during interaction with the environment.

In this study, we synthesize fluorescent Ag2S and Cu2S nanoparticles and manipulate their optical properties through surface treatment. We explore the impact of different shell and ligands on surface traps, stability, and optical properties. Enhanced fluorescence intensity of Ag2S demonstrates the removal of surface defects, while surface treatment of Cu2S reduces surface oxidation, preventing the shift from fluorescent to plasmonic nanocrystals. By acknowledging the impact of surface conditions on nanoparticle behavior, we can pursue the deliberate design of high-quality contrast agents for SWIR imaging.

Photocatalytic Properties of Perovskite Quantum Dots and Their Role in the Degradation of Alkaline Halide Molecules

Selin Dominguez, Sisi Wang and Hedi M. Mattoussi; Florida State University, United States

Since the first successful implementation of solution phase growth of colloidal cesium lead halide perovskite nanocrystals (PNCs), interest in these materials has steadily grown. This has been driven by their unique photophysical properties and the ionic nature of the semiconducting core. One of the most fascinating properties of PNCs is the ability to form anion exchange reactions with the surrounding medium, which offers an alternative route for tuning the photophysical properties of these materials.

We present a detailed study on the photo catalytically assisted anion exchange reaction of CuPbBr3 PQDs dispersed in alkyl chloride solutions. We found that electron transfer from photoexcited PNCs to the surrounding alkyl chloride molecules triggers their electrochemical degradation which produces alkyl radicals and reactive Cl- anions in the medium. The resulting reactive chlorides engage in halide exchange reaction with the PNC cores, resulting in blue shift in the absorption and PL emission properties of the samples. We probe the efficiency of the reaction by varying the nature of the photoexcitation source (e.g., laser source vs UV reactor or sunlight) and the relative reduction potential of the alkyl halide molecules used. We supplement our findings with thorough characterization of the nanocrystal intermediates to track changes in the crystal structure and stoichiometry during irradiation, using optical and fluorescence spectroscopy, powder X-ray diffraction and x-ray fluorescence spectroscopy. These findings bode well for testing the photocatalytic properties of PNCs in general and may have implications in the degradation of chlorinated molecules.

Doping Colloidal Quantum Dots

Marissa Martinez and Matthew C. Beard; National Renewable Energy Laboratory, United States

Doping has been an important method for tuning semiconductor electronic and optical properties, yet doping quantum dots (QDs) still presents a challenge. Herein, we report a facile method to dope PbS, CdSe, and CdPbBr3 quantum dots with Ag, Na, and Br using ligand chemistry. Adding a solution of metal oleates to a QD solution produces a bleach in the QD exciton absorption in the UV-VIS spectrum, and an intraband absorption in the FTIR. We found a higher free-carrier conductivity in solution-doped coupled QD films, compared to as-synthesized, using sheet resistance measurements. This study demonstrates the ability to dope QDs in solution while maintaining colloidal stability and increasing conductivity of the QD solids.

8:00 PM EL10.08.11
Spatial Composition Tuning of Colloidal NiMgO Hole Transport Materials for All-Inorganic Quantum Dot Light-Emitting Diodes

Woon Ho Jung1,1, Byong Jae Kim1,1, Jisu Han1,1, Jaehoon Lim1,1, Yeongho Choi1,1, Yong Woo Kwon1,1 and Hyeonjun Lee2; 1Sungkyunkwan University, Korea (the Republic of); 2Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Rapid progress in the device performance of colloidal quantum dot (QD) based light-emitting diodes (QD-LEDs) proposed the new technical opportunity for next-generation displays. Beyond the premise of QD-LEDs in displays, scientists in this field are now looking forward to realizing brighter and robust lighting sources based on QDs, previously achieved solely by inorganic LEDs and lasing technologies. Unfortunately, the state-of-the-art QD-LEDs have exhibited suboptimal performance due to the large hole injection barrier and difficulty to match electrical property of ETL counterparts. To overcome these deficiencies, we are investigating alternative heavy-metal-free compositions like Ni-based nanocrystals. While nickel sulfide nanocrystals are more commonly known for their localized surface plasmon resonance behavior, recent research shows that stoichiometric NiO nanocrystals fluoresce with a peak between 900 to 1100 nm; more effort is needed to optimize their fluorescence properties and stability. A common factor influencing the photophysical behavior of nanoparticles is their surface properties, including the presence of surface defects and the ligands at the interface between the nanoparticle and the surrounding media. Energy transition processes are highly correlated with these interfacial interactions, impacting both radiative and non-radiative recombination and thus photoluminescence. By modifying the ligand coating and shelling, nanoparticles can be protected from defect-derived nonradiative relaxation and energy loss during interaction with the environment.

In this study, we synthesize fluorescent Ag2S and Cu2S nanoparticles and manipulate their optical properties through surface treatment. We explore the impact of different shell and ligands on surface traps, stability, and optical properties. Enhanced fluorescence intensity of Ag2S demonstrates the removal of surface defects, while surface treatment of Cu2S reduces surface oxidation, preventing the shift from fluorescent to plasmonic nanocrystals. By acknowledging the impact of surface conditions on nanoparticle behavior, we can pursue the deliberate design of high-quality contrast agents for SWIR imaging.
Effect of Charge Transfer to Quantum Dots on Electroluminescence

Hyeongjun Lee¹, Yong Woo Kwon², Hyunjin Cho¹, Doh C. Lee¹ and Jaehoon Lim²; ¹Korea Advanced Institute of Science and Technology, Korea (the Republic of); ²Sungkyunkwan University, Korea (the Republic of)

Recently, quantum dot light-emitting diodes (QLEDs) have extensively utilized electron transport layers (ETLs) based on the metal oxides such as ZnO, which stand out for their high performance in QLEDs. Despite the successful implementation of metal oxide-based ETLs, there is still a puzzle surrounding how they effectively drive QLEDs. Previous studies have primarily attributed this advancement to the modification of energy levels within the ETLs. However, despite the energetic considerations, several reports on metal oxide-based QLEDs have shown driving voltages lower than the optical bandgap of quantum dots (QDs). Additionally, the efficiencies of QLEDs often surpass the theoretical limit dictated by the emissive probability of neutral QDs. This intriguing finding suggests the existence of a concealed mechanism behind the performance improvement of QLEDs.

In this study, we demonstrate that the charge transfer between ZnO-based ETLs and QDs not only affects the energy alignment of QDs in QLEDs but also influences their optical properties. The study for ultraviolet photoelectron spectroscopy represents the overall energy landscape of QLEDs being rearranged centered on the surface states of QDs. The consequence of charge transfer from ZnO-based ETL to the QD surface increases the work function of QDs, providing electrostatic potential gain for hole injection. The spectrally-resolved photoluminescence and electroluminescence results show that carriers injected into individual QDs regulate the injection rate of opposite carriers through Coulombic interaction. By carefully assessing the carrier occupation in QDs, we are able to quantify the emissive probability of QDs on metal oxides. The transfer of electrons from the metal oxides to QDs electrically passivates the surface trap states on QDs, thereby increasing the emissive probability of QDs. The electrobrightening of QDs by metal oxide ETLs pushes the efficiency envelopment of QDs by surface defects.

Our series of analyses indicate an oversimplification in considering the QD ensemble as a single emitter and the ligand-passivated surface as a mere inductor within QLEDs. From a practical perspective, we emphasize the importance of considering individual QDs as discrete emitters and the optoelectronic changes resulting from charge exchange. We believe this consideration would pave the way for the design of efficient QLEDs.

Characterization and Optimization of Gold Nanoparticles Synthesized via Environmentally Benign Electrochemical Synthesis on Chitosan Layers

Harjaial S. Brai¹, Daniel L. Lu¹, Claire Kang², Jacob Zerycki³,⁴ and Michael Cuiffo¹; Stony Brook University, The State University of New York, United States; Stockdale High School, United States; Westview High School, United States; Canyon Crest Academy, United States; Massachusetts Institute of Technology, United States

Previously, palladium and other noble metal nanoparticles have been synthesized on chitosan-coated stainless steel [1][2]. These metal nanoparticles have been shown to have both antibacterial and catalytic properties. Finding ways to synthesize potentially catalytic noble nanoparticles (gold, palladium, and silver) while maintaining their stability under atmospheric conditions is an important goal of materials research. Electrochemically deposited chitosan layers on steel are used as an environmentally benign nucleation support structure for the creation of stable metal nanoparticles. Utilizing electrochemistry to create an abundance of activation sites on the chitosan structure, we have synthesized pure metal nanoparticles of gold.

Electrochemically deposited chitosan layers on steel are used as an environmentally benign nucleation support structure for the creation of stable metal nanoparticles. The steel samples were then air-dried overnight. The chitosan-coated steel samples were used for electrochemical reduction of the gold (III) ions to synthesize nanoparticles on the chitosan layer at voltages ranging from -1.5 V to +1.5 V for 60-120 seconds in order to determine the optimized parameters for gold nanoparticle synthesis, as electrochemistry creates an abundance of activation sites on the chitosan structure. Once the process was complete, the samples were air-dried overnight or placed in a vacuum chamber for several hours.

Various methods of analysis were employed to image and quantify the nanoparticles including Optical Microscopy, Scanning Electron Microscopy (SEM), Fourier Transform Infrared (FTIR) spectroscopy, X-Ray Fluorescence (XRF), Energy Dispersive Analysis by X-rays (EDAX), and cyclic voltammetry. It was also discovered that the nanoparticles created were protected by a thin film or coating of chitosan which prevented oxidation while maintaining viability for catalytic reactions and possibly antimicrobial and antibacterial applications [3]. Exposure to ultraviolet (UV) light following electrochemical deposition was found to enhance abundance and dispersion of nanoparticles formed. However, the amount of pure metal nanoparticles was found to decrease with exposure to UV light due to an increase in the formation of metal oxide nanoparticles. The elimination of trapped hydrogen gas bubbles formed during the cathodic polarization via heating was found to eliminate nucleation sites and lead to the formation of micron-sized clusters, oxides, and little to no pure gold metal. The surface of these mixed nanoparticles was found to be highly chemically reactive.

Future work will include X-Ray Photoelectron spectroscopy (XPS) to determine the oxidation states of the nanoparticles and more experimentation with concentrations and voltages to optimize the parameters for electrochemistry.

Effect of Charge Transfer to Quantum Dots on Electroluminescence in Inorganic Halide Perovskite LEDs

Parvez Akhtar, Raman Aggarwal, Nidhi Dua, Henam S. Devi, Md. S. Hassan and Madhussudan Singh; Indian Institute of Technology Delhi, India

All-inorganic halide perovskite light-emitting diodes (LEDs) exhibit color purity comparable to organic LEDs with significantly greater operational stability. However, owing to the rheological properties of inks of CsPbBr3 with commonly used solvents such as dimethyl sulfoxide (DMSO) deposited on hole injection layers such as poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS), formation of pinhole-free thin films is a challenge. Further, in the perovskite structures (ABX3) [1], surface and grain-boundary defects play a critical role in determining transport and the degree of non-radiative energy loss. In this work, we report on the impact of the use of inexpensive polymers (poly(ethylene) glycol (PEG) and polyvinyl-pyrrolidone (PVP)) on passivating defect states in nanocrystalline CuPbBr3. Precursors cesium bromide (CsBr) and lead bromide (PbBr2) (in DMSO) were heated under vacuum and then optionally combined with the blend PEG:PVP in DMSO and dimethyl formamide (DMF) in a 1:1 ratio to form an ink [2]. X-ray diffraction (Rigaku, Cu-Kα 1.54Å) reveals an orthorhombic phase (ICDD 96-153-3063) with the stoichiometric composition confirmed using energy dispersive X-ray (EDX) analysis. Thin films of control (CsPbBr3) and test (CsPbBr3:PEG:PVP) formed with spin-coating exhibit different nanocrystallite sizes using field-emission scanning electron microscopy (FESEM, JEOL). ~204 nm (control) vs ~101 nm (test). The polymers are seen to assist in regulation of grain sizes, resulting in a narrower size distribution for the test film, and lead to a lower pinhole density (~99% coverage) in the test film vs control (~80% coverage) estimated using image processing techniques on FESEM scan data. However, owing to the increase of surface to volume ratio for the test film, we should expect an increased defect density, leading to a deterioration of the radiative efficiency. To investigate the impact on carrier
lifetimes, we carried out time-resolved photoluminescence (TRPL) using time-correlated single-photon counting (TCSPC) with a pulsed laser (377 nm) (Edinburgh Instruments FLS920). Interestingly, using the bi-exponential fitting and analyzing the bi-exponential model in detail, we were able to observe a non-radiative lifetime (17.82 ns) vs control (9.10 ns). There is a nearly four-fold reduction in the relative strength of the nonradiative tail for the test sample when compared to control, with a ~4.5-fold enhancement in the relative intensities of measured photoluminescence. These results strongly suggest effective passivation of dangling bonds, grain boundaries, etc, which suggests potential Lewis acid-base interactions between Pb2+ and n-bonds in the polymer chains. This interaction was confirmed using a Fourier Transform Infrared (FTIR, Thermo-Fisher) spectrophotometer. Finally, LED devices (PEDOT:PSS/CsPbBr3:PEG/PVP:2,2',2''-(1,3,5-Benzinetriyl)-tris(1-phenyl-1-H-benzimidazole (TPBi)/LiF/Al) were fabricated using a combination of spin coating and thermal evaporation at a pressure 2.3 x 10⁻⁶ Torr (Angstrom Engineering, Evovac). Device characterization yields significant enhancement in electroluminescence (EL, green:518 nm, FWHM: 17nm) of test devices vs control in a manner consistent with the observed enhancement in PL. Briefly: peak brightness (7204 vs 2371 Cd/m²), current efficiency (4.19 vs 0.54 cd/A) and efficacy (2.32 vs 0.29 lm/W), with a slight reduction in the turn-on voltage (2.9 vs 3.3 V), etc. can be attributed to effective defect-passivation despite a seemingly adverse increase in surface to volume ratio. Future work will involve quantification of any device lifetime changes arising from passivation of defects as we expect that the increase of current efficiency is likely to limit degradation of LEDs in demanding applications such as lighting, and high brightness displays.

8:00 PM EL10.08.15 Enhanced Interfaces for Higher Efficiency and Lifetime of Quantum Dot Light-Emitting Diodes Jeonghun Kwak, Geun Woo Baek and Taesoo Lee; Seoul National University, Korea (the Republic of)

Owing to the superior optical properties of quantum dots (QDs), QD-based light-emitting diodes (QLEDs) are becoming established as the next generation of displays as next generation light sources. In recent years, device performance has been steadily enhanced by improving the charge balance within the device as well as increasing the photoluminescence quantum yield of QDs. However, the light-emitting mechanism of QLEDs, the mechanism of carrier injection into QDs, and the factors affecting their operational lifetime are still not clearly understood. Research on these issues is crucial for the practical application of QLEDs. In this work, we show our recent research results on the influence of various interfaces on the efficiency and lifetime of the QLEDs, including the core/shell interfaces of QDs and the charge transport layer/QD interfaces.

8:00 PM EL10.08.17 Hydrodynamically-Modulated Dewetting of Colloidal Solution for Physical Unclonable Functions Yeongin Cho, Jeongsu Pyeon, Hyoungsoo Kim and Yeon Sik Jung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Traditional methods of blocking counterfeiting are prone to detection by potential attackers. In response, Physical Unclonable Function (PUF) has emerged as an alternative security measure. PUF is a specialized function that leverages the inherent unpredictability of physical processes to yield unique responses to specific challenges. PUF offers hardware-based security, mitigating vulnerabilities inherent in software-based systems susceptible to hacking and signal jamming. Recent efforts have aimed to develop optical PUF labels using various randomness sources. These PUF's non-deterministic fabrication process ensures a substantial encoding capacity for robust data security. However, excessively disorderly PUF codes disseminated across the information space might exhibit a deficiency in possessing a distinguishing fingerprint key. Using random optical features for security keys mandates statistical image processing for digitization and key generation. Unfortunately, the processing of analog signals to digitized codes may compromise authentication accuracy resulting from an arbitrary threshold during an image analysis.

We tackle this by utilizing the geometric multi-bit patterning technique, manipulating dewetting of colloidal solution for advanced optical PUFs that exhibit both high randomness and determinism. By placing agglomerated dots of colloidal particles at a specific vertex within geometrically confined polygons, these two contrasting features can be provided to the PUF system through the hydrodynamic modulation of the dots as visual cues. Exploiting binary solvent flow unpredictability in confined spaces during dewetting, we fabricate sophisticated PUF labels in periodic pixel arrays. The fundamental principle stems from instability arising from imbalanced solutal-Marangoni flows in evaporating polygonal droplets. Importantly, the dynamic coating procedures have the capability to induce unforeseeable fluctuations in contact angles at every vertex during each coating iteration. These fluctuations perturb the radial symmetry of the solutal-Marangoni flows within polygonal-shaped droplet, introducing randomness to the final PUF pattern—a phenomenon supported by statistical parameters. This pattern achieves an entropy of 0.977, a uniqueness value of 0.759, and a correlation coefficient of 0.009, all of which are close to the ideal values. It successfully passes the statistical test for random number generators conducted by NIST (National Institute of Standards and Technology), confirming its true randomness, unpredictability, and unclonability. These random PUF labels with quantized signals at deterministic sites enable efficient, accurate, and swift authentication in both encoding and decoding. They also offer reconfigurability, transferability to diverse surfaces, and the potential for enhanced security through fluorescent molecule dyeing.

8:00 PM EL10.08.18 Silica-Encapsulated Quantum Dots with Thiol Ligand Exchange for High Thermal and Photo-Stability Against Moisture Yoon-Jeong Choi, Jeong-Yool Yoo and Byung Doo Chin; Dankook University, Korea (the Republic of)

Colloidal quantum dots (QDs) have attracted attention in various fields including light emitters for the next-generation display due to their high photoluminescence quantum yield (PLQY) and excellent color purity. However, their low stability under harsh conditions, such as exposure to heat and oxygen, limits their wide-scale applications. Barrier films for QD-sheet are widely used but are expensive and dimensionally less effective. Encapsulation of QDs with silica is regarded as one of the reasonable surface modification methods, which has many advantages such as optical transparency, excellent chemical/mechanical stability, and ease of making chemical modifications. The encapsulation of QDs with silica is based on the use of a silane precursor in a solution containing water, ethanol, ammonia, and amines. However, general QDs are extremely sensitive to their surrounding environment and undergo quenching at these solution conditions. As a result, the development of a waterless silica coating method has become a new strategy. Using the waterless method, the thickness of the silica shell can be controlled by the catalyzed hydrolysis and condensation of silane precursors and requires initial surface modification of the QDs with a silane source followed by condensation on the QD surface. However, the QDs often exhibit decreased quantum efficiencies. To address this issue, a reverse microemulsion method has been applied to facilitate the formation of silica-encapsulated QDs. In this study, red-emitting QDs were coated with silica to enhance their thermal and photo-stability via a two-step involving ligand exchange and a reverse microemulsion method. Especially, native oleic-acid-capped hydrophobic QDs were substituted with strongly binding thiol-functionalized ligands, namely, (3-mercaptopropyl) methyl diethoxysilane (MMPDMS). Then, partially-MMPDMS ligand-exchanged-QDs (MOQDs) were coated with silica and additional ligand substitution reaction with hydrophilic ligands such as 3-mercaptopropionic acid were conducted to enhance the incorporation of the QDs in the reverse microemulsion system. The final silica-coated QDs obtained using these two steps showed only a 6-13% reduction in their PLQYs after UV irradiation and upon high-temperature exposure for 7 days, compared to that of the untreated QDs showing a huge drop of 72-80%. Through this research, we see the great potential of our work that QDs with high stability can be used in the color-conversion layer in various ways such as spin coating, inkjet printing, and film manufacturing, expecting significant enhancement of lifetime compared with pristine QDs.
Advancements in Synthesis and Multicomponent Superlattices of Highly Luminescent Lead Halide Perovskite Nanocrystals

Spinel Plasmonic Metal Oxide Nanocrystals, The Role of Antisite Occupation and Faceting on the Observed Plasmon Properties

**Geoffrey F. Stroose**; Florida State University, United States

Plasmonic metals have been a rich area of research for over two decades, exhibiting shape and size dependent extinction spectra. In n-doped wide band gap metal oxide semiconductors, a plasmon feature (ωp) is observed due to the introduction of carriers. In these plasmonic semiconductor nanocrystals (PSNC), the plasmon frequency and spectral shape are correlated with the number of free carriers (n) at the Fermi level, the carrier effective mass (m*), and the faceting of the metal oxide nanocrystal. The stability of the free carrier in these materials is impacted by the nature of the surface passivation. Solid state NMR, high field EPR, and optical techniques allow the free carrier to be probed, the carrier mass measured, and the impact of faceting and surface interfaces to be evaluated. In the presentation, the role of surface, shape, faceting magneto-optical and synthetic approaches to address fundamental questions in classical oxygen vacancy PSNCs WO3-x, and spinel antisite PSNCs CdSn2O4 will be explored.

9:00 AM **ELI0.09.02**

Thermal-Response of Promesogenic-Ligands Functionalized Nanocrystals

**Shengsong Yang**¹, Yifan Ning¹, Yi-Yu Cai², Ruipeng Li³, Yugang Zhang³, Cherie R. Kagan¹ and Christopher B. Murray¹; ¹University of Pennsylvania, United States; ²Brookhaven National Laboratory, United States

Limited by the mobility of building units, assembled superstructures often lack dynamics, narrowing the potential for applications in smart materials. Here we introduce a novel approach using a specifically designed dendritic ligand that exhibits liquid crystal-like behavior at the interface to enable the realization of dynamic superlattices. The ligands act as a thermally triggered lubricant between nanocrystals. It allows the substrate-bound (dried) nanocrystal solids to transform from poorly ordered aggregates to superlattices with high crystallinity and preferred orientation simultaneously when subjected to thermal activation. With the help of in situ X-ray scattering, the process of the reorientation of the superlattices are revealed and the bottom-to-top transition was observed. The superlattice also prefer to expose the most stable facet at the interface to the substrate.

9:15 AM **ELI0.09.03**

Hydrosilylation on Hydrogen-Terminated Silicon Surfaces using Pt(dvs): From Efficient Grafting of Olefins to Platinum-Coated Silicon Nanoparticles for Catalysis

**Pooja Golvari**, Khaled Alkameh, Azina Rahmani, Titel Jurca and Stephen M. Kuebler; University of Central Florida, United States

Hydrosilylation is an effective method for functionalizing the surface of hydrogen terminated Si substrates and Si nanoparticles (H-SiNPs). We report on the efficiency of Pt-catalyzed hydrosilylation using Karstedt’s catalyst on H-SiNPs and H-Si(100) surfaces. In contrast to the well-established catalytic cycle for the hydrosilylation of olefins using tertiary silanes, we observe that the addition of Pt(II) onto H-SiNPs through oxidative addition is irreversible at room temperature. Optimal reaction conditions are required for optimal hydrosilylation of 1-ocetene. Higher temperature enables hydrosilylation of 1-ocetene on the surface of H-SiNPs by favoring reductive elimination of the catalyst. Trapping the catalyst at low temperatures opens a route for the synthesis of Pt(II)-loaded SiNPs that can undergo ligand exchange. Pt-on-Si ensembles were analyzed using Fourier-transform infrared spectroscopy, X-ray photoelectron spectroscopy, transmission electron microscopy, energy-dispersive X-ray spectroscopy, and atomic force microscopy. Calcination renders Pt-on-Si nanostructures catalytically active towards hydrogenation of phenyl acetylene. These robust Pt nanocatalysts are anchored on SiNPs which enables their facile recovery and reuse through centrifugation or filtration.

Advancements in Synthesis and Multicomponent Superlattices of Highly Luminescent Lead Halide Perovskite Nanocrystals

**Maryna Bodnarchuk**¹, ², Ihor Cherniukh², Taras Sukh², Alex Traverset², Rainer Mahrt², Thilo Stoeferle², Gabriele Rainer² and Maksym V. Kovalenko²; ¹Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland; ²ETH Zürich, Switzerland; ³Iowa State University of Science and Technology, United States; ⁴IBM Zurich, Switzerland

Colloidal lead halide perovskite nanocrystals (LHP NCs, APbX3, where A=Cs+, FA+, FA=formamidinium; X=Cl, Br, I) have become a research spotlight owing to their spectrally narrow (~100 meV) fluorescence, tunable over the entire visible spectral region of 400-800 nm, as well as facile colloidal synthesis. These NCs are attractive single-photon emitters and building blocks for creating controlled, aggregated states exhibiting collective luminescence phenomena. Attaining such states through the spontaneous self-assembly into long-range ordered superlattices (SLs) is a particularly attractive avenue. The atomically flat, sharp cubic shape of LHP NCs is also of interest because the vast majority of prior work had invoked NCs of spherical shape. Long-range ordered SLs with the simple cubic packing of cubic perovskite NCs exhibit sharp red-shifted lines in their emission spectra and superfluorescence (a fast collective emission resulting from coherent multi-NCs excited states).

When CsPbBr₃ NCs are combined with spherical dielectric NCs, perovskite-type ABO₃ binary NC SLs form, wherein CsPbBr₃ nanocubes occupy B- and/or O-sites, while spherical dielectric Fe₂O₃ or NaGdF₄ NCs reside on A-sites. When truncated-cuboid PbS NCs are added to these systems, ternary ABO₃-type phase (PbS NCs occupy B-sites). Such ABO₃ SLs, as well as other newly obtained SL structures (binary NaCl, AlB₂- and ABO₃ types, columnar assemblies with disks, etc.), exhibit a high degree of orientational ordering of CsPbBr₃ nanocubes. These mesostructures also exhibit superfluorescence, characterized, at high excitation density, by emission pulses with ultrafast (22 ps) radiative decay and Burnham-Chiao ringing behavior with a strongly accelerated build-up time. Co-assembly of sterically stabilized CsPbBr₃ nanocubes with disk-shaped LaF₃ NCs yields six columnar structures with AB, AB, AB, and AB stoichiometry, not observed before with NC systems comprising spheres and disks. Combining CsPbBr₃ nanocubes with large and thick NaGdF₄ nanodisks results in the orthorhombic SL resembling CaC₂ structure with pairs of CsPbBr₃ NCs on one lattice site. Additionally, we have also implemented two substrate-free methods of SL formation. The first method involves oil-in-oil templated assembly that leads to the formation of binary supraparticles, while the second method utilizes self-assembly at the liquid-air interface.
The rapid industrialization has led to serious problems of environmental pollution and energy shortages, necessitating the need for exploring renewable energy sources that can be produced ecologically without further releasing pollutants, such as molecular hydrogen ($H_2$). Type-I core/shell quantum dot (QD) systems have been long recognized and utilized as efficient, stable, and sustainable light harvesting and emitting materials. Nevertheless, the application of Type-I core/shell QDs in photocatalysis has been restricted due to the strongly confined photogenerated charges within the core, making them catalytically “inert”. In this project, we found that through the decoration of Au satellite-type domains on the surface of Type-I CdS/ZnS core/shell quantum dots, the energy barrier introduced by the wide-bandgap shell material can be effectively overcome and an over-four-hundred-fold enhancement of the photocatalytic $H_2$ evolution rate was achieved compared to bare CdS/ZnS quantum dots. Transient absorption spectroscopic studies indicated that the charges can be effectively extracted and subsequently transferred to surrounding molecular substrates in a sub-picosecond timescale in such hybrid nanocrystals. Based on density functional theory calculations, the ultrafast charge separation rates were ascribed to the formation of an intermediate Au$_2$S layer at the semiconductor-metal interface, which can successfully offset the energy confinement introduced by the ZnS shell. Our findings not only provide insightful understandings of charge carrier dynamics in semiconductor-metal heterostructural materials but also pave the way for the future design of quantum dot-based hybrid photocatalytic systems.

PbS Nanocrystal Surfaces and Their Assemblies William Tisdale, Massachusetts Institute of Technology, United States

PbS quantum dots (QDs) have been widely pursued in applications ranging from solar cells to IR LEDs to photon up/conversion systems and thermoelectrics. Despite their rich history, we continue to discover new things about PbS QD chemistry, photophysics, and self-organization into ordered solids. In this talk, I will highlight recent work from my lab at MIT on the structure of PbS QD surfaces. In particular, I will demonstrate neutron scattering as a powerful emerging tool for the characterization of colloidal QDs and the detailed information that small-angle neutron scattering (SANS) can provide about the ligand layers surrounding QDs. Additionally, I will demonstrate the underappreciated role of unbound – or “free” – ligand in mediating the structure of self-assembled QD superlattices.

Opposite Charge Separation-Induced DUV/Visible Bipolar Photo-Response of Organic/Inorganic Heterojunction Self-Powered Photodetector Taehyun Park, Jaiyung Seo and Hocheon Yoo, Gachon University, Korea (the Republic of)

Recently, bipolar dual-band photodetectors (BDPD) have been spotlighted for emerging applications such as optoelectronic logic gates and machine vision owing to their wavelength-dependent output signals. Compared to conventional unipolar photodetectors, BDPD devices provide clearly distinguishable spectral output signals based on opposite charge separation mechanism to verify the input optical information without further wavelength selection filters or multi-devices. This special ability of BDPD offers higher device densities by reducing the number of unit components, and multi-functionality in a single optoelectronic device. However, challenges such as limited photo-active material combination or complicated device architecture to achieve opposite charge separation still limits the widespread use of BDPDs.

Herein, we present the wavelength-dependent bipolar photo-responsive organic/inorganic heterojunction photodiode based on dually stacked Schottky and pn junctions. The proposed BDPD was fabricated through a simple and cost-effective sequential spin-coating process. To generate oppositely charged two built-in electric fields, back-to-back diode system was demonstrated with only 4 stacked layers consisting of bottom ITO electrode, p-type fluorene copolymer (Poly[9,9-dioctylfluorene-alt-benzothiazole], FXBT), n-type tin-oxide (SnO$_2$) quantum dots (QDs) and transparent conductive polymer electrode (poly[3,4-ethylenedioxythiophene] poly(styrene sulfonate (PEDOT:PSS)). Based on wavelength selective light absorption in Schottky and pn junctions, the proposed BDPD exhibited clearly distinguishable positive and negative photo responses in deep-ultraviolet (DUV) and visible blue wavelength. Finally, we demonstrated BDPD-based emerging applications including NOT, OR, and XOR optoelectronic logic gates, and true random number generation with arc discharge.

3:00 PM **EL10.10.06**

Organic Ligands Mediated Carrier Dynamics in Photochromic Nanoparticles Adam F. Gross, Shirell Klein, Gregory P. Rutkowski and Erik D. Crenshaw, HRL Laboratories LLC, United States

Photochromic materials are useful for glare reduction, optical switches, and laser dazzling protection. While many photochromics darken rapidly, their reversal to a clear state is governed by ambient temperature or a sequence of optical excitations. Slow detinting times limit their use in many applications where a rapid return to a clear state is needed for safety operation. Fast cycling rates may be achieved by Photochromic Cu-doped ZnS nanoparticles were recently discovered where darkening occurs via the reversible oxidation of the dopant (J. Am. Chem. Soc. 2021, 143, 2239–2249; J. Phys. Chem. Lett. 2021, 12, 8129–8133). However, the detinting time depends on the concentration of environmental water and temperature to mediate the capture of a photoexcited hole. Instead of the environment regulating detinting times, ligand engineering can provide a more direct and controllable route to tune detinting. The nanoparticles’ high surface area and small diameters enable placing hole traps on the surface that affect carrier dynamics; conjugated ligands trap photoexcited holes and return the material to a clear state. Control of the amount of conjugation in the ligand and proximity to the surface reduces the detinting time by up to 8 fold. Furthermore, while ZnS is a known photochromic material, we show that Cu-doped ZnS’ darkening mechanism applies more broadly to additional materials. We employed a fundamental computational pipeline to hunt for fingerprints of photochromicity, which enabled us to identify and validate novel visible and NIR photochromic material compositions.

Two in one: Ni-Doped CsPbBr3 Nanocrystals Enabling Photocatalytic Dehydrogenation of Diaryl Hydrazines Haipeng Lu; The Hong Kong University of Science and Technology, Hong Kong

Colloidal semiconductor nanocrystals, also known as quantum dots (QDs), have demonstrated remarkable abilities as photocatalytic systems for organic transformations, with efficiencies that can rival those of traditional molecular catalysts. However, the unique potential of QDs for photocatalysis, which stems from their large surface-volume ratio, tunable chemical composition, and quantum confinement, has yet to be fully explored. In this presentation, we will discuss our recent work on the design of colloidal CdPbBr3 QDs for acceptorless dehydrogenation of diaryl hydrazines under mild conditions. We achieved this by doping CdPbBr3 QDs with Ni²⁺, creating a dual-catalysis system. Specifically, our catalyst combines visible-light active CdPbBr3 as the photoredox catalyst and Ni²⁺ as the proton-reduction catalyst. This dual-catalytic strategy exhibits a broad substrate scope. Transient absorption spectroscopy indicates an ultrafast electron transfer step from the QD to Ni²⁺ dopants upon photoexcitation, which serves as the proton reduction centers. Our work demonstrates a new design strategy for challenging photocatalytic organic transformations using proton-coupled multiple electron transfer processes.

3:45 PM EL10.10.09
Development of Molten Salt Solvents for Synthesis of Ternary and Quaternary III-V Colloidal Nanocrystals via Cation Exchange Justin Ondry1, Jun Hyuk Chang1, Aritrajit Gupta1, Zirui Zhou1 and Dmitri V. Talapin1,2; 1The University of Chicago, United States; 2Argonne National Laboratory, United States

For the most part, colloidal nanocrystals made of III-V materials (e.g., GaAs, InP, GaSb, etc.) are less developed than their corresponding II-VI and IV-VI counterparts in terms of synthetic control and optoelectronic performance. Despite this, colloidal III-V nanocrystals are desirable since these materials have many impressive optoelectronic properties in bulk, they are less toxic than many II-VI and IV-VI phases, and they may have higher chemical and thermal stability. So far only the indium-based III-V materials (e.g., InAs, InP, and InSb) have been prepared as colloidal nanocrystals with high quality. Gallium- and aluminum-based III-V nanocrystals are difficult to synthesize via traditional colloidal synthesis due to the high temperatures needed to crystalize the more covalent III-V materials and the extreme reactivity of Ga⁺ and Al⁺ cations towards organic solvents at elevated temperatures. To address this, we have developed molten salt solvents as reaction media to synthesize several important alloy III-V nanocrystal phases via cation exchange from their corresponding indium pnictide colloidal nanocrystals. In this presentation we will discuss how colloidal In-pnictide nanocrystals can be transformed to their respective InGa-pnictide and InGaAl-pnictide alloy phases via processing in gallium and aluminum containing molten salts. Further we will discuss the importance of the molten salt composition, elucidated using in-situ high temperature UV-vis absorption and Raman spectroscopy, for ensuring chemical stability of III-V nanocrystals in molten salt solvents. From this, we identify Lewis neutral alkali tetrahalогалат (MAlX4) molten salts are the key reactive phase which engender chemical stability of colloidal InAs nanocrystals and allows their subsequent transformation to InGaAs and InGaAlAs using Lewis neutral alkali tetrahalогалат (MAIX4) molten salts. Additionally, we will describe how controlling the redox potential in the molten salt solvents by using reduced gallium halide molten salts is key to protecting InSb from decomposition and thus enabling the synthesis of InGaSb colloidal nanocrystals. Finally, we describe an atomically precise colloidal atomic layer deposition approach to grow wide band gap II-VI shell materials which precisely passivate surface traps enabling bright band edge photoluminescence from molten salt synthesized InP nanocrystals and quaternary InGaPAs nanocrystals. The materials synthesized by the molten salt methods provide access to continuously tunable light emission from the visible to mid IR suggesting these materials could have broad impact in many applications. Together our work provides key insights into strategies to prepare a diverse family of III-V alloy nanocrystals and will likely enable future development of all-III-V colloidal nanocrystals heterostructures via growth of wide band gap shell materials in molten salt solvents.

3:45 PM DISCUSSION TIME

4:00 PM EL10.10.10
Short-Wave Infrared Quantum Dots with High Quantum Yield Through Mercury Cation Exchange Woonseok Lee and Andrew M. Smith; University of Illinois at Urbana-Champaign, United States

Colloidal semiconductor nanocrystals (NCs) are photonic materials with a combination of unique properties such as size-tunable electronic/optical energy levels, high absorption cross-section, high photoluminescence quantum yield (PLQY), long-term photochemical/photophysical stability, and versatile solution-based processability. NCs with optical transitions in the infrared are currently being developed to reduce the cost of infrared optoelectronic devices, which are currently limited to a few high-tech specialized areas, including defense and astronomy. Among the candidate NC materials, mercury chalcogenide (HgE) and mercury cadmium chalcogenide (HgCd1-xE, E) are leading candidates for infrared optics. In comparison with alternative infrared NCs (e.g., InAs and lead chalcogenides), these materials provide extremely wide spectral tunability across the near, mid, and far infrared spectra. Nevertheless, challenges remain in their advancement due to the low reduction potential of mercury ions that limit the high-temperature solvothermal synthesis and difficulties in the precise selection of mercury-to-cadmium ratios in alloys. The cation exchange (CE) reaction can create new functional NCs by replacing one type of cation with another. The product materials which often cannot be synthesized de novo, can inherit the structural integrity of the parent nanomaterials in terms of size, shape, crystal phase, and homogeneity. However, due to the diffusion-limited CE reaction mechanism, achieving fine control of the radial composition of host and guest cations has been challenging. In addition, for some material systems, the slow diffusivity of cations significantly impedes the CE reaction and requires a high reaction temperature, resulting in a loss of structural homogeneity. In this research work, we developed a new CE method that can bypass the diffusion-limited reaction pathways. In particular, we developed a CE conversion of CdSe NCs to HgSe NCs and evaluated the reaction mechanism. Through the improved reaction, HgCd1-xSe NCs exhibit a homogeneous radial distribution of cation species and enhanced overlap of electron and hole wavefunctions, as well as improved PL properties tunable across the short-wave infrared spectrum (~1000–1700 nm wavelength). After shell overcoating, these HgCd1-xSe/CdS/ZnS NCs exhibited excellent optical properties: the PLQY was above 85% and photoluminescence full-width-at-half-maximum (FWHM) was below 110 meV, properties matching those of the parental CdSe-based core/shell NC emitters.

4:15 PM EL10.10.11
Stability Assessment of Binary Mixture of Small Colloidal Nanoparticles Azita Rezvani1, Osama Anwar1 and Doris Seges1,2; 1Institute for Energy and Materials Processes (EMPI), Germany; 2Universität Duisburg-Essen, Germany

Over the past few decades, extensive research has been conducted on the stability and surface interactions of colloidal dispersions consisting of a single component. However, practical formulations in the real world often involve mixtures of colloidal nanoparticles with different components, such as binders and additives. Therefore, it is crucial to have precise control over the stability of these mixtures, as it plays a vital role in various applications like the self-assembly of nanoparticles into complex structures [1, 2] and the recycling or separation of nanoparticles after synthesis [3-4]. However, studies on handling and stability regulation are scarce in the literature, even for binary colloids. This lack is particularly evident for small nanoparticles (~20 nm), which are highly interface-dominated. This can be attributed to significant challenges in characterizing and comprehending the surface interactions in such complex systems of small colloidal nanoparticles.
In this work, we studied the stability regulation of a mixture of colloidal Au nanoparticles (< 20 nm) and an aqueous dispersion of ZnS quantum dots (< 5 nm) as a binary colloid made of nanoparticles of different sizes and compositions. This is a practically relevant model system and of great interest in this context when we try to recycle the smallest nanostructures from complex mixtures, for instance during the recovery of metals from fuel cell or battery electrodes, in a true circular economy. Here, we investigated how the surface ligand and the purification process of Au nanoparticles affect the stability of the hetero-colloid. To do this, we investigated the stability of Au nanoparticles with three different ligands on the surface after mixing them with ZnS QDs, each before and after functionalization of the Au NPs by bis (p-sulfonatophenyl) phenyl phosphine (BSPP). To characterize the mixture, UV-visible spectroscopy as the main method was combined with dynamic light scattering and analytical centrifugation to assess and monitor the stability of both colloidal components over time. This enabled us to understand the stability-controlling parameters and tailor the surface interactions.

Our work presents a general strategy to understand and tailor the stability of a binary mixture of small colloidal nanoparticles which is a challenge. We successfully created a stable binary mixture of BSPP-capped Au nanoparticles with ZnS QDs as a representative model system. We consider this achievement to be a significant initial stride in the characterization and understanding of the surface interactions of real-world multicomponent formulations.

Low-Cost Synthesis of Silicon Quantum Dots and Their Applications on Luminescent Solar Concentrators Jingsjian Zhou, Uppsala University, Sweden

Here, we developed a cost-effective batch synthesis method for silicon quantum dots (Si QDs) with large Stokes shift and high quantum yield (>50% in polymer nanocomposite) for efficient light conversion. These Si QDs were fabricated from an inexpensive commercial precursor (triethoxysilane, TES), using optimized annealing and etching processes. The optical properties of such QDs are similar to those prepared from state-of-the-art precursors (hydrogen silsesquioxane, HSiQ) yet featuring an order of magnitude lower cost. FTIR revealed that the surface oxide on Si QD was closely related to its light conversion efficiency. Based on this mass production method, we are able to investigate many factors when applying Si QDs as fluorophores in luminescent solar concentrators (LSCs), such as the thickness of polymer interlayer, the appropriate UV dose for curing polymer to avoid haze etc. Eventually, we are aiming to create transparent large-area light-harvesting devices serving as "solar windows".

9:15 AM EL10.11.03
Composition-Defined Optical Properties and the Direct to Indirect Transition in Core-Shell Inx,GaxP/ZnS Colloidal Quantum Dots Justin Ondry1, Aritrajit Gupta1, Kailey Lin2, Richard Schaller3, Eran Rabani2,4 and Dmitri V. Talapin1,3; 1The University of Chicago, United States; 2University of California, Berkeley, United States; 3Argonne National Laboratory, United States; 4Lawrence Berkeley National Laboratory, United States

Semiconductor nanocrystals are commonly divided into materials with direct or indirect band gaps based on the relative positions of the top of the valence band and the bottom of the conduction band in crystal momentum (k) space. It has, however, been debated if k is a useful quantum number to describe band structure in strongly quantum-confined nanocrystalline systems, which blur the distinction between direct and indirect gap semiconductors. In bulk III-V semiconductor alloys like Inx,GaxP, the band structure can be tuned continuously from direct to indirect gap by changing the value of x, where for x>0.75, the material behaves as an indirect gap semiconductor. The effect of strong quantum confinement on the direct-to-indirect transition in this system has yet to be established because high-quality colloidal nanocrystal samples have remained inaccessible. Herein we report one of the first systematic studies of ternary III-V nanocrystals by utilizing an optimized molten salt In-to-Ga cation exchange protocol to yield highly emissive Inx,GaxP/ZnS core-shell particles with photoluminescence quantum yields exceeding 80%. As the gallium content is increased in these systems, we observe the quantum yield decreases and the PL lifetime increases indicating the radiative lifetime increases with increased gallium content. This indicates the oscillator strength of the excitonic transition decreases as gallium is incorporated, consistent with increased indirect-like character of the band edge states. Transient absorption spectroscopy on Inx,GaxP/ZnS nanocrystals enables direct identification of the direct-like or indirect-like character of the band edge in Inx,GaxP/ZnS nanocrystals based on the presence or absence of a band edge bleach feature respectively. Further we study the bieexciton lifetimes of Inx,GaxP/ZnS nanocrystals across as broad size and composition range. We identify that bieexciton dynamics are dominated by volume scaling explanations, rather than composition effects, which is consistent with what is observed for many strongly quantum confined binary semiconductor systems. Finally, atomistic electronic structure calculations based on the semi-empirical pseudopotential model are used to calculate absorption spectra, radiative lifetimes, and evaluate band edge degeneracy. The resulting calculated electronic properties are consistent with experimental observations and provide considerable insight into the underlying band character of the excitonic transitions in these systems. Altogether our results provide a detailed picture of the electronic structure of strongly confined alloy III-V nanocrystals which point to key design principles for optimizing optoelectronic properties of strongly confined semiconductor emitters.
Unlocking the Potential of Metal Borides Nanocrystals—A Journey Through Synthesis and Surface Modification Loredana Protesescu; University of Groningen, Netherlands

Metal borides, a versatile class of materials used in various industrial applications such as superconductors, magnetic materials, and hot cathodes, remain under-explored at the nanoscale due to the challenges in synthesizing single-phase nanocrystals (NCs). Their small size, high surface area-to-volume ratio, and well-defined surfaces exhibit unique physical and chemical properties, making them appealing for various applications, including catalysis, energy storage, electronics, and biomedical imaging. While metal-rich borides, like NiB, are mainly used in electrocatalysis, boron-rich metal borides (metal hexaborides, MB6) are highly valued for their broad range of physical properties that vary based on the metal ion present in their structure. For example, CeB6 and LaB6 have low work functions, while CaB6 and SrB6 exhibit high potential for high-temperature thermoelectric applications. Additionally, they are known for their high hardness, making them suitable for ultra-hard protective coatings.

In this presentation, we will showcase a novel method for synthesizing boron-rich MB6 (M= Sr, Ca, Ba, La, Ce) and metal-rich MB2 (M2=Ni, Co, Fe, x=2,3) NCs through solid-state synthesis at low temperatures (380–440°C), as well as a strategy for stabilizing these crystals for use in solution-based mass production processes. Our discussion will highlight the reaction mechanisms in both classes of nanomaterials, demonstrating the versatility of boron chemistry. By using specific surface modifications, including inorganic and organic ligands, we have achieved stable suspensions of these nanocrystals in both polar and non-polar solvents, with the potential for implementation in cutting-edge technologies.

Two-dimensional colloidal nanoplatelets have become an attractive class of colloidal nanocrystals. With their thickness dependent excitonic properties, they exhibit exciting performance in optoelectronic devices. However, the most widely studied family of colloidal nanoplatelets are based on cadmium chalcogenides, which are considered as toxic materials and their optical properties cover very limited range of the electromagnetic spectrum. To overcome these limitations, we studied the synthesis of zinc chalcogenide based nanoplatelets with two different approaches: cation exchange and direct synthesis. For the cation exchange experiments, we firstly synthesized CdSe/ZnS core/shell NPLs and then performed cation exchange. With this approach, we can achieve core/shell nanoplatelets emitting in the blue spectral region (450 – 480 nm) by preserving their narrower emission linewidth (< 30 nm). In the second approach, we tried direct synthesis of zinc chalcogenide based nanoplatelets. We demonstrated that it is also possible to synthesize ZnSe nanoplatelets having zinc-blende crystal structure with direct synthesis approach. With our optimized synthesis conditions, we synthesized two different population of ZnSe nanoplatelets having absorption peaks at 347 and 369 nm.

Selective On-Off-On Polymer Bonded Quantum Dot-Nitroxide Radical Fluorescent Sensor to Detect Cd2+ Ion in Aqueous Media

Effects on the Cd2+ ion detection with developed fluorescent sensor were carried out. Fluorescence Spectroscopy, Fluorescence Microscopy, UV-Vis of this nanoprobe on iCVD deposited crosslinked copolymer film, interaction between the nanoprobe and target heavy metal ion and some parameter production of crosslinked copolymer thin films of glycidyl methacrylate (GMA) and 2,4,6,8-tetramethyl-2,4,6,8-tetravinylcyclotetrasiloxane (V4D4) via iCVD system was performed in this study. Also, experimental studies for investigations of quantum dot-nitroxide radical nanoprobe formation, attachment to the subcutis and partially biotransform into catalytically inactive cerium phosphate over time. In a second example, I will present a methodological approach for the analysis of iron-based nanoparticles after systemic administration and reveal accumulation of iron particles in splenic macrophage subpopulations co-accumulating endogenous iron. Finally, I will showcase the application of multimodal analytical imaging in the assessment of the stability and fate of a diverse set of metal organic framework nanoparticles. Taken together, this presentation discusses how modern analytical methodologies can be harnessed for the label-free tracking of nanomaterials in complex biological environments with single particle sensitivity.

Comprehensive assessment of material alterations and changes in the local tissue surrounding at unprecedented sensitivity decisively contributes to a rational and safer nanomaterial design and development for health applications.

Design of Dendritic Promesogenic Ligands for Liquid Crystal-Nanoparticle Hybrid Systems

Liquid crystal-nanoparticle (LC-NP) hybrid systems allow synergistic interactions between LC matrixes with anisotropic alignment and NP dopants with
versatile functionalities. A uniform, well-dispersed, and highly stable thermotropic LC-NP mixture paves the way for further applications. In this work, a linear promesogenic ligand and two types of dendritic promesogenic ligands with alkyl or oligoethylene glycol (OEG) chains are designed and synthesized to facilitate incorporating NPs into the thermotropic 4-cyano-4'-pentylbiphenyl (SCB) LC matrix. A comparison study between the linear and the dendritic ligands on the capability to promote miscibility and stability of NPs in LCs is conducted. Miscibility test results show that the linear ligand and the OEG-chained dendrimer both perform well in uniformly dispersing NPs in LCs. Dynamic assemblies of NPs assisted by dendritic ligands and driven by aligning and equilibrating of mesogens are captured, showing the potential of manipulating the assembly of NPs through external thermal stimuli. The stability test shows that both types of dendrimers can significantly enhance the shelf-life time and thermal stability of NPs compared to the linear ligand. In particular, Au NPs capped with OEG-chained dendrimers are stable in SCB for 6 months at room temperature and over 10 h at 50 °C. The synthesis of dendritic ligands is highly modulated and can be generalized onto NPs with different dimensions and properties. Tied by the dendritic promesogenic ligands, this LC-NP hybrid system with good uniformity and stability could be further applied to tunable optical displays, responsive materials, etc.

Lifetime Limiting Degradation Mechanisms of State-Of-The-Art UVC LEDs
Enrico Zanon1, Francesco Piva1, Matteo Buffolo1, Nicola Trivellin1, Carlo De Santi1, Nicola Roccati1, Norman Susilo1, David Hauer Vidal2, Antoni Muhin2, Luca Sulmoni2, Tim Wernicke2, Michael Kneissl2, Gaudenzio Meneghesso1 and Matteo Meneghini1, 1University of Padova, Italy, 2Technische Universität Berlin, Germany

In recent years, an increasing interest was generated in ultraviolet (UV) light-emitting diodes (LEDs), owing to their several fields of application, such as sanitation and disinfection, and to their superior efficiency and lower environmental impact compared to traditional UV light sources. Despite that, these devices still suffer from several problems that lead to a limited lifetime compared to their visible counterpart. Nowadays, state-of-the-art commercial UVC LEDs emitting in the 265 to 275 nm wavelength range show a limited lifetime that decreases, together with EQE, with decreasing emitting wavelengths. This could not be a problem if the useful lifetime of the source is determined based on the total number of deliverable doses for the disinfection of a specific virus species, for instance. If we consider the example of Sars-CoV-2, the disinfection energy required is relatively low, and it was demonstrated that by reducing the operating current of the device, the number of provided doses could be six times higher, in the L70 standard. At the same time, considering the disinfection efficiency as a function of the emitting wavelength, a 265 nm LED with an L70 20% lower could provide higher doses with respect to a 275 nm device.

To better understand the physical mechanisms behind this limited lifetime, specific experiments were carried out on research-grade single quantum well (SQW) LEDs. The analysis highlights the correlation between the physical phenomena observed from electro-optical characterizations and degradation processes detected and modeled by means of capacitance deep-levels transient spectroscopy (C-DLTS), deep-levels optical spectroscopy (DLOS), and numerical simulations based on TCAD models. These studies on SQW LEDs were conducted to identify the types of degradation mechanisms, which can be divided into optical and electrical ones. Regarding the degradation of the optical characteristics, two different trends can typically be observed comparing high and low bias levels. By using conventional rate equations, it was demonstrated that a simple increase in non-radiative recombination is not sufficient to reproduce the experimentally-observed changes in the L-I curve but is required the consideration of a decreasing injection efficiency. While the first degradation mechanism is confirmed by several works, the latter is still under investigation, though most preliminary investigations relate it to the accumulation of charged centers in the active region, and to the subsequent formation of a higher injection barrier for holes. Regarding the electrical degradation mechanisms, the worsening of p-contact conductivity and the increase in the concentration of deep-levels participating favoring trap-assisted tunneling (TAT) and sub-turn-on conduction are commonly identified during aging. The former process, associated with an increase in the device turn-on voltage can typically be ascribed to the current-induced deactivation of the magnesium (Mg) dopant located in the proximity of the
Defect Control Strategies for AlN-Based Alloys

Naseem Ud Din, Cheng-Wei Lee, Keisuke Yazawa, William Nemeth, Rebecca Smaha, Nancy Hasegawa, and Prashan Gorai
Colorado School of Mines, United States; National Renewable Energy Laboratory, United States

Tetrahedrally-bonded III-N and related alloys are useful for a wide range of applications, from optoelectronics to dielectric electromechanics. Heterostructural AlN-based alloys offer unique properties for piezoelectric, ferroelectric, and other emerging applications. Atomic-scale point defects and impurities can strongly affect the functional properties of materials, and therefore, it is crucial to understand the nature of these defects and mechanisms through which their concentrations may be controlled in AlN-based alloys. In this study, we employ density functional theory with alloy modeling and point defect calculations to investigate native point defects and unintentional impurities in Al1-xGdxN and Al1-xScxN alloys in the wurtzite phase. We find that the native defect chemistry in both AlN-based alloys is generally similar while differences can be attributed to their electronic band gaps. Among the native defects that introduce deep mid-gap states, nitrogen vacancies (VN) are predicted to be in the highest concentration, especially under N-poor growth conditions. We predict and experimentally demonstrate that VN formation can be suppressed in thin films through growth in N-rich environments [1]. Like AlN, we also find that both Al1-xGdxN and Al1-xScxN alloys are prone to high levels of unintentional O incorporation, which indirectly leads to even higher concentrations of deep defects. Growth under N-rich/reducing conditions is predicted to minimize and partially alleviate the effects of O incorporation. The results of this study provide valuable insights into the defect behavior in wurtzite nitride-based alloys, which can guide their design and optimization for various applications.

Time-Resolved Cathodoluminescence Spectroscopy of Oxygen Related Defects in AlN Layers

Barbara Szafrański, Lukas Peters, Andreas Waag and Tobias Voss
Braunschweig University of Technology, Germany

For the fabrication of AlGaN UV LEDs, a high quality AlN buffer layer on sapphire substrate is a prerequisite for increasing the quantum efficiency. However, in MOVPE it is challenging to achieve a low threading dislocation density (TDD), high transparency of the AlN buffer layer and high light output efficiencies at the same time. Additional processing challenges arise due to excessive wafer bow caused by differences in thermal expansion coefficients between LED stack and substrate. AlN is one of the few compound semiconductors where annealing at high temperatures (HTA) leads to a substantial improvement of the crystal quality without dissociation of the compound. At the same time, the optical transparency is increased and bowing problems are reduced, since much thinner AlN HTA layers can be used in comparison to thick MOVPE-grown buffers. Typical HTA AlN thicknesses are below 500 nm. However, during the annealing process, a large number of point defects is introduced. Among those, oxygen is one of the most prominent defects as the higher chemical affinity of aluminum for oxygen than for nitrogen.

We analyzed the influence of oxygen defects in AlN layers with cathodoluminescence (CL) spectroscopy. For all experiments, we used an AlN sample fabricated by PVD on c-oriented sapphire substrates. The 425 nm thick AlN layer was treated with HTA at 1680°C for 2 hours in N2 atmosphere at normal pressure. SIMS measurements revealed a high oxygen concentration of 2×1020 cm−3 for the studied AlN sample. At room temperature, CL spectroscopy shows a broad (FWHM ~ 400 meV) oxygen related luminescence band centered at about 3.54 eV (330 nm). To study the charge carrier dynamics of the oxygen-related defects in AlN, time-resolved CL measurements have been performed. The defect related emission is characterized by a complex multieponential decay with a fast component of less than 100 ns and a slow component of longer than 10 μs. We attribute the short decay time to the radiative transition from the conduction band-edge states to (VAl-ON) or (VAl-ON)2. The long recombination times might be related to carriers deeply trapped in spatially separated regions of the sample by the impurity-derived electric fields. Further we will discuss the influence of the oxygen concentration in AlN on the recombination times.

Microscale Electronic Properties of Epitaxial Gallium Nitride Surface Defects

Andrew Winchester, Michael Mastro, Travis Anderson, Jennifer Hite and Sujittra Pookpaanratana
National Institute of Standards and Technology, United States; U.S. Naval Research Laboratory, United States

The wide bandgap material GaN is desired for next-generation high power electronics beyond Si and SiC. However, the vertical structures needed for scalable devices suffer from issues related to dislocations and defects, which propagate from the substrate into the epitaxially grown device area. Substrate developments such as strain patterning to coalesce dislocation bundles and alternate scalable growth methods such as the ammonothermal process have produced higher structural quality substrates. However, in both cases, the remaining dislocations and defects are still a major concern for high power device performance and reliability. For example, threading dislocations with screw components are known to exhibit leakage current and are predicted to have mid-bandgap states, while newer ammonothermal GaN substrates may exhibit different defect densities and distributions compared to GaN grown on foreign substrates. Therefore, determining the electronic properties of dislocations and defects at the microscale will provide valuable information for identifying “killer” defects.

Here, we use a combination of laser-based photoemission electron microscopy (PEEM) and conductive atomic force microscopy (cAFM) to investigate the local surface electronic properties of defects and dislocations in GaN epitaxially grown via MOVPE on different substrates. In epitaxy on patterned substrates, we identify surface defects located near strain centers that have a star-shaped appearance with central pits and extending cracks. These star defects exhibit a larger work function and a shifted valence band maximum, and further, show increased reverse bias leakage current compared to the surrounding GaN. For epitaxy on ammonothermal GaN substrates, we instead observe elongated triangular patches that sporadically occur on a face of certain growth ridges. These regions also show altered electronic structure compared to the surrounding GaN, but are instead more resistive under both forward and reverse bias conditions. Our results provide evidence for defective sites likely related to extended dislocations that will lead to degraded device performance.

Defects in Gallium Oxide Imaged by Photoluminescence Microscopy

Matthew D. McCluskey, Cassandra Remple, Benjamin Dutton and John S. McCoy
Washington State University, United States

Photoluminescence (PL) spectroscopy is an important method to characterize dopants and defects in gallium oxide. Common features in the PL spectrum
include the intrinsic UV band, blue and green bands that involve donor-acceptor pairs, and red emission due to Cr\textsuperscript{3+} impurities. PL mapping with excitation wavelengths ranging from 266 to 532 nm reveals the spatial distribution of these features with submicron resolution. In Czochralski-grown β-Ga\textsubscript{2}O\textsubscript{3}:Fe, the Cr\textsuperscript{3+} emission intensity shows striations that are attributed to inhomogeneities during growth. Ir\textsuperscript{4+} can also be imaged through resonant Raman scattering. By comparing the two signals, we can gain insight into Fermi level variations across the sample. In addition to defects in the bulk, PL microscopy has revealed several specific defects on the surface. Some of these localized centers are very bright UV emitters. Raman scans of these bright emitters revealed hydrocarbon peaks, which may point toward the origin of the light emission.

**SESSION EL11.02: UWBG RF and Power Devices**

**EL11.02.01**

**UWBG Semiconductors – The Next Leap in RF and Power Electronics**

*Thomas E Kazior*\(^1\) and Sharon Woodruff\(^2\)

\(^1\)DARPA, United States; \(^2\)Booz Allen Hamilton, United States

Just as the wide bandgap (WBG) semiconductors, GaN and SiC, are revolutionizing RF and power electronics for defense and commercial applications, the unique properties of the ultra-wide bandgap (UWBG) semiconductors hold promise to create the next revolution. However, these materials are in their infancy, and many technical challenges must be overcome before their promise can become a reality. This invited talk will provide an overview of several UWBG research areas of interest to DARPA. These include: 1) methods to integrate dissimilar semiconductor materials, such as UWBG and narrow bandgap (NBG) semiconductors, to create new device structures that leverage the unique properties of the individual material layers, funded under the Heterogeneous Heterostructures (H2) program; 2) methods to integrate high thermal conductivity UWBG materials with WBG and NBG materials to overcome thermal and electric field bottlenecks in traditional RF power devices, funded under the Technologies for Heat Removal in Electronics at the Device Scale (THREADS) program; 3) new approaches to create large diameter, low defect density, single crystal diamond substrates, funded under the Large Area Device-Quality Diamond Substrates (LADDIS) program; 4) the synthesis of doped UWBG materials, the creation of novel UWBG heterostructures and the engineering of electrical and thermal interfaces funded under various smaller efforts; and 5) exploiting the high breakdown field of UWBG materials to achieve unprecedented levels of RF power handling.

**Bridging the Gap: Overcoming Materials and Device Challenges that Limit UWBG Semiconductor Progress**

*David J. Meyer, Virginia Wheeler, Matthew Hardy, Eric Jin, Andrew Lang, Neeraj Nepal, Jason Roussos, Vikrant Gokhale, James Champlain, Brian Downey and Jeffrey Calame*

Naval Research Laboratory, United States

Ultrawide bandgap semiconductors (UWBGs) offer a myriad of electrical, optical, thermal, and mechanical properties that have the potential to unlock previously unattainable levels of performance in coupled-phenomena devices. Despite their known theoretical advantages, progress in UWBG materials and devices has been inhibited by a number of challenges over the past few decades. Practical considerations such as cost, size and consistency of substrate material have made it difficult for the research community to systematically study technical questions that exist with the synthesis and processing of UWBGs. It is exciting to see recent progress in wafer size and affordability of UWBG substrates such as single crystal diamond, AlN, and Ga\textsubscript{2}O\textsubscript{3}; however, proof-of-concept device demonstrations that clearly display the performance benefits of these materials are still needed to further attract interest in the technology.

While the breakdown strength advantages of UWBGs have been clearly verified in the lab by several groups, there are additional challenges that need to be overcome in order to establish this technology’s long-term applicability. This talk will discuss a few of these challenges along with potential approaches being explored to provide solutions:

- **Challenge #1:** Realizing highly mobile electronic charge at sufficient density within UWBG channels and thin films – Conventional approaches such as impurity doping in UWBGs are difficult because many impurities form deep levels within the bandgap (typically 0.2 eV or deeper), resulting in low room-temperature ionization efficiency. Additionally, conventional thin film growth approaches may not provide an energetically favorable environment for the incorporation of dopant atoms on the desired lattice site. Lastly, UWBG materials often have high levels of point or extended defects that can serve as compensation dopants, limiting the concentration of free carriers. A synthesis approach that has been studied by a few groups is the use of metal-modulated molecular beam epitaxy (MME) for the kinetically-controlled incorporation of impurities in AlN thin films. We will discuss our group’s efforts involving Si-doping of AlN with MME.

- **Challenge #2:** Managing high electric fields present in UWBG devices – Common device passivation layers such as SiN\textsubscript{x} and gate dielectrics such as HfO\textsubscript{2} have electric field breakdown strengths in the ~5-10 MV/cm range. As the breakdown strength of UWBGs materials exceeds this range and devices start to operate at 100’s and 1000’s of volts, passive dielectrics in the device will quickly become potential points for catastrophic failure. As much effort as the community is investing in UWBGs thin films, it should also be working to develop complementary dielectrics necessary for device passivation or gate insulation to support long-term reliability. In this talk, we will discuss the concept of relative permittivity engineering for dielectric superjunctions and their use to spread the peak electric fields in UWBG devices.

- **Challenge #3:** Improving the thermal management of high power UWBG devices – A potential future application of UWBGs is in the area of RF power transistors. The current state-of-the-art, GaN, is typically operated in a backed-off power state to prevent acceleration of failure mechanisms due to excessive self-heating during operation, limiting its ultimate RF output power density. While the physics of failure mechanisms in UWBG devices are largely unknown at present, it is likely that thermal management of these devices will need to be co-designed alongside electrical considerations in order for the technology to realize performance benefits. This talk will discuss strategies for device integration with diamond for improved thermal management.

**Comparative Operation of Ultra-Wide Bandgap Devices for Voltage/Power Conversion**

*Jack D Flicker\(^1\), Robert J. Kaplan\(^1\), Jonah Shoemaker\(^2\) and Stephen M. Goodnick\(^3\)

\(^1\)Sandia National Laboratories, United States; \(^2\)Arizona State University, United States

Ultra-Wide-Bandgap (UWBG) semiconductors hold great promise for future power conversion applications, especially for incorporation at grid-level...
currents and voltages (10s-100s of kV, 100s of A). Figures of Merit (FOMs) are often used as a first means to understand the impact of semiconductor material on power semiconductor performance, and, in particular, the Unipolar (or Baliga) FOM is often cited for this purpose. However, the use of UWBG materials in a given application requires the fabrication of devices followed by system insertion. While the benefit of UWBG incorporation in power converters should roughly scale with the UFOM, there are several factors of importance for UWBG incorporation in switching power converters that are not explicitly included in UFOM-type calculations including switching behavior, incomplete ionization, mobility, and temperature dependence.

This talk will give an overview of work under the Ultra Materials for a Resilient, Smart Electricity Grid, a Department of Energy Basic Energy Sciences Energy Frontier Research Center, dedicated to evaluating the impact of UWBG materials in grid-level power electronic converters. Toolsets and modeling efforts will be introduced to evaluate how material characteristics of UWBG semiconductors percolate up to system-level improvements, especially regarding power dissipation for different material systems and device types in switching power converters. An optimization technique for two- and three-terminal devices will be introduced that calculates the minimum power dissipation in a switching power converter for a given system operational regime (reverse voltage, forward current density, frequency, duty cycle, and temperature), thereby allowing utilization of the optimal material/device combination for that application. A variety of UWBG device types and materials systems will be directly compared, e.g., diamond, gallium oxide, and aluminum nitride. This gives an overall roadmap for materials systems and device structures that can be utilized to target UWBGs to specific application areas.

3:00 PM BREAK

3:30 PM *EL11.02.04
Semi-conducting AIN Electrical Devices Alan Doolittle1,4 and Samuel Graham2; 1Georgia Institute of Technology, United States; 2University of Maryland, United States

Aluminum nitride (AIN) is of great interest for high performance power electronics, extreme environment semiconductor devices, radio frequency devices, and deep ultraviolet (DUV) optoelectronics due to its excellent electrical and thermal properties. Compared to other commonly used semiconductors (i.e., Si, SiC, GaN, and β-Ga2O3), AIN has the highest critical electric field and theoretical breakdown voltage, which lead to the highest Baliga’s and Johnson’s figures-of-merit (BFOM & JFOM). AIN also has the second highest saturation velocity, and thermal conductivity among semiconductors with a commercially available substrate3. However, AIN has traditionally only been an insulator without the ability to be converted to a semiconductor via doping. We recently demonstrated substantial bulk doping (carrier concentrations above 1018 cm-3) for both p- and n-type AIN using Be and Si dopants, respectively. From these results, we also demonstrated rectification and a 6 V turn-on in AIN PN diodes1,2,3.

Electrical characterization of homojunction aluminum nitride (AIN) PIN diodes is presented along with an update on the prospects for an AIN FET. Recently, using the metal modulated epitaxy (MME) variation of molecular beam epitaxy that controls the surface chemistry to enable low temperature, high quality epitaxy, substantial bulk n- and p-doping in AIN as well as AIN homojunction PN diodes are demonstrated, overcoming the longstanding barrier to doping of AIN1,2. P-type (p=4.4x1018 cm-3, 0.04 ohm-cm ) and N-type (n=3x1018 cm-3, 0.02 ohm-cm) bulk conducting AIN is demonstrated with a narrow window for substrate temperatures for achieving semiconducting AIN. With proper surface cleaning procedures, MME grown AIN is indistinguishable from the HVPE AIN on sapphire template via TEM. Current-voltage-temperature (IVT) data from 25 °C to 300 °C is used to investigate these diodes. Diodes with poor substrate cleaning shows a kinked, temperature independent IV behavior in the low forward voltage range associated with defect assisted tunneling originating from stacking faults near the re-growth interface. No such kink, no stacking faults but still temperature independent IV is observed for properly cleaned substrates. These quasi-vertical devices consist of 1 µm highly n-type AIN/Si, a lightly Si-doped intrinsic AIN layer with varied thickness, and a 200 nm highly p-type AIN/Be.

IVT measurements from 25 °C to 300 °C in deep forward bias is presently limited by high series resistance originating from contacts to the plasma etched n-type AIN layer which has ~100x higher contact resistance than as-grown n-type AIN. However, the current increases by ~2 orders of magnitude as temperature increases with contact limited specific-resistance improving by ~250x with an activation energy of ~0.3 eV. Forward current below the turn on voltage appear to be dominated by tunneling as suggested by temperature independence. Transistor structures will be discussed and at present are, again, contact limited to ~0.1 A/mm and only modest current modulation. Contact metallization, surface preparation of the AlN templates, and various device surface temperature techniques, such as STTM, for accurate extraction of thermal resistance. Finally, the challenges associated with STTM measurements on structures with small channel spacing and thick metal contacts is discussed and a numerical solution via FEM modelling is proposed.

3:00 PM BREAK

4:00 PM EL11.02.05
Impact of Buffer Layer on the Thermal Performance of Multi Channel AlGaN/GaN Transistors Georges Pavlidis1, Mohammad Jamil1, Bivek Bista1, Francis Vasquez1 and Andrea Centrone2; 1University of Connecticut, United States; 2National Institute of Standards and Technology, United States

The formation of the two dimensional electron gas (2DEG) in AlGaN/GaN high electron mobility transistors (HEMTs) has enabled devices that can operate at both high frequencies (> GHz) and high voltages (> 3 kV). These advantageous characteristics have translated to the commercialization of superior DC converters and high-power density radio frequency (RF) devices. The current record performances of single channel AlGaN/GaN RF transistors, however, have been thermally limited to power densities that are significantly lower than the expected theoretical limits. One approach to improve the power density is the implementation of superlattice based multichannel transistors. The stacking of adjacent 2DEGs has been proven to increase the current density and transconductance of HEMTs.

To maintain a low ON-resistance, the heat generated in these nanostructured devices must be efficiently removed which requires in-depth knowledge of nanoscale thermal transport. Two challenges to overcome include the low cross plane thermal conductivity of superlattices and the high thermal resistance of a thick AlGaN buffer layer. This study investigates the impact of implementing a thinner GaN buffer layer with higher thermal conductivity.

To assess the feasibility of simplifying the thin film structure, the thermal performance of non-castellated multichannel HEMTs is assessed via two techniques: scanning thermal microscopy (SThM) and Raman thermometry. For direct comparison, a multichannel device with a thin GaN buffer layer is demonstrated to achieve the similar thermal resistance to a device that is epitaxially grown on a AlGaN buffer layer that has fewer number of channels. A thermal finite element model (FEM) is developed to explain the discrepancy between the temperatures measured via SThM (surface temperature) and Raman thermometry (depth average). The peak temperature is found to be in the proximity of the topmost channel which highlights the importance of surface temperature techniques, such as SThM, for accurate extraction of thermal resistance. Finally, the challenges associated with SThM measurements on structures with small channel spacing and thick metal contacts is discussed and a numerical solution via FEM modelling is proposed.
X-Band AlGaN/GaN HEMT with Output Power over 20 W/mm and PAE over 50% using High Purity GaN Channel

Kenji Homma, Maciej Matys, Atushi Yamada, Toshihiro Okli and Norikazu Nakamura; Fujitsu Limited, Japan

An AlGaN/GaN high electron mobility transistor (HEMT) is still attractive devices for high frequency amplifier applications due to excellent properties of nitride materials like a wide band gap and large breakdown field. In the recent years, several reports concerning the high output power characteristics of AlGaN/GaN HEMT for X-band applications have been published [1,2]. Practical devices are required to satisfy not only high output but also power saving performance by high efficiency. In this work, we report on our success in simultaneously achieving a power density of more than 20 W/mm and an efficiency of more than 50% in the X-band.

A high-performance X-band AlGaN/GaN HEMT were grown by metal-organic chemical vapor deposition (MOCVD) on a SiC substrate. The devices exhibited a peak transconductance (Gm) of 335 mS/mm and high maximum drain current of 1.34 A/mm. The load-pull measurements performed at 8 GHz corresponding to the target device operating frequency in X-band for devices with gate lengths of 0.25 µm demonstrated a peak power added efficiency (PAE) of 52.6% and a maximum output power density of 21.2 W/mm at 60 V. To the best of our knowledge this is the highest power ever reported for X-band AlGaN/GaN HEMT at Vds = 60 V. We achieved these results by improvement of the current collapse (dc-RF dispersion) in terms of optimizing the growth conditions of the GaN channel on top of the Fe-doped GaN buffer in AlGaN/AIN/GaN heterostructures. In particular, we investigated the impact of growth parameters of the GaN channel layer, such as the growth rate, and V/III ratio on the AlGaN/AIN/GaN HEMT performance. We found that the GaN channel layers grown with the high V/III ratio (about 5000) lead to a suppression of the current collapse in AlGaN/AIN/GaN HEMTs. Based on the photoluminescence (PL) measurements, we attributed the current collapse suppression to the reduction of GaN channel acceptor-like traps related to the carbon impurities. More precisely, for the GaN channel layers grown with the V/III ratio of about 5000, we observed a significant decreases of yellow luminescence from the AlGaN/AIN/GaN heterostructure, which directly correlated with the current collapse improvement. We believe that the achieved progress represents an important step toward the development of high power AlGaN/GaN HEMTs.

Ultra-Wide Bandgap AlGaN-Based N-Polar High Electron Mobility Transistors: From Materials to Devices
Malika Noshin, Xinyi Wen, Rohith Soman, Xiaoping Xu and Subranti Chowdhury; Stanford University, United States

Ultrawide bandgap (UWBG) materials are being widely investigated for high-power and high-frequency electronics [1,2]. While emerging UWBG materials like GaN, possess large bandgap and high critical electric field, AlGaN compositions can potentially have larger Figure of Merit owing to higher sheet carrier concentration and larger mobility. Recently, using N-polar all AlGaN-HEMT we showed simultaneously large drive current, low on-state leakage current as well as > 400 V breakdown voltage [3].

In this work, we discuss the growth and optimization as well as the characterization of N-polar AlGaN channel HEMT with varying Al concentrations. We also probe the composition-dependent surface morphology and transport in these materials, aided by simulation and Hall measurements.

For the growth of the N-polar all-AlGaN HEMT structures, we used the metal-organic chemical vapor deposition (MOCVD) method. We used e-plane sapphire substrates with a 4° miscut towards ω-plane for achieving smooth and high-quality epitaxy. We demonstrated four different HEMT structures with Al mole fraction x = 20%, 30%, 59% and 73% in the AlGaN channel layer. The growth of such MOCVD-grown N-polar all-AlGaN HEMT was optimized at higher temperatures with higher TMAI flow to achieve a crack-free growth and lower dislocation density within the structures.

We measured the stoichiometries of the structures using both symmetric and asymmetric 20-ω scans in X-ray diffraction to incorporate strain effect. After KOH etching the N-polar HEMT showed hexagonal hillock-like structures, confirming the N-polarity of our grown samples. Atomic force microscopy imaging confirmed the good surface morphology with a root mean square surface roughness of <1 nm under 5 µm x 5 µm scan size. We also found that the surface roughness increased for HEMTs with the higher Al mole fraction AlGaN in the channel and barrier layers which can be from strain due to larger lattice mismatch between layers.

To develop a fundamental understanding of the material property and device performance, we explored the effect of Al mole fraction in the transport characteristics of the HEMT structures using Hall measurement. We found a decreasing trend in the mobility with increasing Al mole fraction in the AlGaN channel that can be correlated to alloy-scattering [4] and optical phonon-scattering dominated transport, further explored in our TCAD simulations. Our simulation showed that beyond 73% Al mole fraction, the mobility increases again. Comparing our simulation with the Hall mobility numbers, we can discern that mobility degradation due to surface undulation might be more pronounced for HEMT structures with higher Al percentages. We also fabricated N-polar all-AlGaN HEMT devices with 20% Al composition in the channel. A 10 µm channel length device offered a drive current of ~250 mA/mm. The high drive current can be attributed to the formation of better contacts on the lower-bandgap material and the natural formation of a back-barrier.

To summarize, in this work we reported experimental demonstration of device-quality epitaxial growth of N-polar all-AlGaN HEMT. The success of this study which will be discussed at the presentation led to the first demonstration of >400V breakdown voltage N-polar AlGaN HEMTs. We also explored the correlation between the material surface morphology and transport properties for varying Al compositions. This work will deepen our understanding of the optimization of N-polar AlGaN HEMT for high-power applications.

We acknowledge the funding from ONR (Award No N00014-19-1-2611- P00004) and Dr. Paul Maki for supporting this work.

Polarity Inversion of Scandium Aluminum Nitride (ScAIN) Piezoelectric Thin Films via Addition of Element in Group IVB (C, Si, Ge or Sn) Sri Ayu Anggraeni, Masato Uehara, Kenji Hirata, Hiroshi Yamada and Motoaki Akiyama; National Institute of Advanced Industrial Science and Technology, Japan

The discovery of scandium aluminum nitride (ScAIN) piezoelectric thin film has successfully brought promising improvement to the performance of
modern wireless communication technology, particularly radio frequency (RF) filter [1,2]. The shift toward 6G communication system demands RF filter that can work at much higher frequency and wider bandwidth to allow efficient data transmission. Since integrating multilayers of piezoelectric thin films with different polarities enable an RF filter to function at much higher frequency [3], stacking Al-polar and N-polar ScAlN thin films is expected to be an effective strategy to achieve high-performance RF filter. As a result, controlling the polarity of ScAlN has become paramount for the development of next generation RF filter. Addition of element such as silicon (Si) or germanium (Ge) into AlN was reported to capable of inversing the polarity of aluminum nitride (AlN) [3,4] as well as ScAlN [5,6]. Therefore, in this study, we investigated the effect of addition of each element in group IVB (carbon (C), Si, Ge, tin (Sn)) on the polarization direction of ScAlN thin films.

All thin films were deposited on Si (100) wafer by using radio frequency magnetron sputtering system. Our study reveals that addition of C into ScAlN resulted in thin films with positive piezoelectric coefficient ($d_{33}$), which means addition of C into ScAlN maintained the polarity of ScAlN to be Al-polar. However, addition of either Si or Ge into ScAlN resulted in thin films with negative $d_{33}$ and the $d_{33}$ values have similar magnitude with that of ScAlN. This suggested that addition of Si or Ge could inverse the polarity of ScAlN from Al-polar into N-polar, without significantly decreasing the value of $d_{33}$. In case of Sn, the negative $d_{33}$ that was obtained upon the addition of Sn into ScAlN is an indication that addition of Sn could lead to thin films with N-polarity. However, the $d_{33}$ values of ScSnAlN are lower than that of ScAlN. Our study confirmed that the formation of N-polar ScAlN is largely controlled by both concentration of each additive element (in this case: Si, Ge, Sn) and the concentration of Sc. Effect of addition of each element on polarity distribution, crystal structure and surface states were also investigated in this study.

considered to be the ultimate wide bandgap semiconductor material for applications in high power electronics due to its exceptional thermal and electronic properties. Two recent developments – the emergence of commercially available electronic grade single crystals and a scientific breakthrough in creating a MOS channel in diamond technology, have now opened new opportunities for the fabrication and commercialisation of diamond power transistors. These will result in substantial improvements in the performance of power electronic systems by offering higher blocking voltages, improved efficiency and reliability, as well as reduced thermal requirements thus opening the door to more efficient green electronic systems. In the literature, several diamond-based field-effect-transistors (FETs) have already revealed good on state performance and high blocking voltage capability (~3kV) in a wide range of operating temperatures. The possibility of generating an inversion regime in diamond metal-oxide-semiconductor FET (MOSFET), and the new Deep Depletion regime (D2MOSFET) specific to wide bandgap semiconductors pave the way for a new generation of power devices. The critical part of the transistor is the gate oxide, with electrical charge traps located within the oxide or at its interface with the semiconductor. These traps can screen the gate potential and shift the threshold voltage, making the devices unusable. The current research carried out mainly in Japan and Europe will be presented, with the various device architectures explored, including MOSFET, MESFET, D2MOSFET and rectifiers.

Theoretical Models of High-Field Transport and Impact Ionization in Ultra-Wide Band Gap Semiconductors
Enrico Bellotti, Mike Zhu and Masahiko Matsubara; Boston University, United States

Theoretical models that attempt to predict high-field carrier transport parameters and the values of the carriers’ ionization coefficients are important since they provide an estimate of the expected values and a first order evaluation of the material performance. The direct measurement of ionization coefficients in wide and ultra-wide band gap semiconductor materials is challenging due to the need to operate at high field strengths and the requirement of specific test structures that enable single carrier injection. More often than not, ionization coefficients are inferred from current multiplication data measured in p-n junctions or transistors structures. Unfortunately, sub-par material quality, processing issues and inappropriate measuring techniques have led to ionization coefficients values that are contradictory and with large variation among different datasets.

Developing theoretical models presents its own set of challenges. The established approach is based on a full electronics structure description of the semiconductor material and a suitable model to quantify the interaction of carriers with phonons, impurities and material imperfections. While this methodology has been successful with conventional elemental and compound semiconductors, and it has been applied to some wide band gap materials such as GaN, 4H-SiC [3] and diamond, a number of open issues still exists. The main difficulty is the determination of the carrier-phonon scattering strength at high electric field strengths that cannot be inferred from low-field mobility measurements.

Among all wide band gap semiconductors, 4H-SiC [3] and GaN [4] are the material for which ionization coefficients have been measured by several groups. In the case of GaN, different measured ionization coefficients datasets are available and seems to provide a consistent indication of the expected values. Corresponding theoretical models based on full-band Monte Carlo simulations have been able to predict the correct trends, namely the fact that holes dominate the ionization process, but a quantitative agreement between predicted and measured values has only been achieved recently [5].

This talk will provide an overview of the currently available experimentally measured ionization coefficients for wide band gap semiconductors and compare them to the ones obtained with theoretical models of different complexity. Specifically the development of the theoretical models for high-field transport for 4H-SiC, GaN will be discussed. Three different approaches, one based on empirical carrier-phonon scattering rates, one using the rigid pseudo ion model, and the direct evaluation of the interaction parameters based on a ab-initio DFT approach will be compared, and the outcome for each one of them benchmarked against the measured values. Additionally, the models will be applied to determine the ionization coefficients in ultra-wide band-gap semiconductors including AlGaN alloys, cubic BN [6] and diamond.

Quantitative Disorder Metrics and Structure-Property Relationships in Ga-Based Ultra-Wide Bandgap Semiconductors
Robert Makin1, Andrew S. Messecar1, Nancy S. Muyanja1, Kate Wislang1, Rodrigo Martinez-Gazoni1, Martin Allen1 and Steve Durbin1; 1Western Michigan University, United States; 2University of Michigan–Ann Arbor, United States; 3University of Canterbury, New Zealand

In the context of epitaxial semiconductor layers prepared for electronic devices, disorder is frequently an important consideration. One well-known model for quantifying disorder was developed by Bragg and Williams in the early 1930s, who were concerned with accurately describing the varying degrees of atomic ordering in metal alloys. In their formulation, a numerical order parameter (S) is defined as having a value between 0 (fully randomized lattice) and unity (fully ordered lattice). Traditionally this order parameter is measured using x-ray diffraction techniques, but we have recently demonstrated that electron diffraction, Raman spectroscopy and electron microscopy are equally viable experimental methods. Following the approach of Lakes, Wei and Zunger as applied to semiconductor alloys, it is possible to employ spin-based modeling in conjunction with cluster expansion theory (out to pair-interaction terms) to express a material property P as P(S) = P(S=0,S=1) = P(S=0)S2 − P(S=0), provided that P is dominated by pair interactions. Here, S is the Bragg-Williams order parameter, and x represents the composition (e.g., x = [Ga]/([Ga]+[N])). Consequently, the expectation is that some properties may exhibit a linear dependence on S2 provided that composition is properly accounted for; in fact, this is what has been observed in the case of a number of different semiconductor materials.
In the present study, forty-four Ga2O3 and twenty-eight distinct GaN samples were considered. Ga2O3 layers were grown either by plasma-assisted molecular beam epitaxy or a sol-gel method; GaN was grown by plasma-assisted molecular beam epitaxy. An additional set of samples identified in the literature was also included. The Bragg-Williams order parameter was measured using either in-situ reflection high-energy diffraction, Raman spectroscopy, or electron microscopy image analysis, with several samples characterized by multiple techniques (with S typically agreeing to three decimal places). For the GaN samples measured, S ranged from approximately (0.02 to 0.52), with both nitrogen-rich and gallium-rich compositions in addition to stoichiometric material included. For Ga2O3, experimentally-determined values of S2 ranged from (0.08) to (0.53). As would be expected, a range of band gap energies was measured for the GaN samples, including evidence of inverted bands for some gallium-rich samples as indicated by the observed temperature dependence. In the case of Ga2O3, only stoichiometric samples were included in the initial study, with a range of measured band gap energy between 3.2 eV at S = 0.53 to 5.0 eV at S = 0.08. For the GaN samples, Hall effect mobility values were also measured, with a linear relationship between mobility and S3 and higher mobility values for Ga-rich samples at the same value of S5. Extrapolation of the experimental points suggests that further tuning of S could lead to slightly higher mobility values than what have been reported for undoped epitaxial layers. There are several ways to tune S in a plasma-assisted molecular beam epitaxy process, with a weak dependence on temperature and a stronger dependence on plasma conditions. In contrast, for Ga2O3 grown by PLD, a strong dependence of S on oxygen partial pressure is observed, with a weaker dependence on sapphire substrate plane. For Ga2O3 plasma-assisted molecular beam epitaxy process, with a weak dependence on temperature and a stronger dependence on plasma conditions. In contrast, for Ga2O3 grown by dehydroxylation of GaOOH, a linear relationship between temperature and S2 is observed. Consequently, process parameters can be tuned during epilayer growth to achieve a specific value of S and composition (s), and thereby engineer a desired value of band gap and potentially mobility.

Deciphering 3d Transition Metal Dopants in GaN (and Wide Band Gap Materials) using Ground State and Excited State Density Functional Theory Peter A. Schultz1, Jesse J. Lutz1, Renee Van Ginthoven2 and Arthur H. Edwards2; 1Sandia National Laboratories, United States; 2Air Force Research Laboratory, United States

Doping of gallium nitride (GaN) and (ultra-)wide band gap, (U)WBG, materials is used to control the Fermi level and create functional defects for optoelectronic and spintronic applications. Harnessing the greater temperature tolerance, faster switching speeds, and larger breakdown voltages possible with III-nitrides would profoundly improve the performance of power electronics. To exploit the technological potential of 3d-doped (U)WBG requires greater understanding of 3d defects than currently exists. Fm first identification and characterization of defects in (U)WBG remains fraught. The mismatch between what experiment can measure and definitively identify and what theory can reliably compute is a particularly acute challenge in 3d-doped GaN. Using a generalized gradient approximation (GGA) to density functional theory (DFT) along with a non-jellium local moment countercharge (LMCC) treatment of the charge boundary conditions, we demonstrate accurate predictions of defect levels of magnetic 3d dopants in GaN unhindered by a band gap problem and in agreement with available experimental data. We implement an occupation-constrained DFT (occ-DFT) to self-consistently obtain excited state total energies, and thereby predict vertical and adiabatic optical excitation energies corresponding to photoluminescence (PL) data. These GGA excited-state results agree quantitatively with PL measurements, whereas literature hybrid functional calculations fail qualitatively. In concert, ground state (defect levels) and excited state (PL) calculations mandate wide reinterpretation of GaN experimental literature. The Mn dopant is shown to take charge states as deep as (2+), with corroborating evidence anchored at one end by accurate prediction of the 1.4 eV PL for the Mn(0) and the other end by accurate prediction of PL for a (Mn2 +) defect. The 1.19 eV PL in n-type GaN, attributed to Cr2+ and touted as a promising candidate for a quantum color center, cannot be the Cr1+ – the Cr1+ is stable only in midgap. A combined ground-state/excited-state modeling approach enables more confident identification of defects in (U)WBG, aiding the search to identify, characterize, and design doping regimens to create functional defects with auspicious electronic properties.

Yellow Luminescence in GaN: Predictions for Candidate Defects at Zero and 12 GPa Hydrostatic Pressure Arthur H. Edwards1 and Peter A. Schultz2; 1Air Force Research Laboratory, United States; 2Sandia National Laboratories, United States

Yellow luminescence (YL) has held great interest in GaN. The identity(ies) of the YL defect(s) has been controversial for many years. Recent experimental work by Zvanut et al. and by Narita et al. proved that carbon substituting on a nitrogen (CN) site is one of the components of this identification. This is supported by recent theoretical results, buttressed by the photoluminescence studies of Reshechiov and coworkers, who resolved the zero phonon line (ZPL) and other phonon replicas. These theoretical studies have found other defect candidates predicted to have PLmax and ZPL close to experiment for YL.

There is prior data for YL obtained at high hydrostatic pressure, showing that YL band strongly shifts and broadens, making assignment to a single defect untenable. We perform a detailed study of CN, as well as other candidate defects (V(C)O, C2O3, V(C)O2H, V(C)O2H2, V(C)O2H3, V(C)O2H4) at 0 GPa and 12 GPa using the standard PBE exchange correlation functional with the local moment countercharge (LMCC) method, an alternative to the standard jellium approximation for electrostatic boundary conditions. Prior published LMCC results show that the method reproduces a reasonable proxy for the band gap (3.56 eV (LMCC), vs. 3.3 eV (exp.) bound by the span of all defect levels arising from localized charge states for an extensive set of intrinsic and extrinsic defects. We use this “defect band gap” both to estimate the change in the experimental gap as a function of pressure, and to assign new band edges for calculation of PLmax at 12 GPa. At 0 GPa our results agree well with Lyons et al.: V(C)O, V(C)O2H, and C2 have PLmax within ~0.1 eV of experiment (2.18 eV), and also yield accurate probability for ZPL. We are in reasonable agreement with Lyons et al. that V(C)O:H is within 0.2 eV of experiment ZPL. Our new results at 12 GPa provide crucial chemically discriminating information. First, we find that the prediction of the slope of E0 vs. pressure using the extrinsic defect bands as band edge bounds (36 meV/GPa) is in very good agreement with several experimental values (36-47), where the larger values were taken from the linear coefficient of a quadratic fit, and the lowest was taken from a purely linear fit. For V(C)O, V(C)O2H, and C2, we find that predicted PLmax are no longer close in energy: the value ranges from 2.51 eV to 2.83 eV. Almost all of the change in PLmax is in the ZPL. Even though the Frank-Condon shifts (FCS), the energy difference between PLmax and the ZPL, are quite different for each defect, ranging from 0.2 to 0.55 eV, the changes in FCS with pressure are minimal—10-20 meV. These results point to using hydrostatic pressure, combined with computational predictions, to chemically discriminate PL.

Stability and Molecular Pathways to The Formation of Spin Defects in Wide Band Gap Semiconductors for Quantum Technologies Elizabeth M. Lee; University of California, Irvine, United States

Spin defects in wide-bandgap semiconductors provide a promising platform to create qubits for quantum technologies. Their synthesis, however, presents considerable challenges, and the mechanisms responsible for their generation or annihilation are poorly understood. Here, we elucidate spin defect formation processes in a solid-state crystals for leading qubit candidates—the divacancy complex in silicon carbide [1] and the nitrogen vacancy (NV)
center in diamond. Using ab initio molecular dynamics with enhanced sampling techniques, we characterize the formation mechanism of spin defects. We then predict the conditions favoring the formation of spin defects over the competing process of other undesirable defects. Moreover, we identify pathways to create new spin defects and determine their electronic properties using hybrid density functional calculations. The detailed view of mechanisms that underpin the formation and dynamics of spin defects presented here may facilitate the realization of qubits for designing room temperature quantum devices.

Rutile GeO₂ and GeSnO₂ Alloys: A New Family of Ultra-Wide-Bandgap Semiconductors for Power Electronics
Sieun Chae¹, Hanjong Paik², Kelsey Meng¹, Kyle Bushick¹, John T. Heron¹ and Emmanouil Kipsouakis²; ¹University of Michigan, United States; ²The University of Oklahoma, United States

Ultra-wide-bandgap (UWBG) semiconductors are promising for higher efficiency, reduced size, and lower cost in power-electronics applications. UWBG materials such as diamond, cubic boron nitride (cBN), β-Ga₂O₃, and AlGaN alloys promise order-of-magnitude improvements in power density compared to current technologies (Si, SiC, and GaN). However, none of the above UWBG materials offers all the desired properties needed for high-performance electronics and, despite decades of research and development of alternative UWBG semiconductors, no materials have been demonstrated to date. There is therefore a pressing need to develop synergistic methods that combine predictive theory with experimental synthesis and validation in order to discover and design new UWBG semiconductors that can overcome the limitations of current technologies.

In recent years, our team has advanced the development of rutile GeO₂ and its alloys with SnO₂ as a novel family of UWBG semiconductors that can surpass the state of the art in power electronics. Our predictive atomistic calculations demonstrate that these alloys exhibit superior fundamental properties that can overcome the limitations of current materials. Their band gaps fall in the ultra-wide range, spanning from 3.6 eV for SnO₂ to 4.68 eV for rutile GeO₂. They exhibit ambipolar dopability, with Si⁺, As⁺⁺, Ta⁺⁺, H₂, and F₂ acting as shallow donors, while A⁺⁺ and Ge⁺⁺ acting as acceptors. The predicted carrier mobilities are high (up to 377 cm²/Vs for electrons and up to 29 cm²/Vs for holes at room temperature), while the relative light carrier effective masses prevent the formation of self-trapped polarons. The predicted thermal conductivity is high (up to 31 W/m K at room temperature) and surpasses β-Ga₂O₃, a prediction that we verified experimentally with thermal measurements in unperturbed polycrystalline bulk samples. Overall, we find that the Baliga figure of merit of rutile GeO₂, modified to account for donor ionization, surpasses all known semiconductors, demonstrating its unique potential for energy-efficient power electronics.

Experimentally, we demonstrate the synthesis of single-crystalline GeO₂-based thin films and substrates, which are prerequisites for the fabrication of epitaxial devices. Our results demonstrate the epitaxial stability of GeO₂-based alloys over their entire composition range, while the demonstration of epitaxy on high-quality rutile GeO₂ substrates opens up the possibility of epitaxial single-crystalline thin films. Overall, our work demonstrates the promise of rutile GeO₂-based materials for advancing the state of the art in power electronic devices.

Influence of Local Coordination on the Electronic Structure of Ga₂O₃
Anna Regelant¹, Laura Ratcliff², Takayoshi Oshima³, Felix Nippert², Benjamin Janzen⁴, Elias Kloth¹, Ruediger Goldhahn¹, Martin Feneberg⁵, Oliver Bierwagen⁵, Charlotte Wouters³, Moshab Nofal³, Martin Albrecht⁴, Jack Swallow⁸, Leanne Jones⁹, Pardeep Thakur⁴, Tien-Lin Lee¹, Curran Kalha¹, Christoph Schlueter¹⁰, Tim Veal¹, Joel B. Varley¹¹ and Markus Wagner⁴,6; ¹University College London, United Kingdom; ²University of Bristol, United Kingdom; ³Saga University, Japan; ⁴Technische Universität Berlin, Germany; ⁵Otto von Guericke Universität Magdeburg, Germany; ⁶Paul-Drude-Instit für Festkörperelektronik, Germany; ⁷Leibniz Institute for Crystal Growth, Germany; ⁸University of Liverpool, United Kingdom; ⁹Diamond Light Source, United Kingdom; ¹⁰DESY, Germany; ¹¹Lawrence Livermore National Laboratory, United States

Ga₂O₃ is a key ultra-wide band gap oxide offering a rich structural space, with a number of accessible polymorphs. Its most stable form is monoclinic β-Ga₂O₃, but other polymorphs, including hexagonal α-Ga₂O₃, cubic γ-Ga₂O₃, and orthorhombic α(κ)-Ga₂O₃, are of increasing interest. Although this wealth of possible structures opens opportunities to control and tune structure, electronic structure, and ultimately physical characteristics, the polymorphs beyond β-Ga₂O₃ remain comparatively unexplored. Experimental results are particularly scarce due to current limitations in producing high-quality materials and the lack of theoretical results for the more structurally complex polymorphs.

This study presents an in-depth exploration of the relationship between local coordination environments and the electronic structure of the α, β, γ, and α(κ) polymorphs of Ga₂O₃. The samples investigated are either bulk single crystals or epitaxial films grown using molecular beam epitaxy (MBE) or atomic layer deposition (ALD), selecting the highest quality samples available for each of the polymorphs. We report high-resolution valence band spectra from soft and hard X-ray photoelectron spectroscopy (SXPS and HAXPES) which are directly compared to theoretical partial and total electronic densities of states as calculated within the framework of density functional theory (DFT). Both deep and shallow core level spectra are also compared to DFT results to explore the influence of structure, rather than solely the oxidation state, on the core level behavior. X-ray absorption spectroscopy (XAS) is used to probe the unoccupied states and in combination with SXPS is used to gain an estimate of the changes in the band gaps of the polymorphs. The highly disordered γ-Ga₂O₃ polymorph, we combine DFT with machine learning to screen one million potential structures of γ-Ga₂O₃ to develop a robust atomistic model. We can clearly show that only the lowest energy structural models are able to describe the experimental results from SXPS and HAXPES, providing a new avenue to understand disordered oxides.

Ultimately, this work presents a systematic and comprehensive study of the electronic structure of Ga₂O₃ polymorphs, providing insight into electronic trends and their relationship to crystal structure. This comparative study helps to discern trends between the different structures and advances our understanding of this polymorphic material. It lays the foundation for further exploration of Ga₂O₃ in applications beyond its β phase.

4:15 PM EL11.05.08
First Principles Investigations of NV-Like Centers in Oxides
Vrindu Somjit¹, Joel Davidsson², Yu Jin³ and Giulia Galli¹,³; ¹Argonne National Laboratory, United States; ²Linköping University, Sweden; ³The University of Chicago, United States

The nitrogen vacancy (NV-) center in diamond is a prototypical spin defect with favorable properties, such as long coherence times, and optical addressability and readout. However, the drawbacks of this defect, including incompatibility with telecommunication fiber optics infrastructure and manufacturing challenges, continue to prompt investigations into other host material systems. Recent predictions [1] suggest that several oxides, including CeO₂, CaO, and MgO, may possess long coherence times and thus could serve as promising hosts for quantum applications. However, the defects in these oxide hosts that exhibit such long coherence times are yet to be identified. By leveraging a high-throughput first principles workflow [2], we have
Through comparison of our calculations with experimental results [2], we show that a vast amount of information is contained in a single ODMR curve. By master equation and excited manifold density matrix populations, we calculate ODMR curves to compare with experimental results [2].

Efficient and Accurate Calculations of Electronic Excited States of the Negatively Charged NV-Center in Diamond

Electronic structure calculations of the properties of ultra-wide-bandgap materials and the effect of dopants in such materials can play an important role in the development of high-performance devices for e.g. quantum information science and ultraviolet optoelectronic emitters and detectors. Results of calculations based on the most commonly used method for electronic structure calculations of solids, density functional theory (DFT), reported in the literature on one of the most commonly used systems, the negatively charged NV-center in diamond, have been contradictory and controversial, leaving the impression that much more computationally intensive methods are needed to get accurate results [1]. This applies in particular to the excited states of the defect relevant for optical generation a pure spin state where DFT calculations from different groups have not even agreed on the ordering of the relevant energy levels, the two excited singlet states and the first excited triplet state. A new approach for calculating excited electronic states using density functionals based on direct optimisation and convergence on saddle points on the energy surface [2,3] has, however, been found to give remarkably close results to ‘beyond RPA’ embedding calculations and experimental data [4]. This is an important result as it opens the door for large scale, reliable calculations of other doped ultra-wide-bandgap materials without excessive computational effort. The approach presented makes calculations of excited states in materials similar in computational effort as ground state DFT calculations.

4:30 PM EL11.05.09

Theory of Optically Detected Magnetic Resonance of a Silicon Vacancy in Silicon Carbide

Optically detected magnetic resonance (ODMR) is one tool that can be used to probe the spin character of optically-active color centers in a nondestructive manner, with applications including the identification of radiation-induced defects in semiconductors and quantum magnetometry [1,2]. In ODMR, a color center is optically pumped while a Zeeman magnetic field is swept and the resulting photoluminescence (PL) is measured on a detector. A microwave field is also applied to induce resonant Rabi oscillations, seen as extrema in the PL contrast, and creates a characteristic and reproducible curve. A detailed and fully quantitative simulation of the ODMR of a color center would provide confidence that the foundations of nonequilibrium optical and spin dynamics relevant for ODMR are sufficiently understood, while allowing for the extraction of reliable parameters for spin coherence times, optical transition rates, and microwave coupling strengths.

In this work we simulate room-temperature ODMR of the negatively charged silicon vacancy VSi– V(2) site in 6H-SiC, an emerging candidate for quantum magnetometry, using Lindblad master equations and density matrix populations and compare with experimental results [2]. VSi– in 6H-SiC ODMR can be described as a synthetic atom with S=3/2 ground and excited spin manifolds, separated by 1.397 eV, and a metastable state in the energy gap between these manifolds [2,3]. The Hamiltonian of each spin manifold can be divided into terms which cause coherent transitions between states and subsequent resonances, the magnetic and electric components of the microwave field, and terms that dictate the positions of the resonances, the Zeeman field and zero field splitting. In ODMR the ground and excited spin manifolds are coupled via absorption, spontaneous emission, and nonradiative pathways through the metastable state and we simulate these processes, as well as pure dephasing, with a Lindblad master equation [4]. Using the steady-state solution of the master equation and excited manifold density matrix populations, we calculate ODMR curves to compare with experimental results [2].

Through comparison of our calculations with experimental results [2], we show that a vast amount of information is contained in a single ODMR curve. By fitting our model to experimental results [2] we are able to extract spin Hamiltonian parameters such as zero field splitting, g-factors, microwave electric and magnetic field strengths, Stark coupling coefficients [5], and hyperfine couplings. We are also able to extract absorption, spontaneous emission, and intersystem crossing rates as well as coherence times $T_2^\ast$. Finally, we stress the flexibility of these calculations and their natural extension to ODMR theories of other color centers and polytypes of SiC, and their natural extension to color centers in other wide or ultra-wide bandgap materials, which would be desirable for quantum sensing applications or radiation-induced defect identification.

We acknowledge support from NSF DMR-1921877 and AFOSR MURI "REDESIGN".

Diamond P-i-N and Schottky P-i-N diodes are a promising new technology for high power limiters. Receivers, solid-state amplifiers, and detectors commonly use P-i-N and/or Schottky diodes for protection from high power incident signals. Limiters reflect the majority of excess RF power, but inevitably absorb some portion of the incoming power as well. As dissipated power converts to heat, the thermal impedance and temperature resilience of the limiter diode becomes the primary factor determining device lifetime, reliability, and power handling. Si and GaAs-based P-i-N and Schottky diodes, and even SiC-based Schottky diodes suffer non-recoverable thermal overload upon excess power dissipation. Diamond, by contrast, offers superior thermal conductivity and temperature resilience. Diamond also provides good charge carrier mobility and high electric breakdown field making it an ideal material for next generation high power RF limiters.

Power limiter circuits frequently rely on solid-state P-i-N and/or Schottky diodes to act as a protective buffer for microwave components that are susceptible to damage from high-power signals. Limiters must transmit low power signals with minimal attenuation or distortion, while attenuating high power signals so as not to exceed a prescribed maximum. While solid state power limiters offer the advantages of a long operating life, small size, and flexible use, including integration with other MMIC components, they often require a pre-limiter stage due to limitations in power handling and spike leakage. Diamond diodes with high power handling and spike low leakage promise to eliminate the need for a prelimiter stage by offering significantly enhanced power handling and reduced spike leakage.

In a shunt-connected diode power limiter circuit, the diode remains off for low input signals, with any diode off-capacitance (Coff) contributing to insertion loss (attenuation of low power signals) and limiting the frequency bandwidth. When the magnitude of the input signal exceeds a threshold, the shunt-connected diode turns on. In the on state, the diode acts as a short to ground, resulting in reflection of most incoming RF power. However, on-resistance (Ron) in the diode results in dissipation of some portion of incident power through the limiter circuit. As incident power increases, the power absorbed by the power limiter circuit increases as well. Device overheating from this dissipated power is the primary failure mechanism that sets the maximum power handling of a diode. Using a larger diode can increase power handling at the expense of greater Coff and thus greater insertion loss.

The cutoff frequency figure of merit captures the tradeoff between Coff and Ron and can serve as a useful metric for evaluating the suitability of limiter device technologies for RF applications. Commercially available high power Si P-i-N diodes have an FCO of around 700GHz. The FCO figure of merit, however, does not account for the power dissipation capability of a device. Two devices with the same FCO may dissipate the same power under the same incident conditions, but if one device can handle a greater heat load, it will have better power handling. Therefore, fabricating diodes in a material such as diamond offers a route to dramatically increasing power handling without insertion loss penalty. Compared to the conventional materials systems used for diodes—including Si, GaAs, and SiC—diamond offers over 20x higher thermal conductivity and 2-3x higher maximum operating temperature. While significant material growth and processing challenges remain before diamond matures as an electronics material, the advent of single-crystal substrates and breakthroughs in bipolar dopant incorporation have spurred rapid advances in recent years. If diamond diodes can be achieved with FCO of several hundred GHz, they could be a viable high power-handling alternative for the Si or GaAs diodes in use today.

Improved Nitrogen-Doped Diamond Photoconductivity by Electrode Design

Kelly Woo, Mohamadali Malakoutian, Bhwani Shankar and Srabanti Chowdhury; Stanford University, United States

In photoconductive semiconductor switches (PCSS), the conduction between two terminals on a semiconductor is modulated by the absorption of optical radiation in the gap between the electrodes. This switching device can be applied to pulsed power technology for high speed and jitter free switching. These may include radar, particle acceleration, and pulsed high-power lasers. More recently, as we move towards electroplating of the grid, trigger isolation enabled by PCSSs may enable safer mechanisms for making and breaking high power circuits as well. However, typical materials studied for photoconductive switching, such as Si and GaAs suffer from thermal runaway effects at high power [1]. Since diamond is an ideal material for high power electronics due to its large bandgap (5.47 eV), high breakdown electric field (10 MV/cm), high carrier mobility, high thermal conductivity (10-20 W/cm.K), and low coefficient of thermal expansion (~1.1 um/mK) [2], we chose to study its photoconductive properties and potential as a high power optoelectronic switch.

Past studies have shown photoconductivity in intrinsic diamond by UV-band excimers in high electric fields up to 2 MV/cm [3]. In our devices, however, we utilize nitrogen doped substrates to excite carriers by sub-bandgap photon energies while maintaining the desirable properties of diamond that would facilitate higher breakdown field and better thermal management [4]. In this case, a lower energy, a below bandgap Vis-NIR excitation source is sufficient, which increases the feasibility of PCSS integration. In designing extrinsic PCSS, on/off current ratios should be maximized for high performance switching. In the off state, the material conductance primarily depends on the number of ionized dopants, which is very low in the case of nitrogen doped diamond due to the high activation energy. In the on state, the conduction is increased due to the photogeneration of free carriers through ionization of dopants and traps. In this work, we aim to increase the on-state conductivity by using different metal electrode stacks on both lateral and vertical PCSS configurations. In the vertical configuration, we also aim to demonstrate the higher power capabilities of an extrinsic diamond PCSS.

Testing of the extrinsic diamond PCSS was performed by optically exciting with a frequency doubled Nd:YAG pulsed laser (532 nm) with an output energy of <1 mJ and a full width half maximum (FWHM) of 10 ns. The nitrogen diamond HPHT substrates from Element Six had an average doping...
The growth of high quality heavily (p+) B-doped single crystal diamond (SCD) layers is prerequisite for the successful realization of diamond-based high power PCSS applications, which can be further developed and optimized for higher performance.

This work was supported by ULTRA, an Energy Frontier Research Center funded by the U.S. DOE.

Formation of Ohmic Contacts to (001) Diamond with Nitrogen-Doped Nanocarbon Surface Layers
Evangeline Amonoo, Vishal Jha, Trevor Thornton, Franz Koeck, Robert J. Nemanich and Terry L. Alford; Arizona State University, United States

The electrical properties of Ohmic contacts (i.e., the specific contact resistance) was investigated using the transfer length method (TLM). In this study, the TLM method was employed to analyze the properties of Ohmic contacts using a tri-layer stack of Ti/Pt/Au contacts on a nitrogen-doped n-type conducting nanocarbon (nanoC, Patent No.: US 11,380,763 B2) epitaxial film grown on a (001) diamond substrate. Samples were annealed to monitor any changes in electrical conductivity and specific contact resistance values between the electrode and the nanocarbon layer were 8×10−4 Ωcm2. This is significantly lower than previously reported values by almost two orders of magnitude. The improved contact resistivity attributed to two factors. Firstly, the increased amount of nitrogen incorporation into the nanocarbon film enhanced the electrical conductivity. Nitrogen doping also introduced additional charge carriers, improving conduction properties in the nanocarbon layer. Secondly, the presence of electrically active defects in the film further contributed to the increase in conduction. These findings demonstrate the potential for improved Ohmic contacts in nanocarbon-based electronic devices, offering opportunities for enhanced performance.

Schottky Barrier Diodes Based on B-Doped Single Crystal Diamond Films – An Experimental and Theoretical Methodology Ken Haenen1,2; 1Hasselt University, Belgium; 2IMEC vzw, Belgium

The growth of high quality heavily (p+) B-doped single crystal diamond (SCD) layers is prerequisite for the successful realization of diamond-based high-power electronics. This presentation will zoom in on a combined experimental and theoretical approach of the impact of methane concentration on the deposition of heavily boron-doped (p+) single crystal diamond (SCD), in turn influencing the performance of Schottky barrier diodes based on said layers.

Using (100)-oriented high-pressure high-temperature substrates, optimized CVD growth conditions led to ~1.6 µm lightly B-doped (p) SCD films with an acceptor concentration of (1.0 ± 0.5) × 1020 cm−3 on top of the p+ layers [1]. To fabricate pseudo-vertical Schottky barrier diodes, Ohmic and Schottky contacts were sputtered on the p+ and p layers, respectively.

It was already observed that the forward operation current of the diodes increased proportionally with increasing [CH4]/[H2] ratio (from 0.5% to 3%) used for the CVD of p+ layer. This increase in current is associated with an increase in the doping level of the p+ layers, a direct result of the increase of CH4 concentration in the CVD plasma [1]. The Schottky barrier height and ideality factor of the diodes were determined and compared with theoretical calculations, where an ideal diode (n = 1) with a barrier height variation over the Schottky diode area agreed reasonably well with our experimental results. The diodes fabricated on samples with the p+ layers grown at higher [CH4]/[H2] behaved similarly, except for their non-ideality (n > 1) [2]. To conclude, the voltage-dependent ideality factor of the Schottky diodes will be discussed.

Electrochemical Application of Boron-Doped Diamond Electrodes—Electrochemical Sensors and CO2 Reduction Yasuaki Finag; Keio University, Japan

Boron-doped diamond (BDD) electrodes are very attractive material, because of their wide potential window, low background current, chemical inertness, and mechanical durability. In these years, we have reported several examples for electrochemical sensor applications including novel microring systems for in vivo real-time detection of local drug kinetics.[2] Furthermore, applications for electrochemical organic synthesis[3] and electrochemiluminescence (ECL) systems[4] are also reported. Here, recent developments on electrochemical CO2 reduction using BDD electrodes are presented.

