CuI is a wide bandgap p type transparent semiconductor and owns a high potential to be used in the fields like thin film transistor, Optoelectronic, and memory devices etc. It has many advantages like high hole mobility, good electrical property with a structure disorder. However, a high hole concentration in the CuI leads to a low Current On-Off ratio ( $I_{ON-OFF}$ ) for CuI TFT devices. To solve this issue, Br doping technique is proposed to lower down the hole concentration in the CuBr film so that a better TFT device performance can be obtained. The density functional theory (DFT) results show that the copper vacancy formation energy increases with the CuBr content in the Br-doped CuI film, resulting in lower hole concentration. The CuBr TFTs with different Br content were then fabricated. All the CuBr films were synthesized by the solution method. When the Br concentration increases from 0% to 10%, the hole mobility decreases while the  $I_{ON-OFF}$  ratio increases from the order of  $10^2$  to  $10^4$ . A Br doping concentration of 7.5% shows the best device performance with hole concentration about  $5 \text{ cm}^2\text{V}^{-1}\text{s}^{-1}$  and  $I_{ON-OFF}$  ratio of  $10^4$ . The good p type CuI TFT device performance is a good foundation for the later application of CuI in the fields, including Logic circuits, Optoelectronic etc.

**Polarization-Dependent Optical Properties of Ce-Implanted Quartz** Yuichiro Abe<sup>1,2</sup>, Shun Kanai<sup>1,3,4</sup>, Manato Kawahara<sup>1,2</sup>, Jun Ishihara<sup>5</sup>, Makoto Kohda<sup>2</sup> and Shunsuke Fukami<sup>2,6</sup>; <sup>1</sup>Tohoku University, Japan; <sup>2</sup>Graduate School of Engineering, Tohoku University, Japan; <sup>3</sup>PRESTO, Japan Science and Technology Agency, Japan; <sup>4</sup>National Institutes for Quantum Science and Technology, Japan; <sup>5</sup>Department of Applied Physics, Tokyo University of Science, Japan; <sup>6</sup>Inamori Research Institute for Science, Japan

Nitrogen-Vacancy centers in diamonds and divacancies in SiC are the representative material systems composing solid-state spin qubits with a long coherence time at room temperature [1-4]. While various functionalities, e.g., remote entanglement, quantum sensing, and quantum communications, have been achieved, new qubit material systems may offer a new range of opportunities. One of the most critical material parameters for many quantum applications is the relaxation time  $T_2$ . Here, we focus on quartz as a host material, the most common mineral on the earth, and has been predicted to have a long  $T_2$  without nuclear purification [5]. We choose the  $\text{Ce}^{3+}$  center as a spin center, which often composes a stable spin center in the widegap oxides, e.g., in  $\text{Y}_3\text{Al}_5\text{O}_{12}$ , whose spin state can be controlled through the circularly polarized laser [6].

We implant Ce ion into a naturally abundant single-crystal quartz substrate at room temperature in the air. The implantation dose and energy are  $1.0 \times 10^{14} \text{ cm}^{-2}$  and 100 keV, respectively. Subsequently, the samples are annealed in Ar for 0-9 hours at 700-1000°C. First, we investigate the unpolarized optical properties of Ce-implanted quartz. The unpolarized photoluminescence (PL) spectra are measured with unpolarized He-Cd laser excitation at 325 nm. The unpolarized PL shows similar spectra with the previous studies on the sputter-deposited  $\text{SiO}_2:\text{Ce}$  [7]: unpolarized PL spectra have a prominent peak at around 445 nm, which corresponds to the  $4f-5d$  transitions with different spin-orbit interaction of the  $\text{Ce}^{3+}$  center. We investigate the unpolarized PL of the samples with various annealing conditions. Up to 800°C, as the annealing temperature increases, PL intensity increases, suggesting the formation of luminescent  $\text{Ce}^{3+}$ , while the further increase of the annealing temperature decreases the unpolarized PL intensity, suggesting the formation of the Ce clusters without bright luminescence.

Next, we investigate the polarized optical properties with the samples annealed at 800°C. In a single  $\text{Ce}^{3+}$  center of  $\text{YAG}:\text{Ce}^{3+}$ , the polarization-dependent PL signal corresponding to the spin-dependent  $4f-5d$  transition and the pulsed optically-detected magnetic resonance (ODMR) have been reported at 5 K [6]. We observe that a polarization-dependent optical signal of the Ce-implanted quartz is consistent with the  $4f-5d$  transition of the isolated  $\text{Ce}^{3+}$  centers:  $\sigma^+$  excitation offers a larger  $\sigma^+$  PL emission than that with  $\sigma^-$  at the peak wavelength, and the more prominent  $\sigma^-$  emission at the shoulder wavelength (~560 nm). The degree of circular polarization (DOCP) reaches 15% (5%) at peak (shoulder) wavelength at 5 K. The DOCP monotonically decreases with increasing the measurement temperature, which suggests that the spin-lattice relaxation time  $T_1$  limits  $T_2$  in this material system.

### 8:20 AM EL11/EL13.05

**Fully Solution-Processed Ultraviolet Photodetector Based on Hydrothermally Grown ZnO Nanorod Array** Ajinkya B. Palwe, Tapesh Kumar, Sweta Rani, Shobha Shukla and Sumit Saxena; IIT Bombay, India

Patterned nanostructures exhibit interesting optoelectronic characteristics due to light-matter interaction at the comparable dimension of incident light and material. At a comparable dimension, the optoelectronic response of the nanostructure-based devices is modulated by the size and the periodicity of the structure. Numerous techniques based on top-down and bottom-up approaches are used to obtain patterned nanostructure. However, the solution-based technique is considered to be best due to cost-effectiveness as well as large-area processing. Recently patterned structures of metal oxide semiconductors are getting attention for various optoelectronic devices like photodetectors, solar cells, etc. ZnO is an abundantly available metal oxide that has high absorption coefficient and is highly appropriate for low-cost ultraviolet photodetectors. The hydrothermally patterned ZNA was achieved in two steps of deposition starting with ZnO quantum dots (QDs) seed layer followed by hydrothermal reaction. The as-grown ZNA was treated with ZnO QDs to remove any pin-holes or trap sites. P-type polymer PEDOT:PSS was used for making heterojunction with n-type ZNAs. The carbon electrode at the top was deposited by screen printing of carbon paste.

The optical bandgap increases with decreasing the size/periodicity of the ZNA. ZNR based film and heterojunction devices are investigated for different sizes/periodicity using surface morphology and optoelectronic properties. The ZNA based heterojunction photodetectors have shown improved photoresponse under ultraviolet (UV) light. The maximum photoresponsivity of 9.2 A/W and external quantum efficiency of 3144% are achieved for the ZNA obtained by 20 mM precursor solution. The response time is also fast due to the reduction in surface pin-holes/traps.

**KEYWORDS:** *Hydrothermal deposition; Patterned ZnO; P-N junction, UV photodetector;*

**Flat Optics for Dynamic Wavefront Manipulation** Mark L. Brongersma; Stanford University, United States

Since the development of diffractive optical elements in the 1970s, major research efforts have focused on replacing bulky optical components by thinner, planar counterparts. The more recent advent of metasurfaces, i.e. nanostructured optical coatings, has further accelerated the development of flat optics through the realization that nanoscale antenna elements can be utilized to facilitate local and nonlocal control over the light scattering amplitude and phase. In this presentation, I will highlight recent efforts in our group to realize electrically-tunable metasurfaces employing nanomechanics, tunable transparent oxides, electrochemistry, microfluidics, phase change materials, and atomically-thin semiconductors. Such elements are capable of dynamic wavefront manipulation for optical beam steering, holography and future display technologies. The proposed optical elements can be fabricated by scalable fabrication technologies, opening the door to a wide range of commercial applications.

**Novel Machine-Learning Approaches Based on Metric Learning and Manifold Learning for the Design and Knowledge Discovery in Nanophotonics** Mohammadreza Zandehshahvar and Ali Adibi; Georgia Institution of Technology, United States

This talk is focused on using the machine-learning (ML) approaches based on dimensionality reduction and manifold learning for considerably reducing the dimensionality of the forward and inverse problems in relating the input and output of a nanophotonic system. It is shown that by using manifold learning techniques and simplifying the resulting networks using pruning, the computation complexity of the underlying ML algorithms will be considerably reduced. Furthermore, the importance of using an optimally defined loss function (or metric) for ML algorithms in obtaining priceless information about the properties of photonic nanostructures will be emphasized. It is shown that by moving from conventional mean-squared error to more intelligent metrics, knowledge discovery in nanophotonics will be facilitated along with better visualization of the input-output relationship in these nanostructures. In addition to knowledge discovery, the resulting manifold-learning algorithms can be optimally trained to facilitate the inverse design of such nanostructures while minimizing the structural complexity. As such, this talk will provide the foundation for both knowledge discovery and design in photonic nanostructures using manifold learning and metric learning and their application to the highly desired metaphotonic structures as an example platform.

**11:00 AM \*EL12.01.02**

**Machine Learning Methods for Freeform Metamaterial Design** Jonathan A. Fan; Stanford University, United States

We will discuss computational algorithms based on deep neural networks that can accelerate the design and simulation of nanophotonic devices, using metasurfaces and metamaterials as a model system. We will discuss the use of generative networks to perform population-based optimization and elucidate how the neural network architecture can be tailored to effectively perform freeform optimization. We will also discuss how physics-augmented deep networks can be trained with a combination of data and physics constraints to serve as accurate surrogate electromagnetic solvers. A principal challenge involves configuring the algorithms in a manner that enables application to a wide range of problems, and we show how these concepts can generalize to the simulation and optimization of photonic devices involving a range of domain sizes, fitting parameters, and functions. Together, these algorithms can effectively search for the global optimum three to four orders of magnitude faster than with conventional methods. We anticipate that with proper co-design of the neural network architecture with the scientific computing task, our surrogate solver and optimizer concepts can be adapted to large scale three-dimensional photonic systems.

**11:30 AM \*EL12.01.03**

**Three-Dimensional Metamaterial Absorber for Gas Molecular Sensing** Takuo Tanaka<sup>1,2,3</sup>; <sup>1</sup>RIKEN Center for Advanced Photonics, Japan; <sup>2</sup>RIKEN Cluster for Pioneering Research, Japan; <sup>3</sup>Tokushima University, Japan

Metamaterials have attracted considerable attention due to their capabilities to manipulate light. Recently we applied metamaterial light absorber for

improving the sensitivity of IR spectroscopy. Owing to its plasmonically resonant interaction with incident light wave, and molecules, unwanted background and noises in IR spectroscopy were suppressed, and molecular signals are enhanced and clearly observed at the bottom of the suppressed background. This technique has already been applied for self-assembled monolayer of 16-mercaptohexadecanoic acid molecules on the surface of metamaterial absorber and atto-molar ( $10^{-18}$  mol) level molecular sensitivity was realized [1]. For liquid samples, to introduce target molecules into the hot spot region of the metamaterial absorber, we proposed a metamaterial absorptive device that incorporates with nanofluidics and demonstrated an ultra-high sensitivity of IR absorption detection [2, 3, 4]. In this paper, we introduced metamaterial absorber with three-dimensional vertical-oriented metal-insulator-metal (v-MIM) structure for ultra-sensitive infrared spectroscopic gas molecule sensing [5]. We designed the v-MIM structure with a nano-gap of 25 nm channel which enabled the delivery of small molecules into hot-spot region. We developed the fabrication technique to realize v-MIMs on the surface of Si substrate using electron-beam lithography and reactive ion etching techniques. Owing to small footprint of v-MIM comparing conventional lateral MIM structure, the density of hot spots was dramatically increased resulting in strong signal enhancement and efficient suppression of background light. This metamaterial was applied to carbon dioxide and butane detection designing to exhibit a resonance at  $4033\text{ cm}^{-1}$  and  $2945\text{ cm}^{-1}$  which spectral overlap with the C=O and  $-\text{CH}_2$  vibration mode, respectively. The mutual coupling of these two resonant modes creates a Fano resonance, and their distinct peaks are clearly observed in the corresponding transmission dips. In addition, owing to its small footprint, v-MIM structure allows the detection of a 20 ppm concentration with suppressed background and high selectivity in the mid-infrared region.

#### SESSION EL12.03: Industrial Perspective on Metasurface

Session Chairs: Yongmin Liu and Junsuk Rho

Tuesday Morning, November 28, 2023

Hynes, Level 3, Room 305

#### 8:30 AM \*EL12.03.01

**Large Scale Manufacturing Techniques for Metamaterials and Their Industrial Applications** Ragip Pala; Meta Materials Inc., United States

Development of a scalable nanofabrication technique is essential for the practical realization of nanostructured materials in functional transparent films. META® has developed discrete platform-specific proprietary technologies for large-scale lithography, allowing the manufacture of nanostructures to be carried out with high uniformity and low cost. Using these manufacturing techniques at META®, we design and mass-produce nano-technology-based films with applications in a wide variety of products and markets.

In this talk, I will present large-scale manufacturing techniques at META® including nanoimprinting, roll-to-roll processing, and holographic lithography. I will also discuss various industrial applications in automotive, authentication, 5G communication and consumer electronics. Our customizable patented nano-optics include visual authentication technology, KolourOptik® Stripe, with a unique combination of multiple colors, 3D depth and omni-directional movement. I will describe NANOWEB®, META®'s Roll to roll lithographically fabricated conductor with superior electrical and optical properties. This functional film is configured as a nanostructured conformable metal wire mesh, that is transparent to the naked eye. I will explain how we utilize NANOWEB® to enable smart solutions for distinct functions including electro-optical dimming, transparent antennas, anti-fog heaters and EMI Shielding.

In addition, we are also using a first of its kind Plasma Fusion® deposition technology, which enables high speed coating of any alloy on any type of thin flexible plastic substrate. Large scale and efficient metallization coating of ultra-thin substrate with zero defect, is a critical step for example toward volume production of safe reliable lightweight battery materials, requiring hundreds of millions of square meters per year. We use this metallization step in our roll-to-roll production process for functional films, which for solid state NCORE™ battery current collectors will reduce battery weight, increase safety, significantly accelerate line speed, and hence reduce cost.

#### 9:00 AM \*EL12.03.02

**A Scalable Technology Platform for Creating Meta-Surface Based Optics and Waveguide Combiners for Augmented Reality** Robert J. Visser, Ludovic Godet, Rutger Thijssen, Jinxin Fu, Rami Hourani, Sage Doshay and Guannan Chen; Applied Materials, United States

Optics is increasingly important in modern life, and advances in nanostructure-based flat optical devices hold great promise for revolutionary new opportunities in the display space. Augmented and Virtual Reality (AR/VR) are expected to enable the next ubiquitous computing and communication platform.<sup>[1]</sup> Augmented Reality, Optical metasurfaces also leverage engineered nanostructures to offer the possibility of extreme wavefront control, enabling further miniaturization of imaging and display optical systems and exciting new applications not achievable with conventional optics.<sup>[2,3]</sup> The Engineered Optics™ group at Applied Materials is enabling thinner, light-weight optical systems with precise wavefront engineering to make possible novel optical devices. We have leveraged Applied Materials' materials engineering expertise to develop a platform for the precision fabrication of nanostructured optical devices on 300mm glass wafers, as well as metrology, optical performance characterization, and back-end assembly of these devices. With this platform, we are producing waveguide combiners for AR/VR applications and optical metasurfaces for multi-functional wavefront control in the near infrared. An essential element in designing the process and making choices for equipment is scalability, laying the foundation for large scale industrial manufacturing in a later stage. We have opted to focus on the use of optical lithography Nano Imprint Lithography and a 300 mm equipment for all the etch and deposition steps. This leverages all the experience and the availability of equipment from the Semiconductor Industry. Waveguide combiners are a key component in lightweight augmented reality headset or glasses systems, but are difficult to fabricate to the high precision required for simultaneous high optical image quality of the AR content and clear vision of the real world.<sup>[1]</sup> The Engineered Optics platform includes a fully integrated front-end process flow to make surface relief grating-based waveguide combiner devices for our customers. All our tools are customized to enable handling of transparent substrates of a variety of refractive indices and thicknesses. We produce binary and slanted nanostructures using UV or nanoimprint lithography and etch in high-quality, low-loss optical materials. We can process single- or double-sided devices with high alignment fidelity, and can create desired features with global and local-area processing techniques.

The Engineered Optics platform offers full end-to-end capabilities: after front-end fabrication on 300mm substrates, we optically characterize device performance at the wafer level, then complete back-end singulation, edge blackening, stacking assembly, and final testing. Completed waveguide combiner

devices can then be integrated with light engines and appropriate electronics, power sources, and housings to create final AR glasses or headset devices. The Engineered Optics platform also enables direct fabrication of optical metasurfaces on transparent substrates, without transfer from silicon substrates. We can fabricate the extremely high aspect-ratio structures required for full  $2\pi$  phase control in a variety of extremely low-loss, high-refractive index optical materials.

We are also looking at photonic integrated circuits, optical computing, optical data communication, and beyond.

#### 9:30 AM BREAK

#### 10:00 AM \*EL12.03.03

**Highly Efficient Color Separation and Focusing in Various Color Pattern Arrays of CMOS Image Sensor** Sookyoung Roh, Sungmo Ahn, Choonlae Cho, Hongkyu Park, Sangeun Mun, Sangyun Lee, Junho Lee and Seokho Yun; Samsung Advanced Institute of Technology, Korea (the Republic of)

We designed various types of nanoscale metaphotonic color-routing (MPCR) structures that can significantly improve the low-light performance of CMOS image sensors. Fabricated on a  $1.12\mu\text{m}$  Dual pixel sensor and a  $0.64\mu\text{m}$  Quad-pixel sensor, the MPCR structure separates the incident light energy into the respective color pixels, resulting in a notable increase in quantum efficiency of up to 20%. Our experimental demonstration confirmed a luminance SNR improvement of +1.0 dB under low light condition of 20 lux. Furthermore, this improvement was consistently achieved across different types of color pattern arrangements, further validating the versatility and effectiveness of our MPCR structures.

Pixel miniaturization has been the main driver of product innovation in CMOS image sensors (CIS) for many years, and now pixel sizes are approaching the sub-wavelength diffraction limit. While downsizing pixels enables higher pixel densities and smaller form factors, there is a trade-off between pixel miniaturization and signal-to-noise ratio (SNR). Consequently, the overall performance of CIS is adversely affected due to the reduction in light-receiving areas [1]. To address these inherent physical limitations, alternative approaches involving efficient redistribution of incident light energy can be pursued through the integration of appropriately designed sub-wavelength scale photonic structures. Recent attempts to replace conventional color filters with metasurface structures are noteworthy in this regard [2-4], yet the performance and the process compatibility of the demonstrated devices have been far from commercialization, suffering from severe color crosstalk, poor angular response, complex or impractical fabrication processes, and additional color correction that resulted in lower-than-expected SNR gains.

In this work, we present a new approach to revolutionize current optical stack layers by incorporating sub-wavelength scale metaphotonic color-routing (MPCR) structures. Our research efforts have yielded a wide range of nanoscale MPCR structures with remarkable capabilities to significantly improve the low-light performance of CMOS image sensors. By integrating these structures, we aim to improve sensor performance by manipulating the incoming light more efficiently. We have directly integrated the MPCR structures onto both of Samsung's  $1.12\mu\text{m}$  dual-pixel CIS and  $0.64\mu\text{m}$  quad-pixel CIS. And we characterized the imaging properties along with quantum efficiency compared to the reference sensor. The fabrication process is 100% CMOS-compatible, promising commercialization of high-performance sub-wavelength-pixel CIS.

#### 10:30 AM \*EL12.03.04

**Metasurfaces: From Lab to Mass Markets** Robert Devlin; Metalenz, United States

Optical metasurfaces enable unprecedented control over all aspects of light (phase, wavelength, intensity, and polarization) with a single, planar semiconductor layer. Comprised of subwavelength nanostructures, a single metasurface can carry out optical functions typically requiring four or more conventional refractive and/or diffractive optics, bringing new forms of sensing to mobile form factor for the first time. In addition to the expanded functionality they provide, they also open a route to the manufacture of optical devices in the semiconductor foundry, because they are constructed from CMOS-compatible materials on a planar substrate. This presentation will discuss metasurfaces from fundamental concepts to commercialization and will explore how the performance and large-scale manufacturing advantages of this technology will ultimately allow Metalenz to proliferate forms of sensing that have previously only been accessible in scientific or industrial laboratories.

#### 11:00 AM TRAVEL TIME TO KEYNOTE SESSION

SESSION EL12.05: Wavefront Shaping, Metalens and Applications  
 Session Chairs: Yongmin Liu and Junsuk Rho  
 Tuesday Afternoon, November 28, 2023  
 Hynes, Level 3, Room 305

#### 1:30 PM \*EL12.05.01

**Circularly Polarized Photoluminescence from Chiral Metamaterials and Large Area Fabrication** Vivian Ferry; University of Minnesota, United States

Chirality controls light polarization, leading to emerging applications ranging from 3D displays to anti-counterfeiting to sensing. In the first example, I will show patterned, light-emitting metasurface structures, combining plasmonic structures and patterned, photoluminescent quantum dots. I will show how strategically placing these nanocrystals results in highly tailored circularly polarized photoluminescence, which realize simultaneously high polarization control and photoluminescence intensity. The light-emitting meta-atoms, which consist of cross-linked nanocrystals, are fabricated using direct-write electron beam lithography, realizing lateral feature sizes as small as 30 nm and heights in excess of 100 nm without degradation of the photoluminescence. I will then discuss an alternative strategy that uses additive manufacturing to create large-area metamaterials, and is roll-to-roll compatible. Finally, I will discuss the optical properties of chiral metamaterials formed by block co-polymer assembly and the effects of both the surface termination and bulk structure. I will show that it is possible to realize circular dichroism even in structures that are achiral in the bulk, due to the surface termination.

#### 2:00 PM \*EL12.05.02

**Nanoscale 3D Printing of Structural Colors and Micro Optics** Joel Yang; Singapore University of Technology and Design, Singapore

Structural colors are generated from nanoscale structures of various materials due either to interference or optical resonance effects. The ability to achieve a

wide range of colors by simply tuning geometric properties opens fascinating opportunities to the nanoengineer or nanoscientist to design colors using material properties, sizes and shapes as input parameters. This physical approach contrasts with the chemical approach for synthesizing pigments and dyes. Using semiconductor fabrication methods, 2D structures based on metals and high index dielectrics have been realized, e.g. nanodisks, ellipses, etc. defined with electron-beam lithography and vacuum deposition methods.

Recently, we have extended the generation of structural colors from 3D nanostructures created using two-photon polymerization lithography (TPL). The use of TPL, an additive manufacturing process with sub-micron print resolutions, to produce structures for optical effect is a relatively new endeavor [1]. We have previously shown the fabrication of nanopillars, gratings, mesh-like, and wood-pile photonic crystal structures that appear colorful under white-light illumination.

We now demonstrate the integration of these structural colors with other micro-optical elements, such as microlenses and spiral phase plates. Equipped with TPL as a nanoscale 3D printer, structural color geometries are conveniently integrated in a single print run with other user-defined optics. Doing so enables one to produce structured light from incoherent light sources, holographic color prints, and control of the light-field for 3D representation. We will discuss the use of structural colors combined with micro-optics for enhanced information content and optical security [2].

#### 2:30 PM BREAK

#### 3:00 PM EL12.05.03

**High-Numerical Aperture Metalenses with High Quality Factor** Claudio U. Hail, Morgan Foley, Ruzan Sokhoyan, Lior Michaeli and Harry A. Atwater; California Institute of Technology, United States

In highly resonant optical elements, attaining a high quality factor typically comes at the cost of limited spatial control over the wavefront. Here, we report on dielectric, higher-order Mie-resonant metasurfaces that break this paradigm by realizing high-numerical aperture wavefront manipulation with high-quality factors. Our structure consists of high-index dielectric nanoparticles exhibiting a spectrally overlapped electric dipole and electric octupole mode, which allows for local wavefront manipulation. By appropriately tailoring the nanoparticle dimensions over a range of 545 – 555 nm with a period of 736 nm, we imposed a paraboloidal phase profile at an interface to realize radial metalenses for operation at near-infrared wavelengths with linear TE or TM polarization. The structures were fabricated from an amorphous silicon thin film on a glass substrate by a single step electron beam lithography and dry etching process. We have experimentally demonstrated dielectric metalenses with numerical apertures of up to 0.8 and quality factors of up to 880, in some cases with diffraction-limited performance. Our findings represent a significant advancement compared to previous approaches that have been limited to low numerical apertures or one-dimensional wavefront manipulation.

**Wide Field-Of-View Metasurface Optics—From Fundamentals to Applications** Juejun Hu; Massachusetts Institute of Technology, United States

Wide field-of-view (FOV) is a much coveted feature in many optical systems with wide applications ranging from automotive sensing to biomedical imaging. In this talk, we will start by introducing our work formulating the analytical design frameworks for wide FOV metasurfaces with two distinctive and yet related configurations: imaging and projection optics. We will then proceed to discuss several device implementations guided by the analytically derived designs with applications spanning 3-D sensing, extended depth-of-field imaging, and full-color projection display.