In 2018, we investigated the electrochemical reduction of CO2 in a flow cell using BDD electrodes. The faradaic efficiency (FE) for the production of HCOOH was as high as 94.7%. Furthermore, the selectivity for the production of HCOOH was more than 99%. The rate of the production was increased to 473 µmol m−2 s−1 at a current density of 15 mA cm−2 with a FE of 61%. The FE and the production rate are almost the same as or larger than those achieved using Sn and Pb electrodes. In addition, the stability of the BDD electrodes was confirmed by 24 hours operation.[5] Then, in 2019, we were able to control the selectivity and efficiency with which carbon monoxide (CO) is produced by optimizing certain parameters and
conditions used in the electrochemical process with BDD electrodes, such as the electrolyte, the boron concentration of the BDD electrode, and the applied potential. With a BDD electrode with 1% boron used for the cathode and KClO$_4$ for the catholyte, the selectivity for producing carbon monoxide was high. On the other hand, with a BDD electrode with 0.1% boron used for the cathode and KCl for the catholyte, the production of formic acid was the most evident. *In-situ* ATR-IR measurements during electrolysis showed that CO$_2$ anion radical intermediates were adsorbed on the BDD surface in the KClO$_4$ aqueous solution. Here, switchable product selectivity was achieved when reducing CO$_2$ using BDD electrodes.[6]

Recently, in order to operate on a large scale for industrial applications, an intermittent flow cell system was presented. A stop-start motion of the flow conditions in the intermittent cell was created using a piston pump, and this considerably reduces the rate of electrochemical conversion of CO$_2$ to HCOOH compared to a continuous flow system.[7] Furthermore, we found that an initial electrochemical CO$_2$ reduction reaction could significantly improved the reaction current and Faradic efficiency of the CO$_2$ reduction on BDD electrodes.[8] The effect is referred to as the “self-activation” of BDD. Here, the mechanisms and the effect of self-activation is discussed.

**High Production of Hydrogen Peroxide from Carbonated Water Through Electrochemical Synthesis by Boron-Doped Diamond**

Yusuke Tatsumi$^1$, Andrea Fiorani$^1$, Irkham Irkham$^2$ and Yusaku Einaga$^1$; $^1$Keio University, Japan; $^2$Universitas Padjajaran, Indonesia

**Introduction**

H$_2$O$_2$ is recognized as a powerful oxidizing, bleaching and water treatment agent. It attracts great interest as a green oxidant because it decomposes into water and oxygen. Most of H$_2$O$_2$ is nowadays produced by large-scale anthraquinone auto-oxidation (AO) process, but recently efforts have been made to establish alternative synthetic strategies, because AO process employs anthraquinone, known as a carcinogen, in addition to organic solvents. Electrochemical methods offer some advantage, such as direct synthesis in aqueous electrolytes, and oxygen or water as starting reagents. The boron-doped diamond (BDD) electrode is physically and chemically stable, and it is known for its specific electrochemical property to produce OH radical easily$^1$. For the purpose of analytical applications, we previously demonstrated that BDD electrode can produce H$_2$O$_2$ from water oxidation. Here, we focused our attention on the optimization of H$_2$O$_2$ production on BDD.

**Experimental**

Electrochemical experiments were conducted in a two-chamber cell separated by a Nafion membrane with a three-electrode setup (working electrode and counter electrode: BDD with 1% B/C ratio, reference electrode: Ag/AgCl). H$_2$O$_2$ was produced by electrochemical oxidation in chronoamperometry (CA) at 2.5 V. We investigated the effect of electrolyte solution on the H$_2$O$_2$ production by comparing the electrolyte salt (phosphate and carbonate), and by pH variation. H$_2$O$_2$ was detected by UV-visible spectrophotometry after the reaction with K$_2$MnO$_4$.

**Results & Discussion**

CA was conducted for 2 hours in 1 M KHCO$_3$ and 1 M K$_2$CO$_3$ aqueous solution respectively as the anolyte, and time production was compared. The maximum production was 16.8 mmol cm$^{-2}$, whereas it was 118 mmol cm$^{-2}$ with K$_2$CO$_3$. This suggests that CO$_3^{2-}$ anion was superior to HCO$_3^-$ for H$_2$O$_2$ formation. Due to their equilibrium between CO$_3^{2-}$ and HCO$_3^-$, the ratio of their presence changes with pH. To verify the contribution of CO$_3^{2-}$ to increased H$_2$O$_2$ production, 1 M KHCO$_3$ solution and 1 M K$_2$CO$_3$ solution were mixed to reach the desired pH. CA performed from pH 8 to 12 demonstrated that the amount of H$_2$O$_2$ production increased concurrent to the CO$_3^{2-}$ fraction.

To confirm whether this was due to the effect of the basic solution or carbonate ions, hydrogen peroxide production was conducted either by using 1 M K$_2$CO$_3$ or 1 M K$_2$PO$_4$ solutions (pH 11.9 and 12.9, respectively), and it was found that only the K$_2$CO$_3$ solution produced hydrogen peroxide. Concerning the mechanism, our laboratory suggested that OH radicals generated by electrochemical oxidation of OH$^-$ on BDD oxidized CO$_3^{2-}$ to C$_2$O$_6^{2-}$, that reacts with water finally producing hydrogen peroxide by hydrolysis.$^{12}$ Hydrogen peroxide formation in this work can be considered to have proceeded by a similar reaction pathway.

In addition to the BDD electrode, glassy carbon (GC), fluorinated tin oxide (FTO), and Ni electrodes were used in a 2-hour electrolysis to compare the time dependence of hydrogen peroxide production. The results showed that BDD >> GC > FTO > Ni. Characterization of GC and BDD by SEM after electrolysis demonstrated that the surface of GC electrode was clearly damaged and corroded, while BDD did not reveal any apparent change confirming the high stability of BDD surface. From these results, we demonstrated that BDD can be used profitably to synthetize hydrogen peroxide with a high production rate from aqueous solutions containing carbonate.

**Ammonia Synthesis by Electrochemical Reduction of Nitrate Anion using Boron-Doped Diamond Electrode**

Satoru Kuramochi, Andrea Fiorani and Yusaku Einaga; Keio University, Japan

**Introduction**

Ammonia is currently in great demand as fertilizer or as industrial raw material, however environmental pollution caused by reactive nitrogen species emitted from factories and agricultural wastewater might be an issue. $^{(1)}$ This is in fact true for nitrate, one of the reactive nitrogen species. Therefore, electrochemical nitrate reduction which produces ammonia is a twofold attracting method: 1) abatement of pollutant (nitrate), and 2) highly useful product (ammonia). In addition, it works under mild conditions. Currently, several metal electrodes and many highly complexed catalysts have been reported for electrochemical nitrate reduction. $^{(2)}$ On the other hand, we focused our attention on boron-doped diamond (BDD) electrodes, which have the advantages to be metal-free and a simple bulky material lend high durability to BDD. Therefore, the objective of this study is to generate ammonia by electrochemical nitrate reduction by using BDD electrodes.

**Experimental**

The working electrode was a BDD electrode which was fabricated by Microwave Plasma assisted Chemical Vapor Deposition method, the counter electrode was a platinum plate, the reference electrode was a Ag/AgCl KCl saturated, and the electrolyte was sodium nitrate in water. The optimum potential was determined by performing 1-hour potentiostatic reduction in a cell divided by a Nafion membrane. The mass transport effect on ammonia production was determined by changing the cell setup and stirring conditions. The effect of pH and the composition of the supporting electrolyte (e.g., sodium hydroxide concentration) on the Faraday efficiency of ammonia production was also investigated. In addition, the time dependence of ammonia
production by electrochemical nitrate reduction was measured was conducted for several hours. Ammonia, nitrite and nitrate were quantified by spectrophotometric method.

**Results & Discussion**

The results of constant potential reduction in a divided flow cell showed that ammonia production and Faradaic efficiency were highest at -1.8 V vs. Ag/AgCl. Comparing Faradaic efficiencies by cell and stirring conditions, the divided batch cell with stirring had the highest ammonia production and Faradaic efficiency. This is because the products are not oxidized at the counter electrode in a divided batch cell and the reduction of nitrate anions is diffusion-controlled reaction. When the pH was changed in a phosphate buffer electrolyte, the ammonia Faradaic efficiency was around 70-80% regardless of the pH, without a significant difference. On the other hand, raising the concentration of the supporting electrolyte, in this case sodium hydroxide, increased the Faradaic efficiency of ammonia production. In particular, the ammonia production Faradaic efficiency reached 96.4% when 0.1 M sodium nitrate solution was added of 1 M sodium hydroxide. We found a positive correlation between concentration of sodium hydroxide and charge transfer resistance. During the several hour reduction in 0.1 M sodium nitrate solution, ammonia production was slower than nitrite production at the beginning, but as time progressed, the amount of ammonia production increased while that of nitrite production leveled off. This result suggests that ammonia production by electrochemical nitrate reduction includes sequential reactions. During the 6 hours reduction in 0.1 M sodium nitrate solution added with 1 M sodium hydroxide solution, ammonia production was faster than nitrite production. This result suggests that high concentration of sodium hydroxide promote nitrite reduction to ammonia.

**High-Temperature Annealed Al(Ga)N Templates Deposited by PLD for Optimized Epitaxial Growth of UV-C LEDs**

Kevin Guy1, Aly Zaïer2, Mathieu Bernard1, Julien Brauâ1, Jean-Yves Duboz2, Guy Feuillet2 and Florian Dupont1; 1University Grenoble Alpes, CEA, LETI, France; 2Centre de Recherche sur l’Hétéro-Epitaxie et ses Applications, CNRS, France

UV-C LEDs are intended to replace Hg-based UV lamps in sterilization and bacterial/viral decontamination systems. UV-C LEDs are currently not efficient enough to consider their use on a large scale, due to a poor external quantum efficiency up to 10%. One of the main issues concerns the high dislocation density in the epitaxial Al(Ga)N layers constituting the active layers of the diode. Using Al(Ga)N templates instead of regular AlN templates could be a solution to increase UV-C LEDs efficiency.

This work focuses on the realization of cost-effective Al(Ga)N templates on sapphire by low-temperature sputtering and PLD (Pulsed Laser Deposition). For the first time, AlGaN layers are deposited directly on sapphire substrates by PLD. A great effort has been made to optimize both the deposition conditions and the substrate preparation. Al(Ga)N templates were characterized by XRD (X-Ray Diffraction), AFM (Atomic Force Microscopy) and SEM (Scanning Electron Microscopy). The pros and cons of sputtering and PLD will be discussed by comparing the roughness and the crystallinity of Al(Ga)N templates. The high temperature face-to-face annealing technique is used to strongly increase the crystallinity of the materials. Modifying the annealing temperature and atmosphere can greatly affect the surface morphology and the roughness of Al(Ga)N, which is of great interest for the subsequent growth of UV-C LEDs.

This work is part of the LABEX GANEXT, and realized in close collaboration between CEA-Leti (Grenoble) and CNRS-CRHEA (Valbonne).

**Self-Powered DUV Photodetectors and Their Emerging Applications**

Taehyun Park and Hocheon Yoo; Gachon University, Korea (the Republic of)

Among the various range of ultraviolet rays (400 nm – 10 nm), the deep ultraviolet (DUV) region (280 nm – 200 nm) has been recently spotlighted in risk factor monitoring, chemical, and biological sensing fields owing to its specific light-matter interaction in biomaterials, noise-free detection based on solar blindness, and limited environmental generation conditions including partial discharge, missile plume, and flame. However, there are still challenges to using DUV photodetectors (PDs) in practical applications mentioned above as follows. First, material selection with appropriate energy bandgap, and cost-effectiveness for large-scale fabrication is limited. Second, efficient DUV transparent electrodes to reduce the transmittance loss are absent. Third, high-power consumption issues during the operation limit the use of DUV PDs as a unit sensor of the comprehensive range monitoring system. Here, we introduce our recent efforts implementing cost-effective solution-processed self-powered DUV PDs by systematic strategies including widened energy bandgap through size modulation to quantum dots, synthesizing ultra-wide bandgap oxide semiconductors with great stability, and controlling junction characteristics for effective self-powered operation. We also present our representative DUV PDs-based emerging applications: (i) partial discharge detection [1], (ii) flame sensing for fire monitoring [2], and (iii) blood component identification [3] through facile, and real-time optoelectronic approach. By introducing comprehensive strategies for solution-processed self-powered DUV PDs, this talk suggests the significance and future aspects of the DUV PDs for various emerging applications.

**Reliability Investigation on 265 nm UV-C LEDs from a Commercial Point of View**

Francesco Piva, Matteo Buffolo, Carlo De Santi, Gaudenzio
The reliability of ultraviolet light-emitting diodes (UV LEDs) has acquired relevant importance over the last few years, thanks to increasing requests for disinfection systems, particularly against the Sars-CoV-2 virus. For this reason, it is important to understand how these LEDs perform over time, to identify the criticalities that system designers had to consider. UV-C LEDs are the perfect solution as a UV light source because they are smaller, lighter, with a faster start-up, and environmentally friendly with respect to the classical mercury-based UV lamp. However, these LEDs do not have the same performance as their visible counterparts, showing a still limited lifetime and a low emitted optical power.

In this work, we studied four interesting devices found on the market, with a nominal emitting wavelength of 265 nm and promising electrical-optical characteristics and lifetimes. We carried out accelerated lifetime tests on each sample, choosing as stress current their absolute maximum reported in the datasheet, and evaluating their electrical (J-V), optical (L-J) and spectral (PSD-J) characteristics.

From the electrical characteristics, we found: (i) an increase in subthreshold leakage current in all devices, corresponding to an increase in parasitic conduction paths in the active region associated with an increase in defect generation. (ii) The high operating voltages, from 6 to 8 V, implied elevated power dissipation over time, which led to a fast decrease in optical power. (iii) To provide useful data for the design phase, we extrapolated the junction temperatures, obtaining values from 44 to 84 °C.

Optical characteristics represented an interesting turning point: two devices reached an L90 higher than 140 h, and three of them presented an L70 of at least 650 h. Just one LED showed a limited L70 of 190 h, aligned with classical results reported in the literature. It is interesting to note that one LED does not show significant degradation after 330 h of stress test, caused by a conservative choice of the manufacturer, which indicated an absolute maximum current density much lower with respect to the other devices. For this reason, we decided to exclude this sample from the following analyzes. In terms of emitted optical power, a LED (called LED S) distinguished itself from the others by an OP an order of magnitude higher at the same current density, although it was not the best for lifetime duration.

To conclude our analyses, we decided to compare the most promising LED with emitting wavelength of 265 nm with the most promising LED at 275 nm, studied in previous tests. From the J-V comparison, we noted similar behaviors, with a lower turn-on voltage for the 265 nm device; OP-I followed similar trends, with a higher optical recovery for the 275 nm LED, which implies a slightly longer lifetime. Instead, PSD-J characterization highlighted the same parasitic spectral peaks in both samples, suggesting similar issues in structure optimization.

Other interesting results came when we compared the total number of doses to disinfect the Covid-19 virus that an LED can provide during its lifetime. Considering a dose of 3 mJ/cm², the best 265 nm LED can provide double doses with respect to the 275 nm LED, but their cost is higher, due to the elevated cost of the device. In fact, normalizing these results for device expense, we found that 275 nm LED is the right choice for a disinfection system. But both results are outdated if we consider LED S: despite its lower lifetime, the higher total emitted optical power allowed it to provide 6.5 times the number of doses per LED with respect to the best 265 nm LED, and 3 times the number of doses per LED per Euro with respect to the best 275 nm LED. These results are important design considerations because they show the importance of achieving the best trade-off between wavelength, optical power, and reliability to build an efficient disinfection system.

4:15 PM EL11.09.04

Device Design Considerations for a Monolithically Integrated III-Nitride Infrared-Visible Detector-Emitter

Alireza Lajaniani1, Benjamin McEwen1, Emma Rocco1, Vincent Meyers1, David Hill2, W. K. Chan2 and Fatemeh (Shadi) Shahedipour-Sandvik1; 1University of Albany, United States; 2SRI International, United States

Quantum well infrared photodetectors (QWIPs) have been used for applications such as telecommunication and thermal imaging in astronomy and defense. Recently, III-nitride materials have attracted much attention in the design of QWIPs owing to their large conduction band offset (CBO) up to 2 eV [1], which makes it suitable for a variety of intersubband transition (ISBT) energies [2]. The system’s polarization in the c-direction offers additional design flexibility, permitting further tuning of band offset and therefore of ISBT energies.

One of the challenges impeding the use of III-nitride QWIPs in many applications, such as thermal imaging, is the need for wavelength up-conversion to permit emission in the visible range. Without integrated up-conversion, the QWIP must have an additional readout circuit, which increases the device complexity, size, and weight which is undesirable in many applications such as handheld devices. This challenge was overcome in another material system where monolithic integration of a GaAs/AlGaAs QWIP and light emitting diode (LED) was proposed in 1997 [3] and successfully demonstrated [4]. The principle of integrated QWIP-LED for wavelength upconversion is the photoexcitation of carriers from IR spectral radiation in quantum wells by ISBT and then injection of excited carrier towards the LED for generation of visible light [5]. Such structures require precise control over the thickness of layers and interfaces. Growth of several nm thick layers with high quality interfaces (e.g., in QWIP) is quite challenging in metal organic chemical vapor deposition (MOCVD) of III-nitrides. Of key importance in interface quality is the RMS roughness of each layer, controlled by the time lapse between growth of barrier/well/barrier and growth rate in the layers. Thicknesses of less than 5 nm were required in our QWIP design.

In this work, we present for the first time a design for a monolithically integrated III-N detector-emitter with a target absorption wavelength of 1.5 μm and emission in the visible range. Parametric tuning of QWIP layers compositions and thicknesses is performed with parallel simulations using classical (Sentaurus TCAD) and quantum mechanical (nextnano) modelling. The impact of doping and polarization charges at heterointerfaces of the QWIP structure on the band alignment and absorption is discussed. It is found that p-type doping of the QWIP superlattice is required for absorption of TE polarized light. Doping and composition of the transition layers between QWIP and LED were optimized to promote higher carrier injection efficiency. Experimental limitations and experimental material characteristics are considered to achieve a realistic design. We will present characterization of initial proof-of-concept structures grown by MOCVD, comparing simulated design to experimental characteristics.

References:

BPDs have limitations, such as lower photodetection performance and the need for external bias at specific target wavelengths, when compared to narrow-band PDs. In this study, we propose a BPD with a spinel structure capable of detecting a wide range of wavelengths from ultraviolet (UV) to infrared (IR) by synthesizing zinc gallate (ZnGa2O4) using a solution process. The BPD device was fabricated through a straightforward spin-coating process and thermal evaporation. We formed an n-type ZnGa2O4 layer and a top titanium (Ti) electrode on p-type silicon. The resulting BPD demonstrated distinct photoresponse across various wavelengths, ranging from UV-C to the visible and IR regions. Notably, we achieved an IPHOTO/IPDARK ratio of up to 105 AA-1 at 0 V, indicating that our BPD is suitable for self-powered operation without the need for any external voltage application. To assess the uniformity of the BPD, we fabricated a 10 x 10 array and confirmed the possibility of broadband detection in all 100 devices.

8:00 PM EL11.10.01
Achieving Highly Reliable, High Mobility Spinel Single-Phase IZTO Thin-Film Transistors at a Low Temperature of 300°C
Gwang-Bok Kim; Hanyang University, Korea (the Republic of)

In this study, In0.22Zn0.78Sn0.55O0.95 [d = 0.55] films featuring a spinel single phase are effectively produced at a low temperature of 300 °C by meticulously designing the cation composition and employing a catalytic chemical reaction. Thin-film transistors (TFTs) with an amorphous In0.22Zn0.78Sn0.55O0.95 [d = 0.55] channel layer, created through metal-induced crystallization at 300 °C, display an impressive field-effect mobility of approximately 1.5 cm²/Vs and outstanding stability against external gate bias stress. This can be attributed to the consistent formation of the highly ordered spinel structure. We deduce that the cubic spinel phase of Zn2-ySn1-yIn2yO4 (y = 0.45) film holds great potential as a replacement for semiconducting oxide polycrystalline in the backplane channel components of mobile active-matrix organic light-emitting diode displays.

Site-Selective Laser-Induced Crystallization of Amorphous Ga2O3 Films for the Micropatterning of Ga2O3 Thin Films
Daishi Shiojiri1, Ryoya Kawai1, Satoru Kaneko2,3, Akifumi Matsuda2, and Mamoru Yoshimoto3; 1Kanagawa Institute of Industrial Science and Technology, Japan; 2Tokyo Institute of Technology, Japan

Wide-gap semiconductor materials have been investigated for practical use in various devices because of advantages in these materials’ excellent electronic and optical properties, such as a combination of visible light transparency with electrical conductivity, high voltage resistance, and ultraviolet (UV) light emission and absorption. In past decades, materials with band gaps (Eg) in the 3–4 eV range, such as GaN and SiC, have been the main focus of research efforts. To extend the range of applications using high-power deep-UV light, it is necessary to exploit semiconductors with an Eg above 4 eV. Ga2O3 has been identified as a great potential wide-gap semiconductor with an Eg of > 4 eV. Ga2O3 thin films are promising for a variety of UV-optoelectronic applications and technologies, such as deep-UV-transparent conductive oxides, UV photodetectors, and high-breakdown-voltage field-effect transistor devices. Among the Ga2O3 polymorphs, β-Ga2O3 (monoclinic, space group: C 2/m) is identified as thermodynamically stable phase. Its crystalline thin films have been mostly prepared at moderate to relatively high temperatures (> 400°C) by processes such as pulsed laser deposition, metal-organic vapor phase epitaxy, molecular beam epitaxy, and others. In addition, the surface-structure patterning of the single-crystalline β phase is important for these devices.
for device applications, but there are few reports of low-toxicity and low-temperature fabrication methods, especially for those at room temperature. Eximer laser annealing (ELA) has been widely used for the solid-phase crystallization of amorphous thin films at low temperatures, such as in the manufacturing of poly-Si thin film transistors and demonstrated exfoliation yields of up to 50 – 70 %.

Previously, we reported the room-temperature fabrication of highly oriented β-Ga2O3 thin films on α-Al2O3 substrates [1]. We have also reported the fabrication of epitaxial β-Ga2O3 films on epitaxial NiO(111)-buffered α-Al2O3 substrates using the ELA process [2, 3]. In this study, we report the effects of laser intensity, annealing time, and film thickness on the crystallinity, surface morphology, and optical properties of Ga2O3 thin films to discuss the mechanisms of the excimer laser crystallization. In addition, we also report on a fully room-temperature surface-patterning method for wide-gap β-Ga2O3, characterized by the site-selective laser-induced crystallization of amorphous Ga2O3 thin films and by acid-solution etching processes.

References

meet performance demands, self-heating-induced instability becomes a challenge due to limited heat dissipation paths. This leads to thermally accelerated degradation and increased power consumption. The self-heating effect in TFTs, especially those using organic light-emitting diode (OLED) displays, has not been extensively studied. The study focuses on amorphous indium-zinc-tin oxide (a-IZTO) TFTs, which offer high field-effect mobility and low off-current. The study identifies intrinsic and extrinsic factors contributing to temperature-dependent VTH instability, including subgap density-of-state (DOS) and interface traps. The paper presents an analytical model for temperature-dependent VTH instability and validates it through experiments, DOS extraction, and simulations. The diffusion of hydrogen in a-IZTO TFTs is also examined, and optimal hydrogen incorporation is found to improve performance and thermal VTH stability. The study highlights the importance of material and device design parameters, such as subgap DOS, channel thickness, and gate capacitance, in optimizing oxide semiconductor TFTs for applications like OLED displays, augmented and virtual reality, memory, and logic devices.

In this study, we investigated the impact of temperature on the stability of the threshold voltage (VTH) in self-aligned coplanar amorphous indium-zinc-tin oxide (a-IZTO) TFTs. We developed an analytical model that revealed the importance of device geometry and reducing the subgap density-of-state (DOS) in achieving high stability in a-IZTO TFTs. The validity of the model was confirmed through experiments and computer simulations. The study also examined the role of hydrogen impurities in the performance and VTH stability of a-IZTO TFTs. It was found that incorporating hydrogen in the a-IZTO channels improved TFT performance and thermal stability due to hydrogen acting as a passivation center. However, excessive hydrogen incorporation increased the subgap DOS distribution, resulting in a slight deterioration in thermal stability. Consequently, two strategies were identified to improve the temperature stability of VTH in oxide TFTs. Firstly, minimizing the subgap DOS distribution can be achieved through a post-deposition annealing (PDA) temperature of 320 °C, resulting in reduced subgap DOS and improved thermal stability. This can be attributed to the passivation effect of hydrogen during PDA. Secondly, geometrical engineering of the channel thickness (Tch) and oxide capacitance (COX) can help mitigate the effect of temperature on the VTH shift. A thinner channel and/or higher COX were shown to be effective in achieving stable VTH at varying temperatures. The study discussed the use of careful thermal annealing, mass enthalpy of the channel layer, and interface matching between the channel and gate dielectrics to obtain super-steepest IV characteristics in metal oxides, which can further reduce subgap DOS distribution and enhance thermal stability. The findings of the study have implications for future designs of stable oxide semiconductor TFTs, particularly in applications such as organic light-emitting diodes, augmented and virtual reality, memory, logic, and monolithic three-dimensional devices. Experimental results and computer simulations validated the analytical model, providing valuable insights for the design of oxide TFTs with improved temperature stability of VTH.

This work was supported by the Institute of Information & Communications Technology Planning & Evaluation (IITP) under the artificial intelligence semiconductor support program to nurture the best talents (IITP-2023-RS-2023-00253941) grant funded by the Korea government.

Selective Deposition of Fluid Skin Restorer Passivation Layers for IGZO TFTs using Electrohydrodynamic Jet Printing for Enhanced Electrical Characteristics and Stability Young Wook Kim, Min Seong Kim, Jong Hyuk Ahn, Hyung Tae Kim, Sujin Lee and Hyun Jae Kim; Yonsei University, Korea (the Republic of)

Amorphous oxide semiconductors (AOSs) are commonly used as active layer materials in thin-film transistors (TFTs) due to their notable advantages. Especially, indium–gallium–zinc–oxide (IGZO) based TFTs among AOS-TFTs include attractive mobility (~ 10 cm²/Vs), low off current (< 100 pA), and high transparency (> 80%) in the visible region, making them suitable for display backplanes. However, IGZO TFTs exhibit critical instability issues when exposed to light, temperature variations, bias stress, and ambient gases. One of the significant challenges is the threshold voltage (VTH) shifts caused by O₂ and H₂O exposure in the atmosphere. The adsorption/desorption of O₂ and H₂O molecules can shift the VTH of IGZO TFTs in a positive or negative direction, acting as donor-like or acceptor-like states, respectively. To mitigate this problem, optimal passivation layers (PVLs) are required to prevent the IGZO channel layer from coming into contact with the ambient environment, and numerous studies have focused on developing inorganic and organic material PVLs to address these challenges. Inorganic materials such as SiO₂ and Al₂O₃ have been commonly used, but they require high temperatures and expensive vacuum processes. These conditions are unsuitable for flexible display devices, which are typically manufactured on polymer substrates with low glass-transition temperature (~ 200°C). Moreover, the limited flexibility and brittle properties of inorganic PVLs pose further constraints. In order to overcome the limitations of inorganic PVL, PVL utilizing organic materials such as polydimethylsiloxane (PDMS) and Poly (methyl methacrylate) (PMMA) have been studied. However, due to its unique material properties, organic PVL is inferior to inorganic PVL in the view of barrier performance against ambient gases.

In this study, organic material fluid skin restorer (FSR) with low gas permeability was introduced as PVL of IGZO TFT. To reduce the viscosity of FSR, the solution was prepared by dissolving FSR in ethanol to a concentration of 2 wt% at room temperature with physical stirring. The FSR PVL has an advantage in minimizing the thermal degradation on the device by annealing for 5 min at a low temperature of 100°C compared to PMMA PVL which required 150°C, and 20 min. The electrical characteristics and stability under positive bias stress (PBS) exhibited improvement compared to the devices without FSR PVL, specifically in terms of field-effect mobility 7.22 to 18.95 cm²/Vs, on/off current ratio 2.23×10⁸ to 7.54×10⁸, and subthreshold swing 0.46 to 0.43 V/decade. The VTH shift under PBS of FSR PVL for 10,000s decreased from 6.16V to 4.67V compared to the devices without PVL. These improvements are expected to be due to the diffusion of atoms, such as nitrogen and oxygen from the FSR to the channel layer, and the blocking of the adsorption/desorption of ambient gases such as O₂ and H₂O. Moreover, the electrohydrodynamic (EHD) jet printing method enables selective deposition of FSR on IGZO TFTs. Given its selectivity, transparency, and impressive performance, this material holds a great promise as a valuable resource in the field of printing electronics and transparent devices (e.g., flexible displays, wearable sensors).

Thin Films of ZnS, O) and (Zn, Mg)O as Wide-Band Gap Components in SnS Solar Cells Luis A. López Cruz, P. Karunakaran Nair and M.T. Santhamma Nair; Universidad Autonoma de Mexico, Mexico

Thin films of sulfides and oxides of zinc such as Zn(S, O) and (Zn, Mg)O as wide band gap buffers are known to provide better band alignments than CdS thin-film backdoor solar cells with SnS absorber. We used chemical bath deposition for obtaining thin films of Zn(O, S) and RF sputtering for (Zn, Mg)O films. Thin films of zinc sulfide deposited from aqueous chemical baths of soluble complexes of Zn(II) and thiourea or thioacetamide as sulfide-ion source are Zn(O, S) with a sulfur to zinc ratio of 0.28 to 0.34. The optical bandgap of these films deposited on quartz substrates is around 4 eV. Variations in crystal structure, chemical composition, and band gap occur in the films when the films are heated with S- and Se-vapor at 400 – 500 °C. For example, the films showed XRD peaks characteristic of cubic ZnS and a S/Zn of 0.89 after they are annealed in presence of S at 500 °C under nitrogen. The thin films of (Zn, Mg)O obtained by co-sputtering showed hexagonal crystal structure with band gap 3.2 to 3.8 eV. The electrical conductivity in both these films is of the order of 10⁴ Ω·cm⁻¹. Photovoltaic structures incorporating these films with chemically deposited SnS of cubic and orthorhombic structures as absorber components showed Voc of 480 mV in the case of Zn(S, O) and 508 mV in the case of (Zn, Mg)O buffers.

Characterization of Gold-Catalyzed Gallium Oxide Nanowires Geordon Dorsey¹, Antonio Moore¹, Warren Collins¹, Akira Ueda2, Virginia Lorenzi², Arent M. van der Zande¹ and Richard Mu²; Fisk University, United States; Tennessee State University, United States; University of Illinois at Urbana-Champaign, United States

Final Program 1/25/24
The growth of β-gallium oxide (Ga2O3) nanowires has been achieved by the vapor-solid-liquid method on silicon wafer substrates. In Argon atmosphere, pure gallium was heated to produce gallium vapor and oxidized by background impurities, inside a vertical tube furnace. Since β-Ga2O3 is the most thermodynamically stable phase of Ga2O3 at standard temperature and pressure, and has the monoclinic crystal structure, β-Ga2O3 nanowires were grown in a specific direction. For the growth of β-Ga2O3, the substrates were prepared by treating silicon wafers with hydrofluoric acid, then sputter-coated with a 2 nano meter gold layer. The correlation between the gold nanoparticle diameter and the morphology of the Ga2O3 nanowires was studied. The growth orientation was also investigated for nanowires on these two kinds of substrates via Transmission Electron Microscopy (TEM) characterization. The elemental composition was also verified using Energy-dispersive X-ray spectroscopy (EDS).

Epitaxial Growth and Semiconductor Properties of Novel UWBG Oxides for Power Electronic Devices Kinasev T. E. Etsev1, Emily Garrity2, Cheng-Wei Lee3, Brooks Tellekamp1, Vladan Stevanovic1 and Andriy Zakutayev1; 1National Renewable Energy Laboratory, United States; 2Colorado School of Mines, United States

Electronic devices suitable for high power, high voltage operation and which can withstand high-temperature environments are required for applications in electric vehicles, gas turbines, gas and oil drilling, and other energy-dense systems. For these devices, the active layer determines the application space possible, and ultrawide bandgap semiconductors with suitable carrier mobility and power figure of merit ensure a high breakdown field and limited temperature-induced leakage which are required for high-voltage and high-temperature applications respectively. Among ultrawide bandgap materials, most oxides offer further advantages for operation in oxidizing and reducing conditions as they are chemically robust. A recent high throughput search predicted thirty candidate oxide materials with properties suitable for power electronic applications and among these candidate materials, InBO3, Mg2GeO4, and In2Ge2O7 were identified as having the best potential in high-power device application. Here, we explore the thin film growth and properties of these three novel ternary oxides. Thin films of these novel ternary oxides are grown by Pulsed laser deposition using a KrF Excimer laser of wavelength 248 nm in a vacuum chamber with a base pressure of 10^-6 Torr. Ceramic targets of these ternary oxides were ablated at an average pulse repetition rate of 8 Hz and laser energy of 300 mJ on different single crystalline substrates. Structural, composition and optoelectronic properties of the thin films are explored by x-ray diffraction, x-ray fluorescence, spectroscopic ellipsometry, and x-ray photoelectron spectroscopy. Structural characterization shows that epitaxial spinel-type Mg2GeO4(100) is obtained on ~1.8% lattice mismatch MgAl2O4(100) and MgO (100) substrates. InGe2O7(220) is grown on Al2O3(00.6) and InBO3 thin films on Al2O3(00.6) and YSZ (100) are polycrystalline. Spectroscopic ellipsometry analysis gives a bandgap value of 4.9 eV, 4.0 eV, and 5.1 eV for InBO3, In2Ge2O7, and Mg2GeO4 respectively which matches closely to theoretical predicted values. Preliminary transport measurement for undoped thin films shows that both InBO3 and Mg2GeO4 are semi-insulating while In2Ge2O7 shows sheet resistance >1MΩ. However, detailed defect chemistry calculations further provide insight into the dopability of these materials. Results show that InBO3 has defect chemistry that allows n-type doping under In-rich/O-poor synthesis. Zr also acts as a donor in both InBO3 and In2Ge2O7. These results provide the basis for further material exploration and characterization of these new set of ultra-wide bandgap ternary oxide materials and will pave the way for their potential integration in high-power devices.

Study on Enhanced Electron Field Emission Properties of Graphene Quantum Dots Synthesized by Pulsed LASER Ablation Vincent R. Walsh Rivista, Muhammad Shhezad Sultan, Amanda M. Gracia Mercado, Brad Weiner and Gerardo Morell, University of Puerto Rico - Rio Piedras, United States

Graphene quantum dots (GQDs) and Nitrogen doped graphene quantum dots (N-GQDs) were synthesized by Pulsed LASER Ablation method. The nanostructure and chemical composition of the GQDs were analyzed by means of TEM, HRTEM, Raman, XPS, and FT-IR spectra. Field emission is a quantum mechanical phenomenon where electrons tunnel from the cathode to the anode through vacuum upon an applied electric field. So far, field emission properties of two-dimensional (graphene) and one-dimensional (CNT) carbon nanostructures have been extensively studied. For the first time, to the best of our knowledge, the field emission behavior of GQDs and N-GQDs, deposited on n-Si (100) substrates, is studied. As a candidate of cold cathode, the GQDs display good field emission performance. The Field emission properties of GQDs and N-GQDs were studied by measuring turn-on field (E) and field enhancement factor β. The results show that nitrogen doping improved the field emission properties of GQDs by reducing turn-on field from 13.1 V/μm (GQDs) to 7.9 V/μm (N-GQDs) and enhancing the field enhancement factor β from 1427(GQDs) to 2511(N-GQDs). The field emission behavior of pristine GQDs and N-GQDs is explained in terms of change in the effective microstructure as well as a reduction in the work function as probed by measured characterizations. The enhanced emission properties of N-GQDs are mainly attributed to the upshifting of Fermi energy level and defects produced as a result of Nitrogen doping. The good emission performance of the GQDs field emitters suggests promising applications in next generation vacuum micro and nano electronic devices.

Luminescence characteristics of low-voltage thick-film ELs with evaporated Zn:Mn and spin-coated BaTiO3 dielectrics and microLEDs Shin-ichi Yamamoto1, Koichi Wani1, Taisi Kitawaki1, Oliver A. Durnan2, Vikrant Kumar2, Reem Alshanbari2 and Ioannis Kymissis2; 1Ryukoku University, Japan, 2Columbia University, United States

Thin film electroluminescent (TFEL) devices have been mainly applied as all-solid-state flat panel displays and other light sources. A thin film EL display consists of an emission layer which is an inorganic phosphor, insulator layers, and top and bottom electrodes. The phosphor layer emits light when its cathode, the GQDs display good field emission performance. The Field emission properties of GQDs and N-GQDs were studied by measuring turn-on field (E) and field enhancement properties of two-dimensional (graphene) and one-dimensional (CNT) carbon nanostructures have been extensively studied. For the first time, the best of our knowledge, the field emission behavior of GQDs and N-GQDs, deposited on n-Si (100) substrates, is studied. As a candidate of cold cathode, the GQDs display good field emission performance. The Field emission properties of GQDs and N-GQDs were studied by measuring turn-on field (E) and field enhancement factor β. The results show that nitrogen doping improved the field emission properties of GQDs by reducing turn-on field from 13.1 V/μm (GQDs) to 7.9 V/μm (N-GQDs) and enhancing the field enhancement factor β from 1427(GQDs) to 2511(N-GQDs). The field emission behavior of pristine GQDs and N-GQDs is explained in terms of change in the effective microstructure as well as a reduction in the work function as probed by measured characterizations. The enhanced emission properties of N-GQDs are mainly attributed to the upshifting of Fermi energy level and defects produced as a result of Nitrogen doping. The good emission performance of the GQDs field emitters suggests promising applications in next generation vacuum micro and nano electronic devices.

is not enough for television applications, and full-color devices are not ready. A variation of TFEL known as a thick dielectric EL or TDEL was developed to solve these problems. In this structure, a thick dielectric layer, which is a laminate of high-k material powders, replaces the thin film dielectric in TFEL. The dielectric powder in TDEL is well crystallized through its manufacturing process. It exhibits higher relative permittivity or dielectric constant \( \varepsilon \) than a thin film dielectric, usually deposited by e-beam evaporation or sputtering. Such thick film dielectric layers have a high breakdown voltage and eventually bring about good reliability and high luminance for blue phosphors, which is inevitable for a full-color display. As thick dielectric layers are manufacturable by an atmospheric process, the manufacturing cost can be lower than TFELs. On the other hand, thick dielectric layers require a high temperature sintering process, and a planarization measure is needed on its surface to grow the phosphor layer on it. These constraints in the process prevent the TDEL from being commercialized as a display product.

In this paper, we investigated a structure and process of TDEL having high luminance with lower operating voltage than TFEL. Although the reported TDEL displays so far have a top emission structure, we employed a bottom emission structure instead. As for the thick film dielectric, paste material, which is a mixture of dielectric powders, a binder resin with solvent, and is curable at low temperatures, is employed. The phosphor layer is a conventional ZnS:Mn deposited by an electron beam evaporator and annealed in a sulfur environment. Aiming at a low operating voltage below 100V, the layer thicknesses are minimized. On the other hand, by using MOCVD GaN thin film, microELD was fabricated and compared with low voltage driving.

Manufacturing 2-Inch AlN and Beyond - The Road to 4-Inch AlN Substrates Kasey Hogan, Robert Bondokov, Justin Mark, Griffin Norbury and James Grandusky; Crystal IS, United States

The bulk crystal growth process for aluminum nitride (AIN) has had significant development over the past decade and is now at manufacturing scale. Currently, Crystal IS produces multiple thousands of high quality 2-inch AlN substrates per year. These substrates have demonstrated symmetric (0002) X-ray rocking curve FWHM values as low as 6.7 arcseconds, low UV absorption coefficients of <1 cm\(^{-1}\) at 265 nm, and high room temperature thermal conductivities of 294 W m\(^{-1}\) K\(^{-1}\). AIN has thrived in the UVC LED market as a better suited substrate over sapphire by providing closer lattice matching to Al\(_3\)N-GaN-based epitaxial layers. There exists a desire for larger diameter (4-inch) substrates to realize the potential for AlN technology in power device applications. In 2022, Crystal IS demonstrated similar quality 3-inch AlN and has since continued to expand to the 4-inch diameter. We demonstrate the growth of 4-inch diameter AlIN boules and subsequent wafer characterization, signaling the first commercially available 4-inch substrate to be realized in the near future.

High Performance Self-Powered UV Photodetector Based on Nitrogen-Doped Graphene Quantum Dot Schottky Diode Muhammad Shohzad Sultan1, Wojciech Jadwisienzak2, Brad Weiner* and Gerardo Morell3; 1University of Puerto Rico at Rio Piedras, United States; 2Ohio University, United States

We report a straightforward bottom-up approach for the synthesis of high-quality nitrogen-doped graphene quantum dots (NGQDs). This approach is cost-effective, environmentally friendly, and suitable for production of high quality NGQDs on large-scale. The as-synthesized NGQDs have high crystalline quality with an average size of 3.26 nm, are water soluble, and show strong fluorescence. The UV-vis spectra indicate that N-doping introduces new energy levels into the electronic structure of graphene, which tune the optical properties resulting in photoluminescence quantum yield (PLQY) of 73%. The NGQDs show excitation wavelength-dependent fluorescence with a maximum excitation and emission at 340 and 431 nm, respectively. Using the as-synthesized NGQDs, we fabricated a high-efficiency fast-response self-powered UV photodetector. Under the illumination of 365 nm UV light with power density of 25 mW/cm\(^2\), the NGQD photodetector shows a high photoresponsivity of 37 A/W, detectivity of 1 * 10\(^{11}\) Jones, and external quantum efficiency (EQE) of 12.6 * 10\(^3\) %. This UV photoresponse is fast, with rise time of 0.29 s and fall time of 0.33 s. This work paves the way for the development of graphene-based high-performance optoelectronic devices.

Novel Synthesis and Tuning Optical Properties of High Quantum Yield Nitrogen Doped Graphene Quantum Dots Muhammad Shohzad Sultan1, Wojciech Jadwisienzak2, Alejandra P Flores Rivera1, Brad Weiner* and Gerardo Morell3; 1University of Puerto Rico at Rio Piedras, United States; 2Ohio University, United States

The graphene quantum dots (GQDs) have attracted the attention of researchers due to their excellent properties and potential applications in biomedicines, energy storage devices and photovoltaics. The photoluminescence is one of the most important characteristics of GQDs. The doping of GQDs with Nitrogen atoms is one of the most effective ways to tune their photoluminescence emission and to increase quantum yield. In this work, high-quality Nitrogen-doped graphene quantum dots (N-GQDs) were synthesized by using pulsed laser synthesis method at various irradiation powers of pulsed laser and changing the concentration of nitrogen doping to effectively tune the photoluminescence emission and improve the quantum yield (QY) of as synthesized N-GQDs. The TEM, HRTEM, XPS, XRD, Raman spectroscopy and FTIR were carried out to observe the morphology, size distribution, crystalline structure and to prove successful doping of GQDs with nitrogen atoms. To observe optical properties of as synthesized N-GQDs, the UV-vis and Photoluminescence measurements were carried out. The as-synthesized N-GQDs exhibit high quality crystalline structure of graphene. A high quantum yield was exhibited by the obtained N-GQDs as compare to the pristine GQDs. The obtained N-GQDs with oxygen-rich functional groups exhibit a strong density of 25 mW/cm\(^2\), the NGQD photodetector shows a high photoresponsivity of 37 A/W, detectivity of 1 * 10\(^11\) Jones, and external quantum efficiency (EQE) of 12.6 * 10^3 %. This UV photoresponse is fast, with rise time of 0.29 s and fall time of 0.33 s. This work paves the way for the development of graphene-based high-performance optoelectronic devices.

Mechanisms Unveiled - A Comprehensive Study on Boosting Efficiency in GaN-Based Micro-LEDs Mengyuan Zhanghu, Boyun-Rwool Hyun and Zhaojun Liu; Southern University of Science and Technology, China

Micro Light Emitting Diodes (Micro-LEDs), with a size of 100µm or less, are predominantly utilized in display and lighting applications, thanks to their foundation in III-nitrides. Key materials used include GaN/InGaN for blue and green emissions, and AlGaN/GaN for red. GaN-based LEDs are celebrated for their exceptional traits, such as self-illumination, high brightness, low power consumption, rapid response time, and enduring lifespan. When juxtaposed with traditional LEDs, which are over 100 µm in size, Micro-LEDs shine for their superior efficiency. This stems from enhanced thermal distribution, optimal current density distribution, and reduced junction temperature.

However, numerous studies have revealed a downside to Micro-LEDs. As the size of these devices becomes smaller, there’s a notable decrease in external quantum efficiency (EQE) - a crucial measure of LED performance. This is attributed to sidewall damage incurred during plasma-assisted dry etching in device fabrication, causing non-radiative recombination centers at the surface of the active layers. Given the large perimeter-to-area ratio of smaller devices, they are particularly susceptible to such sidewall damage.
A prevalent technique to mitigate the impact of this damage involves the utilization of sidewall passivation via dielectric materials. Such treatment increases EQE, a combination of internal quantum efficiency (IQE) and light extraction efficiency (LEE), primarily by curtailing surface recombination according to the ABC model. Hence, devices equipped with passivation layers are anticipated to show higher IQE. Determined by the ratio of radiative recombination rate to total recombination rate, the IQE of an LED holds a significant correlation with the diode's ideality factor in the Shockley model. Micro-LEDs with improved IQE should, therefore, demonstrate an ideality factor approximating one - a physical expectation yet to be comprehensively explored!

To systematically probe this conjecture, we fabricated green GaN-based Micro-LEDs, varying in size from 20 to 100 µm and emitting at 520 nm, on a commercially available sapphire substrate. A 50 nm thermal ALD Al2O3 layer was then deposited at 300°C to passivate residual sidewall dangling bonds. Our findings unequivocally demonstrate that this passivation layer bolsters the EQE of Micro-LEDs. An increase in EQE/IQE of Micro-LEDs leads to a decline in ideality factors. As the size decreases, the EQE increases, while the ideality factor descends. It's been observed that the radiative ideality factors for Micro-LEDs can reach 1, aligning with the expectations of the Shockley model. Additionally, we found that the LEE of Micro-LEDs with a passivation layer increases as the device size diminishes. Optical simulations indicate that depositing a dielectric layer with a lower refractive index than III-nitride bolsters light extraction by enlarging the critical angle. In this discourse, we will share a comprehensive presentation of experimental outcomes, along with a detailed analysis of the correlation between the ideality factor and IQE, LEE, and their size dependence, as informed by the ABC and Shockley models.
This α phase exhibits promising potential in power-switching and deep-UV optoelectronics devices, such as Schottky barrier diodes and photodetectors, owing to its ultra-wide bandgap. [2-3] A vertical device structure can provide low on-resistivity and rapid response. One way to realize vertical structure is by incorporating a conductive layer under the active layer. However, the growth of metastable α-Ga2O3 necessitates an epitaxial growth on other substrates, and an insulating α-Al2O3 substrate is usually used, making realizing vertical structure challenging. To address this issue, we featured high-conductive rhombohedral indium tin oxide (rh-ITO) as the bottom electrode. This rh-ITO exhibits the same crystal structure as α-Ga2O3; therefore, it is expected that α-Ga2O3 will be grown epitaxially on the rh-ITO electrode. This study demonstrates heteroepitaxial growth of α-Ga2O3 on rh-ITO electrode and its device applications.

Mist CVD was utilized for the epilayer growth of oxide thin films. Initially, we investigated the growth of α-Ga2O3 on rh-ITO, however, orthorhombic κ-Ga2O3 was grown on bare rh-ITO thin films because of the large lattice mismatch between α-Ga2O3 and rh-ITO (-9.2%). Therefore, to decrease the lattice mismatch, α-Fe2O3 buffer layers with a small lattice mismatch (-1.0 %) were utilized for the growth of α-Ga2O3 thin films. XRD 2θ-ω scans determined that the α-Fe2O3 buffer layer allowed the growth of α-Ga2O3 thin films on rh-ITO thin films. Furthermore, XRD ω scans revealed that α-Ga2O3 thin films were successfully grown in the same in-plane orientations as rh-ITO and c-plane sapphire substrates. These XRD measurements indicated that α-Ga2O3 thin films were epitaxially grown on the rh-ITO/c-plane sapphire substrates.

Next, we conducted device operations using α-Ga2O3 thin films with rh-ITO thin films as bottom electrodes, and fabricated two device architectures, deep-UV photodetectors, and Schottky barrier diodes. For photodetectors, PEDOT:PSS thin films, exhibiting high transparency in the deep UV region to the visible light region, high conductivity, and large work function were utilized for top electrodes. PEDOT:PSS thin films were deposited by mist deposition[4]. The n-type α-Ga2O3 and PEDOT:PSS showed Schottky behavior enabling the separation of the photo-exited hole-electron pairs. The spectral photoresponsivity of the photodetector was measured using a short-circuit current and demonstrated the ability to detect UV-C region light without any bias voltage. The photoresponsivity at 220 nm was 9.7 x 10^4 A/W, exceeding that of a self-powered lateral structured α-Ga2O3 photodetector, thereby suggesting its association with the vertical structure, which can reduce the recombination of photogenerated carriers.[3] Furthermore, we investigated the Schottky barrier diode based on α-Ga2O3 with Ni/Au electrode deposited by thermal evaporation. Current-voltage measurements confirmed the rectification characteristics of the diode, which can be attributed to the Schottky contact between Ni and α-Ga2O3. These results demonstrate the device applications of α-Ga2O3 grown on rh-ITO bottom electrodes using mist chemical vapor deposition, including deep-UV photodetectors and Schottky barrier diodes.

References
the gallium oxide (Ga$_2$O$_3$) roadmap was that recently achieved [1]. Due to the lack of an effective current blocking layer in Ga$_2$O$_3$, this is for any DMOS-like (double-diffused MOSFET) the achievement of a vertical Ga$_2$O$_3$ MOSFET has been difficult. Using the gas diffusion doping technique utilizing magnesium (Mg) doping spin-on-glass (SOG) as a dopant source to form a current blocking layer (CBL), and second, the first demonstration of a vertical Ga$_2$O$_3$ MOSFET with the Mg doped CBL. Vertical Diffused Barrier-Effect-Transistor (VDBFET). At its very first stage of development, the device exhibited an excellent field effect-transistor (FET) behavior with a high on-off ratio of $10^9$ and a decent saturation. If successful, this technology can lead to at least a 3x increase in power density in vertical switches over and above SiC and GaN, and at a lower cost per die. Besides the lack of p-type Ga$_2$O$_3$, thermal management has been a challenge. For achieving high power density at high frequencies, with aggressive device scaling heat generation is unavoidable. However, the room temperature thermal conductivity of β-Ga$_2$O$_3$ (anisotropic; 11-27 Wm$^{-1}K^{-1}$) is the lowest among the technologically relevant semiconductor materials [2].

Polycrystalline diamond epitaxial growth on β-Ga$_2$O$_3$ for device-level thermal management was performed and reported in our recent study. Our work focused on establishing diamond growth conditions on β-Ga$_2$O$_3$ accompanying the study of various nucleation strategies [3]. A growth window was identified, yielding uniform-coalesced films while maintaining interface smoothness. In this first demonstration of diamond growth on β-Ga$_2$O$_3$, a diamond thickness of $110 \pm 33 \, \mu$m and a diamond secondary resistance of $30 \pm 2 \, \Omega \cdot \sqrt{\text{cm}}$ were measured. The film stress was managed by growth optimization techniques preventing delamination of the diamond film. It marked a significant step toward device-level thermal management of β-Ga$_2$O$_3$ electronic devices. These two recent experimental studies set the stage to systematically study and understand the challenges of Ga$_2$O$_3$ technology and create a roadmap beyond GaN.

Electrical and Thermal Properties of BeO Gate Dielectrics for β-Ga$_2$O$_3$ Power Devices

Dohwan Jung1, Yoonseo Jang1, Prakash R. Sultane2, Christopher W. Bielawski3 and Jungwoo Oh4; 1Yonsei University, Korea (the Republic of); 2UNIST, Korea (the Republic of)

Monoclinic gallium oxide (β-Ga$_2$O$_3$) is a promising wide-bandgap semiconductor for power device application. β-Ga$_2$O$_3$ demonstrates superior material performance, including an ultra-wide bandgap of 4.8-4.9 eV, a high breakdown field of approximately 8 MV/cm, and a remarkable bulk electron mobility of ~300 cm$^2$V$^{-1}$s$^{-1}$, showing a Balliga’s Figure of Merit (BFOM) of up to 4444. Despite these properties, the primary drawback of β-Ga$_2$O$_3$ lies in its heat management capabilities. It exhibits a low thermal conductivity of 10-30 Wm$^{-1}K^{-1}$, which is significantly lower compared to other power semiconductors such as GaN (220 Wm$^{-1}K^{-1}$) and SiC (380-342 Wm$^{-1}K^{-1}$), which potentially makes β-Ga$_2$O$_3$ susceptible to malfunctions under high-temperature operation. The use of conventional gate dielectrics for β-Ga$_2$O$_3$ power devices might worsen the thermal dissipation issue. Oxides typically possess low thermal conductivity. For instance, SiO$_2$ exhibits approximately 1.4 Wm$^{-1}K^{-1}$, and HfO$_2$ exhibits approximately 1.2 Wm$^{-1}K^{-1}$ of thermal conductivity. To address these challenges, we propose beryllium oxide (BeO) gate dielectrics for β-Ga$_2$O$_3$ power devices. BeO possesses unique properties, including a bandgap energy of 10.6 eV, a high dielectric constant of 6.8, and most importantly, an extraordinarily high thermal conductivity of approximately 330 Wm$^{-1}K^{-1}$ coupled with high thermal stability. Its thermal conductivity is the highest among oxides, surpassing that of most metals except for copper and silver. Consequently, BeO holds significant potential in improving the heat dissipation capabilities of β-Ga$_2$O$_3$ power devices. However, its application to nanoscale front-end devices has been constrained by the absence of well-established thin film deposition techniques.

In this work, we developed the atomic layer deposition (ALD) of BeO. This technique enables the precise and high-quality deposition of thin film on the substrates. ALD BeO gate dielectrics were successfully grown on β-Ga$_2$O$_3$ substrates. We comprehensively analyzed the physical and electrical properties of ALD BeO deposited on β-Ga$_2$O$_3$. A BeO on β-Ga$_2$O$_3$ was confirmed via a survey scan of X-ray Photoelectron Spectroscopy (XPS). The cross-section TEM image revealed a uniform thickness and a sharp interface between BeO and β-Ga$_2$O$_3$. The crystalline growth of BeO in the (102) diffraction on the β-Ga$_2$O$_3$ substrate was confirmed using Grazing Incidence X-ray Diffraction (GI-XRD). In addition, we analyzed the electrical properties of BeO gate dielectrics on β-Ga$_2$O$_3$ power devices. We determined the conduction band offset (3.4 eV) between the BeO film and β-Ga$_2$O$_3$ substrate using Kraut’s method, which involved the determination of the valence band offset (0.5 eV) using the XPS core level and valence band maximum energies of the BeO film and β-Ga$_2$O$_3$. The bandgap energies of BeO (8.6 eV) and β-Ga$_2$O$_3$ (4.7 eV) were determined using reflection electron energy loss spectroscopy (REELS). The large conduction band offset of ALD BeO on the β-Ga$_2$O$_3$ substantially lowered the gate leakage current of β-Ga$_2$O$_3$ MOS capacitors. The forward leakage current was $2.21 \times 10^6$ A/cm$^2$ at 1 MV/cm for 100 nm Mo electrodes/24 nm BeO dielectrics/β-Ga$_2$O$_3$ substrates, demonstrating the potential of ALD BeO as gate dielectrics for high-performance β-Ga$_2$O$_3$ power devices.

Vertical Van Der Waals Heterojunction Diodes Comprising 2D Semiconductors on 3D β-Ga$_2$O$_3$:

Chloe Leblanc1, Dimusha Herath Mudianeselage2, Seunguk Song2, Huaeruo Zhang1, Albert V. Davydov1, Houqiang Fu2 and Deep M. Jarirwala1; 1University of Pennsylvania, United States; 2Arizona State University, United States; 3National Institute of Standards and Technology, United States; 4Theiss Research, Inc., United States

Monoclinic Gallium oxide β-Ga$_2$O$_3$ is a promising candidate for high-power and high-temperature electronics and UV-range optoelectronic devices. Its advantageous properties include an ultra-wide bandgap, high critical electric field, and affordable bulk single crystal melt-growth techniques at the large production scale. However, single crystalline β-Ga$_2$O$_3$ substrates are seldom explored, in part due to the uncertain effects of the semiconductor’s proven anisotropy. In this study, we fabricated 2D/3D β-Ga$_2$O$_3$ vertical heterojunctions and comprehensively assessed the effect of the choice of 2D material, contact metal and substrate crystalline orientation on their performance. Three orientations of degenerately n-doped β-Ga$_2$O$_3$ were considered: (001), (010) and (2̅10). The structure and properties of our fabricated devices were then evaluated using current-voltage (I-V) measurements at varying temperatures, atomic-force microscopy (AFM) techniques and technology computer-aided design (TCAD) simulations. Scanning transmission electron microscopy (STEM) cross-sectional images verified the clean interfaces of the heterojunctions. We were able to realize high-performing diodes, whose ideality factors ranged from 1 to 3. Our findings suggest that heterojunction performance is optimized by the β-Ga$_2$O$_3$ orientation (2̅10), combined with 2D WS$_2$ exfoliated layers and Ti metal contacts, and show record rectification ratios ($> 10^6$) concurrently with ON current density ($> 10^3$ A/cm$^2$) for application in power rectifiers. The lowest ideality factors along the (2̅10) orientation were 1.33 (BP & Ti/Au contacts), 1.22 (WS$_2$ & Ti/Au contacts) and 1.43 (WS$_2$ & Pd/Au contacts) in line with some of the best
2D/3D van der Waals heterojunction diodes reported in the past. The TCAD simulations were able to verify this, and accurately mimic the (~201) heterostructures' behavior. At large biases and before the junctions reach saturation, the exponential density increase matches the strongly rectifying property of ideal diodes. In such a linear regime, the devices are driven by the diffusion current across the internal 2D/3D potential barrier. Moreover, the reverse and low forward bias regions present current densities that are both very low (<10^10 A/µm²) and independent of the applied voltage. Our findings demonstrate a facile fabrication of strongly rectifying and high current density Ga2O3-based heterojunction diodes and enables this material's potential for new avenues in solid state devices.

Implantation and Activation of Ge and Si Shallow Donors in β-Ga2O3 for Improved Ohmic Contact Formation
Kornelius Tetzner1, Andreas Thies1, Palvan Seyidov1, Nico Thiele1, Ta-Shun Chou2, Jana Rehm3, Ina Ostermay3, Zbigniew Galazka2, Andreas Fiedler2, Andreas Popp2, Joachim Würfl1 and Oliver Hilt1;
1Ferdinand-Braun-Institut, Germany; 2Leibniz-Institut für Kristallzüchtung, Germany
The recent developments in the fabrication of electronic devices based on the semiconductor β-Ga2O3 have demonstrated the high potential of this material to be used in next-generation power electronics applications. Due to the ultra-wide bandgap of 4.8 eV, a high breakdown strength of 8 MV/cm is expected, which could pave the way for power devices with even higher breakdown voltages and efficiencies than are possible with the SiC and GaN counterparts. One major key requirement for high performance electronic devices based on ultrawide bandgap semiconductors such as β-Ga2O3 is the formation of low ohmic contact resistances in order to reduce conduction losses inside the devices. This becomes even more important for RF devices, where the channel resistance is much lower as in high-voltage devices. An effective way to reduce ohmic contact resistances is the use of ion implantation of shallow donors for local n-type doping of the contact region prior to ohmic metal deposition.

In this presentation, we report on the optimum annealing conditions for the activation of Ge-implanted (100) β-Ga2O3 in order to reach low ohmic contact resistances. In this regard, the influence of rapid thermal annealing treatment at temperatures between 900 and 1200 °C on the structural and electrical properties were analyzed. Our studies reveal significant changes in the surface morphology after high-temperature annealing above 1000 °C involving an increase in the surface roughness which is accompanied with a steady increase of the activation efficiency up to almost 20% at annealing temperatures of 1200 °C. Optimum annealing conditions were identified at 1100 °C at which the specific contact resistance is reduced by one order of magnitude down to 4.8 × 10^12 Ωcm² in comparison to non-implanted samples. In contrast to these findings, the surface morphology of Si-implanted (010) β-Ga2O3 with a comparable doping profile remains almost unchanged even after annealing at 1100 °C. Furthermore, the highest activation efficiency of around 60 % is reached at annealing temperatures between 900 and 1000 °C whereas higher temperatures lead to significant reduction. Our investigations verify the severe impact of the anisotropic nature of β-Ga2O3 on implantation processes of shallow donors which is particularly emphasized by the implantation instability of (100) β-Ga2O3 at high beam currents. Comparative experiments on β-Ga2O3 samples with different crystal orientations revealed a massive destruction of the (010) β-Ga2O3 surface after Ge implantation using beam currents around 1 µA whereas no damage was observed for (010) β-Ga2O3 using the same implantation conditions. In summary, our results will reveal and identify important challenges but also the huge potential of ion implantation of shallow donors into β-Ga2O3 in order to reach low ohmic contact resistances.

Optimizing Si Implantation and Annealing in β-Ga2O3 and β-(Al,Ga)2O3 Layers
Katie R. Garn1, Naomi Pieczulewski1, Cameron Gorsak1, Karen Heinselman2, Kathleen Smith1, Thaddeus Ase1, Brenton Noses1, Huili G. X1ng3, Debdeep Jena1, David Muller1, Hari P. Naik2 and Michael O. Thompson1;
1Cornell University, United States; 2National Renewable Energy Laboratory, United States; 3Air Force Research Laboratory, United States
Optimizing thermal activation anneals for silicon ion implantation in β-Ga2O3 is critical for achieving low resistance contacts and selective area doping for advanced device structures. While activation has been widely reported, annealing conditions vary significantly and systematic annealing studies are lacking. We report the impact of time, temperature, and especially the annealing ambient, on the activation of Si in β-Ga2O3 at concentrations from 5×10^18 cm⁻³ to 1×10²⁰ cm⁻³, and in β-(Al,Ga)₂O₃ (x=25%) at concentrations up to 5×10²⁰ cm⁻³. Under optimized conditions, nearly full activation (98%) and high mobility (~70 cm²/V·s) are achieved in β-Ga2O3 at implant concentrations to 1×10²⁰ cm⁻³, with contact resistances below 0.16 Ω·µm for 5×10¹⁹ cm⁻³. Similar optimized anneal conditions for β-(Al,Ga)₂O₃ show promising results with high activation (50%) and mobility recovery (~60 cm²/V·s) at 9% Al.

Unintentionally doped (UID) β-Ga2O3 films (>400 nm) were grown by plasma assisted molecular beam epitaxy, and β-(Al,Ga)₂O₃ layers by metal-organic chemical vapor deposition, on Fe-doped (010) β-Ga2O3 substrates. Samples were ion implanted with Si at multiple energies to yield 65 or 100 nm box profiles with concentrations of 5×10¹⁹ cm⁻³, 5×10²⁰ cm⁻³, or 1×10²⁰ cm⁻³. Dopant activation was achieved by annealing as-implanted films in a load-locked ultrahigh vacuum compatible quartz tube furnace at 1 bar pressure with precisely controlled gas ambient.

The impact of O₂ (partial pressure <1×10⁻⁶ to 1 bar) and H₂O (to 25 ppm) in the annealing ambient condition was determined by mixing trace gases in research grade nitrogen (<1 ppm total impurities). To maintain the stability of the β-Ga2O₃, P₁₂ must be greater than 10⁻⁶ bar, with annealing in vacuum or forming gas resulting in poor activation or decomposition, respectively. The upper limit for P₁₂ is strongly dependent on Si concentration: P₁₂ below 10⁻⁶ bar assures Si activation (~95%) at 5×10¹⁸ cm⁻³ while lower concentration implants (5×10¹⁷ cm⁻³) maintain high carrier activation to oxygen partial pressures above 10⁻⁹ bar. Water vapor is even more critical at ppm concentrations; 25 ppm H₂O reduces active carriers by an order of magnitude 5×10¹⁹ cm⁻³ implants. The effect is reversible, and activation can be recovered by annealing in a “dry” ambient. Optimal results were consistently obtained with the gas ambient intentionally dried below 10 ppb of H₂O.

Recovery of the mobility requires annealing temperatures above 900 °C, with increasing carrier activation and mobility to temperatures as high as 1050 °C, though SIMS shows substantial Si diffusion at temperatures above 1000 °C. 950 °C is identified as an optimized temperature with minimal Si diffusion, with optimal times between 5 and 30 minutes; shorter times show lower mobilities with longer durations showing carrier deactivation. “Over-annealing” behavior is observed at all temperatures and becomes increasingly significant with higher Si concentrations.

Lattice damage and recovery were determined using Rutherford Backscattering Channeling (RBS/C), scanning transmission electron microscopy (STEM), and X-ray diffraction (XRD). XRD showed no evidence of second phase formation and RBS/C and STEM show only partial damage from even 1×10²⁰ cm⁻³ implants. In STEM, damage regions remain crystal-like with no evidence of full amorphization. The remnant aligned β-Ga2O₃ is hypothesized to be volumetrically seeded lattice recovery during thermal annealing. Varying implant doses and implant temperatures (from liquid nitrogen cooled to 600 °C) were used to assess the impact of lattice recovery on lattice mobility.

In conclusion, we demonstrate the importance of optimizing anneal conditions to activate implanted Si carriers in β-Ga2O₃ and extend this understanding to higher concentration Si implants and to activating implants in β-(Al,Ga)₂O₃.
The Applied Science of Gallium Oxide: Lessons, Challenges and Goals

Daniel M. Dryden; Air Force Research Laboratory, United States

Gallium oxide ($\beta$-Ga$_2$O$_3$) is an emerging ultra-wide band gap semiconductor which shows promise across a range of applications due to its high critical breakdown field, readily available n-type dopant species, and low native substrate cost. The Air Force Research Laboratory is particularly interested in $\beta$-Ga$_2$O$_3$ for applications including high-frequency converter operation, power switching, and on-chip power conversion, all of which serve to improve the size, weight, power, and cost of sensors systems. Realizing the potential of $\beta$-Ga$_2$O$_3$ in prototype devices has necessitated clever solutions to challenging problems in materials science and materials engineering. In this talk, we will discuss some of the materials science and engineering challenges $\beta$-Ga$_2$O$_3$ has faced, as well as the solutions that have been implemented. We will discuss the identification and mitigation of Si contamination sources in $\beta$-Ga$_2$O$_3$ epitaxy, optimizing regrowth and liftoff for ohmic contact formation, defect engineering of the oxide-semiconductor interface in $\beta$-Ga$_2$O$_3$ MOSFETs, and challenges in device design for high-temperature applications. We will also discuss open challenges in $\beta$-Ga$_2$O$_3$ that may have solutions in future materials science research.

Computational Thermochemical Stability Analysis of Metal-$\beta$-Ga$_2$O$_3$ Interface
Cheng-Wei Lee$^†$, Andriy Zakutayev$^{2,3}$ and Vladan Stevanovic$^{1,2}$;  
$^1$Colorado School of Mines, United States; $^2$National Renewable Energy Laboratory, United States

Thermochemical stability of metal terminal contacts with wide-band-gap (WBG) semiconductors poses challenges for device fabrication. During the operation at high power and high temperature, such metal/oxygen contacts can react and form interfacial layers that are electronically insulating. Experimental database of standard formation enthalpy of semiconductors can be used to estimate the stability of these metal/semiconductor interfaces but is mostly limited to binary materials. Furthermore, such estimation fails when a competing multi-component oxides (number of metal elements $>2$) has a lower formation enthalpy per oxygen. On the other hand, density functional theory (DFT) databases include not only the binary but also most of the multi-component compounds documented in ICSD. Several efforts in the past, including the approach of fitted elemental-phase reference energies[1], has enabled prediction of formation enthalpy of these compounds using DFT results within chemical accuracy (~50 meV/atom).

Using $\beta$-Ga$_2$O$_3$ as an example, and building on these theoretical models, we perform thermochemical analysis to predict the stability of metal-$\beta$-Ga$_2$O$_3$ interfaces. $\beta$-Ga$_2$O$_3$ has great n-type performance as power electronics and electron affinity (EA) around 4.0 eV. Based on the Schottky-Mott rule, metals with work functions (WF) around 4.0 eV will be ideal as Ohmic contact for $\beta$-Ga$_2$O$_3$. From the stability analysis, we found that Cd, In, Sn, Ti, Pb, and Bi are stable with $\beta$-Ga$_2$O$_3$, and the difference in WF from 4.0 eV is $<0.3$ eV. But we also notice that these metal candidates have low melting temperatures ($<400$ °C) and require very low oxygen partial pressure (<$10^{-10}$ atm) to avoid oxidation when in contact with $\beta$-Ga$_2$O$_3$. Our results are also consistent with experimental findings [3,4] that the commonly used Ti contact is not stable with $\beta$-Ga$_2$O$_3$ at elevated temperature (~400 °C). Based on the results for $\beta$-Ga$_2$O$_3$, we also identified a trend: Metals with smaller work functions, i.e. Fermi levels closer to vacuum level, are generally more reactive with oxygen molecules. Such observation suggests that if a metal oxide’s EA is smaller than the WF of its constituent metal, other metals with WF close to its EA will likely oxidize in contact with the metal oxide. For $\beta$-Ga$_2$O$_3$, the WF of Ga is ~4.3 eV from the vacuum level, which is larger than its EA at ~4.0 eV. To form Ohmic contacts, metals with EA around 4.0 eV are needed but the observed trend suggests that these metals are also likely to oxidize when in contact with Ga$_2$O$_3$. On the other hand, metals with WF $>4.3$ eV are needed to have stable interfaces but these form Schottky contacts. Such dilemma suggests that alternative approaches are needed for $\beta$-Ga$_2$O$_3$ and one alternative is to heavily dope the region near stable Schottky contacts to balance conductivity and stability at metal/semiconductor interfaces. This computational approach can be also used to identify suitable metal contacts for other WBG semiconductors.

Monoclinic β-Ga2O3 is a wide bandgap (4.9eV) semiconducting material that is used for the fabrication of high power and high temperature electronic devices. Like other metal oxides, this material can also be used for the fabrication of gas sensing devices. For this, chemiresistive thin films of β-Ga2O3 have been demonstrated to respond to different gases, like oxygen, hydrogen, methane, and carbon monoxide, at temperatures above 600°C. With the aim of lowering the operation temperature of this material, to make it compatible with Internet-of-Things (IoT) applications, β-Ga2O3 nanowires (NWs) have been reported to respond, i.e., to change their resistance, to relative humidity at room temperature. Following this last idea, in this work we present a fabrication route that allows the direct growth and integration of β-Ga2O3 NWs on top of substrates containing interdigitated electrodes. Here, the β-Ga2O3 has been directly synthesized on top of fused silica substrates containing interdigitated electrodes made from Cr/Pt. The growth of the nanowires was performed at atmospheric pressure and temperatures above 800°C inside a quartz tube inserted in a tubular furnace via a Vapor-Liquid-Solid mechanism, using gold as catalyst and a flux of 500 mI/min of argon as carrier. Two different methods for the generation of the precursor vapor have been used: either metallic gallium or a mixture of gallium oxide and graphite, for which a carbothermal reduction takes place. Structural and chemical characterization has been carried out using scanning (SEM) and transmission electron microscopy (TEM), and X-ray photoelectron spectroscopy (XPS). Furthermore, the samples have been mounted in a home-made stainless-steel miniaturized gas chamber and connected to a gas injections system through mass-flow controllers. Alternating pulses of different gases (diluted relative humidity (RH), CO and NOx) and dry synthetic air have been introduced into the chamber while resistance changes were measured. SEM confirms that long (above 10 micrometer) and thin (below 50 nanometer) nanowires have been synthesized, which bridge the gap between the interdigitated electrodes. Furthermore, TEM confirms the monocystaline and almost defect-free nature of the NWs. A subtle difference between the NWs grown from the two precursor generation methods: for the carbothermal reduction, a carbon-containing interdigitated electrodes. Here, the β-Ga2O3 has been directly synthesized on top of fused silica substrates containing interdigitated electrodes made from Cr/Pt. The growth of the nanowires was performed at atmospheric pressure and temperatures above 800°C inside a quartz tube inserted in a tubular furnace via a Vapor-Liquid-Solid mechanism, using gold as catalyst and a flux of 500 mI/min of argon as carrier. Two different methods for the generation of the precursor vapor have been used: either metallic gallium or a mixture of gallium oxide and graphite, for which a carbothermal reduction takes place. Structural and chemical characterization has been carried out using scanning (SEM) and transmission electron microscopy (TEM), and X-ray photoelectron spectroscopy (XPS). Furthermore, the samples have been mounted in a home-made stainless-steel miniaturized gas chamber and connected to a gas injections system through mass-flow controllers. Alternating pulses of different gases (diluted relative humidity (RH), CO and NOx) and dry synthetic air have been introduced into the chamber while resistance changes were measured. SEM confirms that long (above 10 micrometer) and thin (below 50 nanometer) nanowires have been synthesized, which bridge the gap between the interdigitated electrodes. Furthermore, TEM confirms the monocystaline and almost defect-free nature of the NWs. A subtle difference between the NWs grown from the two precursor generation methods: for the carbothermal reduction, a carbon-rich shell layer is formed around the β-Ga2O3 NWs. This is confirmed by XPS and by Electron Energy Loss Spectroscopy inside the TEM. From an electrical point of view, the major difference is the value of the resistance in dry synthetic air, which is orders of magnitude lower for the NWs with the carbon shell. At room temperature, both type of sensors is sensitive to relative humidity and selective to almost all other gases. In the presentation, the complete gas sensing behavior of these sensors will be presented and the differences will be discussed taking into account the differences in structural and chemical properties of the NWs.

2:45 PM *EL11.12.06 Epitaxial Growth and Phase Stability of α-(Al,Ga)2O3Ricena JinnoThe University of Tokyo, Japan

In recent years, ultra-wide bandgap (UWBG) semiconductor materials ($E_g >3.4$ eV) have attracted much attention as materials for high-power electronics and photonics. α-(Al,Ga)2O3 is an oxide family possessing a UWBG energy spanning 5.4 to 8.6 eV [1]. At the present stage, n-type conductivity control is possible in the Ga-rich region ($E_g >5.5$ eV). However, a recent first-principles study predicts that Si can be an efficient shallow donor up to a bandgap of 7.5 eV (Al compositions of 0.71) for α-(Al,Ga)2O3 [2]. The UWBG larger than 6 eV is unachievable in the nitride semiconductor family, offering the possibility to take semiconductor electronics and photonics into regimes that currently remain out of reach. This talk will focus on the recent progress of phase stability and plasma-assisted molecular beam epitaxy (PAMBE) of α-(Al,Ga)2O3.

The electron gas (2DEG) formed at the interface of δ-Al2O3 substrates, and controllable n-type doping have enabled rapid development in both growth and device processing. However, compared to other wide bandgap semiconductors, the intrinsic channel mobility is relatively low. A potential pathway to overcome this mobility limit is through two-dimensional electron gas (2DEG) formed at the interface of δ-doped β-(Al,Ga)2O3 and undoped β-Ga2O3. In this work, abrupt and smooth heterojunctions were grown at high Al concentrations using metal organic chemical vapor deposition (MOCVD) with TEGa and TEAl precursors.
Prior to growth, (010) β-Ga2O3 plates were etched in hydrofluoric acid (HF) for 30 minutes to minimize parasitic interfacial Si doping. In pure β-
Ga2O3/AlN, we observed a sub-nanometer mobility of 156 and 114 cm²/Vs for 1×10⁷ and 1×10⁸ cm⁻³ Si doping, respectively, with sub-nm RMS roughness.
However, as the Al concentration increases, multiple material challenges must be addressed including interfacial segregation, dopant activation, and
maintaining film smoothness. Using TMAl and TEGa precursors, we demonstrate sub-2 nm RMS roughness for 130 nm β-(Al₀.₉₁Ga₀.₀₉)₂O₃ films. However, the growth temperature of 900 °C is too high for dopant activation due to the reduced cracking temperature. Additionally, TEAL shows potentially lower carbon incorporation because it pyrolyzes via β-hydrogen elimination whereas the growth of AlN can leave behind highly reactive methyl radicals that may incorporate into the film. Surface roughness, carrier activation, and mobility as a function of Al concentration and doping conditions are reported.

Combining effective substrate etching to remove a parasitic conducting channel with a profiled nitrided δ-Al₂O₃, we enable high mobility 2DEGs which will open the possibility for devices with high switching speeds to operate in extreme environments.

Schottky Barrier Diode and MESFET based on Ge-Doped α-Ga2O3 Thin Film Grown by Mist-CVD
Takeru Wakamatsu¹, Yukie Isobe¹, Hitoshi Takekai¹, Kentaro Kaneko² and Katsuhisa Tanaka¹; ¹Kyoto University, Japan; ²Ritsumeikan University, Japan

Gallium oxide (Ga2O3), which is one of the ultra-wide bandgap semiconductors, has attracted considerable attention because of its potential applications for power electronics. Among polymorphs of Ga2O3, β-Ga2O3 is the most stable phase. Although β-Ga2O3-based devices such as Schottky barrier diode (SBD), MESFET and MOSFET have been reported thus far, the fact that β-Ga2O3 substrate is expensive and has a low thermal conductivity is a problem from a point of view of practical applications. On the other hand, α-Ga2O3, which is one of the metastable phases, can be grown on a Sapphire substrate by heteropitaxial growth techniques such as mist-CVD, HVPE and MBE. The sapphire substrate is cost-effective and has a high thermal conductivity, which is preferable for device applications. Nonetheless, there are not so many reports on the α-Ga2O3-based devices including SBD, MESFET and MOSFET.

This is partly because the control of carrier density and achievement of high mobility are not so easy compared with β-Ga2O3. Recently, we successfully obtained Ge-doped α-Ga2O3 thin films by using mist-CVD method with the wider carrier density ranging from 1×10¹⁶ to 1×10²⁰ cm⁻³ and the higher mobility 65.9 cm²/Vs than previous reported Sn-doped α-Ga2O3.[1] In this work, we report on the fabrication of SBD and MESFET based on the Ge-doped α-
Ga2O3 thin films and confirm that the resultant devices exhibit rather high performance. Ge-doped α-Ga2O3 thin films were grown on m-plane sapphire substrates by mist-CVD method. An α-Ga2O3 n' layer (900-1000 nm thick, the donor density, N_D = 1×10¹⁷ cm⁻³) and an α-Ga2O3 n' drift layer (300-600 nm thick, UID) were grown on the m-plane sapphire substrate for SBD. To make a mesa structure, the n' layer was etched with ICP-RIE following photolithography. An ohmic electrode, Ti/Au (20 nm/100 nm thick) or Ti/AITi/Au (30 nm/100 nm/30 nm/30 nm thick) was deposited on the n' layer by electron beam (EB) deposition. After that, the samples were annealed at 400, 450, 470 and 500 °C for 1 min in an N₂ atmosphere. Then, Ti/Au (20/100 nm thick) Schottky electrode was formed by EB deposition. The V-I characteristic of the resultant SBDs was measured and analyzed in terms of the thermionic emission model. The n' value and the barrier height are 1.06-1.19 and 0.95-1.13 eV, respectively. The on-resistance decreases as the annealing temperature is increased. The lowest on-resistance is 3.7 mΩcm² achieved for the device with Ti/AITi/Au (20 nm/100 nm thick) electrode annealed at 500 °C.

Also, we prepared MESFET as follows. First, Fe-doped buffer layer (800 nm thick), Ge-doped channel layer (300 nm thick) and n+ layer (30 nm thick) were grown on an n-plane sapphire substrate. For the mesa device isolation, 500 nm-thick α-Ga2O3 was etched by ICP-RIE. A Ti/Au (20/100 nm thick) was deposited as source and drain electrodes. The n' layer on the channel layer was etched by ICP-RIE. A Ni/Au (30/100 nm thick) was deposited as a gate electrode. From the Hall effect measurements, the carrier concentration, the sheet carrier density, and the electron mobility were evaluated to be 2.1×10¹⁵ cm⁻³, 4.9×10¹² cm⁻² and 44 cm²V⁻¹s⁻¹, respectively. The I-V measurements were conducted for the device with L_g/2L_s/L_d = 3/3/12 μm, where L_g, L_s, and L_d are gate-source, gate and gate-to-drain lengths, respectively. From the output curve (I_GD vs. I_D characteristic), the maximum I_D and the on-resistance were estimated to be 24 mA/mm and 587 Ωmm (at V_GS = V_D = 2 V), respectively. The break down voltage is 364 V (at V_GS = -10 V). From the transfer curve (I_GS vs. I_D characteristic), the threshold voltage, the substrate voltage and the on/off ratio were evaluated to be -9 V, 164 mA/dec and 10⁶, respectively. These values are superior compared to α-Ga2O3-based MESFET reported previously, for which the break down voltage, the on/off ratio and the maximum I_D are 48 V, 2×10⁵ and 35 mA.[1]

Demonstration of 3 kV Schottky Barrier Diodes on α-AlN Epilayers Grown on Bulk α-AlN Substrates by MOCVD
Dinusha Herath Mudivanseelage, Dawei Wang, Zyi He, Bingchen Du and Houqiang Fu; Arizona State University, United States

Aluminum Nitride (AIN) is a promising material for next-generation power electronics due to its remarkable attributes, including an ultra-wide bandgap (6.2 eV), robust breakdown field (12-15 MV/cm), and superior thermal conductivity (340 W/mK). AIN power devices have already shown promising development with high temperature stability and potential to improve energy efficiency and reduce system size for various power conversion applications. Nevertheless, several challenges persist in the growth and fabrication processes, including the high cost and lack of conductive substrates for AIN substrates, growth of high-quality AIN epilayers, and the need for proper Ohmic and Schottky contacts.

In this study, we have grown AIN epilayers on bulk AIN substrates with high Si doping concentration (~1×10¹⁸ cm⁻³) to demonstrate lateral Schottky barrier diodes (SBDs) with kV-class capabilities. The device configuration incorporates Ti/AlNi/Al as Ohmic contacts and Pt/Al for the Schottky contact. The AIN epilayers were grown via metal-organic chemical vapor deposition (MOCVD), utilizing trimethylaluminum (TMAI) and ammonia (NH₃) as the Al and N sources, with SiH₄ employed as the n-type dopant Si precursor. The device structure entails a 1-µm-thick resistive UID AlN underlayer, a 200 nm AlN epilayer, and a 2 nm thick GaN capping layer, to prevent the oxidation of underlying AIN epilayers. High-resolution X-ray diffraction (HR-XRD) confirmed the crystallinegraphic quality of the epilayers. Device fabrication started with rigorous cleaning using acetone, isopropl alcohol and DI water aided by sonication, and HClH₂O (1:2) solution treatment. Subsequently, the Ohmic contacts were patterned using standard photolithography, followed by e-beam evaporation of Ti/AlNi/Al (25/50/25/50 nm) and liftoff. After that, 1000 °C, 1-minute annealing process in N₂ ambient was performed using rapid thermal annealing. Schottky contacts were subsequently patterned, with Pt/Al (30/120 nm) metal deposition and liftoff. The distance between Schottky and Ohmic contacts were varied between 50-350 µm. The devices were tested with a 4200 semiconductor parameter analyzer equipped with a controllable thermal chuck. High voltage measurements were carried out using a Keysight B1505A Power Device Analyzer. The devices exhibit remarkable ON/OFF ratios ranging from 10⁵ to 10⁸ across a temperature range of 30°C - 323 K, exhibiting their robust temperature stability. The current of the devices increases linearly with temperature as more carriers are excited and enabled the current transport. The devices maintain a Schottky barrier height of approximately 0.9 eV, with this value increasing from 0.9 - 2.2 eV as temperature rises, while the ideality factor decreases from 4.8 - 2.5. This degradation in the thermalization current mechanism mainly governed by the resistive nature of the AIN epilayers. Furthermore, temperature-dependent CV measurements verify an increase in carrier concentration with rising temperature. The devices demonstrate decent forward characteristics and exhibit breakdown voltages exceeding 3 kV. At ~3 kV, the devices display a low leakage current of 200 nA. The observed leakage current variation with the area of the Ohmic contact region suggests that surface leakage governs the reverse leakage current. This work serves as a valuable reference for the development of kV-class AIN high-voltage, high-power devices, showcasing significant progress in the field.
Based on results obtained by x-ray diffraction and x-ray reflectometry, Raman and Fourier-transform spectroscopy, atomic force microscopy and scanning epitaxy (FME) in the second step of one MOVPE process and is used to study substrates with five different off-cut angles for three different CFG times.

With this off-cut have the lowest amount of debris, 3D grains consisting of mostly h-BN material [5], on the surface. They also have most intense x-ray plane sapphire substrate [4]. We demonstrate that the highest quality of h-BN layers is obtained for a sapphire substrate off-cut angle of 1 degree. Samples epitaxial layers at temperatures between 1000°C and 1700°C.

Sources, including a sublimation carbon source, atomic carbon source and e-beam carbon source, to grow graphene monolayers on hBN substrates and hBN epitaxial growth process.

Heterostructures can be produced by epitaxy or by exfoliating and stacking of 2D layers, lateral 2D heterostructures can only feasibly be produced by an properties by quantum confinement of electrons or introduction of novel electronic and magnetic states at the interface. Whereas vertical 2D heterostructures can be produced by epitaxy or by exfoliating and stacking of 2D layers, lateral 2D heterostructures can only feasibly be produced by an epitaxial growth process.

We have demonstrated that lateral heterojunctions of hBN and graphene can be grown in-situ using HT-MBE. We used different types of the MBE carbon sources, including a sublimation carbon source, atomic carbon source and e-beam carbon source, to grow graphene monolayers on hBN substrates and hBN epitaxial layers at temperatures between 1000°C and 1700°C.

We will discuss HT-MBE of graphene monolayers in crystallographically oriented hBN trenches, formed ex-situ by catalytic Ni-nanoparticle etching. High-resolution atomic force microscopy (AFM) reveals that graphene monolayers grow epitaxially from the hBN etched trench edges, and merge to form a graphene nanoribbon network.

We will also discuss in-situ HT-MBE of monolayer-thick lateral hBN-graphene heterostructures. Monolayer-thick hBN, grown at a higher temperature of ~1400°C, exhibited armchair edges, minimal aggregate presence, and a reduced but significant width of the hBN monolayer sheet. We have shown that in HT-MBE hBN grows preferentially laterally from the edges of hBN in a mode of step-flow growth, which results in the formation of lateral hBN-graphene heterojunctions. The graphene and hBN regions show a clear epitaxial relationship through the alignment of atomic lattices. Sequential HT-MBE growth of hBN, graphene and a second cycle of hBN growth resulted in the formation of monolayer-thick lateral hBN-graphene-hBN heterostructures, in which a strip of graphene is laterally embedded between monolayers of hBN.

9:00 AM EL11.13.02 Direct MOVPE Growth of High-Quality h-BN on the Wafer-Scale Sapphire: The Role of Substrate Off-Cut Mateusz Tokarczyk, Aleksandra Dabrowska, Grzegorz Kowalski, Rafal Bozek, Jakub Iwanski, Johannes Binder, Roman Stepniewski and Andrzej Wysmolek, Faculty of Physics, University of Warsaw, Poland

Hexagonal boron nitride (h-BN) is an attractive wide bandgap 2D material for possible applications in electronic and optoelectronic devices based on van der Waals heterostructures [1], but direct growth of high-quality h-BN on the wafer-scale is still the bottleneck for future successful implementation of h-BN in industry. Although the synthesis of h-BN by metal-organic vapor phase epitaxy (MOVPE) has already been reported [1-3], there is a fundamental lack in understanding of many basic aspects of this process affecting obtaining a good structural quality and a smooth surface. In particular the role of the substrate off-cut, although well known as being of major importance for the growth of other materials, has not yet been fully addressed so far.

In this communication, we present a study that addresses the influence of the sapphire substrate off-cut angle on the final quality of h-BN obtained in a two-step growth procedure [3]. The main process starts with a self-limiting continuous flow growth (CFG) of a BN buffer followed by flow-modulated epitaxy (FME) in the second step of one MOVPE process and is used to study substrates with five different off-cuts angles for three different CFG times. Based on results obtained by x-ray diffraction and x-ray reflectometry, Raman and Fourier-transform spectroscopy, atomic force microscopy and scanning electron microscopy, we present a comprehensive study that shows that the quality of h-BN epilayers dramatically depends on the off-cut angle of the c-plane sapphire substrate [4]. We demonstrate that the highest quality of h-BN layers is obtained for a sapphire substrate off-cut angle of 1 degree. Samples with this off-cut have the lowest amount of debris, 3D grains consisting of mostly h-BN material [5], on the surface. They also have most intense x-ray
diffraction signal, minimal Raman phonon linewidth and thinnest amorphous BN part. We are able to explain these results by following the evolution of the whole substrate, which includes a thin AlN layer coming from initial nitridation step at the beginning of MOVPE process. This AlN layer is shown to smooth out the surface forming (with sapphire) a kind of “effective substrate” which leads to the observed increase in quality. A detailed analysis of the crystallographic structure of the h-BN obtained layers and mechanisms responsible for the existence of an optimal off-cut angle will be discussed.

Towards Growth of High Quality Cubic Boron Nitride using Fluorine Chemistry

Ali Ebadi Yekta, Avani Patel and Robert J. Nemani; Arizona State University, United States

Boron Nitride (BN) is an ultra-wide bandgap material having a bandgap of 6.4 eV and 5.9 eV for the cubic (c-BN) and hexagonal (h-BN) phases, respectively. The ultra-wide bandgap of both BN phases indicates a high breakdown voltage, possibly even greater than diamond [1]. Moreover, epitaxial c-BN on diamond is expected to have high thermal conductivity. Diamond and c-BN have a small lattice mismatch of 1.4 percent [2]. Therefore, diamond is a candidate for use as a substrate for growth of c-BN. However, the choice of an appropriate substrate among different types of diamond as well as crystallographic orientation can affect the quality of the grown c-BN films. Also, depending on the growth technique, it might be essential to use either p-type or n-type diamond to achieve high-quality c-BN films. The last but not the least, in growing high-quality c-BN films is the method utilized to clean the substrate which is of great significance, too.

Physical vapor deposition (PVD) is one of the techniques that has shown success in growing c-BN layers. Magnetron sputtering, ion-assisted pulsed laser deposition (IALD), ion beam-assisted deposition (IBAD) and mass selected ion beam deposition (MSIBD) are some methods under PVD category that have been exploited to grow pure c-BN [3]. However, utilizing high energy ion bombardment as well as high bias voltage is a must in such methods. Therefore, we should expect high compressive stress on the films which leads to defect formation and delamination of very thick films. Also, slow growth rate of PVD methods, few nm/hrs, prevent us from getting thick, pure c-BN films. To overcome the above obstacles Chemical vapor deposition (CVD) is also suggested for growing c-BN. These methods include DC jet plasma CVD, RF plasma CVD, inductively coupled PECVD and electron cyclotron resonance microwave plasma CVD (ECR MPCVD). The advantage of CVD over PVD is that ion bombardment and high bias voltage are not present to impose compressive stress and the resulting defects. Besides that, faster growth rate of CVD techniques opens up a lot of opportunities to get thick films of c-BN in short processing times [3]. Among the CVD methods, ECR MPCVD has been the most successful technique in getting thick and pure c-BN films due to the fact that processing is done in very low pressure environment down to even Torr. This reduces the contaminants that can interfere with the reaction and improves the precursors reaction on the substrate surface.

In this study we have explored achieving both thick and high quality c-BN films on polycrystalline boron-doped diamond at fast, 100 nm/hrs, and slower, 50 nm/hrs, growth rate. ECR MPCVD method in combination with Fluorine chemistry using H2, BF3, N2, He and Ar gases was utilized. Substrate is In this study we have explored achieving both thick and high quality c-BN films on polycrystalline boron-doped diamond at fast, 100 nm/hrs, and slower, 50 nm/hrs, growth rate. determined dislocation density and types in planar and non-planar GaN, AlGaN and AlN thin films; imaged misfit dislocations in AlGaN HEMT structures; imaged stacking faults in non-polar and semi-polar wurtzite GaN; and mapped strain in GaN thin films [1-5]. The benefits of imaging in the SEM include minimal sample preparation and the ability to produce images from areas ranging in size from square microns to square centimetres. Diffraction analysis can also be combined with energy dispersive X-ray spectroscopy; hyperspectral cathodoluminescence imaging; and electron beam induced current to provide complementary, non-destructive high resolution information on the structural, compositional, luminescence and electrical properties of materials [1-3]. In our presentation we will illustrate our present capabilities with recent results and explore the potential of diffraction imaging in the SEM to underpin fast optimisation of new materials and device structures.

Evaluation of Band Alignment of Rutile-Sn1-xGeO2 by XPS
Yo Nagashima1, Akira Chikamatsu2, Daichi Oka3 and Yasushi Hirose4, 1The University of Tokyo, Japan; 2Ochanomizu University, Japan; 3Tokyo Metropolitan University, Japan

Introduction: An alloy of rutile-type SnO2 and GeO2 (Sn1-xGeO2: SGO) is an ultrawide-gap oxide semiconductor. SGO is expected to be applicable for power electronic and ultraviolet optoelectronic devices because of its wide tunability of bandgap from ~3.7 eV to ~4.7 eV [1, 2]. A unique feature of SGO is a possibility of ambipolar doping, originating from shallow valence band maximum (VBM) of rutile GeO2 (x=1), predicted by first-principles calculations [3, 4]. Although the band alignment (band edge position) of SGO is important for considering dopability in SGO as well as for designing SGO-based heterostructure devices, it has not been experimentally investigated yet. In this study, therefore, we evaluated the position of VBM of a series of SGO epitaxial thin films (x=0-0.6) using X-ray photoelectron spectroscopy (XPS) and determined its band alignment.

Methods: The (001)-oriented SGO thin films (x=0-0.6) were epitaxially grown on Nb:TiO2 (001) substrates by the pulsed laser deposition [1]. Crystal structure and Ge/Sn ratio of the films were confirmed by X-ray diffraction and energy-dispersive X-ray spectroscopy, respectively. In the XPS measurements, valence band and O 2s spectra of the SGO films were measured at 300 K with an Al-Kα X-ray source. The variation of the VBM from the vacuum level as a function of the chemical composition was evaluated using the position of O 2s peak as a reference. Before the XPS measurement, the SGO thin films were annealed at 800 °C for 6 hours in air to remove Sn2+ component from the surface.

Results: VBM of the SGO films became shallower monotonically by 0.5 eV with increase of x from 0 to 0.6, which qualitatively agreed with the prediction by first-principles calculations [3]. On the other hand, the position of VBM was still deeper than the practical level of Fermi energy pinning level for p-type doping, requiring further increase of Ge to realize ambipolar doping. We also estimated the position of conduction band minimum (CBM) using the band gap of SGO determined from the optical absorption spectroscopy. As x increased from 0 to 0.6, CBM also became shallower by 0.8 eV. This rise of CBM position can explain the reduction of donor activation ratio with increasing x, observed in Ta-doped SGO thin films. These results also indicated that a heterostructure consisting of SGO thin films with different Sn/Ge ratio will become a type-II heterojunction.

Low-Temperature Electrical Properties of r-GeSn1-xO2: Alloy Film
Hitoshi Take1, Itsuhiro Kakeya1, Hirokazu Izumi2, Takeru Wakamatsu1, Yuki Isobe1, Kentaro Kaneko3 and Katsuhisa Tanaka1; 1Kyoto University, Japan; 2Hyogo Prefectural Institute of Technology, Japan; 3Ritsumeikan University, Japan

Rutile-type wide and ultrawide band-gap oxide semiconductors, such as r-GeO2 and r-SnO2, are emerging materials for high-power electronics and deep ultraviolet optoelectronics devices [1,2]. Recently, their alloy (r-GeSn1-xO2) has also attracted attentions due to the possibility to modulate its bandgap and electrical properties by tuning the Ge:Sn compositional ratio [2-4]. In addition, Sn-rich r-GeSn1-xO2 exhibits excellent n-type conductivity, which is favorable for future device-oriented researches [2,3]. However, details of its electrical properties including carrier transport mechanisms have not been elucidated yet.

In this study, we investigated low-temperature electron transport properties of Sn-rich r-GeSn1-xO2 thin films (x=0.28 and 0.41). Temperature-dependent Hall effect measurements suggest that the hopping conduction is dominant at low temperatures (<100 K) in both r-Ge0.28Sn0.72O2 and r-Ge0.41Sn0.59O2. Temperature-dependent resistivity measurements indicate that the hopping mechanism at lower temperatures (T ≤ 15 K) is explained by the Efros-Shklovskii variable-range hopping (ES VRH), that is, hopping over the states within the Coulomb gap. In the temperature region, both r-Ge0.28Sn0.72O2 and r-Ge0.41Sn0.59O2 exhibit both negative and positive magnetoresistances. Based on the theory of quantum interference that includes effects of both frozen- and free-electron spins [4,5], it is found that the negative and positive components are attributed to the quantum interference and field-induced spin-alignment, respectively, and the transport mechanism at T ≤ 15 K for both r-Ge0.28Sn0.72O2 and r-Ge0.41Sn0.59O2 corresponds to the ES VRH with large number of scattering centers. The results are coincident with those obtained by the temperature dependence of resistivity. At T ≥ 30 K, the negative magnetoresistance induced by the quantum interference effect decreases as the temperature increases. Moreover, at T ≥ 150 K, both r-Ge0.28Sn0.72O2 and r-Ge0.41Sn0.59O2 show temperature-independent positive magnetoresistance induced by the Lorentz force. It is considered that these results indicate a mixture of the Mott VRH and thermally activated band conduction (T > 100 K) and almost pure thermally activated band conduction (T ≤ 150 K).

We believe that our experimental and analytical results provide a basis for the development of not only r-GeSn1-xO2 but also all the other rutile-type wide and ultrawide band-gap oxide semiconductors.

In the last two decades, there has been considerable research focused on investigating GaN films grown on silicon as a wide bandgap semiconductor material. Optical techniques, such as ellipsometry, have been widely employed for characterizing thin films and bulk materials, enabling the determination of layer thicknesses and surface roughness. X-ray diffraction (XRD) has proven to be an essential tool for analyzing semiconductor crystal structures, while Raman spectroscopy provides insights into the composition and homogeneity of epitaxial semiconductor samples. This study examines four GaN thin films grown on silicon substrates using metalorganic chemical vapor deposition (MOCVD). Variable angle spectroscopic ellipsometry (VASE) measurements were conducted to determine film thickness and surface roughness as well as the dependence of n & k versus wavelength in 250-1000 nm for these GaN on Si samples. The obtained results indicate specific values for each sample: the first sample has a film thickness of 180 nm and a surface roughness of 47 nm, the second sample has a thickness of 106 nm and a surface roughness of 8 nm, the third sample has a thickness of 1004 nm and a surface roughness of 3 nm, and the fourth sample has a thickness of 1510 nm and a surface roughness of 2 nm, as derived from Spectroscopic ellipsometry (SE) fits. The highest recorded refractive index among the four samples is 2.76, XRD measurements were performed on the first two samples, while Raman scattering measurements were conducted on the remaining two samples. The XRD experiments involved wide scans and fine scans with step sizes of 0.1° and 0.005°, respectively. The XRD analysis revealed distinct peaks corresponding to silicon (002) and (004) orientations at approximately 28° and 90°, respectively, in the first sample. Additionally, a weak peak at around 35° indicated the presence of the GaN (0002) peak. In the second sample, the XRD analysis demonstrated clear peaks for the Si substrate (002) and (004) orientations at 28° and 90°, respectively, along with distinct peaks corresponding to GaN at (0002), (0004), and (0006) orientations. Notably, the first-order GaN peak was observed at approximately 34.6°, the second-order peak at around 73°, and the third-order peak at approximately 127°, providing valuable information about the crystallographic properties of the GaN films. Raman scattering measurements were conducted on two samples under a microscope at room temperature, employing different excitation laser powers (5%, 1%, and 0.5%).

The first Raman experiment revealed characteristic peaks at 520 cm⁻¹ for Si, confirming its crystalline nature, while peaks at 365 cm⁻¹ corresponded to the GaN crystallinity characteristics of the E₂ (High) and A₁ (LO) vibrational modes. In the second Raman experiment, distinctive peaks at 520 cm⁻¹, 567 cm⁻¹, and 734 cm⁻¹ were identified for Si, GaN E₂ (High), and GaN A₁ (LO), respectively, further supporting the exceptional crystalline purity of the GaN films grown on silicon substrates. Through these comprehensive surface, structural, and optical characterizations, our study provides compelling evidence of the exceptional crystalline purity of the investigated GaN films on silicon substrates. These findings, achieved through Ellipsometry, XRD, and Raman spectroscopy techniques, enhance our understanding of the surface, structural, and optical properties of GaN films and open up exciting possibilities for their utilization for high-power and spintronic applications.

References

The recent surge in high-power electronic device research has led to the development of various wide bandgap materials. GaN is such a material with immense potential due to its many impressive characteristics, such as high electron mobility and high breakdown voltage, leading to smaller device footprints with better power densities and high efficiency. However, heat dissipation has become a significant concern in high-power semiconductor devices made of GaN, which stems from the combination of low thermal conductivity and increasing power density. This study aims to resolve this issue by incorporating a Q-carbon (quenched form of carbon) interlayer to form continuous diamond films, which have the highest thermal conductivity of any material. Q-carbon is a novel form of carbon that has been rapidly cooled after melting, resulting in its unique properties and potential for use in electronic applications and device fabrication. The growth of large-area Q-carbon has been restricted to low thermally conductive substrates due to the non-equilibrium nature of the synthesis process and a narrow range of parameters. This study addresses the aforementioned limitations by conducting a comprehensive parameter optimization of diamond-like carbon (DLC), the fundamental structure necessary for synthesizing Q-carbon. Initially, the deposition of DLC films onto sapphire substrates is accomplished through the utilization of graphitic carbon targets via pulsed laser deposition (PLD), and subsequent pulsed laser annealing (PLA) is employed to generate Q-carbon, with a comprehensive regulation of laser, deposition, and annealing parameters. This study involves a full systematic investigation of the deposition conditions and identifying the conditions necessary for high-quality HFCVD diamond with uniformity while protecting the GaN layer from deterioration and resolving the thermal mismatch between GaN and diamond. The distinctive combination of features possesses the capability to address the predicament of heat management in GaN devices, thereby advancing the attainment of GaN's theoretical potential in the domains of wireless 5g communications, high-power devices, and other intricate microelectronic systems.

Molecular Beam Epitaxy of Superconducting ZrN Thin Films on GaN Substrates
Breton J. May, Kevin D. Vallejo, David Hurley and Krzysztof Gofryk; Idaho National Laboratory, United States

Group III-Nitride materials have found applications in optoelectronics and photonic devices due to the large variation in direct bandgap spanning from the infrared to the deep ultraviolet. Recent research has pursued the integration of this well-established material system with transition-metal nitrides to create complex heterostructures with additional magnetic or superconducting functionality. ZrN is a well-known refractory conductor with high oxidation resistance, high hardness, and has been shown to be a superconductor at low temperatures. The estimated lattice mismatch of ZrN with InN, GaN, and AlN is 8.5%, -1.5%, and -4.2%, respectively, suggesting strain-free as well as strain-tunable growth on the ternary III-Ns. This work focuses on the epitaxial growth of ZrN on c-plane GaN substrates via molecular beam epitaxy. An electron beam evaporation source and an RF-plasma source were used to supply the Zr and active nitrogen, respectively. Neither reflection high energy electron diffraction (RHEED) nor X-ray diffraction (XRD) revealed any crystalllographic texture of ZrN deposited on fused silica at temperatures >700°C. However, growth of ZrN on c-plane GaN substrates at similar temperatures was epitaxial. RHEED revealed that the ZrN maintains the symmetry of the underlying GaN throughout the entire deposition, and post-growth examination via XRD showed (111) oriented ZrN thin films. RHEED patterns during the regrowth of GaN directly on thicker layers of higher symmetry ZrN suggest a preference for the formation of rotational domains and a slight degree of surface faceting. The electrical transport as a function of temperature and magnetic field of ZrN films has been measured. Initial results of uncapped ZrN thin films reveal a superconducting phase with a critical temperature of ∼10 K and a critical field of 2 T. The critical temperature of the films is lower than reports of bulk ZrN, which could be attributed to strain, the presence of off-stoichiometry or structural disorder, and is under investigation. These results pave the way for integration of additional superconductors and quantum phenomena in existing III-N systems.

2:30 PM EL11.15.06
Reduction of Lattice Mismatch Induced Strain and Critical Thickness Identification for Long-Range Crystallinity Niobium Nitride on 6H-SiC for High Quality SNSPD Detectors
Annelleise Drechsler1,2, Patrick Shea2 and Aristos Christou1; 1University of Maryland, United States; 2Northrop Grumman Corporation, United States

Niobium nitride (NbN) films have garnered significant attention and research recently due to their high critical temperature (Tc) and their usage in infrared-sensitive superconducting nanowire single photon detectors (SNSPDs). Devices fabricated from NbN have demonstrated single photon detection to midwave infrared wavelengths, which unlocks possibilities for novel applications such as long-range laser detection and ranging (LIDAR), interferometry of signals in planetary emissions, quantum key distribution, and optical communications. Due to their polycrystalline nature, NbN films are sensitive to defects stemming from the deposition and fabrication processes referred to as constrictions. These film constrictions effectively reduce the cross-sectional area of the detector nanowire, which in turn limits the critical current and resultant detection efficiency and jitter. NbN films are still, however, among the most promising for practical use and array development due to their high Tc approaching 10K, thus necessitating the development of methods to reduce film defectivity. NbN films utilized for SNSPD fabrication must be thin, typically <100 nanometers. As a result, the film quality and defectivity are highly correlated to the interface between the NbN film and underlying lattice, lattice-mismatch strain, and deposition parameters of the NbN processing. To optimize this interface, a material with similar lattice structures and parameters to NbN must be chosen to minimize intrinsic defect sources. Then the deposition process can be optimized to reduce extrinsic defects. Silicon carbide (SiC) 6H polytype substrates were selected for use as the deposition substrate. 6H-SiC has an in-plane lattice parameter a=3.08Å, leading to a 3.57% lattice mismatch with hexagonal NbN with in-plane lattice parameter of 2.98Å and minimizing strain from lattice mismatch below the critical thickness. SiC can be used to fabricate semiconductor components necessary for focal plan array (FPA) development. NbN films were sputtered onto the substrates in an AJA ATC Orion 8 sputtering tool utilizing a non-reactive RF magnetron process in an inert argon atmosphere to control resultant film stoichiometry. Deposition conditions such as temperature, flow, and pressure were modified, and the resultant films were characterized through x-ray diffraction to determine phase, orientation, crystallinity, and stress. The temperature of the substrate during deposition runs was increased from ambient temperature to 600°C. As temperature increased, XRD peak intensity increased, and crystallite size calculated from peak FWHM increased linearly from 26.07nm to 1618.1nm for 60nm NbN. This substantial increase in crystallinity stemming from increased energy promoting nucleation and growth of higher order crystallites reduces the number of grain boundaries and resultant constrictions within a SNSPD to improve efficiency. High temperatures, however, are not always compatible with semiconductor fabrication necessary for FPA development so pressure modifications were also explored as an alternative. The deposition pressure was increased from 3mTorr to
Epitaxial growth of single-crystalline oxides is one of the fundamental ways to integrate perovskite structures on semiconductors and other oxides, being very attractive for applications as well as fundamental studies, where the film uniformity is greatly enhanced in comparison to polycrystalline films with reduced grain boundaries, superior interfacial conductivity and integration with silicon. However, large-scale epitaxial implantation of complex oxides in consumer electronic devices remains a challenge. Epitaxial deposition techniques, such as molecular beam epitaxy (MBE) and pulsed laser deposition (PLD), require high-temperature and high vacuum systems, with a limited deposition area, which pose problems when during production. Other techniques, such chemical vapor deposition (CVD), can also be used to deposit complex oxides, but generally at growth or post-deposition annealing temperatures over 500°C to achieve epitaxy. Therefore, a thin-film growth technique with reduced complexity and less-energy-intensive conditions, giving epitaxial films in a short growth time is highly desired. Herein, we use an open atmospheric deposition technique, Spatial Atmospheric CVD, mimicking the film growth by PLD, to deposit highly crystalline, epitaxial binary oxide, on various single crystal substrates at 350°C, with similar electrical properties of PLD grown films. Thus, opening the possibility the low cost, large scale, high throughput of epitaxial devices commercially.

Cul Based p Type Thin Film Transistor Wei Wei, Ming Gao, Wang Zhiyong and Chunxiang Zhu; National University of Singapore, Singapore

Cul is a wide bandgap p type transparent semiconductor and owns a high potential to be used in the fields like thin film transistor, Optoelectronic, and memory devices etc. It has many advantages like high hole mobility, good electrical property with a structure disorder. However, a high hole concentration in the Cul leads to a low Current On-Off ratio (ION-OFF) for Cul TFT devices. To solve this issue, Br doping technique is proposed to lower down the hole concentration in the CulBr film so that a better TFT device performance can be obtained. The density functional theory (DFT) results show that the copper vacancy formation energy increases with the CulBr content in the Br-doped Cul film, resulting in lower hole concentration. The CulBr TFTs with different Br content were then fabricated. All the CulBr films were synthesized by the solution method. When the Br concentration increases from 0% to 10%, the hole mobility decreases while the ION-OFF ratio increases from the order of 10^5 to 10^4. A Br doping concentration of 7.5% shows the best device performance with hole concentration about 5 cm^-2V-1s^-1 and ION-OFF ratio of 10^4. The good p type Cul TFT device performance is a good foundation for the later application of Cul in the fields, including Logic circuits, Optoelectronic etc.

Polarization-Dependent Optical Properties of Ce-Implanted Quartz Yukihiro Abe1,2, Shun Kanai1,3,4, Manato Kawahara1,2, Jun Ishihara3, Makoto Kohda2 and Shunsuke Fukami1,6,1; Tohoku University, Japan; 2Graduate School of Engineering, Tohoku University, Japan; 3PRESTO, Japan Science and Technology Agency, Japan; 4National Institutes for Quantum Science and Technology, Japan; 5Department of Applied Physics, Tokyo University of Science, Japan; 6Inamori Research Institute for Science, Japan

Nitrogen-Vacancy centers in diamonds and divacancies in SiC are the representative material systems composing solid-state spin qubits with a long coherence time at room temperature [1-4]. While various functionalities, e.g., remote entanglement, quantum sensing, and quantum communications, have been achieved, new qubit material systems may offer a new range of opportunities. One of the most critical material parameters for many quantum applications is the relaxation time T2. Here, we focus on quartz as a host material, the most common mineral on the earth, and has been predicted to have a long T2 without nuclear purification [5]. We choose the Ce3+ center as a spin center, which often composes a stable spin center in the widegap oxides, e.g., in Y3Al5O12, whose spin state can be controlled through the circularly polarized laser [6]. We implant Ce ion into a naturally abundant single-crystal quartz substrate at room temperature in the air. The implantation dose and energy are 1.0×10^14cm^-2 and 100 keV, respectively. Subsequently, the samples are annealed in Ar for 0-9 hours at 700-1000°C. First, we investigate the unpolarized optical properties of the Ce3+-implanted quartz. The unpolarized photoluminescence (PL) spectra are measured with unpolarized He- Cd laser excitation at 325 nm. The unpolarized PL shows similar spectra with the previous studies on the sputter-deposited SiO2:Ce [7]: unpolarized PL spectra have a prominent peak at around 445 nm, which corresponds to the 4f-5d transitions with different spin-orbit interaction of the Ce3+ center. We investigate the unpolarized PL of the samples with various annealing conditions. Up to 800°C, as the annealing temperature increases, PL intensity increases, suggesting the formation of luminescent Ce3+; the further increase of the annealing temperature decreases the unpolarized PL intensity, suggesting the formation of the Ce clusters without bright luminescence.

Next, we investigate the polarized optical properties with the samples annealed at 800°C. In a single Ce3+ center of YAG:Ce3+, the polarization-dependent PL signal corresponding to the spin-dependent 4f-5d transition and the pulsed optically-detected magnetic resonance (ODMR) have been reported at 5 K [6]. We observe that a polarization-dependent optical signal of the Ce3+-implanted quartz is consistent with the 4f-5d transition of the isolated Ce3+ centers: σ+ excitation offers a larger σ+ PL emission than that with σ− at the peak wavelength, and the more prominent σ− emission at the shoulder wavelength (~560 nm). The degree of circular polarization (DOPC) reaches 15% (5%) at peak (shoulder) wavelength at 5 K. The DOPC monotonically decreases with increasing the measurement temperature, which suggests that the spin-lattice relaxation time T1 limits T2 in this material system.

Fully Solution-Processed Ultraviolet Photodetector Based on Hydrothermally Grown ZnO Nanorod Array
Ajinkya B. Palwe, Tapesh Kumar, Sweta Rani, Shobha Shukla and Sumit Saxena; IIT Bombay, India

Patterned nanostructures exhibit interesting optoelectronic characteristics due to light-matter interaction at the comparable dimension of incident light and material. At a comparable dimension, the optoelectronic response of the nanostructure-based devices is modulated by the size and the periodicity of the structure. Numerous techniques based on top-down and bottom-up approaches are used to obtain patterned nanostructure. However, the solution-based technique is considered to be best due to cost-effectiveness as well as large-area processing. Recently patterned structures of metal oxide semiconductors are getting attention for various optoelectronic devices like photodetectors, solar cells, etc. ZnO is an abundantly available metal oxide that has high absorption coefficient and is highly appropriate for low-cost ultraviolet photodetectors. The hydrothermally patterned ZNA was achieved in two steps of deposition starting with ZnO quantum dots (QDs) seed layer followed by hydrothermal reaction. The as-grown ZNA was treated with ZnO QDs to remove any pin-holes or trap sites. P-type polymer PEDOT:PSS was used for making heterojunction with n-type ZNAs. The carbon electrode at the top was deposited by screen printing of carbon paste.

The optical bandgap increases with decreasing the size/periodicity of the ZNA. ZNR based film and heterojunction devices are investigated for different sizes/periodicity using surface morphology and optoelectronic properties. The ZNA based heterojunction photodetectors have shown improved photoresponsivity under ultraviolet (UV) light. The maximum photoresponsivity of 9.2 A/W and external quantum efficiency of 3144% are achieved for the ZNA obtained by 20 mM precursor solution. The response time is also fast due to the reduction in surface pin-holes/traps.

KEYWORDS: Hydrothermal deposition; Patterned ZnO; P-N junction, UV photodetector;

Three-Dimensional Metamaterial Absorber for Gas Molecular Sensing Takuo Tanaka\textsuperscript{1,2,3}, \textsuperscript{1}RIKEN Center for Advanced Photonics, Japan; \textsuperscript{2}RIKEN Cluster for Pioneering Research, Japan; \textsuperscript{3}Tokushima University, Japan

Metamaterials have attracted considerable attention due to their capabilities to manipulate light. Recently we applied metamaterial light absorber for fabrication technologies, opening the door to a wide range of commercial applications.

From Structuring Light to High-Volume Manufacturing with Flat Optics Federico Capasso; Harvard University, United States

An overview of passive and active metasurfaces, encompassing complex supercell multifunctional types, and structuring light and darkness; inverse designed RGB metalenses specifically for virtual reality, combined organic/silicon telecommunication modulators, metacavities intended for holographic lasing, and XUV metalenses by vacuum guiding will be presented, along with a brief description of high volume semiconductor manufacturing of flat optics for consumer electronics (https://www.electronicsweekly.com/news/business/metalenz-to-move-into-volume-production-with-umc-2023-06/)

Flat Optics for Dynamic Wavefront Manipulation Mark L. Brongersma; Stanford University, United States

Since the development of diffractive optical elements in the 1970s, major research efforts have focused on replacing bulky optical components by thinner, planar counterparts. The more recent advent of metasurfaces, i.e. nanostructured optical coatings, has further accelerated the development of flat optics through the realization that nanoscale antenna elements can be utilized to facilitate local and nonlocal control over the light scattering amplitude and phase. In this presentation, I will highlight recent efforts in our group to realize electrically-tunable metasurfaces employing nanomechanics, tunable transparent oxides, electrochemistry, microfluidics, phase change materials, and atomically-thin semiconductors. Such elements are capable of dynamic wavefront manipulation for optical beam steering, holography and future display technologies. The proposed optical elements can be fabricated by scalable fabrication technologies, opening the door to a wide range of commercial applications.

Novel Machine-Learning Approaches Based on Metric Learning and Manifold Learning for the Design and Knowledge Discovery in Nanophotonics Mohammadreza Zandehshahvar and Ali Adibi; Georgia Institution of Technology, United States

This talk is focused on using the machine-learning (ML) approaches based on dimensionality reduction and manifold learning for considerably reducing the dimensionality of the forward and inverse problems in relating the input and output of a nanophotonic system. It is shown that by using manifold learning techniques and simplifying the resulting networks using pruning, the computation complexity of the underlying ML algorithms will be considerably reduced. Furthermore, the importance of using an optimally defined loss function (or metric) for ML algorithms in obtaining priceless information about the properties of photonic nanostructures will be emphasized. It is shown that by moving from conventional mean-squared error to more intelligent metrics, knowledge discovery in nanophotonics will be facilitated along with better visualization of the input-output relationship in these nanostructures. In addition to knowledge discovery, the resulting manifold-learning algorithms can be optimally trained to facilitate the inverse design of such nanostructures while minimizing the structural complexity. As such, this talk will provide the foundation for both knowledge discovery and design in photonic nanostructures using manifold learning and metric learning and their application to the highly desired metaphotonic structures as an example platform.

Machine Learning Methods for Freeform Metamaterial Design Jonathan A. Fan; Stanford University, United States

We will discuss computational algorithms based on deep neural networks that can accelerate the design and simulation of nanophotonic devices, using metasurfaces and metamaterials as a model system. We will discuss the use of generative networks to perform population-based optimization and elucidate how the neural network architecture can be tailored to effectively perform freeform optimization. We will also discuss how physics-augmented deep networks can be trained with a combination of data and physics constraints to serve as accurate surrogate electromagnetic solvers. A principal challenge involves configuring the algorithms in a manner that enables application to a wide range of problems, and we show how these concepts can generalize to the simulation and optimization of photonic devices involving a range of domain sizes, fitting parameters, and functions. Together, these algorithms can effectively search for the global optimum three to four orders of magnitude faster than with conventional methods. We anticipate that with proper co-design of the neural network architecture with the scientific computing task, our surrogate solver and optimizer concepts can be adapted to large scale three-dimensional photonic systems.

Three-Dimensional Metamaterial Absorber for Gas Molecular Sensing Takuo Tanaka\textsuperscript{1,2,3}, \textsuperscript{1}RIKEN Center for Advanced Photonics, Japan; \textsuperscript{2}RIKEN Cluster for Pioneering Research, Japan; \textsuperscript{3}Tokushima University, Japan

Metamaterials have attracted considerable attention due to their capabilities to manipulate light. Recently we applied metamaterial light absorber for
improving the sensitivity of IR spectroscopy. Owing to its plasmonically resonant interaction with incident light wave, and molecules, unwanted background and noises in IR spectroscopy were suppressed, and molecular signals are enhanced and clearly observed at the bottom of the suppressed background. This technique has already been applied for self-assembled monolayer of 16-mercaptobenzenehexanoic acid molecules on the surface of metamaterial absorber and atto-molar (10^-18 mol) level molecular sensitivity was realized [1]. For liquid samples, to introduce target molecules into the hot spot region of the metamaterial absorber, we proposed a metamaterial absorptive device that incorporates with nanofluidics and demonstrated an ultra-high sensitivity of IR absorption detection [2, 3, 4]. In this paper, we introduced metamaterial absorber with three-dimensional vertical-oriented metal-insulator-metal (v-MIM) structure for ultra-sensitive infrared spectroscopic gas molecule sensing [5]. We designed the v-MIM structure with a nano-gap of 25 nm channel which enabled the delivery of small molecules into hot-spot region. We developed the fabrication technique to realize v-MIMs on the surface of Si substrate using electron-beam lithography and reactive ion etching techniques. Owing to small footprint of v-MIM comparing conventional lateral MIM structure, the density of hot spots was dramatically increased resulting in strong signal enhancement and efficient suppression of background light. This metamaterial was applied to carbon dioxide and butane detection designing to exhibit a resonance at 4033 cm^-1 and 2945cm^-1 which spectral overlap with the C-O and –CH vibration mode, respectively. The mutual coupling of these two resonant modes creates a Fano resonance, and their distinct peaks are clearly observed in the corresponding transmission dips. In addition, owing to its small footprint, v-MIM structure allows the detection of a 20 ppm concentration with suppressed background and high selectivity in the mid-infrared region.

SESSION EL12.03: Industrial Perspective on Metasurface

Large Scale Manufacturing Techniques for Metamaterials and Their Industrial Applications Ragip Pala; Meta Materials Inc., United States

Development of a scalable nanofabrication technique is essential for the practical realization of nanostructured materials in functional transparent films. META® has developed discrete platform-specific proprietary technologies for large-scale lithography, allowing the manufacture of nanostructures to be carried out with high uniformity and low cost. Using these manufacturing techniques at META®, we design and mass-produce nano-technology-based films with applications in a wide variety of products and markets.

In this talk, I will present large-scale manufacturing techniques at META® including nanoimprinting, roll-to-roll processing, and holographic lithography. I will also discuss various industrial applications in automotive, authentication, 5G communication and consumer electronics. Our customizable patented nano-optics include visual authentication technology, KolorOptik® Stripe, with a unique combination of multiple colors, 3D depth and omni-directional movement. I will describe NANOWEB®, META®’s Roll to roll lithographically fabricated conductor with superior electrical and optical properties. This functional film is configured as a nanostructured conformable metal wire mesh, that is transparent to the naked eye. I will explain how we utilize NANOWEB® to enable smart solutions for distinct functions including electro-optical dimming, transparent antennas, anti-fog heaters and EMI Shielding.

In addition, we are also using a first of its kind Plasma Fusion® deposition technology, which enables high speed coating of any alloy on any type of thin flexible plastic substrate. Large scale and efficient metallization coating of ultra-thin substrate with zero defect, is a critical step for example toward volume scale industrial manufacturing in a later stage. We have opted to focus on the use of optical lithography Nano Imprint Lithography and a 300 mm equipment platform.

9:00 AM *EL12.03.02
A Scalable Technology Platform for Creating Meta-Surface Based Optics and Waveguide Combiners for Augmented Reality Robert J. Visser, Ludovic Godet, Rutger Thijssen, Jinxin Fu, Rami Hourani, Sage Doshay and Guannan Chen; Applied Materials, United States

Optics is increasingly important in modern life, and advances in nanostructure-based flat optical devices hold great promise for revolutionary new opportunities in the display space. Augmented and Virtual Reality (AR/VR) are expected to enable the next ubiquitous computing and communication platform.[1] Augmented Reality, Optical metasurfaces also leverage engineered nanostructures to offer the possibility of extreme wavefront control, enabling further miniaturization of imaging and display optical systems and exciting new applications not achievable with conventional optics. [2,3] The Engineered Optics™ group at Applied Materials is enabling thinner, light-weight optical systems with precise wavefront engineering to make possible novel optical devices. We have leveraged Applied Materials’ materials engineering expertise to develop a platform for the precision fabrication of nanostructured optical devices on 300mm glass wafers, as well as metrology, optical performance characterization, and back-end assembly of these devices. With this platform, we are producing waveguide combiners for AR/VR applications and optical metasurfaces for multi-functional wavefront control in the near-infrared. An essential element in designing the process and making choices for equipment is scalability, laying the foundation for large scale industrial manufacturing in a later stage. We have focused to focus on the use of optical lithography Nano Imprint Lithography and a 300 mm equipment for all the etch and deposition steps. This leverages the entire experience and the availability of equipment from the Semiconductor Industry. Waveguide combiners are a key component in lightweight augmented reality headset or glasses systems, but are difficult to fabricate to the high precision required for simultaneous high optical image quality of the AR content and clear vision of the real world.[1] The Engineered Optics platform includes a fully integrated front-end process flow to make surface relief grating-based waveguide combiner devices for our customers. All our tools are customized to enable handling of transparent substrates of a variety of refractive indices and thicknesses. We produce binary and slanted nanostructures using UV or nanoimprint lithography and etch in high-quality, low-loss optical materials. We can process single- or double-sided devices with high alignment fidelity, and can create desired features with global and local-area processing techniques.

The Engineered Optics platform offers full end-to-end capabilities: after front-end fabrication on 300mm substrates, we optically characterize devices and perform critical backend integration. Waveguide combiner

Promising commercialization of high-performance sub-wavelength-pixel CMOS image sensors (CIS) has been the main driver of product innovation in CMOS image sensors (CIS) for many years, and now pixel sizes are approaching the sub-wavelength diffraction limit. While downsizing pixels enables higher pixel densities and smaller form factors, there is a trade-off between pixel miniaturization and signal-to-noise ratio (SNR). Consequently, the overall performance of CIS is adversely affected due to the reduction in light-receiving areas. To address these inherent physical limitations, alternative approaches involving efficient redistribution of incident light energy can be pursued through the integration of appropriately designed sub-wavelength scale photonic structures. Recent attempts to replace conventional color filters with metamaterials have been met with mixed success due to severe color crosstalk, poor angular response, complex or impractical fabrication processes, and additional color correction that resulted in lower-than-expected SNR gains.

In this work, we present a new approach to revolutionize current optical stack layers by incorporating sub-wavelength scale metaphotonic color-routing (MPCR) structures that can significantly improve the low-light performance of CMOS image sensors. Fabricated on a 1.12μm Dual pixel sensor and a 0.64μm Quad-pixel sensor, the MPCR structure separates the incident light energy into the respective color pixels, resulting in a notable increase in quantum efficiency of up to 20%. Our experimental demonstration confirmed a luminance SNR improvement of +1.0 dB under low light condition of 20 lux. Furthermore, this improvement was consistently achieved across different types of color pattern arrangements, further validating the versatility and effectiveness of our MPCR structures.

Metasurfaces: From Lab to Mass Markets

10:30 AM *EL12.03.04

Optical metasurfaces enable unprecedented control over all aspects of light (phase, wavelength, intensity, and polarization) with a single, planar semiconductor layer. Comprised of subwavelength nanostuctures, a single metasurface can carry out optical functions typically requiring four or more conventional refractive and/or diffractive optics, bringing new forms of sensing to mobile form factor for the first time. In addition to the expanded functionality they provide, they also open a route to the manufacture of optical devices in the semiconductor foundry, because they are constructed from CMOS-compatible materials on a planar substrate. This presentation will discuss metasurfaces from fundamental concepts to commercialization and will explore how the performance and large-scale manufacturing advantages of this technology will ultimately allow Metalenz to proliferate forms of sensing that have previously only been accessible in scientific or industrial laboratories.

SESSION EL12.05: Wavefront Shaping, Metalens and Applications

Circularly Polarized Photoluminescence from Chiral Metamaterials and Large Area Fabrication

1:30 PM *EL12.05.01

Chirality controls light polarization, leading to emerging applications ranging from 3D displays to anti-counterfeiting to sensing. In the first example, I will show patterns, light-emitting metasurface structures, combining plasmonic structures and patterned, photoluminescent quantum dots. I will show how strategically placing these nanocrystals results in highly tailored circularly polarized photoluminescence, which realize simultaneously high polarization control and photoluminescence intensity. The light-emitting meta-atoms, which consist of cross-linked nanocrystals, are fabricated using direct-write electron beam lithography, realizing lateral feature sizes as small as 30 nm and heights in excess of 100 nm without degradation of the photoluminescence.

I will then discuss an alternative strategy that uses additive manufacturing to create large-area metamaterials, and is roll-to-roll compatible. Finally, I will discuss the optical properties of chiral metamaterials formed by block co-polymer assembly and the effects of both the surface termination and bulk structure. I will show that it is possible to realize circular dichroism even in structures that are achiral in the bulk, due to the surface termination.

Nanoscale 3D Printing of Structural Colors and Micro Optics

2:00 PM *EL12.05.02

Structural colors are generated from nanoscale structures of various materials due either to interference or optical resonance effects. The ability to achieve a
highly resonant optical elements, attaining a high quality factor typically comes at the cost of limited spatial control over the wavefront. Here, we report on dielectric, higher-order Mie-resonant metasurfaces that break this paradigm by realizing high-numerical aperture wavefront manipulation with high-quality factors. Our structure consists of high-index dielectric nanoparticles exhibiting a spectrally overlapped dipole and electric octupole mode, which allows for local wavefront manipulation. By appropriately tailoring the nanoparticle dimensions over a range of 545–555 nm with a period of 736 nm, we imposed a paraboloidal phase profile at an interface to realize radial metasurfaces for operation at near-infrared wavelengths with linear TE or TM polarization. The structures were fabricated from an amorphous silicon thin film on a glass substrate by a single-step electron beam lithography and dry etching process. We have experimentally demonstrated dielectric metasurfaces with numerical apertures of up to 0.8 and quality factors of up to 880, in some cases with diffraction-limited performance. Our findings represent a significant advancement compared to previous approaches that have been limited to low numerical apertures or one-dimensional wavefront manipulation.

3:15 PM *EL12.05.04
Wide Field-Of-View Metasurface Optics—From Fundamentals to Applications Juejun Hu; Massachusetts Institute of Technology, United States

Wide field-of-view (FOV) is a much coveted feature in many optical systems with wide applications ranging from automotive sensing to biomedical imaging. In this talk, we will start by introducing our work formulating the analytical design frameworks for wide FOV metasurfaces with two distinctive and yet related configurations: imaging and projection optics. We will then proceed to discuss several device implementations guided by the analytically derived designs with applications spanning 3-D sensing, extended depth-of-field imaging, and full-color projection display.

3:45 PM EL12.05.05
Hybrid Metalens Platform for Nanoparticle Levitation and Control in Vacuum Mohamed S. Mohamed; ETH Zürich, Switzerland

Levitated nanoparticle systems have emerged as a promising approach for studying fundamental forces, investigating non-Gaussian quantum states, and probing material properties at the nanoscale. When operated under ultra-high vacuum (UHV), damping of nanoparticle mechanical motion is kept sufficiently low, reducing decoherence and sustaining a high-quality-factor mechanical oscillator which can be exploited for quantum-limited sensing.

One of the main challenges towards implementing nanoparticle levitation in vacuum is the required level of control over trapping potentials, feedback forces, and sources of noise. Control schemes should additionally satisfy vacuum-compatibility and stability requirements. A compact design implementation, especially in an integrated form factor, can further enable a wide range of experiments such as acceleration sensing in dynamic testing or quantum state manipulation in cryogenic systems.

Here, a hybrid chip-scale platform for trapping and control of dielectric nanoparticles in vacuum is presented. The platform features a primary optical trap generated through an optimized polarization-insensitive dielectric metalens which features focal length in the range of 50 – 200 µm and numerical aperture values of up to 0.98. Individual silicon meta-atoms are designed to provide complete 2π phase coverage in the near-infrared wavelength range, with average transmission values exceeding 90%. The near diffraction-limited performance of the metalens alleviates requirements on input power for stable optical trapping. The metalens is patterned in an epitaxial silicon-on-sapphire layer, which exhibits reduced optical losses in comparison to silicon layers prepared by alternative deposition methods. The sapphire substrate provides a broad transparency window for the incident trapping laser beam, while preventing heat build-up given its thermal properties.

The hybrid device design features metallic electrodes embedded within the metalens layer. A dual-ring electrode configuration serves to create a tunable-height Paul trap, where the trapping volume overlaps the focal spot of the optical metalens trap. This is to assist with the loading of nanoparticles into the device by virtue of the deep potential well of the Paul trap. Furthermore, the electrode layer comprises pads for nanoparticle feedback cooling by means of cold damping. The overall architecture can additionally accommodate customized static and dynamic electromagnetic potentials which can be readily applied to the trapped nanoparticle. The overall electrode design enables one to produce structured light from incoherent light sources, holographic color prints, and control of the light-field for 3D representation. We will discuss the use of structural colors combined with micro-optics for enhanced information content and optical security [2].

References
demonstrated with the device using femtogram SiO₂ nanoparticles, down to a pressure of 1 mbar. The collected forward scattering signal allowed for nanoparticle motion tracking using split detection.

The demonstrated platform provides a robust approach for chip-scale nanoparticle levitation and control, which opens the door to highly promising applications in both fundamental and applied science.

SESSION EL12.07: Poster Session
Session Chairs: Yongmin Liu and Junsuk Rho
Tuesday Afternoon, November 28, 2023

8:00 PM EL12.07.01
Stretchable Dielectric Metasurfaces with Electrical Control Hyunjun Kang, Joohoon Kim, Dongmin Jeon and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Metasurfaces are a type of structured surface composed of subwavelength-sized elements that can manipulate light at the nanoscale. Structural colors of metasurfaces are engineered by manipulating light to produce color without relying on dyes. They utilize microscopic or nanoscale structures to interact with light and selectively reflect or transmit certain wavelengths. By designing the size and shape of the sub-wavelength structures, metasurfaces can exhibit a wide color gamut, high color saturation, and even iridescence through precise control over the interaction of light. To improve the tunability, some techniques using phase-transition materials and active materials have been developed. In addition, a stretchable structural color via mechanical stretching has been reported. However, mechanical stretching is difficult to achieve precise and localized stretching. Also, mechanical stress can cause emergency structural damage, material fatigue and deformation. Here, we demonstrate electrically tunable structural color pixels with full-spectrum in the range from 450 to 650 nm. Electrical stretching allows for enhanced control and uniform/reversible deformation of the metasurfaces. By embedding a SiN metasurface in a polydimethylsiloxane (PDMS) substrate and stretching it in radial direction, the distinct reflection colors are tuned. As the period of the meta-atom increases from 310 nm to 450 nm, red-shift of the reflection spectrum is realized, covering from blue color to red color. In addition, since the intensity of light can be adjusted using a polarizer, it shows high-resolution images by adjusting the contrast. The reversible structural colors are promising in anti-counterfeiting, and strain-sensing applications.

8:00 PM EL12.07.02
Single-Step Manufacturing of UV Metasurface using ZrO₂ Nano-PER Joohoon Kim and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

UV light, essential in scientific and technological fields, has various applications ranging from spectroscopy and quantum optics to photolithography and biosensing. Traditional UV optics rely on large optical components, which offer limited functionality and versatility. In contrast, flat optics consisting of subwavelength optical scatter offer compact platforms for precise wavefront manipulation. They enable significant downsizing of optical components and provide diverse functionalities. Nonetheless, UV metasurfaces encounter persistent challenges such as the scarcity of UV materials with low-loss and high-index properties, exorbitant manufacturing costs, and low throughput associated with electron beam lithography [Adv. Mat. 30, 1802632, 2018]. Therefore, low-loss and high-index materials for UV metasurface have been actively studied in recent years: hafnium oxide [Light Sci. Appl. 9, 55, 2020], zinc oxide [Sci. Adv. 8, abn5644, 2022], silicon nitride [ACS Nano 16, 3546-3553, 2022], and niobium pentoxide [Lasersh. Photonics Rev. 13, 1800289, 2019]. However, fabrication processes of the aforementioned materials include not only electron beam lithography but also multi-step etching with a high aspect ratio or atomic layer deposition of a thick layer. In this manuscript, we fully address this long-standing challenge by introducing a zirconium dioxide (ZrO₂) nanoparticle-embedded resin (nano-PER) for a one-step printable platform for UV metasurface. The ZrO₂ nano-PER is synthesized by dispersing ZrO₂ nanoparticles in a UV-curable resin which makes nano-PER printable. Owing to the large bandgap and high refractive index of ZrO₂ nanoparticles, the ZrO₂ nano-PER has a high refractive index and low extinction coefficient over the broadband UV regime. Thus, a designed meta-atom has a conversion efficiency of 88% (λ=325 nm) and 81% (λ=248 nm), respectively. In this method, high-efficiency UV metasurface can be replicated repeatedly using a single step of nanoimprint lithography without any secondary processes, resulting in high throughput and low cost. This method will provide real opportunities for practical applications of UV metasurfaces.

8:00 PM EL12.07.03
Metasurface Selective Nanoimprint by Continuous Lithography with Laser-Induced Graphene on Metal Thin Film Timothy Yee Him Chan and Mitch Guijun Li; The Hong Kong University of Science and Technology, Hong Kong

Efficient and cost-effective fabrication of metasurfaces is crucial for their widespread application in thin film technologies such as optical modulation and chemical sensing. In this study, we propose a laser-based selective nanoimprint method that enables faster and more controlled fabrication of metasurfaces, facilitating the application of different molds onto the target surface with ease. Laser-induced graphene is deposited on a metal thin film, and it is placed on the flexible mold, then the metal thin film will be used to absorb the laser energy to provide pressure on the mold for nanoimprinting the mold pattern onto the target surface. The pressure from the laser source can be controlled precisely, and the target surface can be cured at the same time to stabilize the nanostructure imprinted. By pausing the laser irradiation during the curing process, the mold will return to its original position to create a pulling effect on the nanostructure, this can enhance the height of the nanostructure on the target surface to 2 times or more of the mold structure, from 2.54 µm of the original mold to 7.74 µm on the target surface. The presented approach offers a simple fabrication method with outstanding performance for the construction of selective metasurfaces. It utilizes laser-induced transfer techniques and laser-induced pressure to enable the efficient manufacturing of optical metasurfaces and other 2D-nanostructure-based applications. The demonstrated capabilities of this technique hold great promise for the advancement of metasurface technology and its integration into various thin film devices.

SESSION EL12.08: Tunable Metasurfaces

8:00 AM - EL12.08.01
Optical Metasurfaces for Dynamic Wavefront Control in the Visible Range Ramon Panagagua Dominguez, Institute of Materials Research and Engineering (A*STAR), Singapore

The ability to dynamically manipulate propagating light is critically important in various applications, from optical communications, precision manufacturing or adaptive optics, to metrology and displays. While Spatial Light Modulator technologies offering dynamic control of wavefronts have been around for a long time, they have faced severe difficulties in increasing the spatial precision at which this can be done. As an alternative platform to common liquid crystals or micromirror-based devices, optical metasurfaces have opened a possible pathway to achieve dynamic wavefront control with sub-wavelength spatial resolution by endowing resonant nanoantennas with different tuning mechanisms. In this talk, we will present some of our recent efforts in this regard, particularly in two of the mechanisms that we find most promising for visible light manipulation, namely interfacing nanoantennas with liquid crystals and using low-loss phase-change materials with and without memory.

8:30 AM - EL12.08.02
Dynamic Polarization Control across the Poincaré Sphere with Black Phosphorus Metasurfaces Samuel K. Seal, Souvik Biswas, Meir Grajower and Harry A. Atwater, California Institute of Technology, United States

Controlling polarization of light on-demand can unlock a multitude of applications in optical imaging, sensing, and computing. The electrically tunable crystalline anisotropy of black phosphorus (BP) holds promise for miniaturizing polarization modulators. Here, we report on plasmonic metasurfaces combined with van der Waals heterostructures incorporating twisted BP layers. This design builds on previous single BP layer Fabry-Pérot devices and increases the tuning range from linear trajectories to nearly half the area on the Poincaré sphere.

The proposed device leverages two independently electrically tunable BP layers that have their crystal axes orthogonally aligned, while careful design of the plasmonic nano-disks on top of the heterostructure allows critical coupling of light for enhanced dynamic range of polarization tuning. By incorporating boron-nitride spacer layers and capacitively gating the BP stacks against graphene gates within the heterostructure, we achieve the two degrees of freedom needed to tune polarization across the Poincaré sphere. We will discuss the effects of metasurface design and electronic doping on the Poincaré sphere, as well as highlight our efforts on the fabrication advances of the proposed device.

8:45 AM - EL12.08.03
Free-Space Electro-Optic Modulators using High Quality Factor Metasurfaces Sahil Dagli, Halleh Balch, Sajad Abdollahramezani, Hamish M. Carr Delgado, Varun Dohia, Jefferson Dixon, Elissa Klopfner, Jung-Hwan Song, Jack Hu, Babatunde Ogunlade and Jennifer A. Dionne; Stanford University, United States

Metasurfaces advance optical communications and imaging technologies through their highly miniaturized control of the amplitude, phase and polarization of light. Achieving active tunability within a compact footprint represents a step towards power-efficient, ultrafast data processing and computation. Here, we design, fabricate, and characterize high quality factor metasurfaces as an electro-optically tunable element for photonic devices. Our device uses a hybrid materials platform of silicon on lithium niobate, taking advantage of the high index and lossless properties of silicon and the electro-optic Pockels effect in lithium niobate. We design subwavelength (400 nm width) nanobars of 300 nm thick silicon atop a 300 nm lithium niobate thin film that are fabricated by well-established top-down lithography and wafer bonding techniques in 150x150 um metasurface devices. By introducing subtle geometric perturbations to each constituent nanobar, we enable leaky guided modes resonances coupled to normally-incident free-space light. These guided mode resonances enhance light matter interactions by exciting strongly localized optical fields in the lithium niobate, with mode quality factors exceeding 1000 in both theoretical and experimental demonstrations. Applying a voltage across individual nanoantennas shifts the spectral position of the high-Q resonances, modifying the amplitude of the scattered light from the antenna. We measure an electro-optic coefficient of 3 pm/V when switching the applied voltage between 0 and 20 V. To decrease the nanoantenna length required to generate high-Q resonances, we pattern the ends of the notched bar with photonic bandgap mirrors, enabling the lateral light recirculation of leaky guided waves without causing significant radiation leakage. This allows us to achieve compact (<15 um), high quality factor (>1000) resonator pixelated nanoelements. Our high-Q electro-optic devices provide a foundation for light-weight, reconfigurable, solid-state information processing.

Toward High-Endurance Nonvolatile Reconfigurable Metasurfaces Hyun Jung Kim1, Kiumars Aryana1, Scott Bartram1, Stephen Borg1, William Humphreys2, Cosmin-Constantin Popescu2, Tian Gu2, Juejun Hu1, Hyung Bin Bae1 and Taewoo Lee1; 1NASA LaRC, United States; 2Massachusetts Institute of Technology, United States; 1KAIST Analysis Center for Research Advancement, Korea (the Republic of)

The applications of adaptive optics extend across multiple sectors, encompassing areas such as LiDAR, biological and chemical sensing, and free-space optical communications. The advent of metasurfaces optics with reconfigurability has offered a versatile platform for the design of compact optical components, offering a compelling alternative to their conventional bulky counterparts. In this study, we introduce the PROWESS (Phase change Reconfigurable Optical Wavefront Synthesis System project at NASA LaRC), electrically reconfigurable metasurfaces using low-loss, high-contrast phase change material (PCM), Ge2Sb2Se5Te integrated with IR-transparent silicon microheater for various practical applications. The talk covers a reliable platform for switching large-scale PCM-based devices utilizing a microheater and an architecture for the metasurface switching within an integrated circuit configuration, which is compatible with standard foundry fabrication processes. The utilization of near- to midinfrared transparent silicon microheater in the proposed architecture opens possibilities for the development of reconfigurable transmissive optics such as filters, zoom lenses, and beam steering modules. We demonstrated switching of 140 µm × 140 µm PCM pixel, on a 200 µm × 200 µm silicon microheater for several thousand cycles. Further, we performed an in-depth investigation into the failure mechanism utilizing techniques such as transmission electron microscopy and thermal modeling. Guidelines for device performance improvement are proposed, and an improved design with larger endurance is shown with progress. With further progress, we aim to unlock the full potential of PCM-based devices and advance the field of adaptive optics with demonstrable examples including a reconfigurable beam steerer for ocean surface flash LiDAR and Navigation Doppler LiDAR for precise lunar landing missions.

9:45 AM - EL12.08.06
Toward Accurate Thermal Modeling of Phase Change Material Based Photonic Devices Kiumars Aryana1, Hyun Jung Kim1, Cosmin-Constantin Popescu2, Steven Vitale2, Hyung Bin Bae1, Taewoo Lee1, Tian Gu2 and Juejun Hu1; 1NASA Langley, United States; 2Massachusetts Institute of Technology, United States; 1Lincoln Laboratory, United States; 2Korea Advanced Institute of Science and Technology, United States
Reconfigurable or programmable photonic devices are rapidly growing and have become an integral part of many optical systems. The ability to selectively manipulate electromagnetic waves through electrical stimuli is crucial to advancements of a variety of applications from computing devices to environmental science and space explorations. Chalcogenide-based phase change materials (PCMs) are one of the most promising material candidates for reconfigurable photonics due to their large optical contrast between their different solid-state structural phases. While significant efforts have been devoted to accurately simulating PCM-based devices, there are important aspects that have not been captured in prior models. In this study, we will highlight three key parameters that strongly influence the thermal and phase transition behavior in PCM-based devices: the enthalpy of fusion, the heat capacity change upon glass transition, as well as the thermal conductivity of liquid-phase PCMs. The PCMs studied here for examining the amorphization process are Ge$_2$Sb$_2$Se$_4$Te and Ge$_2$Sb$_2$Te$_5$ with areal size on the order of 140 µm × 140 µm. We further investigated the important topic of switching energy scaling in PCM devices, which also helps explain why the three above-mentioned effects have long been overlooked in electronic PCM memories but only become important in photonics. Our findings offer insight to facilitate accurate modeling of PCM-based photonic devices and can inform the development of more efficient reconfigurable optics.

10:00 AM EL12.08.07
**Embeddable and Steerable Metasurfaces for Active Control of Light Steering**
Seung Yeol Lee, Yujie Luo and Ognjen Ilic; University of Minnesota Twin Cities, United States

Photonic surfaces, such as metasurfaces and metagratings, offer precise control of optical properties such as wavelength, intensity, and polarization, with a crucial role in efficiently focusing and directing light for various applications, ranging from imaging and communication to LiDAR and display technologies. However, typical platforms for metasurface steering and focusing are static and macroscopic, which limits their ability for adaptive control and embedding. To overcome these challenges, we propose a novel design for a microscale magneto-photonics metasurface capable of actively delivering light with high efficiency to a specific location through remote manipulation of its translational or rotational motion using an external magnetic field. This composite particle consists of a tailored surface photonic interface integrated with a magnetic core. To enable effective beam steering during rotation, the photonic surface incorporates metagrating patterns designed to achieve high efficiencies (~90%) for both TM and TE polarizations. The magnetic core, incorporated through a lift-off method, consists of an anisotropic cobalt layer that facilitates programmable collective translational and rotational motion. We describe a control mechanism for positioning and orienting such metasurfaces to deliver light to the targeted spot. We present modeling and experimental data to demonstrate active light steering, and we discuss the tradeoffs associated with scaling the size of this magneto-photonic metasurface. The proposed approach offers a particle-based platform that enables high-fidelity light delivery within the biological transparency window, presenting promising potential for biophotonic applications.

10:15 AM EL12.08.08
**Creation of Frequency Selective Absorbing (FSA) Metasurfaces using 2D Transition Metal Dichalcogenides (TMD)**
Swarnaa Datar, Bisshakha Ray and Siyad Rahim; Defence Institute of Advanced Technology (DIAT), India

Combining 2D materials and metasurfaces is a promising field of research with exotic outcomes like entangled quantum sources, enhanced non-linear effects and application in many interdisciplinary fields. 2D transition metal-dichalcogenides (TMDs) which are semiconductor materials of the type MX$_2$, where M is a transition metal atom (like Ni, Fe, or Co) and X is a chalcogen atom (such as S or Se) are emerging class of materials which have excellent properties like atomic scale thickness, strong spin-orbit coupling, ability to form 2D nanosheets, direct band gap and many other mechanical and electronic properties. These properties make 2D materials lucrative as frequency selective absorbers (FSBs) because of strong electronic polarization and enhanced dielectric loss. By changing M in MX$_2$ one can achieve tunable microwave metadevices. In the present work we have developed inks made of 2-D TMDs. Research on hybrid materials like Fe doped MoS$_2$, doped MoS$_2$-rGO composite, Mo$_2$S$_2$Co$_2$ hybrids, among several others suggests that these materials have high reflection loss. Further, magnetic transition metal dichalcogenides such as NiSe$_2$, CoSe$_2$ and their heterostructures, expediate multiple reflections and scattering of the incident wave, thereby elongating the course of transmission of the incident microwave. This increases dissipation efficiency, along with large specific surface area, which caters to EM absorption. In the present work inks have been developed based on these materials to make them versatile for several applications. Metasurfaces using these paints have tunability of material properties like permeability and permittivity by changing meta structure thickness and dimension allowing to manipulate the course of the electric and magnetic resonance at different frequencies independently, therefore, frequency selective structures can be made. Furthermore, in the present work, the structures have been made using 2D TMD whose conductivity has peaks depending on the percolation threshold at a given frequency for a particular concentration of the 2D structure in the paint. The analysis of the absorption by structures made of such composites is complex. Interestingly, it has been observed that unlike the meta structures created by metals where the absorption band and frequency, solely depend on the structures made, here they seem to also depend on the composition of 2D TMD which is encouraging. This provides an additional method to modulate the properties of FSA. The results are discussed to understand the role of 2D TBM in metadevice fabrication.
To address the challenge of this weak modulation, a new class of silicon nanoantennas supporting high-Q dipolar guided mode resonances (DGMR) has been reported. By subtly breaking translational symmetry, DGMR nanoantennas are guided mode standing waves that can leak into free space and result in high-Q resonances with dipole radiation patterns perpendicular to the antenna. This makes them the ideal element for the efficient modulation of light scattering. While many interesting transfer functions have been explored using this scheme, universal wavefront shaping has yet to be experimentally demonstrated.

Here, we present a universal meta-reflect-array platform made from only high-Q DGMR nanoantennas acting as independent extremely sensitive pixels, enabling strong responses to weak structural tuning. When post-processed to incorporate a reflective ground plane, changes of <2.6% volume fraction across the array are found to facilitate efficient beam steering. To demonstrate that these devices are acting as phase gradient optics and not gratings, we realize beam steering to angles 32.3°, 25.3°, and 20.9°. To apply this concept to dynamic wave-shaping, we replace the structural perturbations with electro-thermal biasing. Although the thermo-optic coefficient of silicon is only 1.8x10⁻⁵ K⁻¹, the extreme sensitivity of DGMRs with high-Q of 2088 can be red-shifted efficiently with minimal temperature change. We exploit the temperature sensitivity by realizing a prototypical electrically programmable multi-element transmissive amplitude display consisting of a structurally uniform Si high-Q meta-reflect array with Ni resistive heating elements encapsulated above silica. With the second Au circuit patterned above, three distinct groups of Ni wires are separated and connected into three Au pads. Applying individual bias voltages to the conducting pads using an SMU, we can tune the intensity transmitted by each high-Q pixel. We have measured the electrically tunable transmission pattern resulting from different voltage distributions using an imaging spectrometer. This compact and efficient dynamic wave shaping prototype with programmable capability can be extended in the future to quicker mechanisms such as carrier injection and the Pockels effect with higher tuning speed, shedding light on high resolution modern flat display technologies and LiDAR beam-steering.

1:45 PM EL12.10.02
Eliminating Nearfield Coupling in Dense High-Quality-Factor Phase Gradient Metasurfaces Samuel Ameyaw, Lin Lin and Mark Lawrence; Washington University in St. Louis, United States

Recent developments in optical technologies call for precise wavefront manipulation and miniaturized and lightweight optical components. Phase gradient metasurfaces, have over the years proven to be a strong candidate for the realization of novel technologies especially in AR, VR, and LiDAR applications. Resonance is a key property of the nanostructured building blocks of a phase gradient metasurface. Boosting the light matter interaction over subwavelength volumes allows many nanoscale objects to be combined to impose smooth spatially varying phase profiles on incident light waves. A crucial metric by which to evaluate the performance of phase gradient metasurfaces is resolution, as it directly influences the accuracy achievable in wavefront shaping as well as the angular field of view. The resolution of phase gradient metasurfaces is predominantly limited by nearfield coupling between neighboring meta-atoms, preventing them from scattering light independently and generating crosstalk. The fact that the impact of coupling scales with Q typically forces a tradeoff between resolution and Q-factor. Coupling can be reduced by shrinking the evanescent decay lengths of the individual modes, thereby reducing the mode overlap. However, there will still be a Q for which the remaining coupling is a problem. Here we show that extremely dense silicon metasurfaces supporting dipolar guided mode resonances can be engineered to entirely suppress near-field coupling for arbitrarily high Q. We reveal a zero-coupling regime occurs when nanoantennas are separated by anisotropic nanofins. Rather than decreasing the field overlap, the fins enhance the longitudinal electric field, allowing it to interfere with the transverse electric field. For a specific nanoantenna width and efficient diffusion, we demonstrate that the interference is perfect, effectively decoupling the high Q dipolar-guided mode resonators in proximity, enabling deep resolution and efficient diffraction.

To demonstrate the power of this new platform, we show how decoupled DGMR metasurfaces, backed by a mirror, can efficiently shape reflected diffraction when independent adjustments are applied to the refractive indices of each nanoantenna. Varying the refractive index of the outer pixels of a three pixel metasurface by only 1.7x10⁻⁵, we achieve steering to the +1st diffraction order with an efficiency of 85%. The tiny index modulation needed is a direct consequence of the giant Q of 192,474. Having a pixel pitch of λ/1.6, the steering also occurs at a large angle of 32°. In beamsplitting we achieve diffraction efficiency of 99% with Q greater than 257,000 and an angle of 1.8x10⁻⁴. Importantly, we believe the Q can be much higher, but such structures become increasingly difficult to model. By increasing the thickness of the silicon film to 383nm, the decoupled regime can even be found with sub-diffraction resolution, pixel pitch=3.2/2.2.

In this case, beamsteering of incident light is achieved to the +1st diffraction order at an angle of 47° with an efficiency of 85%. As the elements in this device have a Q of 68,797, the refractive index bias was only 1x10⁻⁴. Another symptom of nearfield coupling is angular dispersion. With the decoupled nanoantennas, we have been able to achieve angle independence such that the resonant shift of a DGMR with Q≈45k stays below the FWHM for an angle of incidence from -45° to 45°. Our platform provides a route for dense high Q metasurfaces with independent addressability of the constituent meta-atoms paving the way for highly efficient nonlinear and dynamic wavefront shaping.

Magneto-Optic Control of Brewster Quasi Bound States in the Continuum Antonio Garcia-Martín; Instituto de Micro y Nanotecología, CSIC, Spain

Bound states in the continuum (BICs) emerge throughout Physics as leaky/resonant modes that remain, however, highly localized[1]. They have attracted much attention in Photonics, and especially in metasurfaces[2,3]. One of their most outstanding features is their divergent Q-factors, indeed arbitrarily large upon approaching the BIC condition (quasi-BICs) [4,5]. Here we investigate how to tune quasi-BICs in magneto-optic (MO) all-dielectric metasurfaces. The impact of the applied magnetic field in the BIC parameter space is revealed for a metasurface consisting of Si spheres with MO response. Through our coupled electric/magnetic dipole formulation, the MO activity is found to manifest itself through the interference of the (MO-induced) out-of-plane electric/magnetic dipole resonances with the in-plane magnetic/electric (directly induced) dipole, leading to a rich, magnetically-tuned quasi-BIC phenomenology, resembling the behavior of Brewster quasi-BICs for tilted vertical-dipole resonant metasurfaces. Such resemblance underlies our proposed design for a fast MO switch of a Brewster quasi-BIC by simply reversing the driving magnetic field. This MO-active BIC behavior is further confirmed in the optical regime for a realistic YIG nanodisk metasurface through numerical calculations. Our results present various mechanisms to magneto-optimally manipulate BICs and quasi-BICs, which could be exploited throughout the electromagnetic spectrum with applications in lasing, filtering, and sensing [6].

A two-phase nanocomposite design that combines ferromagnetic CoFe₂ nanosheets within the plasmonic TiN matrix. The resulting hybrid metamaterials in vertically aligned nanocomposites (VANs) form with anisotropic properties and magneto-optical coupling effects. First, we present lacks control over crystallinity, introduces surface roughness due to etching, is expensive and time-consuming, making it unfavorable for large-scale synthesis approach to fabricate spiky AuNP arrays in ordered arrays with tunable nanofeatures. We will discuss advances in nanofabrication techniques that enable the patterning of AuNP seeds with designed shape and size. We will describe how different growth conditions can lead to the formation of different nanofeatures on the seeds, resulting in different LSP resonances. Finally, we will discuss the prospects of using spiky AuNP arrays for surface-enhanced Raman spectroscopy (SERS).

Metamaterials—arrays of subwavelength nanoantennas that control the phase, amplitude, and polarization of light—are a promising platform for novel and compact optical technologies and communication. However, dynamic control of metamaterials remains challenging due to weak light-matter interactions and in compact, nanoscale devices. Here, we design and characterize a dynamically-tunable metamaterial, with a high-quality-factor (high-Q) resonance working as both the basis of the lensing behavior and means for efficient modulation with thermal or electrical biasing. Our high-Q lens is constructed via a zone plate architecture consisting of alternating regions with and without resonant character. Both regions consist of 500 nm tall and 320 nm wide silicon nanobars atop a sapphire substrate. Nanobars in non-resonant regions are highly reflective, while nanobars in resonant regions are highly transmissive on resonance due to the inclusion of periodic perturbations, which enable a guided mode resonance with measured Q-factors up to ~1350. By leveraging the thermo-optic effect of silicon, we dynamically control the spectral position of the high-Q resonance to achieve wavelength selectivity of the focusing behavior. Due to the sharp spectral linewidth and amplitude variation of the high-Q resonance, thermal tuning can further result in metamaterial switching, where the lensing behavior is changed between on and off states in response to thermal stimuli. For a device utilizing only moderate Q-factors of ~350, the resonance's FWHM can be shifted with temperature changes of only 50 °C, and the device can be fully switched off when operating at 100 °C. These experiments provide a foundation for dynamic control of a local high-Q wavefront shaping metamaterial. Next, to overcome the low switching speeds of thermal tunability, we simulate and fabricate silicon metamaterials with a silicon nitride straining layer, which breaks the inversion symmetry of the silicon crystal, enabling a non-zero electro-optic coefficient. The stress imparted by the silicon nitride layer can be tuned by varying the deposition conditions to maximize the induced electro-optic effect in silicon. Simulations show a tunability in the resonant wavelength of ~44 pm per applied volt in a vertical bias configuration for an induced second order susceptibility of 40 pm/V, which can be achieved with moderate film strains. For resonances with quality factors ~7,000 in simulation, it is thus possible to switch the device from highly reflective to highly transmissive with low voltages ~15 V due to the narrow linewidth of the resonance. These devices provide a CMOS compatible platform for lightweight, compact, and reconfigurable solid state information processing.

SESSION EL12.11: Bottom-up Fabrication
Session Chairs: Junsk Rho and Shuang Zhang
Thursday Morning, November 30, 2023
Hynes, Level 3, Room 305
fabrication. Conversely, the latter is typically straightforward, affordable, and has better control over atomic composition and crystallinity. However, it struggles to fabricate complex nanopatterns due to thermodynamic constraints. This has been partially circumvented with directed assembly strategies, which consist of colloidal nanoparticles in PDMS templates replicated from a nanofabricated master. However, the nanopattern geometry that could be achieved effectively is still strongly limited to individual particles or low-density 1D arrays, whereas precise and deterministic arrangement of nanostructures in complex and arbitrary nanostructures (needed for nanophotonics and plasmonics applications) have so far remained elusive.

Here, we offer a new approach to obtain arbitrarily complex nanostucture arrays with a single nanoparticle solution with no need for advanced equipment. Nanoparticles are first deposited at the air/water interface in a compact film and then transferred into a nanopatterned template. This highly versatile technique is independent from the specific nanoparticle and can apply to a plethora of materials and shapes. We will show assembly of various materials (Ag, Au, Au-CuO core-shell nanoparticles and nanocubes) into various complex nanopatterns, such as U-shapes, L-shapes, cross-shapes, T-shapes, dodecagonal, and also split-ring resonators on PDMS, that cannot be obtained with conventional assembly techniques. Among other nanoparticle shapes, we focus on nanocubes because they are ideal building blocks for obtaining monocrystalline metalenses. We will show that such assemblies, in which each nanocube unit is precisely assembled as a Lego brick in complex extended arbitrary motifs, can subsequently be transferred into continuous nanostructures via nanocube epitaxy and then transfer-printed to various substrates, including flat and microstructured substrates. Finally, we will show optical characterizations and simulations of the metasurfaces obtained. This strategy potentially offers an alternative to a bottom-up fabrication for metal nanostructuring, which can then be applied to optoelectronic applications.

10:30 AM EL12.11.05
Meta-Structure IR Absorber Applied Microbolometer for Perfect Absorptance and Responsivity Improvement Jeongseun Mo1,2, Dasom Wang1, Ji-Hun Kang3, Jeong Min Baik2 and Won Jun Choi1; 1 Korea Institute of Science and Technology, Korea (the Republic of); 2 Sungkyunkwan University, Korea (the Republic of); 3 Kongju National University, Korea (the Republic of)

In recent years, the demand for high-performance infrared image sensors has increased significantly in various fields, including medical imaging, and Advanced Driving Assistance Systems (ADAS). Microbolometers, which are cooler-free infrared image sensors, have gained popularity due to their affordability and convenience. However, to enhance the performance of microbolometers, it is crucial to achieve high responsivity and detectivity. Effective infrared (IR) absorption is essential for microbolometers to efficiently transfer heat to the thermistor layer and achieve high responsivity ($R_v = \frac{α}{G(1 + ω^2τ^2)^2}$). To address this requirement, we applied a meta-structured IR absorber to enhance the IR absorptance of microbolometers. In this study, we employed an alternating metal-dielectric multilayer films with different refractive index as the IR absorbing medium. A periodic circular structure is introduced to multilayer films for higher absorptance. This structure has been designed to decrease total volume of IR absorbing medium in order to get lower thermal mass so that heat can easily transfer to the thermistor layer. FDTD simulation is conducted to compare the dependence of different sizes of periodic circles and intervals on absorptance of meta-structured multilayered absorber. This result revealed significant improvement in the absorptance of incident light in LWIR region (8-14um), which is commonly used for object detection. For experimental demonstration, IR absorber is deposited by electron beam evaporator based on reported previous research. The experimental results confirmed that the meta-structured IR absorber exhibited higher absorptance compared to the non-meta-structured counterpart. Consequently, we expect that the application of meta-structured IR absorber to microbolometers will facilitate the temperature increase of the thermistor material, leading to a notable improvement in responsivity. In conclusion, the presented research will give an idea of increasing responsivity of microbolometer with drawing up absorptance of IR absorber with meta-structure.

10:45 AM EL12.11.06
Wafer-Scale Manufacturing of Centimeter-Sized Metasurfaces Down to the Deep-Ultraviolet Region Joohoon Kim and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

UV optics play a vital role in both science and technology, from spectroscopy and quantum optics to photolithography and biosensing. Conventional UV optics are primarily based on bulky optical components and have limited functionality and diversity. As an alternative, metasurfaces can provide fine wavefront-shaping platforms with a compact form-factor, resulting in drastic miniaturization of the device and capability of diverse functionality. However, metasurfaces operating in the UV regime face long-standing challenges, such as the scarcity of low-loss and high-index UV materials and patterning limitations (small patterning area, high cost, and low throughput). Recently, UV-transparent materials such as zinc oxide [Sci. Adv. 8, 8, 296444, 2022], silicon nitride [ACS Nano 16, 3546-3553, 2022], and hafnium oxide [Light Sci. Appl. 9, 55, 2020] have been actively studied; however, the fabrication process of these materials is not scalable or easy to manufacture because they include e-beam lithography and multi-step etching with thick layer deposition. Recently, our group developed a scalable manufacturing platform that can produce visible metasurfaces on the wafer scale [Nat. Mater. 22, 474-481 (2023)]. However, a UV-transparent material compatible with our scalable method and patterning resolution remains a challenge for scalable manufacturing of UV metasurfaces. In this work, we fully address this long-standing challenge and mass-produce centimeter-scale UV metalenses by introducing a zirconium dioxide ($\text{ZrO}_2$)-polymer hybrid material and high-resolution ArF photolithography. We find that $\text{ZrO}_2$ has both a high refractive index and low absorption in the UV regime, and is compatible with our scalable method using atomic layer deposition (ALD). Using scalable and easily manufactureable $\text{ZrO}_2$-polymer hybrid material, we succeed in mass-producing centimeter-scale UV metalens for the first time. Owing to the high repeatability of nanoimprint lithography, our method can fabricate wafer-scale UV metalenses at extremely low cost and high throughput. Notably, thin-film coatings in hybrid materials enable strong light confinement, resulting in high efficiency of fabricated metalenses. The proposed method fully addresses the long-standing challenges in the field of UV metasurfaces and presents a practical possibility for the first time that UV metasurfaces can be applied in real life.
Crossing the real axis. This basic understanding helps us engineering electromagnetic fields at interfaces, including, but not limited to, metasurfaces.

Overcoming Optical Losses of Superlenses with Synthetic Waves of Complex Frequency Shuang Zhang; University of Hong Kong, Hong Kong

In conventional optical imaging, Abbe diffraction limits the resolution of feature sizes to larger than half the wavelength. This limit is due to the loss of the subwavelength information carried by evanescent waves. To overcome this limitation, a negative refractive index lens has been proposed to enhance the evanescent waves to recover the deep-subwavelength resolution of imaging. Subsequently, superlenses, made of either natural materials with negative permittivities, or hyperbolic materials with mixed signs of dielectric constants along different directions, have been proposed to attain sub-diffractional limited imaging. Nevertheless, losses are non-negligible in materials with negative parameters, which reduces the deep-subwavelength information of the superlenses and seriously affects the resolution of imaging. To compensate the losses, it has been proposed that gain materials could be incorporated into metamaterial designs or plasmonics, but the setup is extremely complicated and the gain will inevitably introduce instability and noise into the system. Recently, complex-frequency waves with temporally growing or attenuating behaviors have been treated as virtual absorption or gain waves. Some theoretical proposals have been put forward to recover the deep-subwavelength information carried by surface plasmons via excitation of complex-frequency waves (CFW) with temporal attenuation. However, synthesizing CFW is challenging in optical systems from a practical perspective.

To address this challenge, we synthesize CFW signals using a multi-frequency approach. We exploit the fact that a truncated CFW can be expressed as a combination of multiple frequency components with coefficients following a Lorentzian spectral lineshape through the Fourier transformation. We perform measurements at multiple real frequencies and numerically synthesize the field distribution under CFW illumination by combining the measured field plots at different frequencies according to the Lorentzian lineshape. As a proof of the concept, both a SiC slab operating at optical frequencies and a bulk hyperbolic metamaterial operating at microwave frequencies are used as superlenses. We show that, while the spatial resolution of imaging at real frequencies is poor, caused by the inevitable material loss in these systems, an ultra-high resolution imaging can be obtained with the synthesized CFW consisting of multiple frequency components. Our approach successfully overcomes the challenges of experimentally implementing CFW in the time domain, which include the need for precise CFW synthesis and time-gated measurements after reaching the quasi-steady state, and holds great potential for
high-resolution microscopy. Furthermore, the synthesized complex-frequency approach can be extended to other areas of optics, such as plasmonic sensing applications. By leveraging the enhanced quality factor of plasmonic structures, our approach has the potential to significantly improve sensitivity in sensing applications. In addition, the approach can be tailored to different systems and geometries, providing a flexible and versatile tool for improving optical performance.

Disordered Optical Metasurfaces to Create New Visual Effects Philippe Lalanne; CNRS, France

The visual appearance of flat surfaces and curved objects is paramount in life and technology for fine and applied arts. The ERC project UNSEEN aims at creating metasurfaces that offer new visual appearances, unseen in nature so far. The metasurfaces are composed of disordered monolayers of high-index resonant nanoparticles, either deposited from a colloidal solution on solid support or fabricated with ebeam lithography.

We have developed two models to predict the scattering properties of disordered metasurfaces. They allow us to predict design the scattering properties for all wavelength and incident angles. We have validated the models by testing them with experimental data, we have also been able to design a metasurface that generate only two distinct colors (green and violet) under all incidence and viewing angles, a quite strange phenomenon if we consider that usual iridescence provides a continuous variation of color as the incident and viewing angles changes (think to a thin film). For more details on the topic, please refer to K. Vynck et al., Nat. Mater. 21, 1035–41 (2022).

Analysis of the Effect of Material Choice on the Performance of Metasurfaces Junkyong Park, Younghwan Yang, Hyunjung Kang and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

A metasurface is a thin layer that operates at a scale smaller than the wavelength of light. It controls light by using meta-atoms, which are small structures arranged in a specific pattern. These meta-atoms are typically made of plasmonic or dielectric nanomaterials and have the ability to change the properties of light, such as its phase, amplitude, and polarization. As a result, metasurfaces find applications in various fields, including advanced displays, lenses, and sensors in the next generation. Particularly, due to their low optical losses, broadband operation, and compatibility with complementary technologies, dielectric metasurfaces are a promising platform for various photonic applications. Generally, dielectric materials with high refractive indices and low optical losses are favored for the development of highly efficient metasurfaces, which enable the creation of wide-angle beam steering and near-unity noncritical aperture metalenses. Despite the intuitive choice of such materials, the relationship between material properties and metasurface performance remains unclear. In this presentation, we aim to determine the correlation between the refractive index and the performance of metasurfaces. Specifically, we investigate metalenses operating within the visible spectrum and evaluate their efficiency and full width at half maximum (FWHM). By examining these parameters, we aim to gain quantitative insights into how the refractive index influences the effectiveness of metasurfaces in manipulating light in the visible regime.

Algorithmic Optimization of Disordered Plasmonic Metasurfaces using Far-Field Wavefront Shaping Gautier Roubaud1, Sylvain Gigan2, Samuel Grésillon3 and Sébastien Bidauld4; 1ESPCI Paris, France; 2Sorbonne Université, France

Plasmonic metasurfaces have broad applications in wavefront control, surface-enhanced spectroscopy or sensing. However, deterministic nanostructures do not allow an active tuning of these optical properties. By comparison, wavefront shaping techniques in disordered media have shown tremendous flexibility in actively modulating the propagation and focusing of light in space and time. We demonstrate here that delocalized modes in disordered plasmonic metasurfaces can be controlled using far-field wavefront shaping and algorithmic optimization schemes in order to locally modulate their optical responses. By controlling the phase of an incoming femtosecond pulsed laser on a disordered gold metasurface, we optimize the two-photon induced luminescence (TPL) at a chosen position with a typical two-order of magnitude enhancement, indicating a far-field optimization of the optical near-field. The optimization process is performed using a random genetic algorithm and provides the highest enhancement when the metasurface features the highest degree of morphological complexity, close to the percolation threshold (Nano Lett. 20, 3291 (2020)).
Far-field wavefront shaping also provides new degrees of freedom to provide statistical imaging schemes that offset the structural complexity of disordered nanophotonic systems. For instance, using nonlinear luminescence images measured with randomly wavefront-shaped femtosecond excitations, we can independently map the localized and delocalized plasmonic modes on a disordered gold metasurface (ACS Photonics 8, 1973 (2021)).
Manipulating the State of Polarizations at the Nanoscale using a Nonlocal Metasurface

10:45 AM

at a bandwidth less than 10 nm by judiciously arranging the nano-units to induce chirality without the need for precise fabrication of nano-chiral geometry.

We transmitted light using a GMR-based nonlocal metasurface to achieve near-perfect flat-top transmission spectra in simulation and efficiency over 0.8 in effectivly control the polarization state of incident light at a relatively narrow spectral range. We first demonstrate the conversion of polarizations in approaches, thus illustrating the usefulness of the impedance sheet-based simulations method to obtain the metasurface far-field profile.

The surface impedance. This allows for a fast-initial simulation of the metasurface beamsplitter before unit cell simulations. Both approaches are compared splitting phenomena as an initial step in the design process. This technique involves casting the spatially dependent complex reflection coefficients to full-wave, unit cell 3D FEM numerical simulations using realistic material parameters. An excellent agreement can be shown between all three approaches, thus illustrating the usefulness of the impedance sheet-based simulations method to obtain the metasurface far-field profile.

Generation of Arbitrarily Directed Out-Of-Plane Split Beams with Reflective Metasurfaces Brian M. Wells, Joseph F. Tripp and Richard J. Williams; University of Hartford, United States

Metasurfaces, the planar equivalent of metamaterials, have recently gained significant attention due to their physically compact nature, versatility, and ultrathin thickness in the wave propagation direction, significantly suppressing undesirable losses and exotic electromagnetic properties in manipulating propagating waves. In recent years, metasurfaces have been applied to anomalous reflection and refraction, perfect absorption, flat lensing, wave plates, and cloaking. In this work, we present an out-of-plane beam-splitter reflector metasurface design that is not confined to the gradient metasurface paradigm and, as such, is not restricted to beam-splitting into diffraction orders. Instead, we can generate metasurface beam-splitters with arbitrary split beam directionality, including combined in-plane and out-of-plane splitting, such that one of the split beams remains in the plane of incidence while the other split beam is generated outside the plane of incidence.

A reflective metasurface exhibiting simultaneous in-plane and out-of-plane beam-splitting was designed using an approach based on the Fourier transform method of array synthesis. This method involves supplying the desired far-field scattering pattern of the metasurface, in this case, a far-field pattern with two main beams scattering in different planes, and then performing the inverse discrete Fourier transform on this far-field pattern to determine the spatially dependent reflection properties of the metasurface. To validate the approach, an impedance sheet-based simulation is performed to verify the desired beam-splitting phenomena as an initial step in the design process. This technique involves casting the spatially dependent complex reflection coefficients calculated from the Fourier transform method into a spatially dependent surface impedance. The metasurface is then simulated as a 2D plane, defined by the surface impedance. This allows for a fast-initial simulation of the metasurface beamsplitter before unit cell simulations. Both approaches are compared to full-wave, unit cell 3D FEM numerical simulations using realistic material parameters. An excellent agreement can be shown between all three approaches.

Manipulating the State of Polarizations at the Nanoscale using a Nonlocal Metasurface Soo Jin Kim; Korea University, Korea (the Republic of)

Recent development of chiral metasurfaces attracts significant attention from researchers due to their unique abilities to manipulate the spin state of light at the nano-scale. Such functionalities can have potential applications in diverse fields, including quantum communications, biosensing, CD spectroscopy, and nano-scaled imaging. However, despite the progress in developing efficient and compact configurations, there still remain challenges in realizing an effective metasurface with strong circular dichroism (CD) and a spectrally narrow bandwidth of response for the potential applications of spectropolarimetrics.

In this presentation, I will show the nonlocal metasurfaces with a high-Q resonance and how such metasurfaces can be tailored to have the capability to effectively control the polarization state of incident light at a relatively narrow spectral range. We first demonstrate the conversion of polarizations in transmitted light using a GMR-based nonlocal metasurface to achieve near-perfect flat-top transmission spectra in simulation and efficiency over 0.8 in experiments using a method of electro-optic-based wavelength-scanning laser at a narrow spectral bandwidth. Following this, we also focus on the detection of the state of polarization using an ultrathin chiral metasurface by inducing collective chiral resonances in the constituent nanostructures. We design and show the selective transmission of the spin state of light using a nonlocal chiral metasurface, which experimentally features a CD value over 0.8 at a bandwidth less than 10 nm by judiciously arranging the nano-units to induce chirality without the need for precise fabrication of nano-chiral geometry. We further demonstrate that the minimally perturbed geometries of nano-units can efficiently detect the full Stokes parameters by directly tracking the azimuthal and ellipticity paths of the Poincare sphere at a spectrally narrow bandwidth. We believe that the proposed approaches could pave an alternative pathway to realize efficient nonlocal metasurfaces for dивers, nano-scaled polarimetric applications.

Scalable Classical and Quantum Photonics Giovanni Scuri; Stanford University, United States

Novel computational techniques such as photonics inverse design, along with new nanofabrication approaches, play a crucial role in building scalable integrated classical and quantum photonics. Inverse design, a departure from the traditional photonics design approach, can lead to photonics much better than state of the art in many metrics (smaller, more efficient, more robust, a much higher density of integration). This is enabled by development of a computer software which efficiently searches through the space of all possible and fabricable photonic geometries, in any material of interest. On the other hand, future photonic systems also require integration and fabrication of traditional and non-traditional photonic materials, including silicon, silicon-

Water-Soluble Smart-Labeling Platform using Nanoimprint Lithography Hyun jung Kang, Joohon Kim, Hongyoun Kim and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

The food packaging industry is increasingly focusing on sustainability and origin security. Biodegradable plastics and traceability systems like QR codes have been developed to address these concerns. However, there are challenges in ensuring sustainability and traceability. Biodegradable plastics have drawbacks such as specific conditions for degradation, greenhouse gas emissions, higher costs, and recycling difficulties. To overcome these challenges, a new sustainable and anti-counterfeit labeling platform is necessary. Also, traditional coloration methods using dyes and pigments have limitations, but structural coloration inspired by nature offers high resolution, color saturation, wide gamut, and resistance to fading. Recent advancements have demonstrated water-soluble structural colors using materials like polyvinyl alcohol (PVA) and hydroxypropyl cellulose (HPC). However, it has previously been limited by the need for silver deposition due to its low refractive index. We report a new water-soluble nanocomposite ink composed of HPC and TiO2 nanoparticles to increase the refractive index. This ink allows for vivid colors, a wide gamut palette, high saturation, and brightness. The ink is used to print QR codes via nanoimprint lithography. The methods are cost-effective techniques and have minimal environmental impact. This labeling platform has the potential to address waste issues, enhance consumer trust, and provide accurate information about products.

Laser-Based Selective Nanoimprint Method for Fabrication of Optical Metasurfaces as Modulating Layers for Fluorescent Materials

Timothy Yee

The enhancement of fluorescent materials' performance is a significant research area aimed at expanding their utility and versatility. Optical metasurfaces have emerged as a viable solution to manipulate the optical properties of fluorescent material media. In this study, we propose a laser-based selective nanoimprint method that enables fast and controlled fabrication of metasurfaces specifically tailored as optical modulating layers for fluorescent crystals.

The fabrication process involves depositing laser-induced graphene on a metal thin film, then it is placed on the flexible PDMS mold. The mold will undergo laser irradiation for pressurizing the photoresist, the metal thin film will be used as a protective layer to absorb the laser energy, and the laser energy will be converted to kinetic energy to provide pressure on the mold for nanoimprinting the mold pattern onto the photoresist. Precise control of laser-induced pressure allows for accurate replication of the mold pattern, while concurrently curing the photoresist to stabilize the imprinted nanostructures. The photoresist can be cured at the same time to stabilize the nanostructure imprinted, afterwards, we can apply the fluorescent solution to the photoresist by spin-coating. The fabricated metasurface can improve the absorption of the fluorescence materials and it can act as a better gain medium for the fluorescence crystal layer. We are also working on forming the metasurface directly on the crystal by replacing the photoresist with the solution, and then thermal treating the solution to promote fast crystallization.

This innovative approach presents a simple yet highly effective fabrication method for constructing selective metasurfaces as optical modulating layers for fluorescent materials. It utilizes laser-induced transfer techniques and laser-induced pressure to enable the efficient manufacturing of optical metasurfaces so that different metasurface structures and designs can be used for testing. The demonstrated capabilities of this technique hold great promise for the advancement of the integration between metasurface technology and fluorescent materials. The development of optimized metasurfaces as modulating layers can significantly enhance the optical properties and performance of fluorescent materials, paving the way for new applications in fields such as sensing, imaging, and optoelectronic devices.
achieving enhanced photonic functionalities. By controlling nanoantenna dimensions and optimizing silicon quality through rapid thermal annealing, we successfully manipulate light at the nanoscale, enabling the emergence of narrow Fano resonances and the realization of tunable optical functionalities. These findings open up exciting opportunities for advanced optical devices and applications, ranging from sensing to data communication and beyond.

Some Novel Topological Surface Waves Baile Zhang; Nanyang Technological University, Singapore

Topological surface waves are the topological modes on the surface of a 3D topological insulator or semimetal. Typically in a 3D topological insulator, the topological surface states exhibit Dirac cones, while a Weyl topological semimetal can support Fermi arc surface states. Here we discuss some novel types of topological surface states.

The first type is the topological surface states on a 3D Chern insulator. It is known that a 3D bandgap can be characterized by three Chern numbers, defined for three perpendicular planes in momentum space, forming a Chern vector. The vectorial nature of the Chern vector gives rise to novel structures of topological surface states, including torus knots and links. We have implemented a 3D photonic Chern insulator and demonstrated a (2,2) torus Hopf link for such topological surface states.

The second type is the topological surface states on a 3D valley crystal. Valley degree of freedom (DOF) is widely used as a binary DOF in valleytronic materials, and has recently been introduced into acoustic crystals and photonic crystals. Here we generalize the valley DOF into a 3D crystal and demonstrate 3D valley contrasting physics.

Chiral Metaphotonics and Manipulations Cheng-Wei Qiu; National University of Singapore, Singapore

In this talk, we will report the recent progress on how chirality could assist and transcend the designs of advanced metasurfaces, sensing, strong coupling, BIC photonics and optical micromanipulations. In particular, we will report our very recent results on realizing intrinsic chiral metasurfaces where the engineered slant geometry breaks both in-plane and out-of-plane symmetries. Our result achieves intrinsic chiral bound states in the continuum with near-unity CD of 0.93 and quality factor exceeding 2300 for visible frequencies. We will also cast new perspectives on using photonic orbit angular momentum to effectively discriminate single-size and multi-scale chiral nanostructures.

9:00 AM *EL12.20.04
Optical Metasurfaces for Generating and Manipulating Grafted Vortex Beams Xianzhong Chen and Hammad Ahmed; Heriot-Watt University, United Kingdom

Inspired by plant grafting, the technique of generating a grafted vortex beam involves combining two or more spiral phase profiles of optical vortex beams. Recently, there has been significant interest in grafted perfect vortex beams (GPVBs) and perfect vector vortex beams (PVVBs) due to their distinctive optical properties and potential applications. GPVBs exhibit a constant intensity profile and a radius irrespective of topological charges. PVVBs are structured light beams with inhomogeneous polarization and spiral phase profiles. However, the existing method used for generating and manipulating these beams suffers from the complex optical system, large volume, and high cost. These optical systems are impractical for numerous applications, thus creating an urgent need for a compact, simple, and efficient approach to generating and manipulating these beams.

We propose and experimentally demonstrate a metasurface approach to generating and manipulating these beams. A single metasurface is used to generate various GPVBs in multiple channels and PVVBs without relying on the complicated optical setup. The uniqueness of this method is that the superimposed GPVBs have nonuniform orbital angular momentum and asymmetric singularity distributions in different channels, which can be further modulated by introducing initial phase difference in the metasurface design. Our work has demonstrated a compact metasurface platform that performs a sophisticated optical task that is extremely challenging or impossible with conventional optics, opening opportunities for the investigation and applications of these structured beams in a wide range of emerging application areas such as singular optics and quantum science.

SYMPOSIUM EL13

Multiferroics and Magnetoelectrics
November 27 - November 30, 2023

Symposium Organizers
Tianxiang Nan, Tsinghua University
Thermodynamics of Multiferroics

Multiferroics, by definition, are material systems, either as single phases or composites of multiple phases, that exhibit more than one ferroic orders such as ferroelectric, ferromagnetic, or ferroelastic order. One of the objectives of this presentation is to conceptually connect among the classical first and second laws of thermodynamics, the Maxwell relations relating various and multiferroic properties, the Landau theory description of multiferroic phase transitions, as well as thermodynamics and phase-field method of multiferroic domain structures and responses to external fields. It will start from the classical first and second laws of thermodynamics to establish the fundamental equation of thermodynamics for a multiferroic system as a function of its basic thermodynamic variables. According to Gibbs, the fundamental equation of thermodynamics contains all the information about the equilibrium thermodynamic properties of a system, i.e., one can derive all the equilibrium ferroic and multiferroic properties of a system and their mutual relations from its fundamental equation of thermodynamics. On the other hand, irreversible thermodynamics considers all the ferroic phase transitions as internal irreversible thermodynamic processes within a material which generate entropy and dissipate chemical energy, allowing one to establish an energy function of both basic thermodynamic variables and the ferroic order parameters, e.g., through a Landau-type description, for a given multiferroic system. The thermodynamic description of a homogeneous system can be extended to inhomogeneous systems by introducing the contributions of ferroic domain wall energies through gradient or exchange energies as well as long-range elastic, electrostatic, and magnetic energies and by assuming that a local point of a domain structure can be described by the fundamental equation of thermodynamics in terms of both basic thermodynamic variables and ferroic order parameters. One can then apply the thermodynamic energy functions or functionals to construct multidomain and multiphase diagrams in the space of thermal, mechanical, electric, and magnetic variables using thermodynamic analysis, in analogy to the well-known temperature-composition phase diagrams or model the static and dynamic responses of a multiferroic domain structure to external stimuli using computational methods, such as the relaxationary or dynamic phase-field method.

SESSION EL13.02: Magnetoelectric Heterostructures and Nanostructures I

Two-Step Phase Transition Enabled Superelasticity in Quasi-Two-Dimensional Freestanding Perovskite Ferroelectric Films Mingjie Xu and Xiaoping Pan, University of California, United States

Perovskite ferroelectric materials have garnered significant attention due to their unique properties, including ferroelectricity, piezoelectricity, and high stability, making them promising for diverse applications in memory devices and sensors. However, the inherent weak elasticity and brittleness of most perovskite ferroelectrics pose challenges for their integration into flexible electronic devices.

In this study, we present the observation of superelasticity induced by a two-step phase transition in an 8-nm thick freestanding BiFeO3 (BFO) film. Through atomically resolved in situ transmission electron microscopy (TEM) combined with in situ scanning transmission electron microscopy (STEM), we investigate the lattice deformation and atomic rearrangement in the film under mechanical stress, revealing reversible phase transitions and continuous evolution of the c/a ratio. Notably, we observe a remarkably large c/a ratio of approximately 1.53 in a super-tetragonal (S) phase under a lattice strain of approximately 34.4%, surpassing the highest strain reported for freestanding BFO films. This exceptional superelasticity arises from reversible 2-step phase transitions: R-T-S phase transitions, rather than conventional R-T transitions. Density functional theory (DFT) calculations support the crucial role of these 2-step phase transitions in facilitating such unusually large strain.

The experimental results obtained through in situ TEM and STEM techniques provide a comprehensive understanding of lattice deformations and phase transitions occurring in the BFO film under mechanical stress. This work unveils unprecedented superelasticity in freestanding BiFeO3 films and elucidates its fundamental mechanisms, offering novel insights for the design of advanced flexible electronic devices. The exceptional superelastic behavior demonstrated by quasi-two-dimensional freestanding perovskite ferroelectric films highlights their immense potential for a wide range of applications, including flexible electronics, solid-state actuators, and other innovative technologies.

Low-Voltage Magnetoelastic Coupling in Membrane Heterostructures Chang-Beom Eom; University of Wisconsin–Madison, United States

Strain-mediated magnetoelastic (ME) coupling in ferroelectric (FE)/ferromagnetic (FM) heterostructures offers a unique opportunity for both fundamental scientific research and low power multifunctional devices. Relaxor-ferroelectrics, like (1-x)Pb(Mg_{1/3}Nb_{2/3})O_3-xPbTiO_3 (PMN-xPT), are ideal FE layer candidates due to their giant piezoelectricity. But thin films of PMN-PT suffer from substrate clamping which substantially reduces piezoelectric in-plane strains. Here we present the first demonstration of low voltage ME coupling in an all-thin-film heterostructure which utilizes the anisotropic strains induced by the (011) orientation of PMN-PT[1]. We completely remove PMN-PT films from their substrate and couple with FM Ni overlayers to create membrane PMN-PT/Ni heterostructures showing 90 degree Ni magnetization rotation with 3V PMN-PT bias, much less than the bulk PMN-PT ~100V requirement. Scanning transmission electron microscopy and phase-field simulations clarify the membrane response. These results provide a crucial step towards understanding the microstructural behavior of PMN-PT thin films for use in piezo-driven magnetoelastic heterostructures.

Nanoscale Ferroelastic Writing of Ferroelectric Domains Kathrin Dorr; Martin-Luther-Universität-Halle-Wittenberg, Germany

There is a growing effort towards nanomechanics approaches using a scanning probe microscopy (SPM) tip in order to define patterns of ferroic properties. Next to micromachining, pressure-induced phase transitions or the flexoelectric effect, there is the emerging field of ferroelastic nanoscale manipulation. Ferroelasticity can provide access to mechanical manipulation of a local ferroic order parameter (such as magnetization or ferroelectric polarization), if the order parameter is coupled to a distinct lattice distortion. After giving an introduction to recent advances in the field, the talk addresses our work on mechanical tip-induced definition of ferroelectric domains in a prototype ferroelectric copolymer, P(VDF-TrFE). While there is an increasing track record of nanomechanical manipulation by SPM tip in fully crystalline ferroic films, semi-crystalline polymers offer a unique advantage because of their elasticity supporting damage-free strains of several percent.

The ferroelectric copolymer P(VDF-TrFE) (here with 22% TrFE) is one of the most often applied ferroelectric organic materials. The pseudo-hexagonal lattice of P(VDF-TrFE) supports six stable ferroelectric polarization orientations, and, strikingly, the lattice shrinks substantially along the polarization direction. As-prepared films show multiple few-nanometer-wide ferroelectric domains. The electric dipolar disorder is highly critical, leading to strong suppression of the functional electric responses such as dielectric permittivity, direct or inverse piezoelectric effects. In addition, electric poling and switching of P(VDF-TrFE) films require relatively large electric fields, preventing precise electric nanoscale domain writing because of the tip stray fields.

Our spin-coated P(VDF-TrFE) films consist of very densely packed fine crystalline lamellae of the ferroelectric beta-phase. There is a well-defined (110) out-of-plane texture, but no in-plane texture. After vertical electric poling, complex deliberate in-plane domain patterns with tip-related resolution of 50 nm have been defined [1] by scanning with moderate mechanical tip forces (100-300 nN). The mechanical treatment leaves the semicrystalline lamellar structure essentially unchanged, and the surface roughness remains below 3 nm (rms). Importantly for various functional devices, the in-plane piezoelectric response in written domains is massively enhanced, indicating the achievement of efficient ordering of electric dipoles. I will discuss opportunities to exploit mechanically defined nanoscale polarization patterns in functional devices. This work was partially funded by Deutsche Forschungsgemeinschaft (DFG), CRC 762 and TRR 102.

3:00 PM BREAK
Antiferromagnets with two sets of spins against each other pushes the operation of spintronics memory frequencies up to terahertz with a higher areal density, compared with the traditional ferromagnets due to the absence of the stray field and the strong coupling among spins. However, the net zero magnetic moment makes it difficult in probing and controlling the spin state in antiferromagnet. In this presentation, we discuss electrical and optical approaches to detect and manipulate spins, which pave the way for utilizing antiferromagnet in novel spintronic devices.

First, we will discuss the use of magneto-transport or unidirectional spin Hall magnetoresistance (USMR) in FeO layers bilayer and AFM bilayer. USMR has been widely reported in the heavy metal/ferromagnet (HM/FM) bilayer systems. We observed USMR in Pt/FeO bilayers where the FeO layer is an antiferromagnetic (AFM) insulator. Systematic field and temperature-dependent measurements confirm the magnonic origin of the USMR. The appearance of AFM-USMR is driven by the imbalance of creation and annihilation of AFM magnons by spin-orbit torque due to the thermal fluctuation field. Theoretical modeling reveals that the USMR in Pt/FeO is determined by the antiferromagnetic magnon number with a non-monotonic field dependence as compared with that of ferromagnetic materials. The magnonic origin of USMR is further confirmed by temperature-dependent measurements. This first evidence of USMR in other HM/AFM bilayers may be expanded to include the large family of AF insulators and paves the way for the highly sensitive detection of AF spin states in emerging AF spintronics.

Second, we will discuss the use of the quadratic magnetic-optical Kerr effect (QMOKE) to study dynamics of several AFMs. We will describe the experiments of e.g., α-MnTe. This antiferromagnet has a hexagonal close-packed structure with antiferromagnetic ordering along the c-axis. It is a collinear antiferromagnet with three in-plane easy axes, and its Néel temperature is approximately 310K [1,2], which is also known recently as an antiferromagnet, hosting anti-ferromagnetism in macroscopic scale and ferromagnetism in k space [3,4]. The hexagonal NiAs phase of MnFe (α-MnFe) is obtained by MBE on GaAs. We employ the time resolved pump-probe laser quadratic magnetic-optical Kerr effect (QMOKE) to study MnFe. The QMOKE of α-MnFe is more visible due to the spin splitting of electronic states in the k space. The pump process puts the Néel vector deviate from its equilibrium state. The pump results in the loss of the Néel order, referred to as the fast demagnetization, which endures for about 20 ps; the energy is redistributed between the electron, phonon and the magnon. This dynamics of the change of the Néel order is investigated through quadratic MOKE, reflecting the magnon dynamics. The dynamic study will also be used for other materials to compare the differences of the AFM dynamics.

Ferroelectric Control of Spin-Charge Interconversion and Magnetism in Oxide Two-Dimensional Electron Gases Manuel Bibe; CNRS/Thales, France

Two-dimensional electron gases (2DEG) based on SrTiO3 (STO) display fascinating properties such as low-temperature superconductivity and Rashba spin-orbit coupling allowing to interconvert spin and charge currents through the Edelstein effect. We have introduced ferroelectricity in these 2DEGs in order to achieve a non-volatile electrical control of their properties. Practically, we replaced STO by Ca-substituted STO (Ca-STO) which is ferroelectric up to about 30 K and generated 2DEGs either by sputtering a thin Al film or growing perovskite overlayers by pulsed laser deposition. We will present spin-charge and charge-spin conversion measurements and their control by the ferroelectric state. We will also show how magnetism can be introduced in the system and use X-ray absorption spectroscopy and magneto-transport to demonstrate the coexistence of ferroelectricity and magnetism with metallicity. Our data evidence the non-volatile control of polar displacements, magnetization and anomalous Hall effect upon switching the polarization direction, indicating a magnetoelectric coupling. Our results provide new opportunities in quantum matter arising from the interplay between ferroelectricity, ferromagnetism, metallicity, and Rashba spin-orbit coupling in low dimensions.

8:00 PM EL13.04.01
Leveraging Colloidal Assembly to Texture Hexaferrites to Enable Better Performance in RF Devices Jose A. Martinez and Randall M. Erb; Northeastern University, United States

With the implementation of 5G, the telecommunications industry desires enhanced performance of incumbent radio-frequency (RF) devices. Non-reciprocal devices, circulators, and isolators are integral to RF communication systems by isolating the incoming signals from the outgoing signals, exhibiting different electromagnetic wave propagation characteristics in the forward and reverse directions. Such devices rely on soft and hard ferrite materials currently limited in performance by the current achievable saturation magnetization and coercive field levels. Significant work has been applied toward improving the materials synthesis of these ferrite materials to achieve better performance. Specifically, M-type hexagonal ferrites, such as SrFe12O19 (SrM) and BaFe12O19 (BaM), have been studied for their large coercivity, high Curie temperature, good chemical stability, and high corrosion resistance. Here, we investigate the role that both the composition and microstructure of these materials have on the material performance. We tailor the saturation magnetization and the particle geometry of SrM and BaM through hydrothermal synthesis and thermal treatment. Further, we investigate the role of microstructure texturing by aligning ferrite particles in the pre-sintered state by leveraging a colloidal assembly technique that takes advantage of
Enhancement of Magnetic Properties of NdFeB Sintered Magnet by Grain Boundary Diffusion Process with TbAlCu

Bismuth ferrite (BiFeO3) is a lead-free magnetoelectric multiferroic showing antiferromagnetic order and a large spontaneous polarization at room temperature. This antiferromagnetic order in BiFeO3 is complex, where, as a consequence of the Dzyaloshinskii-Moriya interaction (DMI), a small canting of the antiferromagnetic order forms a chiral spin cycloid in bulk samples. Understanding the interplay between the ferroelectric polarization and the spin cycloid, as well as its electric field manipulation, is of great interest in antiferromagnetic spintronics and next generation computation. There is still much to learn about BiFeO3’s intrinsic antiferromagnetic structure in thin films, where epitaxial strain imposed by an underlying substrate can influence the spin texture.

Sputter Deposited Ni-Based Intrinsic Magnetic Topological Insulator Thin Films

Three-dimensional topological insulators (TIs) exhibit unique properties such as topologically protected Dirac surface states (TSS) that enable metallic surface states while the bulk remains insulating. These TIs, including Bi4Sb3Te3 alloys and hexagonal X3OX compounds (X = Bi, Sb, Bi2Sb, Se, Te), also demonstrate the quantum anomalous Hall effect (QAHE). The QAHE occurs when a gap is created in the TSS by introducing perpendicular magnetic fields. By correlating the spin texture to ferroelectric information measured using piezoresponse force microscopy, we are able to explore coupling between the two order parameters. Electric-field-dependent transport shows that the spin cycloid can be manipulated by switching the ferroelectric polarization, which is of great interest in low dissipation magnonics and spintronics.

Heterogeneous Strain Control by Interlayer Addition in Multiferroic Bi2Fe4Mn2O9 Resulting in Thick Film Growth
James P. Barnard1, Jianan Shen1, Yizhi Zhang1, Juanjuan Lu1, Jiawei Song1, Aleem Siddiqui2, Raktim Sarma3 and Haiyan Wang1,1;

In recent work on electronic devices based on multiferroic and ferroelectric materials, thicker films have become a necessity for certain applications, including MEMS magnetic actuators, magnetoelectric antennas designed for energy harvesting, and optical metasurface fabrication. A common roadblock for the synthesis of thicker films is the loss of film-substrate strain effects as the strain relaxes over the larger thickness. For example, the Bi4Fe10Mn2O19 (BFMO) Aurivillius supercell (SC) phase is a multiferroic system that depends on substrate strain to initiate the growth of the phase. In our work, a new seeding technique has been developed that utilizes a heterogeneous film topology to reestablish the required strain to maintain SC phase growth. This is done by the insertion of CeO2 interlayers, which reintroduce the heteroepitaxial strain in the BFMO. The thick BFMO SC phase also maintains the desired ferroelectric and ferromagnetic properties as well as anisotropic optical properties. This technique allows for thicker growths of the BFMO SC phase (over 100 nm) and can also be applied to other Aurivillius or strain-dependent films for device applications, effectively eliminating the current thickness limitations.

Thin Film Surface Acoustic Wave Magnetic Field Sensors: Impact of the Thickness of the Magnetostriective Layer
Jana M. Meyer1, Lars Thumm1, Stefan Moench1, Thorsten Giese1, Simon Fichtner2,3, Vadim Lebedev4, Agne Zukauskaite4, Eckhard Quandt2 and Fabian Lofink1,2;
For the fabrication of surface acoustic wave (SAW) sensors the use of piezoelectric single-crystal substrates (e.g., quartz) is established. Utilizing thin-film technology benefits from larger material flexibility, reduction in chip size, better integrability in standard MEMS and CMOS fabrication technology and thus better scalability. Additionally, it is possible to design multilayer stacks to customise the wave properties to the application purpose. [1] In this context, a piezoelectric AlScN thin film is a promising material, as it combines the advantages from AIN (e.g., high wave velocity, good mechanical and dielectric properties, high thermal conductivity, and high breakdown voltage) with improved electromechanical coupling due to alloying with Sc [2]. AlScN can be fabricated with standard semiconductor technology at reasonable cost on 200 mm silicon wafers. By combining a SAW sensor with a magnetostrictive film, a magnetic field sensor can be realized that is based on the change of the Young’s modulus (E effect) of magnetostrictive films in the presence of an external magnetic field that can be detected as a phase change of the SAW. [1] The SAW is generated by interdigital transducers on top of the piezoelectric AlScN thin film. By the application of a CMP polished SiO2 layer on top of the AlScN, the magnetostrictive film quality is improved by reducing the roughness of the surface. The SiO2 layer also acts as a guiding layer and is used to excite new surface confined SAW modes. High sensitivities of the SAW magnetic field sensor can be obtained by using magnetically soft magnetostrictive films with high magnetostriction like FeCoSiB or FeCoB. [3]

Different layer properties of the sensor stack can be varied (e.g., thickness) and different SAW modes aside from the fundamental Rayleigh mode (e.g., Sezawa mode or shear modes) can be excited in layered thin film structures. Crucial is the thickness of the magnetostrictive FeCoSiB film as it was shown that the sensitivity of the sensor is increasing with the magnetostrictive film thickness [4]. In contrast to the use of bulk piezoelectric substrates like quartz, a post annealing step to induce a uniaxial magnetic anisotropy is possible and the deposition temperature can be elevated to improve the magnetic anisotropy alignment. The influence on the phase shift induced by the applied magnetic field, on the corresponding sensitivity and especially on the frequency dependent noise behaviour of the sensor is investigated and the influence on the different SAW modes compared.

The SAW sensors can be used to measure weak fields at low frequencies as required for biomagnetic applications [5], but is also well suited for current sensing and control applications, such as power electronics [6], benefiting from the large dynamic range (up to 8 orders of magnitude), high bandwidth (>1 MHz) and the possibility of an isolated measurement. [6]

Materials for antiferromagnetic spintronics are becoming a popular topic due to their potential applications in next generation technologies. A primary advantage lies in their stability with external magnetic fields and potentially ultrafast spin dynamics, making them promising candidates for high-speed data storage and processing. A key challenge in this field, however, is the control of the antiferromagnetic order parameter on the nanometer scales applicable to solid state technologies. Bismuth ferrite is a multiferroic material that exhibits both ferroelectric and antiferromagnetic properties at room temperature, making it a unique candidate in the development of electrically controllable magnetic devices. In this material, the magnetic moments are arranged into a long-range spin cycloid, resulting in a unique set of magnetic properties that are intimately tied to the ferroelectric order parameter. Here we show that the propagation axis of this spin cycloid can be deterministically controlled with careful tuning of the ferroelectric order. Through precise application of electric fields, we show reversible control of the spin texture in BiFeO3 thin films and deterministic spin transport that can be traced back to changes in the nanoscale magnetic structure.

Creating a Three-Dimensional Intrinsic Electric Dipole on Rotated CrI3 Bilayers
Shiva Prasad Poudel; University of Arkansas, Fayetteville, United States

New multiferroic platforms by sliding or rotation are being explored in two-dimensional (2D) materials [1,2,3]. Antiferromagnetically-coupled CrI3 bilayers are one of the most studied magneto-electric multiferroic 2D materials [4]. Without considering magnetism, those bilayers possess a crystalline point of inversion, which can only be removed by antiparallel spin configuration between their two monolayers [4]. However, relative rotations between layers break the crystalline point of inversion, resulting in an inherent electric dipole moment P. Magnetoelectric couplings can be enhanced this way on a two-dimensional bilayer that is experimentally accessible [5].

Dynamical Multiferroicity and Magnetic Topological Structures Induced by Orbital Angular Momentum of Light in a Non-Magnetic Material

Lingyuan Gao, Sergei Prokhorenko, Yousra Nahas and Laurent Bellaiche; University of Arkansas, Fayetteville, United States

Many efforts have been made in studying effective magnetization resulting from the temporally varying electric polarization [1, 2]. Such dynamical polarization can be produced by driving collective motions of ions, usually termed as “phonons” in solid-state language. Moreover, numerous recent studies show that light can control the magnetization in crystals by driving optical phonon modes and tuning structural distortions [3-6]. At the zone center of reciprocal space, infrared (IR)- and Raman-active modes, related to electric polarization and polarizability, respectively, can be excited with an ultrafast Terahertz (THz) laser pulse.

In this Talk, we will present an alternative approach to induce effective magnetic field established on the mechanism of dynamical multiferroicity. Instead of focusing on coherently excited chiral phonons, we drive real-space circular motions of ions with a particular type of light—optical vortex (OV) beam. Such light carries an orbital angular momentum (OAM) [7-9], and can manipulate the motion of microparticles as an optical tweezer [10-12]. As a prototype example, we use first-principles-based simulations and demonstrate that in ultrathin ferroelectric Pb(Zr, Ti)O3 films, microscopic electric dipoles indeed rotate with the time-varying OAM field. As a result, orbital magnetic moments of ions are effectively generated resulting in a non-negligible magnetic field even in non-magnetic materials. More intriguingly, we will show that the microscopic magnetic moments on a single layer of this quasi 2D system are arranged in a vortex-type configuration, proving that topological magnetic structures—magnetic merons—can also be produced out of orbital magnetic moments of ions and dynamical multiferroicity.

References:
Magneto-electric spin orbit (MESO) devices have been proposed as an alternative to CMOS devices for computational logic and memory, providing a possible solution to greatly reduce the energy consumption of conventional computers. This is expected to be done by electric field control of the magnetic order parameter of a ferromagnet through the magnetoelectric coupling of a BiFeO$_3$ (BFO) multiferroic attached to a ferromagnet. Here, we demonstrate a simplified version of a MESO device where we remove the ferromagnet entirely, and directly manipulate and measure the antiferromagnetic order of the BFO with electric fields and magnet detection, respectively. Using only the antiferromagnetic BFO in the MESO device is an attractive proposal for such a spintronic memory element due to its robustness against external fields, its lack of stray fields, and its fast switching dynamics. Furthermore, the insulating nature of BFO greatly reduces Ohmic losses in the transfer of spin information via magnons, creating a pathway for realizing ultra-low power spintronics. First, we present a bi-stable state switching of the AFM order, controlled by electric fields and measured using the inverse spin Hall effect in a platinum

\[ \text{H}_\text{m} \] (electric field $E$). The linear ME effect can be extended to optical frequency $\omega$, known as the optical magnetoelectric effect (OME), in which $P(\omega) [M(\omega)]$ is induced by oscillating $H(\omega) [E(\omega)]$ of an electromagnetic wave $[1]$. The OME effect induces nonreciprocal optical phenomena, which will be effective for probing the ME effect in metallic systems, where the linear ME effect responding to a static field is ill-defined. In this study, we investigate the OME effect in an antiferromagnetic (AFM) metal TbB$_4$. TbB$_4$ exhibits two successive AFM phase transition at $T_{N1} = 44$ K and $T_{N2} = 24$ K $[2]$. The magnetic structure in the AFM1 phase at $T_{N2} \leq T \leq T_{N0}$ breaks both space-inversion and time-reversal symmetries (magnetic point group: 4/m'm'm') and allows for the diagonal ME coupling ($\alpha_{11} = \alpha_{22}$, and $\alpha_{ij}$ where $\alpha_{ij}$ is the ME tensor defined as $P_i = \alpha_{ij}H_j$). The diagonal terms of the ME tensor induce nonreciprocal rotation of reflected light (NRR), which refers to the rotation of the polarization of reflected light $[3,4]$. In the AFM1 phase of TbB$_4$, there are two distinct AFM domain states, and the rotation directions of NRR are opposite between the two. Therefore, for the detection of NRR in TbB$_4$, spatial distribution measurements are suitable. Here, we obtain two-dimensional maps of NRR, with magnitudes ranging from $10^4$ to $10^5$ rad in the visible light region, by adopting a difference image sensing technique using polarization modulation of incident light $[5,6]$. As a result, we have successfully detected NRR and visualized AFM domains in TbB$_4$. We expect that our achievement will further promote understanding of ME effects in metallic compounds.

Efficient Voltage Control of Two-Dimensional Magnetic Insulators Shanchuan Liang$^1$, Ti Xie$^1$, Nicholas Blumenschein$^2$, Tong Zhou$^1$, Thomas Ersevim$^1$, Zhihao Song$^1$, Jierui Liang$^1$, Michael A. Susner$^4$, Benjamin Conner$^4$, Shi-Jing Gong$^5$, Jian-Ping Wang$^6$, Min Ouyang$^1$, Igor Zutic$^3$, Adam Friedman$^2$, Xiang Zhang$^7$ and Cheng Gong$^1$; $^1$University of California, Berkeley, United States; $^2$University of Minnesota Twin Cities, United States; $^3$The University of Hong Kong, China

Magnetic insulators (MI), possessing long-range magnetic order while being electrically insulating, allow spin propagation without electrons’ motion and thus promise a unique paradigm of next-generation dissipationless magnetoelectric and magneto-optical devices. While two-dimensional (2D) MIs offer the prospects into the atomic-thin region, efficient electrical control as an essential prerequisite for practical devices remains elusive; fundamental obstacles arise from the difficulty of electrostatically doping insulators and the inability of external electric fields to effectively modify materials’ crystal fields. Here, by constructing a heterostructure consisting of a functional thin film and a 2D magnetic insulator, we achieved a strong and reversible electrical control of
magnetism. The wavefunction overlaps at the heterostructure interface differs greatly under opposite voltages applied, leading to effective control of the coercivities in magnetic hysteresis loops of the 2D magnets. The layered dependence study confirmed that this effective control occurs exclusively for 2D magnets instead of the bulk counterpart, owing to the electrically controllable interfacial wavefunction overlap that could effectively alter the interfacial crystal field. Our work opens up new avenues to usher 2D MIs towards future nanoscale spintronic, magnonic, and magneto-optical applications.

SESSION EL13.06: Magnetoelectric Sensors and Actuators I
Session Chairs: Jiamian Hu and Michael Page
Tuesday Afternoon, November 28, 2023

Removing Magnetic Noise from Composite Magnetoelectric Sensors Jeffrey McCord; Kiel University, Germany

Magnetic field sensors are devices that detect and measure magnetic fields around permanent magnets, electrical conductors, and electrical devices. As such, they are particularly relevant for magnetic applications in IoT, 5G, smartphones, energy, and biomedical engineering. In this context, dedicated research is currently being carried out on novel thin film magnetoelectric (ME) sensor concepts for the detection of magnetic fields down to the picotesla range.

Advanced wide-field magneto-optical Kerr effect microscopy [1] with high temporal resolution is used to study local effects in operating ME composite sensor structures. The realized magneto-spatial analysis of working devices sheds light on magnetization changes due to domain nucleation, domain wall resonances, domain wall bending modes, precessional magnetization effects and spin-wave-like phenomena. Each of these is specific to different types of composite ME sensors, ranging from precessional to modulated to DE to SAW sensor systems. Complementary ME response, noise and detection limit analyses reveal the different magnetic noise mechanisms with different magnetic domain activities for the different sensor types (e.g. [2-5]). Understanding the complex magnetic interactions, strategies and implementations are identified to optimize sensor structures. Single magnetic domain layers are the basis for low noise magnetic thin film sensors due to the absence of magnetic domain walls.

The design and application of magnetic layered structures with minimal noise performance sensitivity is discussed. Beyond magnetic domain engineering [6], other schemes of magnetic noise suppression, based on a combination of sensing and pinning magnetic multilayer stacks are discussed. By introducing magnetic sensing layers with subtractive response to carrier excitations while maintaining sensitivity, the influence of the electrical carrier signal to noise is virtually eliminated [7]. The magnetically enforced reduction of the electrical background signal paves the way for ultra-low noise ME sensor applications capable of detecting picotesla magnetic fields. Fundamental limitations of composite ME sensors beyond magnetic domain activity will be further discussed [5].

Funding by the DFG for the CRC 1261 “Magnetoelectric Sensors: From Composite Materials to Biomagnetic Diagnostics” and collaborations within the CRC are acknowledged.

Dynamically Tunable, Narrowband Terahertz Emitters Designed by Tailoring Magnon-Phonon Interaction in Multilayer Heterostructures Jiamian Hu; University of Wisconsin-Madison, United States

A dynamically tunable, narrowband terahertz (THz) source is much needed for an accurate identification and imaging of chemical and biological species, with wide-ranging applications from security screening to medical imaging and to semiconductor inspection. However, existing pulsed THz sources are mostly single-cycle, broadband, and difficult to tune dynamically. In this presentation, the speaker will first introduce an approach that permits converting a femtosecond laser pulse into a multi-cycle, narrowband THz pulse via resonant magnon-phonon interaction. The peak frequency of the emitted THz pulse can be tuned by up to 50% through a varying bias magnetic field. The speaker will then present computational demonstration of this approach in several carefully designed ferromagnet and antiferromagnet based multilayer heterostructures, which allows us to cover without gaps different frequency ranges (deep millimeter-wave, sub-THz, and >1 THz) of the THz spectrum, tune the polarization, duration, and power of the emitted THz pulse. The demonstration was performed based on an in-house dynamical phase-field model that incorporates the coupled dynamics of magnons, phonons, photons, and plasmons in multiphase systems.

2:30 PM *EL13.06.03
Imaging of Magnetic Particles by Magnetic Susceptibility Particle Mapping (MSPM) Christine Selhuber-Unkel; Heidelberg University, Germany

The imaging of magnetic particles is highly relevant in many biomedical investigations, including disease detection, diagnosis, and treatment. Magnetic Susceptibility Particle Mapping (MSPM) has the potential to emerge as an important tool in this context, as it can be used to detect magnetic nanoparticles in a lab scale device. The system is based on magnetoelectric (ME) sensors that make use of the Delta-E effect, in combination with a permanent magnet, which generates a bias field for the sensor and at the same time magnetizes the SPIONS. The SPIONS in the sample are magnetized by the permanent magnet and generate an additional magnetic field, which is recorded by the ME sensor. To demonstrate the capability of the MSPM as an imaging technique, magnetic particle distributions are assessed in 3D printing scaffolds. In addition, 3D microtumors based on MCF-7 and MDA-MB-231 breast cancer cells were labelled with magnetic nanoparticles assessed by MSPM. The data show the potential of the device as well as new avenues towards a lab scale investigation of biomedically relevant samples at the standard lab scale.
The SAW sensor is constructed on a substrate of piezoelectric ST-cut quartz with gold interdigital transducers (IDTs) for generating the acoustic wave. A
at 10 Hz without the need for an external bias field. This eliminates the requirement for an additional magnetic field source during operation.

These transducers are engineered to concentrate acoustic energy towards a small region in the center of the device allowing driven magnetic precession
much more than was previously possible. Enhanced acoustic absorption and modeling of the response will be shown. These devices promise functionality
which outperforms current state of the art high frequency devices in a novel acoustic wave system that the response facilitates unprecedented size, weight, and power
reduction.

Magnetoelectric delta-E effect sensors utilize the change in the elastic modulus of the magnetostrictive material upon applying a magnetic field, resulting in a
shift in the resonance frequency. Such sensors have demonstrated the potential to detect small-amplitude and low-frequency magnetic fields. It was also
shown that the limit of detection can be improved by using sensor arrays including a large number of sensor elements [1]. However, building compact arrays
and achieving high spatial resolutions using mm-sized sensors is challenging. Moreover, the reproducibility of the sensors is significantly impacted by
the magnetoelastic stress developing in the magnetic layer upon releasing the resonator during the fabrication process [2]. Additionally, sensors with a
cantilever design suffer from inhomogeneous magnetic properties caused by different stress relaxation at the clamping region affecting their performance
[3]. Here, we present an experimental and theoretical investigation of mm-sized delta-E effect sensors employing a free-free beam design that
overcomes the limitations and challenges encountered in previous approaches. To control and minimize the residual stress in the magnetic layer, we use a shadow-
mask deposition technique where the magnetic layer is deposited on the released resonators. The spatial stress distribution can be accurately determined by
combining displacement measurements with a magneto-mechanical model. Different resonance modes are identified, and the dependence of the resonance
frequency shift and the sensitivities on these modes are established. The influence of the anchors and the stiffness tensor components on the resonance
frequency shift are analyzed by combining a magnetoelectric macropin structure and an electromechanical finite element model. Noise performance and the
limit of detection of different sensor geometries are investigated to gain general insight into the relationship between geometry, resonance mode, and sensor
performance. We demonstrate extreme stress control with a minimal change of smaller than 8 MPa in the normal stress components (σ_{11} and σ_{22}) and
smaller than 2 MPa in the shear stress component (σ_{xy}) following the deposition of the magnetic layer. We find that the delta-E effect and sensitivities
exhibit strong dependence on resonance modes, attributed to distinct variations in local magnetic and mechanical properties specific to each mode. We
identify the optimum mode shape and achieve detection limits below 300 pT/Hz^{1/2} at 10 Hz, comparable to macroscopic sensors [4,5]. Overall, we
demonstrate the successful production and miniaturization of delta-E effect sensors with high reproducibility and similar performance to the macroscopic
sensors using the proposed manufacturing process and sensor design. The achieved miniaturization and reproducibility represent a significant step toward
developing fully integrated sensor arrays and emphasize the potential for high spatial resolution and improved detection limits with large sensor arrays or
using flux concentrators.

Surface acoustic wave (SAW) technology is widely utilized in electronics as e.g. filters and sensors. One notable application is their implementation for
magnetic field detection [1]. Currently, magnetic field sensors achieve a limit of detection (LOD) below 40 pT/Hz^{1/2} within the frequency range of
1 Hz to 1 kHz. However, these sensors require an external bias field of approximately 0.4 mT to achieve the desired sensitivity [2]. Alternatively, newly
developed SAW sensors incorporate a sensing layer of FeCoSiB deposited through ion beam deposition. These sensors can achieve a LOD of 71 pT/Hz^{1/2}
at 10 Hz without the need for an external bias field. This eliminates the requirement for an additional magnetic field source during operation.
The SAW sensor is constructed on a substrate of piezoelectric ST-cut quartz with gold interdigital transducers (IDTs) for generating the acoustic wave. A
waveguiding layer made of amorphous SiO\textsubscript{2} is placed on top to confine the wave to the surface, resulting in Love waves. They exhibit an in-plane
displacement perpendicular to the direction of propagation. The IDTs are arranged sequentially to create a delay line, and a magnetostrictive sensing element is positioned between them. This sensing layer consists of a single-layer amorphous (Fe_{20}Co_{60})Si_{31}B_{18} thin film deposited using ion beam
deposition. If a magnetic field is present, it induces changes in the elastic properties of the FeCoSiB due to the DE effect. This alteration in properties leads to
a phase shift in the Love wave. The sensitivity of the sensor to the magnetic field is determined by measuring this phase shift. This measurement is
carried out using a Zurich Instruments UHFLI lock-in amplifier, which employs dynamic phase detection. The phase noise analysis is performed using a
Rhode & Schwarz E5051A VNA phase noise analyzer.
The FeCoSiB coating on the new sensor does not exhibit ideal soft magnetic behavior, but instead displays a more hysteretic behavior with a coercive
field of 0.5 mT. Consequently, this leads to a shift in the sensitivity curve, wherein the maximum sensitivity of 1410 °/mT is achieved at a bias field of 0.75
mT. But, even in the remanence state, the sensor retains a sensitivity of 640 °/mT, whereas other sensors with a more ideal soft magnetic film have a
sensitivity below 100 °/mT. To determine the LOD, the phase noise is divided by the sensitivity. The best sensor, in this case, achieves a LOD of 71
pT/Hz^{1/2} at 10 Hz and 24 pT/Hz^{1/2} at 100 Hz. The magnetic properties, as well as the findings when considering the sensitivities, will be presented.
Furthermore, advances in utilizing LiNbO\textsubscript{3} single crystal substrate, which possesses a significantly higher electromechanical coupling factor than quartz,
The detection of magnetic signals is a significant area where numerous magnetoelastic sensor systems, such as antennas, filters, and magnetometers, are being developed and tested [1]. The use of magnetic signals has the advantage over electrical signals that they are not affected by water, for example, which simplifies communication with underwater vessels and the measurement of biomagnetic signals [1, 2].

The development and fabrication of magnetoelectric cantilever sensors, based on microsystem techniques, are among the primary research focuses of the Collaborative Research Center 1261 at Kiel University [2, 3]. To construct such highly sensitive magnetic field sensors, a wide range of material parameters must be considered. For instance, piezoelectric layers require high piezoelectric coefficients, while magnetic layers should possess soft magnetic properties combined with high magnetostriiction. Commonly used magnetoostrictive materials are FeCoSiB and FeGaB. Amorphous magnetic materials have the advantage of avoiding undesired crystal anisotropies. To further enhance the magnetic behavior, exchange-bias multilayer systems are employed to minimize magnetic noise resulting from domain wall activity. Imprinting anisotropy in the multilayers is crucial for optimal performance, which can be achieved through sputter deposition in a magnetic field, as well as subsequent heat treatment at approximately 250 °C for FeCoSiB. However, higher annealing temperatures may be necessary depending on the blocking temperature of the selected antiferromagnet for biasing, which could lead to crystallization of the amorphous magnetic layers.

Another potential source of unintentional crystallization is the packaging of the devices at the end of production to protect them from environmental influences and facilitate handling. This common method typically requires temperatures of about 400 °C to create a vacuum-sealed capsule. This study focuses on investigating different magnetostrictive materials such as FeCoSiB, FeGaB, FeGaC, and CoFeB, which are fabricated through sputter deposition with multicomponent targets and co-deposited layers [1]. The materials are evaluated using XRD, VSM, and magnetostriuction measurements at different temperatures. The study aims to determine the temperature ranges at which a negative magnetostriction occurs. For example, significant changes in the magnetic behavior of FeCoSiB are observed at temperatures above 300 °C; resulting in a degradation of sensor properties and rendering them unsuitable for vacuum encapsulation by standard wafer bonding.

In this talk, I will illustrate some examples how experimental and electronic coupling can lead to exciting novel properties in oxide films and heterostructures. I will first outline how tri-linear coupling of structural instabilities can lead to improper ferroelectricity in PtTiO$_3$/SrTiO$_3$ superlattices [1]. I will then discuss how such a coupling of instabilities can be used to design artificial ferroelectric and possibly multiferroic materials with a focus on vanadate-based structures [2,3]. In these structures, it was found that the competition between the strain state and the coupling of oxygen octahedra rotations leads to an interesting “transition layer” and a reorientation of the orthorhombic long-axis. This competition can be used for designing an artificial interface with possibly designed electronic properties. The reorientation of the orthorhombic long-axis is also observed in SmNiO$_3$/NdNiO$_3$ nickelate superlattices [4,5] - when an additional insulating spacer layer of LaAlO$_3$ is introduced [6].

This study focuses on investigating different magnetostrictive materials such as FeCoSiB, FeGaB, FeGaC, and CoFeB, which are fabricated through sputter deposition with multicomponent targets and co-deposited layers [1]. The materials are evaluated using XRD, VSM, and magnetostriction measurements at different temperatures. The study aims to determine the temperature ranges at which a negative magnetostriction occurs. For example, significant changes in the magnetic behavior of FeCoSiB are observed at temperatures above 300 °C; resulting in a degradation of sensor properties and rendering them unsuitable for vacuum encapsulation by standard wafer bonding.
manganite films with controlled microstructures and to gain a fundamental understanding of their physical properties. In this talk, we will discuss our strategies and the synthesis and characterization of epitaxial lanthanum manganite thin films. Using perovskite lanthanum manganite as the model system, we examine interface-dependent magnetotransport properties by creating both vertically aligned nanocomposite films and layered heterostructures. Specifically, we will discuss the effect of interfaces (both vertical and lateral interfaces) on the magnetotransport properties of lanthanum manganite films.