#### 3:45 PM EL12.05.05

**Hybrid Metalens Platform for Nanoparticle Levitation and Control in Vacuum** Mohamed S. Mohamed; ETH Zürich, Switzerland

Levitated nanoparticle systems have emerged as a promising approach for studying fundamental forces, investigating non-Gaussian quantum states, and probing material properties at the nanoscale. When operated under ultra-high vacuum (UHV), damping of nanoparticle mechanical motion is kept sufficiently low, reducing decoherence and sustaining a high-quality-factor mechanical oscillator which can be exploited for quantum-limited sensing.

One of the main challenges towards implementing nanoparticle levitation in vacuum is the required level of control over trapping potentials, feedback forces, and sources of noise. Control schemes should additionally satisfy vacuum-compatibility and stability requirements. A compact design implementation, especially in an integrated form factor, can further enable a wide range of experiments such as acceleration sensing in dynamic testing or quantum state manipulation in cryogenic systems.

Here, a hybrid chip-scale platform for trapping and control of dielectric nanoparticles in vacuum is presented. The platform features a primary optical trap generated through an optimized polarization-insensitive dielectric metalens which features focal length in the range of 50 – 200  $\mu\text{m}$  and numerical aperture values of up to 0.98. Individual silicon meta-atoms are designed to provide complete  $2\pi$  phase coverage in the near-infrared wavelength range, with average transmission values exceeding 90%. The near diffraction-limited performance of the metalens alleviates requirements on input power for stable optical trapping. The metalens is patterned in an epitaxial silicon-on-sapphire layer, which exhibits reduced optical losses in comparison to silicon layers prepared by alternative deposition methods. The sapphire substrate provides a broad transparency window for the incident trapping laser beam, while preventing heat build-up given its thermal properties.

The hybrid device design features metallic electrodes embedded within the metalens layer. A dual-ring electrode configuration serves to create a tunable-height Paul trap, where the trapping volume overlaps the focal spot of the optical metalens trap. This is to assist with the loading of nanoparticles into the device by virtue of the deep potential well of the Paul trap. Furthermore, the electrode layer comprises pads for nanoparticle feedback cooling by means of cold damping. The overall architecture can additionally accommodate customized static and dynamic electromagnetic potentials which can be readily applied to the trapped nanoparticle. The overall electrode design enables the above functionalities without significantly perturbing the generated optical potential of the metalens near the trapping zone.

The proposed design was fabricated using a refined approach relying on electron-beam patterning and etching, combined with metal lift-off. Initial testing confirmed UHV compatibility of the device down to a pressure of  $\approx 10^{-7}$  mbar, at the limit of the experimental vacuum chamber. Optical trapping was

demonstrated with the device using femtogram SiO<sub>2</sub> nanoparticles, down to a pressure of 1 mbar. The collected forward scattering signal allowed for nanoparticle motion tracking using split detection.

The demonstrated platform provides a robust approach for chip-scale nanoparticle levitation and control, which opens the door to highly promising applications in both fundamental and applied science.

**Stretchable Dielectric Metasurfaces with Electrical Control** Hyunjung Kang, Joohoon Kim, Dongmin Jeon and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Metasurfaces are a type of structured surface composed of subwavelength-sized elements that can manipulate light at the nanoscale. Structural colors of metasurfaces are engineered by manipulating light to produce color without relying on dyes. They utilize microscopic or nanoscale structures to interact with light and selectively reflect or transmit certain wavelengths. By designing the size and shape of the sub-wavelength structures, metasurfaces can exhibit a wide color gamut, high color saturation, and even iridescence through precise control over the interaction of light. To improve the tunability, some techniques using phase-transition materials and active materials have been developed. In addition, a stretchable structural color via mechanical stretching has been reported. However, mechanical stretching is difficult to achieve precise and localized stretching. Also, mechanical stress can cause emergency structural damage, material fatigue and deformation. Here, we demonstrate electrically tunable structural color pixels with full-spectrum in the range from 450 to 650 nm. Electrical stretching allows for enhanced control and uniform/reversible deformation of the metasurfaces. By embedding a SiN metasurface in a polydimethylsiloxane (PDMS) substrate and stretching it in radial direction, the distinct reflection colors are tuned. As the period of the meta-atom increases from 310 nm to 450 nm, red-shift of the reflection spectrum is realized, covering from blue color to red color. In addition, since the intensity of light can be adjusted using a polarizer, it shows high-resolution images by adjusting the contrast. The reversible structural colors are promising in anti-counterfeiting, and strain-sensing applications.

#### 8:00 PM EL12.07.02

**Single-Step Manufacturing of UV Metasurface using ZrO<sub>2</sub> Nano-PER** Joohoon Kim and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

UV light, essential in scientific and technological fields, has various applications ranging from spectroscopy and quantum optics to photolithography and biosensing. Traditional UV optics rely on large optical components, which offer limited functionality and versatility. In contrast, flat optics consisting of subwavelength optical scatter offer compact platforms for precise wavefront manipulation. They enable significant downsizing of optical components and provide diverse functionalities. Nonetheless, UV metasurfaces encounter persistent challenges such as the scarcity of UV materials with low-loss and high-index properties, exorbitant manufacturing costs, and low throughput associated with electron beam lithography [Adv. Mat. 30, 1802632, 2018]. Therefore, low-loss and high-index materials for UV metasurface have been actively studied in recent years: hafnium oxide [Light Sci. Appl. 9, 55, 2020], zinc oxide [Sci. Adv. 8, abn5644, 2022], silicon nitride [ACS Nano 16, 3546-3553, 2022], and niobium pentoxide [Laser Photonics Rev. 13, 1800289, 2019]. However, fabrication processes of the aforementioned materials include not only electron beam lithography but also multi-step etching with a high aspect ratio or atomic layer deposition of a thick layer. In this manuscript, we fully address this long-standing challenge by introducing a zirconium dioxide (ZrO<sub>2</sub>) nanoparticle-embedded resin (nano-PER) for a one-step printable platform for UV metasurface. The ZrO<sub>2</sub> nano-PER is synthesized by dispersing ZrO<sub>2</sub> nanoparticles in a UV-curable resin which makes nano-PER printable. Owing to the large bandgap and high refractive index of ZrO<sub>2</sub> nanoparticles, the ZrO<sub>2</sub> nano-PER has a high refractive index and low extinction coefficient over the broad UV regime. Thus, a designed meta-atom has a conversion efficiency of 88% ( $\lambda=325$  nm) and 81% ( $\lambda=248$  nm), respectively. In this method, high-efficiency UV metasurface can be replicated repeatedly using a single step of nanoimprint lithography without any secondary operations, resulting in high throughput and low cost. This method will provide real opportunities for practical applications of UV metasurfaces.

#### 8:00 PM EL12.07.03

**Metasurface Selective Nanoimprint by Continuous Lithography with Laser-Induced Graphene on Metal Thin Film** Timothy Yee Him Chan and Mitch Guijun Li; The Hong Kong University of Science and Technology, Hong Kong

Efficient and cost-effective fabrication of metasurfaces is crucial for their widespread application in thin film technologies such as optical modulation and chemical sensing. In this study, we propose a laser-based selective nanoimprint method that enables faster and more controlled fabrication of metasurfaces, facilitating the application of different molds onto the target surface with ease. Laser-induced graphene is deposited on a metal thin film, and it is placed on the flexible mold, then the metal thin film will be used to absorb the laser energy to provide pressure on the mold for nanoimprinting the mold pattern onto the target surface. The pressure from the laser source can be controlled precisely, and the target surface can be cured at the same time to stabilize the nanostructure imprinted. By pausing the laser irradiation during the curing process, the mold will return to its original position to create a pulling effect on the nanostructure, this can enhance the height of the nanostructure on the target surface to 2 times or more of the mold structure, from 2.54  $\mu\text{m}$  of the original mold to 7.74  $\mu\text{m}$  on the target surface. The presented approach offers a simple fabrication method with outstanding performance for the construction of selective metasurfaces. It utilizes laser-induced transfer techniques and laser-induced pressure to enable the efficient manufacturing of optical metasurfaces and other 2D-nanostructure-based applications. The demonstrated capabilities of this technique hold great promise for the advancement of metasurface technology and its integration into various thin film devices.

**Optical Metasurfaces for Dynamic Wavefront Control in the Visible Range** Ramon Paniagua Dominguez; Institute of Materials Research and Engineering (A\*STAR), Singapore

The ability to dynamically manipulate propagating light is critically important in various applications, from optical communications, precision manufacturing or adaptive optics, to metrology and displays. While Spatial Light Modulator technologies offering dynamic control of wavefronts have been around for a long time, they have faced severe difficulties in increasing the spatial precision at which this can be done. As an alternative platform to common liquid crystals or micromirror-based devices, optical metasurfaces have opened a possible pathway to achieve dynamic wavefront control with sub-wavelength spatial resolution by endowing resonant nanoantennas with different tuning mechanisms. In this talk, we will present some of our recent efforts in this regard, particularly in two of the mechanisms that we find most promising for visible light manipulation, namely interfacing nanoantennas with liquid crystals and using low-loss phase-change materials with and without memory.

**8:30 AM EL12.08.02**

**Dynamic Polarization Control across the Poincaré Sphere with Black Phosphorus Metasurfaces** Samuel K. Seah, Souvik Biswas, Meir Grajower and Harry A. Atwater; California Institute of Technology, United States

Controlling polarization of light on-demand can unlock a multitude of applications in optical imaging, sensing, and computing. The electrically tunable crystalline anisotropy of black phosphorus (BP) holds promise for miniaturizing polarization modulators. Here, we report on plasmonic metasurfaces combined with van der Waals heterostructures incorporating twisted BP layers. This design builds on previous single BP layer Fabry-Pérot devices and increases the tuning range from linear trajectories to nearly half the area on the Poincaré sphere.

The proposed device leverages two independently electrically tunable BP layers that have their crystal axes orthogonally aligned, while careful design of the plasmonic nano-disks on top of the heterostructure allows critical coupling of light for enhanced dynamic range of polarization tuning. By incorporating boron-nitride spacer layers and capacitively gating the BP stacks against graphene gates within the heterostructure, we achieve the two degrees of freedom needed to tune polarization across the Poincaré sphere. We will discuss the effects of metasurface design and electronic doping on the Poincaré sphere, as well as highlight our efforts on the fabrication advances of the proposed device.

**8:45 AM EL12.08.03**

**Free-Space Electro-Optic Modulators using High Quality Factor Metasurfaces** Sahil Dagli, Halleh Balch, Sajjad Abdollahramezani, Hamish M. Carr Delgado, Varun Dolia, Jefferson Dixon, Elissa Klopfer, Jung-Hwan Song, Jack Hu, Babatunde Ogunlade and Jennifer A. Dionne; Stanford University, United States

Metasurfaces advance optical communications and imaging technologies through their highly miniaturized control of the amplitude, phase and polarization of light. Achieving active tunability within a compact footprint represents a step towards power-efficient, ultrafast data processing and computation. Here, we design, fabricate, and characterize high quality factor metasurfaces as an electro-optically tunable element for photonic devices. Our device uses a hybrid materials platform of silicon on lithium niobate, taking advantage of the high index and lossless properties of silicon and the electro-optic Pockels effect in lithium niobate. We design subwavelength (400 nm width) nanobars of 300 nm thick silicon atop a 300 nm lithium niobate thin film that are fabricated by well-established top-down lithography and wafer bonding techniques in 150x150 um metasurface devices. By introducing subtle geometric perturbations into each constituent nanobar, we enable leaky guided mode resonances coupled to normally-incident free-space light. These guided mode resonances enhance light-matter interactions by exciting strongly localized optical fields in the lithium niobate, with mode quality factors exceeding 1000 in both theoretical and experimental demonstrations. Applying a voltage across individual nanoantennas shifts the spectral position of the high-Q resonance, modifying the amplitude of the scattered light from the antenna. We measure an electro-optic coefficient of 3 pm/V when switching the applied voltage between 0 and 20 V. To decrease the nanoantenna length required to generate high-Q resonances, we pattern the ends of the notched bar with photonic bandgap mirrors, enabling the lateral light recirculation of leaky guided waves without causing significant radiation leakage. This allows us to achieve compact (<15 um), high quality factor (>1000) resonator pixelated nanoelements. Our high-Q electro-optic devices provide a foundation for light-weight, reconfigurable, solid-state information processing.

**9:00 AM BREAK****9:30 AM EL12.08.05**

**Toward High-Endurance Nonvolatile Reconfigurable Metasurfaces** Hyun Jung Kim<sup>1</sup>, Kiumars Aryana<sup>1</sup>, Scott Bartram<sup>1</sup>, Stephen Borg<sup>1</sup>, William Humphreys<sup>1</sup>, Cosmin-Constantin Popescu<sup>2</sup>, Tian Gu<sup>2</sup>, Juejun Hu<sup>2</sup>, Hyung Bin Bae<sup>3</sup> and Taewoo Lee<sup>3</sup>; <sup>1</sup>NASA LaRC, United States; <sup>2</sup>Massachusetts Institute of Technology, United States; <sup>3</sup>KAIST Analysis Center for Research Advancement, Korea (the Republic of)

The applications of adaptive optics extend across multiple sectors, encompassing areas such as LiDAR, biological and chemical sensing, and free-space optical communications. The advent of metasurfaces optics with reconfigurability has offered a versatile platform for the design of compact optical components, offering a compelling alternative to their conventional bulky counterparts. In this study, we introduce the PROWESS (Phase change Reconfigurable Optical Wavefront Synthesis System project at NASA LaRC), electrically reconfigurable metasurfaces using low-loss, high-contrast phase change material (PCM), Ge<sub>2</sub>Sb<sub>2</sub>Se<sub>4</sub>Te integrated with IR-transparent silicon microheater for various practical applications.

The talk covers a reliable platform for switching large-scale PCM-based devices utilizing a microheater and an architecture for the metasurface switching within an integrated circuit configuration, which is compatible with standard foundry fabrication processes. The utilization of near- to midinfrared transparent silicon microheater in the proposed architecture opens possibilities for the development of reconfigurable transmissive optics such as filters, zoom lenses, and beam steering modules. We demonstrated switching of 140 μm × 140 μm PCM pixel, on a 200 μm × 200 μm silicon microheater for several thousand cycles. Further, we performed an in-depth investigation into the failure mechanism utilizing techniques such as transmission electron microscopy and thermal modeling. Guidelines for device performance improvement are proposed, and an improved design with larger endurance is shown in progress. With further progress, we aim to unlock the full potential of PCM-based devices and advance the field of adaptive optics with demonstrable examples including a reconfigurable beam steerer for ocean surface flash LiDAR and Navigation Doppler LiDAR for precise lunar landing missions.

**9:45 AM EL12.08.06**

**Toward Accurate Thermal Modeling of Phase Change Material Based Photonic Devices** Kiumars Aryana<sup>1</sup>, Hyun Jung Kim<sup>1</sup>, Cosmin-Constantin Popescu<sup>2</sup>, Steven Vitale<sup>3</sup>, Hyung Bin Bae<sup>4</sup>, Taewoo Lee<sup>4</sup>, Tian Gu<sup>2</sup> and Juejun Hu<sup>2</sup>; <sup>1</sup>NASA Langley, United States; <sup>2</sup>Massachusetts Institute of Technology, United States; <sup>3</sup>Lincoln Laboratory, United States; <sup>4</sup>Korea Advanced Institute of Science and Technology, United States

Reconfigurable or programmable photonic devices are rapidly growing and have become an integral part of many optical systems. The ability to selectively modulate electromagnetic waves through electrical stimuli is crucial in the advancement of a variety of applications from data communication and computing devices to environmental science and space explorations. Chalcogenide-based phase change materials (PCMs) are one of the most promising material candidates for reconfigurable photonics due to their large optical contrast between their different solid-state structural phases. While significant efforts have been devoted to accurately simulating PCM-based devices, there are important aspects that have not been captured in prior models. In this study, we will highlight three key parameters that strongly influence the thermal and phase transition behavior in PCM-based devices: the enthalpy of fusion, the heat capacity change upon glass transition, as well as the thermal conductivity of liquid-phase PCMs. The PCMs studied here for examining the amorphization process are  $\text{Ge}_2\text{Sb}_2\text{Se}_4\text{Te}$  and  $\text{Ge}_2\text{Sb}_2\text{Te}_5$  with areal size on the order of  $140\ \mu\text{m} \times 140\ \mu\text{m}$ . We further investigated the important topic of switching energy scaling in PCM devices, which also helps explain why the three above-mentioned effects have long been overlooked in electronic PCM memories but only become important in photonics. Our findings offer insight to facilitate accurate modeling of PCM-based photonic devices and can inform the development of more efficient reconfigurable optics.

**10:00 AM EL12.08.07**

**Embeddable and Steerable Metasurfaces for Active Control of Light Steering** Seung Yeol Lee, Yujie Luo and Ognjen Ilic; University of Minnesota Twin Cities, United States

Photonic surfaces, such as metasurfaces and metagratings, offer precise control of optical properties such as wavelength, intensity, and polarization, with a crucial role in efficiently focusing and directing light for various applications, ranging from imaging and communication to LiDAR and display technologies. However, typical platforms for metasurface steering and focusing are static and macroscopic, which limits their ability for adaptive control and embedding. To overcome these challenges, we propose a novel design for a microscale magneto-photonic metasurface capable of actively delivering light with high efficiency to a specific location through remote manipulation of its translational or rotational motion using an external magnetic field. This composite particle consists of a tailored photonic surface integrated with a magnetic core. To enable effective beam steering during rotation, the photonic surface incorporates metagrating patterns designed to achieve high efficiencies (~90%) for both TM and TE polarizations. The magnetic core, incorporated through a lift-off method, consists of an anisotropic cobalt layer that facilitates programmable collective translational and rotational motion. We describe a control mechanism for positioning and orienting such metasurfaces to deliver light to the targeted spot. We present modeling and experimental data to demonstrate active light steering, and we discuss the tradeoffs associated with scaling the size of this magneto-photonic metasurface. The proposed approach offers a particle-based platform that enables high-fidelity light delivery within the biological transparency window, presenting promising potential for biophotonic applications.

**10:15 AM EL12.08.08**

**Creation of Frequency Selective Absorbing (FSB) Metasurfaces using 2D Transition Metal Dichalcogenides (TMD)** Suwarna Datar, Bishakha Ray and Siyad Rahim; Defence Institute of Advanced Technology (DIAT), India

Combining 2D materials and metastructures is a promising field of research with exotic outcomes like entangled quantum sources, enhanced non-linear effects and application in many interdisciplinary fields. 2-D transition metal-dichalcogenides (TMDs) which are semiconductor materials of the type  $\text{MX}_2$ , where M is a transition metal atom (like Ni, Fe, or Co) and X is a chalcogen atom (such as S or Se) are emerging class of materials which have excellent properties like atomic scale thickness, strong spin-orbit coupling, ability to form 2D nanosheets, direct band gap and many other mechanical and electronic properties. These properties make 2D materials lucrative as frequency selective absorbers (FSBs) because of strong electronic polarization and enhanced dielectric loss. By changing M in  $\text{MX}_2$  one can achieve tunable microwave metadevices. In the present work we have developed inks made of 2-D TMDs. Research on hybrid materials like Fe doped  $\text{MoS}_2$ , doped  $\text{MoS}_2$ -rGO composite,  $\text{MoS}_2/\text{CoSe}_2$  hybrids, among several others suggests that these materials have high reflection loss. Further, magnetic transition metal dichalcogenides such as  $\text{NiSe}_2$ ,  $\text{CoSe}_2$  and their heterostructures, expediate multiple reflections and scattering of the incident wave, thereby elongating the course of transmission of the incident microwave. This increases dissipation efficiency, along with large specific surface area, which caters to EM absorption. In the present work inks have been developed base on these materials to make them versatile for several applications. Metastructures using these paints have tunability of material properties like permeability and permittivity by changing meta structure thickness and dimension allowing to manipulate the electric and magnetic resonance at different frequencies independently, therefore, frequency selective structures can be made. Furthermore, in the present work, the structures have been made using 2D TMD whose conductivity has peaks depending on the percolation threshold at a given frequency for a particular concentration of the 2D structure in the paint. The analysis of the absorption by structures made of such composites is complex. Interestingly, it has been observed that unlike the meta structures created by metals where the absorption bandwidth and frequency, solely depend on the structures made, here they seem to also depend on the composition of 2D TMD which is encouraging. This provides an additional method to modulate the properties of FSA. The results are discussed to understand the role of 2D TMD in metadvice fabrication.

SESSION EL12.10: Nonlocal Metasurface in Frequency Space, BIC and Its Application for Tuning

Session Chairs: Yongmin Liu and Junsuk Rho

Wednesday Afternoon, November 29, 2023

Hynes, Level 3, Room 305

**1:30 PM EL12.10.01**

**High Quality Factor Meta-Reflect-Arrays for Electrical Programmable Wavefront Shaping** Lin Lin<sup>1,1</sup>, Jack Hu<sup>2</sup>, Sahil Dagli<sup>2</sup>, Yuan Meng<sup>1</sup>, Zhihao Xu<sup>1</sup>, Jennifer A. Dionne<sup>2</sup> and Mark Lawrence<sup>1</sup>; <sup>1</sup>Washington University in St. Louis, United States; <sup>2</sup>Stanford University, United States

LiDAR technology allows high-resolution 3D mapping and object identification for distance measuring, revolutionizing remote sensing. It is crucial for autonomous vehicles, AR/VR devices, and AI robots. Among components of LiDAR systems, beam steering is the most crucial part for precise control of the laser beam's trajectory and scanning pattern. The existing techniques, including mechanically rotating mirrors or prisms, microelectromechanical systems (MEMS), liquid crystal (LC), digital micro-mirror devices (DMD), and optical phased arrays (OPAs) have slow response time, mechanical complexity, and bulkiness. For instance, the number of optical elements and the challenge of aligning additional optical elements limit OPA's achievable steering range and resolution. Recent flat optics or phase gradient metasurface spatial light modulators (SLMs) offer promising alternatives. Metasurfaces, which consist of densely arranged diffractive nanoantennas, can manipulate light with enhanced light-matter interaction on a subwavelength scale. However, achieving high diffraction efficiencies with strong modulation is still one of the greatest obstacles for metasurface SLMs. Narrowband resonances, characterized by a high quality factor (Q-factor), are well known to increase the efficiency of modulation. With Q-factor up to  $10^7$ , micro-ring resonators used in integrated electro-optical modulators have achieved unity extinction modulation up to 40 GHz with a few volts. However, Q-factors for free-space light modulation with metasurfaces having subwavelength elements are typically on the order of 10.

To address the challenge of this weak modulation, a new class of silicon nanoantennas supporting high-Q dipolar guided mode resonances (DGMR) has been reported. By subtly breaking translational symmetry, DGMR nanoantennas are guided mode standing waves that can leak into free space and result in high-Q resonances with dipole radiation patterns perpendicular to the antenna. This makes them the ideal element for the efficient modulation of light scattering. While many interesting transfer functions have been explored using this scheme, universal wavefront shaping has yet to be experimentally demonstrated.

Here, we present a universal meta-reflect-array platform made from only high-Q DGMR nanoantennas acting as independent extremely sensitive pixels, enabling strong responses to weak structural tuning. When post-processed to incorporate a reflective ground plane, changes of <2.6% volume fraction across the array are found to facilitate efficient beam steering. To demonstrate that these devices are acting as phase gradient optics and not gratings, we realize beam steering to angles 32.3°, 25.3°, and 20.9°. To apply this concept to dynamic wave-shaping, we replace the structural perturbations with electro-thermal biasing. Although the thermo-optic coefficient of silicon is only  $1.8 \times 10^{-4} \text{ K}^{-1}$ , the extreme sensitivity of DGMRs with high-Q of 2088 can be red-shifted efficiently with minimal temperature change. We exploit the temperature sensitivity by realizing a prototypical electrically programmable multi-element transmissive amplitude display consisting of a structurally uniform Si high-Q meta-reflect array with Ni resistive heating elements encapsulated above silica. With the second Au circuit patterned above, three distinct groups of Ni wires are separated and connected into three Au pads. Applying individual bias voltages to the conducting pads using an SMU, we can tune the intensity transmitted by each high-Q pixel. We have measured the electrically tunable transmission pattern resulting from different voltage distributions using an imaging spectrometer. This compact and efficient dynamic wave shaping prototype with programmable capability can be extended in the future to quicker mechanisms such as carrier injection and the Pockels effect with higher tuning speed, shedding light on high resolution modern flat display technologies and LiDAR beam-steering.

**Eliminating Nearfield Coupling in Dense High-Quality-Factor Phase Gradient Metasurfaces** Samuel Ameyaw, Lin Lin and Mark Lawrence; Washington University in St. Louis, United States

Recent developments in optical technologies call for precise wavefront manipulation and miniaturized and lightweight optical components. Phase gradient metasurfaces, have over the years proven to be a strong candidate for the realization of novel technologies especially in AR, VR, and LIDAR applications<sup>1</sup>. Resonance is a key property of the nanostructured building blocks of a phase gradient metasurface. Boosting the light-matter interaction over subwavelength volumes allows many nanoscale objects to be combined to impose smooth spatially varying phase profiles on incident light waves<sup>2</sup>. A crucial metric by which to evaluate the performance of phase gradient metasurface is resolution, as it directly influences the accuracy achievable in wavefront shaping as well as the angular field of view. The resolution of phase gradient metasurfaces is predominantly limited by nearfield coupling between neighboring meta-atoms, preventing them from scattering light independently and generating crosstalk. The fact that the impact of coupling scales with Q typically forces a tradeoff between resolution and Q-factor. Coupling can be reduced by shrinking the evanescent decay lengths of the individual modes, thereby reducing the mode overlap. However, there will still be a Q for which the remaining coupling is a problem.

Here we show that extremely dense silicon metasurfaces supporting dipolar guided mode resonances can be engineered to entirely suppress near-field coupling for arbitrarily high Q. We reveal a zero-coupling regime occurs when nanoantennas are separated by anisotropic nanofins<sup>3</sup>. Rather than decreasing the field overlap, the fins enhance the longitudinal electric field, allowing it to interfere with the transverse electric field. For a specific nanoantenna width we demonstrate that the interference is perfect, effectively decoupling the high Q dipolar-guided mode resonators in proximity, enabling deep resolution and efficient diffraction.

To demonstrate the power of this new platform, we show how decoupled DGMR metasurfaces, backed by a mirror, can efficiently shape reflected diffraction when independent adjustments are applied to the refractive indices of each nanoantenna. Varying the refractive index of the outer pixels of a three-pixel metasurface by only  $1.7 \times 10^{-5}$ , we achieve steering to the +1<sup>st</sup> diffraction order with an efficiency of 85%. The tiny index modulation needed is a direct consequence of the giant Q of 192,474. Having a pixel pitch of  $\lambda/1.6$ , the steering also occurs at a large angle of 32°. In beamsplitting we achieve diffraction efficiency of 99% with Q greater than 257,000 and  $\delta n$  of  $1.5 \times 10^{-5}$ . Importantly, we believe the Q can be much higher, but such structures become increasingly difficult to model. By increasing the thickness of the silicon film to 383nm, the decoupled regime can even be found with sub-diffraction resolution, pixel pitch =  $\lambda/2.2$ .

In this case, beamsteering of incident light is achieved to the +1<sup>st</sup> diffraction order at an angle of 47° with an efficiency of 85%. As the elements in this device have a Q of 68,797, the refractive index bias was only  $1 \times 10^{-4}$ . Another symptom of nearfield coupling is angular dispersion. With the decoupled nanoantennas, we have been able to achieve angle independence such that the resonant shift of a DGMR with Q~45k stays below the FWHM for an angle of incidence from -45° to 45°. Our platform provides a route for dense high Q metasurfaces with independent addressability of the constituent meta-atoms paving the way for highly efficient nonlinear and dynamic wavefront shaping.

**Magneto-Optic Control of Brewster Quasi Bound States in the Continuum** Antonio Garcia-Martin; Instituto de Micro y Nanotecnología, CSIC, Spain

Bound states in the continuum (BICs) emerge throughout Physics as leaky/resonant modes that remain, however, highly localized<sup>[1]</sup>. They have attracted much attention in Photonics, and especially in metasurfaces<sup>[2,3]</sup>. One of their most outstanding features is their divergent Q-factors, indeed arbitrarily large upon approaching the BIC condition (quasi-BICs) <sup>[4,5]</sup>. Here we investigate how to tune quasi-BICs in magneto-optic (MO) all-dielectric metasurfaces.

The impact of the applied magnetic field in the BIC parameter space is revealed for a metasurface consisting of Si spheres with MO response. Through our coupled electric/magnetic dipole formulation, the MO activity is found to manifest itself through the interference of the (MO-induced) out-of-plane electric/magnetic dipole resonances with the in-plane magnetic/electric (directly induced) dipole, leading to a rich, magnetically-tuned quasi-BIC phenomenology, resembling the behavior of Brewster quasi-BICs for tilted vertical-dipole resonant metasurfaces. Such resemblance underlies our proposed design for a fast MO switch of a Brewster quasi-BIC by simply reversing the driving magnetic field. This MO-active BIC behavior is further confirmed in the optical regime for a realistic YIG nanodisk metasurface through numerical calculations. Our results present various mechanisms to magneto-optically manipulate BICs and quasi-BICs, which could be exploited throughout the electromagnetic spectrum with applications in lasing, filtering, and sensing <sup>[6]</sup>.

**Thermal and Electro-Optic Control of High-Q Metasurfaces for Dynamic Lensing** [Hamish M. Carr Delgado](#)<sup>1</sup>, Elissa Klopfer<sup>1</sup>, Sahil Dagli<sup>1</sup>, Jennifer A. Dionne<sup>1,4</sup> and Mark Lawrence<sup>2</sup>; <sup>1</sup>Stanford University, United States; <sup>2</sup>Washington University in St. Louis, United States

Metasurfaces—arrays of subwavelength nanoantennas that control the phase, amplitude, and polarization of light—are a promising platform for novel and compact optical technologies and communication. However, dynamic control of metasurfaces remains challenging due to weak light-matter interactions and in compact, nanoscale devices. Here, we design and characterize a dynamically-tunable metasurface lens, with a high-quality-factor (high-Q) resonance working as both the basis of the lensing behavior and means for efficient modulation with thermal or electrical biasing. Our high-Q lens is constructed via a zone plate architecture consisting of alternating regions with and without resonant character. Both regions consist of 500 nm tall and 320 nm wide silicon nanobars atop a sapphire substrate. Nanobars in non-resonant regions are highly reflective, while nanobars in resonant regions are highly transmissive on resonance due to the inclusion of periodic perturbations, which enable a guided mode resonance with measured Q-factors up to ~1350. By leveraging the thermo-optic effect of silicon, we dynamically control the spectral position of the high-Q resonance to achieve wavelength selectivity of the focusing behavior. Due to the sharp spectral linewidth and amplitude variation of the high-Q resonance, thermal tuning can further result in metasurface switching, where the lensing behavior is changed between on and off states in response to thermal stimuli. For a device utilizing only moderate Q-factors of ~350, the resonance's FWHM can be shifted with temperature changes of only 50 C, and the device can be fully switched off when operating at 100 C. These experiments provide a foundation for dynamic control of a local high-Q wavefront shaping metasurface. Next, to overcome the low switching speeds of thermal tunability, we simulate and fabricate silicon metasurfaces with a silicon nitride straining layer, which breaks the inversion symmetry of the silicon crystal, enabling a non-zero electro-optic coefficient. The stress imparted by the silicon nitride layer can be tuned by varying the deposition conditions to maximize the induced electro-optic effect in silicon. Simulations show a tunability in the resonant wavelength of ~44 pm per applied volt in a vertical bias configuration for an induced second order susceptibility of 40 pm/V, which can be achieved with moderate film strains. For resonances with quality factors ~7,000 in simulation, it is thus possible to switch the device from highly reflective to highly transmissive with low voltages ~15 V due to the narrow linewidth of the resonance. These devices provide a CMOS compatible platform for lightweight, compact, and reconfigurable solid state information processing.

**Self-Assembled TiN-Based Metamaterials with Anisotropic Properties and Magneto-Optical Coupling Effects** [Jiawei Song](#)<sup>1</sup>, Di Zhang<sup>2</sup>, Ping Lu<sup>3</sup>, Haohan Wang<sup>4</sup>, Yizhi Zhang<sup>1</sup>, Xiaoshan Xu<sup>4</sup>, Julia Deitz<sup>3</sup>, Xinghang Zhang<sup>1</sup> and Haiyan Wang<sup>1</sup>; <sup>1</sup>Purdue University, United States; <sup>2</sup>Los Alamos National Laboratory, United States; <sup>3</sup>Sandia National Laboratories, United States; <sup>4</sup>University of Nebraska-Lincoln, United States

Transition metal nitrides (e.g., TiN) have shown tremendous promise for nanophotonic devices due to their low-loss plasmonic properties and superior high-temperature stability compared to noble metals. Coupling other functionalities with plasmonic nitrides as multifunctional nitride-based hybrid metamaterials presents an enormous opportunity for advanced integrated photonic devices. In this talk, we present a novel approach for creating TiN-based hybrid metamaterials in vertically aligned nanocomposites (VANs) form with anisotropic properties and magneto-optical coupling effects. First, we present a two-phase nanocomposite design that combines ferromagnetic CoFe<sub>2</sub> nanosheets within the plasmonic TiN matrix. The resulting hybrid metamaterials exhibit obvious anisotropic optical and magnetic responses, along with a pronounced magneto-optical coupling response, owing to the unique vertically aligned structure. Second, we demonstrate a complex three-phase nanocomposite design of Au-TiN-CoFe<sub>2</sub> nanocomposites. Compared to the co-growth method that yields three distinct morphologies of Au-CoFe<sub>2</sub> core-shell nanopillars, the templated growth resulted in the formation of highly ordered and uniform single-type core-shell nanopillars (i.e., the CoFe<sub>2</sub> shell with an Au core) in the TiN matrix. Both the co-growth and templated growth TiN-CoFe<sub>2</sub>-Au films exhibit excellent epitaxial quality, hyperbolic dispersion, magnetic anisotropy, and magneto-optical coupling effects. These findings open up exciting opportunities for the development of advanced nanophotonic devices and applications that leverage the enhanced functionalities of plasmonic-magnetic hybrid metamaterials.

**Fabrication of Spiky Gold Nanoparticles in Ordered Arrays with Tunable Nanofeatures** [Jin Jia](#), Nadia Metzkwow, Sang-Min Park, Yuhao L. Wu, Alexander D. Sample, Bundit Diloknawarit, Insub Jung and Teri W. Odom; Northwestern University, United States

Anisotropic gold nanoparticles (AuNPs) with branched spikes, known as spiky AuNPs, are attractive plasmonic materials due to their localized surface plasmon (LSP) resonances. Achieving precise control over the morphology and optical response of spiky AuNPs, as well as arranging AuNPs in ordered arrays on substrates are important for designing metamaterials, biosensors and optoelectronics. This talk will describe a substrate-bound seed-mediated synthesis approach to fabricate spiky AuNPs in ordered arrays with tunable nanofeatures. We will discuss advances in nanofabrication techniques that enable the patterning of AuNP seeds with designed shape and size. We will describe how different growth conditions can lead to the formation of different nanofeatures on the seeds, resulting in different LSP resonances. Finally, we will discuss the prospects of using spiky AuNP arrays for surface-enhanced Raman spectroscopy (SERS).

#### 10:15 AM EL12.11.04

**Nanocube Assembly á La Carte** [Muhammad Luthfi Fajri](#)<sup>1</sup>, Ibtissem Bouanane<sup>2</sup>, Frédéric Bedu<sup>1</sup>, Peeranuch Pongsripong<sup>1</sup>, Olivier Margeat<sup>1</sup>, Judikaël LeRouzo<sup>2</sup>, Patrice Genevet<sup>3</sup> and Beniamino Sciacca<sup>1</sup>; <sup>1</sup>Aix Marseille University, CNRS, CINaM UMR 7325, France; <sup>2</sup>Aix Marseille University, CNRS, IMN2P UMR 7334, France; <sup>3</sup>Université Côte d'Azur, CNRS, CRHEA, France

Arrays of nanopatterns are of high interest in the multidisciplinary field of nanoscale photonics. Conventionally there are two approaches to fabricating such nanopatterns: top-down nanofabrication via electron beam lithography and bottom-up self-assembly. The former can create complex structures but lacks control over crystallinity, introduces surface roughness due to etching<sup>1</sup>, is expensive and time-consuming, making it unfavorable for large-scale

fabrication. Conversely, the latter is typically straightforward, affordable, and has better control over atomic composition and crystallinity. However, it struggles to fabricate complex nanopatterns due to thermodynamic constraints<sup>2</sup>. This has been partially circumvented with directed assembly strategies, which consist of colloidal nanoparticles in PDMS templates replicated from a nanofabricated master<sup>3</sup>. However, the nanopattern geometry that could be achieved effectively is still strongly limited to individual particles or low-density 1D arrays<sup>4,5</sup>, whereas precise and deterministic arrangement of nanoparticles in truly complex and arbitrary nanopatterns (needed for nanophotonics and plasmonics applications) have so far remained elusive.

Here, we offer a new approach to obtain arbitrarily complex nanostructure arrays with a single nanoparticle resolution with no need for advanced equipment. Nanoparticles are first deposited at the air/water interface in a compact film and then transferred into a nanopatterned template. This highly versatile technique is independent from the specific nanopattern and can apply to a plethora of materials and shapes. We will show assembly of various materials (Ag, Au, Au-Cu<sub>2</sub>O core-shell nanoparticles and nanocubes) into various complex nanopatterns, such as U-shapes, L-shapes, cross-shapes, S-shapes, T-shapes, Pancharatnam–Berry metasurfaces, and also split-ring resonators on PDMS, that cannot be obtained with conventional assembly techniques. Among other nanoparticle shapes, we focus on nanocubes because they are ideal building blocks for obtaining monocrystalline nanostructures<sup>6,7</sup>. We will show that such assemblies, in which each nanocube unit is precisely assembled as a Lego brick in complex extended arbitrary motifs, can subsequently be transformed into continuous nanostructures via nanocube epitaxy and then transfer-printed to various substrates, including flat and microstructured substrates. Finally, we will show optical characterizations and simulations of the metasurfaces obtained. This strategy potentially offers an alternative to a bottom-up fabrication for metal nanostructuring, which can then be applied to optoelectronic applications.

#### 10:00 AM BREAK

#### 10:30 AM EL12.11.05

**Meta-Structure IR Absorber Applied Microbolometer for Perfect Absorptance and Responsivity Improvement** Jeongeun Mo<sup>1,2</sup>, Dasom Wang<sup>1</sup>, Ji-Hun Kang<sup>3</sup>, Jeong Min Baik<sup>2</sup> and Won Jun Choi<sup>1</sup>; <sup>1</sup>Korea Institute of Science and Technology, Korea (the Republic of); <sup>2</sup>Sungkyunkwan University, Korea (the Republic of); <sup>3</sup>Kongju National University, Korea (the Republic of)

In recent years, the demand for high-performance infrared image sensors has increased significantly in various fields, including military applications, medical imaging, and Advanced Driving Assistance Systems (ADAS). Microbolometers, which are cooler-free infrared image sensors, have gained popularity due to their affordability and convenience. However, to enhance the performance of microbolometers, it is crucial to achieve high responsivity and detectivity. Effective infrared (IR) absorption is essential for microbolometers to efficiently transfer heat to the thermistor layer and achieve high responsivity ( $R_v = \alpha \eta_b / G(1 + \omega^2 \tau^2)^{(1/2)}$ ). To address this requirement, we applied a meta-structured IR absorber to enhance the IR absorptance of microbolometers.

In this study, we employed an alternating metal-dielectric multilayer films with different refractive index as the IR absorbing medium. A periodic circular structure is introduced to multilayer films for higher absorptance. This structure has been designed to decrease total volume of IR absorbing medium in order to get lower thermal mass so that heat can easily transfer to the thermistor layer. FDTD simulation is conducted to compare the dependence of different sizes of periodic circles and intervals on absorptance of meta-structured multilayered absorber. This result revealed significant improvement in the absorptance of incident light in LWIR region (8-14 $\mu$ m), which is commonly used for object detection. For experimental demonstration, IR absorber is deposited by electron beam evaporator based on reported previous research. The experimental results confirmed that the meta-structured IR absorber exhibited higher absorptance compared to the non-meta-structured counterpart. Consequently, we expect that the application of meta-structured IR absorber to microbolometers will facilitate the temperature increase of the thermistor material, leading to a notable improvement in responsivity. In conclusion, the presented research will give an idea of increasing responsivity of microbolometer with drawing up absorptance of IR absorber with meta-structure.

**Wafer-Scale Manufacturing of Centimeter-Sized Metasurfaces Down to the Deep-Ultraviolet Region** Joohoon Kim and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

UV optics play a vital role in both science and technology, from spectroscopy and quantum optics to photolithography and biosensing. Conventional UV optics are primarily based on bulky optical components and have limited functionality and diversity. As an alternative, metasurfaces can provide fine wavefront-shaping platforms with a compact form-factor, resulting in drastic miniaturization of the device and capability of diverse functionality. However, metasurfaces operating in the UV regime face long-standing challenges, such as the scarcity of low-loss and high-index UV materials and patterning limitations (small patterning area, high cost, and low throughput). Recently, UV-transparent materials such as zinc oxide [Sci. Adv. 8, abn5644, 2022], silicon nitride [ACS Nano 16, 3546-3553, 2022], and hafnium oxide [Light Sci. Appl. 9, 55, 2020] have been actively studied; however, the fabrication process of these materials is not scalable or easy to manufacture because they include e-beam lithography and multi-step etching with thick layer deposition. Recently, our group developed a scalable manufacturing platform that can produce visible metasurfaces on the wafer scale [Nat. Mater. 22, 474-481 (2023)]. However, a UV-transparent material compatible with our scalable method and patterning resolution remains a challenge for scalable manufacturing of UV metasurfaces. In this work, we fully address this long-standing challenge and mass-produce centimeter-scale UV metalenses by introducing a zirconium dioxide (ZrO<sub>2</sub>)–polymer hybrid material and high-resolution ArF photolithography. We find that ZrO<sub>2</sub> has both a high refractive index and low absorption in the UV regime, and is compatible with our scalable method using atomic layer deposition (ALD). Using scalable and easily manufacturable ZrO<sub>2</sub>–polymer hybrid material, we succeed in mass-producing centimeter-scale UV metalenses for the first time. Owing to the high repeatability of nanoimprint lithography, our method can fabricate wafer-scale UV metalenses at extremely low cost and high throughput. Notably, thin-film coatings in hybrid materials enable strong light confinement, resulting in high efficiency of fabricated metalenses. The proposed method fully addresses the long-standing challenges in the field of UV metasurfaces and presents a practical possibility for the first time that UV metasurfaces can be applied in real life.

SESSION EL12.13: Advanced Nanophotonic Design Strategies

**Comprehensive Design of Metasurfaces: The Role of Symmetries in the Position of Complex Frequency Zero Singularities** Patrice Genevet; Université Côte d'Azur, France

Metasurfaces are artificial optical interfaces designed to control the phase, the amplitude and the polarization of an optical wavefront. These optical surfaces rely on the coherent scattering of light by a sizable distribution of nano-scatterers of various shapes and material compositions. Metasurfaces hold great potential for on-chip integration of photonic components, significantly promoting the development of miniaturized optoelectronic systems. Genevet group is working on the physics of Metasurfaces and their applications for directional light collection and emission (imaging systems and VCSEL arrays), and LiDARs. The group recently pioneered disruptive research on the developments in topological and tunable nanophotonics systems. This talk will concern fundamental properties of metasurfaces with emphasis on topological and vectorial metasurfaces. Our work starts from the observation from the fact that because of their radiative coupling to the environment, all optical components are intrinsically non-Hermitian systems, often described by reflection and transmission matrices with complex eigenfrequencies [1,2]. The control and the creation of zero singularities are shown to be the key ingredients to achieve full phase modulation of light. In particular, we rely on complex-frequency analysis to draw conclusions on the physics of metasurfaces and guide the designs towards the engineering of innovative nanophotonic devices. Symmetry breaking -- either explicit or spontaneous -- thus plays significant role in the response of the system, moving the position of Zero singularities of the reflection or transmission matrices from the real axis to the upper part of the complex frequency plane. A universal  $0$  to  $2\pi$ -phase gradient needed for wavefront modulation of an output channel as a function of the real frequency excitation is shown to be linked to the presence of discontinuity branch bridging a Zero and a Pole, i.e a pair of singularities, crossing the real axis[2]. This basic understanding helps us engineering electromagnetic fields at interfaces, including, but not limited to, metasurfaces[3-6]. Non-Hermitian topological features associated with exceptional degeneracies or branch cut crossing are shown to play a surprisingly pivotal role in the design of resonant photonic systems. With our works, we establish a general framework to predict and study the response of resonant systems in photonics and metaoptics.

**Overcoming Optical Losses of Superlenses with Synthetic Waves of Complex Frequency** Shuang Zhang; University of Hong Kong, Hong Kong

In conventional optical imaging, Abbe diffraction limits the resolution of feature sizes to larger than half the wavelength. This limit is due to the loss of the subwavelength information carried by evanescent waves. To overcome this limitation, a negative refractive index lens has been proposed to enhance the evanescent waves to recover the deep-subwavelength resolution of imaging. Subsequently, superlenses, made of either natural materials with negative permittivities, or hyperbolic materials with mixed signs of dielectric constants along different directions, have been proposed to attain sub-diffractive limited imaging. Nevertheless, losses are non-negligible in materials with negative parameters, which reduces the deep-subwavelength information of the superlenses and seriously affects the resolution of imaging. To compensate the losses, it has been proposed that gain materials could be incorporated into metamaterial designs or plasmonics, but the setup is extremely complicated and the gain will inevitably introduce instability and noise into the system. Recently, complex-frequency waves with temporally growing or attenuating behaviors have been treated as virtual absorption or gain waves. Some theoretical proposals have been put forward to recover the deep-subwavelength information carried by surface plasmons via excitation of complex-frequency waves (CFW) with temporal attenuation. However, synthesizing CFW is challenging in optical systems from a practical perspective.

To address this challenge, we synthesize CFW signals using a multi-frequency approach. We exploit the fact that a truncated CFW can be expressed as combination of multiple frequency components with coefficients following a Lorentzian spectral lineshape through the Fourier transformation. We perform measurements at multiple real frequencies and numerically synthesize the field distribution under CFW illumination by combining the measured field plots at different frequencies according to the Lorentzian lineshape. As a proof of the concept, both a SiC slab operating at optical frequencies and a bulk hyperbolic metamaterial operating at microwave frequencies are used as superlenses. We show that, while the spatial resolution of imaging at real frequencies is poor, caused by the inevitable material loss in these systems, an ultra-high resolution imaging can be obtained with the synthesized CFW consisting of multiple frequency components. Our approach successfully overcomes the challenges of experimentally implementing CFW in the time domain, which include the need for precise CFW synthesis and time-gated measurements after reaching the quasi-steady state, and holds great potential for

high-resolution microscopy. Furthermore, the synthesized complex-frequency approach can be extended to other areas of optics, such as plasmonic sensing applications. By leveraging the enhanced quality factor of plasmonic structures, our approach has the potential to significantly improve sensitivity in sensing applications. In addition, the approach can be tailored to different systems and geometries, providing a flexible and versatile tool for improving optical performance.

**Disordered Optical Metasurfaces to Create New Visual Effects** [Philippe Lalanne](#); CNRS, France

The visual appearance of flat surfaces and curved objects is paramount in life and technology for fine and applied arts.

The ERC project **UNSEEN** aims at creating metasurfaces that offer new visual appearances, unseen in nature so far. The metasurfaces are composed of disordered monolayers of high-index resonant nanoparticles, either deposited from a colloidal solution on solid support or fabricated with ebeam lithography.

We have developed two models to predict the scattering properties of disordered metasurfaces. They allow us to predict design the scattering properties for all wavelength and incident angles. We have validated the models by testing them with experimental data, we have also been able to design a metasurface that generate only two distinct colors (green and violet) under all incidence and viewing angles, a quite strange phenomenon if we consider that usual iridescence provides a continuous variation of color as the incident and viewing angles changes (think to a thin film). For more details on the topic, please refer to

K. Vynck et al., Nat. Mater. 21, 1035–41 (2022).

**Analysis of the Effect of Material Choice on the Performance of Metasurfaces** [Junkyeong Park](#), Younghwan Yang, Hyunjung Kang and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

A metasurface is a thin layer that operates at a scale smaller than the wavelength of light. It controls light by using meta-atoms, which are small structures arranged in a specific pattern. These meta-atoms are typically made of plasmonic or dielectric nanoantennas and have the ability to change the properties of light, such as its phase, amplitude, and polarization. As a result, metasurfaces find applications in various fields, including advanced displays, lenses, and sensors in the next generation. Particularly, due to their low optical losses, broadband operation, and compatibility with complementary technologies, dielectric metasurfaces are a promising platform for various photonic applications. Generally, dielectric materials with high refractive indices and low optical losses are favored for the development of highly efficient metasurfaces, which enable the creation of wide-angle beam steering and near-unity numerical aperture metalenses. Despite the intuitive choice of such materials, the relationship between material properties and metasurface performance remains unclear. In this presentation, we aim to determine the correlation between the refractive index and the performance of metasurfaces. Specifically, we investigate metalenses operating within the visible spectrum and evaluate their efficiency and full width at half maximum (FWHM). By examining these parameters, we aim to gain quantitative insights into how the refractive index influences the effectiveness of metasurfaces in manipulating light in the visible regime.