Superconductivity in Layered Square Planar Nickelates Julia Mundy; Harvard University, United States

Since the discovery of high-temperature superconductivity in copper oxide materials, there have been sustained efforts to both understand the origins of this phase and discover new cuprate-like superconducting materials. One prime materials platform has been the rare-earth nickelates; indeed, superconductivity was recently discovered in the doped compound Nd₃Sm₂NiO₁₀ [1]. Undoped NdNiO₃ belongs to a series of layered square-planar nickelates with chemical formula Ndₙ₊₁NiO₂₋₄ and is known as the ‘infinite-layer’ (n = ∞) nickelate. Here, we report the synthesis of the quintuple-layer (n = 5) member of this series, Nd₅NiO₃₋₄, in which optimal cuprate-like electron filling (δ ≈ 0.1) is achieved without chemical doping [2]. We observe a superconducting transition beginning at ~13 K. Electronic structure calculations, in tandem with magnetoresistive and spectroscopic measurements, suggest that Nd₅NiO₃₋₄ interpolates between cuprate-like and infinite-layer nickelate-like behaviour. By engineering a distinct superconducting nickelate, we identify the square-planar nickelates as a new family of superconductors that can be tuned via both doping and dimensionality. [3]

Structural and Electronic Properties of Nickelate Based Superlattices Lucia Varbaro1, Claribel Dominguez2, Jennifer Fowlie2, Lukas Korosec1, Bernat Mundet1, Duncan T. Alexander2 and Jean-Marc Triscone1; 1University of Geneva, Switzerland; 2SLAC National Accelerator Laboratory, United States; 3Institut Català de Nanociència i Nanotecnologia (ICN2), Spain; 4École Polytechnique Fédérale de Lausanne, Switzerland

Rare-earth nickelates belong to the wider family of perovskite oxides. These materials display a characteristic temperature-dependent metal-to-insulator transition (MIT) together with a lowering of the crystal symmetry related to the onset of a breathing distortion of the NiO₆ octahedra units [1,2]. Furthermore, below the Néel temperature (T₆ < TMIT for R = La - Sm and T₆ > TMIT for R = Nd, Pr), these compounds were found to exhibit antiferromagnetic order with the {1/4,1/4,1/4} pseudocubic propagation vector [3-4]. In theory, it has been predicted that the coalescence of breathing distortion and non-centrosymmetric magnetic order could result in a breaking of inversion symmetry within the crystal lattice. Consequently, this would lead to the emergence of an electric dipole, classifying nickelates as type-II multiferroics. [5] Raman spectroscopic data of RNiO₃ single crystals by Ardizzone and al. [6], show that, entering the magnetically ordered phase, additional vibrational modes appear as a possible signature of breaking of inversion symmetry.

In this work, we investigate nickelate thin films and superlattices. Raman experiments were performed on NdNiO₃ and SmNiO₃ thin films, revealing temperature evolution of the Raman spectra rather similar to the one reported in [6]. Moreover, the structural and electronic properties of nickelate superlattices were studied to investigate the characteristic length scale over which a metallic or an insulating phase can be established and the physics that sets it [7]. By growing SmNiO₃/NdNiO₃ superlattices and using experimental and theoretical methods we showed that this length scale depends on the interplay between the energy cost of the boundary between metallic and insulating phases and the energy gain of the bulk phases [7]. To further understand this unusual coupling and the evolution of the structural and electronic order parameters across these phase boundaries, SmNiO₃/NdNiO₃ superlattices were grown with additional insulating LaAlO₃ spacer layers, that should lead to a progressive decoupling of the nickelate layers. Furthermore, the phase boundary cost of maintaining an interface between a metal and an insulator will be exploited as an additional parameter to tune the electronic properties of this class of materials, specifically alternating metallic layers and layers displaying a metal-to-insulator transition within a superlattice, with the aim of forcing a metal into an insulating phase by increasing the density of interfaces.

The samples were grown using RF off axis magnetron sputtering, and are morphologically and structurally characterized using atomic force microscopy (AFM), X-ray diffraction (XRD) and STEM-EELS. Temperature dependent transport measurements will be presented for each different system, giving an overview on electronic and structural couplings, and more generally on the properties of these complex heterostructures.

Giant Magnetolectric Effect and Interactive Control of Magnetic Anisotropy Driven by a Ferroelectric Phase Transition in Ferromagnetic-Piezoelectric Heterostructure Thomas R. Mion1,2, Margo Stanach1,6, Peter Finkel1, and Konrad Busmann; 1NOVA Research, United States; 2U.S. Naval Research Laboratory, United States

Magnetolectric materials and, to a larger extent, multiferroic heterostructures offer a novel route for electric field control of magnetism. We explored the induced magnetic anisotropy of an FeCo/Ag multilayer thin film deposited on the surface of 001 poled (PbIn₁₂₋₄Nb₂₋₁₃Oₓ-Pb(Mg₁₂₋₄Nb₂₋₁₃Oₓ)-PbTiO₃) PIN-PMM-PT single crystal as it is electrically driven through a ferroelectric-ferroelectric phase transition. In PIN-PMM-PT an effective giant piezoelectric coefficient >10,000 pm/V occurs during the phase transition providing strain >0.25% along a principle strain direction. This effect translates into anisotropic strain to the magnetoelastic thin film inducing a giant magnetoelastic effect driven by the induced magnetic anisotropy along the principle strain direction. We measured an effective converse magnetoelastic coefficient ~1.4 × 10⁻⁵ s/m when driven through the phase transition which was more than double the values obtained in the linear piezoelectric rhombohedral phase. The controllable and repeatable nature of the phase transition allows an interactive driving of the induced magnetization making the phenomenon attractive for application in spintronic devices.
Recent Advances and Future Opportunities with Magnetic X-Ray Spectromicroscopies

Spin textures in magnetic materials, and polarization textures in multiferroic materials hold the key to understand and control properties and behavior, that offer tremendous potential for novel applications in future information processing technologies with significant improvements in energy efficiency, processing speed, functionalities, and miniaturization of future microelectronic devices.

An emerging research field in nanomagnetism is the scientific and technological exploration of 3-dimensional magnetic nanostructures that opens the path to exciting novel physical phenomena, originating from the increased complexity in spin textures, topology, frustration, and tailored geometries in three dimensions. This has attracted significant scientific interest and led to intense research addressing a broad spectrum, including stability, dynamics, nucleation, and transport in novel spin textures, such as vortices, skyrmions, chiral bobbers, hopfions, torons, skyrmion tubes, etc. [1]. Analogous structures are also found in multiferroic (polar) materials, such as polar vortices [2], skyrmions [3] and hopfions [4].

Advanced characterization tools that provide magnetic sensitivity to spin textures, disentangling the role of individual components in heterogeneous material at high spatial resolution, ultimately at buried interfaces and in all three dimensions [5], and at high temporal resolution to capture the spin dynamics across scales, are required to address those questions, and are therefore of large scientific interest.

Various magnetic soft X-ray spectro-microscopies [6] using polarized soft x-rays provide unique characterization opportunities to study the statics and dynamics of spin textures in magnetic materials combining X-ray magnetic circular dichroism (XMCD) as element specific, quantifiable magnetic contrast mechanism with spatial and temporal resolutions down to fundamental magnetic length, time, and energy scales.

Current developments of x-ray sources aim to increase dramatically the coherence of x-rays opening the path to new techniques, x-ray photo-correlation spectroscopy (XPCS) [7] that allow unprecedented studies of nanoscale homogeneity, complexity, and fluctuations.

I will review recent achievements and future opportunities with magnetic x-ray spectro-microscopies. Examples will address static properties and dynamic behavior of magnetic hopfions [8] and a 3D metrology of skyrmions using soft x-ray laminography [9].

Imaging Magnetic Skyrmions and Perpendicular Domains under Voltage Control in Metallic Multilayers and 2D Materials

X-ray Photoemission electron microscopy and Magnetic Force Microscopy permit to image strain-coupled ferroelectric and ferromagnetic domains with submicron spatial resolution, thus revealing novel magnetoelectric effects in multiferroic heterostructures. Here, we employ these complementary techniques to demonstrate voltage manipulation of skyrmions and perpendicular domains in magnetic multilayers and 2D materials overlying PMN-PT ferroelectric substrates. The resulting local magnetoelectric effects include transition from worm-like to skyrmion states, stripe domain displacement, nucleation/annihilation of isolated skyrmions and local magnetisation reversals.

Enhancement of Spin-Orbit Torque in Pt/Co/HfOx Heterostructures with Voltage-Controlled Oxygen Ion Migration

Spin-orbit torque (SOT) induced magnetization switching and SOT modulation have been intensely pursued and developed in recent years for efficient spintronic devices. Research has shown that the magnetic anisotropy of ferromagnet (FM) layers can be modified via inducing surface charges or orbital occupancy by interfacing with an oxide layer. Moreover, voltage-controlled oxygen migration can reduce the energy barrier for magnetization switching. The electric-field-driven interfacial oxygen mobility can affect both the SOT strength and sign. However, more research on the oxidation effects at the interfaces of the voltage-controlled magnetism in FM/oxide systems needs to be investigated. In this work, we report the enhancement of damping-like field and SOT efficiency of up to 60% and 23%, respectively, in perpendicularly magnetized Pt/Co/HfOx heterostructures over Pt/Co system at an optimal thickness of 2 nm HfOx. We further verify this enhanced SOT by applying voltages across the Pt/Co/HfOx structure, which allows the O2− migration from HfOx to the Co layer. By using voltage-controlled oxygen ion modulation of interfacial oxidation, we show that the gate voltage affects not only coercivity and anisotropy fields but also the SOT efficiency at room temperature. Our work promotes the SOT enhancement and modulation by oxidation effects for energy-efficient spintronic devices.
Simulation of Magnetoelectric Sensors in Inhomogeneous Magnetic Fields
Mohsen Samadi, Julius Schmalz, Mesut-Ömür Özden, Giuseppe Barbieri and Martina Geeken; Kiel University, Germany

Thin-film magnetoelectric (ME) sensors have the potential for room-temperature, magnetic-shielding-free measurement of a variety of biomagnetic fields from magnetocardiography over deep-brain stimulation signals (DBS) to magnetomyography [1, 2]. Approaches for modelling and simulation of the behavior of different types of magnetoelectric sensors are discussed. Besides the standard excitation with homogeneous magnetic fields, inhomogeneous magnetic-field excitation is considered as found in biomedical applications.

As a first sensor type, cantilever sensors based on strain-coupled thin-film magnetostrictive and piezoelectric layers and their response to inhomogeneous magnetic fields are reviewed [3]. A linear material model is used to calculate the small-signal behavior of sensors at the working point. The elastic, magnetic and electric properties are included in a coupled finite-element-method (FEM) simulation. Second, the magnetic-field response of electrically-modulated magnetoelectric cantilever sensors is investigated [4]. These sensors are electrically excited and operate in a mechanical mode with bending in the short cantilever direction (U-mode). They exhibit a high-quality factor and a promising limit of detection in the pico-Tesla range. It is demonstrated that for specific sensor dimensions and clamping structures a homogeneous response is obtained across the sensor. As a third sensor type, surface-acoustic-wave (SAW) magnetic-field sensors are considered. Our previous results [5] are extended to include microstructuring of the delay line to realize phononic crystals. It has been shown that resonances appear due to the acoustic-crystal structure [6, 7] and here their suitability to magnetic-field sensing is investigated. For all three types of sensors FEM simulation models and results are discussed.

In the next part of the talk, a multiscale simulation approach is introduced for a full system simulation including magnetoelectric sensors, a human head model and electric-dipole excitation to model deep-brain stimulation (DBS). Due to the thin layers in the sensor structure as well as the intricate structure of the brain with different types of tissues this is a highly challenging task. The head model is implemented based on MRI data [8]. Since mesh management is crucial for successfully running simulations, the three-dimensional model is extrapolated and morphological operations are used for filtering and smoothing. The trade-off between surface idealness and performance needs to be considered. The complexity is increased stepwise by starting with a simple three-shell model and proceeding to an increasing number of compartments and more detail. With the multiscale model we calculate electromagnetic field propagation through the head and the magnetoelectric sensor response. The combined calculations allow for the investigation of field concentration effects and inhomogeneous sensor excitation in a realistic geometry, secondary-effects due to conductivity, as well as field effects in the human head caused by the sensor system.

The ability to tune both magnetic and electric properties concomitantly in magnetoelectric (ME) composite heterostructures, consisting of magnetostriective and piezoelectric phases coupled through strain with orders-of-magnitude larger ME coupling coefficient than single-phase multiferroics due to additional functionalities and makes them very promising in many applications and devices [1,2]. This has generated a revived interest in multiferroics, and is projected to play a critical role in next-generation applications ranging from transducers, tunable inductors, gyrators, magnetic sensors to high-frequency filters and communication devices. In this talk we highlight different approaches to achieve maximum ME coupling in heterostructures of magnetostriective films deposited on domain-engineered relaxor ferroelectric single crystals. Much work has been done over the past decade to maximize the magnetoelectric (ME) coupling coefficient, $\alpha_{ME}$, the figure of merit for these composites that can be enhanced through deliberate choice of materials as well as carefully controlling the interface. For the piezoelectric phase, relaxor ferroelectrics have attracted much attention recently due to a piezoelectric coefficient an order of magnitude larger than conventional lead zirconate-titanate [3] especially in proximity to morphotropic phase boundary. In the ME heterostructures we demonstrated that by exploring the large ferroelectric phase transitional strain in piezoelectric substrate, the converse magnetoelectric coupling coefficient is expected to be greatly up to 4x enhanced as compared to linear piezoelectricity [4,5]. In this presentation, the impact of this enhancement will be examined and a path for utilization of this phenomenon in ME composites will be discussed. Magnetoelectric (ME) resonators are of significant interest for next generation near-dc magnetic field sensors, as the direct coupling of highly magnetostriective (FeCo- or FeGa-based alloys) and piezoelectric phases (AIN) enables high magnetic field sub-nT sensitivity with exceptionally low operational power requirements. This talk highlights several programs within the Materials Science & Technology Division at US Naval Research Laboratory focused on the investigation and understanding physics of these ferroic and multiferroic materials, and how current research presents another opportunity to advance acoustic transduction devices, magnetic sensors and electrically small antennas.

Voltage Control of Exchange Coupling: A Novel Way to Switch MRAM Devices Bhagwati Prasad1, Akash Surampalli1, Rajesh V. Chopdekar2, Alan Kalitsov2, Lei Wan2, Jordan Katine2, Derek Stewart2 and Tiffany Santos2; 1Indian Institute of Science, India; 2Western Digital Corporation, United States

Traditional memory devices based on spintronics leverage electric current to ingeniously regulate the direction and movement of electrons’ spin, albeit at the expense of high energy consumption and limited device durability [1, 2]. As a result, with the increasing demand for faster, smaller, and extremely energy-efficient electronic devices, the pursuit of magnetism controlled by voltage has notably intensified. This field offers the potential to create ultra-low-power, non-volatile memory solutions for future computing systems [3, 4].

In this context, we present our latest research on magnetism controlled by voltage via voltage-controlled exchange coupling (VCEC) [5, 6]. To explore the control of exchange coupling through an electric field, we have fabricated magnetic heterostructures with varying thicknesses of Ru and Ir spacer layers. In these layered structures, two ferromagnets (free and reference layers) possessing perpendicular magnetic anisotropy are separated by a non-magnetic Ru and Ir spacer layer. This separation creates an oscillatory interlayer exchange coupling (IEC) as the Ru or Ir layer's thickness varies, as predicted by the RKKY theory.

To quantify the VCEC effect, a bias field is applied across the MgO layer, and resistance-magnetic field loops are measured while a DC bias voltage is effect. This results in a visible gating effect in the minor loops of resistance-magnetic field plots, thus demonstrating the manipulation of exchange interactions between the free and reference layers via an applied electric field. In this way, we demonstrate modulation of the interlayer exchange coupling with the Ru and Ir spacer layers using non-ionic liquid gating such as MgO [6]. These findings provide a route for creating the resistive states of spintronic devices, thereby paving the way for the creation of a new generation of energy-efficient computing devices.

The rapid advancement of technology has generated significant requirements for electrical energy to power electronic devices. A pivotal aspect of this technological progress, for sensors, actuators, and memory devices, involves harnessing the spin of electrons in electronics, known as spintronics. However, a considerable portion of the electric power utilized in spintronics is dissipated as heat through the Joule effect (3–5% of the energy: thousands of millions of dollars annually). Consequently, there is a pressing need to explore novel approaches to develop energy-efficient devices, making it a prominent research topic within the realm of spintronics.

To address concerns regarding energy efficiency and the control of spin states, alternatives to the energy-consuming external magnetic field have been explored: the spin-polarized current injection. However, this approach still generates heat, negatively impacting the overall power efficiency of the device. In this scope, the utilization of applied voltages represents a promising strategy to reduce energy requirements. Materials with magnetoelectric (ME) properties have emerged as leading contenders for future spintronic advancements, as their magnetization and ferromagnetism can be controlled by an electric field.

By incorporating an additional magnetoelectric (ME) layer into the conventional three-layer spin-valve spintronic structure, it becomes possible to create...
electron microscopy (XMCD-PEEM). Additionally, micron-scale strain distribution in PMN-PT is characterized by X-ray microdiffraction and examined
memory and neuromorphic computing.

The fabricated SAW delay line shows a low insertion loss of ~ −10 dB at 2.87 GHz, which is excellent to control the ground st
system. In this work, we present a 2D finite element (FEM) model for a fabricated SAW delay line with S11 minima at 2.87 GHz and −10 dB insertion loss for NV center excitation. The consistency of S parameters between simulation and probing experiments makes the model prospective for SAW delay line design for chemical, biomedical, RF and quantum applications.

Methods

The transmission and receiving IDT A1 electrodes with a fundamental mode of ~2.87 GHz were patterned on bulk LiNbO3 substrate via laser lithography, e-beam lithography, e-beam metal evaporation and lift-off technique. The S parameters were measured by RF probes connected to a vector network analyzer. A 1:1 2D finite element model was built in COMSOL Multiphysics. The electrostatic module was combined with solid mechanics module to simulate piezoelectrically induced Rayleigh wave excited by SAW delay line under different attenuation conditions.

Results

The fabricated SAW delay line shows a low insertion loss of ∼10 dB at 2.87 GHz, which is excellent to control the ground states of NV centers. The simulated S parameters agree well with probe measurement. The displacement and electric field profile demonstrate a high transmission between IDT electrodes. The increased mechanical damping results in decreased Sxy magnitude and diminished modulation of the SAW resonance peak ("triple transit echo") caused by reflections between the IDTs near fundamental mode.

Highly Cyclable Voltage Control of Magnetism in Cobalt Ferrite Nanopillars for Memory and Neuromorphic Applications
Maireann A. de hora1, Aliona Nicolenco2, Monalisha Peda3, Bonan Zhu5, Shinbuhm Lee6, Zhuotong Sun1, Jordi Sort3 and Judith L. Driscoll1; 1University of California, Los Angeles; 2Leibniz Institute for Solid State and Materials Research, Germany; 3Air Force Research Laboratory, United States

Research in digital memory is growing with the increase in popularity of artificial intelligence, machine learning, Internet of Things, and Big Data. This in turn has caused an energy demand that has triggered innovation towards non-volatile memory technologies that do not require continuous power supply. Magnetic memory is a promising non-volatile technology for storing data, but conventional magnetic memory concepts use electrical current to control magnetic properties (i.e. through electromagnets or spin-torque effects) and this can lead to significant energy loss by heat dissipation. On the other hand, tuning the properties of magnetic materials by voltage-driven ion migration (magneto-ionic) gives potential for energy-efficient, non-volatile magnetic memory and neuromorphic computing.

Our study shows large changes in both the magnetic moment at saturation (ms) and coercivity (Hc), of 34% and 78%, respectively, in an array of CoFe2O4 (CFO) epitaxial nanopillar electrodes (~50 nm diameter, ~70 nm pitch, and 90 nm in height) with applied voltage of ~10 V in a liquid electrolyte cell. Furthermore, a magneto-ionic response faster than 3 s and endurance >2,000 cycles are demonstrated. The response time is faster than for other magneto-ionic films of similar thickness, and cyclability is around two orders of magnitude higher than for other oxygen magneto-ionic systems. Using a range of characterisation techniques, the magnetic switching is shown to arise from modulation of oxygen content in the CFO. Also, the highly cyclable, self-assembled nanopillar structures were demonstrated to emulate various synaptic behaviours, exhibiting non-volatile, multilevel magnetic states for analog computing and high-density storage. Overall, CFO nanopillar arrays offer potential to be used as interconnected synapses for advanced neuromorphic computing applications.
with respect to the results of the Fe-Ga magnetoelectric switching. The magnetic reorientation is found to be strongly correlated with the size, shape and crystallographic orientation of the microstructures. In the case of square-shaped structures, size dictates the degree of influence of the strain distribution on both the initialization of the ground state and on the dynamics of the magnetic reorientation during application of voltage. On the other hand, the case of the elliptical microstructures demonstrates the importance of the orientation of the long axis with respect to the crystallographic directions of the PMN-PT, which leads to completely different magnetic responses. This study demonstrates that engineering highly magnetostrictive epitaxial microdevices is possible. It further elucidates that voltage-induced actuation can be largely tuned to achieve the desired type of magnetic switching ranging from vortex circulation reversal, domain wall motion, to a large rotation of magnetization. Because of the outstanding properties of the investigated material system, the reported findings are expected to be of great interest for the realization of next-generation energy-efficient magnetic memory, sensing and actuation devices.

Hidden Order in Cr₂O₃ and α-Fe₂O₃ as a Predictor for (anti-)Magnetoelectricity
Xanthe H. Verbeek, Andrea Urru and Nicola Spaldin; ETH Zürich, Switzerland

With first-principles calculations of Cr₂O₃ and its iron-based analog, α-Fe₂O₃, we show that the different magnetoelectric effects in these materials result from the ordering of hidden magnetic multipoles [1]. Starting from the established connection between ferroically-ordered magnetic quadrupoles and the linear magnetoelectric effect in Cr₂O₃, we explore the presence of additional multipoles. We reveal for the first time anti-ferroically ordered magnetic multipoles in both Cr₂O₃ and isostructural α-Fe₂O₃, in which the global inversion symmetry is preserved by the different magnetic dipolar ordering. Using symmetry considerations, we can relate each of these multipoles and their ordering to linear, quadratic, and cubic (anti-) magnetoelectric effects, where in an anti-magnetoelectric effect the induced moments are ordered antiferromagnetically in the unit cell. We confirm the predicted induced moments using first-principles calculations, showing the lowest response in α-Fe₂O₃, a centrosymmetric magnetic material, to be a linear anti-magnetoelectric effect, revealing the presence of the magnetoelectric coupling despite the preserved global inversion symmetry. Our results demonstrate the existence of hidden magnetic multipoles leading to local magnetoelectric responses, even in centrosymmetric magnetic materials, and broaden the definition of magnetoelectric materials by including those showing such local magnetoelectric responses.

Transfer-doping of diamond has proven to be an attractive alternative to substitutional doping of diamond for the production of high-performance diamond electronic devices, such as Field Effect Transistors. The process, which relies in a low/negative electron affinity chemical termination of the diamond surface e.g. with hydrogen, combined with the application of a surface electron acceptor material of sufficiently high electron affinity, generates a high carrier density, shallow, sub-surface 2D hole gas that may be exploited as a conductive channel in several device applications. Significant progress has been made recently in the further development of transfer doping processes in diamond, virtually eliminating previous issues such as inherent temperature and atmospheric sensitivity and associated instability. Through engineering of surface acceptor materials, charge mobility in the diamond has also seen significant improvement, leading to significant reduction in material resistivity. Alternative chemical surface terminations of diamond have also more recently demonstrated additional routes for the production of high performance electronic devices. This presentation will attempt to provide an overview of these recent and exciting developments in the diamond electronic devices, and speculate on future directions and the potential impact of this accelerating area of research.

We fabricated 2DHG diamond MOSFETs on a (111) highly oriented polycrystalline 1-inch diamond substrate and confirmed that the devices correctly functioned as a FET. The area of the 1-inch substrate is about 55 times larger than that of conventional 3mm square substrate. In this work, we fabricated 220 devices on the 1-inch diamond substrate, and the yield rate was about 95 percent. We found that the yield rate on the 1-inch substrate tends to be much higher than that on the 3mm square substrate. Diamond has outstanding characteristics as a semiconductor, such as wide band gap (5.5 eV), high thermal conductivity (22 W/cmK), and high breakdown field (10 MV/cm). Therefore, diamond is expected to be applied to the next generation’s RF amplifier and power device. However, a problem in fabricating diamond devices is the low yield rate due to the small substrate size. In this work, we fabricated 2DHG diamond MOSFETs on the polycrystalline 1-inch diamond substrate, and we found that the yield rate was greatly improved.

The highly oriented (111) polycrystalline substrate was fabricated by Sumitomo Electric Industries, Ltd. All the devices on the 1-inch substrate are double-finger structure. Firstly, source and drain electrodes were deposited Ti/Pt/Au (20 nm/30 nm/90 nm). After H-termination and isolation, 200 nm of Al2O3 was deposited as the gate insulator. After that, 300 nm of Al was deposited as the gate electrode. 80 percent of all the devices have the gate length Lg = 5 μm and the others have Lg = 2 μm. There are 3 kinds of source/drain length Lsd, 10 μm, 15 μm, and 20 μm. Also, there are 3 kinds of total gate width Wgt, 1 mm, 2 mm, and 3 mm.

The highest maximum drain current density was obtained from the device of Lg = 2 μm, Lsd = 10 μm, and Wgt = 1 mm at Vgs = -40 V and Vds = -40 V, and the result was 151 mA/mm. For all the devices that correctly functioned as a FET, the drain current density was in the range of 100 mA/mm to 150 mA/mm. The decrease in current density was observed as the gate width expanded, but it is assumed that the effect of the grain boundary on the devices is not serious. About 95 percent of yield rate was achieved in this work, and the distribution of the devices that did not function were impartial on the 1-inch substrate. This is because, thanks to the substrate size, photoresists uniformly coated the whole substrate in the fabricating process.

In this work, we fabricated 2DHG diamond MOSFETs on a (111) highly oriented polycrystalline 1-inch diamond substrate and confirmed that the devices correctly functioned as a FET. The highest maximum drain current density was 151 mA/mm, and the yield rate of devices on the 1-inch substrate was greatly improved. Fabricating 2DHG diamond MOSFETs on polycrystalline 1-inch diamond substrate is possible and it contributes to the yield rate improvement.

The efficiency of power devices is critical nowadays for the rise of renewable energy. Wide-bandgap semiconductors, such as silicon carbide (SiC) and gallium nitride (GaN), have advantages over silicon due to their high breakdown electric field and high-temperature operation. However, p-channel wide-bandgap FETs have poor performance compared with their n-channel counterparts due to low hole mobility, which leads to a high ON resistance and high conduction loss. This has constrained the production of complementary circuits with integrated n-channel and p-channel transistors. Diamond is a wide-bandgap material that has a bulk intrinsic hole mobility very high respectively to SiC and GaN, which makes it promising for use in high-mobility p-channel transistors. Due to the high optical phonon frequency and high acoustic phonon velocity of diamond, the number of phonons that participate in carrier scattering is small. Having all the others wide band gap semiconductors characteristics like high electric field, high breakdown voltage and high thermal conductivity also makes diamond attractive for power applications.

Most diamond power metal–oxide–semiconductor field-effect transistors (MOSFETs) have been fabricated using H-terminated diamond surfaces (and afterwards the surface transfer doping) with their unique properties of two-dimensional hole gas (2DHG). The downside of this concept comes from the close proximity of the negatively charged surface acceptors with the 2DHG, the carrier mobility is limited by surface impurities, and increasing the carrier concentration dramatically decreases the hole mobility. Moreover, the negative charges cause a positive shift in the threshold voltage, leading to normally ON characteristics.

In this work we try to find an alternative by realizing p-type OH-terminated diamond surface, taking advantage of the fact that applying a negative potential to a MOS stack leads to an accumulation regime of holes on the diamond surface. However, this happens only if the Fermi level is not pinned due to interface states. Therefore, a good interface quality between diamond and oxide is needed. We realized p-type diamond with a boron concentration approximately 10^{17} atom/cm^2 and a thickness of 0.5 μm on (111) EDP substrate followed by a OH-termination using a wet vapour annealing[1]. We have then realized some metal–oxide–semiconductor capacitors (MOSCAP) on top of it and studied their behaviour. The frequency-dependent capacitance-voltage (C–V) characteristics were examined from depletion to accumulation regimes. The latter one was clearly observed with a very small leakage current. Moreover, we reached accumulation regime around 0V which can lead to realization of a MOSFET with
normally OFF characteristics with very high current in ON state, thanks to the 2DHG. With these promising results, we finally fabricate MOSFETs using the same procedure as MOSCAPs.

In the first part of this presentation, the method will be described in details. Then, the C-V characteristics will be reported and deeply analysed. Lastly, we will show and discuss the first results obtained regarding the MOSFETs and comparing them with finite element simulation as well.

Normally-Off Hydrogen-Terminated Diamond FET with High Temperature ALD Grown HfO2: Devansh Saraswat, Mohamadali Malakoutian, Kelly Woo and Srabanti Chowdhury; Stanford University, United States

Diamond is one of the best candidates for high-power, high-frequency applications due to desirable properties like high breakdown electric field (10 MV/cm), high carrier mobility (3800 cm²/V•s) for holes and 4500 cm²/V•s for electrons) and high saturation velocity (∼10⁵ cm/s) [1].

Due to the difficulty in doping by conventional methods, the two-dimensional hole gas (2DHG) layer below the hydrogen-terminated diamond surface has been widely explored for fabricating field effect transistors. Prior studies have reported sheet density in the range of 10^{11}-10^{13} cm^{-2} [2] and mobility of 50-200 cm²/V•s [3] for the 2DHG, including integrated CMOS operation at high temperatures [4]. For FET fabrication, it is essential to choose a dielectric that can minimize the gate leakage current as well as preserve the 2DHG in the channel. Various dielectrics such as Al₂O₃, ZrO₂, AlN and MoO₃ have been used as a gate dielectric for diamond HFETs. HfO₂ is a widely used high-k dielectric material due its superior dielectric properties, high breakdown field and large band offsets (ΔE−=2.92 eV and ΔE+=1.98 eV) with respect to H-terminated diamond [5]. In this work, Al₂O₃ and HfO₂ were compared as gate dielectric for HFETs. Normally off operation with two orders of higher current was achieved with high-temperature atomic layer deposition (ALD) grown HfO₂ in comparison with Al₂O₃ counterpart, as the gate dielectric.

For device fabrication, a (100) CVD-grown diamond substrate was used. The sample was first oxygen terminated by boiling in a 3:1 mixture of H₂SO₄ and HNO₃ at 200°C for 30 minutes. Then, hydrogen termination was performed in a microwave plasma CVD reactor at 850°C. This was followed by photolithography and oxygen plasma treatment for device isolation. Then, Ti/Pt/Au adhesion pads were deposited using e-beam evaporation. This was followed by gold deposition on hydrogen terminated regions to form the source and drain ohmic contacts. Subsequently, a 10 nm thick HfO₂ layer was deposited at 300°C using ALD. Then, Al₃O₅ gate metal contact with a gate length (L_G) of 1.5 μm was formed. The gate to drain distance (L_DS) varied from 1.75 μm to 3.25 μm. Finally, source and drain contacts were opened using a 6:1 buffered oxide etch (BOE) wet etch.

After device fabrication, DC output characteristics were measured using a probe station. A maximum drain output current of 2.05 mA/mm was achieved for a V GS=−4V. Gate leakage current ≤ 10⁻⁸ mA/mm and a current on/off ratio of 10⁷ were measured. A maximum transconductance (g_m) of 2.06 mS/mm was obtained at V GS=−2V. The threshold voltage was determined to be -1.2V, indicating a normally-off performance. In contrast, our Al₂O₃-based FETs showed poor performance which requires further investigation.

The normally-off behavior in this device is likely due to the decrease in the upward bend bending at the H-diamond surface. This is possibly a result of the desorption of acceptor species during the high-temperature ALD growth. Dielectrics grown at high temperatures are thermally more stable, making the device suitable for high-temperature applications. Further improvement in the device performance can be possible by exposing the substrate to a NO₂ gas environment and by using multiple dielectric layer stacks to improve the channel mobility. The current results show the potential of using high-temperature ALD grown HfO₂ for achieving normally-off behavior in diamond HFETs [6].

Two-Inch High Quality Diamond Heteroepitaxial Growth on Sapphire Seong-Woo Kim: Orbray Co, Ltd, Japan

Diamond semiconductors, owing to their superior properties compared to SiC and GaN, can be used to develop high-end applications, such as power devices, high frequency devices, quantum devices, and sensors. However, the inch-scaled diamond wafer is essential. In this study, Two-inch-diameter high-quality diamond (001) layers were grown on sapphire (11-20) A-plane misoriented substrate. Step-flow growth in diamond is realized thanks to misoriented substrate, and releases tensile strain in diamond layer. Consequently, even if microneedle technique [1] is not used, without breakage, diamond high-quality diamond (001) layers were grown on sapphire (11-20) A-plane misoriented substrate. Step-flow growth in diamond is realized thanks to misoriented substrate, and releases tensile strain in diamond layer.

In this study, results on 3 types of high-end applications will be discussed. One of them is the world largest diamond detector with the dimensions of 20 mm ‘ 20 mm ‘ 0.5 mm was fabricated from a 30 mm ‘ 30 mm heteroepitaxial diamond wafer. The device demonstrated a nuclide discrimination capability for 133Ba, 137Cs and 60Co based on the pulse-height difference. The electrode was used as a cathode to apply -500 V bias voltage. The anode on another side was connected to a charge sensitive preamplifier. The anode was maintained at ground potential. The output signal from the preamplifier was acquired with a digitizer. A digital trapezoidal filter was applied to the waveforms to obtain pulse height spectra.

Today’s environmental requirements for energy efficiency call for better management of electrical energy with minimum leakage at all levels: from DC phone chargers to power transmission via electrical vehicles. Wide bandgap (WBG) semiconductors are better suited for high-voltage and low-loss power devices than the traditional Si-based power devices. The most commonly used are SiC, GaN and diamond with bandgap values of 3.2 eV, 3.4 eV and 5.5 eV respectively. However, the challenge of producing these competitive materials economically and efficiently remains. For example, the fabrication of SiC substrates is very energy-intensive, since it is carried out at 2400°C, i.e. 1000°C higher than for Si. To cite another example, the size of diamond substrates today is no more than a few square millimeters, while 300 mm Si wafers are on the market, limiting the appeal of such a material.

The ability to transfer only a thin layer of high-quality WBG material on a substrate that offers either the advantage of being less expensive or the advantage of its own function (thermal, electrical or insulating…) is therefore very interesting. The Smart Cut™ process combines an ion implantation with a bonding step and allows to create a structure that otherwise could not be made using deposition techniques. Relatively new direct covenant bonding techniques now make it possible to relax the draconian characteristics imposed on surfaces and substrates to enable such bonding with materials renowned for their outstanding properties. This opens up new possibilities in terms of assembly. Significant improvements in electrical performance have been achieved by combining the advantages of a polycrystalline substrate with very low resistivity for their outstanding properties. This opens up new possibilities in terms of assembly.

Low-Temperature Direct Bonding of Diamond—Approach for Fabricating Low-Thermal-Resistance Widegap Devices Naoteru Shigekawa1, Ryo Kagawa1, Jianbo Liang1, Yasuo Shimizu2, Yutaka Ohno2 and Yasuyoshi Nagai2, Osaka Metropolitan University, Japan, ‘Tohoku University, Japan

Characteristics of semiconductor electron devices such as output powers are limited by their temperature rise due to Joule heating in operation (self-heating effects). Device structures with the lowest thermal resistance are, consequently, one of the most important topics in R&D for advanced devices, especially for devices with widegap semiconductors that handle high output powers with high frequencies. Diamond is assumed to be the ideal material as heat spreader because of its high thermal conductivity and excellent electrical properties. In this presentation, we describe results that we obtained by directly bonding of diamond to Si and GaN and discuss the future prospective of direct bonding of diamond. We used surface activated bonding (SAB) technologies, in which two wafers are bonded after removing native oxides on their surfaces by irradiating them with fast atom beams of Ar (surface activation process). In SAB, bonding process is completed without heating bonded wafers in most cases, i.e., junctions of semiconductors with different coefficients of thermal expansion (CTE) can be fabricated.

We bonded a high-pressure high-temperature (HPHT) diamond (001) wafer and a Si (100) wafer using SAB. We found that the diamond/Si junction withstood a 1000°C annealing in spite of a large difference in CTEs between diamond and Si. A high-resolution TEM observation revealed that a poly crystalline SiC intermediate layer was formed at the bonding interface after the annealing, which was assumed to play a role of reducing impacts of the difference in CTEs.

We prepared a GaN/diamond junction by bonding a GaN (0001) surface grown on Si (111) wafer to a diamond (001) wafer and removing the Si (111) wafer for the growth of nitride. We annealed the GaN/diamond junctions at temperatures up to 1000°C and found that the junctions were also tolerant against such a high-temperature annealing.

Recently we transferred an AlGaN/GaN epi layer to diamond using SAB and subsequently fabricated HEMTs. Ohmic contacts on nitride were formed by an annealing at 800°C after bonding to diamond. The temperature rise of the GaN-on-diamond HEMTs was found to be lower than that of on-Si HEMTs with the same nitride structure. The results imply that direct bonding of diamond is promising for fabricating low-thermal-resistance semiconductor devices, especially after transferring active device layers to diamond wafers.

Acknowledgement—This work was supported by the Feasibility study Program of New Energy and Industrial Technology Development Organization (NEDO) and JSPS KAKENHI. TEM samples were fabricated at The Oarai Center and at the Laboratory of Alpha-Ray Emitters in IMR under the Inter-University Cooperative Research in IMR of Tohoku University. The observation of the TEM samples was supported by Kyoto University Nano Technology Hub. AlGaN/GaN epi layers were grown and supplied by Air Water Inc.

Diamond has unique material properties well suited to be used at a broad range of quantum and electronic technologies. However, heterogeneous integration of
Diamond with other materials remains a challenge, mainly due to limited heteropitaxial growth of single-crystal diamond. Here, we discuss a directly bonded single-crystal diamond membrane technique that enables a wide variety of materials integration, including bonding diamond to silicon, fused silica, sapphire, thermal oxides, and lithium niobate. Our direct bonding process combines diamond overgrowth, membrane transfer, and dry surface functionalization, resulting in minimal contamination for high yield and scalable integration. We have demonstrated direct-bonded diamond membranes with thicknesses as thin as 10 nm, and observe a sub-nanometer interfacial region. We demonstrate the use case for integrating these direct-bonded membranes for high-quality nano-photonics, and total internal reflection fluorescence (TIRF) microscopy applications. The demonstrated process provides a key advance in the necessary toolkit needed to realize heterogeneous diamond-based hybrid systems for quantum and electronic technologies.

Diamond Integration on GaN HEMTs: Overcoming the Challenges for Device-Level Thermal Management
Mohamadali Malakoutian, Rohith Soman, Kelly Woo, Anna Kaspersovich, Jeongkyu Kim and Srabanti Chowdhury; Stanford University, United States

In the realm of higher frequency devices, where the gain is of utmost importance, the effective management of heat becomes crucial to maintain Power Added Efficiency (PAE) [1]. Ensuring efficient heat removal necessitates managing the thermal boundary resistance (TBR) between the heat source and the heat spreader, as well as establishing a low thermal resistance path to the heat sink [2]. The integration of diamond near the hot spot holds excellent potential due to its exceptional thermal properties. By incorporating diamond, heat can be effectively spread, thereby enhancing the heat transfer coefficient [3, 4]. The integration of diamond onto GaN HEMTs poses significant challenges, regardless of whether a diamond-first or device-first approach is employed.

In the diamond-first approach, the primary challenge lies in diamond surface roughness, which imposes a limitation on gate length <2 μm through lithography, non-uniformity in the diamond etching, and contacts/pads damage after diamond etching. To address this issue, we have implemented a polishing technique through ion-milling, achieving a surface smoothness of less than 10 nm RMS roughness before carrying out E-beam lithography, and developed a more selective etching process using O2/SF6 mixture in RIE. Additionally, a slanted etching technique was developed for rough diamond surfaces that starts with a 2 μm opening at the top and achieves a gate footprint of less than 100 nm, suitable for X- to W-band applications. In the device-first approach, two key challenges arise: gate dielectric leakage (2-10 mA/mm) and ohmic loss (Rsh=250 Ω∥). To overcome gate leakage, we have modified the gate metal stack from Au/Al to Mo and employed a low-temperature (LT) diamond growth technique at 350-400°C [5], effectively reducing the leakage to <1 μA/mm. As for ohmic loss, we have successfully tackled it by incorporating a thicker N+ regrown region and using a 400°C diamond growth temperature (Rsh=0.24 Ω∥, Rsh=225 Ω∥). These combined measures have proven to be effective solutions in mitigating gate dielectric leakage and reducing the ohmic loss for higher current capabilities – 1 A/mm.

We have successfully integrated LT diamond on GaN HEMTs using the above-mentioned approaches. By implementing the all-around diamond scheme and connecting the top diamond to the heat sink through diamond vias, the channel thermal resistance (Rch) was reduced by 34% from 6.9 to 4.6 K.mm/W, realizing a higher heat transfer coefficient from the channel. This integration resulted in no dispersion (pulsed I-V at 400 ns gate pulse) and lower channel temperature (Tch) compared to the case without diamond. With low TBR (3-5 mK/GW) and high thermal conductivity (TC:300-1000 W/m.K depending on the grain size and thickness), the average and peak Tch dropped by 35% (200 to 130°C at 25 W/mm, measured by L-V thermometry) and over 50% (120°C at 20 W/mm, measured by thermoreflectance imaging), respectively [6]. Our technique not only addresses thermal management challenges for GaN-based power amplifiers but is also compatible with other technologies such as InP, GaOx, SiC, and Si. Proper thermal management can enhance the device’s reliability and lifetime while providing a higher power at higher frequencies.

Diamond Material Pave the way for the Next Generation of Neuronal Implants

Lionel Rousseau, Emmanuel S. Scorsone, Gaëlle Lissorgues, Patrick Poulilchot, Olivier François, Blaise Yvert, Clement Hebert, Serge Picaud and Julie Zhang; 1Université Gustave Eiffel - ESIEE Paris.ESYCOM UMR 9007, France; 2Université Paris-Saclay, CEA, France; 3GIn, France; 4Sorbonne Université / INSERM UMR_S968/ CNRS UMR 7210, France

Brain Computer Interface (BCI) offers a way to restore neuronal dysfunction due to degenerative diseases or accidents. Thus, it becomes possible to restore vision with retinal implant or to offer a way for tetraplegic to control a robot by thinking with electrodes implanted in the cortex and recently to do a digital bridge for paraplegic patient to stand-up and walk. But today these systems are limited by their insufficient stability. Neuronal implants require to operation during 10 years of lifetime, and collect data 24/7 and for 10 hours or more every day. But after several months of implantation, some modification can appear such as swelling of the passivation polymers thus inducing current leakage, or degradation of the electrode material.

With the last development of diamond growth process, it is now possible to integrate this material in micro and nano fabrication process as a standard material to produce sensors or neuronal implants. Diamond properties are very attractive for medical application. Diamond is a biocompatible material and it has no native oxide, so there is no degradation when the structure is placed in water or harsh environment. Diamond is also a high density material, so there are no species that can migrate inside diamond. In addition, conductive diamond, boron doped diamond (BBD) has a wide electrochemistry window that allow to give possibility to inject more current compare to classical metallic electrode.

We have developed a specific process to achieve a very thin full diamond implant combine conductive diamond for the electrode and intrinsic diamond as protective layer. With this structure we take advantages and strength of conductive and intrinsic diamond to achieve an hermetic implant. To validate our full diamond implant, we have done electrical characterizations impedance Spectroscopy and Cyclic Voltammetry. In-vivo experiments have been conducted on several set-ups to record Visual Evoked Potential and Auditory Evoked Potential, assessing the proper functionality of our implants.

To demonstrate their stability, we developed an accelerate long life set-up. The devices placed on PBS solution at a temperature of 77°C. Follow Arrhenius law, at this temperature acceleration factor is around 16, that means for one month in solution, is equivalent to one year and 4 months. This set up is composed of hotplate, and aluminum piece where we placed a hermetic containers with Phosphate Bovine Solution (PBS) and samples. To control integrity of samples an impedance meter is used to record periodically impedance. This type of set-up is also answer at ethical issue and reduce number of animal experimentation.

With this ageing setup, we compared InterDigited Electrodes (IDE) composed of metallic IDE covered with either intrinsic diamond or polymer like SU8. After 29 weeks (around 9 years), diamond is more stable with a variation of 3% at 1 kHz (frequency of interest for neurons recording), compared to SU8 with 50% of variation.

Therefore, intrinsic and doped diamond are very attractive for the next generation of neuronal implants.

Superconducting Diamond Microwave Resonators
Georgina M. Klemencic, Jerome Cuenca, Thomas Brien, Soumen Mandal, Scott Manifold, Simon Doyle, Adrian Porch and Oliver A. Williams; Cardiff University, United Kingdom

Superconducting microwave resonators form the foundation of an increasing number of superconducting technologies for quantum information processing and radiation detection. A specific example is the Kinetic Inductance Detector (KID), which uses a high-Q resonator as a photon detector for purposes ranging from astronomy to security.

In a KID, radiation is detected when an incoming photon breaks a Cooper pair which decreases the frequency of the microwave resonator. The relative size of this shift increases with the penetration depth of the material. Noise in the form of random fluctuations in the resonant frequency can occur due to two-level systems (TLSs), generally ascribed to dangling bonds in amorphous oxides that form at the surface of metallic superconductors. For practical applications, optimising for both sensitivity and signal-to-noise ratio, the superconducting material used for a microwave resonator should ideally have a high penetration depth and a low population of TLSs.

Here, I will present our results on a detailed characterisation of a λ/2 microwave resonator with a fundamental frequency of 409 MHz at 300 mK patterned from boron-doped nanocrystalline diamond (BNCD). We compare the observed resonant frequency to simulations based on the device geometry alone and show that the frequency is reduced by more than half, indicating a very large penetration depth enabled by the granularity of the material. I will also present early measurements of the effect of noise on this resonator and make a comparison to a single crystal equivalent device.

Our data show that BNCD is a good candidate for fabricating microwave resonators requiring a high kinetic inductance fraction. Knowledge of the penetration depth of a material is also vital for the design of low-frequency superconducting devices, including SQUIDs. Our results, therefore, pave the way for more complex superconducting circuits based on BNCD.

References
Josephson junctions (JJs) are weak junctions between two superconductors and have been applied to various devices such as transmon qubits and superconducting quantum interference devices (SQUIDs). SQUIDs are extremely sensitive magnetic sensors. Typical materials for JJs, such as Nb and Al, are weak against oxidation and abrasion. In contrast, superconducting boron (B)-doped diamond has high resistance to oxidation and abrasion. So, it is expected to be applied to robust and highly resistant to degradation superconducting devices.

The first SQUID using superconducting B-doped diamond was reported by S. Mandal [1]. This SQUID using nanocrystalline diamond consists of JJs with 250 nm to 100 nm linewidth weak links. The operating temperature was 400 mK at low magnetic field and 40 mK at high magnetic field, and the maximum voltage modulations ($V_{pp}$) to magnetic field, which is a parameter related to magnetic sensitivity, was 0.35 μV. While the first SQUID using single-crystalline diamond was constructed by JJs with a step edge structure [2]. Operating temperature and $V_{pp}$ of up to 2.6K and 1.1 μV were reported for this type SQUIDs. Single-crystalline superconducting diamonds have different superconducting transition temperatures $T_c$ depending on the growth orientation [3]. (001) B-doped diamond with low $T_c$ (~4.2 K) grows on the step with 230 nm slope 50° produced by etching and regrowth of undoped diamond, and the discontinuity with the heavily boron doped (B:8 x 10^{21} cm^{-3}) (111) layer with high $T_c$ (10 K) forms the step edge JJ. For operating temperatures above the liquid He temperature (4.2 K), it was necessary to fabricate JJs and SQUIDs using only the heavily B-doped (111) layer. SQUIDs consisting of trench-type JJs with the boundaries of discontinuous (111) sectors on trenches formed by focused ion beam (FIB) operated at 10 K and the maximum $V_{pp}$ was 4.0 μV [4]. However, the trench shape formed by FIB was unstable, and it was difficult to obtain uniform JJs characteristics. Therefore, JJs with a single-step structure, consisting of a discontinuity in the heavily B-doped (111) layer deposited on top of a minute step of about 40 nm formed by reactive ion etching (RIE), has been proposed [4,5]. SQUID with single-step JJs is simple and highly reproducible, and operation at 9.5 K has been achieved. However, the $V_{pp}$ of single-crystal diamond SQUIDs was still small compared to SQUIDs made of other materials. Therefore, we have tried to improve $V_{pp}$ by increasing the normal resistance of JJs through $T_c$ width miniaturization. For SQUIDs with single-step JJs, $V_{pp}$ increased significantly from 1.4 μV to 47.7 μV by miniaturizing JJs width from 15 μm to 5 μm. In the JJs miniaturized down to less than 5 μm, however, the etching damage became prominent, and $V_{pp}$ could no longer be expected to improve with this type of miniaturization.

In this study, we propose a new JJ structure, the ridge conduction structure, which is unaffected by etching damage. In ridge conduction structure JJs, first a narrow ridge structure is formed on the undoped substrate by RIE, and then the heavily B-doped diamond has been grown along the ridge. JJs with a 40 nm step as in single-step JJs are formed on top of the ridge structure. The flow path of superconducting current can be restricted on the ridgelines of (111) surface, because growth sectors different from (111) sector show low $T_c$ superconducting on sidewalls without etching the B-doped layer. As a result, we confirmed the operation of JJs and SQUIDs with a minimum JJs width of 3 μm using this structure. Also, we confirmed that the ridge structure conduction reduces etching damage by reducing the residual resistance at 300 nm nanobridges with this structure.
structures, including photonic crystals, ring resonators, and disk resonators, have been successfully fabricated to date. Cavity-quality color centers in diamond with well-developed integrated photonics using hybrid integration techniques such as transfer printing provides a powerful route toward large-scale and multifunctional quantum devices. However, the existing etching technology for diamond photonics is inherently not compatible with reported hybrid integration approaches. For example, the bottom of a diamond nanostructure fabricated using angled etching is a triangular shape that makes it difficult to place on other substrates using conventional pick-and-place techniques. Therefore, it is significant to develop hybrid integration techniques with high yields for scalable diamond quantum photonics, irrespective of the sample structure.

In this work, we propose "pick-flip-and-place" transfer printing for the hybrid integration of a diamond NV triangular nanobeam on chip in a deterministic manner. This approach provides a flat diamond-chip interface and allows for the integration of NV centers on chip with a near-unitsy success rate, irrespective of the width and shape of the diamond nanostructures. In experiment, we demonstrate that an integrated diamond nanobeam containing an ensemble of NV centers can function as a nanoscale quantum sensor. We believe that the proposed approach paves the way for the realization of scalable diamond quantum photonics assisted by cutting-edge integrated photonic technologies. We describe the basic procedure for the proposed nanofabrication and hybrid integration processes based on transfer printing. First, triangular nanobeam containing NV centers with high density (300 ppm) were prepared via vertical dry etching of diamond substrate, followed by a diamond undercut process based on angled etching. We then used transfer printing to select a suitable diamond nanostructure from the processed diamond substrate using a polymethylsiloxane (PDMS) film with weak adhesion. This "weak" PDMS was flipped to lift off the nanostructure from the flipped film using a PDMS film with strong adhesion. This process allows for a flat interface between the diamond nanostructures and photonic chip, which is necessary for high-yield integration. Finally, the transferred diamond nanobeam was integrated by slowly peeling off the film onto an SiO2 substrate, which is a common low-reflective-index material in integrated photonics for efficient light confinement in a waveguide. It is notable that we can perform hybrid integration irrespective of device structure and target materials by using the proposed "pick-flip-and-place" integration approach, enabling us to combine diamond quantum photonics and state-of-the-art photonic integration technology.

To experimentally show that the fabricated device could function as a nanoscale quantum sensor, we performed optically detected magnetic resonance (ODMR) measurements on integrated NV centers. We confirmed an ODMR dip at a microwave frequency of 2.88 GHz with an ODMR contrast of ~0.006 and the width of 7.8 MHz, which is comparable to those measured for bulk diamond. Therefore, we, for the first time, succeeded in the hybrid integration of a diamond nanobeam with an ensemble of NV centers on a chip for quantum sensing. The proposed approach based on transfer printing provides a deterministic route toward a scalable combination of diamond quantum photonics and cutting-edge integrated photonics technologies.
Defects in diamond, such as nitrogen-vacancy (NV) centers and substitutional nitrogen (P1 centers), are particularly promising solid-state platforms to explore. However, the ability to controllably create coherent, two-dimensional spin systems and characterize their properties, such as density, depth confinement, and coherence has been an outstanding materials challenge. We present a refined approach to engineer dense (> 1 ppm*nm), 2D nitrogen and NV layers in both (100) and (111) diamond using delta-doping during plasma-enhanced chemical vapor deposition (PECVD) epitaxial growth. We employ both traditional materials techniques, e.g., secondary ion mass spectrometry (SIMS), alongside NV spin decoherence-based measurements to characterize the density and dimensionality of the P1 and NV layers. We present depth confinement of the spin layer down to ~ 4 nm, high (up to 0.74) ratios of NV to P1 centers, and reproducibly long NV coherence times which are dominated by dipolar interactions between the engineered P1 and NV spin baths. Altogether, the results of our joint materials and qubit-based approach are key elements in the engineering of solid-state-spin systems for the next generation of quantum technologies.\textsuperscript{1,2}

Photonics of the SnV Center in Diamond

Philipp Fuchs, Soniya Nuchikat, Jan Fair, Johannes Goerlitz, Michael Kieschnick, Jan Meijer and Christoph Becher; \textsuperscript{1}Universität des Saarlandes, Germany; \textsuperscript{2}Universität Leipzig, Germany

For many applications in the field of quantum information processing stationary qubits are required, providing long-lived spin coherence and suitable level schemes for coherent control and efficient optical read out. Color centers in diamond, more specifically the group-IV-vacancy centers, have emerged as promising candidates among solid state qubits. They exhibit favorable properties such as individually addressable spins with long coherence times and bright emission of single, close to transform limited photons. Recent experiments have shown that the negatively charged tin-vacancy center (SnV\textsuperscript{−}) combines long spin coherence times at conveniently achievable cryogenic temperatures (~1K) [2,3] with truly lifetime-limited transition linewidths down to 20 MHz [1].

However, exploiting these properties requires active stabilization of the charge state, as the SnV center upon resonant laser illumination can be easily ionized to its double negative charge state (SnV\textsuperscript{2−}) which is optically inactive [3]. To prevent ionization, illumination with a second light field in the blue spectral range is required. We find that the charge stabilization requires the presence of additional defects in the vicinity of the SnV center such as divacancies [3] in the bulk or sp\textsuperscript{2} defects on the surface [4].

Here, we propose a simple rate equation model for the SnV center photophysics that includes this ionization process. We apply the model to an extensive set of measurements on different SnV centers, along with a thorough characterization of the efficiency of our measurement setup. We conclude that a charge-stabilized SnV\textsuperscript{−} center is a nearly ideal single photon source in terms of quantum efficiency, since we can describe any reduced photon rate by ionization to the optically inactive SnV\textsuperscript{2−} charge state without assuming other non-radiative decay channels. We further discuss the occurrence of fluctuating background emission, its suppression via thermal oxidation in air atmosphere and the role of surface defects in the charge transition cycle.

Disposable Electrochemical Biosensor for Ultrasonic Detection of Salivary Cortisol on a Non-Covalently Modified Laser-Induced Graphene Surface for Stress Monitoring

Atul Sharma, Alia Wolff, Ayanna Thomas and Sameer R. Sonkusale; Tufts University, United States

Monitoring stress indicators (such as cortisol) is crucial for understanding and managing the root cause of several cognitive, neurological, cardiovascular and endocrinological diseases. Cortisol negatively affects the regulation of various physiological processes such as carbohydrate metabolism and blood glucose levels. Long-term stress can disrupt homeostasis in the cardiovascular, renal, skeletal, and endocrine systems, leading to the development of chronic diseases [1,2]. Because of its central role, continuous monitoring of cortisol levels in the human body is critical for health and wellness. Current diagnostic techniques are complex and performed at centralized facilities by qualified specialists rather than at the site of therapy, which is critical for real-time monitoring. Electrochemical biosensors based on graphene's conductivity and flexibility are appealing in such contexts. Towards the goal of routine stress-level monitoring, this work realizes the design and development of an ultrasonic and disposable immunosensor based on vertically aligned laser-induced graphene (LIG) electrodes as a transducer surface for non-invasive salivary cortisol monitoring via differential pulse voltammetry (DPV) signal transduction mechanism. The LIG electrode was used due to its wide scalability, high electrochemical stability, increased number of reaction sites, efficient electrical conduction owing to the increased surface area and structurally more uniform alignment of the graphene layer conductivity, and low cost [3]. The LIG electrodes were fabricated using a laser ablation technique (in-house). Before use, the surface of the electrode was cleaned by cyclic voltammetry in 0.50 M sulphuric acid containing 0.10 M KCI as electrolyte. Later, the LIG electrode surface was chemically functionalized with a self-assembled monolayer of pyrene-NHS (1-Pyrenebutyric acid N-hydroxy succinimide) ester incorporating an NHS-activated functional group for the receptor (antibody) immobilization. Furthermore, a monoclonal antibody to salivary cortisol (mAb) was incubated on the Pyr-NHS-LIG electrode surface and
immobilized via peptide bond formation between the carboxyl terminal of the crosslinker and the amine terminal of the antibody. This step is followed by electrode passivation to incorporate an antifouling layer. LIGs structure and electrical conductivity were preserved by using the non-covalent functionalization of Pyr-NHS ester. Cortisol complexation with immobilized mAb-Cort resulted in ferri/ferro redox electrochemistry-mediated measurement. Under optimum experimental settings, the immunosensor performance exhibited a dynamic working range from 100 fgmL^{-1} to 10.0 ngmL^{-1} (R^2 = 0.9982) with a detection limit of 10.0 fgmL^{-1} for cortisol (n=3). The developed immunosensor was successfully deployed to assay human salivary cortisol and showed a strong correlation with established laboratory methods (e.g., ELISA). This offers great promise for point of care monitoring of diseases.

**Investigation of Intracellular Thermogenesis Dynamics using Mitochondria-Targeted Nanodiamond Quantum Thermometry Yoobeen Lee1, Kiho Kim2, Dohun Kim2 and Jin Seok Lee3; Hanyang University, Korea (the Republic of); 3Seoul National University, Korea (the Republic of)**

Intracellular thermometry techniques provide valuable information into biological processes by detecting temperature variations within specific organelles under different physiological conditions. However, miniaturizing biocompatible thermometers to submicrometer sizes and attaching them to organelles pose significant challenges. In this study, we present a novel approach utilizing organelle-targeting nanodiamond quantum thermometry, using nitrogen-vacancy (NV) color centers, to monitor temperature changes during ATP generation within living human skin fibroblast cells. To enable this monitoring, we developed a microscopy system that integrates a coplanar waveguide-incubating chamber and a real-time particle tracking system, facilitating the tracking of nanodiamonds within cells while simultaneously measuring temperature. Using this system, we induced temperature rise based on the thermogenic response by inhibiting ATP synthesis, and measured the resulting changes in temperature within mitochondria, nucleus, and membrane. Our technique can achieve spatially resolved temperature measurements related to mitochondrial thermodynamic and gain insights into the distinct thermodynamic properties in specific organelles within cells.

**Homoeptaxial Diamond Growth Initiation on Smooth CMP Surfaces at Various Mis-Cut Angles**

S M Asaduzzaman and Timothy A. Grotjohn; Michigan State University, United States

Homoeptaxial diamond growth by microwave plasma-assisted CVD is used to grow both doped and intrinsic epilayers of diamond for electronic and quantum applications. Often when different doping types or concentrations are desired, the deposition is done in different diamond deposition systems due to avoiding doping memory effects in the deposition system. This requires that the growth process be re-initiated when the sample is moved to a different deposition system. The initiation of the growth process has been shown to often have defects at the growth initiation boundary as evidenced by optical microscopy, photoluminescence and/or cathodoluminescence. This study aims to investigate the growth process at the initiation of the diamond deposition to improve the boundary between different doped epilayers. An objective in many applications is to have abrupt junction between diamond doped with different concentrations or types.

Experiments were performed on the growth initiation on single crystal diamond substrates with various mis-cut angles from the (001) surface. The mis-cut angle was varied from 0 to 4 degrees as determined by X-ray diffraction measurements. To prepare the smooth diamond surface before growth the substrates were chemical mechanical polishing (CMP) polished to achieve a surface roughness of less than 0.3 nm RA. For a concentration of 0.002 wt% of nanodiamonds in the fluorescent spots. Different concentrations of nanodiamonds were tested, and it was observed that concentrations above 0.5 wt% of nanodiamonds in the nanodiamonds are located using laser scanning microscopy (LSM), and a homemade confocal fluorescence setup is used to map and measure the spectra of the fluorescent spots. Different concentrations of nanodiamonds were tested, and it was observed that concentrations above 0.5 wt% of nanodiamonds in the nanodiamonds. The NV-color center in diamond is a fluorescent defect that shows great potential for quantum information technologies. It acts as a single-photon emitter at room temperature, offers optical spin state preparation and readout capabilities, and exhibits long coherence time and photostability. Integration of these emitters into photonic structures is essential for various applications and can be achieved through the use of nanodiamonds as a platform. Nanodiamonds enable the incorporation of these quantum emitters into a wide variety of host materials and structures. This work focuses on the fabrication of polymeric cylindrical microresonators embedded with NV color centers using the two-photon polymerization (2PP) technique on a nanodiamond-doped photoresist. The fabricated resonators are 50 µm tall, with radii ranging from 30 µm to 15 µm, and the average size of the nanodiamonds is 40 nm. The positions of the nanodiamonds are located using laser scanning microscopy (LSM), and a homemade confocal fluorescence setup is used to map and measure the spectra of the fluorescent spots. Different concentrations of nanodiamonds were tested, and it was observed that concentrations above 0.5 wt% of nanodiamonds in the nanodiamonds. Fabrication was achieved for concentrations ranging from 0.1 wt% to 0.01 wt%, resulting in the identification of multiple fluorescent spots in the structures. However, the quality factors of the resonators were in the range of 10^2 to 10^3. For a concentration of 0.002
defects in diamond. Resonantly and with high probability, making our systems attractive spin-photon interfaces - an important step towards quantum networks based on spin quantum memory. In conclusion, we propose two different approaches to manipulate coherently spin defects and to generate coherent single photons membranes. These structures can be readily integrated in optical microcavities, making them a promising spin-photon interface and an ideal host for a even for diamond structures with low surface-to-volume ratios [4]. We present the method by creating single SiV0 centres in 0.5-3 μm thin diamond measure resonance fluorescence from an NV for the first time without relying on time-bin filtering and extract an NV linewidth of 159 MHz. In two-photon problems. The coupling of a solid-state spin to a microcavity acts on its radiative lifetime via the Purcell effect, on its branching ratio via the cavity coupling and it efficiently funnels the coherent photons out of the diamond [1]. We present an improved NV creation protocol, carbon implantation post-fabrication, which yields to NV centers with excellent optical coherence even in membranes thinner than 2 μm, with over 50% of the emitters showing optical linewidths below 150 MHz [2]. We then embedded one of these diamond membranes (1.6 μm thick) in an open Fabry-Perot optical microcavity. The ZPL count rates are as high as 140 kcts/s under off-resonant excitation, exceeding the state-of-the-art achieved for photonic interfaces based on solid-immersion lenses (SILs). The high photonic flux is achieved through a net Purcell enhancement of 1.8, increasing the fraction of ZPL photons from 3% to 44.7%, an improvement by a factor of 17.5 compared to the NV Debye-Waller factor of 2.55%. By efficient suppression of the resonant excitation, we measure resonance fluorescence from an NV for the first time without relying on time-bin filtering and extract an NV linewidth of 159 MHz. In two-photon protocols for spin-spin entanglement, our platform would increase the entanglement success probability by more than an order of magnitude, and by more than two orders of magnitude with feasible system improvements.

Our versatile cavity design enables us to use any optically-active spin, which ideally combines excellent optical and long spin coherences. To this regard, the neutral charge state of the Silicon-Vacancy centre emerged as a promising defect in diamond and it exhibits cardinal properties required from an optically active solid-state spin such as long spin coherence and stable, strong optical transitions thanks to its high Debye-Waller factor of and its inversion symmetry which makes it insensitive to electric field noise. While the isolation and stabilization of the neutral SiV charge state has recently been made possible using Boron doping, the method is technologically challenging as it requires careful fine-tuning of the B concentration [3]. Using a versatile approach based on hydrogen surface termination, we demonstrate that the charge state of the SiV can be switched between SiV- and SiV0 in a reliable way, even for diamond structures with low surface-to-volume ratios [4]. We present the method by creating single SiV0 centres in 0.5-3 um thin diamond membranes. These structures can be readily integrated in optical microcavities, making them a promising spin-photon interface and an ideal host for a quantum memory. In conclusion, we propose two different approaches to manipulate coherently spin defects and to generate coherent single photons resonantly and with high probability, making our systems attractive spin-photon interfaces - an important step towards quantum networks based on spin defects in diamond.

Laser writing with pulses of duration less than a picosecond presents a diverse platform for the functionalisation of diamond, with a range of different modifications regimes for internal structuring beneath the diamond surface. The laser is tightly focused beneath the surface where non-linear absorption leads to a perturbation of the diamond structure on a scale less than a micrometre, without any damage to the surrounding material or surface. At higher laser pulse energy, the light-matter interaction breaks down the diamond to create a graphic phase. At lower laser pulse energy, a finer process is accessible which can yield a vacancy ensemble, without breakdown of the diamond lattice. These processing regimes are applied for the fabrication of a range of devices, ranging from detectors for harsh environments, to quantum technology and security inscription within gemstones.

We focus this talk on our new results for laser written vias passing through diamond, and the effects on the crystal structure. Surprisingly, increasing the laser dose delivered to the sample causes a transition from a regime in which the written structures display ohmic conductivity into a regime which in which they are insulating in nature. We show that a combination of these regimes can be achieved with laser over-writing to give asymmetric conduction characteristics for the vias. A high-resolution structural characterisation of the laser written features by transmission electron microscopy reveals a diverse range of carbon nanostructures embedded within the diamond, and can be used to explain some of these phenomenon.

This talk presents a method for fabricating nanofluidic devices through the direct femtosecond laser writing of arbitrary long nanochannels between nanocrystalline diamond (NCD) films and glass substrates. Laser writing transforms a portion of the sample into a nanostrut, and the nanostrut is surrounded by two nanochannels generated by film delamination. For an NCD film with an as-deposited thickness of 300 nm, the mean height and the width of a nanochannel made in this way are on the order of 30 nm and 2 μm, respectively, and are tunable to a certain extent by laser pulse energy. Experiments indicate that a nanostrand consists of NCD, non-diamond carbon, and glass particles, which might be mixed with carbon due to laser ablation. It is found that the expansion of the sample material shapes a nanostrut and causes delamination and nanochannel formation. Such an expansion happens, for example, during the transformation of diamond to carbon of other forms [3]. Since the pulse energy needed to ablate the bare glass substrate is much greater than those used for nanochannel writing, one can deduce that nanostrand formation is initiated in the NCD film near the film–substrate interface. The origin of this phenomenon might be the presence of low-quality NCD at that location, which is bound to absorb more light than high-quality NCD [4]. By fabricating a nanofluidic device and performing simulations, it is shown that the nanochannels fill with water through capillary action.

NCD is an appealing material for applications due to its biocompatible, chemical, mechanical, electrical, optical, and quantum properties. Low-cost diamond films can be achieved by plasma-assisted chemical vapor deposition with methane gas diluted in molecular hydrogen as a precursor mixture. With this deposition technique, NCD films are commonly synthesized on substrates seeded with nanodiamonds [5]. NCD can also be doped to make it electrically conductive, paving the way for various applications [6]. Being inexpensive, transparent, and chemically inert, glass is a natural choice for this deposition technique, NCD films are commonly synthesized on substrates seeded with nanodiamonds [5]. The integration of devices for applications in photonics and quantum information technologies requires the development of platforms combining basic elements, such as resonators and waveguides. One promising solid-state optically active systems currently studied for such applications is the nitrogen-vacancy (NV) center in diamond, which is usually produced by irradiating diamond with beams of electrons or nitrogen ions. NV centers can be optically initialized and read out, present long coherence times at room temperature and allows creating protocols to manipulate its spin-state by combining optical and magnetic methods. Furthermore, NV centers can also be used as quantum sensors to detect temperature and magnetic and electric fields. The controlled production and placement of NV centers in photonic structures is of high relevance to engineer devices. In this direction, this work presents results obtained from our efforts to use of fs-laser pulses to generate active and spatially localized NV centers in CVD diamond, as well as the fabrication of polymeric optical microcavities, via two-photon polymerization, incorporated with nanodiamonds containing NV centers. Upon excitation of diamond using 150-fs pulses from a Ti:sapphire laser at 775 nm, with a repetition rate of 1 kHz, we have determined that active defects, with the least damage to the surface, can be generated using pulse fluence in the range of 11 – 34 mJ/cm², as observed by the typical fluorescent emission of NV center. For fluences higher than 34 mJ/cm² the damage on the diamond’s surface started to get too severe, also resulting in lower emission. Our results also revealed that the density of NV centers grows with the number of fs-pulses. The generation process, however, is stochastic. Furthermore, fs-pulse at ~800 nm (86 MHz repetition rate) were used to fabricate, via the two-photon polymerization (2PP), cylindrical resonators incorporated with nanodiamonds presenting centers. Even though the cavity quality factor (Q) decreases with the amount of nanodiamonds, for a cavity with 0.01% of nanodiamonds, Q ~ 10⁵ is achieved. More interestingly, we were able to transform specific nanodiamonds, with Q of about 10⁵. The authors acknowledge FAPESP (grants 2018/11283-7, 2020/08715-2, 2019/27471-0, 2015/17058-7, 2013/07276-1, and 2009/54035-4), Air Force Office of Scientific Research, CNPq, and CAPES for financial support.

Enhanced Photophysical Transition Dynamics of NV Centers in Nanodiamond on Structured Metamaterial Platforms Peng Zheng and Ishan Barman; Johns Hopkins University, United States

While promising as photostable solid-state quantum emitters for biological sensing and imaging applications, nitrogen-vacancy (NV) centers in nanodiamond are limited by their intrinsically inefficient photon generation and extraction from excited NV centers, which restrict the achievable sensitivity and temporal resolution. To overcome these challenges, judiciously structured metamaterials are developed, which can support broadband Purcell enhancement and spatially extended local plasmonic fields for effective plasmon-NV centers coupling. With fluorescence lifetime imaging microscopy characterizations, a simultaneous amplification to the photophysical transition dynamics and emission intensity of NV centers are observed. We envision that the structured metamaterials pave the way for developing superior biological sensing platforms with enhanced sensitivity as well as augmented spatial and temporal resolution.

High-Efficiency Tracible Nanodiamond-Mediated Gene Editing System Development and Application Chia-Ching Chang1,2, Shih-Hwa Chiou1,2 and Yontha Tseng3,1 National Yang Ming Chiao Tung University, Taiwan; 1Academia Sinica, Taiwan; 2Taipei Veterans General Hospital, Taiwan; 3National Cheng Kung University, Taiwan

Nanodiamonds (NDs) are biocompatible crystalline carbon nanomaterials for biomolecules or small molecules delivery into the target cells especially for NDs smaller than 5 nm. By conjugating NDs with red fluorescence protein, mCherry, the distribution of these nano-fluorescence nanoparticles (ND-mCherry) can be traced in the cells or tissues. Moreover, by conjugating linear DNA fragments with all the components of the CRISPR/Cas9 genome editing system, the ND particles became a gene-editing device. X-linked retinoschisis (XLRS) is an inherited retinal disorder disease that leads to reduced visual acuity in affected persons. Genetic analysis indicated that XLRS is caused by mutations c.625T in the RS1 gene. Therefore, RS1 serves as a target for gene editing systems. The low transfection efficiency is one of the major challenges of conventional CRISPR/Cas9 genomic editing systems. In this study, we developed an ND-mCherry-CRISPR / Cas9 gene editing system (ND-mCherry-CRISPR / Cas9). The size of ND is approximately 3 nm, which contained both a target gene sequence and an extra green fluorescence protein gene as a gene expression reporter. This tracible ND-mediated gene editing system is not only delivered genes into hiPSCs and mouse retina but also mediates gene editing events. Therefore, the structure of the mouse photoreceptor layer was loose, and cone/rod cells were also found to be abnormal by the ND-mediated gene editing system introduced. The effective gene editing efficiency is about 10 times higher than conventional CRISPR / Cas9. Namely, ND-mediated gene editing systems can be used as a way to quickly establish animal models of hereditary diseases. Furthermore, by conjugating with the gene correction sequences and our system will be a potential medical device for disease treatment.

Controlling the Interaction of Nanodiamond Surfaces with Physiologic Environments Elisabeth Mayerhofer1, Julia Puck2, Daniela Elena Costea3, Harsh Nitin Dongre1 and Anke Krueger1,2; 1Stuttgart University, Germany; 2Wuerzburg University, Germany; 3University of Bergen, Norway

The application of nanodiamond in quantum sensing, tissue engineering or drug delivery requires a highly defined interaction of the diamond surface with the surrounding medium. The uncontrolled formation of a protein corona is one of the major challenges. Furthermore, the denaturing of surface bound functional moieties as well as the attachment of serum components can lead to a loss of function, masking of functional moieties, the uncontrolled agglomeration of the particles as well as alteration in the uptake mechanism for the introduction of diamond nanoparticles into cells.[1] We have recently reported on the use of a complex zwitterionic moiety for the inhibition of the protein corona formation and the efficient uptake of such functionalized fluorescent nanodiamonds into cells.[2,3] Here, we discuss the control of these undesired effects by the highly defined modification of the diamond surface using different zwitterionic moieties based on differently charged small peptides as well as crown ethers immobilized using short organic linker molecules.

The resulting nanodiamond conjugates have been investigated regarding their dispersibility, colloidal stability and inhibition of protein adsorption. Uptake experiments and cell based assays confirm the low toxicity and high biocompatibility of these functionalized nanodiamonds and elucidate the efficient uptake and release into the cytosol without substantial agglomeration. The influence of differently charged surface moieties will be discussed. Such functionalized nanodiamonds are a promising tool for biomedical and sensing applications as the modular approach allows to introduce additional functional moieties, which can then be used to deliver drug molecules, provide specific interactions for targeting and tissue engineering.

Nanodiamond Facilitated Drug Delivery for Drug Resistant Breast Cancers C.-Y. Huang, Y.-J. Su and Chia-Liang Cheng; National Dong Hwa University, Taiwan

Nanodiamond (ND) has been considered as a biocompatible and feasible platform for efficient cancer drug delivery. Examples have been successfully demonstrated for various cellular and animal models. However, to date, very few or none studies had included the assessment on the effects and efficiency in a quantitative fashion; and the transportation of these ND-drugs to the cancer/tumor sites are still in a less understood state. In cancer therapy, drug resistance may arise due to intercellular microenvironment, cytoskeletal structure, and drug resistance genes causing limited therapeutic effect in cancer treatment.

In this study, we use nanodiamond (ND) as a carrier to improve drug delivery in the 3D cellular model which has been observed drug resistant characterization due to the structure of cellular model. The aim of this study is to compare the penetration ability of ND-drug complex and free anticancer drug treatment in 2D and 3D breast cancerous cells model (MCF-7 and MDA-MB-231). Several variations of the Multi cellular tumor spheroid (MCTS)
Boron-doped diamond is an excellent electrode material due to its large potential window, robustness, and anti fouling properties. While boron-doped diamond in the form of CVD-grown mono or polycrystalline diamond films is already a well-established material, reports on boron-doped nanodiamonds (BNDs) are rare, and BNDs are not broadly accessible. Yet, their potential is tremendous e.g. in (photo) catalysis and biomedicine. BNDs were at first obtained by delamination and milling of CVD films (10.1021/m500573x), showing also some positive effect on conductivity when used for nucleation (10.1016/j.carbon.2014.07.048). A more scalable and promising technique for making of BNDs is a high-pressure high-temperature (HPHT) synthesis from organic molecular precursors. This process offers unprecedented control of the ND size, enables the dopant incorporation in a high concentration, and provides monocristalline NDs (10.1021/acs.bioconjchem.0c00050). Here we investigate whether a nucleation layer from these HPHT BNDs, can potentially lead to better quality (morphology, electrical properties) of the thin (50-200 nm) boron-doped CVD diamond films compared to the standard nucleation with detonation nanodiamonds (DNDs).

We used the BNDs that were synthesized from borabicyclo[3.3.1]nonane dimer C16H30B2 under HPHT conditions (8-9 GPa, 1250°C). The obtained black powder was analyzed by Raman and FTIR spectroscopies, which showed relatively high sp²-C content and an abundance of C-Hx bonds. To obtain pure BNDs, the powder was boiled under reflux in a mixture of H2SO4 and HNO3 (3:1) for 6 hours until the bubbling of the mixture disappeared. Surprisingly, boiling in acids led to complete breakage of the interparticle bonds, and after the centrifugal acid removal, well-dispersed deep blue BND colloid was obtained just by gentle shaking of the sediment. Raman spectroscopy showed a spectrum typical for highly boron-doped diamond without any significant sp³-C content. FTIR and zeta potential analysis showed an oxidized surface (presence of C=O and C-O bonds and negative zeta potential of -31 mV). To lead to better quality (morphology, electrical properties) of the thin (50-200 nm) boron-doped CVD diamond films compared to the standard nucleation with detonation nanodiamonds (DNDs).

To determine the BND size we used small angle X-ray scattering (SAXS) that showed the mode particle size to be 5 nm. TEM analysis confirmed well-crystalline and well-dispersed BNDs. In order to reverse the zeta potential of the BNDs to become positive, the oxidized BNDs were lyophilized and then hydrogenated at 700°C for 3h. After hydrogenation, the zeta potential of BNDs indeed became positive (44 mV), i.e., similar to the intrinsic NDs after hydrogenation which is important for the achievement of densely seeded substrates with a negative zeta potential. The nucleation layer was created on Si substrates as well as on SiO2/Au interdigital electrodes. The morphology and density of the nucleation layers obtained with H-BNDs was investigated by AFM and SEM. Finally, boron-doped CVD diamond film was grown over the nucleation layer on both substrate types, and its morphology, structure, and electrical properties were characterized and compared to the standard nucleation obtained with DNDs.

The temperature dependences of the intensity, peak wavelength, and width of the zero-photon line (ZPL) spectrum from diamond nanoparticles have been used for all-optical thermometry of microscale objects [1-3]. The method is especially effective when it is challenging to apply the thermometry using the optically detected magnetic resonance [4-5]. However, the ZPL spectrum shape varies with particle size due to presumably the difference in the particle shape [3], which produces a different magnitude of the strain in the diamond lattice, and the variation requires calibration of the particle dependence of the three parameters mentioned above. To establish the calibration procedure and estimate the accuracy of the all-optical thermometry, we measured the particle-to-particle variation in the ZPL spectrum between 283–373 K.

Growth of Nanocrystalline Diamond Thin Films from Detonation and HPHT Nanodiamonds: Correlative Microscopy Study
Stephan Stehlik1,2, Katerina Dragounova Aubrechtova2, Ekaterina Shagieva2, Rostislav Medlin1, Petr Belsky1, Tomas Kovarik1, Alexander Kromka2, Stepan Potocky3 and Alexander Hynes, Level 2, Room 209

The nucleation layer formed by diamond nanoparticles (nanodiamonds, NDs) is nowadays probably the most common approach how to facilitate polycrystalline diamond growth on diverse substrates by chemical vapor deposition (CVD). Yet the formation of thin and ultrathin functional diamond films [Stehlik et al., doi 10.1021/acsc.catal.7b04341] gives rise to numerous challenges in terms of adhesion, surface uniformity, layer density, sp2/sp3 carbon phases, grain sizes, grain boundaries, etc. A recent study with oxidized nanodiamonds showed that the nanodiamond material quality (determined by origin and surface modifications) has a pronounced effect on the diamond CVD growth and resulting properties, including the brightness of SiV color centers [Zhang et al., doi 10.1039/d2tc01090a].

Thus, in this work we compare the effect of several types of hydrogenated nanodiamonds (being principally more suitable) for nucleation and growth of nanocrystalline diamond thin films with SiV centers. We employ detonation nanodiamond (NDN) solutions from standard 4 nm DNDs and novel size-reduced 2 nm DNDs and 4 nm DNNs with reduced nitrogen content (< 0.05 at.%), all obtained from pre-production stock (OZM Research). We also employ HPHT NDs of 0-30 nm size (MSY30, Pureon) purified by annealing in air (450°C, 5h). All NDs were hydrogenated by annealing in a hydrogen atmosphere, providing them positive zeta potential and stability in a colloidal solution [Kolarova et al., doi 10.1016/j.diamond.2023.109754]. The nucleation solutions were prepared by sonication of 100 mg NDs in 20 mL water and subsequent centrifugation to remove larger aggregates. Nucleation layers were formed on Si substrates and Si self-sensing AFM probes which were immersed in the nucleation solution and sonicated for 10 min. We applied CVD diamond growth for 5-30 min (10 - 80 nm thickness) using microwave plasma SEKI SDS6K reactor with standard growth conditions (hydrogen 300 sccm, methane 15 sccm, 60 mbar, 3 kW, 800 °C).

Diamond, an ultra-wide-bandgap semiconductor, is an ideal candidate for ultra-high-voltage devices due to its exceptional characteristics such as the high thermal conductivity, the mechanical strength, high carrier mobilities (both of electrons and holes), and the high dielectric breakdown strength. Diamond devices have been remarkably developed thanks to the establishment of microwave plasma chemical vapor deposition (MPCVD) growth techniques including doping control and characterization techniques. In this decade, several diamond power devices have exhibited excellent performances beyond other semiconductors based on the material advantages.

Vertical devices have advantages for high power devices, such as low on-resistance, high blocking voltage and high operation current. However, there are not many reports on vertical diamond power devices due to inadequate device fabrication techniques and difficulty in obtaining doped substrates especially on vertical devices in commercial and military applications. For most electronic and RF applications, UWBG semiconductor-based devices, including β-Ga2O3, can operate at much higher voltages, frequencies, and temperatures than commercially available options, including silicon carbide and gallium nitride. However, the remarkably low anisotropic thermal conductivity of β-Ga2O3 (11-27 Wm⁻¹ K⁻¹) is a significant bottleneck for high-power device applications as it affects the device performance and results in self-heating effects (SHE), which severely limits output power density and maximum current flow of the circuit. To address this issue, the incorporation of a diamond layer that can operate as a heat spreader in Ga2O3-based devices has been investigated due to its extraordinarily high thermal conductivity (~ 2000 W/mK). The deposition of high-quality diamond coatings onto non-diamond substrates, such as β-Ga2O3 films, is a complex task due to several inherent nucleation, growth, stress, and adhesion-related issues. The absence of carbon solubility in β-Ga2O3, a large mismatch in surface energies with a significant difference in thermal expansion coefficient between β-Ga2O3 and diamond, and unfavorable decomposition phenomena during CVD make it difficult to achieve uniform diamond layers with suitable adhesion and nucleation density. This study introduces a novel method for depositing diamond on β-Ga2O3 films using a diamond-like carbon (DLC) through pulsed laser deposition (PLD) and successive pulsed laser annealing (PLA) to form a quenched carbon (Q-carbon) layer, demonstrating improved precision and control in the synthesis of diamond coatings for optoelectronic and electronic devices. In this investigation, we have created strong Q-carbon/β-carbon and Q-carbon/α-carbon heterostructures on β-Ga2O3 films using laser annealing of amorphous carbon films with nanosecond laser pulses above the melt threshold. The energy density required for the PLA is calculated by modeling the laser-solid melt interaction, and a maximum melt regrowth velocity of 12.5 m/s is achieved at a laser energy density of 0.4 J/cm². Raman studies and X-ray photoelectron spectroscopy (XPS) demonstrate the presence of a high sp² content of ~ 81% in the Q-carbon region. Nanodiamonds formed by the PLA process exhibit a distinct Raman peak at 1320 cm⁻¹, with a red shift of approximately 12 cm⁻¹ due to the phonon confinement effect. This research reveals a considerable increase in the nucleation density during diamond deposition by hot filament chemical vapor deposition (HFCVD). A very high seeding density with high-quality delamination-free diamond film growth is possible on the Q-carbon region of the film due to the presence of densely packed diamond tetrahedra in Q-carbon which act as nucleation sites for diamond growth. The nucleation density, diamond quality, and stress values were compared for diamonds on Q-carbon coated β-Ga2O3 and uncoated β-Ga2O3 films. The incorporation of a Q-carbon intermediate layer significantly reduces the compressive stress in diamond films on β-Ga2O3 to 0.37 GPa, compared to 1.23 GPa for films deposited on uncoated substrates. The phase purity of the diamond can be measured by its FWHM of signature Raman peak, with a manually calculated value that matches the direct value obtained from the deconvoluted signal. The values obtained were obtained to be 11 cm⁻¹ and 16.66 cm⁻¹ for Q-carbon coated β-Ga2O3 and uncoated β-Ga2O3, respectively. Thus, this study addresses the critical challenges, i.e., poor adhesion and large thermal mismatch between diamonds and β-Ga2O3 films, which has tremendous implications in realizing efficient β-Ga2O3-based high power devices.
with high-quality.
In this talk, current status and prospects of diamond power devices will be introduced focusing on vertical devices.

10⁶ cm²(V.s) Carrier Mobility Measured in Ultra Pure Diamond by Time of Flight Electron Beam Induced Current Alexandre Portier¹,², Fabrice Donatini³, Denis Dauserger¹, Marie Laure Gallin Martel¹ and Julien Pernot²; ¹University Grenoble Alpes, CNRS, Grenoble INP, LPSC-IN2P3, France; ²University Grenoble Alpes, CNRS, Grenoble INP, Institut Néel, France

Diamond is a very promising material for various applications, and understanding its basic properties is key for the development of future devices. In particular, the low-field mobility of holes has never been measured below ~80 K in ultra-pure diamond. In order to measure this mobility, we developed an innovative Time of Flight electron Beam Induced Current (ToF-eBIC) technique. A 1 ns pulsed electron beam was made to impact the diamond semiconductor, inducing charge carrier creation and motion through the 546 µm thick bulk diamond, under the influence of an applied electric field. The resulting signal was analysed using the transient time technique. Thus, the velocity of electrons and holes was assessed as a function of the temperature from 13 to 300 K and as a function of the electric field with values ranging from 1.5 to 9200 V/cm. A low-field mobility value of 1.03 x 10⁶ cm²/(V.s) was measured for holes at 13 K, demonstrating that diamond is a suitable material to transport charge carriers in a ballistic regime at a scale of ten micrometers.

Electron Contact Strategies for Diamond Enabled with a Nitrogen Doped Nano-Carbon Interlayer Gabriel B. Munro-Ludders, Saurabh Vishwakarma, David J. Smith, Robert J. Nemanich and Franz Koeck; Arizona State University, United States

Ohmic metal contacts to n-type diamond have historically posed a challenge to the fabrication of diamond devices, due to the formation of a rectifying Schottky barrier, which limits the practicality and scope of diamond devices. Nitrogen-doped nanoCarbon films have recently been explored as ohmic interface layers to enable low-resistance ohmic contact with N-type diamond [1]. In this work the electronic interface between nitrogen-doped nanoCarbon interlayers and metals is investigated using photoelectron spectroscopy and transmission electron microscopy, to determine the mechanism of ohmic contact.

Titanium and molybdenum layers were deposited on nanoCarbon films, and each respective metal/nanoCarbon interface was characterized via X-ray Photoelectron Spectroscopy (XPS) and Ultraviolet Photoelectron Spectroscopy (UPS). The n-type SBH was determined to be Φ_B = 3.7 eV and Φ_B = 4.1 eV for the titanium-nanoCarbon and molybdenum-nanoCarbon interfaces, which indicates a partial pinning of the fermi level. Characterization via TEM and electron energy loss spectroscopy reveal the presence of ~4 nm diameter sp³–bonded diamond grains surrounded by a matrix of sp² bonded carbon, indicating a mixed phase material with non-crystalline states. Two models of the contact mechanism, contingent on the density of unfilled surface states after metal deposition, are proposed to understand the ohmic contact mechanism. A sufficiently low surface state density coupled with a high inter-bandgap density may reduce band bending and allow for flat-band contact by filling surface states, unpinning the fermi level. Alternatively, hopping-type conduction near the Fermi level through n*-bonded states into the conduction band may also reduce the effective SBH.

Future work will investigate the electronic interface between nanoCarbon interlayers and n-type diamond substrates, to enable ohmic contact with n-type single-crystalline diamond. Switching between pinned and unpinned contact regimes through modulating the inter-bandgap state density via modifying morphology, doping concentration, and non-carbon chemical composition in the film also presents an avenue for future investigations.

Fabrication of Diamond Membranes and Photonic Nanostructures for Integration of Color Centers Julia Heupel, Lukas Wolfram and Cyril Popov; University of Kassel, Germany

Single-crystal diamond (SCD) in form of thin membranes with incorporated color centers, such as nitrogen-vacancy (NV) centers or silicon-vacancy (SiV) centers, has gained an ever-increasing interest over the years as a highly promising platform for photonic integrated devices or for envisioned applications in quantum information technologies (QITs). To achieve the desired long optical and spin coherence times for QIT applications, such membranes need to be free from lattice defects, paramagnetic impurities, and charge traps. This requires an initial removal of the damaged surface layers from the cut and polished starting material. Additionally, further processing of diamond by e.g., dry etching for fabrication of photonic structures, can lead to higher roughening of the surface due to a micro-masking effect from particles, originating from the polishing procedure. In our work we address the importance of the SCD surface preparation to overcome the above mentioned challenges, which affect the structuring process and critically influence the final quality of the membrane or structured photonic devices as well as their performance.
The fabrication process of SCD membranes with various diameters and thicknesses, exhibiting a low surface roughness down to 0.2 nm, applying inductively coupled plasma reactive ion etching (ICP-RIE) with Ar/Cl₂ and O₂ plasma will be demonstrated. By a variation of the major etching parameters, an enhanced planarization of the surface can be obtained, especially due to a low etch rate of a few nm/min and the Ar/Cl₂ chemistry. These planarized SCD membranes can be successfully bonded via van der Waals forces or via PMMA on plane cavity mirrors and optically characterized in a fiber-based Fabry–Pérot microcavity system regarding their mode structure and finesse. They can be also used, even as starting material for fabrication of 1D or 2D photonic crystal structures applying electron beam lithography (EBL).

The work is financially supported by the German Federal Ministry of Education and Research (BMBF) under the Project “Quantenrepeater.Link” (QR.X).

2:00 PM EL14.15.02
The Highest Concentration NV Ensembles Formed by Heavily Nitrogen-Doping CVD System with Plasma Confinement and High Density Vacancy Formation by Focused Electron Beam Irradiation Yuval Asano1, Kyousuke Hayasaka1, Mayu Ueda1, Kyohtaró Kanehisa1, Kosuke Kimura1, Takashi Tani1, Shinobu Onoda2, Shinpei Enomoto1 and Hiroshi Kawarada1, 2, 1Waseda University, Japan; 2National Institutes for Quantum Science and Technology, Japan; 3Waseda University, Japan

Highly concentrated NV ensembles are expected to be applied to magnetic sensing. Only method for high concentration of nitrogen above 10²⁰ cm⁻³ in diamond is limited to CVD method, because the damage of heavily implanted diamond cannot recover easily. We have successfully fabricated diamond thin films with the world’s highest nitrogen concentration of 8 × 10²⁰ cm⁻³ [1] using a microwave plasma chemical vapor deposition (MPCVD) system that is specially designed to confine plasma to the thickness of a microwave waveguide. This method can also introduce 1 × 10²² cm⁻³ of boron, and diamond with the world's highest superconducting transition temperature has been synthesized. HPHT synthetic (111)-oriented diamond substrates were used. That’s because (111) diamond substrate have the high impurity incorporation efficiency [2]. These CVD films exhibit extremely high crystallinity, as indicated by the Raman spectrum measurement (Laser 532nm), which shows a diamond peak FWHM of 8.6 cm⁻¹, comparable to HPHT diamonds. After fabricating the films, we performed electron beam irradiation using a 300 kV TEM with an electron fluence of 10¹⁵–10¹⁶ cm⁻², resulting in the world’s highest NV concentration of 8.5 × 10²⁰ cm⁻³ [3]. This method is necessary for electron irradiation for high density nitrogen above 1 × 10²⁰ cm⁻³. The quantification of NV concentration was done using the DEER (Double Electron-Electron Resonance) based on NV interactions. DEER is a method of measuring NV concentration from the magnetic dipole interaction strength between NV’s four orientation groups by applying microwaves simultaneously to groups of each different resonance frequencies, so this method utilizes the fact that the decay rate of coherence time is proportional to the number of resonant NV groups in the concentration range of 8.5 × 10⁹ – 1.7 × 10¹⁰ cm⁻³, as confirmed by simulations and experiments [4]. By manipulating the number of resonant NV groups, we determined the NV concentration [3]. Previously, the concentration was estimated from the emission intensity, but when the NV concentration exceeded 10¹⁸ cm⁻³, the saturation of NV concentration occurred without an increase in irradiation fluence. As a result, the estimated values from the emission intensity using the DEER method were higher than those estimated from the emission intensity. However, the obtained NV concentration of 1.0 × 10¹⁰ cm⁻³ is only about 1% yield relative to the nitrogen concentration. Understanding the behavior of nitrogen in CVD diamond could potentially lead to higher NV concentrations. Despite such a high nitrogen concentration, the T₁ was 90 ns, and T₂ was 660 ns, respectively, at a magnetic field of 0.5 T. The nitrogen-doped CVD diamond has advantages for high-density NV ensemble.

Exploring Magnetism in Multiferroics with Scanning NV Magnetometry Paul Stevenson1, Peter Meisenheimer2, Hongrui Zhang2 and Ramamoorthy Ramesh3; 1Northeastern University, United States; 2University of California, Berkeley, United States; 3Rice University, United States

Multiferroic materials hold great promise for next-generation devices, offering a route towards low-power, voltage-based control of magnetic ordering. Realizing this potential, however, requires understanding the coupling between magnetic and ferroelectric degrees of freedom. Using scanning NV magnetometry (SNVM), we are able to resolve the wide range of antiferromagnetic textures in the multiferroic BiFeO₃, revealing previously hidden heterogeneity and allowing us to directly image the effect of applied electric fields.

We also show how SNVM can be used to image multiple field components simultaneously – without ambiguities normally present in reconstructions – by optimizing magnetic field conditions, and how local variations in the refractive index of BiFeO₃ can be imaged below the diffraction limit. These new capabilities demonstrate the broad utility of SNVM for exploring magnetic textures in multiferroic materials.

2:30 PM EL14.15.04
Analysis of Ferro- and Antiferromagnetic Memory Bits by Scanning NV Magnetometry Peter Rickhaus1, Vicent Borras1, Robert Carpenter2, Sebastien Couet1, Liza Zaper1,3, Alexander Stark1, Mathieu Munsch1, Marco Nordmann1, Paul Lehmann1, Kai Wagner1, Christoph Adelmann2, Oleksandr Pylypovskyi2, Paul van der Heide2, Denys Makarov4 and Patrick Maletinsky3, 1Qnami AG, Switzerland; 2Imec, Belgium; 3University of Basel, Switzerland; 4Helmholtz-Zentrum Dresden-Rossendorf, Germany

Storing information in magnetic bits requires excellent control over their nanoscale magnetico properties. A prime example of this challenge are STT-MRAM (spin transfer torque magnetic random access memory) devices - which have rather high failure rates. In order to investigate the sources of potential failure, atetchline that can resolve small magnetic fields with high spatial resolution is required. The request is even more urgent for next-generation magnetic memory materials, such as antiferromagnets, which generate even smaller magnetic signals.

Scanning NV magnetometry (SNVM) is an emerging quantum sensing technique that offers the required sensitivity. Here, we will look at the local magnetic properties of bits in state-of-the-art STT-MRAM devices using scanning-NV magnetometry [1]. Furthermore, we will demonstrate magnetic images of a few hot candidate materials for future magnetic memory devices including antiferromagnetic chromium, BFO [2] and ultra-thin coated CoFeB nanowires [3]. We will reveal magnetic textures that are undetectable with more standard characterization techniques and discuss implications on device fabrication.

In this presentation, our latest work in the development and the use of an ultra-sensitive biosensor based on diamond waveguides will be highlighted. We have during the last years been working on the design and fabrication of mid-infrared (MIR) diamond waveguides. The MIR waveguides together with a broadband tunable quantum cascade laser (QCL), emitting in the so-called molecular fingerprint region, are the two key elements in our newly developed label free MIR biosensor. In our approach MIR light is coupled into microfabricated diamond waveguide structures, which are purposefully designed to sustain single or multimode standing waves. The associated evanescent waves that are created at the waveguide surface will extend into the surrounding media and interact with the analyte thus providing a sensing volume. In existing commercial technologies, attenuated total reflection IR (ATR-IR) spectroscopy, IR light from a thermal emitter is coupled through a millimeter sized diamond crystal, with up to 10 internal reflections in the diamond crystal. This is a powerful technology and is today used for i.e. quality control in medical and food industry, protein analysis, forensics, etc. However, the relatively low sensitivity of this technique hinders its use in many applications. Our biosensor achieves unsurpassed sensitivity due to the large number of standing waves nodes created in our waveguides which roughly can be translated to the number of internal reflections per length unit is maximized. Moreover, the use of a bright QCL laser as a light source further increases the sensitivity of our biosensor – therefore an ultra-sensitive sensor is realized. Finally, the diamond waveguide material facilitates further functionalization by means of organic chemistry thus extending the capabilities of traditional silicon or gold based biosensor technologies, and we demonstrate here one possible route to fabricate selective affinity layers for protein fishing from complex mixtures. Several designs of diamond waveguides are discussed, ranging from thin film diamond slab waveguides, rib waveguides, to microfabricated free hanging diamond waveguides. We have recently showed how AlN can be used as cladding layer to overcome earlier difficulties in guiding light at longer wavelengths (5-10 µm). We will also present how we significantly can increase the sensitivity of the diamond waveguide sensor by depositing a high index film on the diamond waveguide. Using silicon as the high index film also opens up for easy functionalization of the sensor. The diamond waveguide sensor has been tested on different analytes, such as acetone and isopropanol, showing a very stable performance and very high sensitivity. We have therefore started to work on “real-world” chemical sensing applications. Currently, we are analyzing different forms of the protein alpha-synuclein, which is relevant in understanding the mechanism behind Parkinson’s disease. We have previously shown that ATR-IR spectroscopy can be used to analyze the secondary structure of different alpha-synuclein aggregates. Moreover, it is also possible to see the difference in the IR-spectra between the native state and the neurotoxic misfolded state of the protein. However, the ATR element is impractical to functionalize and the sensitivity of the ATR-IR spectroscopy is too low to be used on relevant samples from patients. In contrast, our diamond waveguide biosensor exhibits the desired key properties to analyze the secondary structure of alpha-synuclein at biologically relevant concentrations. Future work includes the functionalization of the diamond waveguide sensor surface to selectively adsorb alpha-synuclein from cerebrospinal fluid, with the ultimate goal to detect Parkinson’s disease at an early stage.

The electronic properties of chemical vapor deposited undoped polycrystalline diamond foils are investigated via continuous and pulsed mode measurements. In continuous mode, our diamond foil operates as a bipolar memristor with a variable onset voltage and internal nanobattery effect. We attribute the memristive properties to a filamentary redox-based resistive switching mechanism with ionic and electronic charge transport through our diamond foil. In order to explain the occurrence of this dip, we consider the hydrogen redox-based switching model. In this model, hydrogen ions are separated from the conductive filament and migrate towards the negatively charged electrode through atomic vacancies and produce a build-up internal nanobattery voltage. This diffusion process is accelerated by local high temperatures produced by the current carrying filament. While current compliance is not necessary for this effect to occur, it is certainly beneficial because a fixed part of the voltage drop occurs due to electrons travelling towards the positive electrode and the rest of the voltage drop occurs due to protons migrating and accumulating at the negative electrode. After the pulse is turned off, a current in reverse direction flows due to the build-up internal voltage as well as repulsion of accumulated positive charge carriers. In pulsed mode operation, our diamond foils exhibit synaptic behavior, similar to the interface between two neurons. Our memristors exhibit high retention times with high on/off ratios up to 10^4 required for logic operations. As an inorganic synapse, our foil exhibits sensory, short-term, and long-term memory effects according to a psychological human memory model. Spike-timing dependent plasticity supports our findings. Furthermore, we observe functionalities commonly found in neurons, such as a mimicked refractory period where our conductive filament corresponds to an axon. We anticipate that our study paves the way for future artificial-neurons-on-a-chip application. Our research findings constitute an important step towards artificial-neurons-on-a-chip application, as well as organic/inorganic brain-electronics interfaces.

Compared to conventional cytotoxic anti-cancer drugs, molecular-targeted medications exhibit reduced toxicity. These drugs are administered to patients at fixed doses, without the need for adjustments based on biomedical indices such as body surface area. However, this therapeutic approach leads to considerable variability in plasma concentration among individuals, often resulting in significant adverse events that necessitate dosage reduction. Recent clinical studies have sought to quantify the correlation between drug concentration and clinical efficacy or toxicity. To enable personalized administration of molecular-targeted drugs, it is imperative to determine plasma concentrations directly at the clinical site. In recent years, advancements in medical
engineering have yielded various portable or wearable biosensors capable of rapid on-site monitoring. Nonetheless, the widespread utilization of these devices has been hindered by insufficient evaluation of accuracy using clinical samples, variability between sensors, and the need for complex and costly fabrication processes. To overcome these challenges, we propose a straightforward approach utilizing boron-doped diamond (BDD), an electrochemical material known for its sustainability. As a proof-of-concept, we selected pazopanib, a molecular-targeting anticancer drug recommended for monitoring. By employing a BDD plate chip measuring approximately 1 cm², our sensing system accurately detected pazopanib concentrations in rat plasma samples within the clinically relevant range. Furthermore, the response of the chip remained stable throughout 60 consecutive measurements, demonstrating its excellent repeatability. When we examined plasma samples collected from orally administered healthy rats and cancer patients using our system, the measured concentrations closely matched those obtained through liquid chromatography with mass spectrometry. Additionally, we evaluated the reproducibility of the BDD chips. Finally, we constructed a portable system featuring a palm-sized sensor housing a chip to facilitate practical implementation. This setup successfully determined drug concentrations from approximately 40 µL of whole blood obtained from dosed rats within a short turnaround time of approximately 10 minutes. By employing this “reusable” sensor-based approach, we can accelerate point-of-care drug monitoring, advance personalized medicine, and potentially reduce medical expenses.

Fabrication of Diamond/Metal Oxide Hybrid Structures: Towards Gas Sensors with Enhanced Sensitivity and Selectivity
Petr Ashcheulov1, Marina Davydova1, Andrew Taylor2, Neda Neykova1, Alexandr Laposa1, Jaromir Kopeček1 and Pavel Hubík1; 1FZU, Czechia; 2CVUT, Czechia

The release of hazardous compounds such as NOx, SOx, CO, NH3, other nitrogen or sulfur-containing compounds, and volatile organic compounds (benzene, toluene, methanol, etc.) in the atmosphere is of significant concern for human health. Therefore, there is a rising demand for advanced chemiresistor sensors, which need to satisfy the following requirements: high sensitivity, selectivity, stability, and reproducibility. In recent years, various metal oxides (e.g., ZnO, SnO2, CeO2) have been recognized as promising materials for the detection/sensing of toxic pollutants and hazardous gases. Yet, chemiresistor sensors based on metal oxides have exhibited rather poor selectivity (i.e., simultaneous sensitivity to reducing and oxidizing gases) along with the necessity of high temperature (> 300°C) operation.

In this work we demonstrate fabrication of hybrid structures based on diamond (intrinsic and boron-doped) and metal oxides (MOx) for their application as active components in gas chemiresistor sensors. We investigate the effect of doping and the diamond structure (planar and/or 3D geometries) on the sensing characteristics of hybrid structures (e.g., sensitivity and selectivity) towards various gases. Fabricated diamond/MOx structures were characterized via various microscopic and spectroscopic techniques, and the effect of their electrical characteristics on the sensing properties is discussed.

Normally-Off Vertical Diamond MOSFETs with Drain Current Density over 200 mA/mm using Oxidized Si Terminated Diamond Channel Formed by Si Molecular Beam Deposition Approaches
Kento Narita1, Kosuke Ota1,2, Yu Fu1, Chiyuki Wakabayashi1, Atsushi Hiraiwa1, Tatsuya Fujishima2 and Hiroshi Kawarada1,2,3; 1Waseda University, Japan; 2Power Diamond Systems, Inc., Japan; 3The Kagami Memorial Research Institute for Materials Science and Technology, Japan

For realization of high-power high-speed miniaturized complementary inverters [1], development of p-type field-effect transistors (p-FETs) corresponding to SiC or GaN n-FETS is essential. Normally-off operation with threshold voltages (Vth) more negative than −3 V are required for power devices with operating voltage above 500 V, but the conventional vertical diamond FETs are normally-on operation (Vth: +15 ~ +30 V) using hydrogen-terminated diamond (C-H) channel [2,3]. In contrast, we have fabricated (001) vertical diamond MOSFETs with oxidized Si terminated diamond (C-Si-O) channel by the reaction of chemical vapor deposition (CVD) SiO2 with diamond and achieved the first normally-off operation (Vth: −9.0 V) in vertical diamond FETs with a maximum drain current density (ID,max) of 108 mA/mm[4]. In this study, by Si molecular beam deposition (MBD) method, we fabricated C-Si-O side-wall channel in vertical diamond MOSFETs for the first time. We obtained the Vth of −4.5 V and the ID,max of 214 mA/mm, which is the highest ID,max among the normally-off vertical diamond FETs.

The C-Si-O channel formation method is as follows. After 200 nm regrown undoped layer was deposited by microwave plasma CVD, SiO2 was deposited 400 nm as a mask by tetraethyl orthosilicate based plasma-enhanced CVD. A p⁺ layer ([B⁺]: 1x10²¹ cm⁻³) was selectively deposited by MPCVD after etching 400 nm of the SiO2 mask and 40 nm of the regrown undoped layer by inductively coupled plasma reactive ion etching. After SiO2 mask removal, the diamond surface was treated with hydrogen oxidation. 0.5 nm-silicon was deposited and followed by in-situ annealing at 1193 K for 15 min in the MBD apparatus. During the annealing in high vacuum, the reaction between C-H and Si occurred and C-Si- happened [5,6]. The C-Si- surface was exposed to air [7], naturally oxidized and transformed to C-Si-O after the C-Si-channel was exposed to air [7].

The vertical device dimensions for source-source length (Lss), effective channel length (Lch), trench width (Wt), gate-drain length (Lgd), trench depth (Dt) and gate width (Wg) are 8 µm, 5.2 µm, 4 µm, 0.4 µm, 3 µm and 25 µm, respectively. The ID,max normalized by the Wg was 214 mA/mm, and the ID2,max normalized by the active area (Lss × Dt × Wt): 2.0 × 10⁴ cm² was 5350 A/cm² at Vgs= −45 V and Vgd= −40 V, and the on-resistance (Ron) was 8.1 mΩcm². The on/off ratio was 10⁴ and gate leakage current was less than 10⁻³mA/mm at Vgs= −10 V. The maximum transconductance (gm,max) was 15 mS/mm, and the maximum field-effect mobility (μFET,max) was 68 cm²/Vs. The Vth was −4.5 V at Vgs= −10 V. As a result, we achieved the normally-off operation of |Vth| > 3 V, and the ID2,max of over 200 mA/mm. The Vth shifted more than 20 V in the negative direction compared to conventional C-H channel vertical diamond FETs [2,3]. The negative electron affinity of C-Si-O surface (~0.25 eV) [7] is weaker than that of C-H surface (~1.3 eV) [8] and the negative fixed charge of Al2O3 on the C-Si-O interface is less than that on the C-H interface. The large negative shift of Vth is due to the smaller band offset and the smaller band bending between diamond and Al2O3 in the C-Si-O channel than in the C-H channel. In the near future, by introducing a p-drift layer, and C-Si-O channel only on the sidewalls, we will realize vertical diamond devices with high breakdown voltage over 1000 V and normally-off operation.

1. Introduction

Tetrahedral amorphous carbon (ta-C) films have been prepared by pulsed laser deposition (PLD) [1-4]. Stock et al. [1] reported that the sp³ carbon ratio \( sp^3 \frac{C}{sp^3 + sp^2 C} \) in the ta-C film prepared using an ArF excimer laser (198 nm) was 80% or more, which was higher than the sp³ ratio (~60%) in the film deposited using a KrF excimer laser (248 nm). Yoshitake et al. [2] reported that the ta-C film prepared in a hydrogen atmosphere had a higher sp³ ratio than the film deposited in an oxygen atmosphere. Cheng et al. [3,4] performed postdeposition-annealing of ta-C with atomic hydrogen irradiation and found that atomic hydrogen etching accelerated crystallization of micro/nano graphite as the annealing temperature rose. In this study, we have deposited diamond-like carbon (DLC) films by PLD using a KrF excimer laser and investigated atomic hydrogen effects on the chemical bonding of the DLC films. We clarified the optimum deposition conditions to promote sp³-bonded carbon atoms in the films. The novelty of this study is that the hydrogen effects were investigated by varying the deposition parameters systematically.

2. Experimental methods

DLC films were prepared on Si(100) substrates by PLD using a KrF excimer laser with a wavelength of 248 nm. The DLC film was deposited at a substrate temperature of RT, a laser repetition rate of 20 Hz, a laser intensity of 0.25 J/pulse using an atomic hydrogen source (hydrogen pressure: 0.01 Pa, tungsten filament current: 4 A) for 60 min as a standard sample. One of the substrate temperature, laser repetition rate, hydrogen pressure, and filament current was varied with the other parameters fixed. The sp³ ratio \( sp^3 \frac{C}{sp^3 C + sp^2 C} \) was determined from C 1s core-level spectra obtained by X-ray photoelectron spectroscopy (XPS).

3. Results and discussion

The DLC films prepared with atomic hydrogen irradiation had higher sp³ ratios than those prepared in a vacuum. Especially, the DLC film deposited at a filament current of 4 A exhibited the highest sp³ ratio. The hydrogen pressure at which the sp³ ratio reached a maximum was found to be 0.01 Pa. When the substrate temperature was increased from RT to 700 °C, the sp³ ratio decreased. It was found that the sp³ ratio in the film deposited at a repetition rate of 20 Hz was higher than that in the film deposited at 10 Hz. The maximum sp³ ratio of 57% was obtained in this study, which was close to that reported in Ref. 1, in which PLD using a KrF excimer laser was employed.

Yasu et al. [5] have reported that the amount of atomic hydrogen generated using a tungsten filament source increases with the filament temperature. C.-L. Cheng et al. [3] have shown that hydrogenated, disordered carbon films are deposited at RT, whereas the graphitization of the films occurs at substrate temperatures above 500 °C, which is facilitated by hydrogen etching. When the filament temperature and hydrogen pressure increase, the amount of atomic hydrogen increases, leading to the acceleration of the formation of C–H bonds and selective etching of sp²-bonded carbons by atomic hydrogen. When the substrate temperature decreases or the repetition rate (the flux of C atoms) increases, the surface diffusion length of C atoms decreases. In this case, C atoms adsorbed on the surfaces are not able to arrive at stable sites, and the film becomes a metastable form of amorphous carbon.

4. Summary

The maximum sp³ ratio of 57% was obtained when the hydrogen pressure, substrate temperature, laser intensity, and laser repetition rate were 0.01 Pa, RT, 0.25 J/pulse, and 20 Hz, respectively.

All-Optical Modulation of Fluorescent Nanodiamonds for Practical Applications Lingzhi Wang and Zhiqin Chu; The University of Hong Kong, Hong Kong

Because of ultrahigh photostability, nanoscale volume emitting strong fluorescent signal, and low cytotoxicity, fluorescent nanodiamonds (FND) containing nitrogen vacancy (NV) centers are regarded as promising fluorescent markers in various applications. Here, based on optical polarization-selective excitation phenomenon of NV centers, we provided FNDs with more useful functions, including orientation measurement and providing high-dimensional anticounterfeiting information. Particularly, our scheme showed two characteristics: 1) easy-to-implement solution; 2) useful functions. Specifically, our scheme can be conveniently achieved based on mature commercial sample and common microscope with slight modification. Utilizing the orientation measurement of FNDs, we provided the information for cell traction force in a new dimension (rotational dimension). Based on the 3D anticounterfeiting information from FNDs, we achieved physical unclonable function labels, well satisfying common commercial and anticounterfeiting requirements. In above application scenarios, our scheme has little negative influence due to all-optical manipulation.

Room Temperature sub-THz (300 GHz) Plasma Wave Generation in p-Diamond TeraFET Muhammad Mahmudul Hasan1, Nezih Pala1 and Michael Shur2; 1Florida International University, United States; 2Rensselaer Polytechnic Institute, United States

The growing demand for efficient and compact terahertz (THz) sources operating at room temperature is driven by their wide-ranging applications in spectroscopy, imaging, and communication systems. Hydrodynamic transport modeling of TeraFETs (Terahertz Field-Effect Transistors) has revealed that p-diamond is a promising material for sub-THz applications beyond 5G. P-diamond, characterized by its large carrier effective mass, exhibits longer momentum relaxation times compared to other semiconductor materials, rendering it advantageous for generating THz radiation at lower frequencies. This paper presents a comprehensive hydrodynamic modeling study of a p-diamond-based TeraFET acting as a THz source. Our simulations show that p-diamond TeraFETs could support channel carrier oscillations at THz frequencies below 1 THz at room temperature operating as THz sources enabled by the Dyakonov–Shur instability.

To investigate the performance of the p-diamond TeraFETs, we conducted a thorough numerical analysis using a 1D hydrodynamic model. This model incorporates viscosity effects and considers damping resulting from electron scattering by impurities and phonons. Our simulations conclusively demonstrate the efficacy of the p-diamond TeraFET in emitting resonant THz radiation at a frequency of 300 GHz at room temperature when biased by a DC current. We explored the dependencies of the resonant oscillations on the channel length, drift velocity, and gate bias. These dependencies guide precise tuning of the emitted THz radiation. Our analysis predicts the minimum drift velocity necessary to overcome the decay factor caused by scattering and viscosity effects, ensuring robust resonant oscillation. These findings shed light on the p-diamond TeraFET’s operation and aid in optimizing its
The hydrogen-terminated (C-H) diamond surface has been used in diamond MOSFETs for its p-type high conductivity[1][2]. So far, we have reported diamond MOSFETs using 2-dimensional hole gas (2DHG), which is induced by the surface dipole formed by hydrogen-carbon bonds. The negatively charged adsorbates are also considered to have an important role to obtain high surface conductivity[3]. In the fabrication of diamond MOSFETs, even if C-H surface is preserved, we noticed that the surface conductivity decreases after several device processing sequences, because of different ambient and high temperature processing condition. In this work, we developed the recovering method of conductivity by irradiating extra negative ions in air on the hydrogen-carbon (C-H) surface to enhance the current density of the C-H diamond surface. The low conductivity of C-H diamond substrate was improved successfully. This result indicates the necessity of negatively charged adsorbates on the C-H diamond surface. It also makes the fabrication of C-H diamond FET more reliable by intentionally introducing additional negative ion formed by corona discharge to the C-H diamond surface.

In this study, the surface of (001) undoped diamond was hydrogen-terminated. Ti/Pt/Au (30nm/20nm/100nm) was evaporated as source/drain electrodes to define the channel length. Before introducing additional negative ion, the current density was 8 mA/mm at VDS = 30 V, with Lch = 5 μm, Wch = 70 μm, which is more than 1 order of magnitude below the current density of C-H diamond channel reported [4]. To increase the conductivity of C-H surface, we introduced a large amount of negative ion by corona discharge near the substrate surface to provide additional negative charge on the hydrogen-carbon surface for 30 min[5]. The change of current density over time was measured. With additional negative ion in the air, the current density increased rapidly from 9 mA/mm to 164 mA/mm in 30 min and saturated. Sheet resistance decreased from 656 kΩ/sq to 38kΩ/sq. The current density maintained the maximum for more than 3 days. All the experiment and measurement were performed in regular air.

The increase of current density indicated the amount of negative charge on the C-H surface has a great influence on the density of polarization-induced 2DHG. The disorption of negatively charged adsorbates in the device processing probably leads to a low density of 2DHG,which results in low conductivity of hydrogen-terminated surface. It takes more than several hours for negatively charged adsorbates to cover the surface. This low conductivity issue can be simply improved by introducing additional negative ion to the C-H surface. This process only takes about 30 minutes in air without using toxic gas such as NO2. Introducing additional negatively charged adsorbates in the device fabrication process is recommended to secure the higher density of polarization-induced 2DHG, higher p-type conductivity and a higher yield of C-H diamond p-FET.

**Iodine Doping in Tetrathiafulvalene Twisted Crystals** St. John Whittaker, Merritt C. McDowell, Shin Kim, Bart Kahr and Stephanie Lee; New York University, United States

Tetrathiafulvalene (TTF), a workhorse of the organic electronics community since it’s superconductor tetracyano-p-quinoxaline methane co-crystal was...
discovered in 1973,[1] is an optically inactive centrosymmetric molecule that crystallizes in an optically inactive centrosymmetric space group P-1 when grown from the melt. We recently discovered that growth-actuated crystal twisting breaks this symmetry to render TTF twisted crystals optically active and thus promising candidates for chiroptoelectronics.[2] In this work, tetraethyfuvalene (TTF) banded spherulites comprising helicoidal fibrils are doped with iodine to improve their conductivity for chiroptoelectronics. Within five minutes of exposure to iodine vapor, TTF film conductivity increased by six orders of magnitude, from 100 pA to 100 µA, accompanied by a color change from pale yellow to dark red. Grazing incidence x-ray diffraction patterns also revealed a change in crystal structure upon iodine doping. The rate of iodine doping was found to depend on the local crystal face presented at the film surface, which alternates between faces as the crystalline fibrils twist about the growth direction, forming concentric “bands” surrounding the spherulite center. Crystal face-dependent iodine intercalation was observed by optical microscopy, light absorbance spectroscopy, and electron dispersive x-ray spectroscopy. Faces corresponding to fast iodine intercalation were previously identified as the 1-11 face.[3] Mueller Matrix imaging revealed that crystal twisting is not disrupted by iodine intercalation, with circular dichroism and birefringence retained after five minutes of film exposure to iodine vapor.

Combined with the orders of magnitude improvement in electrical conductivity, optically active doped TTF banded spherulites will provide a platform to examine chiral-induced anisotropies in electron and photon interactions in molecular semiconductor twisted crystals.

Twisted Hydrogen-Bonded Frameworks

Rochelle B. Spencer, Anna Yusov, Alexandra Dillon,Wantong Wu, Bart Kahr, Michael D. Ward and Stephanie Lee; New York University, United States

Directing the assembly of molecules within hydrogen-bonded frameworks is being extensively explored as a modular crystal engineering strategy to access novel molecular packing arrangements of target molecules. Crystal twisting, a common but little-known phenomenon in molecular crystals, of these frameworks provides an additional handle to not only interrogate crystal orientation-dependent properties but also to impart chirality for chiroptoelectronics. Here, we demonstrate crystal twisting in solution-processed bis(guanidinium)naphthalene-1,5-disulfonate (G)2(1,5-NDS) films in which molecular assembly is driven by hydrogen bonding between guanidinium and sulfonate moieties. When deposited from ethanol in conditions that favor low nucleation densities but high branching rates, (G)2(1,5-NDS) crystallizes as banded spherulites of helicoidal fibrils emanating radially from a single nucleation center and twisting in concert with one another about the growth direction. Scanning electron micrographs (SEMs) reveal tightly packed fibrils that alternate between flat-on and edge-on orientations with respect to the substrate surface with a twisting pitch of ∼ 3 - 4 µm. 2D x-ray diffraction (XRD) patterns collected on (G)2(1,5-NDS) banded spherulites confirm that the crystals adopt a bilayer packing motif with ethanol as guest molecules. These banded spherulites further exhibit band-dependent linear dichroism and birefringence, as well as circular dichroism and birefringence as a consequence of twist-induced loss of symmetry. Given the modular nature of these hydrogen-bonded frameworks to incorporate a broad range of molecular pillars and guests, combining hydrogen bond-directed assembly with crystal twisting will open unexplored avenues in the design of chiroptoelectronic materials.

Chiral Organic Semiconductors – Lending a Hand in Photocatalysis

Asha Muniraz, Rebecca Ingle and Bob Schroeder; University College London, United Kingdom

Society’s ever-growing energy demands and simultaneous rapid depletion of current greenhouse gas-emitting resources showcase the need to find clean, renewable alternatives. Generation of hydrogen through the combined action of sunlight, water, and a photocatalyst, the water splitting reaction (WSR), offers a promising solution to this long-standing problem. However, the WSR suffers from uncontrolled spin alignment of OH radicals, producing hydrogen peroxide (H2O2) as a by-product, which greatly hinders the efficacy and scalability of this process.[1] As chiral molecules are sensitive to electron spin orientation, due to the Chiral Induced Spin Selectivity (CISS) effect, they could behave as spin filters in photocatalysis, thus providing a unique pathway to cleaner energy by impeding hydrogen peroxide formation.[1],[2]

Conjugated polymers are a class of material that have gained increasing attention due to their applications in many electronic devices such as transistors, organic light-emitting diodes (OLEDs) and flexible organic photovoltaics (OPVs). This is owing to their tunable optoelectronic properties, intrinsic flexibility, solution-processability, low cost and abundance. Application of these features to photocatalysis, in combination with the spin selectivity of chiral molecules, could result in efficient, scalable production of hydrogen for clean energy resources.[2],[3]

This work focuses on the synthesis and spectroscopic characterisation of a series of novel, chiral conjugated polymers to generate the desired CISS effect for the suppression of H2O2 in the WSR. Development of these systems relies on gaining a deeper understanding on how the nanoscale chirality impacts the overall chiral expression. We therefore investigate the effect of chiral centre positioning on the polymer microstructure. In addition to pursuing...
Chiral materials with strong linear anisotropies are difficult to accurately characterize with circular dichroism (CD) because of artificial contributions to their spectra from linear dichroism (LD) and birefringence (LB). Recently, we have discovered that CdS magic-sized clusters (MSC) can self-assemble into ordered films that have a hierarchical structure spanning seven orders of length scale [1]. Because of the small size of MSCs and because of their high organic-ligand/core ratio, these hybrid materials have “softer” inter-particle interactions, with access to a richer phase diagram beyond the classical close packed structures seen with larger nanoparticles, resulting in self-organization into isotropic patterns. These films have a strong CD response, but the chiral origins are obfuscated by the hierarchical architecture and LDLB contributions. Here, we derive and demonstrate a method for extracting the “chiroptic” CD signal (CD generated by structural dissymmetry) from hierarchical MSC films and identify the chiral origin [2]. The theory behind the method is derived using Mueller matrix and Stokes vector conventions, making use of a second-order Taylor series expansion to extract the CD. The method is verified experimentally before it is applied to hierarchical MSC and nanoparticle films with varying macroscopic orderings. Each film’s extracted chiroptic CD shares a bisignate profile aligned with the exciton peak, indicating the assemblies adopt a chiral arrangement and form an exciton coupled system. Interestingly, linearly aligned MSC films possess one of the highest g-factors (0.05) among semiconducting nanostructures reported. Further, we derive an expression to model the measured CD using a third order Taylor series expansion which introduces “pairwise interference” contributions to CD spectra that, unlike LDLB contributions, cannot be averaged out of the signal. We find that the third order pairwise interference terms can make noticeable contributions to the simulated CD spectra. Using numerical simulations of the measured CD across a broad range of linear and chiral anisotropy parameters, the LDLB interactions are most prominent in samples that have strong linear anisotropies (LD, LB) but negligible chiral anisotropies, where the measured CD strays from the chiroptic CD by factors greater than 10³. Media with moderate-to-strong linear anisotropy are in great order interference effects in highly anisotropic nanomaterials.

Nonlocal Spin Transport Property of Chemical Vapor Deposition - Grown Tellurium Crystal

Chiral crystalline materials have a unique and robust spin-momentum relation allowing the design of energy-efficient spintronic devices. For example, when electrons flow in chiral materials, the electron spin is polarized either parallel or antiparallel to the current direction. In this work, we report the nonlocal spin transport characteristics of chemical vapor deposition - synthesized single crystalline Te crystal. We apply inversion spin hall effect to measure the current-induced spin in Te crystal. We find that the spin polarization can transport several hundreds of micrometers at room temperature. This work provides resilient testbeds for future development of practical spintronic devices.

Inorganic Chiral Nanoparticles—A Promising Chiral Trigger to Induce Homochirality

Zhifeng Huang; The Chinese University of Hong Kong, Hong Kong

Origin of homochirality is a fundamentally important but yet unanswered question. One of the keys to answer this question is to understand external chiral forces to trigger symmetry breaking, which has been believed to induce the homochirality. Diverse chiral forces have been proposed, but one is missing: inorganic chiral surfaces have an enantiospecific interaction with prochiral molecules, considering the fact when the Earth formed about 4.5 billion years ago, it was prebiotically composed of inorganic minerals, mostly crystalline in nature and some are chiral, followed by the existence of organic life. We are studying chiral forces contributed from inorganic atomically chiral surfaces.

We use glancing angle physical vapour deposition to fabricate inorganic chiral nanoparticles (or CNPs), which have adjustable optical activities in the UV-visible-near infrared region. Inorganic CNPs are made of diverse metals, alloys and oxides, and composed of chiral structures at the atomic scale, including chiral twisting of multi-layers of achiral facets, high-index chiral facets, and chiral defects. Inorganic CNPs enantiospecifically interact with prochiral molecules, leading to an enantiospecific amplification of molecular optical activity, an enantioselective photoinduced cyclodimerization of a prochiral anthracene derivative, and reliable manipulation of symmetry breaking of prochiral helicenes. Our works shed light on the origin of homochirality (or life) stemming from the atomically chiral surfaces of minerals through the enantiospecific interactions with prochiral molecules.

8:30 AM EL15.03.02
Origins of Chirality in II-VI Semiconductor Nanoclusters via Symmetry Breaking

Chenjie Zeng; University of Florida, United States

Chiral semiconductor nanostructures have potential applications in chiral optoelectronics, spintronics, sensors, and catalysis. Compared to organic molecules, the origins of chirality in semiconductor nanomaterials are less understood due to many possible chiral geometries at hierarchical levels. Here, we unveil the intrinsic origins of chirality in II-VI semiconductor nanoclusters by achieving atomic precision in a tetrahedral-shaped CdSe nanocluster and X-ray crystallographic analysis. We show that the chirality emerges from the incorporation of tetrahedral coordination of individual ions into the icosahedral packing of the lattices, breaking the symmetry of the inorganic core from an achiral \( I \) to a chiral \( T \). The chirality in the CdSe core further propagates to the metal-ligand interface, as manifested in the clockwise and counter-clockwise rotations of the interfacial coordination patterns. The asymmetric assembly of ligands on the tetrahedral facets further breaks the cluster symmetry from \( T \) to \( C \). The left- and right-handed enantiomers are co-crystallized as a 1:1 racemic mixture. The resolved atomic structure of the chiral CdSe clusters shed light on the chiral structures observed in the larger
semiconductor nanocrystals and their assemblies.

Inducing Chiral Photoluminescence in Single Photon Quantum Emitters using Chiral Induced Spin Selectivity Effects. Suryakant Mishra, Jennifer Hollingsworth, Eric Bowes, Han Htoon and Andrew C. Jones; Los Alamos National Laboratory, United States

Chiral quantum emitters or non-reciprocal single photon devices have the potential for playing a significant role in future quantum communication-based infrastructure. To date, the realization of circularly polarized quantum emitters generally requires complex and bulky experimental infrastructures such as high magnetic/electric fields and cryogenic-temperatures. One potential means of realizing chiral quantum emission in solid-state systems is Chiral-Induced Spin Selectivity (CISS). This effect is a well-known physical phenomena known to enable control over electronic spins via the asymmetric transport of electronic spins in chiral organic and inorganic systems. We have explored the utilization of CISS effects as a means of manipulating the circular polarization of photoluminescence from single quantum emitters. Here, cadmium selenide-quantum dots are immobilized on a chiral surface prepared using electrodeposition of aniline. We observe both the inducement a significant degree of circular polarized photoluminescence emission and a magnetization-dependent photoluminescence quenching by using a ferromagnet valve in the chiral substrate. These observations illustrate the potential of a CISS-based mechanisms for realizing chiral single photon emission sources in solid-state material devices. By further exploring the dependence of circularly polarized emission on the quantum dot shell thickness and the thickness of the chiral films, we develop and demonstrate a model for the energy transfer pathways experienced by differing spin orientations in this system.

Structure-Property Relationships of Electrospun Cds Quantum Dot Fibers with Mechanically Modulated Reversible Chirality Hansadi Jayamaha, Thomas J. Ugras, Tobias Hanrath, Richard Robinson and Larissa Shepherd; Cornell University, United States

Over the last three decades, electrospinning has gained increasing interest as a synthesis technique for micro and nano fibers due to its tunability and versaility. For the first time, electrospinning induced self-assembly of Cadmium Sulfide (Cds) magic sized clusters (MSCs) and their resulting chiroptical properties are discussed. The MSCs assemble into hexagonal mesophase during synthesis and the higher-level structures arise during the evaporation process. Through electrospinning, multiple hexagonal mesophase bundles are postulated to form twisted nanofibris. These nanofibris collectively constitute the microfiber as the result of self-assembly. Using Field emission scanning electron microscopy (FE-SEM), and atomic force microscopy (AFM) the morphology of the microfibers and the arrangement of the observed fibrillar structures are studied. The chiroptical properties of the fiber mats are extensively studied using Circular dichroism (CD) spectroscopy.

We improve the uniaxial fiber orientation, thereby synthesizing chiral microfibers with high dissymmetric factors ((~0.02) and linear dichroism (LD), comparable to thin films of the same material. Reversible changes in CD signals and reduced electron dipole alignment (i.e., LD) occur on stretching of the fibers embedded in elastomeric films. To study the alignment of the mesohase filament and inter-filament distance upon stretching, Synchrotron based small angle X-ray scattering (SAXS) was used. We confirm a 4-scan method for removing Linear Dichroism-Linear Birefringence (LD-LB) and photo elastic modulator isolating true CD is applicable for such fibrous webs. This work provides the groundwork for further study of electrospun chiral fibers by bringing forth new research questions regarding the assembly of MSCs into fibrous structures.

Room-Temperature Electrically Switchable Rashba-Dresselhaus Effect in a Van Der Waals Ferroelectric Crystal with Persistent Spin Helix Jian Shi; Rensselaer Polytechnic Institute, United States

Here we show the discovery of the persistent spin helix in an organic–inorganic hybrid ferroelectric halide perovskite whose layered nature makes it intrinsically like a quantum well. We demonstrate that the spin-polarized band structure is switchable at room temperature via an intrinsic ferroelectric field. We reveal valley–spin coupling through a circular photogalvanic effect in single-crystalline bulk crystals. The favoured short spin helix wavelength (three orders of magnitude shorter than in III–V materials), room-temperature operation and non-volatility make the hybrid perovskite an ideal platform for understanding symmetry-tuned spin dynamics, towards designing practical spintronic materials and devices that can resolve the control-relaxation dilemma.

10:00 AM EL15.03.06
Noncentrosymmetric and Chiral 2D Quantum Materials Through Screw Dislocations and Structural Tuning Song Jin; University of Wisconsin--Madison, United States

Rationally controlling the structures of two-dimensional (2D) layered materials allows us to tune the electronic structures and quantum states of matter, discover new physical properties, thus enable new applications. We show how the phase, layer stacking and thus physical properties of 2D MX2 materials can be influenced by screw dislocations. Noncentrosymmetry of these MX2 materials and 2D Ruddlesden-Popper (RP) lead halide perovskites could be enabled at the monolayer and bulk crystal structure level by structural tuning and screw dislocations. Furthermore, chiral microplates of MX2 and 2D RP perovskites can be produced via a screw dislocation growth mechanism and the resulting chiroptical properties of individual chiral objects are studied using fluorescence detected circular dichroism (FDCD) microscopy and other polarized spectroscopic/nonlinear optical techniques. Moreover, we achieved systematic interlayer twisting of MX2 spiral layers grown via screw dislocations due to mismatched geometry between Euclidean crystal lattices and non-Euclidean (curved) surfaces to form moiré superlattices, which could lead to novel quantum phenomena. The ability to enable and control noncentrosymmetry, chirality, and twisting of 2D materials open up new dimensions of quantum materials for the study of nonlinear and chiral optical properties, valleytronics and twistronics.

10:30 AM EL15.03.07
Enabling Chiroptical Properties in Achiral 2D Perovskites via Spiral Morphology Willa Mihalyi-Koch, Katherine Parrish, Randall H. Goldsmith and Song Jin; University of Wisconsin--Madison, United States

Chiral 2D halide perovskites are promising semiconducting materials for chiroptoelectronic and spintronic applications. Chirality is typically imparted into 2D perovskites through the incorporation of chiral ammonium spacer cations, resulting in a chiral crystal structure. However, the extent of chirality transfer from the chiral organic cations to the inorganic perovskite network remains debated. In this work, we present another approach to introduce chirality and chiroptical properties into 2D perovskites through nanostructure morphology. By tuning crystallization conditions at an air-water interface, a large family of 2D perovskites with achiral crystal structures can be directly grown into spiral microplates via a screw dislocation growth mechanism. We demonstrated the versatility of this method by synthesizing spiral microplates of 10 different 2D Ruddlesden-Popper lead halide perovskites with various spacer cations,
A key goal of materials science is to develop self-assembling hierarchical materials from nanoparticle building blocks with interesting properties. Understanding the structure-property relationships within these systems will enable the rational design of advanced optical devices. Recently, our group has discovered that CdS magic-sized clusters organize into hexagonal fibers which can self-assemble into ordered films that have a hierarchical structure spanning seven orders of length-scale[1]. These films have demonstrated strong linear and circular dichroism (LD, CD) responses originating from transition dipole alignment and cluster-to-cluster coupling, respectively, but further characterization of the optical properties using lab-based measurements are obfuscated by the samples’ mixed linear and chiral anisotropies[2, 3]. In this work, we pair two synchrotron techniques, microfocused small-angle x-ray scattering (SAXS) and synchrotron radiation Mueller Matrix polarization (MMP) mapping, to unravel the structural and optical anisotropies present in the self-assembled nanocrystal films. These studies have revealed local chiroptical properties stronger than previous measurements from lab instruments; in fact, our measured dissymmetry factors (i.e., absorption g-factor) are the largest reported for inorganic semiconductors, and only an order of magnitude smaller than the theoretical maximum limit of 2. The MMP mapping reveals that the self-organized films contain millimeter-scale domains with a constant CD magnitude and handedness, whereas isotropic films (non-self-assembled) present much smaller micron-scale domains. Further, MMP and SAXS measurements show that within self-assembled, anisotropic films the transition dipole of the clusters are macroscopically oriented in the same direction as the nm-scale fibers. In summary, these experiments have revealed a relationship between the self-assembly process, the orientation of supramolecular nanocrystal fibers, and the handedness of a film’s response. These results - anomalously large chiral anisotropy, orientational control of the clusters and their transition dipoles, and enantiomeric control of chiral domains within nanocrystal films - enable chiral light control for a range of emerging technologies.

11:15 AM EL15.03.10
Decomposition of Layered Double Hydroxides for Accessing Chiral Metal Oxides Aine Coogan1, Lucy Hughes1,4, Finn Purcell-Milthorpe1,2, Seán Cardiff1,2, Valeria Nicolosi1,3,3 and Yurii K. Gun’ko1,3,1; 1Trinity College Dublin, The University of Dublin, Ireland; 2Technological University Dublin, Ireland; 3University College Dublin, Ireland

In recent years, significant research efforts have been directed towards the development of chiral and chiroptically active inorganic nanomaterials, resulting in many new nanomaterials of various forms and morphologies, including quantum dots, nanowires, and tetrapods, among others.1,2 Layered double hydroxides (LDHs) have emerged as a distinct class of ionic two-dimensional (2D) nanomaterials, renowned for their exceptional anion exchange properties, allowing for the incorporation of diverse species within their interlayer spaces, including chiral molecules. Surprisingly, despite this unique chiral environment, there is a notable absence of reported studies exploring the utilisation of LDHs treated with chiral ligands to induce chiroptical activity. While chiral copper (II) oxide (CuO) nanostructures have previously been documented in literature, their synthesis often requires harsh, high-temperature synthetic conditions and the inclusion of expensive surfactants and symmetry-breaking agents to induce circular dichroism (CD) responses in the visible range. Prior to this work, the room temperature synthesis of chiral CuO has remained un-explored to the best of our knowledge. Additionally, the potential for chirality transfer from chiral ligands to LDH-based nanostructures has not been reported. Herein, we present the unique facile approach to the synthesis of chiral CuO nanostructures through an alkaline room-temperature, aqueous treatment of carbonate-intercalated copper-aluminium LDHs (CuAl-CO3 LDHs) with L- and D-Phenylalanine (L- and D-Phe). The resulting 2D CuO nanosheet bundles
display remarkable chiroptical activity, with g-factors up to 0.0035. Time-dependent circular dichroism (CD) powder X-ray diffraction (pXRD) and Fourier (FT)-IR) studies reveal that the initial chirality transfer arises from Phe coordination to the Cu$^2+$ sites, leading to decomposition of the CuAlCO$_3$ LDH to CuO. Self-assembly of the Phe-functionalised CuO nanosheets results in enhancement of the chiroptical activity. This work represents a novel, facile route of accessing chiral metal oxides through decomposition of LDH precursors. The ease of synthesis and induction of strong chiroptical activity in the visible range (400-800 nm) highlights the significance of this work. The resultant new chiral metal oxides hold promise for potential applications in enantiomeric separation and asymmetric catalysis, paving the way for advancements in chiral nanomaterial research.6

DNA-Templated Silver Nanoclusters with Strong Chiroptical Response in the Visible Spectral Region
Rweetuparna Guha, Anna Gonzalez Rosell, Malak Rafik and Stacey Cripps
University of California, Irvine, Irvine, United States

DNA can template the chemical synthesis of few-atom silver nanoclusters with defined chiralities and strong electronic circular dichroism (CD) response. These "Ag$_n$DNAs" have a diversity of sizes, shapes, and optical properties that are selected by the nucleobase sequence of their DNA ligands. Composed of just 10-30 Ag atoms and 1-3 short DNA oligomers, most studies of Ag$_n$-DNAs have focused on their bright visible to near-infrared fluorescence. The DNA sequence-selected chiroptical properties of Ag$_n$-DNAs are also of both fundamental and applied interest and have been far less studied. As an inherently chiral ligand, DNA selects for nanocluster chirality without the need for intensive separation techniques that are typically required for metal nanocluster enantiomer separation, such as chiral chromatography. The chiral properties of Ag$_n$-DNAs hold promise for biomolecular sensing and nanophotonics applications. However, studies of the chirality of Ag$_n$-DNAs prepared to atomic precision are limited to date, and few X-ray crystallographic structures have been reported.

To understand the chiral properties of Ag$_n$-DNAs, we investigated a large set of 19 different atomically precise Ag$_n$-DNA species with emission at the far red/NIR spectral border [1]. The molecular formula of each purified species is determined by high-resolution mass spectrometry and correlated to its optical absorbance, emission, and CD spectra. We find that these Ag$_n$-DNAs are either 6-electron clusters or 8-electron clusters (corresponding to the oxidation state of the silver nanocluster), with distinct absorbance and CD spectral features for these two classes of nanoclusters. 8-electron Ag$_n$-DNAs are stabilized by two DNA oligomer copies and display complex CD spectra with multiple distinct UV and visible transitions. The electron count of these "magic-sized" 8-electron nanoclusters suggests quasispherical geometries. 6-electron Ag$_n$-DNAs, which past studies support have rod-like shapes, exhibit three different ligand compositions, each with its own characteristic CD signatures. Ag$_n$-DNAs stabilized by two oligomer copies exhibit a distinct positive or negative monosignate CD signature aligned with the longest visible absorbance peak of the nanocluster, suggesting a chiral nanocluster core whose handedness is selected by the specific DNA template sequence. Ag$_n$-DNAs stabilized by three oligomer copies exhibit the same visible CD signature but distinct UV CD signatures, suggesting that DNA ligands adopt similar conformations around nanoclusters with three DNA ligands. Finally, Ag$_n$-DNAs stabilized by two oligomer copies and additional chlorido ligands exhibit significantly suppressed visible CD signatures, supporting that the additional atomic ligands suppress nanocluster chirality. The distinct chiroptical signatures and compositions of these four classes of Ag$_n$-DNAs also correlate to distinct excited state emission properties, suggesting that nanocluster electron count and chirality influences both ground and excited state processes in these emitters. This study illustrates the diversity of structure-property relationships for NIR-emissive Ag$_n$-DNAs, which could be harnessed to precisely tune these emitters for applications that exploit their DNA sequence-selected chiral properties. Moreover, the results show that the chiroptical properties of Ag$_n$-DNAs are highly sensitive to nanocluster composition and ligand conformation.

Chiral crystal structures allow optical effects such as natural optical activity, which has long been used to identify chirality. While the symmetry analysis of structural chirality and optical response was carried out many years ago, the details of how microscopic electron wavefunctions generate observed chirality were not completely understood even in the linear case. Studies motivated by the experimental discovery of Weyl semimetals clarified the origin of chirality at low frequency in all chiral metals (the chiral or gyrotropic magnetic effects) and the importance of the orbital magnetic moment. Weyl semimetals are more unique in their nonlinear optical properties, where chiral Weyl semimetals show an exciting kind of quantization in their chiral photocurrent or chiral magnetic effect at the non-interacting level. The second part of the talk concerns how interactions between electrons or spins can lead to the spontaneous development of a chiral order parameter. The specific example discussed in detail is the behavior of triangular lattice Mott insulators, where a chiral spin liquid is shown numerically and analytically to be a competitive state arising near the Mott transition. Experimental signatures of this state, and the rapidly developing experimental situation of triangular lattice compounds, are discussed as an example of how new techniques allow greater understanding of correlated lattice problems.

To evaluate the contribution of Rashba and Dresselhaus effects, we compared the CPGE currents of (\(R\)-S)-methylbenzylammonium halide and (\(R\)-S)-\((2\text{-naphthyl})\text{ethylamine}\)halide. In this presentation, we will quantitatively discuss the chiral discrimination and dispersion intermolecular forces responsible for van der Waals (vdW) interactions, are due to induced-electric dipole induced-electric dipole interaction. They can be affected by molecular chirality in an unexpected way that is connected to the Chiral-Induced Spin Selectivity (CISS) effect, which provides a physical mechanism for the onset of an effective vdw interaction that depends on the relative orientation of the two enantiomers associated to a chiral molecule. This argument provides a path for chiral discrimination, which plays a fundamental role in molecular recognition of bio-molecules and the

**Chiral Magneto-Optical Properties and Chiral Spintronics Based on Chiral Halide Perovskites** Lan-Sheng Yang, Pei-Hsuan Lo, Chin-An Hsu, Yi-Hsiu Hua and Yu-Chiang Chao, National Taiwan Normal University, Taiwan

Chiral halide perovskites can be prepared by solution processing using a mixture of a lead halide and a chiral organic halide as a precursor. Examples of chiral organic halides are \(R\)- and \(S\)-methylbenzylammonium halide and \(R\)- and \(S\)-\((2\text{-naphthyl})\text{ethylamine}\)halide. In this presentation, we will present the chemical composition, morphology, absorption, photoluminescence, quantum yield and carrier lifetime of chiral perovskite films prepared from precursor solutions with different stoichiometric ratios and different halide ratios. The chiral halide perovskite films exhibit chiroptical properties, such as circular dichroism and circularly polarized luminescence, in the absence of an external magnetic field. Symmetrical circular dichroism spectra were obtained. The energy level splitting induced by chiral molecules was estimated by using multiple Gaussian fitting. Once the magnetic field is applied, the magnetic field-induced CD features are superimposed on the intrinsic chirality-induced CD features. In addition, spin organic light-emitting diodes were realized by using chiral halide perovskite film as the spin-polarized hole transport layer. At room temperature, circularly polarized electroluminescence was observed from the spin organic light-emitting diodes in the absence of an external magnetic field.

To evaluate the contribution of Rashba and Dresselhaus effects, we compared the CPGE currents of (\(R\)-S)-methylbenzylammonium halide and (\(R\)-S)-\((2\text{-naphthyl})\text{ethylamine}\)halide. In this presentation, we will quantitatively discuss the chiral discrimination and dispersion intermolecular forces responsible for van der Waals (vdW) interactions, are due to induced-electric dipole induced-electric dipole interaction. They can be affected by molecular chirality in an unexpected way that is connected to the Chiral-Induced Spin Selectivity (CISS) effect, which provides a physical mechanism for the onset of an effective vdw interaction that depends on the relative orientation of the two enantiomers associated to a chiral molecule. This argument provides a path for chiral discrimination, which plays a fundamental role in molecular recognition of bio-molecules and the

**References**

design of chiral material interfaces.

In this contribution, we will explicitly describe a simple model to explore the influence of the CISS effect in vdW forces, and the way this leads to molecular chiral discrimination.

Theoretical Perspective on Chirality-Induced Spin Selectivity and Chiroptical Properties in Layered Halide Perovskites Mikael Kepenekian1, Claudine Katan1, Simon Thébaud1, Jacky Even1, Shangpu Liu2, Felix Deschler3, Alexandre Abhervé4 and Nicolas Mercier1; 1University of Rennes, France; 2INSa Rennes, France; 3Heidelberg University, Germany; 4University of Angers, France

3-dimensional (3D) halide perovskites AMX3 (A: organic cation, M: metal ion, X: halide) have shown spectacular results in optoelectronic devices. However, they offer limited choices of metals and organic cations, which limits the chemical design of optimal materials. This is not the case of lower dimensional materials, e.g. layered (2D) halide perovskites (LHPs) [1], that impose far less constraints over the organic spacer. It then become possible to associate the exceptional optoelectronic properties of halide perovskites with chiral cations to reach promising materials for chiroptical and magnetochiral applications [2].

Here, we report joint experimental and theoretical investigations of LHPs with exceptional (i) chiroptical, and (ii) magnetochiral properties. Firstly, the enantiopure 3BrMBA2PbI4 (MBA = methylbenzylammonium) perovskite thin films exhibit external photoluminescence quantum efficiency as high as 39% and circularly polarized photoluminescence up to 52%, at room temperature [3]. Next, we consider a series of chiral lead-bromide networks which crystallize in enantiomorphic polar space groups P41212 and P43212 for the R and S enantiomers, respectively [4]. Chirality-induced spin selectivity (CISS) effect measurements performed over those materials by magnetic conducting-probe atomic force microscopy (mc-AFM) reveal a spin polarization of about 40% [4].

We use a set of experimental characterizations (e.g. single-crystal x-ray diffraction), and theoretical tools (semi-empirical modeling and density-functional theory based calculations) to describe the chiral-related properties of these LHPs and help the cation engineering of efficient chiral halide perovskites.

Spin Polarized Current Injection from Chiral Halide Perovskites into III-V LEDs Matthew Hautzinger, Kirstin M. Alberi and Matthew C. Beard; National Renewable Energy Laboratory, United States

Spintronic applications integrating conventional group IV and III-V semiconductors suffer from a lack of efficient spin injection techniques. Most works rely on a ferromagnetic layer in combination with a tunnel oxide barrier, to avoid the conductivity mismatch, to inject spin polarized current into the semiconductor. These complicated interfaces are susceptible to defect chemistries inhibiting efficient spin polarized carrier injection. Here, we integrate semiconducting chiral halide perovskite, (R/S-MBA)2PbI4 (MBA = alpha-methylbenzylammonium) with III-V AlGaInP LEDs. The semiconducting (R/S-MBA)2PbI4 injects spin polarized current into the AlGaInP via the chirality induced spin selectivity effect. The spin polarized current produces circularly polarized electroluminescence, with efficiencies regularly achieved of 10 ~ 3% at room temperature and no external magnetic field applied. This remarkable efficiency is due to the pristine semiconductor-semiconductor interface between the (R/S-MBA)2PbI4 and AlGaInP which avoids the problematic conductivity mismatch of ferromagnetic-semiconductor interfaces. We characterized this interface with TEM, XPS, and cross sectional KPFM to show it has excellent interfacial properties with no unintentional barriers introduced. We further prove the circularly polarized emission is the result of spin polarized current injection by measuring the Hanle effect. We observe a decrease in circularly polarized light emission with the application of a magnetic field, as expected from spin polarized current injection. These results present a new method of spin polarized current injection, enabled by a semiconducting CISS layer, which can be applied to numerous spintronic applications.

SESSION EL15.05: Controlling Chirality of Organic-Inorganic Hybrid Perovskites

Structure-Property Tunability using Chirality and Symmetry Breaking in Hybrid 2D Perovskites David B. Mitzi; Duke University, United States

Hybrid organic-inorganic perovskite (HOIP) semiconductors based on metal halide frameworks offer unprecedented opportunity to tailor structural and materials properties using the full flexibility afforded by the associated inorganic and organic components,1 and such tunability offers wide-ranging potential for applications including solar cells, light-emitting devices, detectors, transistors and advanced computing devices. In this talk we will focus on examining the role that the organic cation can play in introducing or impacting chirality, symmetry breaking and associated phase transitions within HOIPs, as well as on the resulting chiroptical (e.g., circularly dichroism),2 spin-selective charge transport (e.g., chirality-induced spin selectivity),3 and electronic structure (e.g., spin splitting of the conduction band)2 characteristics of these systems. Recent examples of such symmetry-related tunability highlight the promise of using the organic component to control light, charge and spin within the wide-ranging HOIP family.

Reference:
Hybrid organic/inorganic halide perovskites are intriguing chiral material systems owing to their excellent optoelectronic properties and potential to impart chirality with the organic A-site cation. Typically, chiroptical properties arise due to structural symmetry breaking from chiral A-site organic cation to the inorganic framework. In the present work, we demonstrate a proximity effect of remote chirality transfer to induce chirality in otherwise achiral 2D halide perovskites. A chiral organic ligand is introduced in the perovskite lattice without altering the structure, thus introducing chirality into existing 2D perovskites. Furthermore, we construct a chirality-composition library with varying the A, B, X-sites, along with the dimensionality, revealing the essential role of each atomic component in the perovskite structure. This approach of remote chirality transfer in halide perovskites could lead to new prospects in terms of composition, spin transport properties, and devices without extensive chemical modifications.

Chirality, a fundamental concept for matters that cannot be superimposed with their mirror images, is ubiquitous in almost all branches of natural science. Due to significance of chirality and wide versatility of chiral materials, in recent years, the concept of chirality can be successfully expanded to variety of different material including quantum dots, liquid crystals, and organic-inorganic hybrid system. Especially, chiral perovskite materials have attracted unprecedented attention as a new type of chiral semiconductors since the first report of chiroptical response in 2017. Different from the inherent chiral organic materials, chirality transfer from chiral organic spacer to achiral inorganic frameworks should be preceded to achieve chiroptical activity in chiral perovskite. Although extensive studies have reported the circular dichroism (CD) in chiral perovskite, the origin of chiroptical response in chiral perovskite ambiguous. Furthermore, several groups reported CD sign inversion behavior when flipping thin films samples, implying that the observed CD signal confined from chiral perovskite thin films might be originated from linear effects. However, due to the poor understanding of CD mechanism and inherent limitation of commercial CD spectrometers, the macroscopic origin of apparent CD behavior has been incorrectly interpreted. From this point of view, we investigate the real origin of apparent and genuine CD response in chiral perovskite thin films by using our home-made Mueller matrix polarimeter (MMP).

From this point of view, we investigate the real origin of apparent and genuine CD response in chiral perovskite thin films by using our home-made Mueller matrix polarimeter (MMP).

Interestingly, based on experimental results from MMP and theoretical decomposition of Mueller matrix parameters, we found that apparent CD behavior is primarily originated from linear birefringence (LB) effects rather than linear dichroism (LD) behavior which is attributed to microscopy preferred orientation of thin films. Furthermore, polarization optical microscopy confirmed that LB effect is closely related with second-order ferroelectric phase transition behavior. To the best of our knowledge, this is first systematic study to clarify the real origin of apparent CD based on the decomposition of Mueller matrix parameter, which is different from the interpretation based on ambiguous LDS/LB effect. Our study unveils the importance of the LB effect on the CD behavior of thin films and provide an in-depth understanding between ferroelectricity and chiroptical response.

Spin-dependent electrochemistry is introduced as an innovative concept for boosting overall photoelectrochemical (PEC) efficiency. Especially, the performance of oxygen evolution reaction (OER) can be improved by the chirality-induced spin-selectivity (CISs) phenomenon based on chiral materials. The CISS can effectively reduce the overpotential of the OER process by aligning the electron spins with specific directions. The parallel-aligned electron spins favor the generation of triplet oxygen ($^3O_2$), which is energetically more stable than the singlet oxygen state ($^1O_2$), while refraining from the formation of competitive by-product of hydrogen peroxide. In this regard, the chiral 2D organic-inorganic hybrid perovskites (OHPs) are considered as a promising spin filter due to their exceptional spin-polarization capability of over 80%. However, there are still underlying intrinsic obstacles to exploit chiral 2D OHPs as spin filters for OER devices. The 2D OHPs structures have poor conductivity along with out-of-plane direction where multiple spin alignment occurs, which restricts further enhancement of OER performance. Such a problem stems from the multi-quantum well structures of OHPs composed of two repeating building blocks, namely organic cations and inorganic frameworks. In addition, the vulnerability of 2D OHPs to water is attributed to the hygroscopic nature of the organic cations, which becomes another hindrance to accomplishing the long-term operational stability of OER devices. Therefore, it is essentially necessary to develop groundbreaking materials that can promote electrical properties and moisture instability while maintaining the chirality of OHPs.

Herein, we introduce chiral 2D OHPs fluorinated methyl-benzylamine (F-MBA) chiral structural isomer cations, which have different structures according to the fluorine location of ortho-, meta-, and para- on the benzene ring. The chirality of the 2D OHPs can be augmented according to the specific chiral cation structures originating from the intensified organic-inorganic halogen-halogen interactions. Moreover, the fluorinated chiral organic cations can not only endow hydrophobic characteristics to OHP systems but also enhance the out-of-plane conductivity by reducing the exciton binding energy. As a result, we have implemented the fluorinated 2D OHPs film on top of BiVO$_4$ photoanode for oxygen production. The fluorinated OHPs spin filter drastically reduces the operational potential with improved structural stability. Our results suggest a promising material design rule to fabricate stable and efficient chiral 2D OHPs spin filter for spin-dependent applications.
can be doped into (S-BrMBA)\textsubscript{2}PbI\textsubscript{4} (S-BrMBA = (S)-(−)-4-bromo-a-methylbenzylammonium), modulating the structural symmetry from a higher symmetry (C\textsubscript{2}) to the lowest symmetry state (P\textsubscript{1}). This structural change occurs when the concentration of S-2-MeBA, measured by solution nuclear magnetic resonance, exceeds a critical level—specifically, for 1.4 ± 0.6 %, the structure remains as C\textsubscript{2}, whereas 3.9 ± 1.4 % substitution induces the structure change to P\textsubscript{1}. Atomic occupancy analysis suggests that one specific S-BrMBA cation site is preferentially substituted by S-2-MeBA in the unit cell, which rearranges the organic layer to break C\textsubscript{2} rotational symmetry. Density-functional theory calculations indicate that the spin splitting along different k-paths can be modulated by cation doping. A true circular dichroism band at the excitation energy of the 3.9% doping phase shows polarity inversion and a ~45 meV blue shift of the Cotton-effect-type line-shape relative to (S-BrMBA)\textsubscript{2}PbI\textsubscript{4}. A trend toward suppressed melting temperature with higher doping concentration was observed. The chiral cation doping system and the associated doping-concentration-dependent structural transition provide a material design strategy for controlling and enhancing symmetry-related properties, such as chiroptical, non-linear optical, spin-related, and ferroelectric properties.

Boosting Non-Centrosymmetric Distortion and Magnetic Properties in Chiral Metal Halide Perovskites Sanghyun Nam\textsuperscript{1}, Jaewook An\textsuperscript{2}, In Hyeok Park\textsuperscript{1} and Young Hoon Kim\textsuperscript{1}; \textsuperscript{1}Yonsei University, Korea (the Republic of); \textsuperscript{2}Chungnam National University, Korea (the Republic of)

Control of spin-polarized currents and magnetic properties in materials are important to demonstrate various spintronic applications such as MRAM and spin LEDs. In conventional semiconductors and metals, spin polarization and magnetization occur by the application of external magnetic fields or fabrication of ultra-thin (~5 nm) layer of the materials, which complicate the fabrication process and device structure. Here, we report novel materials system, hybrid chiral metal-halide perovskites (MHPs), which can control the spin polarization and magnetic properties via simple solution process. MHPs consist of three different atoms or molecules in various crystal structures (representations are ABX\textsubscript{3} and A\textsubscript{2}BX\textsubscript{4} where A is an organic ammonium, B is a transition metal cation and X is a halide anion). First, we synthesize chiral lead (Pb)-based MHPs ((R-/S-MBA)\textsubscript{2}PbI\textsubscript{4} where MBA is methylbenzylammonium) and find that R-/S-MBA cations transfer the chirality to the inorganic metal-halide octahedra (PbX\textsubscript{6}) by the asymmetric electrostatic interaction between ammonium group in MBA and halide in inorganic octahedra. (R-/S-MBA)\textsubscript{2}PbI\textsubscript{4} polycrystalline thin films show circular dichroism (CD) signals with opposite directions which are dependent on the chiral direction of MBA. Furthermore, (R-/S-MBA)\textsubscript{2}PbI\textsubscript{4} show efficient spin selectivity > 80% without external magnetic fields by the chiral-induced spin selectivity (CISS) effect. Second, to solve the toxic problem in Pb-based MHPs, we synthesize Pb-free chiral MHPs that use palladium (Pd) in its site cation. Pd-based MHPs have 0-dimensional orientation of Pd-halide square-planar, where the direction of the orientation depends on the chiral direction in A-site cation, and increased CD signals when mixed halides are used in X-site (anisotropy g-factor (g\textsubscript{CD}) = 3.3 × 10\textsuperscript{-3} in pure chloride, 1.2 × 10\textsuperscript{-2} in pure bromide, 1.8 × 10\textsuperscript{-2} when Br\textsubscript{0.5}Cl\textsubscript{0.5}). We also measured the spin selectivity in Pd-based chiral MHPs. Third, to induce magnetic properties in MHPs in addition to the chirality, we synthesize iron (Fe)-based chiral MHPs with different Fe compositions. Fe-based chiral MHPs show CD signals in the absorption range of metal-halide tetrahedra, which clarify that R-/S-MBA transfers its chirality to the metal-halide tetrahedra. Furthermore Fe-based chiral MHPs exhibit paramagnetism at low temperature, which demonstrate the potential of future MHP materials which have both chirality and magnetic properties.

11:15 AM EL15.05.07
Highly Efficient Chiral 2D/3D Perovskite Artificial Leaf for Spin-Dependent Photocatalytic Overall Water Splitting Hyungseok Lee, Chan Uk Lee, Juwon Yun, Wooyong Jeong, Chang-Seop Jong, Jaehyun Son, Young Sun Park, Subin Moon and Jooho Moon; Yonsei University, Korea (the Republic of)

The intricate nature of the multi-step oxygen evolution reaction (OER) continues to pose a challenge in achieving bias-free photocatalytic water-splitting systems. Several theoretical and experimental studies have suggested that OER efficiency can be significantly improved in chiral material-based photocathodes by utilizing the chirality-induced spin selectivity (CISS) phenomenon. The final product at the photoanode is the oxygen molecules, where the spin alignment of intermediate radicals is favorable to the generation of triplet \textsuperscript{3}O\textsubscript{2} (most stable molecular oxygen species). Considering the energy difference between a singlet \textsuperscript{1}O\textsubscript{2} and triplet \textsuperscript{3}O\textsubscript{2} (the energy of a singlet \textsuperscript{1}O\textsubscript{2} is approximately 100 kJ mol\textsuperscript{-1} higher than that of triplet \textsuperscript{3}O\textsubscript{2}), spin-dependent chemical reactions combined with the CISS phenomenon can play a crucial role in facilitating the OER process. Especially, by promptly aligning the spin distribution of photo-generated charges within the absorber, it could effectively prevent the formation of hydrogen peroxide, leading to a dramatic reduction in overpotential. In this regard, the incorporation of a chiral spin-filter layer on top of the absorber has been recognized as a promising strategy to achieve a significant enhancement on the PEC performance of the solar-driven water splitting system.

Chiral 2D OHIPS have been conventionally employed as spin-filter layer with two distinct enantiomers, namely R- and S-methyl benzylamine (R- and S-MBA). Owing to the weak π-π interaction of the MBA organic cation, however, the coupling effect between the π-electron and p-orbital of the halide in the inorganic framework is relatively weak in chiral 2D OHIPS. To reinforce the coupling effect of chiral 2D OHIPS, we utilized naphthyl ethylamine (NEA) capable of stronger π-π stacking interaction between naphthalene rings. Moreover, the introduction of NEA organic cations can simplify the molecular arrangement of chiral 2D OHIPS, leading to enhanced film crystallinity and improved chiroptical properties. Herein, we demonstrated that the CISS phenomena can become a remarkable approach by adopting NEA-based chiral 2D OHIPS as a spin-filtering layer on the 3D OHIPS photoanode. Our chiral 2D OHIPS exhibited an impressive CISS efficiency of approximately 95%, indicating a remarkable achievement in spin controlling when compared to other chiral materials. Moreover, chiral 2D/3D OHIPS-based water-splitting device achieved enhanced oxygen evolution performance with a reduced overpotential of 0.2 V, high fill factor, and increased photocurrent of 22 mA cm\textsuperscript{-2} at 1.2 V\textsubscript{RHE} compared to a device without a spin-filtering layer. For unbiased water splitting, a perovskite photocathode was connected in parallel with spin-filtering layer adopted 3D OHIPS-based photoanode. Overall solar-driven water splitting was achieved using all the OHIP photoelectrodes, resulting in a remarkable unassisted solar-to-hydrogen efficiency of ~13% and a continuous 100 h stable operation.
metasurfaces. In particular, I will discuss our theoretical and experimental work on nonlocal metasurfaces supporting chiral eigenstates, locally structured with subwavelength resolution. I will also discuss the unique opportunities that chirality and rotational broken symmetry enables in the context of polaritonic systems and time metamaterials.

Active Chiral Plasmonic Metasurfaces Juhwan Kim, Jang-Hwan Han, Gyurin Kim and Hyeon-Ho Jeong; Gwangju Institute of Science and Technology, Korea (the Republic of)

Chiral plasmonics offers a powerful means to control light-matter interactions based on their unique polarization-sensitive chiroptical characteristics, enabling a wide range of applications, including molecular sensing, holographic encryption, and optical filters. In order to fully exploit the potential of chiral plasmonics for industrial applications, it is crucial to develop their active system that can respond to external stimuli and thus allow us to dynamically control their chiroptical responses. However, such active chiral plasmonics are still in their early stages of development. Here, we present an active chiral plasmonic metasurface capable of dynamically controlling the chiroptical response through combinatorial modulation of both the state of light polarization and an external electrical input. The metasurface consists of a wafer-scale array of chiral nanohelices grown using a physical shadow growth technique, with a conductive polymer shell polymerized around the entire surface of helices. The intrinsic dissymmetry factor of this chiral plasmonic metasurface exceeds 0.1, leading to rich polarization-dependent colors. To achieve further extended color dynamics, we electrochemically control the redox state (i.e., refractive index) of the conductive polymer shell, thereby inducing changes in the plasmonically resonating colors of the nanohelices. Remarkably, in conjunction with controlling the state of the light polarization, we achieve full-color dynamics from the single chiral plasmonic metasurface, driven by just input voltages of less than 1 V, highlighting its potential applications in electrochromic displays and filters.

In this presentation, we will discuss the successful fabrication of these chiral plasmonic metasurfaces and provide a comprehensive characterization of their active chiroptical properties. The proof-of-concept applications will also be presented, featuring their impressive fidelity for active coloration.

2:15 PM EL15.06.03
Chirality Induced Second Harmonic Generation in Aligned and Enantiomer Enriched Carbon Nanotubes Rui Xie1, Yuan Tian2, Jacques Doumani1, Andrey Baydin1, Weiran Tu1, Yohei Yomogida1, Fuyang Tay1, Jianing Luo1, Jun Lou1, Kazuhiro Yanagi1, Riichiro Saito2, Junichiro Kono1 and Hanyu Zhu1; 1Rice University, United States; 2Tohoku University, Japan

Aligned assemblies of single-chirality semiconducting carbon nanotubes (CNTs) are ideal materials for developing nanoelectronic, optoelectronic, and quantum photonic devices. Although left- and right-handed CNTs have identical properties in many aspects, enantiomer-dependent properties can manifest in magneto-transport, optical polarization selection, and nonlinear optics. For example, theoretical studies have predicted a large, resonance-enhanced second-order nonlinear optical susceptibility up to nm/V in perfect chiral CNT ensembles, but the value has never been experimentally verified due to mixed chirality components, poor alignment, and low densities. Here, we report the synthesis of centimeter-scale single-enantiomer, highly packed, and aligned (11-5) CNT thin films using the controlled vacuum filtration method. We observed giant second harmonic generation (SHG) from the samples with effective second-order nonlinear optical susceptibility up to 70 pm/V, which corresponds to 350 pm/V for an enantiomerically pure, densely packed and perfectly aligned solid as predicted when the fundamental frequency resonates with the transition of the CNTs at 1000 nm. We confirmed that the SHG signal originates from the inversion symmetry breaking from the intrinsic chirality of the film, instead of surface defects, by angle and polarization dependent SHG measurements. Our findings provide a fast and scalable method for characterizing the alignment and enantiomer purity of CNT films, and establish them as an excellent material for nonlinear optical studies and applications.

Chiral Materials from Perylene Diimide Building Blocks: Twistacenes and Helicenes Colin Nuckolls; Columbia University, United States

This presentation will detail our efforts to create materials from contorted aromatic molecules. In particular, I will discuss how to create helicenes and twistacenes from perylene diimide building blocks. These materials have extraordinary properties as materials. The twistacenes have the largest chiroptic response of any molecular species. The twistacenes helicity is dynamic and can be controlled by light and chemical/electrochemical reductions. These materials excel as photovoltaics, photodetectors, batteries, and pseudocapacitors. The presentation will discuss these opportunities.

4:00 PM EL15.06.05
Bringing Sensitive Circularly Polarized Luminescence Spectroscopy to the Time Domain Antti-Pekka M. Reponen1, Marcel Mattes2, Winald Kitzmann2 and Sascha Feldmann1; 1Harvard University, United States; 2Johannes Gutenberg-Universität, Germany

Materials capable of emitting circularly polarized light (CPL) are promising for breaking efficiency limits in existing optoelectronic applications and may enable entirely new photonic and spintronic technologies. However, reliably detecting CPL with the necessary sensitivity to quantify low dissymmetry factors, while being able to identify and ideally circumvent artefacts arising from linear dichroism, linear birefringence or linearly polarized emitted or scattered light is experimentally challenging [2].

Here we report on our recent efforts to develop CPL detection with the additional dimension of time evolution to achieve broadband, calibration-free CPL spectroscopy with nanosecond time resolution [3]. This technique will serve as a powerful tool to study the dynamics of chiral emitters and to understand how chirality evolves in the excited state.

4:15 PM EL15.06.06
Twisting Photons with Chiral Metal-Halide Semiconductors Haipeng Lu; The Hong Kong University of Science and Technology, Hong Kong

Chiral metal-halide semiconductors (MHS) have recently developed as promising candidates for spin- and polarization-resolved optoelectronic devices. Although several chiral MHS with rich chemical and structural diversity have been reported lately, the fundamental mechanisms governing their chiroptical activity, namely, circularly polarized absorption and emission, remain elusive. In this talk, I will discuss our recent progress in understanding and tuning
the chiroptical activity in chiral MHS. I will first discuss how the chirality is transferred from organic to inorganic component through asymmetric covalent bonding interactions. Their endowed molecular chirality was then studied by circular dichroism (CD). However, we found that the previously reported “apparent” CD in chiral MHS thin films is not an intrinsic chiroptical property, but rather, arising from an interference between the film’s linear birefringence and linear dichroism. We verify the presence of LB and LD effects in both one-dimensional and zero-dimensional chiral MHS thin films. We then establish spectroscopic methods to decouple the genuine CD from other spurious contributions, which allows a quantitative comparison of the intrinsic chiroptical activity across different chiral MHS. The relationship between the structure and the genuine chiroptical activity is then uncovered, which is well described by the chirality-induced spin–orbit coupling in the chiral structures. Meanwhile, we found that high CD signals do not necessarily lead to high circularly polarized luminescence as most of the current chiral MHS display very low photoluminescence quantum yields (PLOY). We will then discuss the reasons of low PLOY in these materials. Finally, we will show our strategies to turn on the circularly polarized luminescence by introducing extrinsic self-trapped excitons in a 0D chiral MHS, and by tuning the inorganic layer thickness in perovskite nanoplatelets.

Twisted Organic Semiconductor Crystals for Chiroptoelectronics
Sehee Jeong, St. John Whittaker, Yongfan Yang, Akash Tiwari, Alexander Shukenberg, Bart Kahnr and Stephanie Lee; New York University, United States

We present crystal twisting, a common albeit little known phenomenon in molecular crystals, as a generalizable strategy to repurpose optically inactive organic semiconductors for chiroptoelectronics. This phenomenon is not limited to specific chemical structures or crystal space groups - twisting has been observed in inorganic, polymer, and small molecule crystals grown from vapor, solutions and melts. Because crystal twisting introduces repeating patterns of crystal orientations perpendicular to the substrate surface as crystals twist about the fast growth direction, <hkl>-dependent material properties are likewise patterned on the microns to millimeter length scale. Twisting also imparts chirality - crystals twist either clockwise or counterclockwise about the growth direction - rendering them optically active. The commonality of crystal twisting enables potentially hundreds of centrosymmetric organic semiconductors designed over the past fifty years to be incorporated into devices that discriminately transmit, emit and detect circularly polarized light. Here we characterize the (chiro)optoelectronic properties of several molecular semiconductors, including triisopropylsilylethynyl anthradithiophene (TIPS ADT) and tetrafluorovalene (TFV), and test their performance in resistors, transistors and photodetectors.

Chiroptical Synaptic Heterojunction Phototransistors: Noise-Reduced Detection of Circularly Polarized Light via Self-Assembled Supramolecular Nanohelices of π-Conjugated Molecules
Jung Ah Lim1, Hanna Lee1, Changsoo Choi1 and Eunji Lee2; 1Korea Institute of Science and Technology, Korea (the Republic of); 2Gwangju Institute of Science and Technology, Korea (the Republic of)

Chiroptical photodetectors have become increasingly important in a range of fields, including chiral imaging, spintronics, and quantum optics. To enable practical chiroptical optoelectronic devices, it is essential to develop high-performance chiroptical photodetectors with high responsivity, sensitivity, polarization direction identification, and device integration feasibility. This study presents the successful demonstration of high-performance chiroptical synaptic phototransistors utilizing heterojunctions comprising a self-assembled nanohelix of a π-conjugated molecule and a metal oxide semiconductor. In this work, heterojunctions consisting of a chiral nanomaterial and semiconductor offer a promising strategy for developing high-performance chiral opticoelectronic devices. To impart strong chiroptical activity, a novel diketopyrrolopyrrole-based, donor-acceptor type π-conjugated molecule decorated with chiral glutamic acid was newly synthesized, capable of supramolecular self-assembly through noncovalent intermolecular interactions. Through hydrogen-bonding-driven, gelation-assisted self-assembly, we obtained supramolecular nanohelix structure consisting of intertwining fibers with strong and stable chiroptical activity in solid-film form. Phototransistors based on interfacial charge transfer at the heterojunction from the chiroptical nanohelix to the metal oxide semiconductor exhibited exceptional chiroptical detection, with a high photocurrent dissymmetry factor and remarkable photoresponsivity.

Iionically Modified Cellulose Nanocrystals Chiral Structures for Electronics
Diana Gaspar1, Paul Grey2, Bruno Mendes2, Madalena Roque2, Rodrigo F. Martins2 and Luis Pereira3,4; 1AlmaScience, Portugal; 2Cenimat|i3N, School of Science and Technology (FCT-NOVA), Universidade NOVA de Lisboa and CEMOP/UNINOVA, Portugal

Many approaches exist in the quest for efficient, abundant, cheap and eco-friendly photonics that can be easily integrated with other platforms for practical applications. Approaches using 3D metamaterials, mesoporous semiconductors, or plasmonics are promising. Nevertheless, these methods often involve complicated fabrication processes that need high energy consumption (such as vacuum and physical vapour deposition) to deposit these materials, which are often not so green, sustainable, typically expensive, and colour-limited. Researchers have sought eco-friendly materials with similar performance and lower energy costs during the past few years, and Nature offers many examples of such materials for our innovation. Natural micro and nanostructures, such as the ones found in beetles or butterflies, have evolved over millions of years to produce periodic patterns that can reflect light. These structures served as inspiration to create artificial analogues using cellulose nanocrystals (CNCs), which can form a chiral nematic liquid crystalline phase when dispersed in water. The chiral order is preserved as the water evaporates, and solid films with 1D photonic crystal properties and iridescent colours are obtained. The intrinsic left-handedness of such structures can interact selectively with left and right-circularly polarized light (LCPL and RCPL). The pitch control and, therefore, the reflected colour is particularly interesting. This manipulation can be done using external stimuli such as magnetic and electric fields, drying processes with different interfaces or playing with the chemistry behind the acid hydrolysis. With this work, we demonstrate that CNC suspensions with low concentrations (~4-5wt.%) with proper evaporation-induced self-assembly conditions lead to the formation of films with interesting photonic properties with a left-handed twisted arrangement. The use of strong acid cation resins to mediate the counterion exchange on commercial CNCs. It was observed that adding different alkali salts to the CNCs anisotropic suspension results in a blue shift of the photonic bandgap with higher salt concentrations and proper distinction between LCPL and RCPL (ΔCPL ≈ 42%). Combining the photonic character of the tailored CNC films, whose photonic bandgap can be matched with the bandgap of light sensitivity of semiconductors, it will be possible to create devices capable of discrimination between LCPL and RCPL signals in the blue region.
Weyl semimetals have been a hot topic in the condensed matter physics community due to their unconventional linear band crossing from the bulk Fermi surface. Breaking of time-reversal or inversion symmetry allows Dirac fermions to split into a pair of Weyl fermions with an opposite chirality at a non-high-symmetry point in momentum space. The circular photogalvanic effect in which the incident helicity determines the generated current vector is direct evidence from the topology and band structure of the chiral Weyl semimetals. Notably, in optical transition near a Weyl node, it has recently been predicted that the magnitude of the CPGE is associated with its monopole charge. Since the nodes with opposite charges are nondegenerate, it also hints at the CPGE response stemming from the Berry monopole charge. Here, we explore the helicity-dependent optoelectronic response of the topological/Weyl semimetal RhSi via time-domain terahertz emission spectroscopy. The remarkable CPGE behavior in in-plane mode was experimentally demonstrated, whereas it did not exhibit notable signatures in out-of-plane mode. We further perform the photoemission measurement, together with optical simulation, to investigate the physical properties of chiral Weyl semimetal RhSi.

In recent years, there has been significant interest in incorporating heteroatoms into polyacetylenic hydrocarbons (PAHs). This exploration of heteroatom-doped variants of extended π-conjugated materials has revealed their distinct and enhanced electronic and photophysical properties. Among the various five-membered aromatic heterocycles, pyrrole stands out as the most electron-rich when compared to its isoelectronic counterparts, furan and thiophene. The synthetic versatility and strong redox activity of pyrrole enable the creation of synthetic frameworks with enhanced p-doping and other desirable material properties. Our research has focused on the synthesis and characterization of novel chiral pyrrole-based PAHs. These include twisted azacoronenes and helicenes incorporating pyrrole units. We are currently investigating their chiroptical, electrochemical, and magnetooptical properties.

Chiral semimetals have been a hot topic in the condensed matter physics community due to their unconventional linear band crossing from the bulk Fermi surface. Breaking of time-reversal or inversion symmetry allows Dirac fermions to split into a pair of Weyl fermions with an opposite chirality at a non-high-symmetry point in momentum space. 1,2-bis[2-(methyl-5-phenyl-3-thienyl)perfluorocyclopentenyl] (BpFCP) single crystals grown from the vapor phase were previously discovered to dynamically twist and coil when irradiated with UV light due to mechanical strain associated with a reversible, light-induced ring closure [1]. Here, we form BpFCP twisted crystals through growth-actuated twisting during crystallization from the melt. At high undercoolings, i.e. large crystallographic driving forces, BpFCP forms banded spherulites comprising helicoidal fibrils that twist in concert with one another as they grow radially from the spherical nucleation center. As-crystallized films appear transparent when viewed using unpolarized light. When imaged between crossed polarizers, on the other hand, concentric bands of interference colors are visible due to continuously rotating refractive indices as the crystals twist about the growth direction. Upon irradiation with UV light to induce the photochromic ring closure, alternating bands in BpFCP spherulites turn dark blue, creating a vibrant stripe pattern. Local Raman spectroscopy on adjacent bands revealed this patterning to be a result of orientation-dependent dichroism of photocyclized crystals, as opposed to orientation-dependent photoreactivity. Film cracking upon UV light exposure suggests that fibrils experience internal stress from photoisomerization-induced shifts in crystal lattice parameters. Mueller Matrix imaging further revealed strong circular dichroism (CD) and birefringence (CB) in BpFCP banded spherulites, with local CD and CB signals changing dynamically during photocyclization. Because banded spherulites expose different crystal orientations at the film surface, they provide a unique opportunity to investigate orientation-dependent chiroptoelectronic properties in these dynamic crystals.
Molecular assemblies with supramolecular chirality have been developed for decades due to their distinctive chiroptical properties. Among the versatile approaches to induce supramolecular chirality, self-assemblies using non-covalent interactions have considered as a great potential for applying biological field and chiroptical devices owing to their high tunability and controllability.

In this work, we designed and synthesized novel quinoid conjugated molecules QuEDOT-(S)-Cn and QuPheDOT-(S)-Cn employing enantiomopure alkyl side chains. Quinoidal moieties are suitable for constructing supramolecular chirality through self-assembly due to their strong π-π stacking property of highly planar structure. QuEDOT-(S)-Cn and QuPheDOT-(S)-Cn had different chiroptical properties in solution and film states depending on the external stimuli (solvents, temp) as well as different chemical structures. Then we conducted diverse analyses such as AFM, POM, SEM, CD, GIWAXS to determine the reason for the difference in anisotropic factors between two molecules. We will explain and discuss the relationship between the behavior of supramolecular chirality and chemical structures. These results suggest chemical designing strategies of organic semiconducting materials in forming supramolecular chirality using self-assembly.

SESSION EL15.08: Tunable Structural Chirality in Materials

Bio-Enabled Chiral Flexible Nanomaterials—From Chiral Emitting Sources to Photonically-Assisted Multilevel Logic Vladimir Tsukruk1,2; Sung Gun Lee3
1Georgia Institute of Technology, United States; 2Institute for Human and Machine Cognition, United States

Bio-enabled hybrid nanomaterials represent a novel class of functional materials, which uses bio-derived materials, bioinspiration and biomimetic approaches to design functional nanomaterials and structures with co-assembled biological and synthetic components to bring best of two worlds: adaptive photonic functions and chiroptical activity, flexibility and mechanical strength, potential sustainability and scalability [1]. Here, we summarize our recent results on functional bio-derived chiral nematic polysaccharides co-assembled with graphene oxides, organic semiconductors, magnetic nanoparticles, and quantum dots for adaptive chiroptical materials, magnetic materials and photonic multi-value logic thin film electronics.

Firstly, we discuss robust photonic nanomaterials from cellulose nanocrystals and nanofibers decorated with highly photoluminescent organic dyes, quantum dots and quantum nanowires for tailored emission of linear and circular polarized light [2, 3]. Secondly, we present results on magnetically steerable uniform photonic organization of cellulose nanocrystals decorated with superparamagnetic nanoparticles to achieve uniform organization [4]. Assembly under weak magnetic field gradients enables transformation from helicoidal cholesteric to uniaxial nematic phase with near-perfect orientation order parameter was achieved across large areas, enhanced mechanical robustness, and fast actuation ability. Finally, we demonstrate biophotonic field effect transistors mediated by circularly polarized excitation with multi-valued logic elements for dramatically elevated encryption ability [5].

Switching Chirality in Microarrays Enabled by Shape-Reconfigurable Spindle Microparticles Mingzhu Liu, Xingyue Han, So Hee Nah, Tianwei Wu, Yuchen Wang, Liang Feng, Liang Wu and Shu Yang; University of Pennsylvania, United States

GIant circular photogalvanic effect has been realized in chiral metals when illuminated by the circularly polarized light. However, the structure itself is not reconfigurable nor can we tune the crystal chirality in the adjacent domains. Here we synthesize spindle-shaped liquid crystalline elastomer microparticles that can continuously change shape from prolate to spherical to oblate upon heating above the nematic to isotropic transition temperature. The shapes are reversed upon cooling. When arranged as microparticles in a honeycomb lattice, the lattice can be switched from a right-handed chiral state to achiral one, then to a left-handed chiral state, without breaking the translational symmetry. Accordingly, the sign of rotation of the polarized light passing through the lattices changes as measured by time-domain terahertz (THz) spectroscopy. Further, we can locally alter the chirality in the adjacent domains using near-infrared (NIR) light illumination. The ability to controllably create chiral states at the boundary of the achiral/chiral domains will allow us to explore complex structures through the interplay of symmetry and topology.

Artificial Photosynthesis Empowered by PSII-Inspired Supramolecular Quantasomes with Chiral Architectures Marcella Bonchio1,2,3; 1University of Padova, Italy; 2INSTM, Italy; 3ITM-CN, Italy

Being the natural-born photoelectrolyzer for oxygen delivery, Photosystem II (PSII) is hardly replicated with man-made constructs. In particular, the PSII organization in natural thylakoids sets key guidelines to rethink the molecular design of groundbreaking artificial photo-electrolysers. Building on the early “quantasome” hypothesis (Science 1964, 144, 1009-1011), PSII mimicry can be pared down to essentials by shaping a photocatalytic ensemble (from the Greek term “soma” = body) where light-quantas trigger water oxidation. We have recently reported on PSII-inspired nanodimensional quantasomes (QS) that readily self-assemble into hierarchical photosynthetic nano-stacks, made of bis-cationic perylenebisimides (PBI2+) as chromophores and deca-anionic tetraruthenate polyoxometalates (Ru4POM) as water oxidation catalysts (Nature Chem. 2019, 11, 146–153). A combined supramolecular and click-chemistry strategy allows to interlock the multi-lamellar architecture emerging from the perylene aromatic stacking in water, while installing tetraethylene glycol (TEG) cross-linkers thus enhancing water harvesting and transport in proximity of the oxygen evolving center (J. Am. Chem. Soc. 2022, 144, 14021-14025).

Our breaking new results deal with the introduction of sugar-based substituents as asymmetry effectors for the assembly of chiral quantasomes evolving using low energy green photons (λ > 450 nm, FEO > 95 %). Action spectra, mass-activity, light-management, photoelectrochemical impendence spectroscopy (PEIS) together with Raman mapping of hydration shells, point to a key role of the supramolecular structure nano-arrays, where the interplay of hydrophilic, hydrophobic and chiral domains is reminiscent of PSII-rich natural thylakoids.

A Multi-Functional Full-Polarized Light Emitting and Controlling Device Jiawei Lyu and Ki Tae Nam; Seoul National University, China

Nanomaterials emitting polarized light directly without using the traditional polarizers are believed to simplify the design of polarization optics and afford higher efficiency, showing great potential in practical applications such as 3D display, hologram, anti-counterfeiting and light communication. While most efforts are focused on improving the polarized light emission performance of specific nanomaterials, of paramount importance is to interface these excellent materials with state-of-the-art industrial technology to make functional devices. Herein, we propose and demonstrate an efficient route to fabricate full-polarized emitting and controlling devices via integrating 3D printing technique with the (micro) LED display technology. We achieved an extraordinarily high degree of linearly and circularly polarized luminescence (CPL) through precise control of the nanomaterial assembly structure. This work reports on the intrinsic chiral behavior in colloidal ultrathin CsPbBr3 nanoplatelets with unprecedented quantitative s-handed value as studied using circular dichroism measurements. Through adjusting various synthetic parameters, such as temperature, Cs and Pb reagent ratios, reaction solvents and stirring direction, we are able to tune the quantitative chiral properties in these nanomaterials. Additionally, the functional aspects such as the
handedness of these nanoplatelets can be tuned using brominated methylenebenzylamines with suitable $r/s$ chirality. We utilize the advantageous procedure of single particle photoluminescence studies to attain insights into the lifetimes and correlate them with the presence and the type of ligands. We reach qualitative arguments based on surface defects and Pb extraction through selected area electron microscopy, and rigorous x-ray diffraction accompanied with Rietveld refinement analyses- to explain the atomic arrangements at the surface of these nanoplatelets which can be tuned through synthetic factors. Optical characterization by absorption and circular dichroism extends these ideas in correlation with microscopy and diffraction factors. These remarkable control of chiral parameters without external stimuli in untreated/as prepared nanoplatelets; and through choice of the ligation combinations hence accomplished highlight the suitability of these ultrathin CsPbBr$_3$ nanoplatelets for applications in a wide range of optical and mechanical applications including chiral superstructures.

11:15 AM EL15.08.07 Tuning Chiroptical Properties of Chiral 2D Hybrid Organic-Inorganic Perovskites Through Mixing Halogen Lan-Sheng Yang, Chun-Yao Huang and Yu-Chiang Chao; National Taiwan Normal University, Taiwan

Chiral 2D halide perovskites have attracted increasing attention due to their exceptional photoluminescence properties, tunable bandgap, and various crystallized structure. However, tuning chiroptical properties of chiral 2D hybrid halide organic-inorganic perovskites have not yet been extensively studied. Here, we report the chirality of chiral 2D halide perovskites through circular dichroism (CD) and circularly polarized photoluminescence (CPL). By varying the mixing ratio of chlorine, bromide, and iodide anions in $S$- or $R$- (MBA)$_2$ Pb$(1-x)$Br$_x$ or $S$- or $R$- (MBA)$_2$ PbBr$_4(1-y)Cl$Y; the mixing of halide ions allows a tunable band gap of the chiral OIHPs, leading to a shift of the CD signal from 495 to 320 nm and the CPL signal from 530 to 485nm. Moreover, it is noticed that the CD signal ascends from $x=0$ to $x=1$ and descends from $x=1$ to $x=4$. Successively, the CD signal ascends from $y=0$ to $y=4$. This difference can be explained that the phase transition of the crystalline structure occurred. Chiral optical asymmetry (g-factor) at $y=4$ has a maximum value of 0.015 compared to other mixing ratios. The CPL signal becomes greatly small after the phase transition because of structural distortion in the inorganic framework and instability. Additionally, the CD sign conversion is discovered as well through mixing halogen. These properties can take advantage of the structural engineering of high-performance chiroptical materials for spin-polarized light-emitting devices. Spin organic light-emitting diodes were achieved by using chiral 2D hybrid halide perovskites film as the spin filter layer. Circularly polarized electroluminescence was observed at room temperature in the absence of an external magnetic field.

11:30 AM EL15.08.09 Leveraging The Preferences in Transition Metal-P/Si Bonding to Design Novel Chiral Materials Kirill Kovnir; Iowa State University, United States

Non-centrosymmetric intermetallic compounds with antisymmetric spin-orbit coupling exhibit a plethora of emergent properties. Chemical bonding preferences in the transition metal silicon-phosphides TM-Si-P create the asymmetric environment around metal atoms resulting in high abundance of non-centrosymmetric chiral and polar crystal structures. The synthesis of those phases is hampered by inertness of TM and Si in contrast to high reactivity and vapor pressure of phosphorus. We developed a comprehensive synthetic strategy allowing to produce single crystals and phase-pure polycrystalline samples of metal tetrel-phosphides. The correlation between the crystal structure, chemical bonding, and optical and properties will be discussed with focus of earth abundant TM for applications.
With circularly polarized THz pulses, we excite a z-cut sample of LiNbO$_3$. The lowest frequency E symmetry phonon modes are doubly-degenerate with polarization angles between THz and probe pulses, we can isolate the Faraday signal from the Kerr signal. However, it can also measure other ultrafast birefringence signals, like the THz Kerr effect. Fortunately, by controlling the relative polarization with a transient birefringence detection scheme. This allows us to measure the transient Faraday effect to detect the creation of an ultrafast and the combined THz pulse with controllable polarization state, all in a succession of four laser shots; the probe response in the absence of a THz pump moment induced by these excited ions loops is then measured with the ultrafast Faraday effect.

Pairs of phonon modes in ferroelectric materials can be excited to create circular or elliptical motion of ions. Depending on the charge of the ions and magnitude of their motions, these ion loops with right or left handedness can induce a magnetic moment, even in originally non-magnetic materials. Therefore, exciting ion loops in ferroelectric solids to dynamically induce magnetic ordering, will make them transiently multiferroic.

In summary, using a 2D THz experimental setup, we can create high-field circularly polarized THz pulses. These circularly polarized THz pulses excite chiral phonon motion in LiNbO$_3$, transiently inducing a magnetic moment that persists longer than the THz excitation pulses. Isolating the Faraday signal from the Kerr signal confirms that the excited chiral phonon motion, so-called ion loops, induces magnetic ordering in non-magnetic LiNbO$_3$. The ability to use circularly polarized THz pulses to control chiral phonon motion will provide many new avenues in the study of condensed matter physics.

Therefore, exciting ion loops in ferroelectric solids to dynamically induce magnetic ordering, will make them transiently multiferroic.
In the present work, we propose a simple chiral plasmonic structure based on crossed elongated bars where light-handedness defines the dominating cross-section absorption or scattering, as it identifies the two different enantiomers in a chiral structure which determine how the system interacts with its environment. The system is yet maintained simple enough to understand the actual nature of the response observed, be open to future developments, and warrant fabrication for future experimental verification [3,4]. Based on this structure, our work demonstrate that, not only through the interactions between different elements it is possible to make the absorption and scattering cross-sections radically and qualitatively different for the two circular polarizations, but also that the dominating cross-section can be switched from absorption to scattering by simply changing the polarization of the impinging beam. Also, we theoretically propose a simple pump-probe experiment using circularly polarized light. [5] In the reported structures, the generation of acoustic phonons is optimized by maximizing the absorption, while the detection is enhanced at the same wavelength -and different helicity- by engineering the scattering properties [6]. Thus, the presented results constitute one of the first steps towards harvesting chirality effects in the design and optimization of efficient and versatile acoustoplasmmonic transducers.

The Interplay Between Dopants and Charge Carriers in Organic Semiconductors Lambert Jan Anton Koster; University of Groningen, Netherlands

In order to make rational improvements of the charge transport properties of doped organic semiconductors, a thorough understanding of this rather complex process is needed. The efficacy of doping is governed by a multitude of steps, including the interactions between (ionized) dopants and charge carriers. In this contribution, we explore the effects of carrier-dopant and carrier-carrier interactions and strategies to mitigate them.

We use kinetic Monte-Carlo simulations to better understand the effects of carrier-dopant and carrier-carrier interactions. Such simulations predict that a larger host-dopant distance can result in a higher Seebeck coefficient for a given electrical conductivity. In order to realize such a system, we use amphiphilic side chains in an n-type donor-acceptor copolymer. The amphiphilic side chain contains an alkyl chain segment that acts as a spacer between the polymer backbone and an ethylene glycol type chain segment. The use of this alkyl spacer can not only reduce the energetic disorder in the conjugated polymer film but can also properly control the dopant sites away from the backbone, which minimizes the adverse influence of counterions. We find that this selectively increases the Seebeck coefficient and the power factor by a factor of ~5.

While it has been recognized that Coulomb interactions between dopants and charge carriers are important, carrier-carrier interactions—interactions among charge carriers—in doped organics have received less attention. In a doped organic semiconductor, however, the number of (free and bound) charge carriers equals the number of reacted dopants. As a result, both types of interactions are of importance for a proper description of the transport properties of doped organic semiconductors.

To study the transport properties in the presence of dopants and including both carrier-carrier and carrier-dopant interactions we once again use kinetic Monte-Carlo simulations. While the conductivity is indeed affected by carrier-dopant interactions, the effect of carrier-carrier interactions appears to be even stronger, especially so at high doping concentrations. Experimentally, we observe that the electrical conductivity of a large number of organic semiconductors shows a maximum: Upon increased doping levels the conductivity decreases. This type of behaviour is commonly attributed to changes in the microstructure as a consequence of doping. However, we find that even when using vapour doping, where there are no observable changes in the microstructure, this behaviour persists. The experimental findings match the Monte-Carlo data very closely, which suggests that the Coulomb interactions among charge carriers is at the root of the limited conductivity at high doping densities.

11:00 AM *EL16.01.02
Dopant-Carrier Coulomb Interactions in Organic Electronics: DOS Shape, Transport, and Carrier Screening Zlatan Aksamija; University of Utah, United States

Organic electronic materials, specifically conjugated polymers, are a cost-effective and environmentally friendly alternative to inorganics. However, they do not possess intrinsic free carriers, which means they must be doped to increase the number of free carriers and boost conductivity. Simultaneously, their low dielectric constant means electrostatic Coulomb interactions between free carriers and dopant counterions are poorly screened. These dopant-carrier interactions dramatically alter the energetics of the states available for transport as well as the dynamics of free carriers. The importance of Coulomb interactions and their impact on the density of states (DOS) via dopant-induced disorder is now well established. In this invited talk, I will discuss our results arising from coupling a model for modification of the electronic density of states (DOS) in the presence of dopants with a phonon-assisted carrier hopping simulation through those states. We expanded the model initially proposed by Arkhipov et al. to include the finite dopant size and minimum dopant-carrier separation, which limit the deepest traps in the tail of the DOS. We use the DOS model as input to the hopping transport simulation to analyze the transport properties of doped conjugated polymers and extract both conductivity and Seebeck coefficient at each doping concentration. We also vary the parameters of the dopants, including their size, energy level, and charge distribution on the dopant counterion to quantify their impact on conductivity.

However, previous studies of hopping transport within the Gaussian Disorder Model did not consider the role of screening the dielectric interactions by the carriers. In our work, we implement screening in the Debye-Hückel formalism and calculate dopant-induced disorder with the resulting electrostatic potential. For a point dopant, this gives the well-known Yukawa potential, which we generalize for dopant charge distributions other than the point charge. Then we solve Pauli Master Equation with Miller Abrahams hopping rates with states from the resulting screened DOS. Our results show that screening has a significant impact on the Seebeck coefficient and shape of the DOS. The thermoelectric power factor increases almost by a factor of 2 at higher doping. We also observe that the log slope of the Seebeck coefficient plotted against the electrical conductivity for different doping concentrations, which was previously thought to have a universal value (-1/4), increases for a more energetically disordered system. By including screening, we were able to reproduce and explain these curves obtained in measurements and connect the change in slope with the change in structure of the host polymer. We conclude that carrier screening of dopant Coulomb interactions plays an important role in transport and thermoelectric properties of polymers, especially at high doping concentrations. Our work refines the understanding of fundamental processes in doped polymers and enables their easier engineering for thermoelectric, photovoltaic and other applications.

11:30 AM EL16.01.03
The Effects of Doping on Transport in Organic Electronics: Analyzing the Dopant-Induced Disorder Andrew Tolton and Zlatan Aksamija; University of Utah, United States

Organic electronic materials, specifically conjugated polymers, are a cost-effective and environmentally friendly alternative to inorganics. However, their low intrinsic conductivity means they must be doped to increase the number of free carriers. Characterizing the effects of doping on organic thermoelectrics has proven to be a long-standing problem. Doping introduces both structural and energetic changes to the polymer, changing the shape of the electronic Density of States (DOS) through the creation of band tails and widening the DOS, resulting in a type of energetic disorder termed dopant-induced disorder (DID). The shape of the DOS resulting from doping can be captured through two parameters: the width of the DOS, termed energetic disorder, and the shape of the DOS, which is quantified by a shape parameter $p$, which can take on values of 1 for an exponential DOS to 2 for a Gaussian one. In our previous work, we showed that DID causes energetic disorder to increase while the $p$ value simultaneously decreases from 2 to below 1 in heavily doped polymers, implying heavy tails. The resulting carrier mobility is impaired by the presence of heavy tails and the deep trap states in them. Doping then simultaneously increases DID, affecting the shape of the DOS, but fills the deepest tail states first, partially counteracting their effect.
To decouple the influences of each of these effects, we fix the shape of the DOS to simulate doping without DID. We then compute both conductivity and thermoelectric Seebeck coefficient at each DOS and carrier concentration using a numerical simulation of phonon-assisted carrier hopping between localized states. The simulation iteratively solves the Pauli master equation with Miller-Abrahams hopping rates. The iteration converges on an out-of-equilibrium distribution function, from which carrier and energy currents are computed, from which we extract conductivity and Seebeck coefficient, respectively. The Seebeck coefficient is a convenient and readily measurable proxy for the carrier concentration as it scales with the position of the Fermi level in the DOS. The Seebeck vs conductivity plot thus reveals the tradeoff induced by doping and captures the impact of the DOS on transport. We find distinct behavior of the Seebeck vs conductivity relation across doping regions, and these behaviors can be described in terms of carrier concentration in conjunction with the key parameters of the DOS: its width (energetic disorder) and shape parameter. The distinct regions on the Seebeck-conductivity curve come from surprisingly simple relationships between doping and several transport parameters, which also allow us to provide qualitative expressions for difficult-to-measure quantities like carrier concentration and carrier-dependent mobility. Ultimately, this analysis clearly displays the underlying effects of doping without the simultaneous obfuscation of DID, allowing us to gain a clearer understanding of the effects of both influences. This work will impact the design of polymer-dopant complexes for reaching higher carrier mobility in future organic electronics.

11:45 AM EL16.01.04
A New Strategy to Greatly Improve The Seebeck Coefficient and Overall Thermoelectric Properties of Conducting Polymers Jianyong Ouyang1, National University of Singapore, Singapore

Conducting polymers emerge as the next-generation thermoelectric materials because of their merits including high conductivity, high mechanical flexibility, low cost and solution processability. However, their Seebeck coefficient is notably lower than inorganic thermoelectric materials by about one order in magnitude. The conventional methods to increase the Seebeck coefficient of conducting polymers including partial doping with a reducing agent or base and energy filtering. Nevertheless, these methods are not very effective, and the overall thermoelectric properties of conducting polymers are not very high. Here, I will present a new strategy to greatly improve the Seebeck coefficient and thus the overall thermoelectric properties of conducting polymers. The ZT value can be comparable to the best inorganic thermoelectric materials at room temperature.

Doping-Enabled Photomultiplication in Narrowband Near-Infrared Organic Photodetectors for Enhanced Detectivity Louis Conrad Winkler1, Jonas Kubiliuski2, Johannes Benduhn1 and Karl Leo1; 1Technische Universität Dresden, Germany; 2Universidade Tecnológica Federal do Paraná, Brazil

Continuous monitoring of food quality, blood oxygen, or industrial processes requires high-throughput near-infrared photodetectors. Due to excellent properties like low-cost, flexibility, and narrowband response, organic photodetectors (OPDs) have vast market potential for such applications. In this work, we utilize the emerging absorption feature of a weakly doped C60 bulk for photo-responses above 1000 nm, circumventing the difficulties of obtaining molecules with a low optical gap and low molecular mass. The unavoidable increase of band-to-band recombination for low-gap systems, which is detrimental to the external quantum efficiency (EQE), is overcome by combining two mechanisms to achieve a strong photocurrent gain. Trap-assisted accumulation, realized by very low doping, and energetic blocking of holes, are utilized to achieve a spectral response (SR) of 15 AW-1 at 1092 nm. Furthermore, spatial doping variations are implemented into the device to boost the absorption within the optical cavity, resulting in a narrow response of 18 nm. This approach allows easy tuning of the resonant wavelength by bulk thickness variations and thus allows spectrally highly resolved measurements. Contrary to OPDs working in the self-powered mode, this detector is optimized for operation under reverse bias. With its high spectral response, low-cost readout circuitry based on CMOS technology could be used for signal detection.

Control of Resistance Temperature Change of Solution-Processed Conductive Polymers for Strain Sensor Applications Yu Kato1, Kenjiro Fukuda2, Takao Someya3,4 and Tomoyuki Yokota1; 1The University of Tokyo, Japan; 2RIKEN, Japan

Organic materials are used in flexible electronics due to their excellent flexibility and simple fabrication using solution processes. Because the resistance of organic materials changes with strain and temperature, flexible strain11 and temperature21 sensors using organic materials have been studied. In such sensors, control of conductivity and resistance temperature change is important. When the device is used as a strain sensor, the resistance temperature change needs to be small to make the sensor less susceptible to temperature. In contrast, when the device is used as a temperature sensor, the resistance temperature change should be large to increase sensitivity. Low conductivity makes the device more sensitive to electronic noise. In this study, we evaluated the influence of the fabrication conditions on the conductivity and temperature characteristics of devices using conductive polymers. Then, we selected a condition and applied it to a strain sensor. Chromium and gold were evaporated on substrates as electrodes. Conductive polymers were spin-coated on the substrates followed by annealing under a nitrogen atmosphere. Conductive polymers consisted of a polymer material and a p-type dopant. The doping concentration in this experiment was 12%, which means that twelve dopant molecules were added per one hundred monomeric units of the polymer. The standard conditions in this experiment were P3HT for the polymer, BCF for the dopant, and 70 °C for the annealing temperature, and the effects of changing these conditions were evaluated. Temperature coefficient of resistance (TCR) is defined as the ratio of resistance change to temperature change. In this study, TCR was calculated using the resistances at 25 and 40 °C. When the device was applied to the strain sensor, a 1-µm-thick parylene was deposited on the device as a passivation layer. A gauge factor, defined as a ratio of resistance change to applied strain, was measured. By adding BCF to P3HT, the conductivity increased by four orders of magnitude, and the TCR changed from 1.3%K to -0.9%K. Increasing the annealing temperature from 70 to 150 °C reduced the conductivity by two orders of magnitude and changed the TCR to -2.0%K. Similar results were obtained when F4-TCNQ was used as a dopant, indicating that the influence of the dopant type on the characteristics was small. When other polymers such as DPP-DTT, PTB7 and PBDT-DPP were mixed with F4-TCNQ, the TCRs were -2.0%K, -2.3%K, and -2.7%K, respectively. Subsequently, we fabricated a strain sensor using P3HT-BCF annealed at a low temperature, which was a condition that exhibited a small resistance temperature change and high conductivity. The gauge factor of the sensor was 5.9 when a tensile strain of 6.6% was applied. The sensor was attached to an arm and detected resistance change during arm bending.

Regioregular poly(3-alkylthiophene)s (P3ATs) constitute an important class of conjugated polymers (CPs) for organic electronic applications. In particular, poly(3-alkylthiophene) (P3HT) is one of the most studied and accessible CPs due to its simple synthesis that enables kilogram scale production. One way to potentially tune CPs properties without affecting electronic properties is to introduce functional groups several carbons away from the conjugated backbone. However, such modifications can affect CPs self-assembly, crystallinity and π–π stacking, making it challenging to optimize properties while maintaining good charge carrier mobility. It is thus essential to better understand how side chain modifications affect desirable properties. Here, we explore using side chain engineering to increase the relative dielectric constant (εr) and to improve the mechanical properties of P3ATs. Results give us guidelines to tune properties while maintaining favorable film morphology for charge carrier mobility.

Conjugated polymers typically have low εr, (3-4), which limits their application. Increasing εr could enhance device performance by promoting excitation dissociation, reducing bimolecular charge carrier recombination, and enhance charge carrier mobility via charge screening. Here, we introduced highly polar methylsulfonyl and methylsulfinyl groups at the end of P3AT side chains. This placement should allow the polar groups to efficiently rotate and increase orientational polarization. High εr values were achieved for these functionalized P3ATs based on an accurate capacitance measurement using a gold/semiconducting polymer/SiO2/n-doped Si configuration. The εr at megahertz and room temperature increased from 3.8 for P3HT to 7.4 for the sulfonylated and 8.1–9.3 for sulfinylated P3ATs. These values are among the highest εr reported for CPs. Grazing-incident wide-angle X-ray diffraction results showed that these polar groups decreased the crystallinity for the polythiophene backbones and interfered with the π–π stacking in the crystalline structure, especially the methylsulfonyl groups. From this study, we conclude that the methylsulfinylated polymers may be promising to provide a balance between high εr and preserving favorable π–π stacking structure for device applications.

Like most CPs, P3ATs tend to be brittle, limiting their application. Interestingly, one of the polymers with high dielectric constant had unusual mechanical properties. We hypothesized that the improved properties were due to the ester group six carbon away from the backbone. To better understand the effect of ester groups on both mechanical and electronic properties, we synthesized two random copolymer series: poly[3-alkylthiophene-2,5-diy]-ray-(3-6-pentanoatehexyl)thiophene-2,5-diy] where alkyl is either hexyl (P3HT series) or dodecyl (P3DDT series). In both series, the ester-functionalized side chain content was varied. The copolymer’s optical, thermal, structural, electrical and mechanical properties were investigated. Optimal mechanical and electrical properties were obtained with 10% ester content, and the mechanical property improvements were maximized when the co-side chain was shorter (hexyl) than the ester-functionalized side chain. The best combination of robustness and charge carrier mobility was thus obtained for the P3HT random copolymer with 10% ester-functionalized side chain; a high fracture strain (29±6%) combined with a high tensile strength (3.5±0.6 MPa) was achieved while maintaining the same high charge carrier mobility than a similar MW P3HT (0.12±0.01 cm2/Vs). These exciting results demonstrate the feasibility of using ester-functionality in optimizing both mechanical and electrical properties of poly(3-alkylthiophene)s.
impact of doping the crystalline and amorphous domains on the density of states (DOS) and how each domain type contributes to charge transport. We measured Seebeck coefficient (α) and electrical conductivity (σ) of gradually dedoping of regiorandom and regioregular P3HT films and their blends. We used wide angle X-ray scattering and UV-Vis-near IR spectroscopy (ε) of gradually dedoping of regiorandom and regioregular P3HT films and fitted data to a phonon-assisted hopping model of charge transport to extract the dopant-induced disorder from the calculated DOS. We show that the regiorandom and regioregular domains in the doped polymer simultaneously contribute to the charge transport with their individual contribution depending on their doping level. We also show that any observable impact of counterion size or paracrystallinity on charge transport can be correlated to polymer-dopant distance, Rs. Our two-DOS model of crystalline and amorphous regions connects well to the observed trends in the α-σ curves of regiorandom and regioregular P3HT blends. Our work shows the amorphous domain encounters a larger dopant-induced disorder and also contributes to charge transport significantly. Thus, it is important to take into account the effect of dopant-induced disorder on particular structural regions while designing polymers and dopants for improved charge transport.

8:00 PM EL.16.03.02
Enhancing the Power Factor of SWNT Thin Films for Organic Thermoelectrics Sooyeon Chang, Prithwish Biswas and Zhiting Tian; Cornell University, United States

Thermoelectrics are regarded as one solution that upcycles waste heat to convert it into a useful resource: electricity. A thermoelectric device utilizes the Seebeck effect across a p-type and n-type material to create a voltage difference from a temperature gradient. Unlike many developments in the area of p-type, many conventional n-type materials have been restricted to inorganics that are toxic and expensive. Here, we focus on organic n-type material through doping and post-treatment which allows us to tune the power factor (PF) even further. Organic single wall carbon nanotubes (SWNT) are known for their high electrical conductivity through electron hopping of valence electrons and have shown potential for thermoelectrics. We have fabricated micron-thick SWNT films using a surfactant to induce an n-type behavior and doped them to further increase the electrical conductivity. The films were measured over 3 months and retained a stable negative Seebeck coefficient, which proves as a promising candidate for long-term thermoelectric devices. We have found that the different annealing temperatures and doping times of the dopant resulted in a distinguished surface morphology where we could improve the electrical conductivity with no diminishing of thermopower.

SESSION EL.16.04: Design of Dopants and Polymers I

Quasi-Instantaneous Doping Mechanism of Organic Semiconductors by a Strong Lewis Acid Melissa Berteanu-Rainville1, Shubham Bhagat2, Thomas Baumgartner3, Emanuele Orgiu1, Christopher Caputo3 and Ingo Salzmann2,2; 1Institut National de la Recherche Scientifique, Canada; 2Concordia University, Canada; 3York University, Canada

The doping of organic semiconductors (OSC) is of crucial importance for applications in electronic devices, where it is used to alter the opto-electronic properties of OSCs. P-type doping is generally achieved via the admixture of strong electron acceptors, i.e. molecules that feature a high electron affinity, in order to remove a full electron from the OSC. Because of their typically conjugated nature such molecules tend to form supramolecular complexes with the organic semiconductor instead of promoting electron transfer, which quenches the efficiency of the dopant. Furthermore, control over structure in doped systems, which is paramount to performances in applications, is difficult to achieve because these molecules do not interact covalently.

In this light, trivalent group XIII Lewis acids (boron, aluminum centers) have been used as dopants, paired with OSCs that contain hard nitrogen atoms to which they can bind covalently. This resulted, for example, in the possibility to tune the bandgap of OSCs by employing acids of different strengths, but not in full electron transfer. In other systems where OSCs do not feature hard basic sites to which LAs can bind covalently, however, full electron transfers were reported, notably in the poly(3-hexylthiophene) (P3HT) - tris(pentafluorophenyl)borane (BCF) system. This came as a surprise as the electron affinity of BCF is thought to be insufficient to induce such electron transfers. As such, it was more recently proposed that this doping proceeds via a proton transfer that can be introduced by water traces even in inert environments, through a mechanism that was calculated to be highly endergonic.

Considering all these findings, we will report on the surprising observation that BCF can readily dope three different thiophene-containing OSCs of relatively low ionization energy in a quasi-instantaneous manner that is at odds with a highly endergonic mechanism. We investigated more closely the doping behavior of several Lewis acids analogous to BCF with P3HT in order to understand the factors determining the ability of Lewis acids to produce such doping. We performed supporting DFT calculations to assess the energetics involved in different possible mechanisms. Altogether, our data strongly suggest that this quasi-instantaneous doping is not mediated by a proton transfer alone, which we will discuss in the framework of the previously suggested doping processes known to be at work for organic semiconductors.

Adduct-Forming and Macromolecular Dopants for Semiconducting Polymers Howard E. Katz, Jinfeng Han, Tushita Mukhopadhyaya, Connor Ganley and Paulette Clancy; Johns Hopkins University, United States

The traditional vision of the dopant-semiconductor interaction, including organic and polymeric semiconductors, is direct electron transfer between the two, leaving a charge carrier on the semiconductor in the form of a mobile radical ion and an oppositely charged counterion. In this presentation, we explore a two-step alternative doping mechanism, by which the dopant forms a covalent adduct with a conjugated polymer segment, and that adduct subsequently participates in the electron transfer that leads to the charge carrier generation. We investigated both p-type and n-type versions of this process, using tris(pentafluorophenyl)borane (TFPB) and fluoride anion (F⁻), respectively, as the adduct-forming species. Many structures of conjugated segments were used as models for the polymer segments that might form adducts with TFPB or F-. Evidence that adducts could serve as dopants was obtained from conductivity and Seebeck coefficient measurements, electron paramagnetic resonance (EPR) spectroscopy, optical absorbance spectroscopy, and Density Functional Theory calculations. Furthermore, we paired the F⁻ dopant with a pyridinium polymer to create an n-type analog of PEDOT-PSS, where the charge transporter and dopant counterion in the conducting composition are both macromolecular, and the electronic conductivity was especially high compared to that obtained from single-molecule dopants.

9:30 AM BREAK
Inhomogeneous Dopant Distribution in Organic Semiconductors: Causes and Consequences for Charge Transport

Marijn Kemerink; University of Heidelberg, Germany

While the effect of the incorporation of dopant molecules on the microstructure of the host material has been intensely investigated, translating these results to electronic properties has received less attention. Here, we will show two case studies of inhomogeneous dopant distribution in organic semiconductors, for which we do a quantitative comparison between experimental data of dopant distributions and conductivity and numerical simulations thereof. For the latter we developed two intuitive tools to produce simplified yet realistic morphologies of doped organic polymers, accounting for the effects of (a) aggregation and phase separation in the semiconducting host material and (b) diffusion and preferential incorporation in specific phases of the dopant. The created morphologies are then used as starting point for kinetic Monte Carlo simulations of charge transport. Importantly, the case studies can be generalized to design rules to achieve high conductivity at low dopant concentrations.

Stable and Tunable Chemical Doping for Organic Semiconductors in Aqueous Solution under Ambient Conditions

Masaki Ishii1,2, Yu Yamashita1,4, Shun Watanabe6, Katsuhiko Ariga1,2,3 and Jun Takeya1,3; 1National Institute for Materials Science, Japan; 2Tokyo University of Science, Japan; 3The University of Tokyo, Japan

Doping levels in chemical doping of organic semiconductors are determined by semiconductor and dopant energy levels. While precise control of doping is required to fabricate advanced devices, as seen in silicon semiconductors, control in doping levels at a scale of thermal energy (25 meV) has been challenging for organic semiconductors. Most of dopants are unstable under ambient conditions owing to the reactivity with water or oxygen in air, which further decreases precision in doping levels. Low precision in doping levels and need for inert processing environment have been bottlenecks for developing and manufacturing advanced organic semiconductor devices employing chemical doping.

In this study, doping levels of organic semiconductors were controlled reproducibly and precisely in aqueous dopant solution under ambient conditions [1]. In our method, chemical doping is based on proton-coupled electron transfer (PCET) reactions that are widely observed in biochemistry, unlike conventional methods that employ single electron transfer reactions. Our aqueous dopant solutions contain dopant salts, pH adjusting agents and PCET-based redox couples. As a PCET-based redox agent, for instance, Benzoquinone/Hydroquinone (BQ/HQ) couple was employed. Through redox reactions, BQ gets transformed into HQ by accepting two electrons and two protons, where its redox potential depends on proton activity, pH, of the aqueous solution following the Nernst equation. A well-known p-type semiconducting polymer, poly[2,5-bis-(3-tetradecylthiophen-2-yl)thieno[3,2-b]thiophene] (PBTTT), was doped by BQ/HQ doping solutions. PBTTT got oxidized when the redox potential of BQ/HQ exceeded the Fermi level of PBTTT in a low pH environment. The positive charge introduced into PBTTT was compensated by intercalation of anions in aqueous solution similarly to anion-exchange doping in organic solvents [2]. Bis(trifluoromethanesulfonyl)imide (TFSI) or bis(nonafluorobutanesulfonyl)imide (NFSI) was employed as dopant anion introduced into PBTTT, which would realize stable doped state owing to their closed-shell structures and hydrophobicity [3].

Doping level of PBTTT was controlled by the pH value of dopant aqueous solution, where the redox potential of BQ/HQ showed pH dependence of 59 mV/pH. According to the optical absorption and conductivity measurements, the doping level of PBTTT increases with decreasing solution pH. Tuning of doping levels were also confirmed by structural analysis based on X-ray diffraction and elemental analysis based on X-ray photoelectron spectroscopy measurements. Doping levels of one PBTTT film were modulated repeatedly by cycles of increase and decrease in solution pH, which demonstrates that both of oxidation and reduction of organic semiconductors take place in our system that develops chemical equilibrium. It was verified that one can control the Fermi level of organic semiconductors reproducibly with a high degree of precision, ca. thermal energy of 25 meV at RT, over a few hundred meV around the band edge. This is a critical range to control electronic properties of semiconductors.

Our PCET-based system provides a facile, scalable, precisely controlled, reproducible and reliable chemical doping method, which would lead to ambient processed organic electronics and bioelectronics.

Doping has been one of the most essential methods to control charge carrier concentration in semiconductors. Excess generation of charge carriers is a key route for controlling electrical properties of semiconducting materials and typically accompanies alteration of electronic structure by the introduction of dopant impurities, both of which have played pivotal roles in making breakthroughs in inorganic microelectronic and optoelectronic devices both at research and industrial levels, especially for Si-based technology. Molecular doping is a facile and effective doping method for various semiconducting materials since it is relatively non-invasive compared to high-energy implantation of ionic impurities used in Si. However, there are main challenges remaining in fully utilizing molecular doping in emerging semiconducting materials such as π-conjugated polymer semiconductors, two-dimensional materials and metal-halide perovskites due to the difficulties in preventing dopant-induced disorder effects while maintaining a high carrier mobility. This talk will introduce concepts that we have developed to minimizing the dopant-induced disorder [1, 2, 3] while mitigating current injection and doping stability issues in electronic devices [4, 5], and finally outline the future challenges remaining in the field to fully uncover the potentials.

Self-Doped Conjugated Polymers and Copolymers - Feasibility and Advantages in Devices Julian Hungenberg, Adrian Hochgesang, Florian Meichsnor and Mukundan Thelakkat; University of Bayreuth, Germany

Mixed iono-electronic conductors are widely studied for accumulation mode (undoped systems) or depletion mode (doped systems) devices. PEDOT:PSS has been established as the working horse for depletion mode organic electrochemical transistors (OECTs) as it consists of the conjugated polymer PEDOT which is intrinsically doped and stabilized by PSS counterions. It is neither soluble in water nor organic solvents, wherefore thin films are processed from aqueous dispersion. This results in a nonuniform film morphology consisting of doped PEDOT-rich domains surrounded by an insulating PSS matrix. This particular structure leads to several drawbacks such as long-term instability. Furthermore, its complex structure hampers the ability for chemical modification.

In contrast to PEDOT:PSS, most conjugated polymers are intrinsic (pristine or undoped) semiconductors and hence show very low electrical conductivities. Therefore, doping is necessary to increase the charge carrier density and thus the electrical conductivity. Upon molecular doping, active redox species are added to the OSC which can donate (n-type) or accept electrons (p-type) generating free charge carriers. For p-type doping, this means a transfer of electrons from the highest occupied molecular orbital (HOMO) of the OSC to the lowest unoccupied molecular orbital (LUMO) of the dopant. Issues here are the requirement of deep-lying dopant LUMO, thus stability against air/water, and the need for high amounts of dopants for charge carrier formation which ultimately disturbs the film morphology.

To address these challenges, our group took high efforts in the field of molecular doping of conjugated polymers. The first concept published takes advantage of HOMO-HOMO doping by mixing two donor materials (OSC-1 and OSC-2). OSC-2 is a chemically oxidized small molecule semiconductor namely Spiro-OMETAD(TFSI), which is capable to oxidize the OSC PDDP[T]:EDOT (OSC-1). Thereby, the doping takes place by an electron transfer from the HOMO_{OSC-1} to the partly occupied HOMO_{OSC-2}. A second work extends this concept through the use of multielectron acceptor salts. For this, oxidized triphenylamines were linked to form multielectron acceptor dopants, which can accept up to four electrons per dopant. This strategy allows for significantly reducing the number of dopant molecules compared to common single electron acceptor dopants.

Here, we present a novel synthetic strategy of a conjugated polyelectrolyte (CPE) based on a polythiophene-derivative toward a stable self-doped system which can be solution-processed from water as well as organic solvents. Our new CPE is intrinsically doped after synthesis, which is promoted by the stabilization of free charge carriers by its ionic side chains. We present self-doping as an elegant way to avoid the use of molecular dopants fully, while still maintaining high and stable conductivity. This was investigated by time-resolved spectroelectrochemistry in aqueous electrolytes by UV-vis spectroscopy in thin films in the dry state as well as conductivity measurements. We were furthermore able to employ our self-doped CPE as a mixed conductor and showed its application in a depletion mode OECT device with high transconductance and currents. By copolymerization with a comonomer, which is not self-dopable, we were able to tune the self-dopability and therefore to switch the transistor's mode of operation towards a well-performing accumulation mode device with a low threshold voltage. These findings could help to study the self-doping processes and to develop new CPEs with low threshold voltages towards innovative device applications.

Challenges in Doping of Organics: Small Molecules vs. Polymers Karl Lee; IAPP, Germany

Controlling the charge carrier densities is a key feature of any semiconductor electronic device. In inorganic semiconductors, general understanding of doping has been achieved early on and research has concentrated on finding dopants in large-gap systems like nitrides. In organic materials, doping is now a routine technique for mass-produced OLED displays and organic solar cells. However, it is still far from a microscopic understanding. Furthermore,
doping in organic systems where both electronic and ionic transport happen has recently generated much interest. In this talk, I will address these two very different systems and discuss recent progress on controlling the doping in small-molecule semiconductors, touching new dopants and high mobility materials, allowing to realize devices like the first organic bipolar transistors. I will compare to recent work on the doping of organic electrochemical transistors (OECTs). These devices have recently been investigated broadly since they offer switching and sensing functionality in an electrolytic environment compatible with biological systems. The mixed electron-ion transport of the devices has consequences for the doping process, making it significantly different from the electrostatic doping of standard FET devices.

Molecular Doping of Conjugated Polymers for Flexible and Printed Organic Thermoelectric Generators Boseok Kang; Sungkyunkwan University, Korea (the Republic of)

Organic thermoelectric generators (OTEGs) have received significant attention as a promising independent energy harvesting solution in the era of the Internet of Things. The OTEG device is attached directly to the surface of heat energy sources and transforms waste heat energy into valuable electricity based on the principle of the Seebeck effect. Several attempts have been made to achieve high-efficiency solution-processed OTEG devices, but there still remains a challenge to improve the thermoelectric figure of merits and the solution processibility for the device fabrication. In particular, doping is essential for controlling the charge carrier concentration in the conjugated organic media and governing charge transport physics, resulting in optimized device performance. In this talk, I will discuss various doping and molecular design strategies for improving the thermoelectric efficiency and solution processibility of conjugated polymers for flexible and printed OTEGs.