### 3:45 PM EL12.13.06

**Algorithmic Optimization of Disordered Plasmonic Metasurfaces using Far-Field Wavefront Shaping** [Gauthier Roubaud](#)<sup>1</sup>, [Sylvain Gigan](#)<sup>2</sup>, [Samuel Grésillon](#)<sup>1</sup> and [Sebastien Bidault](#)<sup>1</sup>; <sup>1</sup>ESPCI Paris, France; <sup>2</sup>Sorbonne Université, France

Plasmonic metasurfaces have broad applications in wavefront control, surface-enhanced spectroscopy or sensing. However, deterministic nanostructures do not allow an active tuning of these optical properties. By comparison, wavefront shaping techniques in disordered media have shown tremendous flexibility in actively modulating the propagation and focusing of light in space and time. We demonstrate here that delocalized modes in disordered plasmonic metasurfaces can be controlled using far-field wavefront shaping and algorithmic optimization schemes in order to locally modulate their optical responses. By controlling the phase of an incoming femtosecond pulsed laser on a disordered gold metasurface, we optimize the two-photon induced luminescence (TPL) at a chosen position with a typical two-order of magnitude enhancement, indicating a far-field optimization of the optical near-field. The optimization process is performed using a random genetic algorithm and provides the highest enhancement when the metasurface features the highest degree of morphological complexity, close to the percolation threshold (Nano Lett. 20, 3291 (2020)).

Far-field wavefront shaping also provides new degrees of freedom to provide statistical imaging schemes that offset the structural complexity of disordered nanophotonic systems. For instance, using nonlinear luminescence images measured with randomly wavefront-shaped femtosecond excitations, we can independently map the localized and delocalized plasmonic modes on a disordered gold metasurface (ACS Photonics 8, 1973 (2021)).

## SESSION EL12.15: Nonlocal Metasurfaces in Momentum Space

Session Chairs: Yongmin Liu and Junsuk Rho

**Metasurfaces for Edge Detection and Quantitative Phase Imaging** [Zhaowei Liu](#); University of California, San Diego, United States

Microscopy has been playing a crucial role in many science and engineering fields. Metasurface as a new emerging tool has shown its unique capability to manipulate light at scales previously thought impossible, opening doors for optical microscopy systems with ultracompact footprint. In my talk, I will present some of our recent development by using metasurfaces to build various compact microscopy systems. Specifically, I will discuss metasurface enabled edge detection, Fourier optical spin splitting microscopy, and various schemes to achieve quantitative phase imaging. Some biological imaging results will be presented by using such metasurface based microscopes.

### 10:15 AM EL12.15.02

**Polarization Independent Broadband Metasurface Edge Detector in Visible Wavelengths** [Ibrahim Tanriover](#), Sina A. Dereshgi and Koray Aydin; Northwestern University, United States

Image processing is of fundamental importance for many emerging technologies such as AR/VR glasses, autonomous driving, and biometric identification. Conventionally, image processing tasks are performed by digital computers. However, the processing time and power consumption of digital computers become a limiting factor with the increasing demand for real time, continuous data processing. With the advent of metamaterials and metasurfaces, optical computing platforms emerged as promising candidates to perform such image processing tasks. In recent years, numerous examples based on spin Hall effect, Pancharatnam–Berry phase, photonic crystals, and surface plasmons were realized. These studies have shown that metasurfaces offer real time image processing with low to none power consumption. However, the previous demonstrations suffer from one or few of the several limitations that are requiring angled incidence, polarization dependence, requiring additional polarizers, narrow operation band, being limited with 1D processing, requiring coherent light, and requiring digital post-processing.

Here, addressing these problems, we propose and demonstrate metasurfaces for 2D isotropic and polarization independent edge detection based on Fourier optics principles. We designed sub-wavelength metallic metasurfaces to perform edge detection. The metasurface consist of co-centric metallic rings that create a spatial transmission profile matching the Fourier transformation of the second order differentiation. We experimentally confirm polarization independent, broadband edge detection with high transmission efficiency under both coherent and non-coherent illumination along the visible range. By further simulations and measurements, we show that the operation range of the metasurface also covers the 800 nm to 1600 nm wavelength range in the near IR. Our results constitute an important step towards the application of metasurfaces for real-life image processing tasks.

#### 10:30 AM EL12.15.03

**Generation of Arbitrarily Directed Out-Of-Plane Split Beams with Reflective Metasurfaces** [Brian M. Wells](#), Joseph F. Tripp and Richard J. Williams; University of Hartford, United States

Metasurfaces, the planar equivalent of metamaterials, have recently gained significant attention due to their physically compact nature, versatility, and ultrathin thickness in the wave propagation direction, significantly suppressing undesirable losses and exotic electromagnetic properties in manipulating propagating waves. In recent years, metasurfaces have been applied to anomalous reflection and refraction, perfect absorption, flat lensing, wave plates, and cloaking. In this work, we present an out-of-plane beam-splitter reflector metasurface design that is not confined to the gradient metasurface paradigm and, as such, is not restricted to beam-splitting into diffraction orders. Instead, we can generate metasurface beam-splitters with arbitrary split beam directionality, including combined in-plane and out-of-plane splitting, such that one of the split beams remains in the plane of incidence while the other split beam is generated outside the plane of incidence.

A reflective metasurface exhibiting simultaneous in-plane and out-of-plane beam-splitting was designed using an approach based on the Fourier transform method of array synthesis. This method involves supplying the desired far-field scattering pattern of the metasurface, in this case, a far-field pattern with two main beams scattering in different planes, and then performing the inverse discrete Fourier transform on this far-field pattern to determine the spatially dependent reflection properties of the metasurface. To validate the approach, an impedance sheet-based simulation is performed to verify the desired beam-splitting phenomena as an initial step in the design process. This technique involves casting the spatially dependent complex reflection coefficients calculated from the Fourier transform method into a spatially dependent surface impedance. The metasurface is then simulated as a 2D plane, defined by the surface impedance. This allows for a fast-initial simulation of the metasurface beamsplitter before unit cell simulations. Both approaches are compared to full-wave, unit cell 3D FEM numerical simulations using realistic material parameters. An excellent agreement can be shown between all three approaches, thus illustrating the usefulness of the impedance sheet-based simulations method to obtain the metasurface far-field profile.

#### 10:45 AM \*EL12.15.04

**Manipulating the State of Polarizations at the Nanoscale using a Nonlocal Metasurface** [Soo Jin Kim](#); Korea University, Korea (the Republic of)

Recent development of chiral metasurfaces attracts significant attention from researchers due to their unique abilities to manipulate the spin state of light at the nano-scale. Such functionalities can have potential applications in diverse fields, including quantum communications, biosensing, CD spectroscopy, and nano-scaled imaging. However, despite the progress in developing efficient and compact configurations, there still remain challenges in realizing an effective metasurface with strong circular dichroism (CD) and a spectrally narrow bandwidth of response for the potential applications of spectropolarimetrics.

In this presentation, I will show the nonlocal metasurfaces with a high-Q resonance and how such metasurfaces can be tailored to have the capability to effectively control the polarization state of incident light at a relatively narrow spectral range. We first demonstrate the conversion of polarizations in transmitted light using a GMR-based nonlocal metasurface to achieve near-perfect flat-top transmission spectra in simulation and efficiency over 0.8 in experiments using a method of electro-optic-based wavelength-scanning laser at a narrow spectral bandwidth. Following this, we also focus on the detection of the state of polarization using an ultrathin chiral metasurface by inducing collective chiral resonances in the constituent nanostructures. We design and show the selective transmission of the spin state of light using a nonlocal chiral metasurface, which experimentally features a CD value over 0.8 at a bandwidth less than 10 nm by judiciously arranging the nano-units to induce chirality without the need for precise fabrication of nano-chiral geometry. We further demonstrate that the minimally perturbed geometries of nano-units can efficiently detect the full Stokes parameters by directly tracking the azimuthal and ellipticity paths of the Poincare sphere at a spectrally narrow bandwidth. We believe that the proposed approaches could pave an alternative pathway to realize efficient nonlocal metasurfaces for diverse, nano-scaled polarimetric applications.

**Scalable Classical and Quantum Photonics** [Giovanni Scuri](#); Stanford University, United States

Novel computational techniques such as photonics inverse design, along with new nanofabrication approaches, play a crucial role in building scalable integrated classical and quantum photonics. Inverse design, a departure from the traditional photonics design approach, can lead to photonics much better than state of the art in many metrics (smaller, more efficient, more robust, a much higher density of integration). This is enabled by development of a computer software which efficiently searches through the space of all possible and fabricable photonic geometries, in any material of interest. On the other hand, future photonic systems also require integration and fabrication of traditional and non-traditional photonic materials, including silicon, silicon-

carbide, diamond, sapphire, and strong electro-optic materials such as lithium niobate, strontium and barium titanate.

### 2:15 PM \*EL12.17.02

**Geometric Phase and Nonlinear Photonic Metasurfaces** Guixin Li; Southern University of Science and Technology, China

Compared to the conventional optical elements, two dimensional photonic metasurfaces, consisting of arrays of antennas with subwavelength thickness, enable the manipulation of light-matter interaction on a more compact platform. Using metasurfaces, the polarization, phase and amplitude of light can be controlled by spatially variant meta-atoms at the subwavelength scale. Many exotic phenomena in linear optics such as imaging with ultrathin flat lenses, optical spin Hall Effect, highly efficient holography etc., have been successfully demonstrated. However, growing demand for integrating more functionalities into an optoelectronic circuit also relies on the availability of tailored nonlinear optical properties of metasurfaces. In this talk, I will share the latest progress in nonlinear photonic metasurfaces. The concept of nonlinear geometric phase and its application in nonlinear wavefront engineering will be discussed.

**Water-Soluble Smart-Labeling Platform using Nanoimprint Lithography** Hyunjung Kang, Joohoon Kim, Hongyoon Kim and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

The food packaging industry is increasingly focusing on sustainability and origin security. Biodegradable plastics and traceability systems like QR codes have been developed to address these concerns. However, there are challenges in ensuring sustainability and traceability. Biodegradable plastics have drawbacks such as specific conditions for degradation, greenhouse gas emissions, higher costs, and recycling difficulties. To overcome these challenges, a new sustainable and anti-counterfeit labeling platform is necessary. Also, traditional coloration methods using dyes and pigments have limitations, but structural coloration inspired by nature offers high resolution, color saturation, wide gamut, and resistance to fading. Recent advancements have demonstrated water-soluble structural colors using materials like polyvinyl alcohol (PVA) and hydroxypropyl cellulose (HPC). However, it has previously been limited by the need for silver deposition due to its low refractive index. We report a new water-soluble nanocomposite ink composed of HPC and TiO<sub>2</sub> nanoparticles to increase the refractive index. This ink allows for vivid colors, a wide gamut palette, high saturation, and brightness. The ink is used to print QR codes via nanoimprint lithography. The methods are cost-effective techniques and have minimal environmental impact. This labeling platform has the potential to address waste issues, enhance consumer trust, and provide accurate information about products.

### 3:45 PM EL12.18.02

**Fabrication of Crystalline-Silicon Metasurfaces for Atom Trapping** Minjeong Kim<sup>1</sup>, Chengyu Fang<sup>1</sup>, David A. Czaplowski<sup>2</sup>, Hongyan Mei<sup>1</sup>, Zhaoning Yu<sup>3</sup>, Sanket Deshpande<sup>1</sup>, Yuzhe Xiao<sup>1,4</sup>, Xuting Yang<sup>3</sup>, Alan M. Dibos<sup>2</sup>, Mark Saffman<sup>3</sup>, Jennifer T. Choy<sup>1,3,3</sup> and Mikhail Kats<sup>1,3,3</sup>; <sup>1</sup>University of Wisconsin - Madison, United States; <sup>2</sup>Argonne National Laboratory, United States; <sup>3</sup>University of Wisconsin-Madison, United States; <sup>4</sup>University of North Texas, United States

Optical bottle beams, distinguished by their localized light intensity minima surrounded by areas of higher intensity, can be used to trap neutral atoms and lower-index particles [1]. In particular, bottle beams are required for blue-detuned trapping of cold atoms, where the atoms are localized within low-intensity regions, resulting in smaller perturbation of the atoms by the trapping laser compared to the more-conventional, red-detuned traps where the atom is in a high-intensity region [2]. Complex beam profiles such as optical bottle beams can be synthesized using optical metasurfaces constructed from arrays of subwavelength structures that locally control the amplitude, phase, and/or polarization response at an interface [3]. Crystalline silicon, characterized by its indirect bandgap, exhibits moderate loss at wavelengths longer than about 500 nm [4], while polycrystalline and amorphous silicon have much higher absorption coefficients these wavelengths [5]. Here, we designed, fabricated, and characterized optical metasurfaces comprised of crystalline silicon for atom trapping, using silicon-on-sapphire (SOS) technology.

We employed a figure of merit to assess the effectiveness of our optical bottle-beam traps [1]. Through the simulation of a single unit cell, characterized by a pillar height of 500 nm and a periodicity of 360 nm, we designed metasurfaces for a wavelength of 770 nm, which is suitable for blue-detuned trapping of rubidium atoms. We fabricated bottle-beam-generating metasurfaces that are 2 mm on a side using a combination of electron beam lithography and silicon etching. In our process, the silicon thickness is 500 nm and the smallest lateral feature is 130 nm, resulting in an aspect ratio of 4:1. Our process is as follows: (1) A SiO<sub>2</sub> hard mask is deposited using plasma-enhanced chemical vapor deposition (PECVD); (2) ZEP520A resist is spun onto the wafer; (3) E-beam exposure and development; (4) Etching of the SiO<sub>2</sub> layer using CHF<sub>3</sub> and O<sub>2</sub> to defined the features in the hard mask; (5) Removal of the resist residue with O<sub>2</sub> plasma; (6) Etching of the Si layer using HBr to produce pillars on sapphire; (7) Removal of the SiO<sub>2</sub> hard mask with buffered oxide etchant (BOE).

The optical performance of the fabricated bottle-beam-generating metasurfaces was evaluated using a 795 nm distributed-Bragg-reflector (DBR) laser normally incident on the metasurface. Using a camera with an objective lens with a numerical aperture of 0.65, we observed the formation of an optical bottle beam with a diameter of 6 μm, in agreement with our electromagnetic modeling. Future work will include the design of more-complex atom-trapping field distributions, and the incorporation of these metasurfaces into atom trapping setups.

**Laser-Based Selective Nanoimprint Method for Fabrication of Optical Metasurfaces as Modulating Layers for Fluorescent Materials** Timothy Yee Him Chan and Mitch Guijun Li; The Hong Kong University of Science and Technology, Hong Kong

The enhancement of fluorescent materials' performance is a significant research area aimed at expanding their utility and versatility. Optical metasurfaces have emerged as a viable solution to manipulate the optical properties of fluorescent material media. In this study, we propose a laser-based selective nanoimprint method that enables fast and controlled fabrication of metasurfaces specifically tailored as optical modulating layers for fluorescent crystals. The fabrication process involves depositing laser-induced graphene on a metal thin film, then it is placed on the flexible PDMS mold. The mold will undergo laser irradiation for pressurizing the photoresist, the metal thin film will be used as a protective layer to absorb the laser energy, and the laser energy will be converted to kinetic energy to provide pressure on the mold for nanoimprinting the mold pattern onto the photoresist. Precise control of laser-induced pressure allows for accurate replication of the mold pattern, while concurrently curing the photoresist to stabilize the imprinted nanostructures. The photoresist can be cured at the same time to stabilize the nanostructure imprinted, afterwards, we can apply the fluorescent solution to the photoresist by spin-coating. The fabricated metasurface can improve the absorption of the fluorescence materials and it can act as a better gain medium for the fluorescence crystal layer. We are also working on forming the metasurface directly on the crystal by replacing the photoresist with the solution, and then thermal treating the solution to promote fast crystallization.

This innovative approach presents a simple yet highly effective fabrication method for constructing selective metasurfaces as optical modulating layers for fluorescent materials. It utilizes laser-induced transfer techniques and laser-induced pressure to enable the efficient manufacturing of optical metasurfaces so that different metasurface structures and designs can be used for testing. The demonstrated capabilities of this technique hold great promise for the advancement of the integration between metasurface technology and fluorescent materials. The development of optimized metasurfaces as modulating layers can significantly enhance the optical properties and performance of fluorescent materials, paving the way for new applications in fields such as sensing, imaging, and optoelectronic devices.

**Extreme Micro/Nanomanufacturing for Metasurface Applications** Huigao Duan; Hunan University, China

Micro/Nanomanufacturing has been playing a key role in the integrated-circuits industry and developing micro/nanosystems. Pushing the micro/nanomanufacturing towards ultrasmall dimension and ultrahigh precision is of great interest and importance for various applications. In this presentation, I will share our efforts in developing new processes such as sketch and peel lithography, greyscale lithography and conformal filling with ion beam polishing portfolio to achieve the multiscale, multidimensional and high-precision fabrication capabilities for functional micro/nanostructures. Novel applications on metasurfaces, transparent electrodes, and optical metadevices will be demonstrated.

#### 8:30 AM EL12.19.03

**Multimode Coupling and Bound States in the Continuum in High-Index Metasurface** Vahid Karimi<sup>1</sup>, Neal Raney<sup>2</sup>, Aaron Holzer<sup>1</sup>, Md Sakibul Islam<sup>1</sup> and Viktoria Babicheva<sup>1</sup>; <sup>1</sup>University of New Mexico, United States; <sup>2</sup>Central New Mexico Community College, United States

Metasurfaces based on high-refractive-index materials have emerged as a promising platform for manipulating light at the nanoscale, enabling a wide range of applications in optics, photonics, and beyond. Through careful control of nanoantenna dimensions and arrangement, one can achieve tunable optical functionalities in high-index metasurfaces. By harnessing the unique properties of these materials, such as their strong light-matter interactions and efficient light confinement, metasurfaces offer unprecedented control over the propagation, polarization, and phase of light. This control opens up new possibilities for developing compact and versatile optical devices with enhanced functionalities, paving the way for advancements in areas such as imaging, sensing, communication, and integrated photonics.

Our investigation focused on a high-refractive-index metasurface, which offers exciting possibilities for manipulating light at the nanoscale. Through careful analysis, we discovered that this metasurface enables multimode coupling and bound states in the continuum, resulting in the emergence of narrow Fano resonances. By examining the reflection and transmission spectra obtained from our experiments, we observed the presence of multiple mode excitations and witnessed the occurrence of the generalized Kerker effect within the nanoantenna array. This highlights the metasurface's remarkable capability to control and manipulate light propagation at the nanoscale.

In addition to studying the metasurface, we also explored the influence of silicon quality on its optical properties. Our findings indicate that the rate of material deposition and subsequent rapid thermal annealing play pivotal roles in enhancing the optical properties of silicon. By mitigating oxidation and minimizing material defects, we observed a significant improvement in silicon quality. This improvement was characterized by an increase in the real part of the refractive index and a decrease in the imaginary part. These insights provide a deeper understanding of the interplay between metasurface design, light manipulation, and silicon quality. They open up avenues for further advancements in the field of metasurfaces, unlocking new possibilities for developing innovative photonic devices and systems with enhanced functionalities and improved performance.

The rapid thermal annealing process at high temperatures plays a vital role in reducing defects and impurities within the silicon material. This results in a more uniform and crystalline structure, leading to decreased light absorption, reduced optical losses, and enhanced light-matter interactions. These improvements in silicon quality enable precise tuning of collective modes within the metasurface, leading to the emergence of new photonic functionalities and improved sensing capabilities across various optical applications. Our investigation demonstrates the potential of high-index metasurfaces for

achieving enhanced photonic functionalities. By controlling nanoantenna dimensions and optimizing silicon quality through rapid thermal annealing, we successfully manipulate light at the nanoscale, enabling the emergence of narrow Fano resonances and the realization of tunable optical functionalities. These findings open up exciting opportunities for advanced optical devices and applications, ranging from sensing to data communication and beyond.

This work was performed, in part, at the Center for Integrated Nanotechnologies, an Office of Science User Facility operated for the U.S. Department of Energy (DOE) Office of Science by Los Alamos National Laboratory (Contract 89233218CNA000001) and Sandia National Laboratories (Contract DE-NA-0003525).

SESSION EL12.20: Virtual Session II: Topological and Chiral Metasurfaces

**Some Novel Topological Surface Waves** [Baile Zhang](#); Nanyang Technological University, Singapore

Topological surface waves are the topological modes on the surface of a 3D topological insulator or semimetal. Typically in a 3D topological insulator, the topological surface states exhibit Dirac cones, while a Weyl topological semimetal can support Fermi arc surface states. Here we discuss some novel types of topological surface states.

The first type is the topological surface states on a 3D Chern insulator. It is known that a 3D bandgap can be characterized by three Chern numbers, defined for three perpendicular planes in momentum space, forming a Chern vector. The vectorial nature of the Chern vector gives rise to novel structures of topological surface states, including torus knots and links. We have implemented a 3D photonic Chern insulator and demonstrated a (2,2) torus Hopf link for such topological surface states.

The second type is the topological surface states on a 3D valley crystal. Valley degree of freedom (DOF) is widely used as a binary DOF in valleytronic materials, and has recently been introduced into acoustic crystals and photonic crystals. Here we generalize the valley DOF into a 3D crystal and demonstrate 3D valley contrasting physics.

**8:30 AM \*EL12.20.03**

**Chiral Metaphotonics and Manipulations** [Cheng-Wei Qiu](#); National University of Singapore, Singapore

In this talk, we will report the recent progress on how chirality could assist and transcend the designs of advanced metasurfaces, sensing, strong coupling, BIC photonics and optical micromanipulations. In particular, we will report our very recent results on realizing intrinsic chiral metasurfaces where the engineered slant geometry breaks both in-plane and out-of-plane symmetries. Our result achieves intrinsic chiral bound states in the continuum with near-unity CD of 0.93 and quality factor exceeding 2300 for visible frequencies. We will also cast new perspectives on using photonic orbit angular momentum to effectively discriminate single-size and multi-scale chiral nanostructures.

**9:00 AM \*EL12.20.04**

**Optical Metasurfaces for Generating and Manipulating Grafted Vortex Beams** [Xianzhong Chen](#) and Hammad Ahmed; Heriot-Watt University, United Kingdom

Inspired by plant grafting, the technique of generating a grafted vortex beam involves combining two or more spiral phase profiles of optical vortex beams. Recently, there has been significant interest in grafted perfect vortex beams (GPVBs) and perfect vector vortex beams (PVVBs) due to their distinctive optical properties and potential applications. GPVBs exhibit a constant intensity profile and a radius irrespective of topological charges. PVVBs are structured light beams with inhomogeneous polarization and spiral phase profiles. However, the existing method used for generating and manipulating these beams suffers from the complex optical system, large volume, and high cost. These optical systems are impractical for numerous applications, thus creating an urgent need for a compact, simple, and efficient approach to generating and manipulating these beams.

We propose and experimentally demonstrate a metasurface approach to generating and manipulating these beams. A single metasurface is used to generate various GPVBs in multiple channels and PVVBs without relying on the complicated optical setup. The uniqueness of this method is that the superimposed GPVBs have nonuniform orbital angular momentum and asymmetric singularity distributions in different channels, which can be further modulated by introducing initial phase difference in the metasurface design. Our work has demonstrated a compact metasurface platform that performs a sophisticated optical task that is extremely challenging or impossible with conventional optics, opening opportunities for the investigation and applications of these structured beams in a wide range of emerging application areas such as singular optics and quantum science.

**Trompe L'oeil Ferromagnetism** Sang Wook Cheong and Fei-Ting Huang; Rutgers University, United States

Ferromagnetism can be characterized by non-zero magnetization (inducing magnetic attraction/repulsion), diagonal piezomagnetism, nonreciprocal circular dichroism (such as Faraday effect), odd-order (including linear) anomalous Hall effect, and magneto-optical Kerr effect. We identify all broken symmetries requiring each of the above phenomena, and also the relevant magnetic point groups (MPGs) with those broken symmetries. All of ferromagnetic point groups, relevant for ferromagnets, ferri-magnets and weak ferromagnets, can certainly exhibit all of those phenomena, including non-zero magnetization. Some of true antiferromagnets, which are defined as magnets whose MPGs do not belong to ferromagnetic point groups, can show those phenomena through magnetization induced by external perturbations such as applied current, electric fields, light illumination, and strain. Such MPGs are identified for each external perturbation. A number of exemplary materials for specific ferromagnetic-like phenomena will be discussed. Since high-density and ultrafast spintronic technologies can be enabled by antiferromagnets, our findings will be an essential guidance for the future magnetism-related science as well as technology.