Enhancing Performance in DPP-based N-type Thermoelectrics for Molecular Doping Utilizing HSP Approach Soyeong Jang1, Diego Rosas Villalva1, Guorong Ma2, Anirudh Sharma1, Andrew Bates2, Abdel H. Amwas1, Xiaodan Gu2 and Derya Baran1; 1Kaust, Saudi Arabia; 2The University of Southern Mississippi, United States

The solubility of conjugated polymers (CPs) significantly determines their device performance. Consequently, understanding the relationship between the solubility of n-type host polymer-dopant-solvent systems and their electronic properties is vital within the CPs realm. This study delves into the impact of various halogenated solvents on the solubility and morphological properties of a novel pyrrole-flanked DPP n-type polymer (2PyDPP-2CNTVT) and Tetrabutylammonium Fluoride (TBAF) as the dopant system. We utilized Hansen Solubility Parameter (HSP) for the solubility study. We employed Grazing Incidence Wide Angle X-ray Scattering (GIWAXS) and Atomic Force Microscopy (AFM) to probe the doped polymer thin films' molecular structural disorders and surface morphology. Our findings indicate that Dichlorobenzene (DCB) solvent has superior solubility affinity for the polymer backbone and dopant. This affinity fosters improved host-dopant miscibility, excellent dopant accommodation, and enhanced film processability. Consequently, this leads to increased electron mobility (μ) of 2.3 cm2 V-1 s-1 and conductivity (σ) of 2.64 S cm-1 compared to films made with alternative halogenated solvents in this study. Additionally, our multidisciplinary experimental approach reveals an improved doping efficiency resulting from the lowest activation energy in the DCB system. These insights propose the DCB solvent as the optimal choice for achieving high μ and electrical conductivity σ in TBAF-doped 2PyDPP-2CNTVT CP film. This work underscores the importance of selecting solvent based on HSP evaluation to maximize the potential of molecular doping into n-type DPP-based CP, mitigating the trade-off between mobility and Seebeck coefficient (S).

Advancements in Molecular Doping of Semicontacting Polymers: Applications in Organic Thermoelectrics Shrayesh Patel; University of Chicago, United States

Molecular doping of semiconducting polymers holds significant promise for organic thermoelectrics, offering tunable electronic properties and ease of processibility. In the first part of the talk, we delve into the fundamental structure-property relationships of sequentially doped thiophene-based polymers, shedding light on dopant segregation, microstructure, and their impact on conduction limits and stability. In the second part, we explore the potential of molecular doping in the development of functionally graded materials (FGMs) for organic thermoelectrics. Specifically, we demonstrate precise compositional control in thin film FGMs through sequential vapor doping of polyythiophene derivatives with 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4TCNQ). Utilizing techniques such as grazing incidence wide angle X-ray scattering (GIWAXS) and Raman spectroscopy, we spatially resolve dopant compositional profiles within the FGM thin films. Additionally, we quantify the lateral distribution of electronic conductivity and Seebeck coefficient, providing insights into the spatial distribution of transport parameters. Our research advances the understanding of structure-transport properties and contributes to the development of efficient organic thermoelectric materials through sequential doping and functional grading.

Enhancing Thermoelectric Properties and Optimization Through Coulombic Interactions and AI-Driven High-Throughput Experiments Kedar Hippalgaonkar1,2; 1Nanyang Technological University, Singapore; 2Institute of Materials Research and Engineering, Singapore

Our studies propose a novel approach to enhance thermoelectric properties in conducting polymers by controlling coulombic interactions, without regulating morphology. We observe a three-fold enhancement in the thermoelectric power factor of OD-PDPP2T-TT compared to PBTTT-C12, attributed to improved counterion screening, verified experimentally by measuring the dielectric constant of the films, and explaining the enhancement through Boltzmann Transport Equations [1]. We establish a correlation between optical absorption signatures and thermoelectric properties, extracting carrier concentration and confirming the importance of charge mobility amidst structural disorder. Furthermore, we demonstrate the benefits of combining high-throughput experiments with machine learning for materials and process optimization, especially by considering optical signatures that directly provide information about doping [2]. Our automated setup enables rapid thin film preparation and characterization, achieving a +10× improvement in learning cycles. By combining regio-regular poly-3-hexylthiophene with carbon nanotubes, we identify optimal compositions achieving high electrical
conductivities [3]. This integrated approach offers insights into enhancing thermoelectric properties and accelerates materials optimization in organic thermoelectrics.

Beyond Doping: Self-Induced Anisotropy Breaks the σ-S Coupling Towards High Performance N-Type Conjugated Polymer Thermoelectrics. Diego Rosas Villalva1, Denis Rerewjanko1, Yongzao Zhang1, Ye Liu1, Andrew Bates2, Anirudh Sharma1, Soyeong Jang1, Xiaodan Gu1, Martjin Kemerink1 and Derya Baran1; 1King Abdullah University of Science and Technology, Saudi Arabia; 2Heidelberg University, Germany; 3The University of Southern Mississippi, United States

In recent years, there has been continuous progress in the development of N-type organic thermoelectric (OTE) due to the synthesis of new conjugated polymers and dopants. The primary focus of most designs has been to enhance doping efficiency and increase electrical conductivity, resulting in values surpassing 102 S cm⁻¹. Although effective, doping encounters limitations because of the inherent inverse relationship between the properties that determine the figures of merit in thermoelectric materials. To advance the field further, alternative approaches are needed beyond optimizing doping efficiency and the host: dopant ratio. In this study, we propose the concept of self-induced anisotropy as a solution to overcome the inverse coupling between electrical conductivity and Seebeck coefficient in N-type OTEs. Previous research has suggested methods like rubbing and drawing to induce anisotropy in π-type OTEs based on thiophenes. In this work, we exploit the interactions between solvent, host, and dopant to induce a preferential orientation. This orientation increases the in-plane delocalization length, thereby improving electrical conductivity while maintaining the Seebeck coefficient. By adopting this approach, we have achieved promising results in the 2DPP-2CNT: V:N-DMBI system. At room temperature, we obtained a Power Factor of 115 μW m⁻¹ K⁻² and a figure of merit of 0.17, which further increased to 188 μW m⁻¹ K⁻² and 0.36, respectively, at 105 C. To explain the origin of self-induced anisotropy, we utilized Hansen Solubility Parameters and established guidelines for formulating solvent-host-dopant systems that can achieve a similar effect. This discovery opens new possibilities for advancing N-type OTEs.

Evaluating Design Rules Towards Enhanced Solid-State Charge Transport in Oligoether-Functionalized Dioxithiophene-Based Alternating Copolymers Abigail A. Advincula1,2,3, Amalie Atassi1, Shawn A. Gregory1, Karl Thorley4, James Ponder2,1,5, Guillaume Freychet6, Austin Jones4, Gregory Su1, Shannon Yee1 and John R. Reynolds1,4; 1Georgia Institute of Technology, United States; 2Air Force Research Laboratory, United States; 3ARCTOS Technology Solutions, United States; 4University of Kentucky, United States; 5UES, Inc., United States; 6Brookhaven National Laboratory, United States; 7Lawrence Berkeley National Laboratory, United States

Understanding solid-state charge transport in chemically doped, electrically-conductive conjugated polymers (CPs) is important to emerging applications which include organic thermoelectrics, transparent electrodes, and bioelectronics. The synthetic tunability of CPs, e.g., backbone or side chain modulation, affords high control over energy levels (i.e., ionization energy/electron affinity), doping processes, and microstructures, factors which influence the electrical conductivity of a given CP system.

This study investigates the solid-state charge transport properties of the oxidized forms of dioxithiophene-based alternating copolymers consisting of oligoether-functionalized 3,4-propyleneedioxythiophene (ProDOT) copolymerized with different aryl groups, dimethyl ProDOT (DMP), 3,4-ethylenedioxythiophene (EDOT), and 3,4-phenylenedioxythiophene (PhedOT) respectively, to yield the copolymers P(EO3)-D, P(EO3)-E, and P(EO3)-Ph. At a dopant concentration of 5 mM FeTos₃, electrical conductivities for these copolymers vary significantly (ranging between 9 S cm⁻¹ and 195 S cm⁻¹) with the EDOT copolymer, P(EO3)-E, achieving the highest electrical conductivity. UV-vis-NIR and X-ray spectroscopies show differences in both susceptibility to oxidative doping and extent of oxidation for the P(EO3) series, with P(EO3)-E being the most doped. Wide angle X-ray scattering measurements indicate that P(EO3)-E generally demonstrates the lowest paracrystallinity values in the series, as well as relatively small π-π stacking distances. The significant (i.e., order of magnitude) increase in electrical conductivity of doped P(EO3)-E films versus doped P(EO3)-D or P(EO3)-Ph films can therefore be attributed to P(EO3)-E exhibiting both the highest carrier ratios in the P(EO3) series as well as good π-π overlap and local ordering (low paracrystallinity values). Furthermore, these trends are in extent of doping and paracrystallinity are consistent with the reduced Fermi energy level and transport function prefactor parameters calculated using the semi-localized transport (SLTO) model. Observed differences in carrier ratios at the transport edge (τc) and reduced Fermi energies [η(c)] suggest a broader electronic band (better overlap and more delocalization) for the EDOT-incorporating P(EO3)-E polymer relative to P(EO3)-D and P(EO3)-Ph. Ultimately, we rationalize improvements in electrical conductivity due to microstructural and doping enhancements caused by EDOT-incorporation, a structure-property relationship worth considering in the future design of highly electrically conductive systems.

4:00 PM EL.16.05.07
Ion-Exchange Doping of Semiconducting Single-Walled Carbon Nanotubes Anup Hawkeye, Aditya Dash, Zhiyong Zhao, Anna Champ, Michael Zharnikov, Martijn Kemerink and Jana Zaumseil; Heidelberg University, Germany

Due to their unique electronic and thermoelectric properties, networks of purely semiconducting single-walled carbon nanotubes (SWNTs) are promising material for thermoelectric generators, which convert a temperature difference produced by waste heat into an electrical current. Dense films of SWNTs can be deposited from dispersion (e.g., by printing) and are mechanically flexible. They reach high electrical conductivities upon p- or n-doping and retain a high Seebeck coefficient. To introduce the charge carrier densities relevant for thermoelectric applications, chemical doping is typically used. However, the remaining dopant counterions are often unstable and the impact of the counterion on the thermoelectric properties of the SWNTs is still not fully explored. The recently developed technique of ion-exchange doping provides a means to exchange the dopant counterion with anions or cations from a huge library of commercially available salts and ionic liquids that do not possess the redox potential to reduce or oxidize the SWNTs themselves. In this work, we fabricated thin film networks of polymer-sorted small and large diameter SWNTs (~99% semiconducting) and chemically p-doped them using ion-exchange doping with a range of dopant counterions at low and high doping levels. Optical and electrical measurements reveal the ion-exchange efficiency and the influence of the counterion size on the electrical and thermoelectric properties.

4:15 PM EL.16.05.08
The Influence of Counterion Structure and Doping Level on the Optical, Electronic, and Thermoelectric Properties of π-Conjugated Polymers Kyle N. Baustert, Askhan Abtahi, Joel H. Bomble, Ahmed Ayyash, Chad Risko, Augustine O. Yusuf and Kenneth R. Graham; University of Kentucky, United States

Many organic electronic devices use chemical or electrochemical doping to introduce charge carriers into π-conjugated polymers (CPs) and change their
optical and electronic properties. As these charge carriers are introduced into a CP, counterions are either created (chemical doping) or injected (electrochemical doping) into the CP to balance the charge associated with the polaron on the CP. The structure of these counterions can exert a pronounced influence on the properties of doped CPs. Understanding how dopants and counterions interact with CPs to influence their optical and electronic properties is thus critical to designing new dopants and electrochemically doped CPs. Here, we focus on the influence of counterion size on the optical, electronic, and thermoelectric properties of selected CPs, including P3HT derivatives and PDPP4T. At the small and large ends of the spectrum we use tetrafluoroborate (BF$_4^-$) and tetrakis[3,5-bis(trifluoromethyl)phenyl]borate (BARF$_2^-$), respectively, where BARF$_2^-$ has a molar volume that is eight times larger than BF$_4^-$.

We find that the electrochemical doping behavior and polaron absorbance of regioregular-poly(3-hexylthiophene), $\text{rr}-\text{P3HT}$, differs significantly depending on whether BF$_4^-$ or BARF$_2^-$ is the counterion. Through comparing $\text{rr}-\text{P3HT}$ to regiorandom-P3HT, rra-P3HT, we attribute the counterion-dependent properties of $\text{rr}-\text{P3HT}$ partly to the ability of the counterion to penetrate the crystalline regions. The large counterion BARF$_2^-$ cannot penetrate the crystalline regions and as a result a higher potential is needed to oxidize $\text{rr}-\text{P3HT}$ with BARF$_2^-$.

Counterion distribution is not the only influential parameter, as the low energy polaron absorbance peak (P1) appears at lower energy with BARF$_2^-$ for both $\text{rr}$- and rra-P3HT, which density functional theory calculations indicate is due to the larger size of BARF$_2^-$ relative to BF$_4^-$ and the resulting increased distance between the charged counterion and charged polaron. Through electron paramagnetic resonance (EPR) measurements we show that the smaller counterion BF$_4^-$, which can penetrate the crystalline regions, results in increased bipolaron formation relative to BARF$_2^-$ as a counterion in $\text{rr}-\text{P3HT}$. Additionally, we find that the choice of counterion impacts both the electrical conductivity and Seebeck coefficient reached at a given charge-carrier concentration for P3HT derivatives and PDPP4T. These results highlight the influential interplay between counterion structure, polymer morphology, and resulting optical, electronic, and thermoelectric properties.

As the processability of electroactive conjugated polymers (CPs) is essential to their application in a range of devices, balancing solubility, processability, and film properties has become a key point of research. Solubilization of the conjugated backbone is typically achieved by introduction of relatively long branched hydrocarbon or oligoether side chains, which allows many degrees of conformational freedom. Such side chains, while enabling a wide range of processing conditions, reduce the relative fraction of active material in the film and obstruct π-π intermolecular interactions, leading to increased localization of charge carriers and compromise many of the desirable properties of the material (such as electrical conductivity). To counteract the deleterious effects introduced by side chains, we report that post-processing side chain removal, exemplified here via ester hydrolysis, significantly increases the electrical conductivity of chemically doped CP films with a corresponding decrease in Seebeck coefficient. In a model alkyl ester functionalized 3,4-propylenedioxythiophene (ProDOT) system, we found that the electrical conductivity of oxidatively doped films increased 10-fold upon side chain removal via hydrolysis. A combination of X-ray photoelectron spectroscopy (XPS), profilometry, and grazing incidence wide angle X-ray scattering (GIWAXS) results show that improvement in electrical conductivity and reduced Seebeck values are not due to an increase in carrier ratio (i.e., number of charge carriers per repeat unit ring), but instead results from an increase in charge carrier density (i.e., number of charge carriers per unit volume) due to densification and increased ordering of active polymer backbone material following side chain removal. This increase in carrier density leads to a reduction in charge localization, thereby improving charge transport, as contextualized using the newly developed semi-localized transport (SLoT) model. Applying this method to 3,4-ethylenedioxythiophene (EDOT) copolymer and homopolymer structures, synthesized via direct arylation polymerization, significantly higher average electrical conductivities are attained, with values ranging from 450 to ~1200 S/cm, depending on the repeat unit structure, in thick (~600 nm) films. In an all EDOT-based system, we observe a change in transport mechanism, from a low electrical conductivity and thermally activated (hopping-like) regime to a high electrical conductivity and thermally deactivated (metal-like) regime. Finally, these results are compared to those of matching oligoether functionalized polymers for a direct comparison of the differences in charge transport between these two reported methods of conductivity enhancement.

The development of highly conductive organic semiconductors has been a longstanding goal in materials science due to their chemical tunability, solution processability, mechanical flexibility, and other unique properties. Conjugated polymers are some of the most promising materials in this respect and have been widely employed in diverse device architectures such as organic field effect transistors (OFETs), organic light emitting diodes (OLEDs), and organic photovoltaics (OPVs). These applications generally require both n-type and p-type semiconducting materials, but the development of p-type conducting polymers has greatly outstripped that of n-type and ambipolar systems. Specifically, n-type materials generally display lower conductivities and mobilities in their doped states and are less stable due to oxidation under ambient conditions. This bottleneck is largely synthetic. Stability against oxidation requires decreasing LUMO levels well below -4.0 eV, yet there are relatively few building blocks that are sufficiently electron withdrawing to achieve this. Furthermore, there are limited design strategies for assembling these building blocks into polymers that retain high backbone planarity and electron delocalization, which are both critical to high mobility and conductivity. Thus, the development of new polymer scaffolds is critical to closing the performance gap between n-type and p-type conjugated polymers.

Polycetylenes (PAs) are attractive as high conductivity polymers, holding the record for highest reported conductivity in an organic semiconductor. However, they are inherently p-type materials. Although the introduction of strongly withdrawing groups to the PA core is straightforward conceptually, there are several practical challenges. Many standard withdrawing groups are too sterically bulky to preserve backbone planarity, and those that remain are generally incompatible with traditional PA syntheses.

We address this issue by developing a new class of PAs consisting of an alternating sequence of maleimide and vinylene units, dubbed maleimide-polyacetylene or mPA. This structure achieves high backbone planarity while still introducing a high density of strongly withdrawing groups, furnishing a
highly conductive polymer with a low LUMO of ~4.2 eV. The maleimide unit is also a facile synthetic handle, which enables the introduction of diverse functionality without perturbing backbone conformation. These polymers were accessed via a new synthetic approach, where a non-conjugated precursor polymer was synthesized via a ring opening metathesis polymerization (ROMP), followed by an efficient elimination to furnish the final polyacetylene. This strategy is scalable and efficient and enables the low synthesis diversity polymers with highly controllable molecular weights. Beyond mPA, it should be generalizable to a range of other electron-deficient polyacetylenes, opening the door to a new class of n-type organic semiconductors.

Negative Polaron in an n-Doped Polymer Semiconductor: Energy Levels and Hubbard U Interactions
Dominique Lungwitz1, Syed Joy2, Ahmed E. Mansour3, Andreas Opitz2, Chamiakara Karunasena4, Hong Li5, Naitik A. Panjwani1, Kartikay Moudgil2, Kan Tang3, Jan Behrends4, Stephen Barlow5, Seth R. Marder6,7, Jean-Luc Brédas8, Kenneth R. Graham9, Norbert Koch10, and Antoine Kahn11; 1Princeton University, United States; 2University of Kentucky, United States; 3Humboldt-Universität zu Berlin, Germany; 4University of Arizona, United States; 5Freie Universität Berlin, Germany; 6Georgia Institute of Technology, United States; 7University of Colorado Boulder, United States; 8Helmoltz-Zentrum Berlin, Germany

Doping organic semiconductors leads to the formation of polarons, positive in the case of p-doping and negative for n-doping. The released carrier polarizes neighboring molecular sites and induces intra- and inter-molecular relaxation. In the traditional picture, the formation of a negative polaron results in two localized levels within the gap: a half-occupied level below the LUMO/CBM, and a doubly occupied level above the HOMO/VBM. Conversely, the formation of a positive polaron results in an empty level below the LUMO/CBM and a half-occupied level above the HOMO/VBM. Recent experimental and theoretical studies have challenged this original interpretation.[1-3] In the case of an added electron (hole), the new picture points to a half-occupied (empty) level below the semiconductor LUMO/CBM, split from an unoccupied (half-occupied) level positioned above (below) the LUMO/CBM (HOMO/VBM). The split corresponds to the intra-molecular Coulomb interaction, also known as Hubbard interaction U.

Interactions

U. allows the direct determination of the Hubbard U.

The Role of Redox Doping in Organic Electronics and Opto-Electronics
Seth R. Marder1; University of Colorado Boulder, United States

Organic semiconductors and hybrid/organic materials have attracted interest for electronic applications due to their potential for use in low-cost, large-area, flexible electronic devices. Here we will report on recent developments pertaining to n-dopants that could impact the charge injection/collection processes in organic light emitting diodes, organic field effect transistors, and organic photovoltaic and hybrid organic/inorganic perovskite devices. We highlight the application of n-doping for the development of electron injection layers for organic light emitting diodes (OLEDs), and their use for doping of electron transport materials which result in high conductivities and in some cases good thermoelectric performance. In the case of OLEDs, it will be shown that photoactivation (as illustrated in the cartoon at the right) can lead to stable doping of materials (i.e. the doping induced conductivity remains relative constant over hundreds of hours) beyond the expected thermodynamic limit, which would be predicted based on a assessment of the effective reduction potential of the n-dopant and the reduction potential of the electron transport material. We will also highlight some of the differences between approaches based upon “dimeric” dopants, vs. hydride donor dopants.

Deprotonation-Based n-Doping of a New Acceptor-Accepter Conjugated Polymer
Andreas Erhardt1,2, Adrian Hochgesang1, John Mohanraj2 and Mukundan Thelakkat1; 1Monash University, Australia; 2University of Bayreuth, Germany

Doped organic semiconductors have proven to be viable materials for heat-to-electrical energy conversion (TE: thermoelectrics). For working large-scale thermoelectric generator devices, the synergistic use of p- and n-type components is necessary. However, as common for organic semiconductors, stable, n-doped polymers are sparse. Besides approaches to solve intrinsic stability issues of the doped acceptor towards ubiquitous oxidizing agents (H₂O and O₂), the choice and underlying mechanism of suitable n-dopants is an open field of research.

Our very recent work reports the design and synthesis of an acceptor-acceptor low LUMO copolymer (“DPP-TPD”, [1]) in conjunction with bulk n-doping using Cs₂CO₃.[2] We present a novel acceptor-acceptor copolymer synthetic strategy using direct arylation polymerization and demonstrate excellent viability for n-doped systems for TE applications. In contrast to previous reports about Cs₂CO₃ n-doped systems, we elucidate the mechanism, that our copolymer is doped via a solid-state acid-base interaction between the polymer and the basic carbonate. The resulting increase of the backbone electron density by deprotonation of the thiophene moiety is accompanied by the formation of bicarbonate. The crucial role of the basicity was demonstrated by comparative doping studies of the host polymer with further organic and inorganic carbonates. The general viability of the concept was evaluated with the strong base n-butyl lithium, which, in agreement with our findings, induces outstanding electron conductivity after thermal annealing. Comparable to N-DMBH hydride/electron transfer, Cs₂CO₃ proton abstraction doping shifts the polymer work function towards the LUMO. Thereby, the anionic doped state is resilient against O₂ but is highly susceptible to H₂O. Based on GIWAXS, Cs₂CO₃ is mainly incorporated into the amorphous region of the film with the help of hydrophilic side chains and has a minor impact on the crystallinity. Together, the synergy between Cs₂CO₃ proton abstraction doping and acceptor-acceptor copolymer strategy creates an n-doped system with promising properties for thermal energy conversion, as evidenced by a remarkable maximum power factor of (5.59 ± 0.39) x 10⁻⁶ W m⁻¹ K⁻² in n-type thermoelectric element.

The main implications and novelty of our work are a: the viability of copolymers, following an acceptor-acceptor design principle, and b: the possibility to n-dope suitable copolymers via deprotonation reactions using simple carbonate dopants, opening a vast field of new n-type dopants.

**Factors Promoting or Inhibiting Charge Transfer in Doped Organic Semiconductors** Ingo Salzmann; Concordia University, Canada

To control the conductivity of organic semiconductors (OSC) and their energy level alignment in heterostructures and at interfaces, OSCs are being electrically doped by introducing guest species into the semiconductor host. The low dielectric constant of semiconducting polymers causes strong Coulomb interactions between carriers and dopants. As a result, carriers cannot be effectively transported through the host polymer network and tend to localize within a few monomer units or π-stacks. These limitations, distinct from those observed in conventionally doped inorganic semiconductors, necessitate novel engineering strategies to not only generate more charge carriers but also reduce unfavorable electrostatic interactions between carriers and dopants in doped semiconducting polymers. This talk will explore straightforward engineering methods to reduce Coulomb interactions between carriers and dopants in highly-doped semiconducting polymers. The corresponding reduction in charge localization and improved transport achieved through these methods will be discussed. Additionally, I will explore the effects of molecular structures that exhibit resilience to the energetic disorder caused by electrostatic carrier-dopant interactions on charge transport properties. Lastly, the talk will introduce the significant thermoelectric performance achieved in our research and discuss the potential of thermoelectric materials based on doped semiconducting polymers for the near future.

**Engineering Carrier-Dopant Interactions to Improve Charge Transport Properties in Highly-Doped Semiconducting Polymers** Kilwon Cho; Pohang University of Science and Technology, Korea (the Republic of)

Doping is a powerful technique that can easily tune the electrical properties of semiconducting polymers and hence, grant flexibility to their applications. Highly-doped semiconducting polymers with high electrical conductivity have found extensive use in thermoelectric materials and bioelectronics. However, the low dielectric constant of semiconducting polymers causes strong Coulomb interactions between carriers and dopants. As a result, carriers cannot be effectively transported through the host polymer network and tend to localize within a few monomer units or π-stacks. These limitations, distinct from those observed in conventionally doped inorganic semiconductors, necessitate novel engineering strategies to not only generate more charge carriers but also reduce unfavorable electrostatic interactions between carriers and dopants in doped semiconducting polymers. This talk will explore straightforward engineering methods to reduce Coulomb interactions between carriers and dopants in highly-doped semiconducting polymers. The corresponding reduction in charge localization and improved transport achieved through these methods will be discussed. Additionally, I will explore the effects of molecular structures that exhibit resilience to the energetic disorder caused by electrostatic carrier-dopant interactions on charge transport properties. Lastly, the talk will introduce the significant thermoelectric performance achieved in our research and discuss the potential of thermoelectric materials based on doped semiconducting polymers for the near future.

SESSION EL16.07: Understanding the Impact of Dopant-Carrier Interactions

**1:30 PM *EL16.07.01**

**Quantifying Polaron Populations in Sequentially Doped Conjugated Polymers** Adam J. Moule¹, Tucker L. Murrey¹, Melissa Berteau-Rainville², Meghna Jha¹, Ingo Salzmann¹ and Mark Mascal¹; ¹University of California, Davis, United States; ²Institut National de la Recherche Scientifique, Canada; ³Concordia University, Canada

Conjugated polymers can be chemically tailored for a variety of electronic device applications. Sequential solution doping with high electron affinity (EA) molecular dopants is the processing technique that has produced molecularly doped polymeric films with the highest conductivity. In spite of numerous studies quantifying the conductivity of molecularly doped polymers as a function of processing conditions, there is no established method to quantify the charge density. The consequence is that the relationship between conductivity, mobility, and charge density is poorly understood, prohibiting meaningful quantitative comparisons between different polymers and dopants. Here we demonstrate a practical method to quantify the polaron density using the material density, molecular volumes, and optical measurements. Importantly, this method enables quantitative comparisons between multiple different polymer and dopant combinations as we demonstrate using P3HT and a series diketopyrrolopyrrole (DPP) co-polymers doped with a series of ultra-high EA cyano- and ester-substituted cyclohexane-1,2,3-trilene-based dopants. The Langmuir isotherm is used to fit the solution concentration dependence of the film polaron mole fraction, which enables characterization of the sequential doping process using a single equilibrium constant. The saturated polaron mole fraction saturates with respect to the energetic driving force for doping, indicating that simply increasing the EA of the dopant is not an effective strategy for obtaining 100% ionization of the polymer monomers. To ground this thermodynamic model, we simulated the density of states (DOS) using Gaussian energy distributions. This DOS model predicts the experimental saturated doping level for every polymer/dopant pair within uncertainty. This data and model demonstrate conclusively that increasing the polaron density has a larger effect on increasing both conductivity and charge mobility than the polymer chemistry or structure.

**2:00 PM *EL16.07.02**

**Considerations on "Double Doping" and an Enhanced p-Dopant Complex** Norbert Koch¹,²; ¹Humboldt-Universität zu Berlin, Germany; ²Helmholtz-Zentrum Berlin, Germany

The double ionization of molecular dopants enables the doping efficiency to rise above 100%. This means increased conductivity can be achieved with fewer dopant molecules, resulting in less disruption to the semiconductor film’s structure. However, current models of doped organic semiconductors based on Fermi-Dirac statistics with two distributions that represent the host and dopant density of states, fail to explain double dopant ionization, and also the analogous situation of bipolaron formation on a host semiconductor polymer. This shortcoming is addressed by considering the energy level renormalization of the frontier molecular orbital levels upon electron transfer between host and p-dopant. Varying the model parameters host-dopant energy level offset, energetic disorder, reorganization energy, and Hubbard U sublevel splitting, robust trends in the fractions of doubly-ionized, singly-ionized, and neutral species are found. The conventionally used p-dopants based on tetracyanoquinodimethane (TCNO) and its derivatives feature limited oxidation strength especially for modern polymer semiconductors with high ionization energy (IE). These small molecular dopants also exhibit pronounced diffusion in polymer hosts. A facile
approach is presented to increase the oxidation strength of several TCNQ-derivatives by coordination with four tris(pentafluorophenyl)borane (BCF) molecules, using a single-step solution mixing process, resulting in bulky dopant complexes. Using a series of polymer semiconductors with IE up to 5.9 eV, the efficiency of doping using such complexes is found to be significantly higher compared to using either of the dopants alone. Additionally, the bulkier structure of the complexes is shown to result in a higher stability against dopant drift in thin films under an applied electric field. The simple approach of solution-mixing of readily accessible molecules thus offers access to enhanced molecular p-dopants.

Unlocking the Full Potential of Electron Acceptor Molecules for Efficient and Stable Hole Injection into Organic Semiconductors Taku Oono, Takuya Okada, Tsubasa Sasaki, Takahisa Shimizu and Hirohiko Fukagawa; Japan Broadcasting Corporation, Japan

Improving the hole injection property are of pivotal importance in the future development of organic optoelectronic devices. Electron acceptor molecules with high electron affinity (EA) are widely used in electronic applications, such as hole injection, p-doping and charge generation. Although p-doping and charge generation have generally been discussed in terms of matching the ionization energy (IE) of organic semiconductors with the EA of acceptor molecules, it has been demonstrated that the EA depends on the charged states of acceptor molecules in recent years [1,2]. In this study, we report a strategy to maximize the potential of acceptor molecules for efficient and stable hole injection into organic semiconductors [3]. This strategy has been developed based on the correlation between the HIL-dependent properties of OLEDs and the actual energy levels around the anodes as determined by both low-energy inverse photoemission spectroscopy and ultraviolet photoemission spectroscopy. Efficient and stable hole injection into an organic semiconductor with a relatively high IE of 5.8 eV is possible by stacking acceptor molecules with EAs of 4.3 and 5.0 eV. This superior hole injection property enables direct hole injection even into materials used as the emitting host for pure blue thermally activated delayed fluorescence (TADF) emitters with a large band gap. A pure blue TADF organic light-emitting diode (OLED) that has both a Commission internationale de l’éclairage (CIE) y coordinate of less than 0.10 and a low turn-on voltage of only 2.67 V was realized by employing a device architecture with no energy barrier in the OLED. The findings are expected to have a wide range of organic electronic applications, such as the efficient hole injection into materials with high IE used in perovskite LEDs, organic thin-film transistors, and organic semiconductor laser diodes.

Imaging the Effect of Nanoscale Morphology on Molecular Doping Efficiency in Conducting Polymers Sung-Joo Kwon1, Rajiv Giridharagopal1, Shinya Chen1, Ramesses Quezada1, Jiajie Guo1, Justin Neu2, Wei You2 and David S. Ginger1, 1University of Washington, United States; 2University of North Carolina at Chapel Hill, United States

Understanding the mechanisms underpinning doping of conducting polymers (CPs) is critical for improving their performance in next-generation organic electronic devices. Although a number of studies have investigated molecular or electrochemical doping of conducting polymers, most work has focused primarily on understanding doping via device-level operation using macroscopic probes. Conducting polymers (CPs) are inherently nanostructured, with a mixture of crystalline and amorphous domains. Thus, understanding the underlying mechanisms behind doping can benefit from nanoscale real-space imaging. Here, we investigate the molecular and electrochemical doping on two CPs with very different reported doping efficiencies (# charges/dopant molecules) using functional atomic force microscopy methods. Specifically, we compare the morphology dependence behind the well-known poly(3-hexylthiophene) (P3HT) polymer, with alkyl sidechains, to a more state-of-the-art polymer p-g(32T-TT) that has been reported to exhibit substantially higher doping efficiencies. We use scanning Kelvin probe microscopy and conductive AFM to investigate local doping and visualize the morphology-dependence of local dopant/counterion accumulation. We use these methods to provide a link between optical measurements of doping with spectroelectrochemistry and local work function variations for films that have been molecularly and electrochemically doped. These results show that doping efficiency is linked to the polymer’s ability to accommodate the dopant in its three-dimensional structure, where P3HT exhibits significant surface aggregation of molecular dopants that limits its ultimate efficiency compared to p-g(32T-TT). We validate these results chemically via time-of-flight secondary ion mass spectrometry, providing a comprehensive view of the interplay between the local structure and ion ingress. This work provides guidance for optimizing future combinations of polymeric materials and molecular dopants to maximize conductivity.

4:00 PM EL16.07.05
Thermal Stability of Organic Hole Transport Layers Stephanie A. Buchholtz, Tobias Antrack, Hans Kleemann and Karl Leo; Dresden Integrated Center for Applied Physics and Photonic Materials, Germany

The electrical conductivity of amorphous doped organic hole transport layers, as used in organic light-emitting diodes (OLEDs), solar cells, or photodetectors, increases with temperature due to the dominant hopping-like transport mechanism. However, the conductivity irreversibly breaks down at a certain temperature. For example, OLEDs and organic photovoltaics have operating temperatures up to 80°C and 145°C, respectively. In addition, the active layer of an organic solar cell is deposited on the top hole transport layer and has to be annealed at temperatures up to 140°C for a higher efficiency. The reasons for this breakdown are unknown, impeding the development of more stable devices. Here, we show a relation between the breakdown of the conductivity and the glass transition of the small molecule host materials and find that the choice of the dopant and the doping concentration significantly affects the thermal stability of the layer. Based on our investigations, we develop different hypotheses about the cause of the breakdown. With our results, we devise strategies to improve the thermal stability of organic hole transport layers.

Counterion Control and the Electronic Structure of Polaronic and Bipolaronic In Doped Conjugated Polymers Benjamin J. Schwartz; UCLA, United States

When an electron is removed from a conjugated polymer, such as poly(3-hexylthiophene-2,5-diyl) (P3HT), the remaining hole and associated change in the polymer backbone structure from aromatic to quinoidal is referred to as a polaron. Bipolarons are created by removing the unpaired electron from an already-oxidized polymer segment. In electrochemically-doped P3HT films, polarons and bipolarons are readily observed, but in chemically-doped P3HT films, bipolarons rarely form. We explain this observation by studying the effects of counterion position on the formation of polarons, strongly coupled polarons, and bipolarons using both spectroscopic and X-ray diffraction experiments and time-dependent density functional theory (TD-DFT) calculations. The counterion positions control whether two polarons spin-pair to form a bipolaron or whether they strongly couple without spin-pairing. When two counterions lie close to the same polymer segment, bipolarons can form, with an absorption spectrum that is blue-shifted from that of a single polaron. Otherwise, polarons at high concentrations do not spin-pair, but instead J-couple, leading to a redshifted absorption spectrum. The counterion location
needed for bipolaron formation is accompanied by a loss of polymer crystallinity, so that bipolarons can form only in disordered regions of conjugated polymer films. Our TD-DFT calculations of polaron and bipolaron predict absorption spectra that match well with experiment, providing strong evidence that TD-DFT is correctly capturing the electronic structure of the doped material. Several groups, however, who looked at the energies of the Kohn-Sham orbitals from (non-time-dependent) DFT calculations, have recently argued that the traditional band picture is incorrect for doped conjugated polymers. Instead, these non-time-dependent DFT calculations suggest that polaron creation causes only one unoccupied state to move into the band gap near the valence band edge while half-filled states in the conduction and valence bands bend downward in energy. To understand the discrepancy, we also performed an analysis using natural transitional orbitals (NTOs) that shows that our TD-DFT calculations indeed reproduce the traditional band picture of polarons and bipolarons. Taken together, our experimental and theoretical results agree that controlling the counterion location and using the property level of theory is critical to understanding the electronic structure of polarons and bipolarons on doped conjugated polymers.

8:30 AM EL16.08.01
Electrical Doping Stabilizes Organic Nanoparticle Dispersions for the Eco-Friendly Fabrication of Solar Cells
Felix Manger, Jonas Armleder, Philipp Marlow, Karen Fischer, Holger Roehm, Christian Sprau and Alexander Colsmann; Karlsruhe Institute of Technology, Germany

Nanoparticle dispersions allow the use of eco-friendly processing agents for the solution deposition of organic semiconductor thin-films for photovoltaic and other optoelectronic applications. Omitting surfactants, which are commonly used to stabilize dispersions, is essential to not jeopardize the solar cell performance. In this work, electrical doping is used to charge the organic nanoparticles. The resulting electrostatic repulsion between the nanoparticles stabilizes the dispersion. Different doping concepts are deployed, compared and their effect on the nanoparticle stabilization is explored. Preference is given to volatile dopants which evaporate from the nanoparticulate light-harvesting layer after thin-film deposition. Finally, using electrical doping and the corresponding electrostatic stabilization, novel surfactant-free nanoparticle dispersions from high-performance organic semiconductors are synthesized by nanoprecipitation, giving rise to record solar cell power conversion efficiencies beyond 10%.

8:45 AM EL16.08.02
Efficient N-Doping in Organic Semiconductors by Novel Approaches and Materials Design
Antonio Pacchetti; Northwestern University/Flexterra Inc, United States

In this presentation we will report new strategies to efficiently n-doped organic semiconductor films. Thus, starting from initial work investigating molecular n-doping of naphthalenediimide (NDI) and isomeric benzothiadiazole (isoBT) based polymers we explored how variations in polymer backbone composition, regiochemistry, thin-film processing, and doping affect major film morphology and charge transport characteristics in transistor and diode architectures. For instance, we showed that NDI-(TVT) (TET) [x=100%, TVT = thiienyl-CH=CH-thienyl; TET = thiienyl-CH=CH-thienyl] charge transport in transistor has a unique dependence on the x,y values. Thus, we explored how charge transport is affected in diodes as well as how NDI-(TVT) (TET) (polymer acceptor) + polymer donor solar cells perform. Finally, we recently discovered new approaches to enhance doping efficiency and conductivity via 1, tuning film morphology by favoring molecule dopant penetration and, 2, using catalysts that promote the semiconductor+dopant reaction. The latter strategy enables excellent doping efficiencies and conductivities for several organic semiconductors.

9:00 AM *EL16.08.03
The Role of Carrier Density and Morphology on Charge Transport
Anna Kohler; University of Bayreuth, Germany

Charge carrier mobility is a decisive factor in controlling the efficiency of organic solar cells (OSCs) and field effect transistors (OFETs). This presentation will discuss how the mobility will be influenced by factors including aggregation, local morphology or carrier density. We employ kinetic Monte-Carlo simulation to study the charge transport.

9:30 AM BREAK
Doping of organic semiconductors plays an important and growing role in organic electronics, ranging from organic light emitting diodes and organic solar cells to thermoelectrics and bioelectronics. However, unlike Si, where parts per million dopant concentrations can significantly alter conductivity, doping organic semiconductors with molecular dopants typically requires a much higher concentration. Complex interplay between the microstructure, electronic structure and molecular interactions of the polymer and dopants has prevented systematic understanding. Progress is largely dependent on heuristically guided, slow, trial-and-error experimentation. Furthermore, only $p$-type doping has been widely implemented in organic semiconductors, and $n$-type doping has met with limited success. Thus, developing air-stable $n$-dopants is an important objective for the field of molecular dopants.

Supported by the DoD MURI program, the DOPE Center aims to transform the field of solution-processed, doped conducting polymers by 1) co-designing optimized $p$- and $n$-doped conducting polymer systems and achieving facile $n$-doping, 2) extending our recent, paradigm-changing discovery of photoredox doping in conjugate polymers, 3) accelerating the pace of data generation by collaborative workflow integration of robotic experimentation and machine learning (ML) and artificial intelligence (AI) approaches, 4) creating fundamental knowledge that informs novel materials synthesis and system optimization.

This talk will introduce the DOPE Center, and progress made up to this point. Importantly, the DOPE Center welcomes collaboration, and hopes to serve as a coalescing point to work with the large community to rapidly advance the field.

11:00 AM *EL16.08.06
Nanomechanics of Materials used in Flexible Electronics Deepak Venkateshvaran and Leszek J. Spalek; University of Cambridge, United Kingdom

Organic semiconductors are multifunctional soft electronic materials that play an impactful role in the flexible electronics industry. Their use spans printed electronic circuits, large area displays, flexible solar energy harvesters, and implantable bioelectronics. For their competitive optical, electronic, thermoelectric, and spin-based properties, these soft electronic materials attract significant academic engagement, seeding new technologies for the future. [1, 2, 3]

Although macroscopic flexibility on the centimetre to metre scale is a unique selling point for organic semiconductor technology, not much is known about their mechanical properties on the nanoscale. Quantification of these nanomechanical properties, together with an understanding of nanoscale stiffness tunability and homogenisation, holds significant potential for fundamental and applied science. [4, 5]

During the last decade, the development of high precision atomic force microscopes has made it possible to quantify the mechanical properties of organic polymers on the scale of a few polymer chains. Techniques such as higher eigen mode imaging make it possible to visualise molecular ordering on the nanoscale under ambient conditions with ease. These techniques allow one to correlate molecular ordering with the stiffness that such ordering manifests.

In this talk, the science and technology of precision nanoscale measurement of mechanics will be spotlight. The interrelation between molecular organisation and nanomechanical properties in high-performance polymers used for organic electronics will be shown. [6, 7] A quantification of differences in strain within organic nanocrystal polymorphs will also be demonstrated. The measurement techniques demonstrated in this talk are extendable to a wide variety of multifunctional materials with a broad range of elastic properties and have significant use in both academia and industry.

MXenes (carbides, nitrates, oxy carbides and carbonitriles of early transition metals) are a very large family of 2D materials. They have a chemical formula of M_n+1X_yT_z, where M is a transition metal (Ti, Mo, Nb, V, Cr, etc.), X is either carbon and/or nitrogen (n = 1, 2, 3 or 4), and T represents surface terminations (O, OH, halogens, chalcogens). The large variety of structures and compositions, availability of solid solutions on M and X sites, and control of surface terminations offer a plethora of materials to produce and investigate. Combining their plasmonic properties with ease in aqueous processing, high electronic conductivity (over 20,000 S/cm), biocompatibility, and excellent mechanical properties, which exceed other solution-processable 2D materials, MXenes have the characteristics enabling numerous applications. However, the properties of MXenes depend on their synthesis method. Selective etching of Al, Si or Ga is acidic electrolytes is the most common approach. However, the use of molten salts for selective etching has been gaining the momentum, as MXenes with uniform halogen surface terminations can be produced. Hydrothermal and electrochemical selective etching methods have been introduced. Finally, CVD synthesis and topochemical synthesis using graphene/graphite or metal oxide add a new dimension. A critical overview of various synthesis techniques will be provided.

References:
The synthesis of MAX phases and their two-dimensional siblings MXenes, especially when pushing beyond Ti-based compounds, is far from trivial. Our group uses diverse preparation techniques to access new versions of these intriguing types of materials, recent examples include Cr₅GaC in the shape of carbonaceous microwires, hollow and full microspheres as well as hitherto unknown carbonitride phases, such as Cr₅GaC₁₋ₓNx and V₅GaC₁₋ₓNx. We specialize in non-conventional methods, such as sol-gel chemistry and microwave heating to synthesize the MAX phases.

In this talk, I will highlight two of our recent projects: (i) Our work on a unique \(3+1\) MAX phase (Mo₂Ti₇V₃)AlC₆, its structural investigation and transition to the respective MXene including its electrocatalytic properties. (ii) The transition from a MAX-like \(2+2\) compound MoGa₂C to the fully exfoliated MXene Mo₅CT, as well as Mo-doped variants.

All materials are structurally characterized by diffraction and microscopy techniques and a deeper understanding of their chemical composition, formation mechanism and stability is obtained through spectroscopy and thermogravimetric methods.

1:30 PM  *EL17.02.01  MXenes: Science, Applications and Hype  Michel W. Barsoum  Drexel University, United States

At this juncture there is no doubt that MXenes have captivated the world’s interest and with good reason. The number of potential applications is quite numerous and diverse. The use, or addition, of MXenes can boost some properties sometimes to record levels; in other cases it allows for herewith new applications for 2D materials. Their chemical diversity is also a huge attractor. As MXenes - like other new materials - get more popular, they are accompanied by hype. With hype comes responsibility. Hying, or overpromising, is bad for the field in general and should be curtailed. In this talk I differentiate between work done in the name of science that has little chance of applicability and other work that may lead to applications. The fundamental, and quite difficult problem to solve, with MXenes is that because we are dealing with essentially a few – 2, 3, 4 - of highly reactive transition metals layers interleaved with C or N, it will be very difficult indeed to render them oxidation resistant. It follows that applications where MXenes are placed in \textit{open}, aqueous-based systems will be few and far between. Hying such applications - while not simultaneously solving the stability conundrum for times commensurate with the time of use in said applications - is irresponsible since they fall under the purview of science. Another example of hype is work on MXene-based supercapacitors. To date, most of supercapacitor work on MXenes makes use of dilute aqueous-based electrolytes. We have shown that when using such electrolytes, such as sulphuric acid, the self-discharge rate is quite high which, in turn, would again greatly limit the scope of applicability of such devices. Other potential pitfalls will be discussed.

2:00 PM DISCUSSION TIME

2:15 PM  *EL17.02.03  MXenes: A Family of Materials  Marley Downes¹, Christopher E. Shuck¹, Robert Lord¹, Mark Anayee¹, Mikhail Shekhirev¹, Ruocun (John) Wang¹, Tetiana Hryhorchuk¹, Martin Dahlqvist², Johanna Rosen² and Yury Gogotsi²  Drexel University, United States; ²Linköping University, Sweden

MXenes are two-dimensional (2D) transition metal carbides, nitrides, and carbonitrides typically synthesized from layered MAX-phase precursors. With over 50 experimentally reported MXenes and a near-infinite number of possible chemistries, MXenes are the fastest-growing family of 2D materials. They offer a wide range of properties, which can be altered by their chemistry (M, X, T) and the number of metal layers in the structure, ranging from two in MₓTₓ to five in MₓTx. Only one MₓTx MXene, Mo₅VCₓ, has been reported. Herein, we report the synthesis and characterization of two new phase-pure MoₓAXₓ mixed transition MAX-phase phases, (TiTa)₄AlC₆ and (TiNb)₄AlC₆, and their successful topochemical transformation into (TiTa)₄Cl₄T₄ and (TiNb)₄Cl₄T₄, MXenes. The resulting MXenes were delaminated into single-layer flakes, analyzed structurally, and characterized for their thermal and optical properties. This establishes a family of MoₓAXₓ MAX phases and their corresponding MXenes. These materials were experimentally produced based on guidance from theoretical predictions, opening the door to exciting new applications for MXenes.

2:30 PM  *EL17.02.04  Tailoring of Vacancy Concentration and Pore Size in MXenes  Johanna Rosen  Linköping University, Sweden

MXenes show great prospects for surface-related applications owing to their large surface area and unique physical and chemical properties. MXenes with vacancies, whether ordered or randomly distributed, have shown a significant property enhancement, particularly in energy storage devices. Generally, randomly ordered vacancies in 2D monolayers have the possibility to conglomerate and form pores of different size. The performance can then be further enhanced, allowing interaction with various inorganic and organic species depending on the pore size. I will present a general experimental approach for tailoring vacancy concentration and pore size in a selection of well-known MXenes, inspired by theoretical calculations. The method is based on alloying of the parent MAX phases, where the concentration of the alloying element is directly correlated to the vacancy concentration (pore size) in the resulting MXene. The synthesized MXenes are shown to have a large surface area, and are further characterized with respect to structure, composition, and selected properties. The formation of pores is shown to significantly enhance the capacitance, and the materials are predicted to have selectivity towards inorganic and organic chemical species which can play an important role in molecular separation and energy related applications.

MXenes for Solid-State Electrochemical Energy Storage Masashi Okubo; Waseda University, Japan

Layered transition-metal carbides/nitrides (MXenes) are an emerging family of electrochemical energy storage materials. When used as an electrode material with a liquid electrolyte, MXenes exhibit Li+ intercalation without large structural changes, which enables fast ion transport as well as dense charge storage in the open interlayer space between MXene nanosheets. It is well known that the Li+ intercalation of MXene electrodes is significantly affected by liquid electrolytes. However, the charge storage using MXene electrodes in inorganic solid electrolytes has rarely been investigated. Especially, the strain-free property of MXene should be beneficial to maintaining solid-solid interface, which enabling long-term cycling of all-solid-state batteries. In this work, we investigate the charge storage behavior of various MXene electrodes with solid electrolytes. After clarifying the strain-free charge storage mechanism through the MXene–solid electrolyte interface, we exploit it for the stable operation of a strain-free ASSB using MXene as a negative electrode material.

4:00 PM EL17.03.02
Bringing Together Laser Treated MXene and Titania Nanotubes Towards Composite Electrode Material Active under Visible Light Katarzyna Skrzela1, Duszejic Kousa1, Miroslaw Sawczak1, Vit Strnark2, Petr Szeczmyk1, Jan Hanus1, Ondrej Kylia1 and Katarzyna Grochowska1; 1The Szewalski Institute of Fluid-Flow Machinery Polish Academy of Sciences, Poland; 2University of South Bohemia in Ceske Budjovice, Czechia; 3Charles University, Czechia

For the past 20 years, taking into account as the starting date the discovery of the extraordinary properties of a single layer graphene, finally the materials exhibiting 2D architecture have gained more attention. Among family of chalcogenides and boron nitrides that became so popular, the carbides and nitrides of transition metals became a rising star due to the attractive properties [1]. In MXene flake one can find a layer of transition metal and interlayer of carbon with some termination (O, OH, F or Cl) that are linked also to the metallic part. Most of known MXene synthesis routes involved fluoride-containing compounds, either aqueous or molten salts treatment of the MAX phase. Despite individual sheets are obtained they are still formed in a specific stack of several micrometters providing some problem when the composite with other materials should be achieved. To overcome this problematic issue we propose laser treatment as an additional step in the fabrication route. The fabrication of Ti3C2Tx is performed in a quite typical way including mixing of MAX phase with HF and HCl solution and further delamination supported with NaCl. Microscopic investigation revealed that MXene sheets form agglomerates and additional efforts should be undertaken. Therefore, the MXene powder was frozen using liquid nitrogen and on such frozen material a liquid isopropanol was poured. Then beam of 1064 nm generated by pulsed Nd:YAG laser was irradiating frozen Ti3C2Tx. The interaction between laser and this material results in its ablation and its capture in a liquid medium. During the process the solution above the frozen material become grayish and such liquid was collected after different periods of time. Both the resonant peak at 120 cm\(^{-1}\) and the out-of-plane vibrations at 736 cm\(^{-1}\) of Ti3C2Tx are clearly visible on the Raman spectrum confirming the preservation of the MXene structure. Finally, the material was used for the modification of surface provided by titania nanotubes obtained via anodization of Ti plates and Ti spattered layer. The modification was carried out via treatment with TiCl4/Ti3C2Tx solution followed by thermal annealing. The SEM inspection revealed that the initially smooth and thin walls of titania were uniformly overgrown and more porous but any agglomerates clogging the tubular interior were not detected. Cyclic voltammetry curves recorded for the series of modified titania electrodes indicated enhanced photoresponse under both visible and UV-vis light. In a particular case where the electrode was exposed to visible light, almost 20 times higher photocurrent at 0 V vs. Ag/AgCl/0.1 M KCl comparing to bare titania was reached. Apart from the improved photoresponse, the electrochemical activity of modified titania in the cathodic range was significantly changed, namely the cathodic current was much higher than the one registered for bare titania. For example at -1.0 V, bare titania exhibits nearly 0.1 mA/cm\(^2\) whereas for the modified substrate the recorded current equals 2.6 mA/cm\(^2\). It should be underlined that when the treatment of titania was carried out with TiCl4 solution but without addition of laser treated MXene, such electrochemical response was not achieved. It indicated that the presence of MXene is crucial for greatly improved electrochemical and photoelectrochemical properties of the composite electrode material. Summarizing we would like to show the unique laser treatment of 2D metal carbide material and its possible usage for formation of the composite with inorganic platform exhibiting promising electrochemical and photoelectrochemical properties being of high importance for development in the research area of water splitting and photoconversion.

4:15 PM EL17.03.03
Investigation of Electrochemical Properties of Carbonitride MXenes with Different Nitrogen Contents Chun-Pei Chan1,2, Teng Zhang2, Kateryna Shevchuk2, Raocun (John) Wang3 and Yury Gogotsi3; 1National Chi Nan University, Taiwan; 2Drexel University, United States

Carbonitride MXenes with different nitrogen-to-carbon ratios have been fabricated. As the nitrogen content increases, the plasmonic resonance and A1g characteristic peaks in the Raman spectra become weaker, indicating successful nitrogen substitution in the carbon (X) sublattice of MXene. An additional redox peak in the cyclic voltammetry (CV) curves further confirms the presence of nitrogen species in the carbonitride MXenes. When utilized as the anode material in a supercapacitor with a 3M aqueous sulfuric acid electrolyte, the highest specific capacitance achieved by a carbonitride MXene is approximately 370 Fg\(^{-1}\) at a scan rate of 2 mVs\(^{-1}\). The fitting results of XPS spectra demonstrate the reduction in both carbide and nitride signals, and C-Ti-F becomes the dominant surface termination after electrochemical cycling. The carbonitride MXene with the highest nitrogen level exhibits the best rate capability but the worst cyclic stability. It also shows inferior Coulombic efficiency at lower scan rates. In contrast, the Lithium-delaminated Ti3C2 material has the best cyclic stability. The results of Electrochemical Impedance Spectroscopy (EIS) align with the CV results for the carbonitride MXenes. It has been demonstrated by Starcaser Potensio-Electrochemical Impedance Spectroscopy (SPEIS) that, with a higher nitrogen content, a less negative applied potential is required to achieve smaller impedance and interlayer spacing.

4:30 PM EL17.03.04
V2C and Nb2C MXenes: An Emerging Tunable Platform for Nanophotonics Alexandra Boltasseva1, Jeffery Simon2, Colton Fruehlin1, Stefano Ippolito1, Danzhen Zhang2 and Yury Gogotsi2; 1Purdue University, United States; 2Drexel University, United States
MXenes, or transitional metal carbides, carbon nitrides, and nitrides, have recently emerged as a fascinating class of two-dimensional nanomaterials. These materials follow the chemical formula $\text{M}_n+1\text{X}_n\text{Tx}$. A prototypical MXene, Ti$_3$C$_2$Tx has been studied extensively over the past two decades demonstrating remarkable electrical and optical properties and utilized for linear optical devices such as broadband absorbers, and nonlinear devices like saturable absorbers in lasing cavities. Here, we expand upon our group’s previous work with Ti$_3$C$_2$Tx to new members in the MXene family, specifically V$_2$C and Nb$_2$C. By employing ellipsometry, we investigate the optical response of V$_2$C and Nb$_2$C. Our findings reveal a metallic transition for V$_2$C at longer wavelengths, while Nb$_2$C retains its dielectric nature due to the higher carrier concentration in V$_2$C. This transition from dielectric to metallic behavior is marked by the permittivity crossing zero in a region known as epsilon-near-zero (ENZ), which holds significant implications for optical technology. Furthermore, our research demonstrates that the ENZ point can be manipulated by adjusting the film thickness of V$_2$C, thereby affecting both its linear and nonlinear properties. These findings lay the foundation for future device development utilizing various members of the MXene family, including the creation of layered metamaterials.

8:00 PM EL17.04.01
Etching Mechanism of Aluminum Layers during 2D MXene Synthesis Chi Won Ahn; NNFC, Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Understanding the etching mechanisms of MXene and obtaining direct insights into the influence of etchants on structural features and defects are of critical importance for improving MXene properties, optimization of etching protocols, and exploring new MXene compositions. Despite their importance, such studies have been challenging because of the monoatomic thickness of the A-element layers being etched and aggressive etchants that hinder in situ studies. Here, we visualize the etching behavior of the Ti$_3$AlC$_2$ MAX phase in different etchants at the atomic scale using focused ion beam and electron microscopy. We also report on the structural changes in the Ti$_3$AlC$_2$ phase as a function of etching time and etchant type (LiF/HCl, HF, or NH$_4$F/H$_2$O) to reveal the etching mechanism for the first time.

8:00 PM EL17.04.02
Controlling the Interlayer Spacing of Two-Dimensional Titanium Carbide (MXene) Membranes for Selective Ion Separations in Water Yaguang Zhu, Austin J. Booth, Kimberly Ventura-Martinez and Kelsey B. Hatzell; Princeton University, United States

MXenes are an emerging class of two-dimensional nanomaterials with promising applications in critical resource recovery, energy storage, and desalination. Specifically, MXene membranes are able to selectively separate cations based on charge and ionic radius, with low permeation rates for large and/or multivalent cations but high permeation rates for alkali-metal cations such as Li$^+$. Fine-tuning of this ion sieving behavior could enable the energy-efficient recovery of lithium and other critical metals from wastewater. More recently, aluminum ions (Al$^{3+}$) have shown the ability to "lock" the interlayer spacing of MXene membranes via intercalation between MXene nanosheets, preventing other cations from intercalating and preserving the selectivity of these membranes over time. Other ions, as well as water molecules, can also readily intercalate between MXene layers; furthermore, intercalation can strongly affect water adsorption/desorption.

The exchange rates and mechanisms of ions and water within these confined interlayer spaces remain poorly understood, yet understanding these mechanisms is critical to the use of MXenes for advanced ion sieving technologies. To explore these processes, we have examined the changes in MXene membranes' interlayer spacing in response to intercalation (and exchange after pre-intercalation) with a variety of metal cations, including hydrophilic ions such as Mg$^{2+}$ as well as more hydrophobic cations such as Cs$^+$. We have also investigated the effects of water intercalation on interlayer spacing, especially the ability of hydrophilic cations to introduce additional layers of water between MXene nanosheets. Understanding how to reliably control the interlayer spacing (i.e., pore size) of MXene thin films will improve our ability to design selective ion sieves for metal recovery from water.

8:00 PM EL17.04.03
Development of Rapid Synthesis Method of MAX Phase Composites by Combination of Induction Heating and Self-Propagating High-Temperature Synthesis Daisuke Nishine, Ryosuke Numata, Riku Sawamura, Taro Shimomura, Mahito Yamamoto and MitsuRU Inada; Kansai University, Japan

MXene, a two-dimensional layered material, is expected to be applied in a wide variety of fields. Generally, MXene is prepared by etching MAX phase. Therefore, it is very important for MXene research to develop a low-cost and simple method to synthesize the MAX phase. In most cases, the MAX phase is synthesized by high-temperature heating at around 1500°C under high pressure. Hot-pressing, spark plasma sintering, and other methods are used to satisfy these synthesis conditions, but they are specialized, expensive, and sometimes require several hours to synthesize the MAX phase. Therefore, it is desirable to develop a simple, low-cost and rapid synthesis method.

We have developed an original, low-cost and simple MAX-phase synthesis equipment by combination of the induction heating (IH) and the self-propagating high-temperature synthesis method. The IH method can rapidly heat a sample in a carbon crucible up to about 2000°C. This rapid heating induces local chemical reactions. The heat of the chemical reaction then propagates throughout the sample and then the MAX phase is synthesized. We have tried to synthesize two types of MAX phases using this equipment. One is Ti$_3$AlC$_2$ and the other is V$_2$AlC. XRD measurements and SEM observations showed that both MAX phases were successfully synthesized. It should be noted that this method can synthesize both in vacuum and in inert gas atmosphere. And it took less than a minute from the start of heating to the end of synthesis. These results indicate that this method is one of the candidates for a low-cost, simple, and rapid MAX phase synthesis method that can be applied to various types of MAX phase synthesis.
MXenes are a rapidly growing family of two-dimensional (2D) transition metal carbides and nitrides which are promising for various applications, including energy storage and conversion, electronics, and healthcare. Hydrofluoric acid-based etchants are typically used for large-scale and high-throughput synthesis of MXenes. Herein, we present a computational thermodynamic model with experimental validations to explore the feasibility of fluorine-free synthesis of MXenes by dry selective extraction (DSE) from precursor MAX phases using iodine vapors at elevated temperature. A range of MXenes with iodine surface terminations are systematically screened using first-principles calculations to find candidates with high phase stability and low etching energy. We further demonstrate a thermodynamic model based on the CALculation of PHAse Diagrams (CALPHAD) approach, using Ti3C2I2 as an example, to assess the Gibbs free energy of the reaction and the state of the byproducts (e.g., gas or solid) as a function of temperature and pressure. Based on the assessment, the optimal etching temperature and vapor pressure are predicted, and further verified by experiments. This work opens an avenue for scalable, fluorine-free dry synthesis of MXenes with compositions and surface chemistries that are not accessible using wet chemical etching.

8:00 PM EL17.04.05
Microwave-Assisted Hydrothermal Synthesis of MXene-Derived Bilayered Vanadium Oxides for Aqueous Zinc Ion Battery
Shang-Tung Chiang and Majid Beidaghi; Auburn University, United States

V2O5 shows great promise as a cathode material in zinc-ion batteries (ZIBs) due to its impressive theoretical capacity of 589 mAh/g, which is based on a two-electron transfer mechanism. However, its limited conductivity poses a significant challenge to its widespread application. In this study, we propose a universal approach to produce high-rate cathodes by creating heterostructures through a single-step process of ion intercalation and phase transition of MXene-derived hydrated vanadates. In our experiment, we introduced Zinc ions (using ZnCl2) into the V2C MXene precursor to increase the spacing between layers, and then applied hydrothermal treatment using a microwave. This significantly reduced the synthesis time from several hours to 15 minutes while maintaining the excellent conductivity of MXene and the high theoretical capacity of V2O5. The resulting material, denoted as Zn-V2C-V2O5, exhibits a high specific capacity of 352 mAh/g at 0.1 A/g and demonstrates remarkable cycling stability. These findings position Zn-V2C-V2O5 as a promising candidate for cathode materials in Zn-ion batteries, offering a new approach for enhancing zinc ion storage in vanadium-based materials.

8:00 PM EL17.04.06
Reaction Barrier and Desorption Energy Co-Determined CO2 Electroreduction Selectivity on Mo2C-Based Catalysts by Modulating Terminations Species and Defects
Caibong Liao, Zhonghan Zhang, Zheng Liu, Shuzhou Li and Yeng Ming Lam; Nanyang Technological University, Singapore

Using electrocatalysts to convert CO2 to useful products via CO2 reduction reaction (CO2RR) is one of the solutions to greenhouse gases problems. Recently, MXenes have been recognised as potential CO2RR electrocatalysts for its efficiency and tunability. However, comprehensive understanding on the relationship between CO2RR performance and terminations of MXenes still remains open. For the sake of rational design for effective catalysts, Mo2CTx, a widely applied type of MXenes, is used as the model to systematically investigate the effect for CO2RR from terminations via density functional theory (DFT) calculations. In this study, it is verified that different terminations over Mo2CTx exhibit different CO2RR performances. This work puts forward that the selectivity is co-determined by desorption energy and reaction barrier of each product. Slabs completely covered with -O- or -F are tended to produce HCOOH, while slab with full -OH coverage are inclined to generate CO. Furthermore, results from a reconstructed slab based on one published experimental work with mixture terminations of 5.5% F, 5.5% Vacancy, 33.5% O, and 55.5% OH shows good consistency for the major products (selectivity towards CO products as HCOOH >> CO >> CH4 >> CH2OH). Additionally, this study predicts CO2RR performance of Mo2C-O2 with 0%, 5.6%, 11.1%, and 100% oxygen vacancy (OV). The models with 5.6% or 100% OV are beneficial to generate more valuable final products - methanol or methane, respectively, while the model with medium OV (11.1%) tend to produce CO. This work provides useful insight and guidance to future research that utilizing terminations of MXene to design CO2RR electrocatalysts, especially for Mo2CTx systems.

Broad-Wavelength Light-Driven Hybrid MXene/Molecular Crystal Actuators Actuated inside Tissue-Like Phantoms
Dong Wook Kim1, Yuki Hagihara2, Hideko Koshima2 and Metin Sitti1; 1Max Planck Institute for Intelligent Systems, Germany; 2Waseda University, Japan

Significant progress has been made in the research of molecular crystals that can undergo light-driven actuation. This progress has been achieved through the development of different molecules and the identification of driving mechanisms. However, the crystals that have been developed so far have primarily been driven by ultraviolet (UV) or blue light, and the use of red or near-infrared (NIR) light for actuation has not been explored. In this study, we have successfully created molecular crystals that can be actuated by light across a broad range of wavelengths, including UV, visible, and NIR light, using the photothermal effect. To achieve this, we incorporated titanium carbide (Ti3C2T x) MXene nanosheets into salicylideneaniline crystals. Unlike the original thin molecular crystals, which only exhibited slow bending under UV light due to photosomerization, the addition of the MXene layer enabled rapid actuation of the molecular crystals at various thicknesses and wavelengths. The hybridization of MXene with molecular crystals not only provides strong biocompatibility but also allows for the bending of the hybrid crystals within agar phantoms that mimic biological tissue. Furthermore, we demonstrated that this MXene hybridization approach can be extended to other common molecular crystals, including different derivatives of salicylideneaniline and anisole.

Enhancing The Ion Intercalation of MXene in Molecular Crowding Electrolytes
Chaofan Chen, Albert de Kogel and Xuehang Wang; TU Delft, Netherlands

The charge storage mechanism and performance of the MXenes electrode are highly dependent on the electrode and electrolyte composition. For example, Ti3C2Tx has shown rapid pseudocapacitive (de)intercalation of protons and transformation between the oxygen surface groups (=O) and hydroxyl (-OH) groups in acidic aqueous electrolytes. As a result, Ti3C2Tx exhibit an ultrahigh volumetric capacitance of 1500 F cm-3 in H2SO4 electrolyte. In less corrosive neutral aqueous electrolytes, the cation intercalation is accompanied by negligible charge transfer, leading to ultrafast charge storage. Consequently, a moderate capacitance with superior cycling stability is reported by neutral electrolytes compared to acidic electrolytes.

Compared to dilute aqueous electrolyte, which has a limited electrochemical stability window (ESW), the water-in-salt (WIS) electrolyte possesses a large ESW owing to the depressed activity of free water. Besides, the unique solvation structure of WIS electrolyte induces novel solvation-free Li+ intercalation and increases capacitance. As a result, WIS electrolyte helps overcome the drawback of the low energy density of MXene in neutral aqueous electrolytes. We further explored the electrochemical behavior of 2D Ti3C2 MXene in safe, low-cost, and environmentally benign polyethylene glycol (PEG)-based molecular crowding electrolytes (MCE). The addition of PEG-based molecular crowding agents can also widen the potential window of the MXene electrode up to 1.6 V due to the suppressed hydrogen evolution reaction. Additionally, a pair of redox peaks at ~0.25 V/0.05 V vs. Ag (cathodic/anodic)
emerged in cyclic voltammetry after adding the PEG, yielding an additional 25% capacitance. We used in-situ XRD to reveal the charge storage mechanism in MCE electrolytes. Interestingly, we observed the co-insertion of the molecular crowding agent PEG-400 during the Li+ intercalation process. As a result, Ti3C2Tx electrodes presented a large interlayer space change of 4.7 Å during a complete charge/discharge process.

MXene Functionalized Kevlar Yarn via Automated Dip Coating Lingyi Bi1, William Perry1, Robert Lord1, Ruocun (John) Wang1, Tetiana Hryhorchuk1, Alex Imman1, Oleksiy Gogotsi2, Vitaliy Balitskiy3, Veronika Zahorodna2, Ivan Baginskiy2, Stepan Vorotilo1, Genevieve Dion1 and Yury Gogotsi1; 1Drexel University, United States; 2Materials Research Center, Ukraine

The rise of the Internet of Things (IoT) has spurred extensive research on integrating conductive materials into textiles to turn them into sensors, antennas, energy storage devices, and heaters. MXenes, owing to their high electrical conductivity and solution processability, offer an efficient way to add conductivity and electronic functions to textiles through simple dip coating. However, manual development of MXene-coated textiles restricts their quality, quantity, and variety. Here, we developed a versatile automatic yarn dip coater tailored for producing continuously high-quality MXene-coated yarns and conducted the most comprehensive MXene-yarn dip coating study to date. Compared to manual methods, the automatic coater provides lower resistance, superior uniformity, faster speed, and reduced MXene consumption. It also enables rapid coating parameter optimization, resulting in a thin Ti3C2Tx coating uniform over a 1 km length on a braided Kevlar yarn while preserving its excellent mechanical properties (over 800 MPa) and adding Joule heating.

SESSION EL17.05: MXenes Electrochemistry and and Electrochemical Applications
Session Chairs: Abdoulaye Djire and Seon Joon Kim

MXenes and Two-Dimensional Transition Metal Carbo-Chalcogenides as Electrocatalysts for Hydrogen Evolution Reaction Elham Loni1, Ahmad Majed1, Kun Liang1, Anika Tabassum1 and Michael Naguib1; 1Tulane University, United States; 2Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, China; 3University of the District of Columbia, United States

MXenes are a group of two-dimensional (2D) materials composed of transition metal carbide, nitrides, and carbonitrides denoted as Mn+1XnTx; M is an early transition metal, X is carbon/nitrogen, and T stands for surface terminations. These materials are created by selectively etching thin metal layers from layered ceramics. MXenes have shown great promise in various electrochemical energy storage and conversion applications. For instance, Ti3CNT, MXene demonstrated an onset overpotential of 53 mV and an overpotential of 148 mV at 10 mA/cm² when used as an electrocatalyst for the hydrogen evolution reaction (HER). Another class of 2D materials called transition metal carbo-chalcogenides (TMCCs) combines characteristics of MXenes and transition metal dichalcogenides on an atomic scale. They are synthesized via solid-state synthesis at ambient pressure, followed by intercalation and delamination in water without the use of surfactants. The conductive carbide core and catalytically active chalcogenides surface of TMCCs make them appealing as electrocatalysts. In this study, we will present the large-scale synthesis and characterization of various TMCCs (e.g., Ta2Se2C, Ta2S2C, Nb2S2C, and their solid solutions: (Ta2X2C; y = 0.25, 0.5, and 0.75). Additionally, we will discuss the electrochemical performance of MXenes and TMCCs as electrocatalysts for the HER.

8:30 AM EL17.05.02
Tuning the Structure of MXene-Based Composites for Electrochemical Carbon Dioxide Reduction Guangxin Sun1,2, Chunnian He3, Andrew B. Wong1,3 and Elham Loni1; 1National University of Singapore, Singapore; 2The Joint School of NUS-TJU, China; 3Tianjin University, China

The electrochemical CO2 reduction reaction (CO2RR) is a promising way to valorize CO2 and realize net-zero CO2 emissions. For CO2RR, MXene is a good candidate that can adsorb CO2. However, one of the critical challenges for CO2RR is the control of selectivity. In our case, titanium carbide-based MXene materials were usually found to have high competing hydrogen evolution reaction (HER) performance, where HER is a competing reaction to CO2RR. Therefore, to improve selectivity to CO2RR products, we tuned the electronic structure of MXene to suppress HER and enhance the CO2RR performance via a cations-alloying method. Through systematic investigations, we found that the MXene electronic structure can be tuned, which accompanies microstructure evolution, which is dependent on the reduction potentials of introduced cations. Additions of cations with lower reduction potentials, e.g., Na+, Co2+, Ni2+, did not change performance significantly, while Cu2+ and Ag+ have significant effects, which was confirmed by systematic characterizations.

Taking the in-situ reduced Ag nanoparticle decorated MXene as a model system, we demonstrate that these materials showed a significant improvement in CO2RR performance. The ratio of CO to H2 in the product can be tuned in the range of 1:3 to 1:1 by changing the added amount of Ag+. The result can be attributed to the change in electronic structure. With a moderate addition of cations and moderate redox reaction between MXene and cations, the electronic structure can be tuned while the MXene microstructure is maintained. Therefore, with the well-kept MXene structure, the electrons can be transferred from MXene to Ag nanoparticles, and the HER performance is suppressed. With much more cation addition, the MXene structure was degraded, which resulted in nearly 100% HER.

8:45 AM EL17.05.03
Rational Selection of Transition Metals in M4C3: MXenes to Control the Electrocatalytic Hydrogen Evolution Reaction Anupma Thakur, Nithin Chandran B S, Brian Wyatt and Babak Anasori; Indiana University-Purdue University Indianapolis, United States

2D MXenes have shown great promise as active materials in electrocatalytic hydrogen evolution reaction (HER). In this work, we present the selection of
transition metal elements (V, Nb, Ta) in three MxCTx MXenes (VxCTx, NbxCrT, TaCxT) to control their electrocatalytic performance for HER using an experimental approach. We synthesized VxCTx, NbxCrT, TaCxT MXenes from their parent MAX phases via a selective etching route using hydrofluoric acid, followed by an organic intercalant (tetramethylammonium hydroxide)-assisted delamination. Further, we used an ion exchange process to modify the MXenes’ surface chemistry and interlayer spacing by replacing (TMA+) with Li+ cations. By comparing the electrocatalytic HER performance of the resulting VxCTx, NbxCrT, TaCxT MXenes, we demonstrate the role of exposed transition metals (V, Nb, Ta) on the basal plane. Notably, VxCTx MXenes exhibit the lowest HER overpotential of ~ 248 mV at 10 mA cm−2 under acidic conditions (0.5 M H2SO4), surpassing NbxCrT (~317 mV at 10 mA cm−2) and TaCxT MXenes (~426 mV at 10 mA cm−2). This improved performance can be attributed to the catalytically active vanadium basal planes in VxCTx. Our findings provide insight into the design of efficient and cost-effective catalysts through the rational selection of transition metals in MXenes for application as HER catalysts and tailoring electrocatalytic properties of 2D materials for sustainable energy applications.

9:00 AM EL17.05.04
Elucidating the Interactions Between Different Transition Metal Cations and Ti3C2Tx MXene Through Intercalation Method for Electrochemical Applications Shianlin Wee, Dario Gomez Vazquez and Maria Lukatskaya; ETH Zurich, Switzerland

MXenes, are a family of two-dimensional (2D) transition metal carbides, nitrides and/or carbonitrides.[1] The intercalation of different metal cations and organic molecules into MXenes’ electronic and electrochemical properties have been widely reported.[2][3][4] However, transition metals (TMs) which have distinct electrochemical behaviors[5][6] have not been explored in the literature of MXenes’ intercalation. Therefore, we herein compared the intercalation effects of different TM cations including (Ni2+, Co2+, Zn2+, Mn2+) on Ti3C2T, for offering a general insight on the influences of multi-valent, redox-active TMs on MXenes. In particular, the changes on the physiochemical and electrochemical properties of MXenes were investigated using different in-situ and ex-situ methods, for a better understanding on the interfacial interactions between TM cations and MXenes in the confined environment of MXenes’ multilayer structures. Additionally, we studied the TM-intercalated MXenes in hydrogen evolution reaction to further explore the their electrocatalytic performances. This work serves as a foundation for the fine-tuning of MXenes’ properties by utilizing a variety of TM cations intercalation for different electrochemical systems.

9:15 AM EL17.05.05
Electrochemical Charge Storage Process of TiC2T in Neutral Aqueous Electrolyte Chaofan Chen1, Glenn Quek2, Albert de Kogel1, Ruipeng Li3, Xueheng Wang2 and Guillermo Carlos Bazan2; 1Department of Radiation Science and Technology, Delft University of Technology, Netherlands; 2Department of Chemistry and Chemical & Biomolecular Engineering, National University of Singapore, Singapore; 3Brookhaven National Laboratory, United States

MXenes, a group of two-dimensional transition carbides/nitrides, have demonstrated remarkable performance as pseudocapacitive electrodes, owing to their unique transition metal oxide-like surface, large interlayer spacing and high electrical conductivity[1]. The charge storage behavior of MXene electrodes is strongly dependent on the interaction between MXene surface chemistry and the electrolyte solution[2]. In acidic electrolyte, the (de)intercalation of hydrated H+ (from) into Ti3C2T, interlayer leads to a reversible conversion between -O and -OH surface groups, which is accompanied by the Ti valence change[3]. Consequently, Ti3C2T displays a pseudocapacitive behavior with a mirrored redox peaks emerged in the CV curve. In contrast, Ti3C2T electrodes typically exhibit EDL-like behavior in neutral aqueous electrolytes, with a rectangular CV and a sloping GCD curve within a narrow (ca. 1.2 V) potential window, resulting in a relatively lower capacitance (80 -120 F g−1)[4]. Recently, it has been found that the charge storage mechanism of MXene electrodes in different electrolytes can be elucidated through in-situ UV-Vis spectroscopy[1].

Engineering the MXene electrode and optimizing the electrolyte composition have the potential to further enhance the pseudocapacitive performance of MXenes in different electrochemical systems. Application of the interference between MXenes’ surface chemistry and interlayer spacing by replacing (TMA+) with Li+ cations. By comparing the electrocatalytic HER performance of the resulting VxCTx, NbxCrT, TaCxT MXenes, we demonstrate the role of exposed transition metals (V, Nb, Ta) on the basal plane. Notably, VxCTx MXenes exhibit the lowest HER overpotential of ~ 248 mV at 10 mA cm−2 under acidic conditions (0.5 M H2SO4), surpassing NbxCrT (~317 mV at 10 mA cm−2) and TaCxT MXenes (~426 mV at 10 mA cm−2). This improved performance can be attributed to the catalytically active vanadium basal planes in VxCTx. Our findings provide insight into the design of efficient and cost-effective catalysts through the rational selection of transition metals in MXenes for application as HER catalysts and tailoring electrocatalytic properties of 2D materials for sustainable energy applications.

Final Program 1/25/24
A family of two-dimensional transition metal carbides and nitrides (MXenes) raises interest for many applications due to their high electrical conductivity, mechanical properties [1], and potential tunable electronic structure [2], nonlinear optical properties [3], and the ability to be manufactured in the thin film state [4]. However, their chemistry that is key to the development of these applications, still remains poorly understood [5,6]. In this presentation, we will discuss recent progress in understanding fundamental MXene chemistry and harnessing it for suppressing unwanted reactions and prolonging the stability of these materials.

For example, suppressing oxidation and hydrolysis at high pH was demonstrated an effective way to prolong shelf-life and stability of MXene aqueous colloids [7]. Use of polyphosphate also has been shown to improve the chemical stability of MXene aqueous colloids [8]. Other selected examples illustrating connections between understanding MXene chemistry and development of their applications will also be considered.

MXenes have sparked a rapidly growing interest for applications in biomedical research and medicine. Alongside with the remarkable combination of properties and scalable processability, the growing selection of tunable MXene species, and the increasing recognition of their broad biocompatibility are paving the way for the integration of MXenes in high-performance sensing and therapeutic platforms.

In this talk I will first highlight the most recent developments of MXene-based biomedical technologies, particularly in the areas of sensing, therapeutics, and regenerative medicine. Then, I will present our most recent work on Ti3C2Tx MXene-based wearable and implantable bioelectronics for recording and stimulating brain and muscle activity. Due the combination of high conductivity and low electrochemical impedance, these human-scale MXene bioelectronics can establish highly conformable interfaces with the body without the need for any conductive adhesives and gels that are typically required with conventional metal-based electrodes. Furthermore, the low density and low magnetic susceptibility mismatch between Ti3C2Tx and biological tissues enable artifact-free clinical imaging with magnetic resonance (MRI) and computed tomography (CT), which is precluded when using metals such as Pt. Finally, we recently demonstrated that Ti3C2Tx films and devices can be effectively sterilized with clinical thermal and chemical sterilization processes, without any degradation of their properties and structure.

To illustrate the potential of Ti3C2Tx, MXene bioelectronics, I will review examples of application in cognitive neuroscience research, clinical neurological monitoring, and neuromuscular rehabilitation. In conclusion of the talk, I will discuss the opportunities and challenges for clinical translation and commercialization of MXene-based medical technologies.

**Bioelectronics and Beyond: MXenes for Sensing, Treating and Restoring Human Health**

Flavio Vitale; University of Pennsylvania, United States

William J. Scheideler; Dartmouth College, United States

3D continuous mesoscale architectures of nanomaterials provide opportunities to enhance performance and integration of electrochemical biosensors through control over the distribution of active sites and facilitation of ion transport. We present 3D printed microporous electrochemical biosensors integrating biocompatible 2D Ti3C2Tx MXenes to monitor antibiotic drug release in tissue engineering scaffolds. The 3D microporous Ti3C2Tx MXene is synthesized by a simple deposition of MXene ink on a microscale 3D-printed polymer scaffold coated in conductive ZnO:Al. Due to the microporous hybrid structure of Ti3C2Tx MXene, direct electron transfer is facilitated and the 3D biosensors displayed efficient detection of common antibiotics such as gentamicin and vancomycin. The engineered 3D pore structure exposes more electrochemically active surfaces of MXene, resulting in remarkable sensitivity for detecting gentamicin concentrations from 10 nM to 1 mM and vancomycin concentrations from 100 nM to 1 mM, which are 1000 times more sensitive than planar 2D films of MXene. Additionally, this study characterized the suitability of these implantable sensors for bone tissue regeneration applications. Osteoblast-like (MG-63) cells are seeded on the microporous 3D MXene architectures for 3, 5, and 7 days. An increased concentration of cells is noted over the 7 days along both the edges and pores where MXene had been deposited, demonstrating biocompatibility and clinical translation potential. Based on these results, this combination of 3D scaffolds with biocompatible 2D Ti3C2Tx MXene materials can provide a platform for mediator-free biosensing, enabling new applications for in vivo monitoring of drug elution.

**3D Microporous Ti3C2Tx MXene for Electrochemical Sensing of Antibiotics in Tissue Engineered Scaffolds**

Anand P. Tiwari; Katie Hixon and William J. Scheideler; Dartmouth College, United States

3D printed microporous electrochemical biosensor scaffolds are fabricated using 2:1 Ti3C2Tx MXene and 3D-printed polymer scaffolds to act as drug delivery platforms, enable cell growth, and monitor antibiotic release for tissue engineering applications. Ti3C2Tx MXene is a 2D MXene with high electrochemical activity and excellent biocompatibility that is of interest for biomedical applications. The high electrochemical activity of Ti3C2Tx MXene enables the integration of micro- and nanoscale architectures that can function as drug delivery platforms in tissue engineering scaffolds.

**Effect of 2D MXenes on The Densification and Stability of Boron Carbide-Ti3C2 Composites**

Sai Varun Sunkara1, Brian Wyatt2, Yuzi Liu1, Subramanian Sankaranarayanan1, Babak Anasori2, Andreas Rosenkranz2 and Anirudha Sumant1; 1Argonne National Laboratory, United States; 2Purdue University, United States; 3University of Chile, Chile

The materials community has witnessed remarkable progress over recent decades in exploring various attractive properties of MXenes due to their excellent, physical, chemical, and mechanical properties. These properties encompass its outstanding physical, chemical, and mechanical attributes, all of which have demonstrated exceptional potential across diverse application domains, ranging from energy storage, and electromagnetic shielding, to advancements in biological and medical technology. Recent interest in exploring their tribological properties is rooted in their layered structure and ability to shear easily coupled with their robust mechanical properties. While numerous studies have been published showcasing MXenes' promise as an additive under lubricated conditions or as a solid lubricant in dry environments, the critical factor of long-term stability as a reliable lubricant in either scenario has remained unproven, thereby constraining its full application potential within the lubrication industry.

In this current work, we study an ordered double transition metal MXene (Mo2TiC2) and demonstrate its exceptional tribological performance in dry nitrogen atmosphere using macro-scale pin-on-disc tribo-testing. We demonstrate sustained superlubricity, with a friction coefficient as low as 0.005, persisting over the extensive course of linear sliding, spanning an astonishing distance of 86 kilometers, with no signs of failure and minimal wear rates. We will elucidate the intricate mechanisms governing wear and friction, which underpin such extraordinary tribological performance. Additionally, we explain the pivotal role played by tribo-catalytic reactions at the sliding interface, which yield a stable, lubricious tribolayer. This milestone achievement represents a game-changer across a spectrum of tribological applications and marks a significant leap forward in the development of innovative solid lubricants based on MXene.

**Sustained Superlubricity in Mo2TiC2 MXenes Facilitated by Tribocatalytic Reaction at The Sliding Interfaces**

**Effect of 2D MXenes on The Densification and Stability of Boron Carbide-Ti3C2 Composites**

Nithin Chandran B1,2, Kartik Neman1, Anupma Thakur2,3 and Babak Anasori1,2; 1Purdue University, United States; 2IUPUI, United States; 3Indian Institute of Technology Madras, India

MXenes are explored as additive materials for structural and high-temperature applications due to high temperature stability and two-dimensional(2D) layered morphology. Boron carbide (B4C) holds significance as a structural ceramic due to its superior hardness (up to 43 GPa) along with low density (2.52 g cm−3), and high melting point (2763 °C). However, poor sinterability of B4C is attributed to the presence of strong covalent bonds between boron and carbon, the presence of nanoscale B2O3 on the surface, and low self-diffusion coefficients. Incorporating 2D MXenes in the B4C matrixes can improve the fracture toughness. MXenes' layered morphology combined with covalidol stability due to their high negative zeta potential (-35 to -50 mV) allows additive-free self-assembly on ceramic grains, leading to their uniform distribution in the sintered ceramic composite. In this work, we demonstrate the preparation of green bodies of B4C with nanometer-thin Ti3C2Tx MXene flakes via electrostatic self-assembly. The prepared green bodies of MXene-wrapped B4C, up to 10 wt% MXene, are sintered by pressure-assisted spark plasma sintering. We also discuss the effect of MXene flake concentration on the improvement of B4C sinterability and mechanical properties. Our study present the first use of MXene in B4C manufacturing and MXenes effects on
the densification and stability of boron carbide sintered ceramics and offers insights into the potential of MXenes as sintering additives in ceramic systems.

Hynes, Level 2, Room 208

3:30 PM *EL17.08.01
Applications of 2D Metal Carbides in Catalysis Yue Wu; Iowa State University, United States

Many novel applications have been discovered for 2D metal carbides (MXenes), among which catalysis is a unique one. Due to their different crystal structures, MXenes behave differently from conventional bulk carbides. In this presentation, we will discuss the metal-support interactions observed in different MXene systems and how they alternate the catalytic reactions, including alkane dehydrogenation, methane coupling, and electrochemical reactions, from both experimental studies and theoretical modelings. These newly-discovered metal-support interactions could enable MXenes as exciting platforms for reactions important to petrochemical industry and low-carbon energy development.

4:00 PM EL17.08.02
Environmentally Stable Organo-MXene Gas Sensors Based on Surface Chemical Functionalization Seon Joon Kim; Korea Institute of Science and Technology, Korea (the Republic of)

The demand for low-power chemical sensing has been increasing due to the emergence of flexible, portable, and wearable devices. To achieve this, two-dimensional (2D) nanomaterials have drawn attention due to their high surface area, high tunability, and room-temperature operation. Among them, MXenes especially show outstanding performance due to their simultaneous existence of high electrical conductivity and high-density surface functional groups. However, issues such as limited environmental stability need to be addressed for further utilization. Here, we introduce ligand-grafting surface chemical functionalization methods to develop organo-MXene gas sensors that have enhanced environmental stability over pristine MXene gas sensors. Based on the good dispersibility of organo-MXenes in organic solvents, a self-assembly method was designed and employed to fabricate nanometer-scale thin film gas sensors. Gas responses were greatly enhanced compared to that of pristine MXene where the modification of surface tail groups allowed tunable selectivity toward various VOC gases. Furthermore, organo-MXene gas sensors showed good stability in ambient environments for extended periods of time.

4:15 PM EL17.08.03
Three-Dimensional MoS2/MXene Heterostructure Aerogel for Chemical Gas Sensors with Superior Sensitivity and Stability Hamin Shin1, Seulgi Kim2, Jaewoong Lee3, Jihan Kim4, Dongji Lee2 and Il-Doo Kim5; 1Korea Advanced Institute of Science and Technology, Korea (the Republic of); 2Chungbuk National University, Korea (the Republic of)

The concept of integrating diverse functional 2D materials into a heterostructure provides unparalleled platforms for exploring novel physics not accessible in a single 2D material. Here, physical mixing two 2D catalytic materials, MXene and MoS2, followed by freeze drying is utilized to successfully fabricate a 3D MoS2/MXene van der Waals heterostructure aerogel. The low temperature synthetic approach effectively suppresses significant oxidation of the Ti3C2Tx MXene, and results in a hierarchical, and freestanding 3D heterostructure composed of high-quality MoS2 and MXene nanosheets. Functionalization of MXene with MoS2 catalytic layer substantially improves sensitivity and long-term stability toward detection of NO2 gas, and computational studies are coupled with experimental results to elucidate that the mechanism behind enhancements in the gas sensing properties is effective inhibition of HNO2 formation on MXene surface, due to the presence of MoS2. Overall, this study has a great potential for expansion of applicability to other classes of two-dimensional materials as a general synthesis method, thus laying a foundation to be applied in future fields of catalysis and electronics.

4:30 PM EL17.08.05
MXene-Based Engineering for Photoelectrochemical Detection by Combining Nanozyme and Oxygen Reduction Akhilesh B. Ganganboina; National Institute of Materials Sciences, Japan

Efficient photoelectrochemical (PEC) detection requires a deep understanding of the processes involved in generating, separating, and reacting photoinduced carriers at interfaces. However, slow interfacial reactions and the need for appropriate photoactive layers pose significant challenges to constructing advanced PEC platforms. In this study, platinum single-atom catalysts (Pt SACs) were integrated onto CuO2 and two dimensional MXene as a proof of concept, amplifying PEC signals by boosting oxygen reduction reactions. As a newly emerging class of 2D materials, Ti3C2Tx MXene was used as fantastic support to uniformly anchor Cu2O nanoparticles due to its electronegative surface. Pt SACs were also shown to exhibit efficient peroxidase-like activity, depressing PEC signals through Pt SACs-mediated enzymatic precipitation reactions. By utilizing the oxygen reduction and peroxidase-like activity of Pt SACs, a robust PEC sensing platform was successfully constructed for the sensitive detection of SARS-CoV-2. This research provides valuable insights into the use of SACs for sensitive PEC analysis.

8:00 PM EL17.09.01
The Adsorption Ability of Urea on Single 3d Metal Doped MXene (TiC2Tx) via DFT Calculations and Experiments Caihong Liang, Zhihao Yen, Teddy Salim and Ying Ming Lam; Nanyang Technological University, Singapore
Dialysis is a process used to remove excess urea toxins from the body through adsorption or conversion. Urea adsorption by emergent 2D materials such as MXenes is one probable approach. However, MXenes synthesized by the safer and easier MILD method (MILD Ti3C2Tx) has lower affinity to urea, which can be improved by surface modifications. Density Functional Theory (DFT) studies indicate that oxygen-terminated Ti3C2Ox, which is the dominant species on MILD Ti3C2Tx, have a much better urea adsorption ability when introduced with Cu, Co, and Ni dopants and the corresponding adsorption energy (Eads) are −2.16 eV, −1.91 eV and −1.78 eV respectively. These adsorption energies are much more favourable than the undoped one (Eads = −0.52 eV). Experimentally, the adsorption studies found that low concentration of Cu, Co, Ni on Ti3C2Tx showed a removal efficiency of 21.9 %, 6.0 % and 0.2 %, respectively, much better than 0 % removal efficiency of unfunctionalized Ti3C2Tx. Both DFT calculations and experiment showed that various metal functionalized MXenes has similar trend for urea adsorption, highlighting the feasibility of using computational approach to predict urea adsorption and further opening a new promising direction for the urea adsorption.

8:00 PM EL17.09.02
Langmuir-Like Adsorption Behavior of Amine Ligand for Surface Chemistry of MXene Woojae Jeong, Hwansoo Shin and Tae Hee Han; Hanyang University, Korea (the Republic of)

Surface chemistry is important to comprehend the stability of oxidation and dispersion of MXene in different organic media, thereby expanding its potential applications. Amine ligands is a potential candidate to modify the surface of MXene nanosheets due to strong interaction between Amine functionalities and MXene surface. Among those, Oleylamine (OAm) is a promising ligand due to its amine functionalities and commercial availability. The OAm is grafting onto MXene by covalent bonds through nucleophilic reactions and hydrogen bonding at room temperature. Furthermore, the OAm develop monolayer on MXene surface behavior by Langmuir-like adsorption. It is finely confirmed by that the slope decreases as the OAm concentration increases in coverage vs Cl. The monolayer formation occurs in two distinct steps: a lying-down phase followed by an ordered monolayer. The OAm grafted MXene nanosheets (OAm-MX) represent highly stable dispersion in various organic solvents including non-polar solvents, as well as excellent oxidation stability. This be attributed to the hydrophobic properties and steric stabilization induced by the long alkyl chain of OAm on the MXene surface. Moreover, the OAm-MX nanosheets was faceted assembled by solution process on the various substrate, demonstrating enhanced coating performance. Therefore, this study provides key comprehension of the adsorption behavior and interaction between amine ligands and MXene nanosheets for the surface chemistry of MXene.

8:00 PM EL17.09.03
High Performance Waste-Based Triboelectric Nanogenerators with Sulfur-Rich Polymer and MXene Sungsu Kim1,1, Woongbi Cho1,1, Hyenhoon Lee2,1, Minbaek Lee2, Tae Hee Han1 and Jeong Jae Wie1,1, 1Hanyang University, Korea (the Republic of); 2Inha University, Korea (the Republic of)

Recently, we reported utilization of inverse-vulcanized sulfur-rich polymer (SRP) prepared by surplus annually generated 7 million tons during petroleum refining processes, as tribo-negative materials for a triboelectric nanogenerator (TENG). Since the TENG generates power by charge separation on friction surfaces, utilization of fluorine with the highest electron negativity induced excellent electron-withdrawing ability is widely used in the TENG. Previous studies employed F2 gas or fluorine polymers to enhance SRP tribo-negative characteristics. However, F2 is toxic, and the TENG with fluorine-rich polymers requires higher output current to stably operate electronic devices. Herein, we introduce MXene as a filler for the reinforcement of SRP tribo-negative characteristics. MXene is a metallic 2D nanomaterial with a high electronic conductivity and specific surface area. Hence, the inclusion of minute amount of MXene can significantly improve the electric properties of composites. In a same area 12.5 cm2-sized, incorporating 0.4 wt% MXene into the SRP composite in the TENG without using toxic gas had shown output voltage and current 2-fold and 3-fold higher compared to the neat SRP. We believe that the SRP/MXene composites will contribute to the advancement of waste-based and self-powered devices in the form of the TENG.

8:00 PM EL17.09.04
Revolutionizing Greenhouse Gas Monitoring with Layered MXenes: Room-Temperature Chemoresistors Niravkumar J. Joshi, Sachin T. Navale and Albert Romano-Rodriguez, University of Barcelona, Spain

Greenhouse gas (GHG) emissions, particularly carbon dioxide, methane, and nitrous oxide, are the primary cause of global warming and climate change. To effectively monitor the actual impact of emission of these gases, specialized gas measurement systems that are specifically adapted are necessary. Currently, National surveillance agencies rely on highly sensitive, selective, complex, bulky, and expensive systems to monitor the environment. These systems serve as reference units and are only installed in a few specific, mostly fixed, key locations. However, in order to achieve a more comprehensive monitoring approach and develop climate models, it is essential to have a distributed network of sensing system. This can be achieved through the deployment and connection of numerous gas sensing systems enabled by the Internet of Things (IoT). These devices need to be sensitive, selective, and energy-efficient, although they may have lower accuracy and precision compared to the reference instruments. Existing commercial sensors do not meet all the necessary requirements, highlighting the need for new and enhanced functional nanomaterials and sensors. The objective of this research is to demonstrate the current state of development regarding advanced miniaturized gas sensing devices for monitoring GHG emissions. For this, we have developed a chemiresistive sensor platform that utilizes a layered structure of 2D MXenes, serving as an advanced sensing platform for detecting GHGs. The layered MXenes were synthesized using a chemical etching method involving a strong HF etchant, resulting in the formation of multilayered Ti3C2TX (MXene) sheets. These MXene sheets were then integrated onto a chip with interdigitated electrodes to form a microsensor. In this way, a low-cost gas-sensitive sensor for methane (CH4) was developed, which exhibited superior selectivity in front of other gases. Throughout this research, a comprehensive investigation of the synthesis and of greenhouse gas detection application of these 2D MXenes has been conducted. This study is expected to pave the way for the utilization of a broad range of MXenes as highly sensitive sensors for greenhouse gases.
Hybrid MXene-Polydopamine (PDA) nanocomposites have emerged as a promising targeted and effective photothermal therapy (PTT) platform. PTT serves as efficient photothermal agents, while PDA provides a versatile coating that promotes biocompatibility and allows surface functionalization for targeted therapy.

Our research has inspired a new hybrid skin strategy that exploits the full potential of materials for developing functional coatings for various applications. The hybrid MXene-PDA nanocomposites exhibit excellent photothermal conversion efficiency due to the strong light absorption of MXenes and efficient heat transfer facilitated by the PDA coating. The nanocomposites can be easily functionalized by targeting ligands or biomolecules, enabling selective accumulation and internalization in cancer cells. Moreover, the MXene-PDA nanocomposites can be further engineered to release therapeutic agents, such as chemotherapy drugs, in response to the photothermal effect, achieving combined photothermal-chemotherapy treatment.

Hybrid MXene-Polydopamine (PDA) nanocomposites have emerged as a promising targeted and effective photothermal therapy (PTT) platform. PTT utilizes light-absorbing materials to convert light energy into heat, resulting in localized hyperthermia that selectively damages cancer cells. However, challenges such as limited photothermal conversion efficiency, inadequate tumor targeting, and potential side effects hinder the clinical translation of PTT. MXenes, a class of two-dimensional transition metal carbides/nitrides, possess exceptional optical absorption properties in the near-infrared (NIR) region, where biological tissues exhibit maximum transparency. The combination of MXenes with PDA offers synergistic advantages for enhanced PTT. MXenes serve as efficient photothermal agents, while PDA provides a versatile coating that promotes biocompatibility and allows surface functionalization for targeted therapy.

The hybrid MXene-PDA nanocomposites exhibit excellent photothermal conversion efficiency due to the strong light absorption of MXenes and efficient heat transfer facilitated by the PDA coating. The nanocomposites can be easily functionalized by targeting ligands or biomolecules, enabling selective accumulation and internalization in cancer cells. Moreover, the MXene-PDA nanocomposites can be further engineered to release therapeutic agents, such as chemotherapy drugs, in response to the photothermal effect, achieving combined photothermal-chemotherapy treatment. This research highlights experimental results in developing MXene-PDA nanocomposites for targeted and effective PTT. The synthesis methods employed to fabricate the nanocomposites, including surface modification and functionalization, are discussed, along with their photothermal conversion efficiency and biocompatibility. We explored the effect of PDA layer thickness over MXene flakes on PTT. Antibodies for various types of cancers were used as targeting ligands to remove contaminants on the sample surface, but sputtering also affects the inherent surface condition. In such case, gas cluster ion beam (GCIB) provides an alternative way to clean the sample surface, while causing less damage. Accordingly, herein we present on GCIB treatment of MXene samples, and outline property differences before and after carbon compounds are removed from the MXene surface.

Enhancing Heating Efficiency and Protection of MXene Through Graphene Skin Dongjun Kang and Tae Hee Han; Hanyang University, Korea (the Republic of)

Titanium carbide MXene has outstanding characteristics of high electrical conductivity and facile processability in benign water solvents, and has been highlighted as a versatile Joule heating material with low-voltage operation with stable heating performance. However, MXene can be easily oxidized in warm and damp environments due to its plentiful hydrophilic functional groups on sheets. In addition, the high convective heat loss from the MXene surface limits their heating efficiency. Therefore, we tailored a multifunctional graphene skin (with a thickness of ~370 nm) for MXene, to protect the venerable surface properties of MXene. Both MXene and graphene layers have tortuous pathways with similar layered structures; however, the water impermeability of graphene was ~70 times higher than that of bare MXene due to narrow d-spacing and the hydrophobic nature of graphene skin. In addition, we found that the heat loss regulation effect of graphene skin increased the heating efficiency, indicating that the graphene skin is promising for developing adaptive heating materials. Our research has inspired a new hybrid skin strategy that exploits the full potential of materials for developing functional coatings for various applications.

Hybrid MXene-Polydopamine Nanocomposites for Targeted and Effective Photothermal Therapy Igor Iatsunsky1, Daniel Aguilar-Ferrer3, Maksym Pogorelov5, Oleksiy Gogotsi and Emerson Coy1; 1Adam Mickiewicz University, Poland; 2University of Latvia, Latvia; 3Suny State University, Ukraine; 4Materials Research Center, Ukraine

Light-energy conversion and heat transfer in MXene nanocomposites can be enhanced by modifying their surface with polydopamine (PDA). PDA is a self-assembled polymeric coating that can be engineered for targeted drug delivery, light energy conversion, and heat transfer. In this work, we developed hybrid MXene-PDA nanocomposites for targeted and effective photothermal therapy (PTT). MXene provides high electrical conductivity and facile processability in benign water solvents, suitable for electric Joule heating. However, MXene is susceptible to oxidation in warm and damp environments due to its hydrophilic functional groups. The MXene-PDA nanocomposites, therefore, serve as an efficient electric Joule heating material with low voltage operation and stable heating performance. However, MXene can be easily oxidized in warm and damp environments due to its plentiful hydrophilic functional groups on sheets. In addition, the high convective heat loss from the MXene surface limits their heating efficiency.

We designed a multifunctional graphene skin (with a thickness of ~370 nm) for MXene to protect the MXene surface and to enhance heat transfer. The graphene skin is composed of a graphene layer with a chemical functionalization layer that improves its adhesion to the MXene surface. The MXene-PDA nanocomposites were synthesized by controlling the thickness of the PDA layer and the MXene surface functionalization layer. The MXene-PDA nanocomposites showed high heating efficiency and protection of the MXene surface, as confirmed by experimental results. The hybrid MXene-PDA nanocomposites are promising for developing adaptive heating materials that can be used in various applications, such as targeted drug delivery and photothermal therapy.

Electrochemically Modulated Interaction of MXenes with Microwaves Danzhen Zhang, Meikang Han, Christopher E. Shuck, Bernard McBride, Teng Zhang, Ruocun (John) Wang, Kateryna Shevchuk and Yury Gogotsi; Drexel University, United States

Controlling the reflection and absorption of incident electromagnetic waves at gigahertz frequencies in thin films is important for protecting electronics and humans. The ability to dynamically depress electromagnetic wave jamming is significant for enabling communication while protecting electronics. However, conventional electromagnetic interference (EMI) shielding materials don’t offer this capability. MXenes, as a large family of two-dimensional transition metal carbides and nitrides, have shown a broad range of EMI shielding performance as well as different energy storage mechanisms from electric-double-layer capacitance to pseudocapacitive behavior. Herein, we report a method for active control of electromagnetic wave interactions with various MXene films, including Ti3C2Tx, Ti2CnTx, V3CnTx, Nb2CTnTx and Nb4C3Tn, leading to EMI shields with unprecedented bidirectional modulation of shielding capability. The reversible tunability of EMI shielding effectiveness was achieved by electrochemically driven ion insertion/desorption and charge
transfer in MXene layers with different electrolytes, accompanied by expansion and shrinkage of layer spacing, as well as a change in the oxidation state of the transition metal. An EMI shielding ‘switch’ was demonstrated through the electrochemical oxidation of MXene films. Our results offer opportunities to develop smart EMI protection with active modulation, which is different from conventional ‘static’ shielding and can adapt to demanding environments.

9:30 AM *EL17.10.06 Enhancing MXene's Heating Functionality Through Surface Modification Taehyuk Kwon, Hanyang University, Korea (the Republic of)

MXenes are a class of two-dimensional materials with potential applications in fields such as thermal management and high-temperature materials. In this talk, I focus on two key aspects: the thermal evolution of Ti3C2Tx MXene during annealing and the grafting behavior of amine ligands for MXene surface modification. (1) The thermal decomposition behavior of MXene is explored using X-ray photoelectron spectroscopy (XPS) and two-dimensional correlation spectroscopy (2D-COS), providing insights into its structural changes, providing practical information for thermal applications of MXene. (2) Surface modification strategies are employed to enhance MXene's stability and dispersibility. Oleylamine (OAm) is grafted onto MXene nanosheets, resulting in improved oxidation and dispersion stability. The modified MXene exhibits excellent solution processability and coating performance. Additionally, the potential of OAm-MX as a heating element is investigated, leading to the development of a scalable electrothermal heating membrane with high efficiency. These advancements broaden the applications of MXene in thermal management and water desalination.

10:30 AM *EL17.11.01 Plasmonic Properties of 2D MXenes Sarah B. King1, Joseph Spellberg1, Janek Rieger1, Calvin Raah1, Francisco Lagunas2, Robert F. Klie3, Di Wang4, Dmitriy V. Talapan1, Jordan A. Hachtel4 and Abdoulouaye Djire1, University of Chicago, United States; 2University of Illinois at Chicago, United States; 3Oak Ridge National Laboratory, United States; 4Texas A&M University, United States

Despite their tremendous potential as plasmonic materials because of their 2D metallic properties, very little is known about the fundamental plasmonic resonances of MXenes. This is primarily due to irregularity in plasmonic responses from mixed surface terminations and varying material shape and thickness. In this talk, I will discuss experimental methods we are using in my group to probe the nanoscale plasmonic response of MXenes, both traditional mixed-terminated Ti3C2Tx as well as singly terminated MXenes synthesized by both CVD and molten salt synthesis, Ti3C2Cl2 and Ti3C2Clx. Leveraging the time-resolution and spatial-resolution of time-resolved photoemission electron microscopy we are investigating the evolution of plasmonic fields in MXenes in space and time. Using the (MAC)-STEM/EELS facility at ORNL we can directly image energy-resolved plasmonic resonances of MXenes, where we find that surface oxidation substantially decreases the plasmonic response of Ti3C2Cl2. Together our experiments highlight the variation in nanoscale plasmonic properties of MXenes and opportunities for control.

11:00 AM *EL17.11.02 Ultrastark Photoexcitations in 2D MXenes Lyubov V. Titova; Worcester Polytechnic Institute, United States

MXenes are 2D transition metal carbides and nitrides with electronic properties that can be tuned by their chemistry and structure. Metallic-like conductivity, flexibility, high optical damage threshold and ease of processing owing to their hydrophilicity, make MXenes candidates for a host of electronic and optical applications. We use ultrastark optical and THz spectroscopic techniques to investigate the nature and behavior of photoexcitations in MXenes of different chemistries. We show that electronic and optical properties of MXenes can be engineered by choices of the transition metals and their order as well as by controlling the intercalants in the interlayer gaps [1,2]. Furthermore, we demonstrate that MXenes with high free carrier density show promise as polarizers and tunable electromagnetic interference shields in the THz range [3,4].

11:30 AM EL17.11.03 Stability of Pseudocapacitive Energy Storage in Ti3C2Tx MXene over Wide Temperature Range Ruocun Wang, Mark Anayee, Teng Zhang, Yuan Zhang, Mikhail Shekhirev, Kateryna Shevchuk and Yuriy Gogotsi; Drexel University, United States

Pseudocapacitors have the potential to achieve high energy and high power density simultaneously, a holy grail for electrochemical energy storage. However, one obstacle facing pseudocapacitors is their shorter lifetime compared to commercial supercapacitors using the double-layer charge storage mechanism. In MXene-based pseudocapacitors, this concern is pronounced particularly at high temperatures due to the limited stability of the active material in contact with aqueous solutions, which can lead to oxidation and hydrolysis. This work shows that Ti3C2Tx MXene thin-film electrodes in 5 M H2SO4 possess excellent rate capabilities from -50 °C to 100 °C but also a sufficient lifetime at 70 °C using a float test holding at -0.9 V vs. Hg/Hg2SO4 reference electrode. Post-mortem characterization using X-ray photoelectron spectroscopy, Raman spectroscopy, and scanning electron microscopy with energy-dispersive X-ray spectroscopy showed no signs of oxidation in the bulk of the film. This work suggests sufficient electrochemical stability of Ti3C2Tx MXene as a negative electrode in proton aqueous electrolytes across a wide temperature range, making it promising for pseudocapacitor energy storage.
Metal Ion-Driven Gelation in MXenes for Multiproperty and Multifunctional Hydrogels and Aerogels

**Stefano Ippolito** and **Yury Gogotsi**; Drexel University - Drexel Nanomaterials Institute, United States

To date, MXenes include over fifty different structures and compositions, with more than a hundred compositions predicted computationally (more than a thousand if surface terminations are also taken into account), being the largest known family of 2D materials. Owing to their extremely versatile structural and chemical composition, as well as surface chemistry, MXenes are one-of-a-kind materials in many research fields, embodying a true revolution in materials science. They introduce a large number of 2D building blocks in materials science, providing an exciting and wide-ranging portfolio of physicochemical properties and promoting the production of several MXenes-based hybrid systems for numerous applications. Here, we will discuss the production of all-MXene hydrogels and aerogels, where the gelation process is induced by metal ions. Taking advantage of the coordination chemistry between -OH groups on the surface of MXene flakes (resulting from the wet chemical etching steps) and metal ions, the gelation (in aqueous environment) is very fast (< 5 min) and the physicochemical properties of the resulting hybrid systems are strongly related to the nature of the MXene/metal ion dyad. Rheological measurements show a strong relationship between the metal ion and the mass tangent $tan\delta$ (equal to the ratio between
Developing Vitrimer-MXene Laminated Sheets for Stimuli-Responsive Coatings and Improved Composite Functionality

Organic-inorganic hybrid structures found in nature, e.g., nacre (“mother-of-pearl”), are often remarkably tough and exhibit multi-functional properties due to highly ordered arrangements of organic and inorganic components in such structures at the nanometer-to-micron length scale. Inspired by these hierarchical biological structures, this work details our efforts to fabricate a hybrid composite of ordered, alternating layers of organic vitrimer polymer and inorganic MXenes. Vitrimers, as a new class of polymers, ideally exhibit thermoset-like behavior at lower temperatures and thermoplastic-like behavior at higher temperatures due to their permanent yet dynamic polymer networks. MXenes, as a class of inorganic two-dimensional (2D) transition metal carbides and nitrides, exhibit excellent metallic conductivity, good transparency in the visible wavelength range, and high photon-to-phonon conversion efficiency.