**11:00 AM \*EL13.01.02**

**Controlling the Topologically-Protected Magnetoelectric Switching in Multiferroic GdMn<sub>2</sub>O<sub>5</sub>** Andrei Pimenov<sup>1</sup>, Louis Ponet<sup>2</sup>, Janek Wettstein<sup>1</sup>, Anna Pimenov<sup>1</sup>, Maksim Ryzhkov<sup>1</sup>, Kefeng Wang<sup>3</sup>, Sang Wook Cheong<sup>3</sup>, Maxim Mostovoy<sup>4</sup> and Sergey Artyukhin<sup>5</sup>; <sup>1</sup>TU Vienna, Austria; <sup>2</sup>Ecole Polytechnique Federale, Switzerland; <sup>3</sup>Rutgers, The State University of New Jersey, United States; <sup>4</sup>University of Groningen, Netherlands; <sup>5</sup>Istituto Italiano di Tecnologia, Italy

Manipulating magnetic moments by electric fields has been an everlasting goal for fundamental research. Recently, we could demonstrate a peculiar magnetoelectric behavior in multiferroic GdMn<sub>2</sub>O<sub>5</sub> showing a switching through a cycle of four states when the magnetic field is ramped up and down [1]. In this sequence, half of the spins undergo a rotation of about 90° each time the magnetic field is ramped leading to a full-circle 360° rotation when applying and removing a magnetic field two times in a series. GdMn<sub>2</sub>O<sub>5</sub> thus acts as a magnetic crankshaft that converts the back-and-forth variations of the magnetic field into a circular spin motion. This peculiar four-state magnetoelectric switching emerges as a topologically protected boundary between two different series, 1→2→3→4→1 and 1→4→3→2→1, respectively. Further on, in a certain range of experimental parameters the 4-state sequence becomes topologically trivial. In this regime, the external electric field adds a key parameter of the switching. We show that in such case the electric voltage allows a full control over the four magnetoelectric states in GdMn<sub>2</sub>O<sub>5</sub>.

**11:30 AM \*EL13.01.03**

**Thermodynamics of Multiferroics** Long-Qing Chen; The Pennsylvania State University, United States

Multiferroics, by definition, are material systems, either as single phases or composites of multiple phases, that exhibit more than one ferroic orders such as ferroelectric, ferromagnetic, or ferroelastic order. One of the objectives of this presentation is to conceptually connect among the classical first and second laws of thermodynamics, the Maxwell relations relating various and multiferroic properties, the Landau theory description of multiferroic phase transitions, as well as thermodynamics and phase-field method of multiferroic domain structures and responses to external fields. It will start from the classical first and second laws of thermodynamics to establish the fundamental equation of thermodynamics for a multiferroic system as a function of its basic thermodynamic variables. According to Gibbs, the fundamental equation of thermodynamics contains all the information about the equilibrium thermodynamic properties of a system, i.e., one can derive all the equilibrium ferroic and multiferroic properties of a system and their mutual relations from its fundamental equation of thermodynamics. On the other hand, irreversible thermodynamics considers all the ferroic phase transitions as internal irreversible thermodynamic processes within a material which generate entropy and dissipate chemical energy, allowing one to establish an energy function of both basic thermodynamic variables and the ferroic order parameters, e.g., through a Landau-type description, for a given multiferroic system. The thermodynamic description of a homogeneous system can be extended to inhomogeneous systems by introducing the contributions of ferroic domain wall energies through gradient or exchange energies as well as long-range elastic, electrostatic, and magnetic energies and by assuming that a local point of a domain structure can be described by the fundamental equation of thermodynamics in terms of both basic thermodynamic variables and ferroic order parameters. One can then apply the thermodynamic energy functions or functionals to construct multidomain and multiphase diagrams in the space of thermal, mechanical, electric, and magnetic variables using thermodynamic analysis, in analogy to the well-known temperature-composition phase diagrams or model the static and dynamic responses of a multiferroic domain structure to external stimuli using computational methods, such as the relaxational or dynamic phase-field method.

SESSION EL13.02: Magnetoelectric Heterostructures and Nanostructures I

**Two-Step Phase Transition Enabled Superelasticity in Quasi-Two-Dimensional Freestanding Perovskite Ferroelectric Films** Mingjie Xu and Xiaqing Pan; University of California, United States

Perovskite ferroelectric materials have garnered significant attention due to their unique properties, including ferroelectricity, piezoelectricity, and high stability, making them promising for diverse applications in memory devices and sensors. However, the inherent weak elasticity and brittleness of most perovskite ferroelectrics pose challenges for their integration into flexible electronic devices. In this study, we present the observation of superelasticity induced by a two-step phase transition in an 8-nm thick freestanding BiFeO<sub>3</sub> (BFO) film. Through atomically resolved in situ transmission electron microscopy (TEM) combined with in situ scanning transmission electron microscopy (STEM), we investigate the lattice deformation and atomic rearrangement in the film under mechanical stress, revealing reversible phase transitions and continuous evolution of the *c/a* ratio. Notably, we observe a remarkably large *c/a* ratio of approximately 1.53 in a super-tetragonal (*S*) phase under a lattice strain of approximately 34.4%, surpassing the highest strain reported for freestanding BFO films. This exceptional superelasticity arises from reversible 2-step phase transitions: R-T-S phase transitions, rather than conventional R-T transitions. Density functional theory (DFT) calculations support the crucial role of these 2-step phase transitions in facilitating such unusually large strain. The experimental results obtained through in situ TEM and STEM techniques provide a comprehensive understanding of lattice deformations and phase transitions occurring in the BFO film under mechanical stress. This work unveils unprecedented superelasticity in freestanding BiFeO<sub>3</sub> films and elucidates its fundamental mechanisms, offering novel insights for the design of advanced flexible electronic devices. The exceptional superelastic behavior demonstrated by quasi-two-dimensional freestanding perovskite ferroelectric films highlights their immense potential for a wide range of applications, including flexible electronics, solid-state actuators, and other innovative technologies.

**2:00 PM \***

**Low-Voltage Magnetoelectric Coupling in Membrane Heterostructures** Chang-Beom Eom; University of Wisconsin--Madison, United States

Strain-mediated magnetoelectric (ME) coupling in ferroelectric (FE) / ferromagnetic (FM) heterostructures offers a unique opportunity for both fundamental scientific research and low power multifunctional devices. Relaxor-ferroelectrics, like (1-x)Pb(Mg<sub>1/3</sub>Nb<sub>2/3</sub>)O<sub>3</sub>-(x)PbTiO<sub>3</sub> (PMN-xPT), are ideal FE layer candidates due to their giant piezoelectricity. But thin films of PMN-PT suffer from substrate clamping which substantially reduces piezoelectric in-plane strains. Here we present the first demonstration of low voltage ME coupling in an all-thin-film heterostructure which utilizes the anisotropic strains induced by the (011) orientation of PMN-PT[1]. We completely remove PMN-PT films from their substrate and couple with FM Ni overlayers to create membrane PMN-PT/Ni heterostructures showing 90 degree Ni magnetization rotation with 3V PMN-PT bias, much less than the bulk PMN-PT ~100V requirement. Scanning transmission electron microscopy and phase-field simulations clarify the membrane response. These results provide a crucial step towards understanding the microstructural behavior of PMN-PT thin films for use in piezo-driven magnetoelectric heterostructures.

**Nanoscale Ferroelastic Writing of Ferroelectric Domains** Kathrin Dorr; Martin-Luther-Universität-Halle-Wittenberg, Germany

There is a growing effort towards nanomechanics approaches using a scanning probe microscopy (SPM) tip in order to define patterns of ferroic properties. Next to micromachining, pressure-induced phase transitions or the flexoelectric effect, there is the emerging field of ferroelastic nanoscale manipulation. Ferroelasticity can provide access to mechanical manipulation of a local ferroic order parameter (such as magnetization or ferroelectric polarization), if the order parameter is coupled to a distinct lattice distortion. After giving an introduction to recent advances in the field, the talk addresses our work on mechanical tip-induced definition of ferroelectric domains in a prototype ferroelectric copolymer, P(VDF-TrFE). While there is an increasing track record of nanomechanical manipulation by SPM tip in fully crystalline ferroic films, semi-crystalline polymers offer a unique advantage because of their elasticity supporting damage-free strains of several percent.

The ferroelectric copolymer P(VDF-TrFE) (here with 22% TrFE) is one of the most often applied ferroelectric organic materials. The pseudo-hexagonal lattice of P(VDF-TrFE) supports six stable ferroelectric polarization orientations, and, strikingly, the lattice shrinks substantially along the polarization direction. As-prepared films show multiple few-nanometer-wide ferroelectric domains. The electric dipolar disorder is highly critical, leading to strong suppression of the functional electric responses such as dielectric permittivity, direct or inverse piezoelectric effects. In addition, electric poling and switching of P(VDF-TrFE) films require relatively large electric fields, preventing precise electric nanoscale domain writing because of the tip stray fields.

Our spin-coated P(VDF-TrFE) films consist of very densely packed fine crystalline lamellae of the ferroelectric beta-phase. There is a well-defined (110) out-of-plane texture, but no in-plane texture. After vertical electric poling, complex deliberate in-plane domain patterns with tip-related resolution of 50 nm have been defined [1] by scanning with moderate mechanical tip forces (100-300 nN). The mechanical treatment leaves the semicrystalline lamellar structure essentially unchanged, and the surface roughness remains below 3 nm (rms). Importantly for various functional devices, the in-plane piezoelectric response in written domains is massively enhanced, indicating the achievement of efficient ordering of electric dipoles. I will discuss opportunities to exploit mechanically defined nanoscale polarization patterns in functional devices. This work was partially funded by Deutsche Forschungsgemeinschaft (DFG), CRC 762 and TRR 102.

**Spin Hall Magnetoresistance and Quadratic Magneto-Optic Studies of Antiferromagnets** Kang L. Wang; University of California, Los Angeles, United States

Antiferromagnets with two sets of spins against each other pushes the operation of spintronics memory frequencies up to terahertz with a higher areal density, compared with the traditional ferromagnets due to the absence of the stray field and the strong coupling among spins. However, the net zero magnetic moment makes it difficult in probing and controlling the spin state in antiferromagnet. In this presentation, we discuss electrical and optical approaches to detect and manipulate spins, which pave the way for utilizing antiferromagnet in novel spintronic devices.

First, we will discuss the use of magneto-transport or unidirectional spin Hall magnetoresistance (USMR) in  $\text{Fe}_2\text{O}_3$  bilayer AFM bilayer. USMR has been widely reported in the heavy metal / ferromagnet (HM/FM) bilayer systems. We observed USMR in Pt/ $\alpha$ - $\text{Fe}_2\text{O}_3$  bilayers where the  $\alpha$ - $\text{Fe}_2\text{O}_3$  is an antiferromagnetic (AFM) insulator. Systematic field and temperature-dependent measurements confirm the magnonic origin of the USMR. The appearance of AFM-USMR is driven by the imbalance of creation and annihilation of AFM magnons by spin-orbit torque due to the thermal fluctuation field. Theoretical modeling reveals that the USMR in Pt/ $\alpha$ - $\text{Fe}_2\text{O}_3$  is determined by the antiferromagnetic magnon number with a non-monotonic field dependence as compared with that of ferromagnetic materials. The magnonic origin of USMR is further confirmed by temperature-dependent measurements. This first evidence of USMR in other HM/AFM bilayers may be expanded to include the large family of AF insulators and paves the way for the highly sensitive detection of AF spin states in emerging the AF spintronics.

Second, we will discuss the use of the quadratic magnetic-optical Kerr effect (QMOKE) to study dynamics of several AFMs. We will describe the experiments of e.g.,  $\alpha$ -MnTe; This antiferromagnet has a hexagonal close-packed structure with antiferromagnetic ordering along the c-axis. It is a collinear antiferromagnet with three in-plane easy axes, and its Néel temperature is approximately 310K [1,2], which is also known recently as an altermagnet, hosting anti-ferromagnetism in macroscopic scale and ferromagnetism in k space [3,4]. The hexagonal NiAs phase of MnTe ( $\alpha$ -MnTe) is obtained by MBE on GaAs. We employ the time resolved pump-probe laser quadratic magnetic-optical Kerr effect (QMOKE) to study MnTe. The QMOKE of  $\alpha$ -MnTe is more visible due to the spin splitting of electronic states in the k space. The pump process puts the Néel vector deviate from its equilibrium state. The pump results in the loss of the Néel order, referred to as the fast demagnetization, which endures for about 20 ps; the energy is redistributed between the electron, phonon and the magnon. This dynamics of the change of the Néel order is investigated through quadratic MOKE, reflecting the magnon dynamics. The dynamic study will also be used for other materials to compare the differences of the AFM dynamics.

**Ferroelectric Control of Spin-Charge Interconversion and Magnetism in Oxide Two-Dimensional Electron Gases** Manuel Bibes; CNRS/Thales, France

Two-dimensional electron gases (2DEG) based on  $\text{SrTiO}_3$  (STO) display fascinating properties such as low-temperature superconductivity and Rashba spin-orbit coupling allowing to interconvert spin and charge currents through the Edelstein effect. We have introduced ferroelectricity in these 2DEGs in order to achieve a non-volatile electrical control of their properties. Practically, we replaced STO by Ca-substituted STO (Ca-STO) which is ferroelectric up to about 30 K and generated 2DEGs either by sputtering a thin Al film or growing perovskite overlayers by pulsed laser deposition. We will present spin-charge and charge-spin conversion measurements and their control by the ferroelectric state. We will also show how magnetism can be introduced in the system and use x-ray absorption spectroscopy and magnetotransport to demonstrate the coexistence of ferroelectricity and magnetism with metallicity. Our data evidence the non-volatile control of polar displacements, magnetization and anomalous Hall effect upon switching the polarization direction, indicating a magnetoelectric coupling. Our results provide new opportunities in quantum matter arising from the interplay between ferroelectricity, ferromagnetism, metallicity, and Rashba spin-orbit coupling in low dimensions.

**Leveraging Colloidal Assembly to Texture Hexaferrites to Enable Better Performance in RF Devices** Jose A. Martinez and Randall M. Erb; Northeastern University, United States

With the implementation of 5G, the telecommunications industry desires enhanced performance of incumbent radio-frequency (RF) devices. Non-reciprocal devices, circulators, and isolators are integral to RF communication systems by isolating the incoming signals from the outgoing signals, exhibiting different electromagnetic wave propagation characteristics in the forward and reverse directions. Such devices rely on soft and hard ferrite materials currently limited in performance by the current achievable saturation magnetization and coercive field levels. Significant work has been applied toward improving the materials synthesis of these ferrite materials to achieve better performance. Specifically, M-type hexagonal ferrites, such as  $\text{SrFe}_{12}\text{O}_{19}$  (SrM) and  $\text{BaFe}_{12}\text{O}_{19}$  (BaM), have been studied for their large coercivity, high Curie temperature, good chemical stability, and high corrosion resistance. Here, we investigate the role that both the composition and microstructure of these materials have on the material performance. We tailor the saturation magnetization and the particle geometry of SrM and BaM through hydrothermal synthesis and thermal treatment. Further, we investigate the role of microstructure texturing by aligning ferrite particles in the pre-sintered state by leveraging a colloidal assembly technique that takes advantage of

anisotropic morphology, magnetic fields, and vibrational stimulus. We additionally provide perspective on the current materials limitations and opportunities in these magnetic RF devices.

**Enhancement of Magnetic Properties of NdFeB Sintered Magnet by Grain Boundary Diffusion Process with TbAlCu** [Dong Hyun Lee](#)<sup>1,2</sup>, Seong Chan Kim<sup>1,3</sup>, Juyoung Baek<sup>1</sup>, Donghwan Kim<sup>4</sup>, Sang Hyub Lee<sup>4</sup>, Hyesun Yoo<sup>2</sup>, Dalhyun Do<sup>3</sup>, Dong Hwan Kim<sup>1</sup>, JongWook Roh<sup>2</sup> and Jeongmin Kim<sup>1</sup>; <sup>1</sup>Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of); <sup>2</sup>Kyungpook National University, Korea (the Republic of); <sup>3</sup>Keimyung University, Korea (the Republic of); <sup>4</sup>Star Group Ind. Co., Ltd., Korea (the Republic of)

A strong coercivity enhancement of the commercial NdFeB magnets with the magnetic properties of  $iH_c = 22.76\text{--}22.48$  kOe and  $(BH)_{\max} = 48.61\text{--}48.58$  MGOe is demonstrated by the grain boundary diffusion (GBD) process with low-melting point  $\text{Tb}_{80}\text{Al}_{(x-20)}\text{Cu}_x$  ( $x = 0\text{--}20$ ) alloys. The maximum coercivity enhancement was obtained from the diffused magnet with  $\text{Tb}_{80}\text{Al}_{15}\text{Cu}_5$ , in which the value increased from 12.25 to 22.76 kOe by GBD process. Microstructural investigation with the electron probe micro analysis reveals that the enhancement of coercivity in the GBD magnets is mainly due to magnetic isolation by continuous Nd-rich grain boundary phases and Tb-rich shells. Tb diffusion through grain boundaries at a lower temperature than 900 °C, and consequently developed continuous and thin Tb-rich shell structures. Especially, the partial replacement of Tb by Al and Cu in diffusion sources resulted in higher coercivity with consuming fewer Tb elements (0.8 wt%) in the samples with  $\text{Tb}_{80}\text{Al}_{(x-20)}\text{Cu}_x$ , which are much lower than that in the samples with Tb metal (1.0 wt%). The results show that Cu and Al addition in diffusion source can effectively improve Tb diffusion efficiency by modifying intergranular Nd-rich phase. This work may shed light on the reduction of heavy rare earth in NdFeB sintered magnets.

#### 8:00 PM EL13.04.03

**Evolution of Antiferromagnetic Spin Texture in MBE-Grown Epitaxial Multiferroic BiFeO<sub>3</sub>** [Maya Ramesh](#)<sup>1</sup>, Peter Meisenheimer<sup>2</sup>, Isaac Harris<sup>2</sup>, Sajid Husain<sup>2</sup>, Shiyu Zhou<sup>3</sup>, Zhi (Yao)<sup>4</sup>, Paul Stevenson<sup>5</sup>, Lucas Caretta<sup>3</sup>, Ramamoorthy Ramesh<sup>6</sup> and Darrell Schlom<sup>1</sup>; <sup>1</sup>Cornell University, United States; <sup>2</sup>University of California, Berkeley, United States; <sup>3</sup>Brown University, United States; <sup>4</sup>Lawrence Berkeley National Laboratory, United States; <sup>5</sup>Northeastern University, United States; <sup>6</sup>Rice University, United States

Bismuth ferrite (BiFeO<sub>3</sub>) is a lead-free magnetoelectric multiferroic showing antiferromagnetic order and a large spontaneous polarization at room temperature. This antiferromagnetic order in BiFeO<sub>3</sub> is complex, where, as a consequence of the Dzyaloshinskii-Moriya interaction (DMI), a small canting of the antiferromagnetic order forms a chiral spin cycloid in bulk samples. Understanding the interplay between the ferroelectric polarization and the spin cycloid, as well as its electric field manipulation, is of significant interest for antiferromagnetic spintronics and next generation computation. There is still much to learn about BiFeO<sub>3</sub>'s intrinsic antiferromagnetic structure in thin films, where epitaxial strain imposed by an underlying substrate can influence the spin texture. As a model system, we have synthesized epitaxial thin films (2-100 nm) of BiFeO<sub>3</sub> on (110) TbScO<sub>3</sub> substrates via oxide molecular-beam epitaxy (MBE). This allows us to synthesize BiFeO<sub>3</sub> thin films with an unparalleled structural quality where even small amounts of strain (0.1% in the case of TbScO<sub>3</sub>) can have a large impact on the spin texture. In this work, we explore how epitaxial strain from the substrate affects the formation and orientation of the spin texture in BiFeO<sub>3</sub> using nitrogen-vacancy magnetometry (NV magnetometry) and spin transport measurements. NV magnetometry uses a nitrogen vacancy implanted at the tip of a diamond cantilever which acts as a single-spin magnetometer to sensitively map nanoscale surface stray fields. By correlating the spin texture to ferroelectric information measured using piezoresponse force microscopy, we are able to explore coupling between the two order parameters. Electric-field-dependent transport shows that the spin cycloid can be manipulated by switching the ferroelectric polarization, which is of great interest in low dissipation magnonics and spintronics.

#### 8:00 PM EL13.04.04

**Sputter Deposited Ni-Based Intrinsic Magnetic Topological Insulator Thin Films** [Rui Huang](#)<sup>1</sup>, Bin Luo<sup>1</sup>, Alexandria Will-Cole<sup>1</sup>, Serhiy Leontsev<sup>2</sup>, Valeria Lauter<sup>3</sup>, Michael McConney<sup>2</sup>, Michael Page<sup>2</sup> and Nian Sun<sup>1</sup>; <sup>1</sup>Northeastern University, United States; <sup>2</sup>Air Force Research Laboratory, United States; <sup>3</sup>Oak Ridge National Laboratory, United States

Three-dimensional topological insulators (TIs) exhibit unique properties such as topologically protected Dirac surface states (TSS) that enable metallic surface states while the bulk remains insulating. These TIs, including  $\text{Bi}_{1-x}\text{Sb}_x$  alloys and hexagonal  $\text{X}_2\text{Q}_3$  compounds ( $\text{X} = \text{Bi}, \text{Sb}, \text{Bi}_{1-x}\text{Sb}_x$ ;  $\text{Q} = \text{Se}, \text{Te}$ ), also demonstrate the quantum anomalous Hall effect (QAHE). The QAHE occurs when a gap is created in the TSS by introducing perpendicular magnetic order and breaking time reversal symmetry, resulting in spin polarized, chiral edge currents while maintaining an insulating bulk state. Magnetic order can be introduced through compositional doping, stoichiometric intrinsic magnetic TI (MTI), or proximity-induced magnetization (PIM) methods. Although the QAHE has been observed in experiments for each of these methods, the temperatures involved are currently impractical for technology, being in the milliKelvin range. A phenomenological trend is that the magnetic ordering temperature (Curie temperature,  $T_C$ , or Néel temperature,  $T_N$ ) is typically at least ten times higher than the observed QAHE temperature. In our previous work, we studied the interfacial magnetic phases of sputtered  $\text{Bi}_2\text{Te}_3/\text{Ni}_{80}\text{Fe}_{20}$  and confirmed with selected area diffraction the existence of the  $\text{NiBi}_2\text{Te}_4$  phase. We found a relatively high  $T_N$  of 63 K; thus, this phase is very promising to exhibit a high QAHE state. Here we expand our work on Ni-based MTI materials through sputtering single-phase Ni-doped  $\text{Bi}_2\text{Te}_3$  films, an intrinsic MTI. We present crystallographic structure characterization and temperature dependent magnetometry. To further understand the depth-dependent nuclear and magnetic structure we performed polarized neutron reflectometry.

#### 8:00 PM EL13.04.05

**Heterogeneous Strain Control by Interlayer Addition in Multiferroic Bi<sub>3</sub>Fe<sub>2</sub>Mn<sub>2</sub>O<sub>x</sub> Resulting in Thick Film Growth** [James P. Barnard](#)<sup>1</sup>, Jianan Shen<sup>1</sup>, Yizhi Zhang<sup>1</sup>, Juanjuan Lu<sup>1</sup>, Jiawei Song<sup>1</sup>, Aleem Siddiqui<sup>2</sup>, Raktim Sarma<sup>2,3</sup> and Haiyan Wang<sup>1,1</sup>; <sup>1</sup>Purdue University, United States; <sup>2</sup>Sandia National Laboratories, United States; <sup>3</sup>Center for Integrated Nanotechnologies, United States

In recent work on electronic devices based on multiferroic and ferroelectric materials, thicker films have become a necessity for certain applications, including MEMS magnetic actuators, magnetoelectric antennas designed for energy harvesting, and optical metasurface fabrication. A common roadblock for the synthesis of thicker films is the loss of film-substrate strain effects as the strain relaxes over the larger thickness. For example, the  $\text{Bi}_3\text{Fe}_2\text{Mn}_2\text{O}_x$  (BFMO) Aurivillius supercell (SC) phase is a multiferroic system that depends on substrate strain to initiate the growth of the phase. In our work, a new re-seeding technique has been developed that utilizes a heterogeneous film topology to reestablish the required strain to maintain SC phase growth. This is done by the insertion of  $\text{CeO}_2$  interlayers, which reintroduce the heteroepitaxial strain in the BFMO. The thick BFMO SC phase also maintains the desired ferroelectric and ferromagnetic properties as well as anisotropic optical properties. This technique allows for thicker growths of the BFMO SC phase (over 100 nm) and can also be applied to other supercell Aurivillius or strain-dependent films for device applications, effectively eliminating the current thickness limitations.

#### 8:00 PM EL13.04.07

**Thin Film Surface Acoustic Wave Magnetic Field Sensors: Impact of the Thickness of the Magnetostrictive Layer** [Jana M. Meyer](#)<sup>1</sup>, Lars Thormählen<sup>2</sup>, Stefan Moench<sup>3</sup>, Thorsten Giese<sup>1</sup>, Simon Fichtner<sup>1,2</sup>, Vadim Lebedev<sup>3</sup>, Agne Zukauskaitė<sup>4</sup>, Eckhard Quandt<sup>2</sup> and Fabian Lofink<sup>1,2</sup>;

<sup>1</sup>Fraunhofer ISIT, Germany; <sup>2</sup>Kiel University, Germany; <sup>3</sup>Fraunhofer IAF, Germany; <sup>4</sup>Fraunhofer FEP, Germany

For the fabrication of surface acoustic wave (SAW) sensors the use of piezoelectric single-crystal substrates (e.g., quartz) is established. Utilizing thin-film technology benefits from larger material flexibility, reduction in chip size, better integrability in standard MEMS and CMOS fabrication technology and thus better scalability. Additionally, it is possible to design multilayer stacks to customise the wave properties to the application purpose. [1] In this context, a piezoelectric AlScN thin film is a promising material, as it combines the advantages from AlN (e.g., high wave velocity, good mechanical and dielectric properties, high thermal conductivity, and high breakdown voltage) with improved electromechanical coupling due to alloying with Sc [2]. AlScN can be fabricated with standard semiconductor technology at reasonable cost on 200 mm silicon wafers.