In this work, we demonstrate the fabrication of highly ordered, ultra-thin (nearly single to a few layers) MXene films onto thin, free-standing sheets of vitrimer, yielding electrically conductive, highly transmissive vitrimer-MXene sheets for self-healing coatings and multi-functional composites. Large area (20 x 20 cm), thin (~65 µm) free-standing vitrimer sheets are first obtained utilizing industrially-relevant compression molding techniques. Thermomechanical testing (TGA, DSC, DMA, TMA, micro-indentation) indicates excellent spot-to-spot consistency in the fabricated sheets. Subsequently, a thin film of MXene is deposited onto the vitrimer sheet surface using an advanced deposition technique that leverages Rayleigh-Benard convection and the Marangoni effect. Surface morphology and mechanical properties of the vitrimer-MXene sheets are investigated at different length scales using micro-indentation testing and quantitative nanomechanical (QNM) analysis. UV-vis measurements and electrical conductivity measurements additionally indicate reasonably good transparency (>75 %T in the visible spectrum) and electrical conductivity values (~100 S/cm) for the vitrimer-MXene scales using micro-indentation testing and quantitative nanomechanical (QNM) analysis. UV-vis measurements and electrical conductivity measurements enhancing vitrimer functionality towards structurally robust electronic applications.

In this study, we developed structural strategies of MXenes-MXene aerogels could result crucial to produce gas and/or particle capture and sensing systems, whose regeneration via Joule heating might be possible because of their high electrical conductivity and versatile thermal properties. Also, the metal ions trapped within the MXene porous structure can be converted to metal clusters by simple thermal annealing (performed at 300°C, under Ar/H2), allowing the formation of ferromagnetic particles for electromagnetically sensitive and other related applications. Moreover, due to their tunable porosity, mechanical properties, and composition, MXene aerogels are being tested for acoustic insulation/damping and sensing as well. Finally, thanks to the abovementioned gelation process, MXene hydrogels and aerogels can be shaped in many forms, including fibers that might be use for bioelectronics and sensing. Finally, this versatile approach can be employed for several metal ions and MXene structures, leading to the production of hybrid systems with tunable properties according to envisaged applications.

[Accepted Manuscript]

3D printing is an emerging technology for many applications, including electronics. On the other hand, to gather the applications’ requirements with the possibility to produce complex 3-dimensional structures, the development of novel 3D printable materials is necessary. In this context, we studied the synthesis of 3D printable photocurable resins embedding Ti$_3$C$_2$$_x$-MXenes, a class of 2D layered materials with outstanding electrical and electronic properties.

Starting from the pioneering works of Y. Gogotsi and M.W. Barsoum, MXenes envisage promising performances in different fields like energy storage[1], electromagnetic shielding[2], photodetectors[3], sensors[4] and electrocatalysis[5]. Nevertheless, their translation to devices nowadays is mainly limited to 2D configuration or conventional production processes.

Herein the motivation for this work stands for the development of stable polymeric inks suitable for Digital Light Processing (DLP) 3D printing technology using Ti$_3$C$_2$$_x$-MXenes as functional fillers. Those were successfully synthesized using Ti$_3$AlC$_2$ as a MAX phase precursor etched by a strong acid (hydrofluoric acid- HF) and using tetrabutylammonium hydroxide (TBAOH) as an intercalator, providing a few layered flakes presentation. Then, employed to fabricate complex 3D composite structures with high printing fidelity. To enhance the material’s electrical conductivity, annealing treatments have been performed, followed by a complete characterization of the so obtained. The results show that objects with improved electrical conductivity have been successfully obtained. To this end, this achievement would open new perspectives towards developing complex 3-dimensional electronic applications.

MXene and Their Surface Functionalization for the Development of Functional MXene Organic Inks

Tae Yun Ko
Korea Institute of Science and Technology, Korea (the Republic of)

Due to their unique metallic conductivity, transparency, and outstanding solution processability in water, MXenes have been attracted to many potential applications such as EMI shielding, energy storage, and electronic applications. However, oxidation instability of aqueous MXene dispersions and poor dispersion stability in organic solvents prevent the utility of MXenes in potential applications. Surface functionalization of MXene is critical for controlling the dispersion system, surface chemistry, processing, physicochemical properties, and applications. Herein, we designed and conceptualized various organic ligands that can improve oxidation stability and organic dispersibility of the functionalized MXene. The recently developed surface functionalization methods demonstrate a range of processes for synthesizing MXene organic inks into composites with different polymer and metal nanoparticles without chemical oxidation issues. Moreover, utilizing these functional inks as highly efficient electrodes, it is also possible to achieve fine patterning and direct writing on hydrophilic or hydrophobic substrates with excellent conductivity.

9:15 AM EL17.14.05
Controlling Aerosol-Jet Printed Mxene Flakes Morphology for Neural and Energy Storage Applications

Javier Gutierrez Gonzalez1,2,3, Dahnam Spurling1, Tara McGuire1, Ke Li1, Ian Woods1, Adrian G. Dervan2,3, Valeria Nicolosi1,3 and Fergal O’Brien1,2

1 Trinity College, Ireland; 2Tissue Engineering Research Group, Royal College of Surgeons in Ireland (RCSI), Ireland; 3Advanced Materials Bio-Engineering Research Centre (AMBER, RCSI and TCD), Ireland

MXenes are a class of 2D layered materials consisting of carbides and nitrides of transition metals which has found application in a wide range of fields due to their excellent electrical conductivity, charge storage, and biocompatibility. Mainly used as aligned flakes, under certain processing conditions these 2D flakes can also fold in crumpled 3D structures. Despite being occasionally associated with faulty deposition, crumpled MXenes hold untapped potential, harboring intriguing properties that remain largely unexplored. Thus, the main goal of this study was to investigate the uncharted role that crumpled MXenes can play in both neural and energy storage applications.

In this work, the production of crumpled and aligned MXene (Ti$_3$C$_2$$_x$) flakes morphologies was systematically studied by using high-resolution Aerosol Jet 3D printing, while assessing their novel physical properties, such as roughness, conductivity, and optical properties. Furthermore, cell line -derived and primary neurons were plated on either morphology to examine the ability of both forms to support neuronal growth and development. In addition, to assess the potential utility of crumpled MXenes for energy storage applications, crumpled MXene flakes were used as a conductive spacer between aligned MXene layers for developing an all-MXene supercapacitor.

By modifying several 3D printing parameters, MXene flakes could both align and crumple at specific mass and sheath flow regimes, depending on the nozzle size, speed, and solvent mixture, while flake morphology was rapidly monitored using the in-built camera. To assess biocompatibility, mouse neurons were seeded on printed crumpled and aligned MXene films, revealing distinct behavior depending on the flake morphology: crumpled MXene facilitated higher cell adhesion (as indicated by DNA count and immunostained cells), whereas neurons grown on aligned MXene films possessed longer neurite outgrowth. Further analysis using mouse primary neurons, resulted in healthy neuronal growth on both types of MXene for 8 days, while crumpled surfaces elicited decreased expression of GFAP, as observed in image analysis, suggesting reduced astrocitary reactivity.

MXene supercapacitors were aerosol jet printed with the first layer being a highly conductive aligned MXene current collector, followed by alternating layers of crumpled and aligned MXene, resembling a lasagne structure. This hierarchical architecture effectively prevented excessive restacking of the
flakes by smartly combining both morphologies, preserving a nanoporous network and achieving up to 65 (F/g) gravimetric capacitance, 193 (F/cm^2) volumetric capacitance and 88 (mF/cm^2) areal capacitance. Taken together, these results demonstrate that crumpled and aligned MXenes can be easily 3D printed with Aerosol Jet printing; both MXene morphologies exhibited unique characteristics when supporting neuronal growth, and also powered energy-dense lasagne structured supercapacitors. This study highlights the need for precise management of MXene deposition and customized flake design, encouraging material scientists to intensify the study of crumpled MXenes and other 2D materials, and their application in multiple fields including biomedicine, electronics and energy storage.

Understanding Light-Matter Interactions of MXene Family of 2D Materials
Hyngho Kim¹,², Danzhen Zhang¹,², Teng Zhang¹,² and Yury Gogotsi¹,²; ¹A.J. Drexel Nanomaterials Institute, United States; ²Drexel University, United States

The MXene family, two-dimensional transition metal carbides, nitrides, and carbonitrides, have been the subject of extensive research activities for the past decade. Recent developments in the molten-salt route have enabled the engineering of MXenes’ surface termination groups. For example, molten-salt route synthesized TiC2Tx is found to have a vis-NIR absorption band centered at ~880 nm, which is red-shifted from 770~800 nm for the acid route prepared TiC2T x with O, OH, and F terminations. The origin of this vis-NIR absorption band is yet to be understood, and the red-shift is difficult to explain by carrier density with the surface plasmon concept. Instead, we adapt an interband transition mechanism with consideration of light polarization to explain both UV and vis-NIR absorption bands of MXenes. The light-matter interactions of MXenes will be analyzed by using in-situ UV-vis spectroscopy under electrochemical modulation and Raman spectroscopy, and correlated with the literature on nonlinear optics, ultrafast terahertz spectroscopy, and pump-probe transient absorption. The important relationships between photons, electrons, and phonons in MXene, which are important for numerous applications of those materials, will be discussed.

Application of Two-Dimensional Metal Carbides (MXenes) for the Removal of Emerging Contaminants from Water
Khaled Mahmoud; Hamad Bin Khalifa University, Qatar

Characteristic properties of two-dimensional (2D) transition metal carbides and nitrides (MXenes), such as high conductivity, hydrophilicity, and catalytic activity have led to a growing research interest in their use in environmental remediation and water treatment applications. The ability to process MXenes into flexible films with negative surface charge and hydrophilicity adds a possibility to control ion flux and biofouling by applying a small potential to the membrane. MXene shows a much higher antibacterial efficiency toward both Gram-negative and Gram-positive bacteria as compared with other 2D nanomaterials. Consequently, MXene membranes demonstrated outstanding water flux, and selective rejection of salts and organic molecules, which makes them ideal UF/NF membrane materials. Moreover, MXene has been successfully used for the efficient adsorption and removal of heavy metals such as Hg, Cu, and Ag. This talk summarizes the recent advances in the applications of MXenes as adsorbents, desalination membranes, electrodes for electrochemical deionization, and catalytic or antibacterial agents for water purification and other environmental remediation processes. The overview also features discussions on the computational attempts, biocompatibility, and environmental impact in the exploration of MXenes for water applications, highlighting the challenges and opportunities of these advanced 2D materials. The biocompatibility and cytotoxicity assessment of MXene and its impact on the environment will be highlighted.

10:45 AM EL17.15.02
The Effect of Lateral Size and Surface Functional Groups on Membrane Performance of the TiC2Tx MXenes
Kiandokht Pakravan and Majid Beidaghi; Auburn University, United States

The applications of MXenes in membrane-based separation technologies have been rapidly expanding in recent years due to their hydrophilicity, exceptional flexibility, superior thermal stability, high electrical conductivity, and large surface area. In this presentation, we demonstrate significant enhancement in the performance of MXenes (TiC2Tx) membranes through understanding the effects of lateral sizes and surface chemistry of MXenes on the permeability and separation properties of the fabricated membranes. Single-layer TiC2Tx nanosheets with different lateral sizes were obtained by applying high-power sonication with varying times to MXene dispersion. The resulting MXene dispersions were used to fabricate membranes for studying the effect of lateral size on the membrane performance. Also, to investigate the effect of surface chemistry on membrane performance, TiC2Tx was synthesized by two different methods. The first method was the conventional MXene synthesis based on the MILD etching method, where delamination and etching were performed in a single step using a mixture of LiF and HCl as the etchant. The second method used a mixed acid etchant (HF/HCl) followed by delamination with LiCl. The existence of HF in the mixed acid method results in a higher concentration of -F functional groups, which can decrease the hydrophilicity of MXene membranes. Our initial permeability measurements indicate that membranes fabricated using MXenes with smaller lateral sizes have higher permeability compared with MXenes membranes with larger flakes. Also, the permeability of the MXene membrane varies across different methods.

11:00 AM EL17.15.03
Highly Efficient Electrochemical Performance of MXene-Based Nanocomposites for Capacitive Deionization of Metals and Cations
Ruoy-An Doong; Nai-Ying Wang and Thi Kim Anh Nguyen; National Tsing Hua University, Taiwan

MXenes, a promising 2D materials derived from MAX phases, have been potentially applied to energy storage devices and pollution purification systems including ion-sieving membranes and ion removal. MXene has also established its prospective as electrodes for capacitive deionization (CDI) application...
for water purification and reuse due to the similar principle of charge storage in supercapacitors that uses the faradaic ion intercalation phenomenon. Electrode materials for asymmetric capacitive deactivation, by combining carbonaceous materials with metal oxides, have emerged as a potential electrode material for CDI applications, which enable high ion removal capacity in comparison with devices containing only carbon materials. In this study, MXene based nanocomposites including MoS2@MXene and Prussian blue analogues (PBA)@MXene have been fabricated to serve as the electrode materials for symmetric and asymmetric CDI applications. Results show that all the developed nanocomposites have a high surface area, suitable pore texture, and low electrical conductivity to accelerate the electron and ion transfer rate. The specific electrosorption capacities (SECs) of the MXene-based nanocomposites are in the range of 39.5 – 43.8 mg/g with a charge efficiency of > 82%. Additionally, the as-developed MXene nanosheet has an excellent selective adsorption capacity toward heavy metal and ammonium ions removal. The TiC2 MXene can selectively electroadsorb NH4+ with the SEC of 40 mg/g. When combining the vanadium aluminum carbide (V2AlC-OHx) with activated biochar (AB), the asymmetric AB/V2AlC-OHx device exhibits a superior deionization performance for Cr(VI) removal. These results clearly demonstrate the superiority of the as-developed MXene nanocomposites and can pave a gateway for combining MXene materials with novel metal oxides for highly efficient deionization of salty water as well as toxic metal and inorganic ions in water and wastewater treatment.

Two-dimensional (2D) transition metal carbides, nitrides, and carbonitrides (MXenes) are rapidly growing as nanomaterials in biomedical research. Considering the central importance of the immune response for any clinical translation of nanomaterials, we explored the potential biomedical applications of MXenes and their immune impact exploiting our expertise on the biological effects of 2D materials.[1-4] To satisfy a critical unmet need to detect 2D materials at the single-cell level while measuring multiple cell and tissue features, we proposed the “Label-free single-cell tracking of 2D materials by mass cytometry and MIBI-TOF Design” strategy, enabling nanomaterial detection while surveying a comprehensive biomarker panel.[5] The advantage of this approach is that it provides a powerful tool for the investigation of MXene biodistribution and immune modulation. The MXene immune system was examined using the Luminex technology. MXene immune profiling revealed that MXene treatment can affect specific immune mediators. The immune impact of MXenes was evaluated on human primary immune cells by flow cytometry and CyTOF on 17 distinct cell populations. Moreover, 40 secreted cytokines were measured in the cytometry range while avoiding overlap with more than 70 available tags. We demonstrated their detection in 15 human immune cell populations. We used mass cytometry to capture MXene biocompatibility and cytokine production after their uptake. In vitro biodistribution experiments using a mixture of MXenes in mice confirmed the versatility of our strategy and revealed MXene accumulation in the main organs.

In conclusion, envisioning future MXene-based biomedical nanotools and drug nanofORMulations we further explored MXene immune modulation and antiviral activity taking SARS-CoV-2 as a model.[6,7] We analyzed four SARS-CoV-2 genotypes. When viral inhibition was tested in vitro, TiC2 was able to reduce SARS-CoV-2 infection by 85%. Among other MXenes tested, Mo2Ti2C also showed antiviral properties. Proteomic and functional annotation analysis revealed that MXene-treatment exerts specific inhibitory mechanisms. The immune impact of MXenes was evaluated on human primary immune cells by flow cytometry and CyTOF on 17 distinct cell subpopulations. Moreover, 40 secreted cytokines were analyzed by Luminex technology. MXene immune profiling revealed the biological and functional implications of MXene interaction with immune cells. We demonstrated the ability to inhibit T cell-dendritic cell interactions, evaluating the modulation of CD40-CD40 ligand interaction, two key co-stimulatory molecules for immune activation. We confirmed the biocompatibility at the single-cell level on 17 human immune cell subpopulations by single-cell mass cytometry. Finally, we explored the molecular mechanism underlying MXenes-mediated downregulation of antigen presentation-associated genes. Our findings set the basis for further MXene investigation as a negative modulator of the immune response in inflammatory and autoimmune diseases. Taken together, our results provide a comprehensive understanding of the biocompatibility of MXenes for the safe development of multi-functional nanosystems in biomedicine.

**The Influence of Hydration on the Mixed Charge Conduction of Conjugated Polymer Films**
*Sahika Inal; King Abdullah University of Science and Technology, Saudi Arabia*

Organic mixed (ionic and electronic) charge conductors and electrochemical phenomena at the solid-liquid interface have garnered significant attention for applications in bioelectronics, electrochromics, energy storage/generation, neuromorphic computing, and thermoelectrics. These devices operate in electrolytes that render ions mobile in the film, making the coupling between electronic and ionic charges crucial. An example of such a device is the organic electrochemical transistor (OECT), a high-gain transducer commonly used to monitor bioelectronic signals. In this talk, I will show that the ions entering the semiconducting polymer channel are hydrated, and the water they bring inside the channel significantly affects OECT performance, which can be traced back to changes in the overall structural order. I will show the generality of this phenomenon with p and n-type materials. I will demonstrate how the amount of water the film takes governs its dielectric constant and the polaronic species formation. I will introduce one synthetic method and one postprocessing approach that can limit the water uptake of the film during device operation. These approaches enhance the mixed conductivity of polymers while preventing material degradation with oxygen, leading to OECTs with longer shelf life and operational stability.

**Are Existing OECT Models Broad Enough? The Role of the Counter Ion and Ionic Contact Blocking**
*Sapir Bittons and Nir Tessler; Technion-Israel Institute of Technology, Israel*

OECTs have many advantages making them a promising technology for the future of electronics and bio-electronics. They have high transconductance which leads to a high sensitivity [1], and low operating voltage [2]. They can be fabricated on flexible substrates, [3] are scalable, and cost-effective for mass production. [4] The above attributes make them suitable for various applications, including healthcare (biosensors, drug delivery devices), robotics (sensors and actuators), and flexible electronics (e-skins, displays). However, they have limitations and challenges, such as stability and reversibility issues, manufacturing complexity, and the need for further optimization in certain applications. [5]

In our study, we simulated an OECT with PEDOT: PSS as the semiconductor layer. At the ON state, no cations are present in the bulk, resulting in a hole current within the PEDOT: PSS bulk. Conversely, at the OFF state, cations penetrate the bulk, depleting it and causing a significant drop in current. The above is well-known and detailed modeling has already revealed the importance of the ions' distribution with the semiconducting layer. [6,7]

Here we expand on previous studies using the industry-standard device simulator Sentaurus by Synopsys. Using the ion (“hydrogen”) diffusion module allows for self-consistent simulation of the ionic electronic conduction as well as the contact phenomena. The first new observation to report is that, like in some memory technologies, ion accumulation close to the contact interface blocks the contact injection. In fact, this contact blocking plays an important role in obtaining low enough off currents.

Next, since the counterions (anions) are explicitly incorporated into the model, we report their influence on the OECT's conductance. We will present hole, cation, and anion distributions in the electrolyte and semiconductor for ON and OFF states under three scenarios: (1) Anions can move freely in the
electrolyte but are blocked by the semiconductor. (2) Anions can move freely in the electrolyte and penetrate the semiconductor, and (3) Anions are static in the electrolyte (as in solid electrolytes). We identify the scenario resulting in the highest transconductance and demonstrate the potential role of the electrolyte's counter ions (anions) in achieving best-performing OECTs.

We will discuss how our new findings suggest that the models used abundantly to describe OECT’s performance may not be general enough. [8]

Ion-Associated Charge Transport in Conjugated/Non-Conjugated Polymer Layers for Wet and Dry Electronic Devices Takeo Saga; Waseda University, Japan

Electro-active organic polymers (i.e. p-conjugated polymer conductors/semi-conductors) have attracted increasing interest for organic electronics applications, such as solar cells, field-effect transistors, and batteries, because of their facile integration to soft/flexible device configurations, and environmentally benign/sustainable feedstock compared with rare metals, etc. Non-conjugated, redox-active polymers such as radical polymers have also attracted research attention to their utilization as an electrode-active material for rechargeable batteries and a charge-transport layer for electronic devices. Any of these applications, the role of associated ion transport is indispensable for efficient charge injection, transport, and storage. Here we take three examples: a) stable charge-storage in radical/conducting polymers, b) modulated charge-transport in the radical-containing resistive memory, and c) efficient charge collection through polymer semiconductors in the perovskite solar cells, and discuss each role of ions for charge-transport in electro-active polymers.

1:30 PM EL18.02.01
Asymmetric Side-Chain Engineering of Thiophene-Based Polymers for Organic Electrochemical Transistor Applications Preeti Yadav and Christine Luscombe; Okinawa Institute of Science and Technology Graduate University, Japan

Conjugated polymers with mixed ion-conducting properties have recently gained considerable attention due to their potential applications in various emerging technologies spanning from bioelectronics to energy harvesting and storage. The soft and biocompatible nature of conjugated polymers coupled with their mixed conduction properties has been leveraged to develop many organic bioelectronic devices including organic electrochemical transistors (OECTs), neural probes, organic electronic ion pumps, and conducting polymer actuators. Among these, an OECT device comprising of a redox-active organic semiconductor layer interfacing a source, a drain electrode, and an electrolyte solution is capable of directly transducing small ionic fluxes into electrical signals making it ideal for sensing biomolecules. To achieve a high-performing OECT device, carrier mobility, and ion transport should be balanced in such a way that maximum transconductance is achieved, highlighting the crucial role played by crystallinity and morphology in mixed conduction. Therefore, it is important to establish an in-depth understanding of the chemical structure of the semiconducting polymer, charge transport, and morphology for designing high-performance OECT materials. In this work, we have synthesized polythiophene derivatives and explored how the polymer morphologies will affect carrier mobility and ion transport. The fundamental design idea is to obtain a highly planarized polymer structure by enhancing the side-chain organization through the incorporation of asymmetric side chains. Specifically, we investigate the effect of the enhanced side-chain organization on film morphologies, carrier mobility, and ion transport. Thiophene monomer is synthesized using Stille coupling and subsequently polymerized using Kumada catalyst transfer polymerization. The obtained polymer is characterized using NMR, MALDI, DSC, TGA, UV-vis absorption spectroscopy, and cyclic voltammetry. The morphologies and microstructure of the polymer films are examined using AFM and GIWAXS followed by OECT device fabrication and characterization.

Operando Studies of Organic Mixed Ionic-Electronic Conductors: Structure, Composition and More… Jonathan Rivnay; Northwestern University, United States

Organic mixed ionic-electronic conductors (OMIECs) have gained considerable interest in bioelectronics, power electronics, circuits and neuromorphic computing. These organic, often polymer-based semiconductors rely on a combination of ionic transport, electronic transport, and high volumetric charge storage capacity. Despite recent progress and a rapidly expanding library of new materials, a full understanding of fundamental processes of OMIECs remains largely unexplored. Critically, useful studies require us to probe these systems in device-relevant conditions, fully considering the effects of ions and solvent on microstructure and transport. To this end, we report on recent efforts towards structure/composition-property relations in high performance organic mixed conductors using ex-situ, in-situ, and operando scattering and spectroscopic techniques. We use a combination of GIWAXS, GISAXS, XPCS, E-QCMd, UV-Vis, XRF, as well as device measurements to explore kinetics, composition, and structural evolution during electrochemical operation. Importantly, these findings provide novel insights into materials design for enhancing device performance and stability.

2:15 PM EL18.02.03
Probing Polarons in Mixed Conductors via the Photoinduced Stark Effect Christopher Grieco, Abdul Rashid Umar and Austin Dorris; Auburn University, United States
Conjugated polymers are promising candidates for high performance bioelectronics due in part to their ability to conduct ions and charge carriers simultaneously. However, the fundamentals of mixed ion and charge transport, including their complex dependence on polymer structural dynamics occurring in operando, remain unclear due to limited characterization methods. Using ultrafast transient absorption spectroscopy, we demonstrate a new approach to probing the nature and local environment of polarons in a mixed conducting, electrochromic polymer, 3,4-propylenedioxothiophene-co-3,4-ethylenedioxythiophene (ProDOT-co-EDOT).[1] Selectively photoexciting hole polarons via the P1 and P2 polaronic transitions causes spatial separation of the hole from its counterion during thermalization. The resulting electric field, which induces a Stark shift of the bandgap transition of nearby polymer chains, creates signals in the transient spectrum that reflect the electronic structure and environment of the charge carrier. As a first step, we show how this optical spectroscopy method, which effectively senses polarons in both amorphous and crystalline domains, can be implemented in spectroelectrochemical measurements to elucidate mixed conduction mechanisms.

2:30 PM EL18.02.04
Swelling of Side Chain Free Polymers upon Electrochemical Cycling Lucas Flagl1, Lee Richter1, Jiajie Guo2, David S. Ginger2 and Jianguo Mei2;
1NIST, United States; 2University of Washington, United States

Organic mixed ionic-electronic conductors (OMIECs) are an exciting class of new materials with a range of potential applications including biosensors, electrochromics, and neuromorphic computing. For many of these applications the performance of n-type materials trails p-type materials by at least an order of magnitude. Recently, a pair of side-chain less polymers have been demonstrated as promising n-type OMIECs. These materials challenge the existing understanding of this class of materials, where polar (often ethylene glycol) side chains enable electrolyte and ion ingress, which subsequently enables volumetric doping. Here, we seek to understand the swelling during electrolyte contact and during redox cycling of these side chain less materials using in-situ GIWAXS. These measurements reveal drastic differences in how the two polymers swell in response to applied bias. In water-based electrolytes, BBL shows a redox induced swelling upon first passage, and remains swollen during subsequent doping cycles. In contrast, PBDF does not show any lattice expansion when in contact with water regardless of doping state. However, in propylene carbonate electrolyte PBDF shows a reversible melting during dedoping to the point where all diffraction peaks disappear. Upon electrochemical redoping, the crystallinity returns to its original level. Additionally, in the partially doped state the lattice spacing depends strongly on the exact doping state. We investigate this melting/recrystallization and swelling phenomena in relation to conductivity of the system. Overall, this work provides insights into the role of swelling in side-chain less OMEIC materials which can inform design rules moving forward.

3:15 PM *EL18.03.01
Electronic and Ionic Conduction in Radical-Containing Small Molecules and Polymers Bryan W. Boudouris; Purdue University, United States

Optoelectronically active small molecules and polymers have made critical inroads in many solid-state electronic devices (e.g., organic field-effect transistors), and excitingly, organic molecules capable of providing mixed electronic and ionic conduction offer unique opportunities in many application areas including bioelectronic devices. Here, we describe electronic and ionic conduction in both low molecular weight and polymeric materials containing stable open-shell sites. While the chemical nature of the two classes of materials differs, the key premise is that controlling the spatial distance between the radical groups is critical for electronic transport and that the redox behavior of open-shell species allows for facile ion transport if it is controlled appropriately.

First, we demonstrate how control of the local structure in radical-containing small molecules and polymers impacts charge transport in these materials. In one example, we implement radical polymers, which are macromolecular materials that have flexible polymeric backbones and pendant groups that bear stable open-shell moieties. In contrast to almost all other optoelectronically-active polymers, radical polymers lack backbone conjugation and are completely amorphous in the solid state. Despite this shift in macromolecular design archetype, we demonstrate that the solid-state electrical conductivity of a designer radical polymer exceeds 20 S m\(^{-1}\), and this places this nonconjugated polymer conductor in the same regime as many grades of common commercially-available, chemically-doped conjugated conducting polymers. Thus, this work presents an alternate design paradigm for next-generation organic electronic materials. In a second example, small molecules that bear stable radical groups and form macroscopic single crystals are evaluated. Specifically, we quantified the electrical conductivity in two organic radical single crystals and demonstrated that a subtle change in atomic connectivity drastically alters the macroscopic electronic properties of the materials. One radical-based crystal had an electrical conductivity of ~3 S m\(^{-1}\), which is the highest value for nonconjugated radical conductors over a 1 µm-scale reported to date. However, the other radical crystal has a 1,000-fold lower conductivity despite their extremely similar molecular structures. The temperature-dependent conductivity follows the variable range hopping mechanism for both radical crystals, and the difference in effective charge mobility is the reason for the conductivity difference. These results present a clear picture of the design rules and charge transport mechanism for radical-based materials.

Next, we describe how a blend of a common conjugated polymer, poly(3-hexylthiophene) (P3HT), and a radical polymer (i.e., a macromolecule with a nonconjugated backbone and with stable open-shell sites on its pendant groups), poly(4-glycidoxy-2,2,6,6-tetramethylpiperidine-1-oxyl) PTEO, allows for the creation of high-performance organic electrochemical transistors (OECTs) through a unique mixed conduction mechanism. Second, we will discuss how this type of archetype can be translated to biomedical device applications through a practical demonstration of a stretchable and flexible polymer-based biosensor. This bioelectronic device is inkjet-printed atop a commercial soft contact lens in a high-throughput manner, and our electroretinogram (ERG) sensor shows performance that is superior to current clinical gold standards in human subjects. In this way, we couple the materials science mixed organic electronic conductors to translational performance to demonstrate clear patient impact.

3:45 PM EL18.03.02
Generalised Framework for Controlling and Understanding Ion Dynamics with Passivated Lead Halide Perovskites Tomi Baikie1, Philip Calado2,
Metal halide perovskite solar cells have gained widespread attention due to their high efficiency and high defect tolerance. The absorbing perovskite layer is as a mixed electron-ion conductor that supports high rates of ion and charge transport at room temperature, but the migration of mobile defects can lead to degradation pathways. We combine experimental observations and drift-diffusion modelling to demonstrate a new framework to interpret surface photovoltage (SPV) measurements in perovskite systems and mixed electronic ionic conductors more generally. We conclude that the SPV in mixed electronic ionic conductors can be understood in terms of the change in electric potential at the surface associated with changes in the net charge within the semiconductor system. We show that by modifying the interfaces of perovskite bilayers, we may control defect migration behaviour throughout the perovskite bulk. Our new framework for SPV has broad implications for developing strategies to improve the stability of perovskite devices by controlling defect accumulation at interfaces. More generally, in mixed electronic conductors our framework provides new insights into the behaviour of mobile defects and their interaction with photoinduced charges, which are foundational to physical mechanisms in memristivity, logic, impedance, sensors and energy storage.

4:00 PM EL18.03.03
Ion-and Charge Transport in Dense Films of Semiconducting Single-Walled Carbon Nanotubes

Dispensers of purely semiconducting single-walled carbon nanotubes (SWCNTs) can be sorted and purified by polymer-wrapping and subsequently printed into thin or thick SWCNT films that are suitable for various electronic devices. Here, we demonstrate that these porous composites of conjugated polymer and semiconducting nanotubes enable mixed electronic and ionic transport with high charge carrier mobilities in electrochemical transistors with different electrolytes. The ionic transport and hence also the effective volumetric capacitance of the nanotube network can be increased substantially by changing from a hydrophobic polyfluorene copolymer with alkyl sidechains to one with tetraethylene glycol sidechains, thus reaching over 200 Fcm⁻¹V⁻¹s⁻¹ as the product of carrier mobility and volumetric capacitance (ACS Appl. Mater. Interfaces 2022, 14, 8209). We find that the maximum conductance for hole transport in SWCNT networks also depends on the size of the electrolyte anions, suggesting a direct impact on the delocalization of charge carriers along the nanotubes. Furthermore, we monitor the ion movement and thus charge transport confinement within a nanotube network by spatially resolved in-situ Raman- and photoluminescence spectroscopy and explore the role of the network morphology and density for both charge and ion transport. Finally, we demonstrate the direct sensing of cupric ions and indirectly of glyphosate in water-gated transistors with polyfluorene copolymer-wrapped nanotubes (Nanoscale 2022, 14, 13542).

4:15 PM EL18.03.04
Controlling Mixed Ionic-Electronic Conducting Polymer Properties with Amphiphilic Chemical Design Strategies

Semiconducting polymers bearing hydrophilic glycol side chains can transport aqueous electrolytes through their bulk, allowing for the simultaneous movement of electronic and ionic charges during electrochemical doping (therefore called organic mixed ionic-electronic conductors, or OMIECs). Their mixed charge transport properties, chemical tunability and easy synthetic scalability make them attractive materials for bioelectronic devices such as transistors [1] and charge storage devices [2]. While hydrophobic alkylated polythiophenes have demonstrated favourable charge transport properties [3] and the ability to operate stably in devices such as field-effect transistors, upon glycolation (making them into OMIECs) some of these favourable properties are deteriorated. For example, heavily glycolated polythiophenes have shown to excessively swell when electrochemically doped in the presence of an aqueous electrolyte [4], damaging their operational stability and charge transport properties. We explore how amphiphilic chemical design strategies can be leveraged to design OMIECs that retain their operational stability and high charge transport properties. We explore two strategies – 1) the random copolymerisation of alkylated and glycolated repeat units together and 2) using homopolymers with both alkyl and glycol moieties on their side chains. In the first case we find that a small level of alkylation leads to a large increase in the electrochemical cycling stability of the OMIEC, while leaving the electrochemical doping characteristics broadly unchanged. When using homopolymers with mixed alkyl/glycol side chains, we show how the size of the alkyl group on the side chain can control the polymer backbone conformation, impacting its electronic transport properties. Through a joint experimental/theoretical approach we identify the underlying microstructural mechanism behind both the inhibited swelling in alkyl/glycol copolymers and the effect on the backbone morphology in amphiphilic homopolymers. We identify the driving forces causing them to adopt their particular microstructure and draw parallels between the formation of micelles and vesicles in surfactants. Identifying these mechanisms and their driving forces in OMIEC systems will aid in the design of future polymers which optimise the transport of both ionic and electronic charges, while having high operational stability and charge transport properties.

conductivity. As one approach, modulating the energy filtering effect at the component interfaces can enhance the Seebeck coefficient with only a slight reduction in electrical conductivity. In this presentation, I will report an effective strategy to significantly enhance the thermoelectric properties of PEDOT:PSS by integrating core-shell PEDOT/poly(pyrrole) (PPy) nanowires to form multiple sequential interfaces and enabling more effective energy filtering process in between. By tailoring the energy barriers among PEDOT/PPy/PEDOT:PSS interfaces, the Seebeck coefficient of the PEDOT:PSS composites was increased by ∼ 46% with only a slight decrease in electrical conductivity. As a result, a significant improvement of over 85% in power factor was achieved compared with pristine PEDOT:PSS.

8:00 PM EL18.04.02

Textile-Embeddable Fibrobirn Organic Electrochemical Diodes with Rectifying, Complimentary Logic and Transient Voltage Suppression Function for Wearable E-Textile Circuits

Kwang-Hun Choi1,2, Soo Kin Kim1,2, Ho Won Jang2, Changsoon Choi1, Hyunsu Ju1 and Jung Ah Lim1,2; 1Korea Institute of Science and Technology, Korea (the Republic of); 2Seoul National University, Korea (the Republic of); 3Korea University of Science and Technology, Korea, (the Republic of)

Electronic textile (E-textile) is considered ideal wearable platforms for human-machine interaction due to their flexibility and comfortable-wearing textile properties. For realization of a multi-functional, fully integrated E-textile circuit system, fibrobirn electronic devices become a key component that can merge a multifunctionality of integrated circuits and a textile nature. Here, we propose a fibrobirn electrochemical diode (IOED) as a building block for E-textile circuits. The IOED is fabricated by twisting metal/polymer semiconductor/ion gel coaxial microfibers and microfiber electrodes. The IOED exhibits a prominent asymmetrical current flow similar to that of the diode, with a rectification ratio of over 100. From the fundamental studies on the electrochemical interaction between polymer semiconductors and ions, we reveal that the faradaic current by electrochemical reaction originates an abrupt current increase under a forward bias. Then, the threshold voltages of devices are determined by the redox potential of the polymer semiconductor. The IOED exhibit great bending and washing robustness, and was embeddable on the textile platform by its one-dimensional architecture (diameter < 300 μm). It also could be expanded to integrated circuit systems by simply merging the electrode threads, the full-wave rectifiers and logic gates (AND/OR) could be easily accomplished on textiles. Furthermore, it was also confirmed that IOED could be utilized as a protection device, a IOED integrated electrocardiogram monitoring system could be protected from circuit damage by instant transient voltages. Our approach offers a new form factor for electrochemical diodes and we believe that this work will contribute to the development of next-generation wearable E-textile circuit systems.

8:00 PM EL18.04.03

Aerosol Jet Printed Organic Electrochemical Transistors using n-Type Naphthalene Dimide-Based Small-Molecule Organic Mixed Ionic-Electronic Conductor Seongdae Kang1, Paul Lavryshyn1, Jaxin Fan1 and Manisha Gupta4; 1University of Alberta, Canada; 4Polytechnique Montréal, Canada

Organic semiconductors are capable of transporting both the ionic and electronic charges representing a new class of material: organic mixed ionic-electronic conductor (OMIECs). OMIECs have been used for a variety of organic electronics, including organic electrochemical transistors (OECTs) and energy conversion/storage devices. Most reported OMIECs are hole-transporting p-type polymeric material, such as PEDOT:PSS and polythiophene derivatives. In contrast, electron-transporting n-type OMIECs are less reported and often have poorer performance and stability, despite their need in energy conversion/storage devices. Most reported OMIECs are hole-transporting p-type polymeric material, such as PEDOT:PSS and polythiophene derivatives. In contrast, electron-transporting n-type OMIECs are less reported and often have poorer performance and stability, despite their need in energy conversion/storage devices.

The transconductance of the OECT is affected by its intrinsic material figure-of-merit (μC*) and channel geometry. Drop-casted gNDI-Br2 devices pose a challenge for practical applications due to their unpredictable channel geometry and hence their repeatability. To resolve this issue, we fabricated gNDI-Br2 OECTs using an aerosol-jet 3D printing technique with the Optomec Aerosol Jet 5X 3D printer. This method creates the sub-micron size aerosols using ultrasonic atomization which are deposited onto the substrate via a nozzle. Owing to the AJ5X 3D printing system, we were able to manipulate the OECT channel geometry and fabricate repeatable OECT devices. Additionally, for the aerosol jet printing, the gNDI-Br2 solution with low evaporation rate was required while transitioning to an aerosol. By using low-volatile solvent for the solution and aerosol-jet 3D printing, the gNDI-Br2 molecules were evenly distributed onto the substrate, resulting in higher crystallinity as compared to the drop-casted OECTs. This resulted in an improved performance of the gNDI-Br2 OECT (gmax = 1.12 ms, μC* = 0.75 F cm-1V-1). Moreover, we achieved a fully printed n-type OECT by printing other component, including metal electrodes onto flexible polymer substrates. Using this gNDI-Br2 OECT, we were able to fabricate aerosol-jet printed complementary logic circuit with a PEDOT:PSS p-type counterpart.

8:00 PM EL18.04.04

Ionic Liquid Driven Enhancements in the Electromagnetic Interference Shielding Capabilities of Carbon-Based Polymer Composites Paul AlMalah1,2, Cedric Vancayzooele1, Pierre-Henri Aubert1, Frédéric Vidal1, Giao T.M. Nguyen1, Paolo Bondavalli1 and Cédric Pleisse1; 1IC Cergy-Paris Université, France; 2Thales Research & Technology, France

Electromagnetic interference (EMI) has emerged as a crucial problem in the modern world because of the rapid proliferation of electronic and telecommunication systems, which emit electromagnetic radiation that may perturb the performance of electronic devices on one hand, and could be harmful to the human body on the other [1]. As a result, considerable endeavors have been devoted to the development of efficient materials for EMI shielding/absorption. Polymers and polymeric composites with a wide array of fillers, especially carbon-based fillers have been widely used as promising candidates in the development of commercially viable EMI shielding materials. Lately, extensive research efforts have been put forward, towards effective dispersion of the fillers throughout the matrix. Ionic liquids have emerged as a promising dispersing agent for CNTs through non-covalent functionalization by interacting with the CNTs surface through π-π, cation-π or even Van der walls interaction [2]. They have been also used as fillers in metamaterial structures, where they actively engage in attenuating the electromagnetic wave thanks to their polarity [3]. Accordingly, it would be really interesting to develop a shield where we can take advantage of the already proven excellent EMI shielding capabilities of carbon based composites and in exploring the
capabilities of ionic liquids in a more active manner in a polymer matrix.

Here, we introduce the use of carbon-based nanomaterials (MWCNT, Graphene derivatives) incorporated in ionogels as effective EMI shields. These ionogels combine the unique properties of ionic liquids and their ability to attenuate the electromagnetic wave through dipole reorientation and translational motion (movement of the ions). The structural support is provided by the gel matrix, which also aids in matching the impedance of the shield with the surrounding environment, while the presence of carbon-based nanomaterials not only facilitated the formation of conductive pathways but also introduced interfacial polarization and dipole polarization between them and the ionic liquid-gel matrix. The ionogels exhibited remarkable performances across a wide frequency range, where the presence of the ionic liquid led to an enhanced absorption of the electromagnetic wave, with over 97% attenuation, of which over 55% is by absorption. Morphological characterizations revealed the homogeneous envelopment of the CNTs by the ionic liquid enhancing the interfacial polarization. The electrical conductivity measurements confirmed the conductive behavior of the carbon-based nanomaterial incorporated ionogels, which is essential for effective EMI shielding.

Elucidating the Role of Side-Chain Polarity of Conjugated Polyelectrolytes by Doping Through Organic Electrochemical Transistor Sung Hyun Lee1, Changwha Jung1, Hyunho Jeong1, Chaeyeon Park2, Soonyong Lee2, Han Young Woo2 and Hyunjung Lee2; 1Kookmin University, Korea (the Republic of); 2Korea University, Korea (the Republic of)

Conjugated polyelectrolytes (CPEs) exhibit a novel structure composed of electron or hole conducting r-conjugated backbone and ion conducting pendant ionic functionalities. Anionic narrow-band-gap CPE named poly[2,6-(4,4-bis-potassium butansulfonate-4H-cyclopenta-[2,1-b:3,4-b]-dithiophene)-alt-4,7-(2,1,3-benzothiadiazole)] (PCPDTBTSO3K, or CPE-K) is well known for self-doped property which is fabricated as a channel material for organic electrochemical transistor (OECT).

In this work, electronic and ion transport is studied by OECT system. Different types of polarity of side chain attached to the same backbone that contains an alternating D-A units of cyclopentadiithiophene (CDT) and benzothiadiazole (BT) were synthesized. The effect of different polarity was examined as a channel material by using gel-type ionic liquid electrolyte (1-Ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide-[EMIM][TFSI]-) which allows wider range of gate voltage and constant measurement conditions etc. All three channel materials each showed ON and OFF state both in accumulation and depletion mode only by changing the polarity of gate and drain voltage. Ion transport mechanism was compared through OECT system by measuring transfer/output curve, µC+ value and response time etc. Our work allows for maximizing doping effect through ion penetration and utilize as a dual mode switching system.

Study on the Impact of Ions Uptake on the Thermoelectric Performance in Organic Electrochemical Transistors Hyunho Jeong1, Changwha Jung1, Sung Hyun Lee1, Chaeyeon Park2, Soonyong Lee2, Han Young Woo2 and Hyunjung Lee2; 1Kookmin university, Korea (the Republic of); 2Korea University, Korea (the Republic of)

The aim of our research is to explore the effects of penetrated ions in the polymer matrix by electrochemical doping on the thermoelectric performance in organic electrochemical transistors (OECTs). Controlling the Seebeck coefficient and electrical conductivity values of organic thermoelectric (TE) materials has been widely studied. However, earlier works were primarily conducted based on the chemical doping method. In terms of controlling the TE performance, the electrochemical doping method has the advantage of finely tuning doping levels by changing the applied gate voltage (Vg). Anions or cations from ionic liquid penetrate the polymer matrix depending on the sign of applied gate voltage and modulating the conductivity. This method provides an easy way to study the TE performance of organic TE materials.

Generally, the focus is on the doped organic TE materials by penetration of mobile ions, and penetrated ions induced Seebeck coefficient is seldom considered. The temperature gradient causes not only the potential difference created by the polymer film but also the potential difference due to ions in the ionic liquid moving by the Soret effect. Thus, it is essential to clarify the contribution of ions to TE performance for further application.

Here, we demonstrate the influence of the uptake of mobile ions in an electrolyte (1-Ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide, ([EMIM][TFSI])) on TE performance using different polarity side chain polymers. We characterize the time-dependency of the potential difference between the cold side electrode and the hot side electrode based on the OECT system to investigate the ionic and electronic induced Seebeck coefficient separately.

Molecular Design for Tunable Ionic Thermopower with High Stretchability Minju Park; Korea Research Institute of Chemical Technology, Korea (the Republic of)

Wearable and stretchable electronics have attracted tremendous attention due to their wide applications in various areas. However, the lack of efficient, light-weighted and environmental friendly power sources has been the bottleneck that hinders the wide applications of wearable technologies. One of the attractive solutions is the thermoelectric generators (TEGs), which can directly convert waste heat from human body or environment into electricity. Though great development has been achieved with conventional TEGs, present inorganic thermoelectric materials still suffer from rigid properties and low Seebeck coefficient (several hundred uV/K scale), which requires an integration of hundreds of elements. To overcome these challenges, ionic thermoelectric materials utilizing ionic transport open up new possibilities for the recuperation of waste heat due to their enormous Seebeck coefficient, which can operate supercapacitors by energy harvesting.

Herein, we introduce intrinsically stretchable acrylamide based polymers (PAM) as the ion conductive materials comprising graphene derivatives, which possess high stretchability and excellent thermoelectric performance. Interestingly, ionic conductivity and thermopower could be tunable according to the molecular structure of graphene-based additives. Chemical structure of graphene-based additives was successfully modified by covalent functionalization with phenylsulfonic acid (SGO) and amine species (NGO), resulting in strong positive and negative charged graphene nanosheets, respectively. Induced charge could significantly affect to Coulombic interaction between ion and polymer, or ion and solvent, rendering in large difference in ion concentration under temperature gradient. As a result, the proposed materials exhibit excellent and tunable Seebeck coefficient (up to 39.7 mV/K) as well as remarkable stretchability. The ionic thermoelectric performance was sustained during multiple stretch-release cycles (50% strain, 1000 cycles), which demonstrates high durability under severe deformation. Furthermore, we fabricate ionic thermoelectric supercapacitors (ITESC) with ionogels, demonstrating the heat-to-electricity conversion was successfully established. These findings show a promising strategy to obtain multifunctional ionic thermoelectric materials by engineering the molecular structures, and demonstrate the great potential of ionogels for harvesting low-grade heat in human-comfortable humidity environments.
Pyrene Dianhydride Condensation Ladder Polymer: Synthesis and Film Characterization. Katherine Johnston, Emma Mikita and Julia A. Schneider; Fordham University, United States

Organic materials that display mixed-conductance—the ability to conduct both ions and electrons—are actively sought after for their possible use in organic electrochemical transistors and sodium-ion batteries, among many other applications. Of only a few n-type polymers reported to display mixed-conductance, poly(benzobisimidazobenzophenanthrolinedione) (BBL) is the most promising to date. Its conjugated ladder structure makes it very environmentally stable and its ability to maintain a planar backbone when swelling in ionic media has led to high capacitance and electron mobility. The success of BBL in terms of its mixed-conductance has renewed interest in the study and development of n-type ladder polymers. We will present the synthesis of a new mixed-conducting material, a pyrene-based ladder polymer, poly(benzimidazobenz(d,e,f)phenanthrenedione) ladder (BPyl), formed from the polyecondensation reaction between our pyrene diimide monomer unit and 1,2,4,5-tetraaminobenzene tetrahydrochloride (TAB.4HCl). The larger aromatic core of BPyl vs. BBL influences the packing of the polymer, and therefore, how well the polymer can form films and perform in electronic devices. We will study and present how BPyl and BBL differ in regard to their film making abilities using spectro-electrochemical analysis, UV-Vis, and TEM. The capacitance of BPyl will also be measured and reported.

Through our synthesis of the pyrene diimide monomer, two isomers are produced. We will present the synthesis and characterization of each isomer in its diimide forms. The pyrene diimide units themselves and their spectral and electrochemical properties are useful to study for future incorporation into conjugated polymers. Pyrene is impactful as a core for these molecules due to its unique fluorescence property: excimer formation. Excimer formation causes a shift in fluorescence when the molecule is close to a neighboring molecule and can be a useful way to visualize the molecule’s ability to stack or congregate. Determining the monomers’ ability to form excimers can help with determining their ability to pack when in the polymer form. The synthesis of both pyrene diimide isomers will be presented with their fluorescence spectrum, which demonstrate excimer formation at higher concentrations.

Enhancing Adhesion of PEDOT Coatings on Metal Electrodes: A Promising Approach Sara Ebrahimie, Fabio Cicoira and Sadaf Khoomortezaei; Polytechnique Montreal, Canada

The use of electrodes as biomedical devices in healthcare is undergoing innovative advancements, employing novel techniques that bridge the gap between biological systems and electronics. Nonetheless, traditional metallic electrodes encounter a substantial hurdle in the form of impedance, impeding the smooth transmission of electrical signals within living tissues. To tackle this challenge, recent breakthroughs suggest the utilization of poly(3,4-ethylenedioxythiophene) (PEDOT), an organic conducting polymer, as a solution to overcome the impedance obstacle [1]. PEDOT exhibits favourable qualities that make it an excellent candidate for bioelectronic devices. These desirable characteristics include its ability to maintain low impedance, high conductivity, excellent electrochemical stability, and biocompatibility, rendering it an optimal material for such applications [2]. When left uncoated, copper electrodes are susceptible to rapid oxidation, which challenges their direct compatibility with a PEDOT coating. To address this limitation, we propose applying nickel-phosphorus and gold/nickel-phosphorus layers onto the copper electrodes (Au-Ni-P/Cu). This coating approach helps overcome the compatibility between the electrodes and the PEDOT material [3]. Afterward, the process involves depositing PEDOT onto the surface of the electrodes. The primary goal is to develop cutting-edge biomedical electrodes that exhibit enhanced conductivity, minimized impedance, and improved mechanical adhesion to the underlying metal substrate. However, it has been observed that PEDOT does not adhere adequately to the metal substrates [4]. In this work the main strategy employed for enhancing adhesion is etching the substrate. The Ni-P/Cu electrodes were prepared through electroleo plating, and applied gold and PEDOT layers onto the Cu electrodes. The deposition of PEDOT onto the electrodes was achieved using galvanostatic chronopotentiometry (CP) electropolymerization, gradually transforming the electrodes into a dark blue colour. The chronoanoperometric method yielded PEDOT films that were uniform and consistent across the electrodes. To analyze and characterize the PEDOT coatings on both Ni-P/Cu and Au-Ni-P/Cu electrodes, several techniques were employed, including electrochemical impedance spectroscopy (EIS) and cyclic voltammetry (CV) in a phosphate-buffered saline solution (PBS), X-ray photoelectron spectroscopy (XPS), and scanning electron microscopy (SEM). The adhesion of the coatings to the substrate was evaluated through sonication and a tape test, demonstrating their robustness and strong adherence. Furthermore, the electrochemical and mechanical stability of the PEDOT material, doped with LiClO4, on the metal electrodes was successfully demonstrated by optimizing the conditions of the electro-polymerization process and pre-treatments of the substrates.

Enhancing Adhesion of PEDOT Coatings on Metal Electrodes: A Promising Approach Sara Ebrahimie, Fabio Cicoira and Sadaf Khoomortezaei; Polytechnique Montreal, Canada

Advanced in Operando Atomic Force Microscopy Studies of the Gating Mechanisms at Metal Oxide Ion-Gated Transistors Luis P. Camargo1,2, Lariel C. Neres1,3, Martin S. Barbosa4, Ramin Karimi1, Jose R. Herrera1 and Clara Santato1; 1Polytechnique Montreal, Canada; 2State University of Londrina, Brazil; 3State University of São Paulo (UNESP), Brazil; 4Federal University of Goias, Brazil

Characterization of interfaces by advanced techniques in operando, including Atomic Force Microscopy (AFM), are gaining significance in the scientific investigation of electrochemical devices since they permit to follow materials’ dynamics, which in turn are linked to device performance. Ion-Gated Transistors (IGTs) enable the modulation of electronic conductivity in a semiconducting channel upon the application of an electrical bias between the channel material and the gate electrode, through an ionic medium. Metal oxides such as WO3 and TiO2 as channel materials interfaced with ionic liquids, possibly including Li ions, by AFM, force-distance profiling. The aim of the study is to shed light on phenomena and processes such as ion layering, ion packing density and shrinking, and ion reorientations. Scanning probe studies have been paralleled by computational efforts (Molecular Dynamics, MD). AFM force-distance profiling in conjunction with simulation methods, allows the characterization and understanding of the structure of the EDL and its evolution with the applied bias, thus permitting optimizing device performance.
Investigating Doping/Dedoping Processes in Electropolymerized Organic Mixed Ionic-Electronic Conductors Meijing Wang1, 2, Janine Mauzeroll2 and Fabio Cicoira1, 3, Polytechnique Montréal, Canada; 2McGill University, Canada

Organic electrochemical transistors (OECTs) based on organic mixed ionic-electronic conductors (OMIECs), which possess both electronic and ionic transport capabilities, have shown promising application potentials in bioelectronics. 3 OECTs utilize the reversible doping/dedoping properties of active OMIEC channel materials by applying a gate voltage across the electrolyte to modulate the channel conductance. 3 Although there has been extensive research to understand the working principle which involves mixed ionic and electronic transport, the study on the fundamental understanding of ionic transport and injection/ejection is still limited. For example, in one of the model OMIECs, poly(3,4-ethylenedioxythiophene) (PEDOT) doped with organic polyanions poly(styrenesulfonate) (PSS), the doping mechanism is believed to be mainly due to the insertion of cations from the electrolyte to the PEDOT:PSS film. However, when small anion-based dopants, such as ClO4- and BF4-, are used in the PEDOT system, the anions may be released from the material to the electrolyte. 5 The doping/dedoping mechanisms are therefore becoming more complicated. To better understand these doping/dedoping processes, we utilized an in situ film fabrication method, electropolymerization, to prepare PEDOT-based films with various dopants, such as PSS, ClO4-, and BF4-. This approach allows the material properties to be better adjusted by controlling the dopant type, dopant concentration, and other electropolymerization parameters. 3

The polymer films were deposited on the source and drain electrodes and grow gradually to cover the gap in between. The effects of dopant type, concentration, and deposition time on the performance of OECTs were systematically studied. Next, the electrochemical quartz crystal microbalance (EQCM), which can monitor the mass exchange between the film and electrolyte, was incorporated to explore the doping/dedoping behavior. Our work contributes to a deeper understanding of the ionic charge transport in small anion-doped OMIECs and the working mechanism of corresponding OECTs.

Side chain engineering of polar hydrophilic substituents on the mixed conductor backbones has been proved as a successful strategy in developing robustbioelectronic devices, including organic electrochemical transistors (OECTs). However, prevailing design principles rely heavily on the ethylene glycol moiety, limiting the ability to tailor chemistry to serve the vast application scope for OECTs. In this work, we report a family of carboxylic acid functionalized polythiophenes, poly-[3-(4-carboxyalkyl)-thiophene-2,5-diy]-, processing with a varying carboxyalkyl chain lengths (propyl, butyl, and pentyl) as a novel hybrid alkyl-polar side chain moiety. With the aid of a fully aqueous processing strategy, this family of material provides an opportunity for a comprehensive evaluation of both the length effect of alkyl spacer and the impact of carboxylic acid functionality on the electrochemical characteristics in aqueous environment. Our results show that longer alkyl spacers in carboxylic acid functionalized side chain yield disadvantages for achieving higher volumetric capacitance (*), however, significantly reducing detrimental swelling, with 3P3PeiT exhibiting a thickness change upon passive swelling of only +1.9%. By integrating these high-performance mixed conductors into planar OECT architectures, it has been found that polymer bearing with butyl spacer exhibits the highest performance (=128.6 6.5), which render them as one of the best performing conjugated polyolelectrolytes. By integrating these high-performance mixed conductors into both interdigitated and planar OECT architectures, material dependent properties were evaluated, including device performance and stability as well as geometry dependent effects. Furthermore, in-situ Raman spectroscopy and doping/dedoping studies are also conducted which provide meaningful insights into structural reorganization and optical progression upon electrochemical doping/de-doping, yielding a molecular level understanding toward ionic-electronic coupling and device operation upon varying side chain length. Overall, through these extensive and methodical investigations, we were able to uncover distinct properties associated with the increased alkyl length in these carboxylated polythiophenes. Our study highlights that even minor alterations and structural variation in the side chain can have a significant impact on electrochemical, optical, microstructural, and electrical properties of a polymeric mixed conductor.
machine learning models were trained to predict the transistor performance. Gaussian Process Regression (GPR) algorithms tuned by Bayesian optimization showed the best predictive accuracy amongst the trained models, which enables narrowing down of the combinations of experimental parameters and investigation of the degree of vertical phase separation under the predicted parameter space. Our technique can serve as a guideline for elucidating the underlying complex parameter-property-performance correlations in solution-based thin-film processing, thereby accelerating the optimization of various thin-film devices in the future.

Vertical-Structure Improves The Strain Limit of OMIEC-Transistors Shilei Dai, Zhongrui Wang and Shiming Zhang; The University of Hong Kong, Hong Kong

Organic mixed ionic-electronic conductors (OMIECs), also known as organic mixed conductors, such as PEDOT:PSS, are becoming increasingly important materials in various applications. One typical application is the development of organic electrochemical transistors (OECTs), which enable high sensitivity at low power consumption. PEDOT:PSS OECTs find significant applications in diverse fields, including brain-machine interfaces and ubiquitous wearable biosensing.

To enhance the robustness for skin-integrated applications, stretchable OECTs (sOECTs) have been developed [1]. However, most sOECTs require OMIECs films to possess good mechanical properties, which limit their use in this emerging area.

In this study, we introduce the design of vertical sOECTs [2]. The unique vertically sandwiched structure between the source, OMIEC channel, and drain electrodes enables significantly higher stretchability, surpassing the strain limit of OMIECs. sOECTs developed with this design can be stretched in arbitrary directions, making them suitable for a wide range of skin-interfaced bioelectronic applications.

Dual Gate Electrochemical and Transistors and Inverters based on WO3 for Improved Transconductance and Dynamic Response Luis Pereira1,2; 1FCT NOVA, Portugal; 2AlmaScience, Portugal

Electrolyte-gated transistors (EGTs) and electrochemical transistors (ECTs) have received special attention over the last decade due to their advantages, deriving from using electrolytes as gate dielectrics. These include low operating voltages, printability and solution processability, low contact resistances, and the possibility of fabricating new device architectures. High driving currents due to electric double layer (EDL) capacitance (C DL ) in EDL transistors (EDLTs) or 3D-channel formation in ECTs, complement the list and open routes for their application in biosensors, electrochemical logic gates, wearable electronics, or low-power consumption and flexible devices.

This work shows a novel architecture of ECTs based on the electrochromic material WO3. Introducing a fourth electrode behind the channel (Back-electrode -BE) stabilized drain current, as electrons can be channeled into the active layer for electrochemical reactions. Additionally, control over the ion movement in the channel and the electrolyte and, consequently over the occurring redox reactions is possible. As a consequence thereof, it was found that Von can be controllable through the applied voltage at the BE (VBE ) and that VOn can be shifted from any negative VG up to 0 V and possibly beyond.

The devices can be ‘programmed’ to work in normally-off (enhancement) or normally-on (depletion) mode. On-Off ratios of 105 and transconductances of 0.35 mS were achieved. Dynamic characterization with an asymmetric square (VG between -6 and 4 V) wave potential demonstrated On-Off ratios of 4 orders of magnitude for frequencies up to 1 Hz. Data suggests that the cut-off frequency lies way beyond that value. It was demonstrated that with precise control over VOn, electrochemical logic inverters with two identical devices are feasible, presenting very high and controllable gains. The possibility of keeping load and driver transistors respectively at normally-on and normally-off makes transistor sizing redundant. Further, with this transistor architecture, problems like small logic swings or small noise margins, usually related to enhancement-load inverters, can be counteracted.

Unraveling The Critical Hydration Effect on Size-Dependent and Ion-Specific Ion Pairing Inside Sub-1nm Graphene Nanoslits Fan Feng, Zhe Liu and Dan Li; The University of Melbourne, Australia

The intriguing phenomena of ion pairing and salt aggregation inside two-dimensional nanoslits have recently been reported in experiments and numerical simulations, leading to the anomalous gate-voltage modulated ion transport and memoresistive properties. An in-depth grasp of the intricate mechanisms governing this ion pairing effect is imperative for engineering advanced materials with specific functionalities and heightened performance. Nevertheless, despite extensive investigations into the dielectric properties of confined water and its confining medium, a unified understanding of how ion-pairing effects are governed by the interplay of hydration effect and nanoconfinement has remained elusive.

This study delves into this ion pairing effect within sub-1nm graphene nanoslits and offers a novel insight into the mechanisms driven by hydration effects. Conducting atomic-level molecular dynamics (MD) simulations of alkali ion electrolytes within multilayered graphene membranes, we unveil a nuanced dependence on slit size and ion-specific behaviors influencing the ion pairing phenomenon, which are confirmed in our experiments. Furthermore, we conclude that the complicated dehydration and renormalization processes primarily determine the propensity for nanoconfined ion-pairing effects, by displaying a comprehensive analysis of the structural and energetic characteristics of water molecules within the hydration shells. We validate this mechanism by elucidating both slit-size and ion-specific effects: as the slit size decreases from 1nm to 7 Å, the structure of the hydration shell becomes increasingly ordered, resulting in a corresponding reduction in entropic free energy; on the other hand, the ion-specific effect is driven by distinct enthalpic changes associated with the formation of larger ion clusters, rather than the mere presence of individual ion pairs.

Ultrafast Dynamics of n-Type Organic Mixed Ionic-Electronic Conductors for Photoelectrochemical Transistor Applications Christopher E. Petoukhoff1, Victor Druet1, Latifah Almullah1, Nisreen Alshehri1, Catherine De Castro1, Sophie Griggs2, Maryam Alsufyani2, Iain McCulloch2, Sahika Im1 and Frederic Laquai1; 1King Abdullah University of Science & Technology (KAUST), Saudi Arabia; 2University of Oxford, United Kingdom

Conjugated polymer-based mixed ionic-electronic conductors (OMIECs) have been widely employed as the active materials in the channel of organic electrochemical transistor (OECT) devices, which are ideal for electronic devices in aqueous media. Due to their ease of chemical functionalization, tunable softness, and flexibility, polymer OMIECs are uniquely suited for biological applications, where OECT devices are expected to play a major role. Although the photosensitivity of conjugated polymers has been widely studied and applied for solar cells, photodetectors, and photocatalysts, the light-sensitivity of polymer OMIECs has been largely underexplored in OECT devices. While there have been several reports on light-sensitivity of organic photoelectrochemical transistors (OPECTs) employing OMIECs, these have largely relied on incorporation of additional light-
sensitive inorganic materials at the gate terminal. Very recently, we have demonstrated that a single n-type OMIEC can serve as the photoactive material in OPECT devices, without additional materials in the gate terminal [1]. We then demonstrated for a variety of different n-type OMIEC polymers that the intrinsic photosensitivity of the polymer is critically important for achieving large open circuit potentials, which must be balanced against the transconductance for the best performance of OPECT devices [2].

In this breaking news contribution, we discuss the origin of the photosensitivity of five different OMIECs. We combine doping-induced absorption (DIA), femtosecond transient absorption (TA), time-resolved photoluminescence (TRPL), and time-resolved THz (TRTS) spectroscopies to investigate the excited state dynamics. We compare the photoexcited species in dry, intrinsic OMIEC films and demonstrate that the instantaneous formation of intramolecular charge transfer (ICT) excitons is largely responsible for facilitating charge dissociation at interfaces, such as either at the ITO or electrolyte interface. We demonstrate that the exciton lifetime plays a critical role in determining the open-circuit potential of photoelectrochemical cells. However, the responsibility of OPECT devices is balanced by the dark transconductance, which is orders of magnitude larger for self-doped polymers, having conductivities on the order of 190 ohms-per-cm. Finally, we show that the exciton-to-charge conversion process is faster when the OMIEC is immersed in electrolytic solutions, which we attribute to the increased dielectric constant of the medium.

Navigating The Complex Hole-Transport Material Additive Cocktail: Doping Methodologies for Small-Molecule HTMs Benjamin Vella, Madeleine McRoberts, Graeme Cooke and Pablo Docampo; University of Glasgow, United Kingdom

Most organic molecular hole transporters used in perovskite solar cells require effective doping to reach conductivity values necessary to achieve maximum device efficiencies. This is typically achieved by incorporating a cocktail of additives including tert-butylpyridine, ionic salts (LiTFSI, Zn(TFSI)) and metal complexes (FK209) which results in the partial oxidation of the semiconducting material, introducing additional free holes within the HTL and thus providing effective hole transport. However, a detailed study of the relationship between doping level and the quantity of free holes within the matrix has not been carried out. Indiscriminately adding the same additive cocktail to different HTM systems can lead to sub-optimal doping and an excess of reactive substances within the film that can catalyse degradation mechanisms. In this study, we investigate a range of HTMs possessing amide or imine linker groups. Our research highlights that oxidation and doping are not synonymous, and while oxidation generally leads to doping, this is not always the case. In addition, we reveal the intricate relationship between the different additives and the doping mechanism as a function of the chemical structures used. We conclude that a ’one size fits all’ approach to HTM doping can lead to the misdiagnosis of effectively oxidised molecules, and therefore propose spectroscopic techniques to monitor the efficacy of doping, promoting rational HTM design and expediting the characterisation of new HTMs.

Regioregularity Effects on Mixed Conduction in a Glycolated Polythiophene Dilara Meli1, Ella Kelly2, Joshua Tropp1,2, Ruiheng Wu1 and Jonathan Rivnay1,2; 1Northwestern University, United States; 2Kalamazoo College, United States; “Texas Tech University, United States

Organic mixed ionic/electronic conductors (OMIECs) are a versatile class of materials that have found use in a wide variety of applications, from bioelectronics to neuroropic computing. Much effort has been devoted in recent years to improve OMIEC performance, primarily focusing on systematic side chain and backbone engineering. Usually, novel OMIECs are characterized in organic electrochemical transistor (OECT) test beds from which the figure of merit, $\mu C^*$ (mobility × volumetric capacitance), is extracted. $\mu C^*$ is an attractive metric for comparison, as it scales with device dimensions. However, care must be taken to emphasize that $\mu C^*$ is not only dependent on synthetic chemistry, but also processing conditions and operating electrolyte environments.

Most prominent high-performing OMIECs synthesized to date are only available at the lab scale, leading to large batch-to-batch variability. Such issues of replicability further hinder systematic structure-property studies. To this extent, we herein study a commercially available glycolated polythiophene OMIEC, P3MEEET. Previous work on this polymer has revealed strong dependence of $\mu C^*$ on operating electrolyte environment, an effect found to also be molecular weight dependent. It was shown that doping occurred with cation expulsion in KTFSI electrolytes, but via traditional anion uptake in NaCl electrolyte. This had dramatic impacts on charge percolation, which ultimately resulted in large observed differences in mixed conductivity.

To further probe the interplay between microstructure and electrolyte choice, we study regiorandom (RRa) and regioregular (RR) P3MEEET operated in two model electrolytes, aqueous KCl and KTFSI. Surprisingly, we observe little difference in $\mu C^*$ for as-cast microstructures between the RRa and RR polymers. GIWAXS of as-cast RRa films reveals strong lamellar diffraction and DSC shows distinct side-chain melting. RRa P3MEEET is found to preferentially order edge-on, while the RR polymer shows more distinct face-on scattering. We further conduct electrochemical quartz crystal microbalance (EQCM) measurements to probe doping kinetics in both polymers.

Studies of post-processing treatments on other RR glycolated polythiophenes, in particular annealing, have previously been shown to dramatically affect swelling and thus mixed conduction. Here, we find strong dependence of $\mu C^*$ on structural changes when operated in KCl electrolytes, whereas in KTFSI electrolytes $\mu C^*$ appears relatively unchanged given the same post-processing conditions. In particular, annealed RRa polymers in KCl show improved performance, whereas RR polymers exhibit a decrease in $\mu C^*$. For the RRa polymer, this enhancement is primarily driven by an increase in $C^*$ due to annealing, which is in contrast to the RR polymer which experiences a decrease in $C^*$.

In summary, we find that post-processing tunes mixed conductivity differently given differences in polymer regioregularity. However, these effects are also dependent on electrolyte environments, further emphasizing that $\mu C^*$ must be treated as a system figure of merit.
Doped organic semiconductors have proved attractive for future device applications such as thermoelectrics, bioelectronics and spintronics. At low doping levels, coulombic trapping of intercalated counter ions is believed to limit charge transport while at high doping levels conductivity is limited by disorder in the material. However, a more detailed understanding of the couplings between the charge/spin carrying polarons of these materials and their environment remains sought after. Work has been done to understand such interactions in undoped materials by means of field induced Electron Spin Resonance (ESR) and has yielded valuable insight into the intimate couplings between charge, spin and structural dynamics. Here, we extend that work to the study of systems systematically doped in-situ by means of an electrochemical transistor architecture and investigate the effects of interactions between polarons and with the counterions as function of temperature and varying doping levels. We complement the ESR measurements with Nuclear Magnetic Resonance (NMR) characterisation which has been shown to be a powerful technique for characterising ion dynamics in polymeric semiconductors. We therefore use NMR to understand ionic motion and interactions in these systems and explore how they could impact the electronic properties of the material.

Ion Trapping and Induced Ordering of Regiorandom Poly(3-hexylthiophene) upon Repeated Electrochemical Doping Seth Jackson, Rand Kingsford, Garrett Collins and Connor G. Bischak; University of Utah, United States

Conjugated polymer organic mixed ionic electronic conductors (OMIECs) are promising materials for bioelectronics and other electronic devices. How these materials behave with repeated electrochemical doping matters for the stability and longevity of these devices. In this work, we employ a combination of grazing incidence wide-angle X-ray scattering (GIWAXS), UV-vis spectroelectrochemistry, and nanoscale imaging of the ions with photoinduced force microscopy (PiFM) to monitor film morphology changes in regiorandom poly(3-hexylthiophene) (RRa P3HT) when exposing the polymer film to various aqueous electrolytes upon repeated electrochemical doping. When using potassium bis(trifluoromethansulfonyl)imide (KTFSI) as our electrolyte, we see increased ion trapping and an increase in crystalline order in RRa P3HT, as well as the crystallization of TFSI- ions, upon repeated electrochemical doping. Upon thermal annealing at 120 °C after continuous doping of RRa P3HT with TFSI-, we see a significant increase in lamellar stacking intensity compared to the film without thermal annealing. When comparing less chaotropic ions to TFSI-, we see these ions do not order RRa P3HT to the same extent as TFSI-.

Seth Jackson, Rand Kingsford, Garrett Collins and Connor G. Bischak; University of Utah, United States

Improve the electrical, mechanical and adhesive properties of PEDOT:PSS Jianyong Ouyang; National University of Singapore, Singapore

Poly(3,4-ethylenedioxythiophene):Polystyrene sulfonate (PEDOT:PSS) is a popular mixed ion-electron conductor, and it can have important application in many areas. However, its electrical, mechanical and adhesive properties must be greatly improved for the practical application in some areas. Here, I will present some of our methods to significantly improve the electrical, mechanical and adhesive properties. We also demonstrate their application in wearable/flexible electronics.

Tailored Design of Mixed Ionic-Electronic Conductors for both P-Type and N-Type OECTS Mukundan Thelakkat1,2, Adrian Hochgesang1, Andreas Erhardt1, Gert Krauss1, Florian Meichsner2 and Philip Schnode1; 1University of Bayreuth, Germany; 2Bavarian Polymer Institute, Germany

Mixed ionic electronic conductors (MIECs) were designed by various strategies of polymer architecture. For all materials, cyclic voltammetry (CV), spectroelectrochemistry (SEC), ultraviolet photoelectron spectroscopy (UPS), Ultraviolet-Visible (UV-Vis) absorption spectroscopy, and organic field effect transistor (OFET) characterization were carried out and these properties demonstrate the suitability for OECT (organic electrochemical transistor) devices. For p-type OECTs, conjugated polyelectrolytes and their copolymers based on polythiophene family was first designed and studied [1-2]. The concept was extended to hydrophilic polythiophenes carrying different oligoethylene glycol (OEG) substituents [3]. The advantage of the latter class is that cross-linking is necessary to prevent the thin films from delamination. The concept of OEG substitution and the required degree of OEG substitution was further applied in the class of poly(diketopyrrolopyrrole) copolymers using different comonomers [4]. For this, four Polydiketopyrrolopyrroles (PDPPs) with increasing ethylene glycol (EG) content and varying nature of comonomer were synthesized. The studies of these hydrophilic PDPPs in NaCl electrolyte-gated OECTs reveal that a high amount of OEG on the DSP moiety is essential for MIEC. The PDPP containing 52 wt.% EG exhibits a high volumetric capacitance of 338 F cm⁻³ (at 0.8 V), a high hole mobility in aqueous medium (0.13 cm²V⁻¹s⁻¹) and a µc* product of 45 F cm⁻¹V⁻¹s⁻¹. OECTs using this polymer retained 97 % of its initial drain-current after 1200 cycles (90 min of continuous operation). In cell-growth medium, the OECT-performance was fully maintained as in NaCl electrolyte. In vitro cytotoxicity and cell viability assays reveal the excellent cell compatibility of these novel systems, showing no toxicity after 24 h of culture. Due to the excellent OECT performance with a considerable cycling stability for 1200 cycles and an outstanding cell compatibility, these PDPPs render themselves viable for in vitro and in vivo bioelectronics.

For the n-type OECTs, two different classical acceptor motifs diketopyrrolopyrrole (DPP) and thiophylpyrrolodione (TPD) are copolymerized to yield the acceptor-acceptor polymer, Poly(DPP-TPD) [5]. The fundamental design idea is to maximize the electron affinity, thus increasing the ambient stability of the reduced state against oxygen and water while ensuring high ion compatibility through the incorporation of hydrophilic oligoethylene glycol N-substituents. Additionally, a highly planarized polymer structure is anticipated, due to the extended non-covalent interactions (conformational locking) between the carbonyl oxygen and the thiophene protons. The acceptor-acceptor system poly(DPP-TPD) for n-type devices exhibit high electron affinity (EA), and good electron mobility (µdoped), in addition to the electrochemical reduction of polymer films in aq. electrolyte. In n-type OECTs, poly(DPP-TPD) demonstrates a moderate threshold voltage of Vth = 0.58 V, and an outstanding µc* value of 7.62 F cm⁻¹V⁻¹s⁻¹. Cycling studies consisting of pulsed on- and off-switching of the device at gate voltages between Vg = 0.6 - 0.8 V in the saturation regime reveal high stability for more than 2700 cycles with rapid switching kinetics.

Mechanically Adaptive Mixed Ionic-Electronic Conductors Based on a Polar Polythiophene Reinforced with Cellulose Nanofibrils Youngseok Kim1, Mariza Mone1,2, Sozan Darabi1,2, Sepideh Zokaei1, Lovisa Karlsson1, Mariavittoria Craighero1, Simone Fabiano4, Renee Kroon1 and Christian Müller1; 1Chalmers University of Technology, Sweden; 2Wallenberg Wood Science Center, Chalmers University of Technology, Sweden; 3Linköping University, Sweden; 4Wallenberg Wood Science Center, Linköping University, Sweden

Conjugated polymers with oligoether side chains are considered as one of the promising active materials for organic electrochemical devices due to their ability to facilitate mixed ionic-electronic conduction in the electrolyte. However, they tend to have a low glass transition temperature and, consequently, a low elastic modulus, which prevent their use if mechanobut materials are required. Carboxymethylated cellulose nanofibrils (CNF) are found to be a suitable reinforcing agent for a soft polythiophene with tetraethylene glycol side chains. Dry nanocomposites feature a Young’s modulus of more than 400 MPa, which reversibly decreases to 10 MPa or less upon passive swelling through water uptake. The presence of CNF results in a slight decrease in electronic mobility but enhances the ionic mobility and volumetric capacitance, with the latter increasing from 164 to 197 F cm⁻¹ upon the addition of 20 vol% CNF. Overall, organic electrochemical transistors (OECTs) feature a higher switching speed and a transconductance that is independent of the CNF content up to at least 20 vol% CNF. Hence, reinforced conjugated polymers with oligoether side chains facilitate the design of mechanically adaptive mixed ionic-electronic conductors for wearable electronics and bioelectronics.

The von Neumann architecture was designed for processing tasks serially. The amount of data produced in the present intelligent era renders this architecture unable to keep up. As a result, new solutions, such as neuromorphic parallel computing, are being developed to increase data storage and processing speed. There are concerns, however, about the sizes of the chips composed of synaptic transistors and their parallel computing capacity. In this work, we present the effect of poly (3-hexylthiophene) (P3HT) film thickness on the synaptic behavior and response time of ion-gated transistors (IGTs) based thereon. The P3HT films' thickness varies from 50 to 300 nm. The drain-source current, Ids, and charge carrier mobility increase with thickness, likely due to an increased degree of crystallinity in the films with the thickness. The presence of crystalline domains is expected to increase the de-doping time (time to remove the anions from the p-type P3HT channel). In turn, this increases the transistor response time and permits to achieve rapid switching kinetics.

Engineering Response Time and Synaptic Behavior of Organic Ion-Gated Transistors Through Structural Modifications Ramin Karimi1, Zhaojing Guo1, Afzal-Alamad Dar1, Lariel C. Neres1,2, Patrick Dang1 and Clara Santato1; 1Polytechnique Montreal, Canada; 2State University of São Paulo (UNESP), Brazil

The von Neumann architecture was designed for processing tasks serially. The amount of data produced in the present intelligent era renders this architecture unable to keep up. As a result, new solutions, such as neuromorphic parallel computing, are being developed to increase data storage and processing speed. There are concerns, however, about the sizes of the chips composed of synaptic transistors and their parallel computing capacity. In this work, we present the effect of poly (3-hexylthiophene) (P3HT) film thickness on the synaptic behavior and response time of ion-gated transistors (IGTs) based thereon. The P3HT films’ thickness varies from 50 to 300 nm. The drain-source current, Ids, and charge carrier mobility increase with thickness, likely due to an increased degree of crystallinity in the films with the thickness. The presence of crystalline domains is expected to increase the de-doping time (time to remove the anions from the p-type P3HT channel). In turn, this increases the transistor response time and permits to achieve transition from short-term plasticity (STP) to long-term plasticity (LTP). Further, increasing the thickness of the channel increases the plasticity and paired-pulse facilitation (PPF) index.

The molecular weight (MW) is another parameter that we consider to control synaptic functions and response time. The XRD patterns of films obtained from three different MW, low (ca. 24 kDa), intermediate (ca. 42 kDa), and high (ca. 91 kDa), show that the degree of crystallinity decreases with increasing MW. This is expected to strongly affect ion permeability, and therefore the advancement of doping and redistribution time of anions. In conclusion, we propose a methodology to control the response time and synaptic functions of IGTs with changing P3HT MW at constant film thickness or varying the thickness of channel fixing MW.
Organic mixed ionic-electronic conductors such as poly(3,4-ethylenedioxythiophene):poly(styrene sulphonate) (PEDOT:PSS) have attracted attention as materials for the fabrication of organic electrochemical transistors (OECTs) for bioelectronics. The PEDOT:PSS dispersions are typically blended with (3-glycidoxypropyl)trimethoxysilane (GOPS) before spin-coating to ensure strong adhesion of the films to device substrates and maintain their long-term stability in aqueous solutions. However, blending with GOPS changes the morphology of PEDOT:PSS films, affecting their electrical properties and significantly reducing the performance of OECTs. Here, we functionalized the surface of the substrates with GOPS to introduce a silane monolayer with epoxy groups before spin-coating PEDOT:PSS. The resulting films were compared to those obtained by blending and showed similar long-term stability in aqueous solutions under passive conditions and electrochemical cycling. However, the surface functionalization approach led to increased electronic conductivity (2650 ± 467 S cm⁻¹), higher transconductance (24 ± 4 mS μm⁻¹), and [μC*] value (376 ± 74 F cm⁻¹ W⁻¹ s⁻¹) in OECT devices, and larger volumetric capacitance (109 ± 5 F cm⁻³). Detailed characterization using time of flight secondary ion mass spectrometry (TOF-SIMS), atomic force microscopy (AFM), and X-ray photoelectron spectroscopy (XPS) confirmed that the silane crosslinker was not present in the bulk of the film which allowed an increased phase separation between PEDOT and PSS, and the formation of enlarged PEDOT-rich domains. We expect that this study will strengthen the case for the functionalization of substrates with GOPS instead of the conventional blending approach for the development of stable films in water and high-performance organic mixed ionic-electronic conductors for biological interfaces.

SESSION EL18.07: Theory and Simulations for Mixed Ionic-Electronic Conductors

1:10 PM EL18.07.01
Operando Experiments and Continuum Modeling of Mechanical Breathing and Multiphysics Coupling in Organic Mixed Ionic-Electronic Conductors
Kejie Zhao; Purdue University, United States

Organic mixed ionic-electronic conductors (OMIECs) are the core functioning component in electrochemical devices such as organic electrochemical transistors (OECTs) and bioelectronics owning to their unique capability of mixed conduction. In electrochromic polymers, the cyclic redox reaction is associated with a mechanical breathing strain, which deforms the OMIECs and degrades the device reliability. We measure the breathing strain, the evolution of the mechanical properties of electrochromic thin films, and mechanical damage using customized environmental nanoindentation. Further, we formulate a continuum theory following the thermodynamics framework to describe the concurrent transport of charge carriers, mechanical swelling, and phase separation in the OMIEC. The free energy consists of contributions from the deformation of the polymer chains, the mixing of the polymer with salts and solvents, the electrostatic field, and the two-phase interfaces. We implement the theory into a finite element model and study the mechanics and electrochemistry of the OMIEC channel in an electrolyte-gated OECT. The computational model replicates the electrochemical performance of an OECT which agrees well with the experiments. Overall, this work provides a basic understanding of electrochemical and mechanical behaviors of organic mixed conductors.

Modelling the Performance of a Novel Mixed Ionic-Electronic Conductor Based on SmCoO3
Nora H. de Leeuw; University of Leeds, United Kingdom

One of the main challenges facing solid oxide fuel cell (SOFC) technology is the need to develop materials capable of functioning at intermediate temperatures (500-800°C), thereby reducing the costs associated with SOFCs. Here, a novel SOFC cathode material is presented, predicted through a holistic approach of a combination of complementary computational techniques to optimise the material properties. This approach is transferable to any material optimisation problem and allows the effect of A/B-site doping to be understood, on the scale of the individual property, but also the device as a whole. The electronic, magnetic, and physical properties as well as the thermal behaviour of Sm0.75A0.25Co1-xMnxO2.88 (A = Ca, Sr; x = 0.125, 0.25) is systematically described, showing important trends and correlations that are directly coupled to its potential practical application in sustainable energy generation. The magnetic and electronic structures of these materials were directly coupled to the electronic conductivity, a finding that is applicable to other perovskite systems and to the wider energy materials community. Furthermore, evaluating the ionic conductivities of Sm0.75A0.25Co1-xMnxO2.88 (A = Ca, Sr; x = 0.125, 0.25), a distinct improvement is identified in comparison to both SmCoO3, and the traditional cathode material strontium-doped lanthanum manganate. By coupling the electronic and ionic conductivity properties to the thermal expansion coefficients, we have shown that this material is compatible with traditional SOFC electrolytes. Combining all these insights from density function theory calculations and molecular dynamics simulations strongly suggests that Sm0.75A0.25Mn0.25Co0.75O2.88 possesses the necessary properties that are desirable in an efficient intermediate temperature SOFC cathode material.

Proton and Small Polaron Association and Migration in H₂V₂O₇, H₂Ta₂O₇, H₂MoO₇, H₂WO₄
Pjotrs Zguns and Bilge Yildiz; Massachusetts Institute of Technology, United States

Neuromorphic computing based on electrochemical random access memory (ECRAM) enables low-energy computing and nanosecond timescale operation [1–3]. The nanosecond switching relies on fast proton and small polaron diffusion in the working channel materials, transition metal oxides. Here we investigate the fundamental limit of mixed proton–polaron diffusion in H₂V₂O₇, H₂Ta₂O₇, H₂MoO₇, and H₂WO₄ by means of first-principles calculations. We apply the DFT+U method to describe the electronic structure and polaron localization and polaron association in the host oxide lattice. By investigating various spatial arrangements of these defects, we identify the ground state configuration of the proton–polaron. We probe microscopic factors that control carrier mobility, viz. the migration barriers and proton–polaron association energy (i.e., the energy required to break the pair). Our results indicate that the polaron migration barrier is comparable to the association energy in V₂O₇, on the order of 0.1 eV–0.2 eV, highlighting that the attraction between polarons and protons plays an important role in diffusion. Altogether, these computations will help us to identify the most suitable oxide for nanosecond switching of ECRAM devices.

References
Organic mixed electronic and ionic conductors based on conjugated polymers with polar side chains are attractive candidates for electrodes in electrochemical devices. Their electrochemical and redox properties can be tuned through choice of polymer backbone and side chain [1, 2] while the processible nature of the polymer materials facilitates both manufacture and recycling. When applied as electrodes in electrochemical energy storage devices, conjugated polymer electrodes show excellent charging and discharging rates, high coulometric efficiency and compatibility with simple aqueous electrolytes. However, their specific capacity and their operational stability need to be improved [3]. In this work, we use electrochemical measurements and modelling to investigate the relationship between polymer chemical structure and the redox properties, charging behaviour and cycling stability of the polymer electrodes. We focus on the effect of side chains, since small changes in side-chain composition or structure can significantly influence the electrode properties. We use molecular dynamics simulations for series of polymers, to investigate how the side chain polarity influences polymer packing [4]; how the composition of mixed polar and non-polar side chains influences film swelling and stability; how backbone and side-chain structure influence electrode properties. We use molecular dynamics simulations for series of polymers, to investigate how the side chain polarity influences polymer packing [4]; how the composition of mixed polar and non-polar side chains influences film swelling and stability; how backbone and side-chain structure influence electronic transport properties; and how polymer-ion interactions depend on the ion type. Finally, we consider design strategies for enhancing specific capacity. The findings can help to develop chemical designs for improved conjugated polymer electrodes for aqueous environments.

In-Plane Orientation of Organic Mixed Ionic-Electronic Conductors to Enhance Charge Transport Properties [Isabelle Holzer1, Demetra Tsokkou1, Shubhadrup Guchait2, Badr Jismy2, Martin Brinkmann2, Nicolas Leclerc2 and Natalie Banerji1; 1University of Bern, Switzerland; 2CNRS University of Strasbourg, France

Organic mixed ionic-electronic conductors (OMIECs) are perfectly suited to interface biology and electronic devices as they enable both ionic and electronic transport; feature mechanical flexibility; can be successfully fabricated in versatile processing conditions; and are synthetically tunable.1 While most recent progress in bioelectronics has been focused on device fabrication and comparing performance of different materials, there is still a lack of a more in-depth understanding of the fundamental processes occurring in functioning OMIECs.2 The charge transport is happening mainly on the π-conjugated backbone of the organic semiconductor, while ions penetrate the bulk material. In PBTTT, a polymer with high charge-carrier mobility, ion uptake in the polymer matrix can be facilitated by incorporating alkyl side chains with an ether group, further improving the performance.3,4 Therefore, in this study we use high temperature rubbing to orient PBTTT-20 films helping to unravel the fundamental processes of both the charge and ion transport. For comparison the same experiments were carried out with an OMIECs model material P3HT, which was already characterized by multiple different research groups.5 Combining electrochemical and chemical doping with spectroscopic techniques and chronoamperometry the oxidation behavior of the OMIECs was investigated. Foremost, with in-situ terahertz (THz) spectroscopy we can detect the scattering frequencies of charge carriers in semiconductors, this allows us to get the intrinsic nanoscale conductivity and short-range mobility of the studied OMIECs, which is not affected by any grain boundaries or electrodes. The analysis of the complex THz conductivity unveils the mobility and density of charges altogether. We were able to get conductivities of more than 1000 S cm⁻² for P3HT and PBTTT-20 for electrochemical doping. Furthermore, with chemical doping conductivities of more than 2000 S cm⁻² were obtained and band like transport behavior was observed for PBTM-20, showing the large effect of high in plane orientation of OMIECs.

Influence on the Performance of Organic Electrochemical Transistors of PEDOT:PSS Blends with Polyethylene Oxide of Different Molecular Weight [Chun-Yuan Lo1, Lucas Flagg2 and Laura V. Kayser1; 1University of Delaware, United States; 2National Institute of Standards and Technology, United States

The addition of polyethylene oxide (PEO) to organic mixed ionic-electronic conductors, such as PEDOT:PSS, is commonly done to improve biocompatibility, hydrophilicity, or stretchability. In particular, when blended with PEDOT:PSS, PEO has been shown to change the microstructure of the thin films. In this study, we were interested in the effect of PEO on mixed ionic-electronic transport properties, particularly when the films are immersed in aqueous solutions such as for organic electrochemical transistors (OECTs). PEO is water soluble and therefore could easily leached out of the films when immersed in water or an aqueous electrolyte. We studied PEO of two different molecular weights (MW), 400 Da (low MW) and 20,000 Da (high MW), in
PEDOT:PSS:PEO blends at 5 8\% PEO in solution, and crosslinked with GOPS. We monitored the composition of the spin-coated films by X-ray photoelectron spectroscopy (XPS) over a period of 4 hours of immersion in water. We found that most, if not all low MW PEO is removed from the films after 2 hours of immersion, while for high MW PEO, nearly 50\% was still present in the films with a stable concentration after 1-2 h. In both cases, we noted the removal of excess PSS in the films, which is common for PEDOT:PSS immersed in water. The removal of PEO and PSS following water immersion was also confirmed by a significant reduction in film thickness, as measured by profilometry and atomic force microscopy. We then performed transconductance measurements on OECT devices to extract the mobility-capacitance product, \( \mu C^* \), of our PEDOT:PSS formulations. In all cases, without PEO, or with low or high MW PEO, the transconductance increased significantly after immersion in water, consistent with the removal of insulating material. What was more surprising, however, was a much higher \( \mu C^* \) when low MW PEO was used as an additive and then removed by soaking in water. The \( \mu C^* \) values obtained, which have yet to be validated externally, are higher than those obtained when doping with ethylene glycol and close to that of previously reported crystalline PEDOT:PSS obtained by sulfuric acid treatment. We are still exploring the exact reasons for this increase, but it seems to stem from both an increase in the charge mobility and volumetric capacitance (up to 129\%\ F cm\(^{-3}\)). GIWAXS measurements did not indicate a change in film crystallinity, but spectroelectrochemistry revealed a higher charge density which is consistent again with the removal of PSS and PEO from the films. This study provides an avenue towards improving the performance of PEDOT:PSS electrodes without using sulfuric acid. We also hope to encourage others to study the fate of polymeric additives and small molecules in devices operating under aqueous conditions.

Phase Separation in Mixed Ionic and Electronic Conductors for Information Storage

Yivang Li; University of Michigan, United States

Mixed ionic and electronic conductors (MIECs) enable vast changes in chemical composition induced by electrochemical currents and voltages. This electrochemically-induced change in chemical composition enables a substantial chemical capacitance, which can be harnessed for energy storage and emerging microelectronic devices. This change in composition can yield phase transformations and spinodal decomposition in MIEC materials due to materials thermodynamics. In this presentation, we show how this phase separation in metal oxide MIECs enables the coexistence of multiple physical states that are identical in energy. By switching between these physical states, we can provide a thermodynamically nonvolatile form of information storage. We demonstrate this phenomenon in two types of memory cells: resistive memory and electrochemical memory. We anticipate that phase separation can be broadly generalized to other forms of MIECs.
Organic mixed ionic and electronic conductors (OMIECs) are a novel material class, emerging as potential enablers for devices as diverse as actuators, biosensors and neuromorphic computing. In an OMIEC, volumetric doping (gating) of the active material is achieved through ingress of electrolyte ions, under potential control. This opens unique transduction modalities due to the mixed (ionic and electronic) modes of conduction. However, the complex changes in film structure: swelling by both electrolyte and counter ion coupled with electrochemical doping, requires in-situ and in-sensando measurements to develop quantitative process-structure-function relationships. Side-chain modification, typically by the introduction of oligoethylene glycol (oEG) units, of traditional semiconducting polymers, has emerged as a powerful paradigm for OMIEC material design. We have applied in-situ grazing incidence X-ray diffraction (GIXD) to the study of oEG modified polythiophenes, p3MEEMT[1], pg(3T2) and pg(1T2-g5T2). [2] All are regio-random, but differ in terms of the length of the oEG side chain (2 units for P3MEEMT, 3 units for pg(3T2), and up to 5 units for pg(1T2-g5T2)) and in repeat unit symmetry. While the optoelectronic properties of these polymers are similar, consistent with the common backbone, the swelling behavior of the polymers were notably distinct. With moderate thermal annealing, all polymers exhibit semicrystalline behavior, typical of polyniophenes, with an edge-on habit of pi-stacked lamella. When characterized in-situ we find a remarkable disordering of the pg(3T2) in the neutral, dedoped state. Effectively no diffraction can be observed. However, a degree of order comparable to that observed ex-situ (dry) is obtained upon doping. This severe doping induced ordering is similar to that observed in doped regio-random P3HT[3] and is consistent with the enhanced pi-pi interaction (evidenced by a decrease in the interchain separation) typically observed for doped polyniophenes. This electrolyte induced “melting” is also present in the asymmetric sidechain p(g1T2-g5T2) but is absent in the shorter side chain polymer. While significant effort has been placed on characterization of swelling in OMIECs, the observation of nominal melting of semicrystalline material has not been extensively discussed and may limit the oEG content. In general, order within the polymer is considered important to electronic transport [4] thus the doping induced ordering may be essential to the final device performance.

Tailoring Organic Semiconductors for Mixed Ionic and Electronic Transport
Christian Nielsen, Queen Mary University, United Kingdom

The emerging research field of organic bioelectronics has developed rapidly over the last few years and elegant examples of biomedically important applications including for example in-vivo drug delivery and neural interfacing have been demonstrated. The organic electrochemical transistor (OECT), capable of transducing small ionic fluxes into electronic signals in an aqueous environment, is an ideal device to utilise in bioelectronic applications. Initially, nearly all OECTs were fabricated with commercially available PEDOT:PSS, heavily limiting the variability in performance. We have previously shown that tailor-made semiconducting polymers are fully capable of matching the performance of PEDOT:PSS and over the last few years the library of mixed ionic-electronic polymers for OECT applications have expanded significantly. To capitalise on this development and the versatility of the organic chemistry toolbox, further materials development is needed. In my talk I will discuss our recent work in this area covering examples of both molecular and polymeric semiconducting materials and their performance in organic electrochemical transistors.

4:00 PM EL18.09.05
Nanoscale Mapping of Ions, Polarons and Bipolarons in Organic Mixed Conductors
Seth Jackson, Garrett Collins and Connor G. Bischak, The University of Utah, United States

Organic mixed ionic-electronic conductors have emerged as promising materials for biosensors, bioelectronics, neuromorphic computing, and electrochromics. These technologies all operate based on electrochemical doping of organic mixed ionic-electronic conductors, which are most commonly conjugated polymers. The locations of ions, polarons, bipolarons directly impact how electronic charge carriers move through the OMIEC matrix. Using photoinduced force microscopy (PiFM) with visible, near-infrared, and infrared wavelengths, we generate maps of ion, polaron, and bipolaron densities with ~10 nm spatial resolution. In poly(3-hexylthiophene), we demonstrate using a combination of UV-vis spectrophotometry, in-situ X-ray scattering (GIWAXS), nanoscale stiffness mapping, and PiFM, that ions and polarons reside preferentially in crystalline regions. We extend these initial studies to other OMIEC polymers with oligo(ethylene glycol) side chains to visualize the arrangement of ions, polarons, and bipolarons in the polymer matrix.

Effect of Backbone Linearity on Mixed-Conductance in New Pyrene Dianhydride-Based Conjugated Ladder Polymers
Julia A. Schneider, Katherine Johnston, Emma Mikita and Emil Jaffal; Fordham University, United States

We report the synthesis of a new organic n-type ladder conjugated polymer, poly[benzimidazobenzophenanthroline (BPyL)], for applications utilizing mixed ionic-electronic semiconductors. This pyrene-based ladder polymer is an exciting core-expansion of the high performing naphthalene-based polymer, poly(benzimidazobenzophenanthroline) (BBL), but unlike BBL, it allows for structural variety in the conjugated backbone. Electronic charge transport and ion diffusion in organic conjugated polymers are both dependent on interchain interactions, yet maximizing these processes equally is a significant challenge toward achieving mixed conducance. The crystalline assemblies necessary for charge transport can often limit ion diffusion and hinder the capacitance of the material. While studies have shown that amorphous films perform better due to uniform swelling by the electrolyte, the insertion of conjugation-break spacers or hydrophilic side chains leads to decreased charge transport. With BPyL, we present a new approach for controlling polymer crystallinity by tuning backbone linearity using “linear” and “bent” isomeric monomers. We have synthesized two isomers of pyrene dianhydride for the polycondensation with 1,2,4,5-tetraaminobenzene tetrahydrochloride (TAB.4HCl) into conjugated ladder polymers. By tuning the ratio of pyrene comonomers we can impact film-formation ability and performance. We will present comparisons of BBL and BPyL (linear and bent) via spectro-electrochemical analysis, TEM imaging, electrochemical characterization, and organic electrochemical transistor (OECT) devices.

4:45 PM EL18.09.07
Revealing The Microstructure of Hydrated Conjugated Polymers using Cryogenic Electron Microscopy
Masoud Ghasemi and Enrique Gomez; The Pennsylvania State University, United States

Organic mixed ionic-electronic conducting (OMIEC) polymers have attracted a tremendous amount of attention due to their easy tunability and potential for various applications, such as neuromorphic computing and biosensing. Among different OMIECs, poly(3,4-ethylenedioxythiophene);polystyrene...
sulfonate (PEDOT:PSS) is the most widely used polymeric system due to its commercial availability and ease of processibility as an aqueous dispersion. PEDOT is a p-type conjugated polymer with poor solubility in both polar and nonpolar solvents, hence it is usually processed along with PSS which also serves as a dopant to induce positively charged electronic carriers in PEDOT. It has been shown that both the electronic and mechanical properties of PEDOT:PSS can be modulated through post-processing or the application of different additives. Despite its wide range of applications, the underlying mechanisms behind the improvement in the mechanical properties of PEDOT:PSS in the presence of additives remains poorly understood. In this work, we use cryogenic electron microscopy (Cryo-EM) to investigate micro- and nano-structure of PEDOT:PSS in different hydrated and swollen states. Our results suggest that in a hydrated state PSS rich regions of the PEDOT:PSS swell while the PEDOT-rich phases maintain an interconnected network which highlights the importance of a charge percolation pathway as well as the amorphous phase connectivity to achieve high mobility and stretchable OMIECs. Our findings may pave the way to a deeper understanding of OMIECs and their structure-function relationships.

Monolithic Integration of Single-Crystalline 2D Standalone Circuitry Enabled by Ultra Low Temperature Growth

Jeehwan Kim; Massachusetts Institute of Technology, United States

It is necessary to find a strategy to obtain single-crystalline TMDs on a Si wafer without transfer for seamless integration of TMDs for CMOS technologies. However, so far, epitaxial methods has been an only way to obtain single-crystalline TMDs which requires a single-crystalline hexagonal substrate and transfer them onto the Si wafer. Here my team at MIT has succeeded to directly grow single-crystalline MoS2 and WSe2 on a HfO2-coated Si wafer without needing to have an epitaxial seeding. We geometrically confine the growth of the first set of nuclei by defining selective growth trenches before the second set of nuclei is introduced. By utilizing the edge of trenches as a heterogeneous nucleation site, we were able to grow TMDs as low as at 380 oC which will enable monolithic integration of logic devices on various circuitry. Also, such low temperature direct non-epitaxial singe-crystalline growth methods lay foundations to finally obtain vertically stacked complementary FETs by monolithic integration of MoS2 nMOS on top of WSe2 pMOS.

Area-Selective Atomic Layer Deposition on a 2D Monolayer Lateral Superlattice

Jeongwon Park1, Seung Jae Kwak2, Won Bo Lee2, Yongjoo Kim3 and Kibum Kang4; 1Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of); 2Seoul National University (SNU), Korea (the Republic of); 3Kookmin University, Korea (the Republic of)

Recently, area-selective atomic-layer-deposition (AS-ALD), which allows the direct deposition of target material on the desired area using a deposition barrier, has emerged as an advanced patterning process. In conventional AS-ALD (CAS-ALD), various barriers, including self-assembled monolayers, surface terminations, and inherent selectivity in metal-insulator combinations, have been deployed. Nevertheless, these barriers have not yielded satisfactory results when confronting highly reactive ALD precursors or when handling diverse materials in AS-ALD. Furthermore, CAS-ALD, which selectively deposits materials in predefined regions through top-down patterning, has not successfully reduced pattern sizes beyond the resolution of optical lithography.

In this research, we report a novel superlattice-based AS-ALD (SAS-ALD) using a 2D lateral superlattice as a patterning template. The lateral superlattice is grown by coherent lateral epitaxy of monolayer MoS2 and MoSe2 with chemical vapor deposition (CVD) process. Due to the unique feature of lateral growth in 2D materials, the superlattice is composed of linear patterns of MoS2 and MoSe2. Interestingly, we have discovered that when various materials (Al2O3, HfO2, Ru, Te, Sb2Se3, and TiN) are deposited via ALD on the MoS2-MoSe2 lateral superlattice, they selectively deposit only on the MoSe2 regions, resulting in linear patterns of target materials.

Since the width of linear pattern is determined by the duration time of gaseous CVD precursors, a scaling down is significantly easier compared to conventional patterning methods. As a result, we patterned target materials on the lateral superlattice template with a sub-10 nm half pitch size. Furthermore, unlike CAS-ALD, which controls the chemisorption of ALD precursors, SAS-ALD has a completely new mechanism that utilizes physisorption
differences and diffusions. Through molecular dynamics (MD) simulations and density functional theory (DFT) calculations, we confirmed that the adsorption energy of ALD precursors on 2D transition dichalcogenides (TMDs) is influenced by local strain and curvature of TMDs. Importantly, we observed that the most stable adsorption of the precursors occurs on the compressed MoSe₂ valley region, which has compressive strain and concave surfaces. The computational results were further supported by experimental evidence showing initial nucleation of ALD materials on the compressed MoSe₂ valley region. Based on the physiosorption differences and diffusion of ALD precursors, SAS-ALD has been able to selectively deposit various materials such as Al₂O₃, HZO₂, Ru, Te, SbSe₃, and TiN. Additionally, we successfully achieved Al₂O₃ AS-ALD using a trimethyl aluminum, the highly reactive precursor, and this was possible even at a few nanometer scales. SAS-ALD, based on a novel mechanism, allows for patterning of target materials in a linear shape using a 2D lateral superlattice template. From a patterning perspective, the width is controlled by the duration time of CVD precursor, making scaling down very easy. In addition, in terms of AS-ALD, we were able to effectively fabricate various materials in very narrow patterns. This technology is expected to have even greater potential when combined with guide patterns created through photolithography for precise positioning. Additionally, since SAS-ALD utilized 2D TMDs as pattern templates, we anticipate that various 2D/3D hybrid structures can be created.

Reconfigurable Mixed-Kernel Heterojunction Transistors for Personalized Support Vector Machine Classification Justin Qian¹, Xiaodong Yan¹, Jiuhu Ma², Aoyang Zhang³, Stephanie Liu¹, Matthew Bland¹, Kevin Liu¹, Xuechun Wang⁴, Vinod K. Sangwan⁴, Han Wang⁵ and Mark C. Hersam⁶⁷
¹Northwestern University, United States; ²University of Southern California, United States

The continual increase in the volume of data generated by sensors, robots, and mobile devices poses a challenge for cloud computing centers in terms of power costs, efficiency, accessibility, and scalability. In particular, artificial intelligence (AI) based classification has shown tremendous potential in a variety of applications such as signal processing and image recognition but often has huge data and energy costs due to the underlying von Neumann architecture of complementary metal-oxide-semiconductor (CMOS) chips. In contrast, the use of edge computing to locally analyze and process data has the potential to alleviate the burden on large data centers, while also improving latency, security, and privacy. Because edge computing resources are often limited, edge-based hardware needs to be more power-efficient than conventional graphics processing units (GPUs), application-specific integrated circuits (ASICs), or field programmable gate arrays (FPGAs).

This presentation will discuss edge computing at the device level using a highly reconfigurable mixed-dimensional dual-gated MoS₂/carbon nanotube (CNT) van der Waals heterojunction device achieved in a self-aligned manner. By tailoring the density of electric-field screening through control over CNT density and overlapping heterojunction area, the heterojunction device is shown to generate tunable Gaussian, sigmoid, and mixed Gaussian/sigmoid functions. These heterojunction-generated functions are then used as kernels for support vector machine (SVM) based arrhythmia detection from electrocardiogram (ECG) signals. For a single device, mixed kernels were found to outperform purely Gaussian and purely sigmoid kernels. Bayesian optimization was further used to determine the optimal Gaussian/sigmoid hyperparameters and mixing ratio for a full mixed-kernel library that was generated from the integration of two devices, resulting in exceptionally high classification accuracies. Compared to existing literature on Gaussian transistors and CMOS circuits, our mixed-kernel heterojunction (MKH) transistors show unprecedented tunability in a compact four-terminal geometry with close to two orders of magnitude fewer circuit elements. In this manner, CNT-MoS₂ MKHs have the potential to be widely applicable to SVM classification in diverse wearable and edge applications.

11:30 AM *EL19.01.04
Hexagonal and Amorphous Boron Nitride Thin Films Hyeon Suk Shin; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Hexagonal boron nitride (hBN) is a promising two-dimensional (2D) material owing to its unique optical properties in the deep-UV region, mechanical robustness, thermal stability, and chemical inertness. hBN thin films have gained significant attention for various applications, including nanoelectronics, photonics, single photon emission, anti-corrosion, and membranes. Thus, wafer-scale growth of hBN films is crucial to enable their industrial-scale applications. In this regard, chemical vapor deposition (CVD) is a promising method for scalable high-quality films. To date, considerable efforts have been made to develop continuous hBN thin films with high crystallinity, from those with large grains to single-crystal ones, and to realize thickness control of hBN films by CVD. However, the growth of wafer-scale high crystalline hBN films with precise thickness control has not been reported yet. The hBN growth is significantly affected by substrate, in particular the type of metals, because the intrinsic solubilities of boron and nitrogen depend on the type of metal. In this talk, state-of-the-art strategies adopted for growing wafer-scale, highly crystalline hBN are summarized, followed by the proposed mechanisms of hBN growth on catalytic substrates [1]. Furthermore, various applications of the hBN thin films are demonstrated, including a dielectric layer, an encapsulation layer, a wrapping layer of gold nanoparticles for surface enhanced Raman scattering, a proton-exchange membrane, a template for growth of other 2D materials or nanomaterials, and a platform of fabricating in-plane heterostructures. In addition, amorphous BN (aBN) as a counterpart of crystalline hBN is introduced [2]. Detailed structural characterisation indicates that a-BN, as sp²-hybridised, with no measurable crystallinity, and mechanically robust, with excellent diffusion-barrier characteristics. The aBN thin film shows ultralow dielectric constant (~2.5), indicating great potential for its applications in Cu interconnects of integrated circuits.

SESSION EL19.02: Advances in the Assembly of Van der Waals Heterostructures
Session Chairs: Andrew Mannix and Hyeon Jin Shin
Monday Afternoon, November 27, 2023
Hynes, Level 3, Room 309

1:30 PM *EL19.02.01
Ultraclean Layer Transfer and Atomic Reconstruction in Twisted TMD Lattices Roman Gorbaschev; University of Manchester, United Kingdom

Layer-by-layer assembly of van der Waals (vdW) heterostructures underpins new discoveries in solid state physics, material science and chemistry. Despite successes, all current assembly techniques use polymeric supports which limit their cleanliness, ultimate electronic performance, and potential for optoelectronic applications. In the first part of the talk, I will introduce a polymer-free platform for heterostructure assembly using re-usable flexible silicon nitride membranes. This approach enables production of heterostructures with interfaces free from interlayer contamination and correspondingly excellent (opto)electronic behaviour. In addition, eliminating polymeric supports allows new possibilities for vdW heterostructure fabrication: assembly at temperatures up to 600°C, and in different environments including ultra-high vacuum (UHV) and liquid submersion. We demonstrate UHV heterostructure
assembly for the first time and show the reliable creation of moiré superlattices with over x10 improvement in homogeneity. In the second part of the talk, I will review our recent progress on twisted bilayer TMDs bilayers in the reconstruction regime. I will discuss their atomic structure observed in STEM, which is strikingly different for aligned (R) and anti-aligned (H) TMD monolayer orientations. This difference gives rise to correspondingly different optoelectronic properties, with ferroelectric domains arising in the former case and piezoelectric charge texturing in the latter. I will report our recent investigation of sliding ferroelectricity, and its switching behaviour observed in double gated structures using the electron channelling contrast SEM.

2:00 PM *EL19.02.02
More Magic with Atomic Crystals Jiwoong Park, University of Chicago, United States

Atomically thin crystals, that are grown, combined, and integrated in large scale, can enable novel properties previously unimaginable. Such "magical" properties can span functional dimensions that go beyond widely-explored electronic phenomena, resulting in extreme thermal, photonic, and mechanical properties. In this talk, I will discuss recent examples with such magical properties realized with atomic crystals. First, we demonstrated three atom thick photonic waveguides, named delta-waveguide, that can generate light plane waves that propagate freely along the waveguide plane but confined along the out-of-plane direction. This enables integrated two-dimensional photonics and seamless mode matching with free-beam optics. Second, we demonstrated the fabrication and measurements of wafer-scale atomic crystal membranes on water that behave like a freestanding mechanical film. We discover that these membranes are not flat; instead they self-wrinkle with the wrinkle morphologies following a universal scaling law, as shown by continuum mechanics theory. This enables a tuning of their mechanical moduli over multiple orders of magnitude.

Exploring the Inter-Layer Interactions of 2D Materials with Sub-Angstrom Resolution Modulated Nanoindentation Ryan Khan, Daniel Vizoso, Frank Delrio and Remi Dingreville; Sandia National Laboratories, United States

As the field of 2D materials continues to grow, more intriguing and complex structures will be discovered, increasing the demand for techniques to properly characterize the local nanoscale mechanical properties of all and any varieties of materials. While traditional nanoindentation can measure the in-plane modulus of suspended films over holes, the technique fails to accurately determine the out-of-plane modulus, requiring such large indentation depths that substrate effects cannot be distinguished. We employ modulated nanoindentation with Angstrom resolution (MoNI/AI), a novel technique that enables non-destructive measurements of the out-of-plane elasticity of ultra-thin materials with sub-angstrom level indentation depths. With such high resolution, even atomically thin materials can be examined in their most practical state on any underlying substrate, without erroneous contributions from the substrate. MoNI/AI has been previously used to explore local pressure induced phase transformations only possible in few layer 2D materials. In our work we explored the multi-layer stiffness dependence of deposited graphene and uncovered a peak transverse stiffness in bilayer graphene that was previously unknown. We complemented these findings with MD simulations and other characterization techniques to further elucidate this phenomenon providing a deeper insight of the inter-layer forces and interactions in graphene and other 2D materials.