By combining a SAW sensor with a magnetostrictive film, a magnetic field sensor can be realized that is based on the change of the Young's modulus (E effect) of magnetostrictive films in the presence of an external magnetic field that can be detected as a phase change of the SAW. [1] The SAW is generated by interdigital transducers on top of the piezoelectric AlScN thin film. By the application of a CMP polished SiO<sub>2</sub> layer on top of the AlScN, the magnetostrictive film quality is improved by reducing the roughness of the surface. The SiO<sub>2</sub> layer also acts as a guiding layer and is used to excite new surface confined SAW modes. High sensitivities of the SAW magnetic field sensor can be obtained by using magnetically soft magnetostrictive films with high magnetostriction like FeCoSiB or FeCoB. [3]

Different layer properties of the sensor stack can be varied (e.g., thickness) and different SAW modes aside from the fundamental Rayleigh mode (e.g., Sezawa mode or shear modes) can be excited in layered thin film structures. Crucial is the thickness of the magnetostrictive FeCoSiB film as it was shown that the sensitivity of the sensor is increasing with the magnetostrictive film thickness [4]. In contrast to the use of bulk piezoelectric substrates like quartz, a post annealing step to induce a uniaxial magnetic anisotropy is possible and the deposition temperature can be elevated to improve the magnetic anisotropy alignment. The influence on the phase shift induced by the applied magnetic field, on the corresponding sensitivity and especially on the frequency dependent noise behaviour of the sensor is investigated and the influence on the different SAW modes compared.

The SAW sensors can be used to measure weak fields at low frequencies as required for biomagnetic applications [5] but is also well suited for current sensing and control applications, such as power electronics [6], benefitting from the large dynamic range (up to 8 orders of magnitude), high bandwidth (> 1 MHz) and the possibility of an isolated measurement. **The Structural, Dielectric and Ferromagnetic Analysis of (BF)<sub>(1-x)</sub>(BST)<sub>x</sub>O<sub>3</sub> for Magnetic Applications** Satyam Kumar, Mohan K. Bhattarai, Sunny Choudhary, Shweta Shweta and Ram Katiyar; University of Puerto Rico- Rio Piedras, United States

In this work, we studied the effect of doping BST (Ba<sub>0.75</sub>Sr<sub>0.25</sub>TiO<sub>3</sub>)<sub>(1-x)</sub> in BFO (BiFeO<sub>3</sub>). The [(BF)<sub>(1-x)</sub>(BST)<sub>x</sub>O<sub>3</sub>] (0 < x < 0.2) were synthesized by the solid state reaction route. The XRD spectra exhibited the pure perovskite phase and Raman spectroscopy analysis supported it. The SEM image reveals the uniform size of grains ~ 3 μm and EDS analysis shows the stoichiometry of various compositions, which is further supported by the XRF results.

The temperature-dependent dielectric measurement was carried out over a wide frequency band (100Hz- 1MHz) obtained high dielectric constant and low loss. The electrical measurement analysis shows the reduced leakage current due to Ba, Sr, and Ti doping on BFO. The electric field polarization (P-E hysteresis) shows a ferroelectric behavior, and the magnetic properties of the material were studied with the Physical Property Measurement System (PPMS) in VSM mode.

#### 8:00 PM EL13.04.11

**A Miniaturized Magnetolectric Wireless Power Transfer System with an Integrated DC Magnetic Bias** Hao Ren; ShanghaiTech University, China

In this abstract, we present a miniaturized magnetolectric wireless power transfer (MEWPT) system with a MEWPT receiving antenna and a spiral-coil-based transmitter. Four DC magnets are integrated onto the MEWPT receiving antenna to significantly reduce its overall dimension while providing a DC magnetic bias of 190 Oe for optimal performance. Electrochemical polarization characterizations are adopted to analyze the performance of the WPT receiving antenna, which reveal that maximum output power of 4.096 and 1.155 mW are obtained when the distance between the transmitter and receiving antenna are 0 and 0.5 cm, respectively, which corresponds to record energy conversion efficiency(ECE) of 2.64% and 0.654%, the highest among all MEWPT systems to date. The output power is improved by at least 49.3 times compared with the MEWPT system without integrated DC magnets. We demonstrate that the MEWPT system can power low power electronics, showing its potential applications in internet of things (IoT) and implantable medical devices (IMD).

Wireless power transfer (WPT) system, which transfers energy without a physical link, has received significant research interest. Due to the advantages of small dimension, low operation frequency and low transmission loss, MEWPT systems have been presented in the past few years as a promising technology. However, MEWPT systems require a DC magnetic bias for optimal performance and prior arts have implemented large electromagnets, Helmholtz coils or externally positioned magnet bias systems, which increases the system dimension. Furthermore, prior MEWPT studies report low energy conversion efficiency (ECE). In this paper, we report a miniaturized MEWPT system with an integrated DC magnetic bias, which significantly reduces the MEWPT system dimension. A 10-turn spiral coil is implemented as the WPT transmitter and a ferrite plate backplate is integrated on the spiral coil to enhance its transmitting performance. Electrochemical polarization characterizations, including the output voltage versus current characterization and output power versus current characterizations are adopted to systematically analyze the performance of the MEWPT receiving antenna. The equivalent internal resistance of the MEWPT receiving antenna is obtained by linearly fitting the output voltage versus current curve. The MEWPT receiving antenna shows an output power of 4.096 mW and 1.155 mW when the distance between the transmitter and receiving antenna is 0 cm and 0.5 cm, which corresponds to record ECE of 2.64% and 0.654% among all MEWPT systems to date. The equivalent internal resistance of the MEWPT receiving antenna is measured to be 5.04 kΩ when the output power is at 4.096 mW. We demonstrate that the MEWPT system can wirelessly power low power light emitting diodes and microchips at a distance of 0.5 cm, which demonstrates the potential applications in IoT and IMD. As the input voltage to the inductive coil transmitter decreases, the output voltage of the receiving antenna linearly decreases. The directivity and off-axis characteristics of the MEWPT receiving antenna are also measured, which shows that the directivity and off-axis distance have a significant impact on the MEWPT receiving antenna performance.

**Electrical Control of Magnetic Texture in a Multiferroic Oxide** Peter Meisenheimer<sup>1</sup>, Shiyu Zhou<sup>2</sup>, Hongrui Zhang<sup>1</sup>, Sajid Husain<sup>1</sup>, Isaac Harris<sup>1</sup>, Lucas Caretta<sup>2</sup>, Paul Stevenson<sup>3</sup> and Ramamoorthy Ramesh<sup>1,4</sup>; <sup>1</sup>University of California, Berkeley, United States; <sup>2</sup>Brown University, United States; <sup>3</sup>Northeastern University, United States; <sup>4</sup>Rice University, United States

Materials for antiferromagnetic spintronics are becoming a popular topic due to their potential applications in next generation technologies. A primary advantage lies in their stability with external magnetic fields and potentially ultrafast spin dynamics, making them promising candidates for high-speed data storage and processing. A key challenge in this field, however, is the control of the antiferromagnetic order parameter on the nanometer scales applicable to solid state technologies. Bismuth ferrite is a multiferroic material that exhibits both ferroelectric and antiferromagnetic properties at room temperature, making it a unique candidate in the development of electrically controllable magnetic devices. In this material, the magnetic moments are arranged into a long-range spin cycloid, resulting in a unique set of magnetic properties that are intimately tied to the ferroelectric order parameter. Here we show that the propagation axis of this spin cycloid can be deterministically controlled with careful tuning of the ferroelectric order. Through precise application of electric fields, we show reversible control of the spin texture in BiFeO<sub>3</sub> thin films and deterministic spin transport that can be traced back to changes in the nanoscale magnetic structure.

**8:00 PM EL13.04.14**

**Creating a Three-Dimensional Intrinsic Electric Dipole on Rotated CrI<sub>3</sub> Bilayers** Shiva Prasad Poudel; University of Arkansas, Fayetteville, United States

New multiferroic platforms by sliding or rotation are being explored in two-dimensional (2D) materials [1,2,3]. Antiferromagnetically-coupled CrI<sub>3</sub> bilayers are one of the most studied magneto-electric multiferroic 2D materials [4]. Without considering magnetism, those bilayers possess a crystalline point of inversion, which can only be removed by antiparallel spin configuration between their two monolayers [4]. However, relative rotations between layers break the crystalline point of inversion, resulting in an inherent electric dipole moment **P**. Magnetoelectric couplings can be enhanced this way on a two-dimensional bilayer that is experimentally accessible [5].

This work was funded by MonArk NSF Quantum Foundry, supported by the National Science Foundation Q-AMASE-i program under NSF Award DMR-1906383. Calculations were performed on Cori at the National Energy Research Scientific Computing Center (NERSC), a U.S. Department of Energy Office of Science user facility operated under contract No. DE-AC02-05CH1231, the Arkansas High-Performance Computing Center's Pinnacle supercomputer, and the Tempest Research Cluster at Montana State University.

**8:00 AM \*EL13.05.01**

**Interfacial Néel Temperature Tuning for Voltage-Controlled Antiferromagnetic Spintronics** Christian Binek<sup>1,2</sup>, Ather Mahmood<sup>1,2</sup>, Jamie L. Weaver<sup>3</sup>, Syed Qamar Abbas Shah<sup>1,2</sup>, Jeffrey W. Lynn<sup>3</sup> and Peter Dowben<sup>1,2</sup>; <sup>1</sup>University of Nebraska-Lincoln, United States; <sup>2</sup>Nebraska Center for Materials and Nanoscience, United States; <sup>3</sup>National Institute of Standards and Technology, United States

Nonvolatile, voltage-controlled Néel vector rotation in the absence of an applied magnetic field is a much-desired material property in the context of antiferromagnetic spintronics. It enables ultra-low power, ultra-fast, nonvolatile memory, and logic device applications. We achieve this voltage-control by Boron (B) alloying the magnetoelectric antiferromagnet Cr<sub>2</sub>O<sub>3</sub>. It transforms Cr<sub>2</sub>O<sub>3</sub> into a multifunctional single-phase material enabling electric field driven  $\pi/2$  rotation of the Néel vector.

Voltage-controlled Néel vector rotation is detected with the help of heavy metal (Pt) Hall-bars in proximity of pulsed laser deposited B:Cr<sub>2</sub>O<sub>3</sub> films. Together with results from scanning probe microscopy measurements which are sensitive to topography and surface boundary magnetization, the mechanism of voltage-controlled Néel vector reorientation is explained in terms of voltage-induced orientation of polar nanoregions. Their macroscopic orientation polarization is accompanied by piezoelectric straining which causes reorientation of the magnetic easy axis due to magnetoelastic coupling. To facilitate operation of B:Cr<sub>2</sub>O<sub>3</sub>-based devices in CMOS environments, the Néel temperature,  $T_N$ , of the functional film must be tunable to values significantly above room temperature. Cold neutron depth profiling and x-ray photoemission spectroscopy depth profiling reveal thermally activated B-accumulation at the B:Cr<sub>2</sub>O<sub>3</sub>/vacuum interface in thin films deposited on Al<sub>2</sub>O<sub>3</sub> substrates. We attribute the B-enrichment to surface segregation. Magnetotransport data confirm thermally controlled B-accumulation at the interface where the device properties reside. The increased B-concentration increases  $T_N$  from 334 K pre annealing to  $T_N=477$  K post annealing within an interface layer of about 50 nm thickness. Scaling analysis determines  $T_N$  as a function of the annealing temperature. Stability of post-annealing device properties is evident from reproducible Néel vector rotation at 370 K performed over the course of weeks.

**A Lattice Perspective on Bismuth Ferrite** Doru C. Lupascu; University of Duisburg-Essen, Germany

Bismuth ferrite is our Drosophila system for multiferroicity at room temperature. One of the facts that has been giving the society large headaches is its low

magnetolectric coupling. In this presentation it is shown that this decoupling of the magnetic and electric orders happens fundamentally at the unit cell level. Antiferromagnetism and the cycloidal ordering of the Dzyaloshinskii–Moriya interaction generated magnetic moments are not even necessary to be considered for explaining the low coupling.

Our data from a nuclear solid state technique show that the magneto-electric coupling in the magnetic sub-lattice is actually enormous. The oxygen octahedral around the iron site experience a large tilt due to the onset of magnetic ordering. The Bi-containing complementary sub-lattice on the other hand is practically unaffected by this large structural change in its direct vicinity. Relation to classical magnetolectric coupling schemes are drawn.

The second part of the presentation will then deal with applications of this knowledge to the tuning of magnetic, electric and photon interaction properties in custom designed nanoparticles. Photocatalytic applications, hyperthermia treatment and net magnetization studies will be shown for nanoparticles differently doped on the two sub-lattices tuning strain and magnetic coupling. Surface effects will be considered.

##### **Dynamical Multiferroicity and Magnetic Topological Structures Induced by Orbital Angular Momentum of Light in a Non-Magnetic Material**

Lingyuan Gao, Sergei Prokhorenko, Yousra Nahas and Laurent Bellaiche; University of Arkansas, Fayetteville, United States

Many efforts have been made in studying effective magnetization resulting from the temporally varying electric polarization [1, 2]. Such dynamical polarization can be produced by driving collective motions of ions, usually termed as “phonons” in solid-state language. Moreover, numerous recent studies show that light can control the magnetization in crystals by driving optical phonon modes and tuning structural distortions [3-6]. At the zone center of reciprocal space, infrared (IR)- and Raman-active modes, related to electric polarization and polarizability, respectively, can be excited with an ultrafast Terahertz (THz) laser pulse.

In this Talk, we will present an alternative approach to induce effective magnetic field established on the mechanism of dynamical multiferroicity. Instead of focusing on coherently excited chiral phonons, we drive real-space circular motions of ions with a particular type of light–optical vortex (OV) beam. Such light carries an orbital angular momentum (OAM) [7-9], and can manipulate the motion of microparticles as an optical tweezer [10-12]. As a prototype example, we use first-principles-based simulations and demonstrate that in ultrathin ferroelectric Pb(Zr, Ti)O<sub>3</sub> films, microscopic electric dipoles indeed rotate with the time-varying OAM field. As a result, orbital magnetic moments of ions are effectively generated resulting in a non-negligible magnetic field even in non-magnetic materials. More intriguingly, we will show that the microscopic magnetic moments on a single layer of this quasi 2D system are arranged in a vortex-type configuration, proving that topological magnetic structures—magnetic merons—can also be produced out of orbital magnetic moments of ions and dynamical multiferroicity.

The authors acknowledge the support from the Grant MURI ETHOS W911NF-21-2-0162 from Army Research Office (ARO) and the Vannevar Bush Faculty Fellowship (VBFF) Grant No. N00014-20-1-2834 from the Department of Defense. We also acknowledge the computational support from the Arkansas High Performance Computing Center for computational resources.

##### **Three's Company: On Order Parameters in Magnetic Ferroelectrics** Manfred Fiebig; ETH Zurich, Switzerland

In magnetic ferroelectrics (“multiferroics”), magnetic and electric orders emerge independently (“type I”), or the former induces the latter (“type 2”). For type I, magnetic and electric order parameters are independent, and for type II, they are rigidly coupled. I argue that multiferroics with a coexistence of three order parameters combine the best of the type-I and type-II worlds. We have rigidly coupled order parameters, yet with a certain freedom to link magnetization and polarization to each other. Inversion, magnetolectric transfer of domain patterns, or antiferromagnetic domain vortex formation are among its consequences. While these examples are of a predominantly conceptual nature, there are also connections to device applications that I will discuss.

##### **The Spin Spiral in Multiferroic BiFeO<sub>3</sub>—Effects of Strain and Electric Field** Ramamoorthy Ramesh<sup>1</sup> and Peter Meisenheimer<sup>2</sup>; <sup>1</sup>Rice University, United States; <sup>2</sup>University of California, Berkeley, United States

The multiferroic BiFeO<sub>3</sub> (BFO) system seems to have an unending fountain of scientific and technological questions that the community is able to focus on. With the advent of NV-diamond based ultrahigh resolution magnetic probes, it is now possible to image with very high spatial resolution the spatial mapping of the spin spiral. Using epitaxial thin films (prepared by MBE, PLD and Sputtering), we are attempting to answer two questions: 1. What happens to the spin spiral as we impose epitaxial strain on the BFO layer through heteroepitaxy? This is being studied by using substrates of different lattice mismatch with BFO as well as the thickness of the BFO layer. 2. The second question pertains to what happens to the spin spiral when the ferroelectric polarization is switched by applying an electric field. This we are exploring using a combination of NV diamond based imaging as well as nonlocal spin transport studies. These studies are providing us with a wealth of information on the intrinsic magnetolectric coupling in this system. These experimental studies are being complemented with theoretical studies to throw light on the origins of the spin transport behavior.

##### **Switchable, Anisotropic Magnon Propagation Through the Spin Cycloid in Multiferroic BiFeO<sub>3</sub>** Isaac Harris<sup>1,2</sup>, Sajid Husain<sup>2,1</sup>, Maya Ramesh<sup>3</sup>, Peter

Meisenheimer<sup>1</sup>, Darrell Schlom<sup>3</sup>, Zhi (Yao)<sup>2</sup> and Ramamoorthy Ramesh<sup>4,1</sup>; <sup>1</sup>University of California, Berkeley, United States; <sup>2</sup>Lawrence Berkeley National Laboratory, United States; <sup>3</sup>Cornell University, United States; <sup>4</sup>Rice University, United States

Magneto-electric spin orbit (MESO) devices have been proposed as an alternative to CMOS devices for computational logic and memory, providing a possible solution to greatly reduce the energy consumption of conventional computers. This is expected to be done by electric field control of the magnetic order parameter of a ferromagnet through the magnetoelectric coupling of a BiFeO<sub>3</sub> (BFO) multiferroic attached to a ferromagnet. Here, we demonstrate a simplified version of a MESO device where we remove the ferromagnet entirely, and directly manipulate and measure the antiferromagnetic order of the BFO with electric fields and magnon detection, respectively. Using only the antiferromagnetic BFO in the MESO device is an attractive proposal for such a spintronic memory element due to its robustness against external fields, its lack of stray fields, and its fast switching dynamics. Furthermore, the insulating nature of BFO greatly reduces Ohmic losses in the transfer of spin information via magnons, creating a pathway for realizing ultra-low power spintronics. First, we present a bi-stable state switching of the AFM order, controlled by electric fields and measured using the inverse spin Hall effect in a platinum detector wire. Second, we demonstrate anisotropic magnon propagation in BFO, where the direction of magnon transport relative to the propagation of the spin cycloid in BFO – made visible by novel nitrogen vacancy center imaging techniques – is paramount to the retention of magnon spin information. With a better understanding of the controllable magnons in BiFeO<sub>3</sub>, we aim to demonstrate novel AFM memory devices for energy efficient spintronic applications.

#### 11:15 AM EL13.05.07

**Observation of Optical Magnetoelectric Effect in an Antiferromagnetic Metal TbB<sub>4</sub>** Takeshi Hayashida<sup>1</sup>, Keito Arakawa<sup>1</sup>, Kenta Kimura<sup>1,2</sup>, Ryusuke Misawa<sup>1</sup>, Tatsuya Miyamoto<sup>1</sup>, Hiroshi Okamoto<sup>1</sup>, Fumitoshi Iga<sup>3</sup> and Tsuyoshi Kimura<sup>1,1</sup>; <sup>1</sup>The University of Tokyo, Japan; <sup>2</sup>Osaka Metropolitan University, Japan; <sup>3</sup>Ibaraki University, Japan

In media breaking space-inversion and time-reversal symmetries simultaneously, intriguing cross-couplings between electric and magnetic properties emerge. A representative example is the linear magnetoelectric (ME) effect, that is, the induction of electric polarization  $P$  (magnetization  $M$ ) by an applied magnetic field  $H$  (electric field  $E$ ). The linear ME effect can be extended to optical frequency  $\omega$ , known as the optical magnetoelectric effect (OME), in which  $P(\omega)$  [ $M(\omega)$ ] is induced by oscillating  $H(\omega)$  [ $E(\omega)$ ] of an electromagnetic wave [1]. The OME effect induces nonreciprocal optical phenomena, which will be effective for probing the ME coupling in metallic systems, where the linear ME effect responding to a static field is ill-defined. In this study, we investigate the OME effect in an antiferromagnetic (AFM) metal TbB<sub>4</sub>. TbB<sub>4</sub> exhibits two successive AFM phase transition at  $T_{N1} = 44$  K and  $T_{N2} = 24$  K [2]. The magnetic structure in the AFM1 phase at  $T_{N2} \leq T \leq T_{N1}$  breaks both space-inversion and time-reversal symmetries (magnetic point group:  $4/m'm'm'$ ) and allows for the diagonal ME coupling ( $\alpha_{11} = \alpha_{22}$ , and  $\alpha_{33}$ , where  $\alpha_{ij}$  is the ME tensor defined as  $P_i = \alpha_{ij}H_j$ ). The diagonal terms of the ME tensor induce nonreciprocal rotation of reflected light (NRR), which refers to the rotation of the polarization of reflected light [3,4]. In the AFM1 phase of TbB<sub>4</sub>, there are two distinct AFM domain states, and the rotation directions of NRR are opposite between the two. Therefore, for the detection of NRR in TbB<sub>4</sub>, spatial distribution measurements are suitable. Here, we obtain two-dimensional maps of NRR, with magnitudes ranging from  $10^{-5}$  to  $10^{-4}$  rad in the visible light region, by adopting a difference image sensing technique using polarization modulation of incident light [5,6]. As a result, we have successfully detected NRR and visualized AFM domains in TbB<sub>4</sub>. We expect that our achievement will further promote understanding of ME effects in metallic compounds.

**Lattice Distortions, Electronic and Magnetic Orders in Multiferroic BiFeO<sub>3</sub>** Valeri Petkov; Central Michigan University, United States

The presence of a spin cycloid and zero net magnetization negate any linear magnetoelectric coupling (MEC) between the polarization and magnetization in BiFeO<sub>3</sub> (BFO), hampering its usage in practical applications. It has been found that the problem can be alleviated by reducing BFO to nanoscale dimensions or chemical substitution but the underlying physics behind the improved MEC remains unknown. In the talk, we will show results from recent total x-ray scattering studies on nanosized [1] and La substituted [2] BFO indicating that both approaches have a common structural origin. That is, both approaches induce lattice distortions, which reduce the lattice symmetry leading to nonzero magnetization while largely preserving the ferroelectricity. We argue that lattice degrees of freedom in multiferroics often appear as lattice distortions which entangle their electronic and magnetic orders, providing a convenient mechanism to manipulate them as desired.

Magnetic insulators (MI), possessing long-range magnetic order while being electrically insulating, allow spin propagation without electrons' motion and thus promise a unique paradigm of next-generation dissipationless magnetoelectric and magneto-optical devices. While two-dimensional (2D) MIs usher the prospects into the atomic-thin region, efficient electrical control as an essential prerequisite for practical devices remains elusive; fundamental obstacles arise from the difficulty of electrostatically doping insulators and the inability of external electric fields to effectively modify materials' crystal fields. Here, by constructing a heterostructure consisting of a functional thin film and a 2D magnetic insulator, we achieved a strong and reversible electrical control of

magnetism. The wavefunction overlaps at the heterostructure interface differs greatly under opposite voltages applied, leading to effective control of the coercivities in magnetic hysteresis loops of the 2D magnets. The layered dependence study confirmed that this effective control occurs exclusively for 2D magnets instead of the bulk counterpart, owing to the electrically controllable interfacial wavefunction overlap that could effectively alter the interfacial crystal field. Our work opens up new avenues to usher 2D MIs towards future nanoscale spintronic, magnonic, and magneto-optical applications.

SESSION EL13.06: Magnetolectric Sensors and Actuators I

**Removing Magnetic Noise from Composite Magnetolectric Sensors** Jeffrey McCord; Kiel University, Germany

Magnetic field sensors are devices that detect and measure magnetic fields around permanent magnets, electrical conductors, and electrical devices. As such, they are particularly relevant for magnetic applications in IoT, 5G, smartphones, energy, and biomedical engineering. In this context, dedicated research is currently being carried out on novel thin film magnetolectric (ME) sensor concepts for the detection of magnetic fields down to the picotesla range.

Advanced wide-field magneto-optical Kerr effect microscopy [1] with high temporal resolution is used to study local effects in operating ME composite sensor structures. The realized magnetospatial analysis of working devices sheds light on magnetization changes due to domain nucleation, domain wall resonances, domain wall bending modes, precessional magnetization effects and spin-wave-like phenomena. Each of these is specific to different types of composite ME sensors, ranging from resonance to DE to SAW sensor systems. Complementary ME response, noise and detection limit analyses reveal the different magnetic noise mechanisms with different magnetic domain activities for the different sensor types (e.g. [2-5]). By understanding the complex magnetic interactions, strategies and implementations are identified to optimize sensor structures. Single magnetic domain layers are the basis for low noise magnetic thin film sensors due to the absence of magnetic domain walls.

The design and application of magnetic layered structures with minimal noise performance sensitivity is discussed. Beyond magnetic domain engineering [6], other schemes of magnetic noise suppression, based on a combination of sensing and pinning magnetic multilayer stacks are discussed. By introducing magnetic sensing layers with subtractive response to carrier excitations while maintaining sensitivity, the influence of the electrical carrier signal to noise is virtually eliminated [7]. The magnetically enforced reduction of the electrical background signal paves the way for ultra-low noise ME sensor applications capable of detecting picotesla magnetic fields. Fundamental limitations of composite ME sensors beyond magnetic domain activity will be further discussed [5].

Funding by the DFG for the CRC 1261 “Magnetolectric Sensors: From Composite Materials to Biomagnetic Diagnostics” and collaborations within the CRC are acknowledged.

**Dynamically Tunable, Narrowband Terahertz Emitters Designed by Tailoring Magnon-Phonon Interaction in Multilayer Heterostructures** Jiamian Hu; University of Wisconsin-Madison, United States

A dynamically tunable, narrowband terahertz (THz) source is much needed for an accurate identification and imaging of chemical and biological species, with wide-ranging applications from security screening to medical imaging and to semiconductor inspection. However, existing pulsed THz sources are mostly single-cycle, broadband, and difficult to tune dynamically. In this presentation, the speaker will first introduce an approach that permits converting a femtosecond laser pulse into a multi-cycle, narrowband THz pulse via resonant magnon-phonon interaction. The peak frequency of the emitted THz pulse can be tuned by up to 50% through a varying bias magnetic field. The speaker will then present computational demonstration of this approach in several carefully designed ferromagnet and antiferromagnet based multilayer heterostructures, which allows us to cover without gaps different frequency ranges (deep millimeter-wave, sub-THz, and >1 THz) of the THz spectrum, tune the polarization, duration, and power of the emitted THz pulse. The demonstration was performed based on an in-house dynamical phase-field model that incorporates the coupled dynamics of magnons, phonons, photons, and plasmons in multiphase systems.

**2:30 PM \*EL13.06.03**

**Imaging of Magnetic Particles by Magnetic Susceptibility Particle Mapping (MSPM)** Christine Selhuber-Unkel; Heidelberg University, Germany

The imaging of magnetic particles is highly relevant in many biomedical investigations, including disease detection, diagnosis, and treatment. Magnetic Susceptibility Particle Mapping (MSPM) has the potential to emerge as an important tool in this context, as it can be used to detect magnetic nanoparticles in a lab scale device. The system is based on magnetolectric (ME) sensors that make use of the Delta-E effect, in combination with a permanent magnet, which generates a bias field for the sensor and at the same time magnetizes the SPIONs. The SPIONs in the sample are magnetized by the permanent magnet and generate an additional magnetic field, which is recorded by the ME sensor. To demonstrate the capability of the MSPM as an imaging technique, magnetic particle distributions are assessed in 3D printing scaffolds. In addition, 3D microtumors based on MCF-7 and MDA-MB-231 breast cancer cells were labelled with magnetic nanoparticles assessed by MSPM. The data show the potential of the device as well as new avenues towards a lab scale investigation of biomedically relevant samples at the standard lab scale.

**Nonreciprocity and Nonlinearity in Hybrid Magnetoacoustic Devices** Derek Bas<sup>1</sup>, Roman Verba<sup>2</sup>, Piyush Shah<sup>1</sup>, Serhiy Leontsev<sup>1</sup>, Abbass Hamadeh<sup>3</sup>, Michael Wolf<sup>1</sup>, Andrew Franson<sup>1</sup>, Alexei Matyushov<sup>4</sup>, Michael Newburger<sup>1</sup>, Philipp Pirro<sup>3</sup>, Mathias Weiler<sup>3</sup>, Nian Sun<sup>4</sup>, Vasyly Tyberkevych<sup>5</sup>, Andrei Slavin<sup>5</sup> and Michael Page<sup>1</sup>; <sup>1</sup>Air Force Research Laboratory, United States; <sup>2</sup>Institute of Magnetism, Ukraine; <sup>3</sup>Technische Universität Kaiserslautern, Germany; <sup>4</sup>Northeastern University, United States; <sup>5</sup>Oakland University, United States

Nonreciprocity, the property of merit for a variety of RF components such as isolators and circulators, is typically difficult to achieve with the magnitude required for applications. To this end, I will discuss discoveries of non-reciprocity and non-linearity in surface acoustic waves interacting with magnetic materials. Giant Nonreciprocity of 48.4 dB (ratio of 1:100,000) is achieved in the transmission of surface acoustic waves on a lithium niobate substrate coated with ferromagnet/insulator/ferromagnet (FeGaB/Al<sub>2</sub>O<sub>3</sub>/FeGaB) multilayer structure. This same structure has now also demonstrated very large phase shifts due to a similar interaction, and the nature of the magnetic ordering and coupling to the acoustic system will be discussed. Nonlinearity will also be discussed and is demonstrated using focused interdigitated transistors employing curved fingers, in contrast to the straight fingers typically used. These transducers are engineered to concentrate acoustic energy towards a small region in the center of the device allowing driven magnetic precession much higher than was previously possible. Enhanced acoustic absorption and modeling of the response will be shown. These devices promise functionality which outperforms current state of the art high frequency devices in a novel acoustic wave system that facilitates unprecedented size, weight, and power reduction.

**4:00 PM EL13.06.05**

**Miniaturized Delta-E Effect Magnetic Field Sensors** Fatih Ilgaz<sup>1</sup>, Patrick Wiegand<sup>1</sup>, Benjamin Spetzler<sup>2</sup>, Robert Rieger<sup>1</sup> and Franz Faupel<sup>1</sup>; <sup>1</sup>Kiel University, Germany; <sup>2</sup>Ilmenau University of Technology, Germany

Magnetoelastic delta-E effect sensors utilize the change in the elastic modulus of the magnetostrictive material upon applying a magnetic field, resulting in a shift in the resonance frequency. Such sensors have demonstrated the potential to detect small-amplitude and low-frequency magnetic fields. It was also shown that the limit of detection can be improved by using sensor arrays including a large number of sensor elements [1]. However, building compact arrays and achieving high spatial resolutions using mm-sized sensors is challenging. Moreover, the reproducibility of the sensors is significantly impacted by the anisotropic stress developing in the magnetic layer upon releasing the resonator during the fabrication process [2]. Additionally, sensors with a cantilever design suffer from inhomogeneous magnetic properties caused by different stress relaxation at the clamping region affecting their performance [3]. Here, we present an experimental and theoretical investigation of  $\mu\text{m}$ -sized delta-E effect sensors employing a free-free beam design that overcomes the limitations and challenges encountered in previous approaches. To control and minimize the residual stress in the magnetic layer, we use a shadow-mask deposition technique where the magnetic layer is deposited on the released resonators. The spatial stress distribution can be accurately determined by combining displacement measurements with a magneto-mechanical model. Different resonance modes are identified, and the dependency of the resonance frequency shift and the sensitivities on these modes are established. The influence of the anchors and the stiffness tensor components on the resonance frequency shift are analyzed by combining a magnetoelastic macrospin model and an electromechanical finite element model. Noise performance and the limit of detection of different sensor geometries are investigated to gain general insight into the relationship between geometry, resonance mode, and sensor performance. We demonstrate extreme stress control with a minimal change of smaller than 8 MPa in the normal stress components ( $\sigma_{11}$  and  $\sigma_{22}$ ) and smaller than 2 MPa in the shear stress component ( $\sigma_{12}$ ) following the deposition of the magnetic layer. We find that the delta-E effect and sensitivities exhibit strong dependence on resonance modes, attributed to distinct variations in local magnetic and mechanical properties specific to each mode. We identify the optimum mode shape and achieve detection limits below 300 pT/Hz<sup>1/2</sup> at 10 Hz, comparable to macroscopic sensors [4,5]. Overall, we demonstrate the successful production and miniaturization of delta-E effect sensors with high reproducibility and similar performance to the macroscopic sensors using the proposed manufacturing process and sensor design. The achieved miniaturization and reproducibility represent a significant step toward developing fully integrated sensor arrays and emphasize the potential for high spatial resolution and improved detection limits with large sensor arrays or using flux concentrators.

**Love Wave Magnetic Field Sensor Operating Without External Bias Field** Felix Weisheit<sup>1</sup>, Viktor Schell<sup>1</sup>, Elizaveta Spetzler<sup>1</sup>, Jeffrey McCord<sup>1</sup>, Dirk Meyners<sup>1</sup>, Eckhard Quandt<sup>1</sup> and Susana Cardoso de Freitas<sup>2</sup>; <sup>1</sup>University of Kiel, Germany; <sup>2</sup>INESC Microsystems and Nanotechnologies, Portugal

Surface acoustic wave (SAW) technology is widely utilized in electronics as e.g. filters and sensors. One notable application is their implementation for magnetic field detection [1]. Currently, magnetic field sensors have achieved a limit of detection (LOD) below 40 pT\*Hz<sup>1/2</sup> within the frequency range of 1 Hz to 1 kHz. However, these sensors require an external bias field of approximately 0.4 mT to achieve the desired sensitivity [2]. Alternatively, newly developed SAW sensors incorporate a sensing layer of FeCoSiB deposited through ion beam deposition. These sensors can achieve a LOD of 71 pT\*Hz<sup>1/2</sup> at 10 Hz without the need for an external bias field. This eliminates the requirement for an additional magnetic field source during operation.

The SAW sensor is constructed on a substrate of piezoelectric ST-cut quartz with gold interdigital transducers (IDTs) for generating the acoustic wave. A waveguiding layer made of amorphous SiO<sub>2</sub> is placed on top to confine the wave to the surface, resulting in Love waves. They exhibit an in-plane displacement perpendicular to the direction of propagation. The IDTs are arranged sequentially to create a delay line, and a magnetostrictive sensing element is positioned between them. This sensing layer consists of a single-layer amorphous (Fe<sub>80</sub>Co<sub>20</sub>)<sub>78</sub>Si<sub>12</sub>B<sub>10</sub> thin film deposited using ion beam deposition. If a magnetic field is present, it induces changes in the elastic properties of the FeCoSiB due to the  $\Delta E$  effect. This alteration in properties leads to a phase shift in the Love wave. The sensitivity of the sensor to the magnetic field is determined by measuring this phase shift. This measurement is carried out using a Zurich Instruments UHFLI lock-in amplifier, which employs dynamic phase detection. The phase noise analysis is performed using a Rhode & Schwarz FSWP phase noise analyzer.

The FeCoSiB coating on the new sensor does not exhibit ideal soft magnetic behavior, but instead displays a more hysteretic behavior with a coercivity field of 0.5 mT. Consequently, this leads to a shift in the sensitivity curve, wherein the maximum sensitivity of 1410  $^{\circ}$ /mT is achieved at a bias field of 0.75 mT. But, even in the remanence state, the sensor retains a sensitivity of 640  $^{\circ}$ /mT, whereas other sensors with a more ideal soft magnetic film have a sensitivity below 100  $^{\circ}$ /mT. To determine the LOD, the phase noise is divided by the sensitivity. The best sensor, in this case, achieves a LOD of 71 pT\*Hz<sup>1/2</sup> at 10 Hz and 24 pT\*Hz<sup>1/2</sup> at 100 Hz. The magnetic properties, as well as the findings when considering the sensitivities, will be presented. Furthermore, advances in utilizing LiNbO<sub>3</sub> single crystal substrate, which possesses a significantly higher electromechanical coupling factor than quartz,

will be discussed. LiNbO<sub>3</sub> also allows higher excitation frequencies to be used, which is expected to result in a further increase in sensitivity.

**Temperature Stability of Magnetic Materials for Highly Sensitive Magnetoelectric Sensors** Lars Thormählen<sup>1</sup>, Bin Luo<sup>2</sup>, Nian Sun<sup>2</sup>, Eckhard Quandt<sup>1</sup> and Dirk Meyners<sup>1</sup>; <sup>1</sup>University of Kiel, Germany; <sup>2</sup>Northeastern University, United States

The detection of magnetic signals is a significant research area where numerous magnetoelectric sensor systems, such as antennas, filters, and magnetometers, are being developed and tested [1]. The use of magnetic signals has the advantage over electrical signals that they are not affected by water, for example, which simplifies communication with underwater vessels and the measurement of biomagnetic signals [1, 2]. The development and fabrication of magnetoelectric cantilever sensors, based on microsystem techniques, are among the primary research focuses of the Collaborative Research Center 1261 at Kiel University [2, 3]. To construct such highly sensitive magnetic field sensors, a wide range of material parameters must be considered. For instance, piezoelectric layers require high piezoelectric coefficients, while magnetic layers should possess soft magnetic properties combined with high magnetostriction. Commonly used magnetostrictive materials are FeCoSiB and FeGaB. Amorphous magnetic materials have the advantage of avoiding undesired crystal anisotropies. To further enhance the magnetic behavior, exchange-bias multilayer systems are employed to minimize magnetic noise resulting from domain wall activity. Imprinting anisotropy in the multilayers is crucial for optimal performance, which can be achieved through sputter deposition in a magnetic field, as well as subsequent heat treatment at approximately 250 °C for FeCoSiB. However, higher annealing temperatures may be necessary depending on the blocking temperature of the selected antiferromagnet for biasing, which could lead to crystallization of the amorphous magnetic layers.

Another potential source of unintentional crystallization is the packaging of the devices at the end of production to protect them from environmental influences and facilitate handling. This common method typically requires temperatures of about 400 °C to create a vacuum-sealed capsule.

This study focuses on investigating different magnetostrictive materials such as FeCoSiB, FeGaB, FeGaC, and CoFeB, which are fabricated through sputter deposition with multicomponent targets and co-deposited layers [1]. The materials are evaluated using XRD, VSM, and magnetostriction measurements at different temperatures. The study aims to determine the temperature ranges at which a negative magnetic change occurs. For example, significant changes in the magnetic behavior of FeCoSiB are observed at temperatures above 300 °C, resulting in a degradation of sensor properties and rendering them unsuitable for vacuum encapsulation by standard wafer bonding.

**Exploiting Structural and Electronic Coupling in Transition Metal Oxide Heterostructures** Jean-Marc Triscone<sup>1</sup>, Hugo Meley<sup>1</sup>, Duncan T. Alexander<sup>2</sup>, Clémentine Thibault<sup>1</sup>, Lucia Varbaro<sup>1</sup>, Lukas Korosec<sup>1</sup>, Claribel Dominguez<sup>1</sup>, Bernat Mundet<sup>3</sup>, Jennifer Fowlie<sup>4</sup>, Marta Gibert<sup>5</sup>, Marcus Schmitt<sup>6</sup>, Philippe Ghosez<sup>6</sup> and Stefano Gariglio<sup>1</sup>; <sup>1</sup>University of Geneva, Switzerland; <sup>2</sup>EPFL, Switzerland; <sup>3</sup>Institut Català de Nanociència i Nanotecnologia (ICN2), Spain; <sup>4</sup>SLAC National Accelerator Laboratory, United States; <sup>5</sup>TU Wien, Austria; <sup>6</sup>Université de Liège, Belgium

In this talk, I will illustrate through some examples how electronic and structural coupling can lead to exciting novel properties in oxide films and heterostructures.

I will first recall how tri-linear coupling of structural instabilities can lead to improper ferroelectricity in PbTiO<sub>3</sub>/SrTiO<sub>3</sub> superlattices [1]. I will then discuss how such a coupling of instabilities can be used to design artificial ferroelectric and possibly multiferroic materials with a focus on vanadate-based structures [2,3]. In these structures, it was found that the competition between the strain state and the coupling of oxygen octahedra rotations leads to an interesting "transition layer" and a reorientation of the orthorhombic long-axis. This competition can be used for designing an artificial interface with possibly designed electronic properties. The reorientation of the orthorhombic long-axis is also observed in SmNiO<sub>3</sub>/NdNiO<sub>3</sub> nickelate superlattices [4,5] - when an additional insulating spacer layer of LaAlO<sub>3</sub> is introduced [6].

**Interface-Dependent Magnetotransport Properties of Perovskite Lanthanum Manganite Thin Films** Pinku Roy<sup>1,2</sup>, Aiping Chen<sup>2</sup> and Quanxi Jia<sup>1</sup>; <sup>1</sup>University at Buffalo, United States; <sup>2</sup>Los Alamos National Laboratory, United States

Enhanced functionalities and/or emergent behavior, often not accessible from the individual constituents, could be produced by interfacing certain materials at different length scales. Over the years, major advances have been made to synthesize high crystallinity epitaxial perovskite lanthanum

manganite films with controlled microstructures and to gain a fundamental understanding of their physical properties. In this talk, we will discuss our strategies in the synthesis and characterization of epitaxial lanthanum manganite films. Using perovskite lanthanum manganite as the model system, we examine interface-dependent magnetotransport properties by creating both vertically aligned nanocomposite films and layered heterostructures. Specifically, we will discuss the effect of interfaces (both vertical and lateral interfaces) on the magnetotransport properties of lanthanum manganite films.

**Superconductivity in Layered Square Planar Nickelates** [Julia Mundy](#); Harvard University, United States

Since the discovery of high-temperature superconductivity in copper oxide materials, there have been sustained efforts to both understand the origins of this phase and discover new cuprate-like superconducting materials. One prime materials platform has been the rare-earth nickelates; indeed, superconductivity was recently discovered in the doped compound  $\text{Nd}_{0.8}\text{Sr}_{0.2}\text{NiO}_2$  [1]. Undoped  $\text{NdNiO}_2$  belongs to a series of layered square-planar nickelates with chemical formula  $\text{Nd}_{n+1}\text{Ni}_n\text{O}_{2n+2}$  and is known as the ‘infinite-layer’ ( $n = \infty$ ) nickelate. Here, we report the synthesis of the quintuple-layer ( $n = 5$ ) member of this series,  $\text{Nd}_6\text{Ni}_5\text{O}_{12}$ , in which optimal cuprate-like electron filling ( $d^{8.8}$ ) is achieved without chemical doping [2]. We observe a superconducting transition beginning at  $\sim 13$  K. Electronic structure calculations, in tandem with magnetoresistive and spectroscopic measurements, suggest that  $\text{Nd}_6\text{Ni}_5\text{O}_{12}$  interpolates between cuprate-like and infinite-layer nickelate-like behaviour. By engineering a distinct superconducting nickelate, we identify the square-planar nickelates as a new family of superconductors that can be tuned via both doping and dimensionality. [3]

### 9:30 AM BREAK

### 10:00 AM EL13.07.05

**Structural and Electronic Properties of Nickelate Based Superlattices** [Lucia Varbaro](#)<sup>1</sup>, Claribel Domínguez<sup>1</sup>, Jennifer Fowlie<sup>2</sup>, Lukas Korosec<sup>1</sup>, Bernat Mundet<sup>3</sup>, Duncan T. Alexander<sup>4</sup> and Jean-Marc Triscone<sup>1</sup>; <sup>1</sup>University of Geneva, Switzerland; <sup>2</sup>SLAC National Accelerator Laboratory, United States; <sup>3</sup>Institut Català de Nanociència i Nanotecnologia (ICN2), Spain; <sup>4</sup>École Polytechnique Fédérale de Lausanne, Switzerland

Rare-earth nickelates belong to the wider family of perovskite oxides. These materials display a characteristic temperature-dependent metal-to-insulator transition (MIT) together with a lowering of the crystal symmetry related to the onset of a breathing distortion of the  $\text{NiO}_6$  octahedra units [1,2].

Furthermore, below the Néel temperature ( $T_N < T_{MI}$  for  $R = \text{Lu} - \text{Sm}$  and  $T_N = T_{MI}$  for  $R = \text{Nd}, \text{Pr}$ ), these compounds were found to exhibit antiferromagnetic order with the (1/4, 1/4, 1/4) pseudocubic propagation vector [3-4]. In theory, it has been predicted that the coalescence of breathing distortion and non-centrosymmetric magnetic order could result in a breaking of inversion symmetry within the crystal lattice. Consequently, this would lead to the emergence of an electric dipole, classifying nickelates as type-II multiferroics. [5]. Raman spectroscopic data of  $\text{RNiO}_3$  single crystals by Ardizzone and al. [6], show that, entering the magnetically ordered phase, additional vibrational modes appear as a possible signature of breaking of inversion symmetry.

In this work, we investigate nickelate thin films and superlattices. Raman experiments were performed on  $\text{NdNiO}_3$  and  $\text{SmNiO}_3$  thin films, revealing temperature evolution of the Raman spectra rather similar to the one reported in [6].

Moreover, the structural and electronic properties of nickelate superlattices were studied to investigate the characteristic length scale over which a metallic or an insulating phase can be established and the physics that sets it [7]. By growing  $\text{SmNiO}_3/\text{NdNiO}_3$  superlattices and using experimental and theoretical methods we showed that this length scale depends on the interplay between the energy cost of the boundary between metallic and insulating phases and the energy gain of the bulk phases [7].

To further understand this unusual coupling and the evolution of the structural and electronic order parameters across these phase boundaries,  $\text{SmNiO}_3/\text{NdNiO}_3$  superlattices were grown with additional insulating  $\text{LaAlO}_3$  spacer layers, that should lead to a progressive decoupling of the nickelate layers.

Furthermore, the phase boundary cost of maintaining an interface between a metal and an insulator will be exploited as an additional parameter to tune the electronic properties of this class of materials, specifically alternating metallic layers and layers displaying a metal-to-insulator transition within a superlattice, with the aim of forcing a metal into an insulating phase by increasing the density of interfaces.

All the samples were grown using RF off axis magnetron sputtering, and are morphologically and structurally characterized using atomic force microscopy (AFM), X-ray diffraction (XRD) and STEM-EELS. Temperature dependent transport measurements will be presented for each different system, giving an overview on electronic and structural couplings, and more generally on the properties of these complex heterostructures.

**Giant Magnetolectric Effect and Interactive Control of Magnetic Anisotropy Driven by a Ferroelectric Phase Transition in Ferromagnetic-Piezoelectric Heterostructure** Thomas R. Mion<sup>1,2</sup>, Margo Staruch<sup>3</sup>, [Peter Finkel](#)<sup>2</sup> and Konrad Bussmann<sup>2</sup>; <sup>1</sup>NOVA Research, United States; <sup>2</sup>U.S. Naval Research Laboratory, United States

Magnetolectric materials and, to a larger extent, multiferroic heterostructures offer a novel route for electric field control of magnetism. We explored the induced magnetic anisotropy of an  $\text{FeCo}/\text{Ag}$  multilayer thin film deposited on the surface of 001 poled  $(\text{Pb}(\text{In}_{1/2}\text{Nb}_{1/2})\text{O}_3\text{-Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3\text{-PbTiO}_3)$  PIN-PMN-PT single crystal as it is electrically driven through a ferroelectric-ferroelectric phase transition. In PIN-PMN-PT an effective giant piezoelectric coefficient  $>10,000$  pm/V occurs during the phase transition providing strain  $>0.25\%$  along a principle strain direction. This effect translates into anisotropic strain to the magnetoelastic thin film inducing a giant magnetoelastic effect driven by the induced magnetic anisotropy along the principle strain direction. We measured an effective converse magnetolectric coefficient  $\sim 1.4 \times 10^{-5}$  s/m when driven through the phase transition which was more than double the values obtained in the linear piezoelectric rhombohedral phase. The controllable and repeatable nature of the phase transition allows an interactive driving of the induced magnetization making the phenomenon attractive for application in spintronic devices.

**Recent Advances and Future Opportunities with Magnetic X-Ray Spectromicroscopies** Peter Fischer<sup>1,2</sup>; <sup>1</sup>Lawrence Berkeley National Lab, United States; <sup>2</sup>University of California, Santa Cruz, United States

Spin textures in magnetic materials, and polarization textures in multiferroic materials hold the key to understand and control properties and behavior, that offer tremendous potential for novel applications in future information processing technologies with significant improvements in energy efficiency, processing speed, functionalities, and miniaturization of future microelectronic devices.

An emerging research field in nanomagnetism is the scientific and technological exploration of 3-dimensional magnetic nanostructures that opens the path to exciting novel physical phenomena, originating from the increased complexity in spin textures, topology, frustration, and tailored geometries in three dimensions. This has attracted significant scientific interest and led to intense research addressing a broad spectrum, including stability, dynamics, nucleation, and transport in novel spin textures, such as vortices, skyrmions, chiral bobbbers, hopfions, torons, skyrmion tubes, etc. [1]. Analogous structures are also found in multiferroic (polar) materials, such as polar vortices [2], skyrmions [3] and hopfions [4].

Advanced characterization tools that provide magnetic sensitivity to spin textures, disentangling the role of individual components in heterogeneous material at high spatial resolution, ultimately at buried interfaces and in all three dimensions [5], and at high temporal resolution to capture the spin dynamics across scales, are required to address those questions, and are therefore of large scientific interest.

Various magnetic soft X-ray spectro-microscopies [6] using polarized soft x-rays provide unique characterization opportunities to study the statics and dynamics of spin textures in magnetic materials combining X-ray magnetic circular dichroism (X-MCD) as element specific, quantifiable magnetic contrast mechanism with spatial and temporal resolutions down to fundamental magnetic length, time, and energy scales.