3:15 PM *EL19.02.05
Electronic and Electrochemical Properties of Moiré Superlattices Daniel K. Bediako; University of California, Berkeley, United States

The formation of moiré superlattices alters the electronic band structure in a manner that is systematically dependent on the interlayer twist angle, but spontaneous strain relaxation has considerable impact on the resulting physics. This talk will focus on the use of four-dimensional scanning transmission electron microscopy measurements to map lattice relaxation in bilayer and trilayer moiré superlattices and how these structural perturbations impact both the correlated electron physics of the materials as well as their interfacial electrochemical behavior measured by scanning electrochemical cell microscopy.

3:45 PM *EL19.02.06
Introduction to the MonArk NSF Quantum Foundry Hugh Churchill; University of Arkansas, United States

The MonArk Quantum Foundry is an NSF program jointly led by Montana State University and the University of Arkansas with a mission to accelerate two-dimensional materials research for quantum technologies. The rapid prototyping and characterization capabilities of the foundry will be used to serve a broad range of collaborators and users interested in the development of 2D materials and devices for quantum technologies. In this talk I will provide an introduction to the goals and capabilities of MonArk, which are centered on robotic and AI-assisted creation, identification, and fabrication of 2D quantum materials and devices. I will provide a status report on the development of these capabilities and an outlook for the collaborator and user program that will begin in 2024.

4:15 PM *EL19.16.07
Upconversion Electroluminescence in Plasmonic Van der Waals Tunnel Diodes Goki Eda; National University of Singapore, Singapore

Plasmonic tunnel junctions comprising van der Waals semiconductor are an attractive platform where the interplay between inelastically tunneling electrons, surface plasmons, and excitons is expected to give rise to novel light emission phenomena. Here, we report observation of peculiar upconversion electroluminescence in van der Waals tunnel diodes comprising a monolayer transition metal dichalcogenide (TMD) in the electron tunneling pathway. The device exhibits bimodal electroluminescence with a broad low energy band and a narrow high energy band. Interestingly, the high energy emission, which is attributed to the TMD ground exciton, is found to turn on at applied biases significantly lower than the threshold defined by its emission energy, whereas the low energy emission, which arises from plasmonic emission, strictly obeys the quantum cut-off. We examine several possible model and show that momentum-indirect excitation of high energy carriers enabled by inelastic electron tunneling is a key component enabling the apparent energy gain.

SESSION EL19.03: Poster Session I: 2D Materials—Liquid-Phase Deposition and Growth
Session Chairs: Kibum Kang and Andrew Mannix
Monday Afternoon, November 27, 2023
Hynes, Level 1; Hall A

8:00 PM EL19.03.02
Various inorganic materials have been identified as potential candidates for high-performance photocatalysts. However, their solar-to-energy conversion efficiencies still fail to meet commercial requirements. The main hurdle is the rapid recombination of photoexcited electrons and holes in single-phase materials. A viable predicted approach to suppress charge recombination is coupling two materials to form a two-dimensional (2D) heterostructure that physically separates photoinduced electrons and holes in different layers. In this work, the heterostructure-based paradigm was tested and a scalable solution synthesis of epitaxial ZnO-MoS2 heterostructure was developed. A 2D ZnO-MoS2 heterostructure was synthesized under hydrothermal conditions by stabilizing intermediate Zn-hydroxide states on a functionalized MoS2 surface. Detailed characterization showed the formation of multilayer heterostructure with MoS2 flakes intercalated between large size ZnO plates. The performance of this heterostructure was evaluated using photocatalytic degradation of rhodamine B. A degradation efficiency of 70% was measured within 90 minutes of visible light irradiation, almost doubling the efficiency of the corresponding single-phase materials or their physical mixtures.

8:00 PM EL.19.03.04
Electrochemically Exfoliated BCN-Cu Nanosheet Electrocatalysts for Efficient Green Hydrogen Evolution: Tuning the Intermolecular Electron Transfer
Naseeh K. Allam; American University in Cairo, Egypt

The search for materials with superior electrocatalytic performance has attracted attention during the past few years aiming to identify a convenient material that works at a low overpotential with long-term stability. Herein, we introduce an innovative technique to fabricate two-dimensional BNC heterostructure nanosheets with various Cu:BCN weight ratios. The fabricated composites showed unique electrocatalytic properties for hydrogen evolution reaction (HER). The morphology and structure of the electrocatalysts were characterized using field emission scanning electron microscopy, Raman, Fourier transform infrared spectroscopy, and X-ray photoelectron spectroscopy techniques. Remarkably, this study reveals the effect of electrochemical chronopotentiometry on facilitating electrochemical exfoliation and hence enhancing the catalytic activity of the fabricated nanosheets. This effect was further confirmed via density functional theory (DFT) calculations, unveiling the effect of the formed oxide layer on the charge transfer process. The overpotential of the 0.125 Cu-BCN composite at a current density of -10 mA/cm2 vs RHE is 50% lower than that of pristine BCN. These findings were also affirmed by the DFT calculations, which showed that incorporating copper on BCN has significantly reduced the G* value of the HER and subsequently accelerates the kinetics of the reaction and the overall catalytic activity of the material.

8:00 PM EL.19.03.05
Predicting Mechanical Properties of Nanocomposites Embedded with Carbon-Based Low Dimensional Materials
Abigail L. Eaton, Marco Fielder and Arun K. Nair; University of Arkansas, United States

Carbon-based low dimensional materials, such as 1D carbyne and 2D cyclo[18]carbon (C18), offer a broad range of material properties that may be beneficial for the development of metal-matrix nanocomposites. However, the interface properties of these carbon-based materials with metal matrix could affect the nanocomposite mechanical properties. Thus, it is important to study the interface properties and perform mechanical testing of the nanocomposites embedded with carbon-based low dimensional materials to determine the most efficient material combinations to improve the mechanical properties. Using molecular dynamics and density functional theory methods, we develop and study the interface properties of carbon-based materials embedded in Cu metal matrix. We focus on the use of 1D carbyne, 2D C18, and 2D C18-carbyne hybrids due to their low dimensionality and range of strength and elasticity. We then conduct uniaxial tensile testing of the nanocomposites to determine if the nanomaterials improve their mechanical properties when compared to single crystal Cu. From the mechanical property prediction and interface analysis, it is possible to determine the nanocomposite that would be most compatible for future development and applications.

8:00 PM EL.19.03.07
Synthesis of Layered Conducting Polymer Electrode for Superior Ultracapacitor Performance
Duy Pham; Kennesaw State University, United States

Ultracapacitors (UCs) are electrochemical energy storage (EES) devices that provide fast charge-discharge capabilities and large storage capacity. UCs are comprised of two electrodes that house an electrolyte solution with a porous separator. Electrochemical double layer capacitors (EDLC) that are comprised of carbon-based materials such as activated carbons have an electrostatic charge storage mechanism, also known as non-Faradic charge transfer. The other well-known UCs are pseudocapacitors that are comprised of conducting polymers or metal oxides and have a redox charge storage mechanism, known as Faradic charge transfer. Currently, pseudocapacitors are thoroughly researched, however, the role of conducting polymer structure and property as a function of the deposition method currently remains limited. In this work, conducting polymer electrodes, polypyrrole (PPy) are synthesized using electrochemical depositions with controlled cycles and their performance is investigated. The UCs will be tested using cyclic voltammetry (CV), electrochemical impedance spectroscopy (EIS), and galvanostatic charge/discharge (GCD) to understand the role between deposition cycles and electrochemical performance. Material characterization such as XRD and FT-IR with surface morphology such as SEM are analyzed to give more insights into charge kinetics between these variations of cycles.

8:00 PM EL.19.03.08
Graphene Based Nanofibrous Scaffold for Embedding Bacteriorhodopsin for Bioengineered Memory Application
Philip Byrne, Evan McCarthy and Isaac Maewing; Fairfield University, United States

The photoactive protein, Bacteriorhodopsin (bR), is being implemented into optical memory applications, most notably for its photochemical and thermal stability. Due to this photochemical stability, bR can remain in one of two stable photostates, bR (ground state) and Q (elevated state), which are used to designate binary bits ‘0’ and ‘1’. The challenge with this phenomenon is that the Q photo state has a low quantum yield, meaning that bR will not absorb enough photons to undergo photoisomerization. To increase the quantum yield of the photocycle, a molecular dynamics simulation involving graphene monolayer and crystal structure of the bR protein was performed to study the adsorption and preservation of the photostates of bR, where it was found that graphene has a potential to increase the quantum yield. However, a major challenge is to have a porous surface with even distribution of graphene nanoparticles to employ it as a scaffold to anchor the bR protein. The porosity of the surface would help anchor the protein onto the surface and the distribution of graphene nanoparticles would ensure proper chemical interactions. Such a porous surface is achieved through electrospinning where nanofibrous scaffold of polyvinyl alcohol (PVA) with graphene nanoparticles is utilized to immobilize the bR protein. Four different scaffolds on aluminum and Indium Titanum Oxide (ITO) surfaces are fabricated with and without graphene having PVA as a common matrix with optimized electrospinning parameters including flow rate, nozzle collector distance, voltage between nozzle and collector, viscosity of the polymer solution and type and configuration of the collector. It is found that the synthesized nanofibers have average diameters of ~200nm with graphene monolayers embedded within the nanofibrous scaffolds. The resulting scaffolds are characterized using scanning electron microscopy (SEM), profilometry and electrochemical impedance spectroscopy (EIS) to quantify its physical and electrical properties and are compared to the control PVA-bR scaffolds without graphene. The
Solar Assisted Expansion of Graphite Flakes for an Effective Exfoliation of Graphene Sheets

Shanavas Shajahan1,1, Rami A. Elkaffas1 and Yarjan Abdul Samad1,2; 1Khalifa University of Science and Technology, United Arab Emirates; 2University of Cambridge, United Kingdom

Synthesis of scalable monolayer or few-layered graphene sheets is challenging due to the complex production processes [1-3]. Liquid phase exfoliation is considered as one of the most feasible techniques to produce industrially scalable [1] defect-free graphene sheets [4,5]. In ultrasonic exfoliation techniques, long exposure (up to 48 hours) [6] of graphene sheets to the ultrasonic waves considerably decreases its lateral size [7], which limits the mechanical and electrical properties of produced graphene sheets [8]. In this study, we successfully achieved the preparation of graphene sheets with high (4-5 mm) lateral sizes through pre-expanding the graphite through solar-assisted expansion process [9]. The graphite flakes with a lateral size of about 600 μm are intercalated with the perchloric acid (HClO4) at 120 °C for 30 min to prepare stage II intercalated graphite (S2IG). In the S2IG, HClO4 is intercalated in between every two layer of graphene sheets, which can be confirmed through Raman analysis [10]. The S2IG is expanded by focusing sunlight on its surface using a simple magnification lens (diameter = 75 mm, focal length = 10 cm). The solar expansion process (SEP) resulted in the formation of expanded graphite with an expansion ratio of about 1:240 (graphite: expanded graphite) and lateral size of solar expanded graphite is about 400 μm, which is similar to the intercalated graphite flakes. The solar expanded graphite is exfoliated through probe sonication (500-watt, 20 kHz) for 20 min to obtain few-layer graphene sheets [11]. Raman analysis confirms the formation of defect-free solar expanded graphite as well as few-layer graphene sheets. The obtained results clearly show that the lateral size of graphene sheets can be enhanced by pre-expanding the graphite sheets through solar irradiation before the probe sonication process.

Long-Lived Charge Separation in Large-Area, Single Crystal MoS₂ Monolayers Interfaced with Non-Fullerene Acceptor Y₆
Christopher E. Petoukhoff, Zheng Yang, Shahidul Alam, Nisreen Alshehri, Jose P. Jurado Carlin, Catherine De Castro, Vincent Tung and Frederic Laquai; King Abdullah University of Science & Technology (KAUST), Saudi Arabia

Semiconductor heterojunctions based on 2D transition metal dichalcogenides (TMDs) have displayed record thickness-normalized current densities and absorption coefficients, particularly when interfaced with organic semiconductors [1]. As such, 2D TMDs have been employed as both charge transport layers in organic [2] and perovskite photovoltaics [3], as well as the active layer in mixed dimensional organic-2D heterojunctions [4]. MoS₂ and WS₂ have been demonstrated as alternative hole transport layers in high-efficiency organic photovoltaics (OPVs), leading to devices having greater than 17% power conversion efficiencies [5,6]. However, these works have focused on either mechanically-exfoliated, single-crystal TMDs or liquid-phase exfoliated films, which either limit the size or the homogeneity of the resulting devices. There have not yet been works incorporating large-area, single crystal TMD monolayers as hole transport layer materials for OPVs.

In recent years, the advancement of OPV efficiencies has largely been driven by the development of non-fullerene acceptor materials, such as the molecule BTP-4F (i.e., Y₆). This molecule has sub-units of electron donating (D) and accepting (A) groups, in the form of A-D-A′D-A structure, which give rise to large exciton delocalization with excitons having charge-transfer-like character. In fact, there has been growing evidence that neat Y₆, unlike most neat organic semiconducting materials, can generate charge-separated states even without a donor/acceptor interface typical for OPVs.

In this work, we investigate the charge generation, transfer, and separation processes that occur when neat Y₆ is interfaced with large-area, single crystal MoS₂ monolayers. We explore these processes using femtosecond transient absorption (TA) and time-resolved photoluminescence (TRPL) spectroscopies. Our results demonstrate that MoS₂/Y₆ interfaces lead to long-lived charges in both the MoS₂ and Y₆ layers. We will compare the impact of MoS₂ on charge separation in neat Y₆ compared to a typical donor:acceptor blend, PM6:Y₆. These results demonstrate the viability of using MoS₂ as an effective hole transport layer in high-efficiency solar cells, particularly for single component OSCs fabricated from Y₆-type materials.

Roulseau⁵, Feng Gang⁶, Kai Xiao⁷, Jiuhua Chen⁷, Yumeng Li⁸ and Bo Li⁸; Villanova University, United States; ¹University of Illinois at Urbana Champaign, United States; ²Oak Ridge National Laboratory, United States

Ultrathin and mechanically robust structures and devices with nanoscale dimension resolution are critical for miniaturized nanoelectromechanical systems (NEMS) and integrated circuited (IC). It is extremely challenging to achieve such structures from hybrid inorganic-organic systems because the lack of controllability of depositing/assembling organic structures. The attainment of precise fabrication control and comprehension of atomic-level interactions stands as the principal objectives of this research. Here, we propose the utilization of monolayer two-dimensional (2D) materials, such as graphene and MoSe₂, synthesized through chemical vapor deposition (CVD), as 2D atomic templates to induce the epitaxial assembly of orthorhombic polyethylene (PE) crystals. By meticulously regulating the assembly temperature and time, the growth of PE lamellar crystals can be modulated, ranging from a few nanometers to hundreds of nanometers with an accuracy of sub-nanometer resolution. Adding PE will not only increase the mechanical robustness of 2D materials in fabricating the suspended structures, but also create a dielectric layer with controlled thickness to realize ultrathin device fabrication. The incorporation of polymer nanocrystals, monolayer graphene, and MoSe₂ yields a pioneering category of hybrid nanostructures, wherein the crystalline architectures of both constituents are highly controlled, thereby potentially reshaping the paradigm for manufacturing superior materials and devices with precisely engineered structures and properties.

8:00 PM EL19.04.04
2D Materials Junction-Templated Photoelectrochemistry
Radha Raman¹,²,³, Ya-Ping Hsieh² and Mario Hofmann³; ¹National Central University, Taiwan; ²Academia Sinica, Taiwan; ³National Taiwan University, Taiwan

In recent years, the development of lateral junctions between 2D materials has enabled a new class of nanostructures with precise transitions in electronic structure. In this study, we utilized the unique carrier transport properties of lateral junctions to conduct photoelectrochemistry with unprecedented spatial resolution and dynamic controllability. By electrostatically confining electrons within the junction, we were able to localize electrochemical reactions with nanometer precision in their lateral position. We have also developed a scalable process for the formation of graphene pn-junction networks that is compatible with various materials and techniques, including dielectrophoretic deposition. The high spatial selectivity of the deposition process allowed us to create complex 1D fractal-shaped nanostructures with ultrahigh Raman enhancement. Furthermore, we have extended our study to utilize MoS₂ junctions to photo-deposit gold nanoparticles. The incorporation of MoS₂ lateral junctions facilitated the deposition of gold nanoparticles with high spatial resolution. The resulting nanostructure morphology can be used for various applications including surface-enhanced Raman spectroscopy and nanoelectronics.

These results offer exciting possibilities for the assembly of a new type of neural network based on axon-like guided growth of interconnected neurons. Such a network could have significant applications in the development of evolvable, brain-like future electronics. The potential of this technology highlights the importance of continued research in the field of photoelectrochemically deposited nanostructures on 2D material lateral junctions.

Exploring Two-Dimensional Indium Oxide for Memristive Switching: Fabrication, Characterization and Potential Applications
Kuan-Hung Chen¹, Chang Hsun Huang¹, Chen-Yuan Weng², Chen-Chih Hsiang¹, Yi-Hsiang Yen³ and Yi-Chia Chou¹; ¹Nation Taiwan University, Taiwan; ²National Yang Ming Chiao Tung University, Taiwan

Since its groundbreaking discovery in 2004, graphene has captivated the scientific community[1], igniting an unprecedented interest in the exploration of
Two-dimensional materials (2DMs) have garnered immense attention due to their exceptional properties resulting from their reduced dimensionality, charge carrier confinement, and dangling-bond-free surface. Their distinct nature holds tremendous potential for applications in the scaling era of semiconductor devices, propelling researchers into a realm of innovation. In particular, liquid indium-based alloys have emerged as highly promising candidates in the realm of printed electronics, owing to their low melting point, high stability, and remarkable conductivity. A novel top-down technique called liquid metal printing (LMP) has ushered in a new era for the production of 2D metal-oxide films, operating at lower temperatures and simplifying the fabrication process compared to traditional deposition methods. By skillfully tailoring the temperature and oxidation time during LMP, researchers have been able to control the ionization efficiency of the analytes. The WS2 nanosheet allowed for a sensitive detection of commonly prescribed immunosuppressive drugs including cyclosporine A and tacrolimus in the body fluids of transplant patients. Moreover, this technology holds immense significance as it enhances our understanding of the precise characteristics of oxygen defects and our ability to control the oxygen vacancies in atomically thin oxide interfaces; this discovery holds promise for the application of InOx devices in constructing artificial neural network. This discovery holds promise for the application of InOx devices in constructing artificial neural network.

Evolution of Bandgap in WS2 from Monolayer to Multilayer
Xu He, Jinping Tian, Saen Xie and Antoine Kahn; Princeton University, United States

Transition metal dichalcogenides (TMDs) are 2D van der Waals materials with a chemical formula MX2, where M represents a transition metal such as tungsten (W) or molybdenum (Mo) and X represents a chalcogen atom such as sulfur (S) or selenium (Se). TMDs are layered compounds and can be stacked from mono- to multi-layer films. Unlike graphene, which has a zero gap, TMDs are more versatile in their applications in electronics due to their sizable electronic gaps, tunable with composition and thicknesses. Many theoretical works have been done to study and predict the electronic structures of these materials. It is now a consensus that TMD electronic gaps decrease as the number of layers increases. However, no experimental study has been completed to show how the electronic gap evolves from monolayer to multilayer structures.

In this work, we explore the evolution of optoelectronic properties such as energy level positions, electronic gap (Eg), and exciton binding energy (Eb) using ultraviolet and inverse photoelectron spectroscopies (UPS / IPES), complemented with Raman spectroscopy and photoluminescence (PL) measurements. High-quality large-scale monolayer and multilayer continuous films of WS2 are grown by chemical vapor deposition on p-Si (with a native SiO2 layer). Raman spectroscopy and PL help differentiate between mono- and multi-layer films. UPS and IPES are used to measure occupied and unoccupied states and determine valence band maximum (VBM), conduction band minimum (CBM), Fermi level position, and associated ionization energy, electron affinity, and Eg. We find that the valence (conduction) states shift toward (away from) the vacuum level from mono- to multi-layer films, decreasing the electronic gap from 2.29 eV to 1.61 eV. The optical gap (Eg) measured by PL for the monolayer film is 1.96 eV. Finally, by subtracting Eg from Ecm, we determine Eb for the monolayer film to be ~0.33 eV. Further studies are being conducted on other TMDs, including WS2, to confirm our findings. These experimental studies will shed light on understanding TMDs bandgap evolution, making predictions on bandgap and energy levels possible for new TMD materials. This will help better decide on TMDs for appropriate band alignments in devices such as LEDs and solar cells where suitable energy levels are of essential importance.

High Drift Velocity in Multilayer Indium Selenide at High Electric Fields
Youngwook Soek1,2, Hanyoel Jang2, YiTaek Choi2, Heungsoon Im2, Kenji Watanabe1, Takashi Taniguchi1, Jungbyo Nah4 and Kayoung Lee4; 1Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of); 2Gwangju Institute of Science and Technology (GIST), Korea (the Republic of); 4National Institute for Materials Science, Japan; 4Chungnam National University, Korea (the Republic of)

Creating a high-frequency electron system demands a high saturation velocity (υsat). Herein, we report high-field transport properties of multilayer van der Waals indium selenide (InSe). The InSe is on a hexagonal boron nitride substrate and encapsulated by a thin, non-continuous indium layer, resulting in an impressive electron mobility that approaches 3000 cm2/Vs at room temperature. Along with the high mobility, the temperature dependence characteristics of the insulating state reveals the presence of minimal disorder and impurities in our InSe. By utilizing four-terminal pulsed measurements, the drain current (Ids) at high drain bias (Vds) was accessed, reaching up to 3.8 mA at 8 V. υd vs Vds was measured at different carrier densities and temperatures, which were converted into electron drift velocity (υd) vs electric field (F). υd vs F data allow us to extract υsat values, which are as high as 1.8 x 106 cm/s at room temperature, superior to those of other gapped 2D semiconductors. Finally, we suggest an optical phonon emission model modified for parabolic dispersion to explain the current saturation, and determine the optical phonon energy of InSe as 22.9 meV, which is close to the theoretically expected value of monolayer InSe.

Applications of Ambipolar Molybdenum Disulfide with Van der Waals Contacts
Jungi Song1, Suyeon Lee1, Youngwook Sook1, Yeonghyeon Ko1, Hanyoel Jang2 and Kayoung Lee4; 1KAIST, Korea (the Republic of); 2Gwangju Institute of Science and Technology, Korea (the Republic of)

Two-dimensional (2D) materials are promising to replace silicon because they do not exhibit performance degradation when scaled down to the nanoscale. However, their high contact resistance and Fermi-level pinning hinder the modulation of a single 2D semiconductor into n-type and p-type, and restrict their potential applications. To overcome those limitations, ambipolar transistors, which can dynamically switch the type of majority carriers, have been proposed. However, a few semiconductors with small bandgaps, such as graphene, black phosphorus, and tungsten diselenide, have shown ambipolar properties. Achieving ambipolar characteristics in 2D materials with a relatively large bandgap remains challenging. Here, we show ambipolar molybdenum disulfide (MoS2) transistors by employing van der Waals contacts. MoS2 shows great potential for the future semiconductor industry, thanks to its sufficient bandgap (1.2–1.9 eV), decent mobility, stability, and mature large-area growth technology. Our devices achieve outstanding ambipolar current characteristics, with both PMOS and NMOS On-Off current ratios > 106 and two-point hole mobility > 23 cm2/V*s. By utilizing the ambipolar current characteristics, we have designed a new multifunctional electronics that is reconfigurable between an ambipolar transistor, an n-type transistor, a p-type transistor, and a complementary inverter. We demonstrate a new multifunctional electronics that is reconfigurable between an ambipolar transistor, an n-type transistor, a p-type transistor, and a complementary inverter.
Atomic layer deposition is a great tool for growing large-scale high-quality monolayer (ML) MoS2 and with a dedicated high temperature post-deposition treatment the amount of sulfur vacancies can be controlled. Sulfur-containing atmospheres, such as H2S, lead to MoS2 with low number of sulfur vacancies and increased stability against oxidation in air, whereas post-annealing treatments in N2 increase the number of vacancies and the material is more prone to oxidation. Post-deposition annealing treatments thereby offer a great possibility to tune the properties of the 2D layer.

Here we show that the sulfur vacancy-rich ML MoS2 films oxidize already at room temperature, which strongly affects the photoluminescence yield, the MoS2-Al2O3 substrate interaction and the structural integrity of the films. We used X-ray photoelectron spectroscopy to monitor the formation of MoO3 and possibly MoS2-Ox after exposure to air and to quantify the number of sulfur defects in the films. Atomic force microscopy (AFM) measurements allow us to pinpoint the exact regions of oxidation and to develop a dedicated low temperature heating procedure to remove the oxidized species, leading to MoO3-free MoS2 films. Interestingly, AFM and Kelvin probe force microscopy show that the MoS2-Al2O3 substrate coupling is changed, which also affects the ML MoS2 work function significantly (variations by approximately 300 meV). In addition, the reduction in MoS2-substrate coupling leads to a 10-fold increase in the PL intensity, and the ratio between trions and neutral excitons is changed.

Our work highlights the importance of oxidized sulfur vacancies and provides useful methods to measure and manipulate the number of vacancies on MoS2. Furthermore, the changes in the MoS2-substrate interaction via sulfur vacancies and oxidation offer a new pathway to tune the optoelectronic properties of the 2D films.

Band Tunability of 2-Layer MoS2/SiO2 Interface with The Use of Inorganic Salts in Liquid-CVD Sulfurization Alessio Lamperti, Pinaka Panii Tummalala1,2,3, Alessandro Cataldo1, Sara Ghomi1,4, Christian Martella1, Valeri Afanasiev2 and Alessandro Molle1; 1IMM-CNR Agrate Brianza, Italy; 2KU Leuven, Belgium; 3Università Cattolica del Sacro Cuore, Italy; 4Politecnico di Milano, Italy

Among two-dimensional (2D) transition metal dichalcogenides (TMDs), molybdenum disulfide (MoS2), in the semiconducting 2H phase, is one of the most extensively studied, because of its stability, versatility, and applicability in several fields, such as electrochemistry, optoelectronics, and microelectronics [1, 2]. To achieve sustainable exploitation of 2D-MoS2, a scalable synthesis over large macroscopic areas is required. In this respect, chemical vapor deposition (CVD) is a versatile and cost-effective method to address the deposition of high-quality few-to-single layers MoS2 with controlled thickness, uniformity and defectivity up to the wafer scale and with satisfactory carrier mobility [3]. Having 2D-MoS2 based microelectronic devices as target, the electron band alignment at MoS2/SiO2 interface is a key-parameter dictating the electrostatic properties of the stacks such as built-in voltages, transistor thresholds, as well as the tunneling barrier heights. Therefore, the electrostatic control of the MoS2/SiO2 interface, entailing the energy barrier height at the junction and the emergence of interface dipoles, is essential to overcome parasitic or undesired short-channel effects in ultra-scaled field-effect transistors (FETs) based on MoS2 [1], or to fabricate compliant stacks in ultra-thin sub-threshold slope tunneling FET [4].

Despite previous attempts that used the use of inorganic salts, such as NaCl, is effective in promoting selective extended 2D-MoS2 growth [5], no attention has been put on the electrical properties at the MoS2/SiO2 interface. Here, we performed internal photoemission (IPE) spectroscopy, a method successfully applied to 2D layered materials interfacing [6], on large-area (cm²) bi-layers MoS2 directly grown on SiO2/Si substrates via liquid precursor CVD (L-CVD) sulfurization, where the ammonium heptamolybdate (AHM) Mo precursor, is provided via solution deposition with inorganic salts (NaCl, NaOH, KCl, KI) spun over the substrate, to assess any possible effect of these inorganic molecules on the MoS2/SiO2 interface properties, in particular to determine the energy band sulfurization of MoS2 with SiO2. We measured IPE thresholds from 3.9 to 4.2 eV, depending on the type of inorganic salt in solution, which in any case disagrees with the 3.6 eV value obtained in CVD grown MoS2 from MoO3 and S powders with the assistance of organic perylene-3,4,9,10-tetraacarboxylic acid tetra-potassium salt (PTAS) [7]. To in-depth elucidate the origin of such discrepancy, we performed structural, morphological, and chemical analysis (SEM, AFM, Raman, XPS). For the case of NaOH, we revealed the presence of Na and OH residuals. Our findings are consistent with the emergence of Si-OH dipoles at the interface that individually dependent with each surface treatment in use, thus explaining the observed 0.6 eV energy widening in the IPE threshold.

Our study evidence the impact of the junction characteristics, and thus the need to consider them, on the real electrical behavior of devices integrating 2D materials, with critical implications on proposed models and reported values so far. We also report a relatively easy route to tune the band alignment at 2D-MoS2/SiO2 interface, a fundamental property to consider in the perspective of direct integration of 2D materials in the process flow for microelectronics devices.

This study was supported by the Government of Italy through Ministero dell’Università e della Ricerca (MUR) under the PRIN projects “sSTAR”, n. 2017RKWTMY and “PHOTO” n. 2020RPEPNH.

Galvanic Displacement Across Single-Layer Graphene for The Deposition of Metal Nanoparticles Isabelle Cunitz and Rohit Karnik; Massachusetts Institute of Technology, United States

This work aims to advance the scientific and engineering understanding of galvanic displacement reactions as buffered by a monolayer of graphene, specifically by investigating palladium deposition on graphene on a copper foil substrate via galvanic displacement between the copper and palladium (II) ions in solution. To understand palladium nanoparticle deposition and determine how this process can be controlled, electrochemical thermodynamics and classical nucleation theory are first synthesized into a thermodynamic model of the system. Next, scanning electron microscopy is used to characterize palladium deposition on the graphene/copper surface after galvanic displacement. Copper etch pits are observed to form during the reaction, maintaining contact between the deposition solution and the copper and thereby ensuring that the reaction is not self-limiting under the conditions studied. Palladium is observed to preferentially deposit along atomic steps in the copper foil, at graphene defects where the copper is exposed to the deposition solution, and at etch pits. The effects of varying palladium concentration and graphene/copper surface treatments are characterized, and these results are synthesized to propose a mechanism of palladium deposition via galvanic displacement through graphene. Finally, galvanic displacement is investigated in a novel engineering application, as a method of sealing graphene defects for the synthesis of centimeter-scale nanoporous atomically thin membranes. Palladium nanoparticles deposited on the graphene surface are observed to largely survive graphene transfer to a support membrane substrate, as well as mounting and...
use in aqueous diffusion cell experiments. However, diffusion experiments show that graphene treated via galvanic displacement has higher leakage than untreated graphene, indicating that under the reaction conditions studied here, galvanic displacement has a net effect of graphene defect enhancement rather than defect sealing. This work contributes new insights regarding galvanic displacement as a method of modifying monolayer graphene, as well as exploring this method in the novel application of membrane separations. With further development, this simple, quick, and inexpensive technique for the fabrication of 2D material/nanoparticle composites may have a myriad of applications relevant to sustainability and beyond.

Substrate Effects on Spin Defects in Two-Dimensional Hexagonal Boron Nitride
Chi-Che Wu and Elizabeth M. Lee; University of California, Irvine, United States

Two-dimensional (2D) hexagonal boron nitride (hBN) is a single atom thick wide band gap semiconductor with high thermal conductivity and chemical stability. Negatively charged boron vacancies (V_B^-) in hBN have recently emerged as a promising platform for quantum sensing and quantum information science applications, owing to their long spin coherence times even at room temperature. Here, we investigate electronic structure properties of V_B^- in 2D hBN on top of solid-state substrates using density functional theory calculations and ab initio molecular dynamics simulations. By using substrates ranging from metals (e.g., copper) to insulators (e.g., silica), we discuss how the substrates and their surface chemistry can greatly impact the electronic and mechanical stability of V_B^-.

Our results suggest ways to control the spin defect properties for 2D materials using substrate engineering and surface modification.

Synthesis of V-Doped WTe2 Nanolayers and Single Crystals
Vera M. Gospodinova, Dimitre Dimitrov, Peter Rafailov, Nikola Malinowski, J.F. Sierra and Sergio Valenzuela; IOMT-BAS, Bulgaria; ISSP, Bulgaria; Catalan Institute of Nanoscience and Nanotechnology (ICN2), Spain

The discovery of 2D topological insulator in monolayer 1T'-WTe2 indicates great potential for novel electronic, spintronic, and quantum metrology. Theoretically, the interaction between the topological states and the magnetic ordered states of 2D-WTe2 enables the modulation of Weyl semimetal states by an external magnetic field and potentially the creation of a quantum anomalous Hall phase [1-3]. However, currently, ferromagnetism in layered 1T'-WTe2 is still not observed. We are attempting to synthesize nanolayers/flakes of 1T'-WTe2 with vanadium doping in order to induce magnetism. V-doped WTe2 nanolayers/flakes were synthesized in an atmospheric pressure CVD (APCVD) quartz tube reactor with three independent thermal zones. LP (liquid precursors) method based on ammonium metatungstate hydrate (AMT) and ammonium metavanadate (ammonium(V)) or vanadium(V) oxide sulfate (VOSO4) with addition of PTAS was used for the synthesis. The obtained nanolayers/elusters/flakes were studied by optical microscopy and Raman spectroscopy. In addition, we are reporting growth of V-doped WTe2 single crystals by using flux (high-temperature solution) method. Particularly the self-flux method was used for crystal growth, and tellurium was used as a solvent (flux). The grown crystals were studied by XRD, XPS and Raman spectroscopy and the typical for WTe2 X-ray diffraction patterns and Raman modes were observed. Vanadium incorporation (1.8 at. %) in the crystal structure was detected by XPS measurements. The estimated overall elemental composition in at. % confirms the presence of vanadium.

Photogeneration at a Dirac/Charge-Compensated Semimetal Heterojunction based on Graphene and WTe2
Farima Farahmand, Ao Shi and Nathaniel Gabor; University of California, Riverside, United States

The unique photocurrent characteristics of pristine pure heterojunctions composed of atomically thin materials remains a new frontier in optoelectronics. A novel pairing of a Dirac semimetal and a charge-compensated semimetal provides an opportunity to investigate photogeneration when photo-thermoelectric, photovoltaic, and other important photogeneration effects coexist. We employ near-infrared scanning photocurrent microscopy to investigate the dynamics of photoinjected carriers in graphene/WTe2 heterojunctions. Our experiments revealed that the charge-compensated semimetal WTe2 has a higher mobility than the graphene, and the heterojunctions exhibit a detectable photocurrent. Our findings highlight the important role that the photo-thermoelectric effect plays in the photogeneration process.

Atomic Reconstruction of Large-Lattice-Mismatched Transition Metal Dichalcogenides Heterobilayers into Strained-Commensurate Structures
Seongchul Hong, Ji-Hwan Baek, Yunyeong Chang, Hong M. Nguyen, Changheon Kim, Yeonjoon Jung, Hyoengseok Lee, Kenji Watanabe, Takashi Taniguchi, Jangyup Son, Hyeonseok Cheong, Myoung Kim and Gwan-Hyoun Lee; Seoul National University, Korea (the Republic of), Sognak University, Korea (the Republic of), National Institute for Materials Science, Japan, Korea Institute of Science and Technology, Korea (the Republic of)

Moiré superlattices between vertically stacked van der Waals (vdW) layers with twist angle or lattice mismatch generate periodic moiré potentials, which induce renormalization of electronic band structures and corresponding modulation of electrical and optical properties of moiré crystals. In addition, lots of references that have been paid for spontaneous atomic reconstruction of small-mismatched vdW layers into periodic commensurate domains separated by incommensurate boundaries because of unprecedented physical properties of these unique vdW layers. Unlike small-mismatched vdW layers, the spontaneous reconstruction has not been observed in large-mismatched vdW layers owing to their large formation energy of commensurate structures. Here, we report thermally induced atomic reconstruction of a large-mismatched MoS2/MoS2 heterobilayer (lattice mismatch = 3.88%) into a strained-commensurate (SC) heterostructure that has angle- and lattice-matched commensurate domains separated by saddle point (SP) structures through hBN-
encapsulation annealing. We verified that the SP structure has large dilatational and shear strains of 4% and the SC structure exhibited splitting of the intralayer excitons owing to the inhomogeneous strain distribution. Our work verifies that even hetero-bilayers with large lattice mismatches can transform into lattice-aligned heterostructures regardless of twist angle and expands our understanding for electrical and optical properties of vdW heterostructures with new stacking sequences.

A High-κ Wide-Gap Layered Dielectric for Two-Dimensional Van der Waals Heterostructures
Ariadne C. Catto1, Luis F. da Silva1, Eduardo Lobet2 and Elson Longo3; 1Federal University of Sao Carlos, Brazil; 2Universitat Rovira i Virgili, Spain

Metal semiconducting oxides (MOXs) have been widely employed in gas sensors due to their potential features, such as high sensitivity, selectivity, rapid gas detection, and stability. N-type MOXs (e.g. SnO2, WO3, ZnO, and α-Fe2O3) have been successfully applied as sensing elements in gas sensor devices for the detection of a variety of toxic gases, such as NO2, NH3, O3, and H2S. Among the n-type MOXs, hematite (α-Fe2O3) nanosstructures have gained attention due to their high oxygen ion mobility at the surface material, excellent chemical and thermal stability under ambient atmosphere, and low cost. Despite its advantages, few studies have investigated the sensing activity of hematite. Therefore, efforts have been paid to improving the sensing performance of α-Fe2O3 by using distinct strategies, such as combination with other components including noble metals, semiconductors, and carbon-based materials. Among these, graphene has received considerable attention due to its unique two-dimensional (2D) structure, high electron conductivity and mobility, and high surface area. Also, various MOXs may be combined with GO and/or rGO resulting in a self-assembled heterostructure with unique properties for the most diverse applications. Regarding gas sensing applications, hydroporphic graphene-based materials have been cited as an effective way to be employed in gas sensor devices leading to high sensitivity and selectivity even in high humidity conditions. Motivated by these considerations, we report here a versatile approach towards the production of advanced materials based on (3D/2D) α-Fe2O3/graphene sheets heterostructure to be applied as a resistive NO2 gas sensor. The effect of different amounts of addition ratios of graphene on the sensing performance has been studied. The α-Fe2O3/Gr heterostructures were obtained by hydrothermal method and the crystalline phase, morphological, and surface properties were studied by XRD, FESEM, TEM and XPS techniques. Additionally, we successfully combined experimental and DFT calculations to understand the role played by the heterointerface and the chemical environment along the exposed surfaces α-Fe2O3/Graphene sheets in the sensing properties towards NO2 gas. The gas sensing experiments show that the α-Fe2O3/graphene heterostructure gas sensor has better sensing performance for NO2 than the pristine graphene, such as high response, excellent selectivity, and low detection limit. The effects of temperature and moisture on the NO2 sensitivity of α-Fe2O3/graphene heterostructures were also investigated. The optimal operating temperature for the highest gas response is around 150 °C, and the formation of α-Fe2O3/graphene heterostructure improved the exposed surfaces α-Fe2O3/Graphene sheets sensitivity for NO2 gas. Furthermore, the selectivity was also evaluated by exposing the heterostructures to different gases such as O3, NH3, and CO. These findings show that (3D/2D) α-Fe2O3/Graphene sheets heterostructures have a remarkable potential for practical applications as NO2 gas sensor in environmental monitoring devices.

Synthesis and Characterization of (3D/2D) α-Fe2O3/Graphene Heterostructure for Application as a Toxic Gas Sensor
Muhammad Shehzad Sultan1, Wojciech Jadowsiezczak*, Alejandra P Flores Rivera1, Brad Weiner1 and Gerardo Morell1; 1University of Puerto Rico at Rio Piedras, United States, *Ohio University, United States

Nitrogen doped graphene quantum dots (GQDs) have been widely used for various optoelectronic devices as a photoactive material due to their high absorption coefficient and tunable bandgap. However, the low mobility of NGQD films results in poor charge collection and device performance. By combining NGQDs with graphene into hybrid NGQD/Graphene photodetectors, photocarriers from NGQDs are transferred to graphene, improving charge collection and transport, and drastically increasing the photoresponsivity. In this study, we report the preparation of a NGQD/Graphene heterostructure in order to investigate the effect of NGQD on the photoactive response of graphene. Using UV–vis absorption and photoluminescence (PL) spectra, the optical properties of NGQD/Graphene heterostructure were measured. Moreover, to investigate their electronic and charge transfer properties, we fabricated the photodetectors with pristine graphene quantum dots and NGQD/Graphene heterostructure to analyze and compare their photoactive electrical properties. Under illumination, NGQD/Graphene PD showed an increase in both current and carrier mobility as compared to NGQD PD. The increased current and carrier mobility of NGQD/Graphene PD is due to the presence of a large number of photoexcited charge carriers. This is explained by NGQDn n-type doping effect on graphene, which reduces the accumulation of holes in the active p-channel near the insulating layer and causes charge to be transferred from the NGQDs to the graphene. As a result, we discovered a charge transfer effect in the NGQD/Graphene heterostructure, which could be used in optoelectronic devices.
The unique optical properties of transition metal dichalcogenide (TMD) monolayers have attracted significant attention for both photonics applications and fundamental studies of low-dimensional systems. TMD monolayers of high optical quality, however, have been limited to micron-sized flakes produced by low-throughput and labor-intensive processes, whereas large-area films are often affected by surface defects and large inhomogeneity. Here we report a rapid and reliable method to synthesize macroscopic-scale TMD monolayers of uniform, high optical quality. Using 1-dodecanol encapsulation combined with gold-tape-assisted exfoliation, we obtain monolayers with lateral size $>$ 1 mm, exhibiting exciton energy, linewidth, and quantum yield uniform over the whole area and close to those of high-quality micron-sized flakes. We tentatively associate the role of the two molecular encapsulating layers as isolating the TMD from the substrate and passivating the chalcogen vacancies, respectively. We demonstrate the utility of our encapsulated monolayers by scalable integration with an array of photonic crystal cavities, creating polariton arrays with enhanced light-matter coupling strength. This work provides a pathway to achieving high-quality two-dimensional materials over large areas, enabling research and technology development beyond individual micron-sized devices.

**Unraveling the Role of Dopant Clustering in Magnetic Impurity Doped Monolayers of Transition Metal Dichalcogenides**

Rohan Younas, Guanyu Zhou and Christopher L. Hinkle; University of Notre Dame, United States

Efforts to achieve above room temperature ferromagnetism in monolayers of transition metal dichalcogenides (TMDs) through substitutional doping with magnetic impurities are actively being pursued for energy-efficient logic and memory devices. However, the current limitations stem from phase separation and multi-layered growth at heavy doping levels, restricting the doping in monolayers to levels well below the threshold established by density functional theory (DFT) for above room temperature Curie temperature. On the other hand, room temperature magnetism has been frequently observed at significantly lower doping levels (0.1-1%), but this magnetism arises from a combination of substitutional dopants, point defects, contaminants, interstitials, or edge states. As a result, the origin of purely substitutional doping-induced ferromagnetism remains a subject of debate.

Towards this end, this study employs molecular beam epitaxy to achieve up to 30% substitutional doping of vanadium (V) and iron (Fe) in a monolayer of tungsten diselenide, surpassing the doping requirements (>15%) indicated by DFT for room temperature ferromagnetism. Magnetometry measurements, however, reveal the absence of ferromagnetism down to a temperature of 4 K in these phase-pure films, with only the phase-separated films exhibiting any room temperature ferromagnetic behavior at Fe doping levels exceeding 30%. Structural characterization utilizing plan-view transmission electron microscopy reveals significant dopant clustering, even at modest doping levels (~5%), which serves as the primary factor responsible for the absence of ferromagnetism in phase-pure films. Remarkably, these observations align with DFT calculations, which predict a low formation energy for dopant clustering, leading to a weakened exchange interaction that subsequently suppresses ferromagnetism. The insights gained from this exploratory study offer a promising pathway to attain high doping densities in monolayer TMDs while emphasizing the influence of dopant clustering on the magnetic properties of the films.

**Structure-Property Relations of Quantum Emitters in 2D Materials** Su Ying Quek; National University of Singapore, Singapore

Quantum emitters in the form of point defects in 2D materials are of interest as scalable single photon sources for photonics-based quantum technologies. It is important to know the optical signatures of intrinsic defects, but also critical to be able to controllably synthesize quantum emitters with desirable and known optical properties. In this work, we use state-of-the-art first principles calculations to elucidate the structure-property relations of quantum emitters in the wide-bandgap hexagonal boron nitride (hBN) layer, as well as in transition metal dichalcogenide (TMD) monolayers. Defects in hBN can be controllably created by carbon implantation and electron or ion bombardment. We present the photophysical properties of defects derived from boron vacancies and carbon impurities [1], as well as preliminary results on other point defects created by the electron or ion bombardment process. Comparisons are made with recent experiments. In the second part of the talk, we discuss the optical properties of unintended oxygen-related defects and intentional substitutional defects in TMDs. We find that chalcogen vacancies in WSe$_2$ are readily passivated by oxygen, and oxygen interstitials are a possible source of large resistance changes originating from magnetic interlayer coupling at low temperatures. We demonstrate the switching of the bistable state and further confirmed by 1/f$^2$ features in the noise power spectrum. Three fluctuation categories in the resistance change were detected: small changes from the magnetic interlayer coupling at low temperatures, and persistent large resistance changes originating from magnetic interlayer coupling at low temperatures. We demonstrate the switching of the bistable state and further modulate the cut-off frequency of RTNs with bias. The observed electrical switching of a tunable bistable state in magnetic 2D materials can be utilized for low-power spintronics.

**9:30 AM EL19.07.04**

**Magnetic Fluctuations in V-Doped WSe$_2$**

Dinh Loc Duong$^{1,2}$, Lan-Anh T. Nguyen$^1$, Jinbao Jiang$^4$, Tuan Dung Nguyen$^1$, Philip Kim$^4$, Min-kyu Joo$^6$ and Young Hee Lee$^4$; $^1$Department of Physics, Montana State University, United States; $^2$Montana State University, United States; $^3$Center for Integrated Nanostructure Physics, Institute for Basic Science, Korea (the Republic of); $^4$National University of Defense Technology, China; $^5$Harvard University, United States; $^6$Sookmyung Women's University, Korea (the Republic of)

Vanadium-doped tungsten diselenide (V-doped WSe$_2$) reveals ferromagnetic order at room temperature, which can be controlled by a gate bias. In this presentation, we report electrically tunable magnetic fluctuations associated with RTNs in V-doped WSe$_2$ at a low doping concentration using vertical tunneling graphene/V-WSe$_2$/graphene devices. We identify bistable magnetic states from discrete Gaussian peaks of the RTN histogram, which were further confirmed by 1/f$^2$ features in the noise power spectrum. Three fluctuation categories in the resistance change were detected: small changes from the intrinsic fluctuations between magneticdomains at high temperatures, anomalous large resistance changes over a wide range of temperatures, and persistent large resistance changes originating from magnetic interlayer coupling at low temperatures. We demonstrate the switching of the bistable state and further modulate the cut-off frequency of RTNs with bias. The observed electrical switching of a tunable bistable state in magnetic 2D materials can be utilized for low-power spintronics.

**Elucidating Ferromagnetic Properties of Fe-Doped MoS$_2$, WSe$_2$ and WS$_2$ at Various Temperatures**

Mengni Fang$^2$, Hee Suk Chung$^2$, Jae Hyuck
In this study, we present the synthesis and characterization of Fe:MoS$_2$, Fe:WSe$_2$, and Fe:WS$_2$ to elucidate their magnetic properties. The Fe-doped TMD processing [7, 8] leads to the emergence of diluted magnetic semiconductors (DMS). These DMS materials combine the advantages of semiconductors with ferromagnetic behavior, enabling the development of spintronic devices for efficient information storage and processing [7, 8].

In this study, we present the synthesis and characterization of Fe:MoS$_2$, Fe:WSe$_2$, and Fe:WS$_2$ to elucidate their magnetic properties. The Fe-doped TMD materials were synthesized using contact-growth, of which detailed synthesis methods are reported elsewhere [5, 9]. To determine the ferromagnetic properties of synthesized materials, various techniques were employed: the structural and morphological characterizations were carried out using techniques such as optical, atomic force microscopy (AFM), and scanning transmission electron microscopy (STEM), confirming their successful synthesis and the presence of desired structural features. Furthermore, vibrating sample magnetometry (VSM) measurements were performed to determine the macroscopic magnetic properties, including coercivity and saturation magnetization. These measurements indicate that Fe:WSe$_2$ displays a more pronounced ferromagnetic signal than that from Fe:MoS$_2$. Further investigation is needed to gain deeper insights into the underlying mechanisms responsible for these observations.

This research may pave the way for developing novel TMD materials with tailored magnetic properties for low-power spintronics applications and quantum information science.

Controlling Quasiparticle Excitations in 2D Solids Through Atomically Precise Heterostructures Alexander Weber-Bargioni and John C. Thomas; Lawrence Berkeley National Laboratory, United States

In this presentation, we investigate how atomically defined heterostructures, such as 2D stacks, 1D boundaries within a 2D material, and 0D vacancies and substitutes in 2D materials, localize new protected states that host quasiparticle excitations. Quasiparticles are emergent excitations in condensed matter systems that behave like particles, but are not elementary particles like electrons or protons. In 2D solids, a wide variety of quasiparticle excitations can be experimentally accessed, including localized electrons, excitons, superconducting states, and polaritons, as well as more exotic systems like Tomonaga Luttinger liquid. Each specific quasiparticle excitation is a result of a specific crystalline symmetry. By inducing atomically defined 0D, 1D, and 2D heterostructures, it is possible to localize, protect, and create novel quasiparticle excitations.

We demonstrate how to engineer heterostructures into 2D Transition Metal Dichalcogenides and visualize the resulting electronic structure using Scanning Tunneling Microscopy. We discuss the resulting quasiparticle excitations that we directly capture using Scanning Tunneling Microscopy, as well as Time Resolved optical Spectroscopy. We show how 0D heterostructures or defects in 2D MoSe$_2$ and 2D WS$_2$ carry intrinsic point defects that substantially modify electronic properties. For instance, individual S vacancies create two-level systems within the band gap with extremely high spin-orbit coupling, and can mediate single photon emission via optical or electric stimulation. We also demonstrate how C-H for S or Se substitutes in 2D WS$_2$ and 2D WSe$_2$ form locally charged hydrogen-like states. Upon deprotonation, the localized carbon radical hosts a deep in-gap state with a net spin and electron-phonon coupling that is similar to NV color centers in diamond, but with atomistic control. Furthermore, individual Chalcogen Vacancies can be decorated with a variety of different adatoms, creating new types of 0D heterostructures, such as Co-S substitutes that could become relevant for Quantum Information Science.

In 1D heterostructures, such as Mirror Twin Boundaries in MoSe$_2$ or WS$_2$, we discovered atomically thin metallic conductors that undergo a quantum phase transition at low temperature to form a Tomonaga Luttinger Liquid (TLL). TLLs are correlated electron systems, where electrons couple to form a bosonic system, and that can foster partial electron and spin transport. As a 2D heterostructure, we explore WS$_2$/WSe$_2$ stacks, where we study the formation and recombination channels of interlayer excitons formed in WS$_2$/WSe$_2$ stacks, which may relate to the recently reported formation of excitonic Bose-Einstein condensates. Another fascinating area of research is coupling quasiparticles to form new quasiparticles. By stacking 2D WSe$_2$ on linear plasmonic cavities, we were able to couple excitons to plasmons, creating plexcitons. We use techniques such as photo low-temperature Scanning Tunneling Microscopy, near-field optical microscopy, and low-temperature time-resolved optical spectroscopy to investigate the properties and behavior of these quasiparticle excitations.

11:00 AM *EL19.07.07

Moiré Minibands, Interlayer Coupling and Hybridization in vdW Stacks from Optical Spectroscopies Ursula Wurstbauer; University of Münster, Germany

Two-dimensional (2D) materials exhibit unique properties due to their atomically thin structure and weak van der Waals (vdW) coupling between layers. This vdW nature allows for the precise engineering of 2D quantum systems through stacking, twisting, and inducing defects. External stimuli, such as electric or magnetic fields and charge doping, enable in-situ control of these systems.

In this study, we employ advanced optical spectroscopy methods to characterize interlayer coupling, interfacial quality, interlayer hybridization, and miniband formation in twisted vdW homo- and heterobilayers prepared from semiconducting transition metal dichalcogenides (TMDs) such as MoSe$_2$, WSe$_2$. Photoluminescence and spectroscopic imaging ellipsometry (SIE) provide insights into the hybridization of band-edge and higher-lying interband transitions [1, 2]. Non-resonant Raman spectroscopy is used to study the phonon fingerprint, which is sensitive to interlayer coupling, strain, and doping [3-
Resonant Raman spectroscopy (RRS) is found to be highly sensitive to exciton-phonon coupling [5,6], and electronic Raman known as resonant inelastic light scattering (RILS) allows spectroscopy of Moiré mini-bands by probing collective electronic inter-miniband excitations [7]. Our research aims to deepen our understanding of the interplay between interlayer coupling, hybridization, and mini-band formation in 2D materials. These findings have implications for the design and development of novel quantum devices and applications.

We acknowledge funding by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under projects Wu 637/4-1, 4-2, 7-1 and SPP 2244.

11:30 AM *EL19.07.08 Overcoming Industrial Challenges in Implementing 2D Materials in CMOS Byun Kyung-Eun, Minsu Seol, Junyoung Kwon, Alum Jung and Min Seok Yoo; Samsung Advanced Institute of Technology, Korea (the Republic of)

Two-dimensional (2D) transition metal dichalcogenides (TMDs) have received great attention for their potential role as the channel material in electronic devices. Although 2D materials have demonstrated exceptional promise in academic research, significant industrial challenges must be confronted to integrate them into next-generation Complementary Metal-Oxide-Semiconductor (CMOS) technologies. In this talk, we highlight the significant challenges that the industry faces in implementing 2D materials into current semiconductor devices. These include issues related to material synthesis with high-throughput, fast and nondestructive characterization, proper integration processes for TMDs. We'll present the ongoing research about growth, characterization and integration. We demonstrate high-throughput production of 9-inch wafer scale MoS2 and WS2. Utilizing our TMD, we have successfully achieved the TMD FETs on an 8-inch wafer scale through a conventional CMOS process, demonstrating consistent electrical performance with a high yield of over 99%. Through our research on TMD FET structures, we have achieved remarkable advancements in device performance. We're also accelerating the Lab to Fab transition by using artificial intelligence (AI), which proves beneficial in predicting material behaviors and optimizing processing parameters. The talk will provide insights into the extensive efforts companies are making to navigate these challenges.

SESSION EL19.08: 2D Semiconductors—Synthesis I
Session Chairs: Andrew Mannix and Hyeon Jin Shin
Tuesday Afternoon, November 28, 2023
Hynes, Level 3, Room 309

1:30 PM EL19.08.01 Unconventional vdW Heterostructures Assembled from Bespoke 2D Atomic and Molecular Lattices Thomas J. Kenpa, Reynolds Dziobek-Garrett, Ona Ambrozaite, Yifei Zhu and Tara Weiss; Johns Hopkins University, United States

Quantum materials have the potential to revolutionize sensing, analytical instrumentation, information processing, and energy conversion. Unconventional vdW superlattices assembled from precisely tailored 2D atomic and molecular lattices encode heterointerfaces which can provide an unprecedented control over charge, exciton, and spin states leading to unique artificial quantum solids. Realizing such superlattices requires not only rational, mechanism-driven chemical synthesis of atomically-precise 2D crystals, but also careful optical spectroscopy and device studies for rigorous determination of fundamental properties and intrinsic limits. In this talk I will discuss our key prior achievements and emerging results towards the assembly of these unconventional superlattices. First, we show that innovative surface-treatments and precursor chemistries can dramatically alter the dimensionality, morphology, and defect level of 2D transition metal dichalcogenides (TMD) grown by chemical vapor deposition (CVD). Second, we demonstrate the promise of gas-phase methods for the synthesis of single monolayer 2D molecular lattices (e.g., metal-organic frameworks), and also demonstrate their response to chemical, optical, and electrical stimuli through device transport and scanning probe measurements. Finally, we show that the merger, through direct CVD deposition or exfoliation and transfer, of these 2D crystals yields unique heterointerfaces that can elicit photon upconversion, modulation of lattice phonons, and control of exciton dynamics. Ultimately, the unprecedented array of chemical, dielectric, and mechanical potentials that such superlattices can support open unique opportunities for breakthroughs in optics, sensing, information processing, and sustainability.

1:45 PM EL19.08.03 Metallorganic Chemical Vapor Deposition of Epitaxial MoS2 and WS2 on Group III-Nitrides Shalini Kumari, Dorota Kowalczyk, Chen Chen, Nicholas Trainor, Seung H. Lee, Tim Mirabito, Nicholas D. Redwing and Joan M. Redwing; The Pennsylvania State University, United States

Scalable vapor phase deposition methods are rapidly developing enabling epitaxial growth of transition metal dichalcogenides (TMDs) monolayer and few-layer films on wafer-scale substrates. C-plane sapphire has been the primary substrate used so far for TMD epitaxy as it is crystallographically compatible with the hexagonal TMD lattice, is thermally stable at high temperatures and is available in large area at low cost. However, the direct lattice mismatch between the TMDs and sapphire is large and while there is commensurability which reduces the effective mismatch, the lattice off-sets lead to translational defects between coalescing domains. In contrast, the group III-nitrides (GaN and AlN) are nearly directly lattice matched to MoS2 and WS2 making them intriguing substrates for TMDs epitaxial growth. WS2 and MoS2 have a lattice mismatch of only 1.1 % and 0.8 % to the lattice parameter of GaN, whereas WS2 and MoS2 have a lattice mismatch of only 1.3 % and 1.6 % to the lattice parameter of AlN respectively. In addition, direct growth of TMDs on GaN opens up prospects for novel 2D/3D heterostructures for bipolar and hot electron transistors and optoelectronics.

In this work, we present the growth, structural, and optical properties of fully coalesced MoS2 and WS2 monolayer to few layer films grown on GaN and AlN epitaxial templates on sapphire via Metallorganic Chemical Vapor Deposition (MOCVD). Molybdenum hexacarbonyl (Mo(CO)6), tungsten hexacarbonyl (W(CO)6) and hydrogen sulfide (H2S) were used as precursors in a N2 and H2 carrier gas for the growth of MoS2 and WS2 on 1 x 1 cm2 GaN and AlN substrates. The relative thermal and chemical stability of GaN and AlN can significantly affect the epitaxial growth of TMDs. For example, in the
absence of NH$_3$. GaN begins to decompose at elevated temperatures in H$_2$ while AlN remains relatively stable. Therefore, for TMD growth on GaN, the same techniques used in large scale decomposition and growth temperature and flow rate/growth rate were tuned to prevent GaN decomposition and pit formation before the MoS$_2$/WSe$_2$ covers the surface. In this study, the growth temperature was varied from 900 to 1000 °C; growth time from 10 to 25 minutes, and molybdenum and tungsten precursor flow rates from 0.0006 to 0.0033 sccm whereas the H$_2$ flow rate was maintained at 400 sccm. All the growths were done with a moderate reactor pressure of 50 Torr using N$_2$ and H$_2$ as the carrier gas. AFM and FESEM were carried out to characterize the surface coverage and morphology of the layers. Spatially resolved Raman and photoluminescence spectroscopy were used to investigate the uniformity of the growth across the sample. The TMD films were continuous with thicknesses of mono- to few layers although pits were present in films grown on GaN at elevated temperature and reduced growth rate. The presence of $A_g$ and $E_g$ Raman modes for MoS$_2$ and WSe$_2$ were observed at room temperature. The MoS$_2$ and WSe$_2$ films exhibit strong photoluminescence at room temperature centered around 1.9 eV and 2 eV respectively. The structural, microscopic, and optical properties of the MoS$_2$ and WSe$_2$ monolayers on GaN and AlN will be discussed in detail in the meeting. We emphasize the opportunities for the compatible integration of 2D/3D TMDs/III-V nitrides heterostructures without any transfer process by a fine-tuned deposition, which can have wide implications for the performance of future electronic and optoelectronic devices.

2:00 PM EL.19.08.04 Multiscale Structural Analysis of Epitaxially Grown 2D Layers using Four-Dimensional Scanning Transmission Electron Microscopy Hanako Okumo, Djojerd Dosenovic, Samuel Dechamps, Matthieu Jamet and Alain Marty; CEA-Grenoble, France

Epitaxial growth is a route to achieve highly crystalline continuous 2D layers. In recent years, large scale epitaxial growth of graphene and various transition metal dichalcogenides (TMDs) have been demonstrated by many research groups. However, high quality layer production with expected electrical properties is still challenging due to the imperfection of nucleation control. For instance, slight misalignment and symmetrical crystal inversion in neighbouring nucleation sites result in domain junctions, at the stage of coalescence, containing a large number of atomic defects and which drastically degrades material quality. The presence of polymorphs, such as 2H and 1T’ in the TMDs, also modifies their electronic properties.

In order to control growth process and to predict intrinsic properties of grown material up to wafer scale as a patchwork of defect structures, multiscale structural analysis should be accessible in routine way. X-ray diffraction (XRD) gives a precise information on material quality regarding the crystallinity and the angular distribution at nm scale, while scanning transmission electron microscopy (STEM) imaging offers today the capability to study the detailed local atomic structures such as vacancies, grain boundaries as well as the associated chemical composition at atomic scale. However, these techniques do not reveal complete material characteristics because of the gap in scale between the information obtained by different techniques. Four dimensional (4D)-STEM is a new acquisition technique allowing to simultaneously record 2D images in real and reciprocal spaces. Multiple information, from structure to electric field, at different scales can be reconstructed from signals appearing in diffraction pattern acquired at each pixel of the beam scan. In this work, we demonstrate an analytical process using 4D-STEM to study epitaxial 2D materials grown in both laboratory and industrial scales. Orientation, polarity and phase maps in various TMD monolayers, such as WS$_2$ and WSe$_2$, are reconstructed at micron scale from 4D-diffraction datasets and directly correlated with both large scale XRD analysis and related atomic defect structures revealed by STEM imaging. This structural mapping technique allowed the localization of various domain junctions as well as quantitative information on their density. In addition, the technique was also applied in epitaxial vdW heterostructures for mapping local twist angles. The results show the capacity to construct structural overview of synthesized materials from large scale down to atomic scale, which provides reliable information necessary to develop high quality 2D materials and further to enable theoretical prediction of material properties based on large-scale realistic structure models.

2:45 PM *EL.19.08.05 Understanding Salt-Promoted Metal Organic Chemical Vapour Deposition of Transition Metal Dichalcogenides Jinfeng Yang, Ryo Mizuta, Ye Fan, Vitaly Babenko and Stephan Hofmann; University of Cambridge, United Kingdom

Scalable integrated process pathways remain a key challenge for ultrathin 2D device materials particularly for potential opto-electronic device applications. For transition metal dichalcogenides (TMD), the use of salts to enhance chemical vapour deposition (CVD) has become widespread, yet the underpinning understanding remains limited. We employ operando scanning electron microscopy (SEM) and environmental X-ray photoelectron spectroscopy (XPS) to systematically study the role of salt-based growth promoters. We focus on WSe$_2$ as a model system and explore surface-based mechanisms linked to sodium tungstates, NaOH and NaCl on SiO$_2$ and sapphire substrates in conjunction with widely used gaseous (MO)CVD precursors. We report various hot salt substrate corrosion phenomena that lead to the substrate spreading of W intermediates and significantly influence the growth mechanisms. We can directly resolve the formation and wetting behaviour of liquid droplets and show that the growth scenario particularly for mono-layers is not following a vapour-liquid-solid (VLS) model. Holistic calibration of SE contrast allows us to reveal WSe$_2$ nucleation and in-plane growth kinetics. Our discussion brings together the wider literature including mechanisms of 1D TMD nanotube formation.

3:15 PM EL.19.08.06 Modified Self-Flux Synthesis of Centimeter-Scale Transition Metal Dichalcogenides Luke Holtzman, Madisen Holbrook, Nicholas Olsen, Xiaoyang Zhu, Abhaya Narayan Pasupathy, James Hone and Katayun Barmak; Columbia University, United States

Two-dimensional transition metal dichalcogenides (TMDs) are a highly attractive class of materials due to their novel electronic and optoelectronic properties and the ability to use them as a platform for assembling heterostructures. Self-flux crystal growth of TMDs has been shown to grow bulk TMDs with the lowest defect densities of any synthesis technique, maximizing the ability to study their unique, intrinsic phenomena [1-3]. However, the current self-flux crystal growth method produces TMD crystals smaller than 1 mm$^2$ on average, making monolayer-exfoliation difficult and limiting applications to single devices. Additionally, these crystals are too small to use macroscopic exfoliation techniques such as gold-assisted exfoliation, which require crystals greater than 2 mm in diameter and can isolate entire monolayers from every layer of a bulk crystal. [4]

In this work, we use a modified flux-synthesis thermal cycle containing an optimized dwell temperature and temperature cycling Ostwald ripening to increase the crystal area of ultralow defect density TMDs by more than ten-fold. The crystal growth kinetics as a function of temperature are determined, and directly correlated with both large scale XRD analysis and related atomic defect structures revealed by STEM imaging. In this work, we use a modified flux-synthesis thermal cycle containing an optimized dwell temperature and temperature cycling Ostwald ripening to increase the crystal area of ultralow defect density TMDs by more than ten-fold. The results show the capacity to construct structural overview of synthesized materials from large scale down to atomic scale, which provides reliable information necessary to develop high quality 2D materials and further to enable theoretical prediction of material properties based on large-scale realistic structure models.

Many van der Waals (vdW) layered two-dimensional (2D) materials host exotic transport phenomena such as topologically protected surface states and quantum Hall effects which exhibit strong size dependence at nanoscale dimensions. When formed into 1D nanowires, additional materials property engineering via lateral confinement can be achieved. The tunability of 2D materials with nanowire morphology makes them an attractive platform for studying fundamental physics and for use in next generation microelectronics; however, reliable fabrication methods that can produce narrow nanowires with high aspect ratios are currently lacking.

Here, we report the thermomechanical nanomolding (TMNM) of bulk vdw layered materials to make nanowires with consistent crystal orientation, narrow widths under 40 nm, and high aspect ratios. In TMNM, elevated temperatures and pressures are used to extrude a material through a nanoporous mold to form nanostructures. Until now, TMNM has been reported for metallic glasses and 3D crystalline materials to form 1D nanowires. We demonstrate the use of this technique to successfully fabricate nanowires with widths ranging from 10 – 120 nm of four vdw layered materials: Te, InSe, Bi2Se3, and BiTe2. Atomic resolution scanning transmission electron microscopy (STEM) imaging shows the high crystalline quality of the molded nanowires. While the molding direction was perpendicular to the layer planes in the bulk crystal, crystal rotation occurs during TMNM such that the layers consistently lie along the growth axis of the molded nanowire. We find that the length of the nanowires increases with decreasing width during molding, suggesting that interfacial diffusion along the pores of the mold is the growth mechanism. This work expands the capabilities of TMNM as a straightforward approach to fabricate nanowires of 2D materials with uniform morphology and crystallographic orientation. Furthermore, lateral confinement of the nanowires affords by TMNM provides an additional tuning knob for materials properties.

Wafer-scale epitaxial growth of single crystal TMD monolayers is of significant interest to advance 2D device applications. MOCVD is a promising approach for TMD growth on c-plane sapphire as it enables the use of high substrate temperatures (800-1000°C) and chalcogen/metal ratios (10^3-10^5) which are beneficial for epitaxy. Previously we reported a multi-step process for MOCVD growth of WS2 on sapphire which involves nucleation, ripening and lateral growth. The nucleation temperature was found to be crucial for achieving single orientation domains and coalesced layers with minimal inversion domain boundaries. In this study, we report the effects of nucleation temperature and film microstructure on the resulting optical and electrical properties of the monolayers.

Coalesced WS2 monolayers were grown on 2” diameter c-plane sapphire in a cold-wall horizontal MOCVD reactor with an inductively heated graphite susceptor with gas-foil wafer rotation. W(CO)6 was used as the metal precursor while H2S was the chalcogen source with H2 as the carrier gas at 50Torr reactor pressure. The multi-step process consisted of a 30sec nucleation at temperatures ranging from 800°C to 950°C followed by 10min ripening in H2S, and then lateral growth for 20min at 1000°C, which gives rise to a coalesced monolayer across the entire 2” wafer. After growth, the substrate was cooled in H2S to 300°C to inhibit the decomposition of the obtained WS2 films. A coalesced monolayer of WS2 was achieved on 2” c-plane sapphire over the nucleation temperature ranges from 800°C to 950°C. AFM indicates that the WS2 monolayers are fully coalesced, with a bilayer coverage of less than 20%. Interestingly, stripe-pattern contrasts due to variations in the adhesion of the WS2 monolayer to the underlying sapphire were observed under FESEM and the density of stripes increased as the nucleation temperature was raised from 800°C to 950°C. In-plane XRD phi-scans confirm that the films are epitaxially oriented with respect to the sapphire over the nucleation temperatures from 800°C to 950°C with the (11-20) of WS2 aligned with the (11-20) of α-Al2O3. The FWHM of both the phi-scan peak and 2theta-scan peak of WS2 decreased as the nucleation temperature was reduced. The sample nucleated at 800°C demonstrated the lowest FWHM of -0.26° in the phi-scan peak, indicating larger crystalline domains and reduced In-plane rotational misorientation of the WS2 domains compared to the higher temperature samples. Room temperature photoluminescence measurements of the films on sapphire reveal an increase in the PL peak position from 1.9eV to 2.0eV as the nucleation temperature was increased from 800°C to 950°C.

The variations in the structural and optical properties of the WS2 films with nucleation temperature are attributed to differences in the extent of coupling of the WS2 to the underlying sapphire. The WS2 grown at 800°C nucleation temperature exhibits the strongest coupling to the underlying sapphire as evidenced by the narrow FWHM of the in-plane XRD phi-scan peak, the lack of stripe contrast from buckling in the FESEM image and the red-shift in the PL peak indicating residual strain in the layer. In contrast, the WS2 grown at 950°C nucleation temperature exhibits weaker coupling consistent with buckling contrast in the FESEM image, a broader FWHM for the XRD phi-scan peak and a PL peak at 2.0eV. To test this hypothesis, the films were transferred from the growth substrates and onto sapphire to remove the coupling arising from epitaxy. For the transferred WS2 film grown at 800°C, a substantial increase in the PL intensity and a blueshift in the PL peak position to 1.95eV were observed, indicating a reduction in strain within the film after the transfer process. Additional results correlating the structural and optical properties of the WS2 monolayers to the transport properties of field-effect devices will be reported.

Large-Area Epitaxial Hexagonal Boron Nitride for Hydrogen Generation by Radiolysis of Interfacial Water
Johannes Binder, Aleksandra Dabrowska, Mateusz Tokarczyk, Katarzyna Ludwiczak, Rafal Bozek, Grzegorz Kowalski, Roman Stepieniewski and Andrzej Wysinolek; Faculty of Physics, University of Warsaw, Poland

Hydrogen is an important building block in global strategies toward a future green energy system. To make this transition possible, intense scientific efforts are needed, also in the field of materials science. Hexagonal boron nitride (h-BN) is a very promising candidate for such applications, as it has been demonstrated that micrometer-sized flakes are excellent barriers to molecular hydrogen. However, it remains an open question whether large-area layers...
fabricated by industrially relevant methods preserve such promising properties.

We address this issue and show results on the growth of epitaxial h-BN on 2-inch sapphire wafers by metalorganic vapour-phase epitaxy (MOVPE) [1-5], which is currently regarded as one of the most promising growth techniques. This technique allows to grow hBN layers, with thicknesses of tens of nm [1,3], and can serve as a substrate for the direct growth of van der Waals heterostructures on the wafer-scale [4].

In this work, we show that electron-beam-induced splitting of water creates hBN bubbles that effectively store molecular hydrogen for weeks [5]. The bubble formation can be observed in-situ in a scanning electron microscope, giving us the unique possibility to visualize the hydrogen generation process. Raman spectroscopy proves the presence of molecular hydrogen and experiments with heavy water provide evidence that hydrogen generation is triggered by the radiolysis of water captured at the van der Waals interface. By performing a stress test we could also demonstrate that H2 remains in the bubble even after extreme wear and deformation (over 500 cycles of deflation and inflation by changing the ambient pressure), highlighting the suitability of our large-area epitaxial material for possible hydrogen storage applications.

Our findings show that epitaxial h-BN by MOVPE is not only a potential candidate for the growth of large-area van der Waals heterostructures and hydrogen storage but also holds promise for the development of unconventional hydrogen production schemes [5].

Graphene Origami: Evolution of the Morphology of Free-Standing Few-Layer Graphene in Plasma Synthesis Claudia-F. Lopez Camara, Paolo Fortugno, Markus Heidelmann, Hartmut Wiggers and Christof Schalch; University of Duisburg-Essen, Germany

Since discovered, graphene has shown to be a very versatile material due to its unique properties, which makes it suitable to multiple applications, ranging from sensing to batteries. Even though free-standing graphene flakes have traditionally been synthesized using exfoliation techniques, interest on gas-phase synthesis is on the rise due to its suitability for process scale-up and for generating graphene with very low oxygen content. Yet, the growth of free-standing few-layer graphene (FLG) during plasma synthesis leads to a variety of morphologies, such as turbostratic graphene (typically less than ten graphene layers), and the growth mechanism is essentially unknown.

Using spatially resolved thermophoretic sampling directly from the area of the graphene formation zone for transmission electron microscopy (TEM) analysis, we studied the morphology of graphene flakes in different growth stages. Single-layer and few-layer graphene were observed, and a morphology pattern evolution was discerned depending on time and reaction conditions. Based on these investigations, we propose a folding-based growth and structure formation process, leading to a conceptual mechanism of few-layer graphene formation and growth, starting from initial round single-layer graphene to, eventually, carbonaceous nanoparticles. The edges resulting from the folding have also been investigated, revealing that graphene does not seem to break at the bends but fold similar to rolling up carbon nanotubes and without opening new reactive sites for further growth.

Breathable MOFs Layer on Atomically Grown 2D SnS2 for Stable and Selective Surface Activation Ji-Soo Jang; Korea Institute of Science and Technology, Korea (the Republic of)

Two-dimensional (2D) materials (MoS2, SnS2, MXene, black phosphorus (BP), and graphene oxide) with intriguing physicochemical properties such as abundant reactive edge-sites, tunable electrical properties, and mechanical flexibility, have been developed for broad applications in chemical sensing, electrocatalysis, filtration membrane, and energy storage systems. Among various 2D materials, SnS2 (IV-VI A group), which is a semiconducting layered structure with a large bandgap of ~2.2 eV and has many advantages (low-cost, nontoxic, and environmental friendly properties), can be catered well into the broad applications. Based on these interesting material properties of SnS2, 2D SnS2 is widely used as active surface reactor with rapid, sensitive, and selective surface reactivity to various molecules including ions, gases, and biomolecules. Even though the outstanding and exceptional characteristics of SnS2 has been proved in many previous studies, its poor stability due to oxidation and degradation issues under the ambient operation conditions limits the practical usage of SnS2.

In this work, we newly developed ‘Sandwich’ like hybrid materials platform, 2D SnS2 layer covered by uniformly porous ZIF-8, employing in-situ growing methods. First of all, the 2D SnS2 layer (1st layer) was directly grown on the Si based sensor substrate through ALD method, and as such, strong bonds between active material (SnS2 in this case) and the sensor substrate are able to be formed. Then, the in-situ growing of ZIF-8 was followed on the heterogeneous SnS2 layers, so the defect free ZIF-8 covered the whole SnS2 layers. The top-side of ZIF-8 membrane and bottom-side SnS2 play critical role for molecular sieving and chemical detection, respectively. Due to the uniform pore distribution of ZIF-8 layer on the SnS2 sensing layer, H2O molecules can be reliably blocked by ZIF-8 breathable layer, while target NO2 molecules can selectively penetrate through the ZIF-8 layer. Therefore, our hybrid materials exceptionally showed high stability and selective surface activity from the chemical sensing case study and the underlying mechanisms were further investigated in the atomistic level using theoretical calculations.

High-Throughput Production of an Atomically Thin Nano-Dot Array for Enhanced Exciton-Exciton Interactions Jeongin Yeo1, Seungjae Lim2, Taeowan Kim2, Jae-Ung Lee2 and Joonki Suh1,1; 1Ulsan National Institute of Science and Technology, Korea (the Republic of); 2Ajou University, Korea (the Republic of)

Monolayer transition metal dichalcogenides (TMDs) are an appealing material platform for investigating and manipulating excitonic properties in the atomically thin limit due to their intrinsic strong Coulomb interactions and alleviated screening effects. To date, a number of such studies have been conducted to determine the excitonic physics or control their dynamics by diverse experimental approaches including electrostatic gating, magnetic field manipulation and strain engineering. However, physically confined excitonic transport through nanostructuring is not handled yet. Herein, we introduce a high-throughput nanofabrication of laterally confined monolayer TMDs in a hexagonal array. The fabricated nanodots of monolayer TMDs are approximately 20 nm wide far below typical exciton diffusion length of monolayer TMDs. We then investigated their photoluminescence (PL) characteristics by performing a series of power, wavelength (2.25–2.82 eV), and temperature dependent measurements. We observed the unconventional emission in sub-20 nm WS2 nanodots, which is presumably associated with the physically confined excitonic transport behavior and reconstructed band structure. This platform is suitable tool for understanding of confined quasi-particle transport behavior and size-dependent PL study, providing a broader insight for fundamental excitonic many-body interactions and related dynamics.

A Practical Hydrogenated Graphene Gas Sensor for CO2 Monitoring Solimar Collazo1,1, Samuel Escobar1,2, Brad Weiner1,1 and Gerardo Morell1,1; 1University of Puerto Rico at Rio Piedras, Puerto Rico; 2National Institute of Standards and Technology, United States

The development of a practical gas sensor is of great interest for monitoring toxic and non-toxic gases that might endanger our safety and wellbeing in different settings. Here, we present a gas sensor based on hydrogenated graphene for monitoring carbon dioxide (CO2). Hydrogenated graphene was synthesized using a single-step method directly onto an insulating substrate plated with gold. The material was characterized using Raman spectroscopy, X-ray photoelectron spectroscopy (XPS), and X-ray diffraction (XRD). The interaction of the hydrogenated graphene with CO2 was systematically studied at different parts per million (PPM) to determine the detection limits of the sensor. Our results show that the hydrogenated graphene-based sensor is capable of sensing CO2 at mid-PPM levels with a CO2 responsivity of ~176.21. The biosensor was also found to detect CO2 at low ppm values, making it suitable for use as a biosensor for aerobic cellular respiration and regular CO2 emission sensing. We have successfully developed a versatile and practical gas sensor based on hydrogenated graphene for CO2 monitoring. The sensor's detection limits, and responsivity make it suitable for a wide range of applications, including monitoring of CO2 emissions and aerobic cellular respiration. The simplicity of the synthesis method used also makes it a promising candidate for large-scale production.
The group-III chalcogenides are an emerging class of van der Waals semiconductors with potential for applications in electronics, optoelectronics, and photonics. Further, material properties such as work function and band gap vary dramatically as the material is thinned toward the 2D limit. In this talk, we present experimental studies of the electronic and optical properties of van der Waals heterostructures containing the layered group-III chalcogenides. We analyze the effect of charge transfer within the structure as a function of layer thickness and compare the electronic performance with the more common TMD-based heterostructure devices.

Twisted van der Waals (vdW) heterostructures exhibit periodic variations, leading to a new type of in-plane superlattice known as moiré superlattice/pattern which modifies considerably the optical properties of excitons in transition metal dichalcogenides (TMD) vdW heterostructures. Here, we report on optical and magneto-optical properties of WS₂/MoSe₂ heterobilayers with twist angles around 0° and 60° under out-plane magnetic fields up to 20 T [1]. We observed two neutral exciton peaks in the PL spectra: the lower energy one exhibits a reduced g-factor relative to that of the higher energy peak, and much lower than the recently reported values for interlayer excitons in other vdW heterostructures such as WSe₂-MoSe₂. In addition, similar values of g-factors are obtained for samples with twist angles of approximately 0° and 60° which indicates a weak hybridization between the intralayer and interlayer excitons for this heterostructure. Furthermore, time resolved PL experiments reveal that the lifetimes of the moiré exciton emission peaks are much shorter (< 50 ps) than the values reported in the literature for the interlayer excitons in other TMD heterostructures (~ 2 ns), which also indicates a weak exciton hybridization. The observed reduction of the g-factor value for the moiré exciton was explained by the quantized center-of-mass momentum of the moiré-confined exciton resulting in a exciton motional mass value away from the exciton band edge. In general, our experimental and theoretical results provide evidence that such a discernible g-factor stems from the spatial confinement of the exciton in the potential landscape created by the moiré pattern, due to lattice mismatch and/or inter-layer twist in heterobilayers [1].

Atomic layer deposition (ALD) is a key technology for many materials, such as solar energy production or infrared sensing, which makes the growth of free standing (strain free) layers of CdTe of particular interest. In 2017, Kim et al demonstrated that it is possible to guide the growth of a material through one or few monolayers of 2D materials, even if the polarity of the substrate below the 2D material is strong enough. This technique, called “remote epitaxy”, has been applied successfully to a wide range of III-V / 2D systems, such as the epitaxial growth of GaN on hBN / GaN substrate, or GaAs on Graphene / GaAs substrate. Epitaxially grown layers are then easily transferred and the 2D coated substrate can be re-used for future growths. Despite this great success with III-V materials, remote epitaxy of II-VI semiconductors hasn’t been studied much. From a purely theoretical point of view, CdTe with its higher ionicity than GaAs or GaN should be a good candidate for remote epitaxy. However, a transfer step is required to obtain 2D coated substrates, with its lot of difficulties (polymeric contamination, degradation of the 2D surface, oxidation of the substrate…), whereas high quality surface and interface are required to perform remote epitaxy.

Another approach to bypass the need of 2D material transfer would be to perform epitaxy on a reconstructed passivated surface. It has been proven recently (Jovanovic et al, 2020) that sapphire could act as a quasi van der Waals substrate for such a growth of CdTe via the in-situ formation of a monolayer of tellurium at the interface. In such a case, the substrate surface, free from dangling bonds, allows for an easy transfer of the epitaxially grown CdTe membrane. But, unlike with “remote epitaxy”, growth is not seeded by the polar substrate, and one can ask what is the impact on the crystalline quality of the epitaxial layer?

In this communication, we will present the results of MBE grown CdTe film on both sapphire and graphene wet-transferred onto CdZnTe. The crystalline quality of the grown CdTe film is discussed based on SEM, AFM and X-ray diffraction. Graphene quality is checked out prior and after epitaxy based upon Raman spectroscopy. Additional XPS analysis were performed to evaluate substrate oxidation and graphene cleanliness. Results of CdTe layer removal and manipulation will also be presented.

In this work, atomic layer deposition (ALD) is conducted for growing Wide Bandgap Metal Oxides (ZnSnO) as buffer layers on p-type selenium (Se) absorbers, which was used in the first solid-state solar cell in 1883 and has a high absorption coefficient and mobility, making it a p-type absorber for wide energy gap (~1.8-2.2 eV) thin film solar cells. In addition, direct bandgap, earth-abundance, simple composition, non-toxicity, low melting point and environmental stability make Se inexpensive and developable for solar cells. However, in the n-type buffer layer perspective, so far, has not found a suitable buffer layer for modulating conduction band offset (CBO) between n-type buffer layers and p-type Se absorbers.

The benefit for using ALD growth ZnSnO can be summarized as the following points: (1) ZnSnO is wide band gap material (~3.2eV); (2) Controllable of Zn and Sn ratio, which can intentionally modulate the CBO become spike type (i.e., 0°<CBO<0.5 eV); (3) ALD can effectively growth larger scale of thin-film and precisely control the thickness. Finally, the result presented the Zn1-xSnxO (x=7%) under the optimization of ZnO and SnO ratio, the power conversion efficiency can be achieved at about 2.68%.
We report atomically coherent layer-by-layer epitaxial growth of MoS$_2$/WS$_2$ van der Waals (vdW) heterostructure with metal-organic chemical vapor deposition (MOCVD) which enables vertical stacking of atomically thin semiconductors without interlayer atomic mixing. Engineering the miscut angle of c-plane sapphire substrate, we first achieved the epitaxial growth of single crystalline WS$_2$ monolayer (ML) template as base layer. Single crystalline textured was confirmed by microscopes and transmission electron microscope (TEM) studies. Moreover, low energy electron diffraction (LEED) measurements at several different points perfectly exhibited 3-fold symmetry without any angle deviation. We also demonstrated coherent ML-by-ML epitaxial growth of MoS$_2$ on top of single crystalline WS$_2$ film. VdW epitaxy is kinetically controlled in the near-equilibrium limit, resulting in the tunable two-dimensional (2D) vdW electronic systems. Coherent monolayer stacking was verified by transmission electron microscope studies and optical characterization. Our AA’(2H) and AB(3R) stacked MoS$_2$/WS$_2$ heterostructures showed strong interlayer coupling. Furthermore, electronic and optoelectronic properties of coherent vdW heterostructures were obtained. Our work suggests synthetic material platform of various 2D coherent heterostructures for future application in electronic and photonic nano devices.

Hynes, Level 3, Room 309

8:30 AM *EL19.11.01 Metalorganic Chemical Vapor Deposition of Wafer-Scale Transition Metal Dichalcogenide Monolayer and Heterostructures Joan M. Redwing; The Pennsylvania State University, United States

Wafer-scale synthesis of transition metal dichalcogenide (TMDs) monolayers is of significant interest for device applications to circumvent size limitations associated with the use of exfoliated flakes. Metalorganic chemical vapor deposition (MOCVD) has emerged as a promising technique for scalable synthesis of TMD films as it enables growth at high temperatures and chalcogen overpressures which are beneficial for epitaxy and provides good control over precursor flux which is necessary for the synthesis of heterostructures.

Our work has focused on MOCVD growth of epitaxial semiconducting TMDs (MoS$_2$, WS$_2$ and WSe$_2$) on 2” diameter c-plane sapphire substrates. Metal hexacarbonyls (Mo$_2$CO$_6$, W$_2$CO$_6$) and hydrides (H$_2$S, H$_2$Se) are used as precursors with H$_2$ as the carrier gas in cold-wall MOCVD reactor geometries. Pre- annealing the sapphire surface in H$_2$S or H$_2$Se modifies the nucleation behavior of TMDs on sapphire which is attributed to passivation of dangling bonds on the sapphire surface. Passivation of step terraces can drive nucleation to occur preferentially at step edges on sapphire leading to unidirectional domains and a concomitant reduction in mirror twin defects. In situ spectroscopic ellipsometry is demonstrated to be an effective real time monitor of TMD growth even at the sub-monolayer level which can be exploited to track surface coverage as a function of time under varying growth conditions. The ability to precisely control and modulate precursor flux during growth is used to synthesize in-plane heterostructures that enable localized exciton confinement and emission.

9:00 AM EL19.11.03 Growth of Width-Controlled Single Atomic Layer TMD Nanoribbons Xufan Li and Avetik R. Harutyunyan; Honda Research Institute USA Inc., United States

Controlling the width of single atomic layer transition metal dichalcogenides (TMDs) offers additional degree of freedoms for engineering their properties and enabling applications in fields for next generations of optoelectronics, quantum computing, communication, and sensing. However, direct and controllable synthesis of TMD nanoribbons, especially for the appealing width range below 30 nm, remains challenging. Therefore, developing facile methods for their direct and controllable synthesis is of central importance. We present a new growth method for single and double atomic layer of TMD nanoribbons with width down to sub-10 nm. Nanoribbons are grown via precipitation from the pre-deposited nanoparticles via vapor-liquid-solid mechanism in which the nanoparticle diameter also controls the width of nanoribbon. We also present the evolution of electrical and optical properties of the nanoribbons with their width reduction due to the corresponding dimension confinement and the results of their performance in the quantum electronics, particularly as a single electron transistor and single photon emitter.

9:15 AM *EL19.11.04 The Impact of Boron and Nitrogen Isotopes on the Properties of Hexagonal Boron Nitride James H. Edgar, Eli Janzen and Thomas Poirier; Kansas State University, United States

Hexagonal boron nitride (hBN) is a two-dimensional dielectric material prized for its potential electronic, optoelectronic, and nanophotonic device applications. Here we describe how its properties are affected by changing its boron and nitrogen isotopes. hBN consists of 20% $^{10}$B and 80% $^{11}$B, and 99.6% $^{14}$N and 0.4% $^{15}$N when it is synthesized from sources with the natural distribution of isotopes (hBNnat). Isotopic disorder is greatly reduced when hBN is synthesized using an isotopically enriched boron source, either $^{10}$B or $^{11}$B. Consequently, the phonon polariton propagation length and lifetimes are increased by factors of eight and four times in monoisotopic hBN crystals. Due to reduced phonon scattering, the thermal conductivity is also increased, by as much as 50% to 650 Wm$^{-1}$K$^{-1}$ for hBN at room temperature. Reducing the density of nuclear spin disorder motivates the synthesis of hBN with the $^{15}$N isotope: $^{14}$N and $^{15}$N have nuclear spins of 1 and $\frac{1}{2}$ respectively. Thus, both DC sensitivity of the boron vacancy $V_{\text{B}}$ to magnetic fields is increased by a
factor of four with $h^{10}\text{B}^{15}\text{N}$ over $h\text{BN}$.

These hBN crystals with controlled isotope concentrations were grown at atmospheric pressure from molten metal solutions of nickel, chromium, and enriched boron in contacted with nitrogen gas at 1550 °C. By slow cooling (1-4 °C/h), hBN is synthesized and its crystals precipitate on the surface of the metal. This technique produces high quality hBN crystals, as indicated by their narrow $E_g$ Raman peak widths (<3 cm$^{-1}$) for $h\text{BN}$ and strong photoluminescence intensities at energies greater than 5.75 eV. This is a versatile, scalable technique for making high quality, large area, hBN single crystals with low residual impurity concentrations.

High Crystalline Quality PtSe$_2$ Films for High Frequency Optoelectronics

Pierre Legagneux and Eva Desges; Thales Research & Technology, France

Transition metal dichalcogenides (TMDs) are very attractive two-dimensional materials for optoelectronic applications, due to their various and tunable bandgaps, to the strong light-matter interaction per 2D layer and to the possibility to transfer and integrate these 2D materials on CMOS or photonic platforms.

While the most well-known TMDs (MoS$_2$, WSe$_2$,…) exhibit a bandgap in the visible range, PtSe$_2$ is an original and remarkable TMD particularly adapted for optoelectronics in the infrared (IR) domain. It exhibits a bandgap varying from 1.2eV (monolayer) to 0.2eV (bilayer) and becomes semi-metallic from few layers to bulk. Thus, PtSe$_2$ absorption can be easily tuned to absorb IR light by varying its thickness from two to multilayers. PtSe$_2$ is air stable and particularly adapted for high-frequency optoelectronics with a very high theoretical (4000 cm$^{-2}$/V.s) and a high experimental (e.g. ~200 cm$^{-2}$/V.s) carrier mobility at room temperature (Note that larger mobilities are reported in the literature which remain however difficult to measure due to the difficulty to estimate actual carrier concentration in semimetal multi-layered PtSe$_2$).

Due to its high intrinsic qualities, PtSe$_2$ is studied to fabricate high frequency photodetectors operating at the 1.55 µm telecom wavelength. Based on transferred thin PtSe$_2$ films grown by CVD, 17 GHz bandwidth photodetectors have been fabricated on a SiO$_2$/Si substrate and 35 GHz bandwidth waveguide photodetectors have been realized on a silicon nitride platform.

High frequency optoelectronics requires both efficient photodetection and high-speed transport and thus materials exhibiting high crystalline quality. PtSe$_2$ has been synthesized by mechanical exfoliation, CVD, thermally assisted conversion and molecular beam epitaxy (MBE). To evaluate PtSe$_2$ crystalline quality, most groups have studied the full width at half maximum (FWHM) of the in-plane Eg Raman peak and shown that thinner is the Eg peak, higher is the crystalline quality and the electrical conductivity.

Here, we have studied the growth of high quality PtSe$_2$ by MBE on sapphire, which is a low cost, insulating substrate and have fabricated high frequency optoelectronic devices on 2 inches substrate wires. We show 8-nm thick PtSe$_2$ films exhibiting average FWHM Eg values as low as 3.7 cm$^{-1}$ and electrical conductivities as high as 1.5 mS. Integrated in a coplanar wave guide, we demonstrated a 1.55 µm photodetectors with a 60 GHz bandwidth and optoelectronic mixers exhibiting a flat response between 1 and 30 GHz. Optoelectronic mixing is a key technical enabler for future broadband and multifunctional RF systems such as radio-over-fiber communication systems, radar systems, and satellite payloads.

To further increase PtSe$_2$ crystalline quality, we are studying two methods: step-guided epitaxy and van der Waals epitaxy. Step-guided epitaxy on sapphire consists in growing on dedicated vicinal surfaces to favor the oriented nucleation of the crystals at the steps (this method has been demonstrated by other groups for MoS$_2$ and WS$_2$ on sapphire). We will also show first results targeting van Der Waals (vdW) epitaxy of PtSe$_2$ on h-BN.

10:30 AM EL19.11.07

Reproducible Synthesis of Ultrahigh-Quality Graphene by Oxygen-Free Chemical Vapor Deposition

Xingzhou Yan$^1$, Jacob Amontree$^1$, Christopher DiMarco$^1$, Pierre Levesque$^1$, Tehseen Adel$^1$, Madisen Holbrook$^1$, Christian Cupo$^1$, Dihao Sun$^1$, Kenji Watanabe$^4$, Takashi Taniguchi$^4$, Cory Dean$^1$, Angela R. Hight Walker$^3$, Katayun Barmak$^1$, Richard Martel$^2$ and James Hone$^1$; 1University of Illinois at Urbana-Champaign, United States; 2Université de Montréal, Canada; 3National Institute of Standards and Technology, United States; 4Université de Montréal, Canada; 5National Institute of Standards and Technology, United States; 6National Institute for Materials Science, Japan

Progress in translating advances in the growth of graphene by chemical vapor deposition (CVD) to applications has been hindered by challenges in quality and reproducibility, as well as the lack of a simple model of growth kinetics. Here we show that eliminating trace oxygen leads to fast and highly reproducible CVD graphene growth. The dependence of growth rate on growth time, temperature, and CH$_4$ pressure follow straightforward trends, while previously unobserved behavior is seen for H$_2$ pressure. A compact kinetic model is constructed to describe the graphene growth behavior, which can be used to guide graphene synthesis. We confirm that ppm-level oxygen disrupts growth by etching the graphene edges, and map the boundary between growth and etching in the presence of H$_2$. We demonstrate that trace oxygen causes two major sources of disorder in CVD-grown graphene: pinholes and amorphous carbon deposition. Finally, we grow epitaxial graphene on sapphire-supported Cu(111) films. The graphene shows few wrinkles, no evidence of amorphous carbon, and an ultra-low defect density. After dry transfer and device assembly, this graphene shows electrical transport behavior virtually indistinguishable from that of exfoliated graphene, both at room temperature and at low temperature.

10:45 AM EL19.11.08

In-Situ TEM of Atomic Reconstructions in 2D Transition Metal Dichalcogenides

Yichao Zhang$^1$, Chia-Hao Lee$^1$, Ji-Hwan Baek$^2$, Huijie Ryu$^2$, Gillian Nolan$^1$, Gwan-Hyong Lee$^1$ and Pinshane Y. Huang$^1$; 1University of Illinois at Urbana-Champaign, United States; 2Seoul National University, Korea (the Republic of)

Scanning transmission electron microscopy (STEM) provides uniquely powerful tools to study the interfacial structure and transformations of 2D materials up to atomic resolution. Here, we utilize 2D multilayer stacks to create nanoscale laboratories for studying the atomic structure, structural transformations, and properties of 2D interfaces inside the STEM. We utilize graphene encapsulation in combination with a MEMS-based heating holder to conduct in-situ studies of solid-solid phase transformations and interfacial restructuring in 2D transition metal dichalcogenides. The graphene encapsulation protects the 2D materials from the vacuum environment of the STEM, enabling high temperature studies up to 1000°C. We use these structures to directly visualize the layer-by-layer phase transformation of MoTe$_2$ and the lattice reconstruction of 2D moirés.

First, we study the interfacial reconstruction mechanisms of twisted bilayer transition metal dichalcogenides (MoSe$_2$ and WSe$_2$) using in situ aberration-corrected STEM and dark-field transmission electron microscopy (DFTEM). We discover a new mechanism of local reconstruction from moiré patterns to parallel (3R) and/or antiparallel (2H) domains in twisted bilayer 2D transition metal dichalcogenides (TMDs). Unlike previous reports, where the twist angle is altered by the rotation of a whole flake, we observe the nucleation and growth of commensurate domains through the formation and migration of grain boundaries. We capture the dynamic process of nucleation and growth of the aligned structure through a series of atomic resolution STEM images combined with atom-tracking analysis. These results provide new insights into the mechanisms of interlayer rotation at the atomic scale and potential methods for engineering the structure of moiré superlattices.

Second, we examine the atomic mechanisms of phase transitions of MoTe$_2$. MoTe$_2$ exhibits multiple structural and electronic phases at room temperature (2H, 1T', and Td) that can be easily manipulated with different stimuli, making it a promising candidate for phase-change memories, high-performance transistors, and broadband photodetectors. We combine dark-field TEM and aberration-corrected STEM to image the phase transitions of few-layer MoTe$_2$...

**Giant Magnetoresistance of Dirac Plasma in High Mobility Graphene**

Alexey Berdyugin1,2, Na Xin1, James Lourenco1, Piranavan Kumaravadivel1, Alexander Kazantsev1, Zefei Wu1, Ciaran Mullan1, Julien Barrier1, Alexandra Geim1, Irina Grigorieva1, Artem Mishchenko1, Alessandro Principi1, Vladimir Falko1, Leonid Ponosarenko2 and Andre Geim1;

1The University of Manchester, United Kingdom; 2National University of Singapore, Singapore; 3The University of Lancaster, United Kingdom

The most recognizable feature of graphene’s electronic spectrum is its Dirac point, around which interesting phenomena tend to cluster. At low temperatures, the intrinsic behaviour in this regime is often obscured by charge inhomogeneity but thermal excitations can overcome the disorder at elevated temperatures and create an electron–hole plasma of Dirac fermions. The Dirac plasma has been found to exhibit unusual properties, including quantum-critical scattering and hydrodynamic flow. However, little is known about the plasma’s behaviour in magnetic fields. Here we report magnetotransport in this quantum-critical regime. In low fields, the plasma exhibits giant parabolic magnetoresistivity reaching more than 100 per cent in a magnetic field of 0.1 tesla at room temperature. This is orders-of-magnitude higher than magnetoresistivity found in any other system at such temperatures. We show that this behaviour is unique to monolayer graphene, being underpinned by its massless spectrum and ultrahigh mobility, despite frequent (Planckian limit) scattering. With the onset of Landau quantization in a magnetic field of a few tesla, where the electron–hole plasma resides entirely on the zeroth Landau level, giant linear magnetoresistivity emerges. It is nearly independent of temperature and can be suppressed by proximity screening, indicating a many-body origin. Clear parallels with magnetotransport in strange metals and so-called quantum linear magnetoresistance predicted for Weyl metals offer an interesting opportunity to further explore relevant physics using this well defined quantum-critical two-dimensional system.

1:45 PM EL19.12.02

**Two-Fold Anisotropic Superconductivity in Bilayer Td-MoTe2**

Zizhong Li1, Apoorv Jindal2, Alex Strasser1, Yangchen He1, David Graf1, Wenkai Zheng1, Kenji Watanabe2, Takashi Taniguchi3, Luis Balicas4, Xiaofeng Qian4, Abhay Narayan Pasupathy5 and Daniel A. Rhodes1;

1University of Wisconsin Madison, United States; 2Columbia University, United States; 3Texas A&M University, United States; 4National High Magnetic Field Laboratory, United States; 5NIMS, Japan; 6Kyoto University, Japan

Non-centrosymmetric 2D superconductors offer an opportunity to explore superconducting behaviors with large values of anisotropy. Among the non-centrosymmetric families, Td-MoTe2 is a representative material because of its rich phases. Notably, Td-MoTe2 is the first 2D materials that demonstrated a coupling between ferroelectricity and superconductivity, and this ferroelectric switching can be simply controlled by electrical gating. Here, we will present on the superconducting behavior in bilayer Td-MoTe2 under the application of an applied magnetic field along different directions in-plane and under differing displacement fields and doping densities. Importantly, we find that bilayer Td-MoTe2 has two-fold symmetric superconducting behavior as a function of in-plane magnetic field angle that maximizes along the a-axis, parallel to the mirror plane. The two-fold anisotropy is preserved in the entire superconducting region, even with the interaction of strong Rashba spin-orbit coupling, and we find that the two-fold symmetric superconductivity exists after the ferroelectric switching. Our findings generally agree with previously observed results in multilayer and monolayer Td-MoTe2 and the expected spin-orbit enhanced upper critical fields as found in DFT calculations.

2:00 PM *EL19.12.03*

**Few-layer 2M and Td-TMDs: Topologically Nontrivial States, Superconductivity and Ferroelectricity**

Apoorv Jindal1, Amartyaayoti Sahai1, Zizhong Li1, Yangchen He1, Takashi Taniguchi3, Kenji Watanabe2, James Hone1, Turan Birsoy2, Rafael Fernandez3, Cory Dean4, Abhay Narayan Pasupathy5 and Daniel A. Rhodes1;

1Columbia University, United States; 2University of Minnesota, United States; 3Texas A&M University, United States; 4University of Wisconsin - Madison, United States; 5National Institute for Materials Science, Japan

I will discuss our most recent results on superconductivity in bilayer Td-MoTe2. For bilayer Td-MoTe2, the influence of an electrostatic gate allows us to identify a unique superconducting state that relies on Fermi surface nesting between hole and electron pockets. As a result, we show that the superconducting state can be completely quenched by an electrostatic gate. Concomitant to this effect, ferroelectricity resulting from interlayer sliding is also present in bilayer Td-MoTe2, resulting in a hysteretic behavior of superconductivity with respect to an applied out-of-plane electric field. This behavior allows for the first investigations of how internal polarization might conflict with or enhance superconductivity in the two-dimensional limit. Time allowing, I will discuss our results on a similarly structured TMD in the few-layer limit, the topologically nontrivial 2M-WSe2.

2:30 PM BREAK

**Van der Waals Josephson Junctions for 2D Superconducting Qubits**

Jesse Balgley1, Xuanjing Chu1, Jinho Park1, Ethan Arnault2, Martin V. Gustafsson1, James Hone1 and Kin-Chung Fong1;

1Columbia University, United States; 2Massachusetts Institute of Technology, United States; 3Raytheon BBN Technologies, United States

State-of-the-art superconducting qubits currently face numerous materials-limited roadblocks to increasing coherence times for fault-tolerant computing while shrinking form factors for scalability. Two-dimensional van der Waals (vdW) materials offer an ideal platform to circumvent these issues owing to their single-crystallinity, low defect density, and lack of dangling bonds. In particular, the vdW semiconductor WSe2—whose band gap is ~5x smaller than that of vdW insulator hBN—can exhibit tunneling through ~10 layers, enabling Josephson junctions with exceptional tunnel barrier homogeneity and lower loss compared to deposition-grown junctions by confining fields in ultra-clean vdW interfaces while achieving 100x smaller qubit area. We characterize the electronic properties of vdW Josephson junctions with ultra-high-purity WSe2 barriers and discuss their potential in small-footprint, long-coherence-time superconducting qubits.
Iron-based high-Tc FeTe,Se, (FTS) has been proposed to host unconventional superconductivity. Recent scanning probe and ARPES experiments imply spontaneous time-reversal symmetry breaking in FTS systems. In this work, we report the field-free superconducting diode effect in FTS van der Waals Josephson junctions (vJJ). Non-reciprocal superconducting critical current can be observed in the absence of external magnetic field, which directly manifests spontaneous time-reversal symmetry breaking in FTS systems. The polarity and efficiency of the diode effect are also stochastic, which can be randomly reset by performing a thermal cycle above the superconducting critical temperature Tc. This suggests the time-reversal symmetry breaking ordering is closely tied to the superconducting states. The stochasticity also provides insights into ferromagnetic domain behaviors of superconducting surface states.

4:00 PM EL19.12.06
2D-Material-Based Superconducting Quantum Devices Xuming Chu1, Jesse Balgley1, Jinho Park1, Ethan Arnault2, Martin V. Gustafsson3, James Hone4 and Kin-Chung Fong4; 1Columbia University, United States; 2Massachusetts Institute of Technology, United States; 3Raytheon BBN Technologies, United States

Two-dimensional van der Waals (vdW) materials are promising platforms for superconducting quantum devices due to their single-crystallinity, low defect density, and lack of dangling bonds. Additionally, vdW materials offer a novel knob of gate-tunable electronic properties, including carrier density and superconducting gap energy, and can be readily combined into quantum device heterostructures such as Josephson junctions (JJs). JJs made from vdW materials can boast homogeneity across large (~1000 μm2) areas making them practical as novel sub-THz JJ emitters whose frequency can be tuned with a gate voltage as opposed to changing the bias current. We characterize the dc and microwave electronic properties of vdW materials and show they are compatible with high-quality-factor superconducting quantum devices. We also present numerical calculations of the emitting properties of gate-tunable Josephson junctions based on vdW superconductors and semiconductors and show that they can meet desirable performance criteria, including narrow linewidths < 1 MHz and appreciable output power at the microwatt level.

4:15 PM EL19.12.07
Probing Complex Many-Body Interactions in 2D Heterostructures Jyoti Katoch; Carnegie Mellon University, United States

Two-dimensional (2D) materials provide unprecedented opportunity to engineer their physical properties by modification to the electronic structure utilizing external perturbations—strain, gating, adsorbates, defects, twist-angle, and interface engineering. This is expected to cause changes to the Hamiltonian describing the system and has resulted in exotic phenomena such as superconductivity, bound quasiparticles, topological states as well as magnetic phases, with implications for novel electronics and spin-device applications. In this talk, I will present our work on directly visualizing (without any assumption) the electronic structure of atomically thin systems utilizing in-operando angle-resolved photoemission spectroscopy with nanoscale spatial resolution (nanoARPES) on 2D heterostructures and their fully functional devices. I will present the experiments which demonstrate on-demand tuning of the electronic band structure in atomically thin systems, such as transition metal dichalcogenides (TMDs) and graphene, by varying the twist-angle between the atomic layers and external dopants. Specifically, I will discuss the electric field tuning of the electronic interactions that result in van Hove singularity and flat bands in twisted bilayer graphene and twisted double bilayer graphene heterostructures. In addition, I will discuss our results where we observe the formation of quasiparticle polaron due to many-body interactions in graphene/TMDs heterostructures.

4:45 PM EL19.12.08
Polymer–Free Assembly of Van der Waals Heterostructures Wendong Wang1,2, Nicholas Clark1,2 and Roman Gorbachev1,2; 1National Graphene Institute, United Kingdom; 2The University of Manchester, United Kingdom

2D heterostructures present an optimal approach for the synthesis of novel materials with highly adjustable properties, including electron topology and correlation effects. Currently, the prevailing method for constructing van der Waals heterostructures involves the "tear and stack" technique, wherein individual 2D layers are stacked using a polymer stamp. However, this approach easily traps contaminants at the heterostructure interface, leading to limitations in atomic cleanliness and electronic performance of the resulting heterostructures. To address this issue, we have developed a novel polymer-free stacking method that employs flexible, transparent, and thermally stable metallized silicon nitride membranes (SiN). These SiN membranes enable precise and rapid transfer of 2D flakes to desired locations in various environments, including air, argon glovebox, and ultrahigh vacuum, at elevated temperatures of up to 300°C. The elevated temperature during the fabrication process facilitates the removal of surface-absorbed contaminants from the 2D heterostructure interfaces. To showcase the merits of this polymer-free transfer technique, we successfully fabricated and assessed distinct heterostructures. In initial experiments, we achieved hBN/graphene/hBN heterostructures exhibiting remarkably bubble-free regions, accompanied by mobility values reaching 3×10^6 cm^2/Vs^-1. Moreover, we demonstrated the fabrication of a more intricate LED structure with a bubble-free area 25x30 μm, completed within a mere 10-minute timeframe. Furthermore, a twisted monolayer/bilayer graphene on an hBN substrate displayed minimal variation in twist angles, with deviations of merely 0.016° over a length of 10 μm. Lastly, the SiN membrane method enables the large-scale transfer of 2D materials synthesized via chemical vapour deposition (CVD) from the growth substrate, devoid of any polymer involvement.
graphene/SiC interface, which is a reconstructed carbon layer on SiC (0001). It is possible to convert this BL to quasi-freestanding monolayer graphene by intercalation of a foreign element [2]. In this method, foreign atoms enter the BL/SiC interface to terminate the interfacial Si atoms, and the BL is decoupled from the substrate. The intercalated atoms are thus arranged in two-dimension and covered by graphene. The intercalation of the ferromagnetic element Fe can manifest intriguing physical properties such as perpendicular magnetic anisotropy and spin injection to graphene. Meanwhile, due to the affinity of Fe with Si and C, its intercalation is challenging. So far, several studies are reporting Fe intercalation in graphene/SiC [3]; however, the direct observation of its interface structure is missing. Here, we performed a uniform Fe intercalation and observed its interface structure at the atomic scale with cross-sectional transmission electron microscopy (TEM).

The uniform BL sample was prepared by annealing a single crystalline 4H-SiC (0001) substrate at 1500°C in an Ar atmosphere. Fe intercalation was carried out by vacuum deposition of a thickness of about 10 nm at room temperature, followed by annealing at around 660°C. The samples thus obtained were characterized by Raman spectroscopy (λ=532 nm), X-ray photoemission spectroscopy (XPS, hv=1486.6 eV), and TEM. The TEM observations were performed using a JEM-ARM200F-type microscope at an accelerating voltage of 200 kV. The thin specimen for TEM was prepared by the conventional Ar-ion thinning method.

From the Raman spectra of the sample, the BL was successfully converted to monolayer graphene. The Fe 2p spectrum of XPS suggests the presence of metallic Fe or Fe silicide on the sample surface, even after air exposure. A high-resolution TEM (HRTEM) observation of this sample revealed a layered contrast of graphene on the substrate surface. More importantly, uniform atomic layers of Fe were identified at the graphene/SiC interface by a high-angle annular dark field scanning TEM (HAADF-STEM) observation and energy dispersive X-ray spectroscopy (EDX) analysis. The number of these Fe layers was two to four over a wide range of observations. The interlayer distance between the first and second layers of Fe was ~2.4 Å. Such a structure has not been reported for Fe, Fe-oxide and Fe-silicide in their bulk form. In this Fe-intercalated graphene/SiC, modulation of the magnetic structure of Fe and spin injection to graphene can be expected.

8:00 PM EL19.13.04 Second-Harmonic Generation Imaging Microscopy with Ps Pulsed Lasers Bita Rezania, Volker Buschmann, Christian Oelsner and Maria Loidolt-Krueger; PicoQuant GmbH, Germany

Second harmonic generation (SHG) imaging microscopy is a nonlinear optical imaging technique that uses SHG as a contrast mechanism to produce high-resolution images. SHG occurs in materials with non-centrosymmetric crystal structures. Therefore, SHG imaging has been applied for characterization of 2D semimetallic, transition-metal dichalcogenides (TMDs) such as WS2; and MoS2, lithium niobate crystals, PZT thin films, graphene, lanthanides, and even biological tissues. It provides information on the crystal lattice, assesses crystal quality and maps grain boundaries, defects, and mechanical strain. Furthermore, SHG imaging reveals the number of stacked layers as well as their orientation with respect to each other.