Current developments of x-ray sources aim to increase dramatically the coherence of x-rays opening the path to new techniques, x-ray photo-correlation spectroscopy (XPCS) [7] that allow unprecedented studies of nanoscale heterogeneity, complexity, and fluctuations.

I will review recent achievements and future opportunities with magnetic x-ray spectro-microscopies. Examples will address static properties and dynamic behavior of magnetic hopfions [8] and a 3D metrology of skyrmions using soft x-ray laminography [9].

**Imaging Magnetic Skyrmions and Perpendicular Domains under Voltage Control in Metallic Multilayers and 2D Materials.** Massimo Ghidini<sup>1,2,3</sup>; <sup>1</sup>University of Parma, Italy; <sup>2</sup>Diamond Light Source, United Kingdom; <sup>3</sup>University of Cambridge, United Kingdom

X-ray Photoemission electron microscopy and Magnetic Force Microscopy permit to image strain-coupled ferroelectric and ferromagnetic domains with submicron spatial resolution, thus revealing novel magnetoelectric effects in multiferroic heterostructures.

Here, we employ these complementary techniques to demonstrate voltage manipulation of skyrmions and perpendicular domains in magnetic multilayers and 2D materials overlying PMN-PT ferroelectric substrates. The resulting local magnetoelectric effects include transition from worm-like to skyrmion states, stripe domain displacement, nucleation/annihilation of isolated skyrmions and local magnetisation reversals.

**Enhancement of Spin-Orbit Torque in Pt/Co/HfO<sub>x</sub> Heterostructures with Voltage-Controlled Oxygen Ion Migration** Shuo Wu, Tianli Jin, Funan Tan, Ching Ian Ang, Gerard Joseph Lim and Wensiang Lew; Nanyang Technological University, Singapore

Spin-orbit torque (SOT) induced magnetization switching and SOT modulation have been intensely pursued and developed in recent years for efficient spintronic devices. Research has shown that the magnetic anisotropy of ferromagnet (FM) layers can be modified via inducing surface charges or orbital occupancy by interfacing with an oxide layer. Moreover, voltage-controlled oxygen migration can reduce the energy barrier for magnetization switching. The electric-field-driven interfacial oxygen mobility can affect both the SOT strength and sign. However, more research on the oxidation effects at the interfaces of the voltage-controlled magnetism in FM/oxide systems needs to be investigated. In this work, we report the enhancement of damping-like field and SOT efficiency of up to 60% and 23%, respectively, in perpendicularly magnetized Pt/Co/HfO<sub>x</sub> heterostructures over Pt/Co system at an optimal thickness of 2 nm HfO<sub>x</sub>. We further verify this enhanced SOT by applying voltages across the Pt/Co/HfO<sub>x</sub> structure, which allows the O<sup>2-</sup> migration from HfO<sub>x</sub> to the Co layer. By using voltage-controlled oxygen ion modulation of interfacial oxidation, we show that the gate voltage affects not only coercivity and anisotropy fields but also the SOT efficiency at room temperature. Our work promotes the SOT enhancement and modulation by oxidation effects for energy-efficient spintronic devices.

**Simulation of Magnetolectric Sensors in Inhomogeneous Magnetic Fields** Mohsen Samadi, Julius Schmalz, Mesut-Ömür Özden, Giuseppe Barbieri and Martina Gerken; Kiel University, Germany

Thin-film magnetolectric (ME) sensors have the potential for room-temperature, magnetic-shielding-free measurement of a variety of biomagnetic fields from magnetocardiography over deep-brain stimulation signals (DBS) to magnetomyography [1, 2]. Approaches for modelling and simulation of the behavior of different types of magnetolectric sensors are discussed. Besides the standard excitation with homogeneous magnetic fields, inhomogeneous magnetic-field excitation is considered as found in biomedical applications.

As a first sensor type, cantilever sensors based on strain-coupled thin-film magnetostrictive and piezoelectric layers and their response to inhomogeneous magnetic fields are reviewed [3]. A linear material model is used to calculate the small-signal behavior of sensors at the working point. The elastic, magnetic and electric properties are included in a coupled finite-element-method (FEM) simulation. Second, the magnetic-field response of electrically-modulated magnetolectric cantilever sensors is investigated [4]. These sensors are electrically excited and operate in a mechanical mode with bending in the short cantilever direction (U-mode). They exhibit a high-quality factor and a promising limit of detection in the pico-Tesla range. It is demonstrated that for specific sensor dimensions and clamping structures a homogeneous response is obtained across the sensor. As a third sensor type, surface-acoustic-wave (SAW) magnetic-field sensors are considered. Our previous results [5] are extended to include microstructuring of the delay line to realize phononic crystals. It has been shown that resonances appear due to the acoustic-crystal structure [6, 7] and here their suitability to magnetic-field sensing is investigated. For all three types of sensors FEM simulation models and results are discussed.

In the next part of the talk, a multiscale simulation approach is introduced for a full system simulation including magnetolectric sensors, a human head model and electric-dipole excitation to model deep-brain stimulation (DBS). Due to the thin layers in the sensor structure as well as the intricate structure of the brain with different types of tissues this is a highly challenging task. The head model is implemented based on MRI data [8]. Since mesh management is crucial for successfully running simulations, the three-dimensional model is extrapolated and morphological operations are used for filtering and smoothing. The trade-off between surface idealness and performance needs to be considered. The complexity is increased stepwise by starting with a simple three-shell model and proceeding to an increasing number of compartments and more detail. With the multiscale model we calculate electromagnetic field propagation through the head and the magnetolectric sensor response. The combined calculations allow for the investigation of field concentration effects and inhomogeneous sensor excitation in a realistic geometry, secondary-source effects due to conductivity, as well as field effects in the human head caused by the sensor system.

**Negligible Magnetic Losses at Low Temperatures in Liquid Phase Epitaxy Grown  $Y_3Fe_5O_{12}$  Films** Alexandria Will-Cole<sup>1</sup>, James L. Hart<sup>2</sup>, Valeria Lauter<sup>3</sup>, Alexander Grutter<sup>4</sup>, Carsten Dubs<sup>5</sup>, Morris Lindner<sup>5</sup>, Timmy Reimann<sup>5</sup>, Nichole Valdez<sup>1</sup>, Charles Pearce<sup>1</sup>, Todd Monson<sup>1</sup>, Judy Cha<sup>2</sup>, Don Heiman<sup>6,7</sup>, Nian Sun<sup>6</sup> and Bin Luo<sup>6</sup>; <sup>1</sup>Sandia National Laboratories, United States; <sup>2</sup>Cornell University, United States; <sup>3</sup>Oak Ridge National Laboratory, United States; <sup>4</sup>National Institute of Standards and Technology, United States; <sup>5</sup>Innovent E.V. Technologieentwicklung, Germany; <sup>6</sup>Northeastern University, United States; <sup>7</sup>Massachusetts Institute of Technology, United States

Yttrium iron garnet ( $Y_3Fe_5O_{12}$ , YIG) has a unique combination of low magnetic damping, high spin wave conductivity, and insulating properties that make it a highly attractive material for a variety of applications in the fields of magnetics and spintronics. While the room temperature magnetization dynamics of YIG have been extensively studied, there are limited reports correlating the low temperature magnetization dynamics to the material structure or growth method. Here we investigate liquid phase epitaxy grown YIG films and their magnetization dynamics at temperatures down to 10 K. We show there is negligible increase in the ferromagnetic resonance linewidth down to 10 K which is unique when compared with YIG films grown by other deposition methods. From the broadband ferromagnetic resonance measurements, polarized neutron reflectivity, and scanning transmission electron microscopy, we conclude that these liquid phase epitaxy grown films contain negligible rare-earth impurities present, specifically the suppression of Gd-diffusion from the  $Gd_3Ga_5O_{12}$  substrate into the  $Y_3Fe_5O_{12}$  film, and therefore consequently insignificant magnetic losses attributed to the slow relaxation mechanism. Overall, liquid phase epitaxy YIG films have a YIG/GGG interface that is 5 times sharper and has 10 times lower ferromagnetic resonance linewidths below 50 K than comparable YIG films produced by other deposition methods. Thus, YIG films grown by liquid phase epitaxy are ideal for low temperature experiments/applications that require low magnetic losses, such as quantum transduction and manipulation via magnon coupling. SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

SESSION EL13.10: Magnetolectric Sensors and Actuators III

**8:30 AM \*EL13.10.01****Ferroics, Multiferroics and Magnetolectrics: Reconsidering New Paths to Large Transduction, Ultra-Low Power Sensors and Giant Energy Conversion** Peter Finkel, Margo Staruch, Thomas R. Mion and Konrad Bussmann; Naval Research Laboratory, United States

The ability to tune both magnetic and electric properties concomitantly in magnetolectric (ME) composite heterostructures, consisting of magnetostrictive and piezoelectric phases coupled through strain with orders-of-magnitude larger ME coupling coefficient than single-phase multiferroics due to additional functionalities and makes them very promising in many applications and devices [1,2]. This has generated a revived interest in multiferroics, and is projected to play a critical role in next-generation applications ranging from transducers, tunable inductors, gyrators, magnetic sensors to high-frequency filters and communication devices. In this talk we highlight different approaches to achieve maximum ME coupling in heterostructures of magnetostrictive films deposited on domain-engineered relaxor ferroelectric single crystals. Much work has been done over the past decade to maximize the magnetolectric (ME) coupling coefficient,  $\alpha_{ME}$ , the figure of merit for these composites that can be enhanced through deliberate choice of materials as well as carefully controlling the interface. For the piezoelectric phase, relaxor ferroelectrics have attracted much attention recently due to a piezoelectric coefficient an order of magnitude larger than conventional lead zirconate-titanate [3] especially in proximity to morphotropic phase boundary. In the ME heterostructures we demonstrated that by exploiting the large ferroelectric phase transitional strain in piezoelectric substrate, the converse magnetolectric coupling coefficient is expected to be greatly up to 4x enhanced as compared to linear piezoelectricity [4,5]. In this presentation, the impact of this enhancement will be examined and a path for utilization of this phenomenon in ME composites will be discussed. Magnetolectric (ME) resonators are of significant interest for next generation near-dc magnetic field sensors, as the direct coupling of highly magnetostrictive (FeCo- or FeGa-based alloys) and piezoelectric phases (AlN) enables high magnetic field sub-nT sensitivity with exceptionally low operational power requirements. This talk highlights several programs within the Materials Science & Technology Division at US Naval Research Laboratory focused on the investigation and understanding physics of these ferroic and multiferroic materials, and how current research presents another opportunity to advance acoustic transduction devices, magnetic sensors and electrically small antennas.

**9:00 AM EL13.10.02****Voltage Control of Exchange Coupling: A Novel Way to Switch MRAM Devices** Bhagwati Prasad<sup>1</sup>, Akash Surampalli<sup>1</sup>, Rajesh V. Chopdekar<sup>2</sup>, Alan Kalitsov<sup>2</sup>, Lei Wan<sup>2</sup>, Jordan Katine<sup>2</sup>, Derek Stewart<sup>2</sup> and Tiffany Santos<sup>2</sup>; <sup>1</sup>Indian Institute of Science, India; <sup>2</sup>Western Digital Corporation, United States

Traditional memory devices based on spintronics leverage electric current to ingeniously regulate the direction and movement of electrons' spin, albeit at the expense of high energy consumption and limited device durability [1, 2]. As a result, with the increasing demand for faster, smaller, and extremely energy-efficient electronic devices, the pursuit of magnetism controlled by voltage has notably intensified. This field offers the potential to create ultra-low-power, non-volatile memory solutions for future computing systems [3, 4].

In this context, we present our latest research on magnetism controlled by voltage via voltage-controlled exchange coupling (VCEC) [5, 6]. To explore the control of exchange coupling through an electric field, we have fabricated magnetic heterostructures with varying thicknesses of Ru and Ir spacer layers. In these layered structures, two ferromagnets (free and reference layers) possessing perpendicular magnetic anisotropy are separated by a non-magnetic Ru and Ir spacer layer. This separation creates an oscillatory interlayer exchange coupling (IEC) as the Ru or Ir layer's thickness varies, as predicted by the RKKY theory.

To quantify the VCEC effect, a bias field is applied across the MgO layer, and resistance-magnetic field loops are measured while a DC bias voltage is in effect. This results in a visible gating effect in the minor loops of resistance-magnetic field plots, thus demonstrating the manipulation of exchange interactions between the free and reference layer via an applied electric field. In this way, we demonstrate modulation of the interlayer exchange coupling with the Ru and Ir spacer layers using non-ionic liquid gating such as MgO [6]. These findings provide a route for modifying the resistance states of spintronic devices, thereby paving the way for the creation of a new generation of energy-efficient computing devices.

**9:15 AM EL13.10.03****Proving the Suitability of Polymer-Based Magnetolectrics for Spintronic Applications** Pedro Martins<sup>1</sup>, Senentxu Lanceros-Mendez<sup>2</sup> and Rui Carvalho<sup>1</sup>; <sup>1</sup>Universidade do Minho, Portugal; <sup>2</sup>BCMaterials, Basque Center for Materials, Applications and Nanostructures, Spain

The rapid advancement of technology has generated significant requirements for electrical energy to power electronic devices. A pivotal aspect of this technological progress, for sensors, actuators, and memory devices, involves harnessing the spin of electrons in electronics, known as spintronics. However, a considerable portion of the electric power utilized in spintronics is dissipated as heat through the Joule effect (3–5% of the energy: thousands of millions of dollars annually). Consequently, there is a pressing need to explore novel approaches to develop energy-efficient devices, making it a prominent research topic within the realm of spintronics.

To address concerns regarding energy efficiency and the control of spin states, alternatives to the energy-consuming external magnetic field have been explored: the spin-polarized current injection. However, this approach still generates heat, negatively impacting the overall power efficiency of the device. In this scope, the utilization of applied voltages represents a promising strategy to reduce energy requirements. Materials with magnetolectric (ME) properties have emerged as leading contenders for future spintronic advancements, as their magnetization and ferromagnetism can be controlled by an electric field.

By incorporating an additional magnetolectric (ME) layer into the conventional three-layer spin-valve spintronic structure, it becomes possible to create

electrically tunable spintronic devices. This is achieved by exploiting the interface between the ME layer and the ferromagnetic-free layer. The introduction of this ME layer brings about a significant reduction in power consumption, estimated to be two orders of magnitude lower when compared to traditional devices.

In the broader context of the global technological landscape, which is witnessing the rapid and widespread implementation of revolutionary advancements such as Industry 4.0, the Internet of Things, and digitalization, the production of ME materials is facilitated by additive manufacturing tools. These tools not only enable the efficient manufacturing of ME materials but also ensure safety during the production process, productivity, reduced time requirements, miniaturization, and sustainability.

Among the different & available ME materials, polymer-based ME materials have been specifically selected to demonstrate their suitability for spintronic applications, due to their flexibility, high ME coupling, and printability, making them ideal for integration into spintronic devices. In particular, P(VDF-TrFE) (poly(vinylidene fluoride-trifluoroethylene)) has been selected as the piezoelectric matrix material due to its exceptional piezoelectric response, which is the highest among all polymers ( $d_{33} \approx 30$  pC/N). Three different types of magnetostrictive fillers were incorporated into the polymer matrix: CoFe<sub>2</sub>O<sub>4</sub> nanoparticles, Fe<sub>3</sub>O<sub>4</sub> nanoparticles, and NdFeB microparticles.

Results show that an AC electric field of 10 V/f  $\approx$  13 MHz applied on samples with 20 wt.% of magnetic filler produced magnetic fields of  $\approx$  8 Oe in all three composites, that correspond to converse ME coefficients of 4.1, 4.4, and 6.5 mG.cm.V<sup>-1</sup>, respectively for P(VDF-TrFE) composites with NdFeB, Fe<sub>3</sub>O<sub>4</sub> and CoFe<sub>2</sub>O<sub>4</sub> fillers. CoFe<sub>2</sub>O<sub>4</sub> fillers induced the highest converse ME coefficient due to their highest magnetostriction ( $\approx$ 250 ppm)

Such performance holds promise for spintronic (low field sensing and memory applications) once the generated magnetic fields are greater than the ones needed for recently reported spin-valve structures (0.4 Oe).

### 9:30 AM EL13.10.04

**2.87 GHz SAW Delay Lines for Efficient Spin Control of NV<sup>-</sup> Centers** Bin Luo<sup>1</sup>, Andreas Winkler<sup>2</sup>, Hagen Schmidt<sup>2</sup>, Benyamin Davaji<sup>1</sup>, Derek Bas<sup>3</sup>, Michael McConney<sup>3</sup>, Michael Page<sup>3</sup>, Beaver Nathaniel<sup>1</sup>, Paul Stevenson<sup>1</sup> and Nian Sun<sup>1</sup>; <sup>1</sup>Northeastern University, United States; <sup>2</sup>Leibniz Institute for Solid State and Materials Research, Germany; <sup>3</sup>Air Force Research Laboratory, United States

#### Motivation

Owing to long coherence time, high fidelity and easy optical initiation and readout of quantum states tuned by magnetic excitations over a broad temperature range, NV<sup>-</sup> centers are intriguing solid-state platforms for quantum computing, communication, information processing and sensitive non-invasive nanoscale magnetic sensors. The SAW delay line driven spin wave enabled by magnon-phonon interactions exhibits superior properties of high-power efficiency, low noise and small footprint, leading to efficient voltage control of NV<sup>-</sup> center and quantum transduction between hybrid quantum systems. In this work, we present a 2D finite element (FEM) model for a fabricated SAW delay line with S11 minima at 2.87 GHz and  $\sim -10$  dB insertion loss for NV center excitation. The consistency of S parameters between simulation and probing experiments makes the model prospective for SAW delay line design for chemical, biomedical, RF and quantum applications.

#### Methods

The transmission and receiving IDT Al electrodes with a fundamental mode of  $\sim 2.87$  GHz were patterned on bulk LiNbO<sub>3</sub> substrate via laser lithography, e-beam lithography, e-beam metal evaporation and lift-off technique. The S parameters were measured by RF probes connected to a vector network analyzer. A 1:1 2D finite element model was built in COMSOL Multiphysics. The electrostatic module was combined with solid mechanics module to simulate piezoelectrically induced Rayleigh wave excited by SAW delay line under different attenuation conditions.

#### Results

The fabricated SAW delay line shows a low insertion loss of  $\sim -10$  dB at 2.87 GHz, which is excellent to control the ground states of NV<sup>-</sup> centers. The simulated S parameters agree well with probe measurement. The displacement and electric field profile demonstrate a high transmission between IDT electrodes. The increased mechanical damping results in decreased Sxy magnitude and diminished modulation of the SAW resonance peak ("triple transit echo") caused by reflections between the IDTs near fundamental mode.

**Highly Cyclable Voltage Control of Magnetism in Cobalt Ferrite Nanopillars for Memory and Neuromorphic Applications** Muireann A. de hora<sup>1</sup>, Aliona Nicolenco<sup>2</sup>, Monalisha Peda<sup>3</sup>, Tuhin Maity<sup>4</sup>, Bonan Zhu<sup>5</sup>, Shinbuhm Lee<sup>6</sup>, Zhuotong Sun<sup>1</sup>, Jordi Sort<sup>3</sup> and Judith L. Driscoll<sup>1</sup>; <sup>1</sup>University of Cambridge, United Kingdom; <sup>2</sup>Cidtec, Spain; <sup>3</sup>Universitat Autònoma de Barcelona, Spain; <sup>4</sup>Indian Institute of Science Education and Research Thiruvananthapuram, India; <sup>5</sup>University College London, United Kingdom; <sup>6</sup>DGIST, Korea (the Republic of)

Research in digital memory is growing with the increase in popularity of artificial intelligence, machine learning, Internet of Things, and Big Data. This in turn has caused an energy demand that has triggered innovation towards non-volatile memory technologies that do not require continuous power supply. Magnetic memory is a promising non-volatile technology for storing data, but conventional magnetic memory concepts use electrical current to control magnetic properties (i.e. through electromagnets or spin-torque effects) and this can lead to significant energy loss by heat dissipation. On the other hand, tuning the properties of magnetic materials by voltage-driven ion migration (magneto-ionics) gives potential for energy-efficient, non-volatile magnetic memory and neuromorphic computing.

Our study shows large changes in both the magnetic moment at saturation ( $m_s$ ) and coercivity ( $H_c$ ), of 34% and 78%, respectively, in an array CoFe<sub>2</sub>O<sub>4</sub> (CFO) epitaxial nanopillar electrodes ( $\sim 50$  nm diameter,  $\sim 70$  nm pitch, and 90nm in height) with applied voltage of  $-10$  V in a liquid electrolyte cell. Furthermore, a magneto-ionic response faster than 3 s and endurance  $>2,000$  cycles are demonstrated. The response time is faster than for other magneto-ionic films of similar thickness, and cyclability is around two orders of magnitude higher than for other oxygen magneto-ionic systems. Using a range of characterisation techniques, the magnetic switching is shown to arise from modulation of oxygen content in the CFO. Also, the highly cyclable, self-assembled nanopillar structures were demonstrated to emulate various synaptic behaviours, exhibiting non-volatile, multilevel magnetic states for analog computing and high-density storage. Overall, CFO nanopillar arrays offer potential to be used as interconnected synapses for advanced neuromorphic computing applications.

### 10:00 AM EL13.10.06

**Imaging of Voltage-Controlled Switching of Magnetization in Highly Magnetostrictive Epitaxial Fe-Ga Microstructures on PMN-PT** Maite Goiriena<sup>1,2</sup>, Zhuyun Xiao<sup>3,4</sup>, Rachel Steinhardt<sup>5</sup>, Victor Estrada<sup>3</sup>, Nobumichi Tamura<sup>4</sup>, Rajesh V. Chopdekar<sup>4</sup>, Alfredo García-Arribas<sup>2</sup>, Abdón Sepúlveda<sup>3</sup>, Darrell Schlom<sup>5,5</sup>, Rob N. Candler<sup>3,6</sup> and Jeffrey Bokor<sup>1,4</sup>; <sup>1</sup>University of California, Berkeley, United States; <sup>2</sup>University of the Basque Country, Spain; <sup>3</sup>University of California, Los Angeles, United States; <sup>4</sup>Lawrence Berkeley National Laboratory, United States; <sup>5</sup>Cornell University, United States; <sup>6</sup>California NanoSystems Institute, United States

The magnetoelectric behavior of epitaxial Fe-Ga microstructures on top of (001)-oriented PMN-PT piezoelectric substrate is investigated under magnetic electron microscopy (XMCD-PEEM). Additionally, micron-scale strain distribution in PMN-PT is characterized by X-ray microdiffraction and examined

with respect to the results of the Fe-Ga magnetoelectric switching. The magnetic reorientation is found to be strongly correlated with the size, shape and crystallographic orientation of the microstructures. In the case of square-shaped structures, size dictates the degree of influence of the strain distribution on both the initialization of the ground state and on the dynamics of the magnetic reorientation during application of voltage. On the other hand, the case of the elliptical microstructures demonstrates the importance of the orientation of the long axis with respect to the crystallographic directions of the PMN-PT, which leads to completely different magnetic responses. This study demonstrates that engineering highly magnetostrictive epitaxial microdevices is possible. It further elucidates that voltage-induced actuation can be largely tuned to achieve the desired type of magnetic switching ranging from vortex circulation reversal, domain wall motion, to a large rotation of magnetization. Because of the outstanding properties of the investigated material system, the reported findings are expected to be of great interest for the realization of next-generation energy-efficient magnetic memory, sensing and actuation devices.

**10:15 AM EL13.10.07**

**Hidden Order in Cr<sub>2</sub>O<sub>3</sub> and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> as a Predictor for (anti-)Magnetoelectricity** Xanthe H. Verbeek, Andrea Urru and Nicola Spaldin; ETH Zürich, Switzerland

With first-principles calculations of Cr<sub>2</sub>O<sub>3</sub> and its iron-based analog,  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, we show that the different magnetoelectric effects in these materials result from the ordering of hidden magnetic multipoles [1]. Starting from the established connection between ferroically-ordered magnetic quadrupoles and the linear magnetoelectric effect in Cr<sub>2</sub>O<sub>3</sub>, we explore the presence of additional multipoles. We reveal for the first time anti-ferroically ordered magnetic multipoles in both Cr<sub>2</sub>O<sub>3</sub>, and isostructural  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, in which the global inversion symmetry is preserved by the different magnetic dipolar ordering. Using symmetry considerations, we can relate each of these multipoles and their ordering to linear, quadratic, and cubic (anti-) magnetoelectric effects, where in an anti-magnetoelectric effect the induced moments are ordered antiferromagnetically in the unit cell. We confirm the predicted induced moments using first-principles calculations, showing the lowest response in  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, a centrosymmetric magnetic material, to be a linear anti-magnetoelectric effect, revealing the presence of the magnetoelectric coupling despite the preserved global inversion symmetry. Our results demonstrate the existence of hidden magnetic multipoles leading to local linear magnetoelectric responses, even in centrosymmetric magnetic materials, and broaden the definition of magnetoelectric materials by including those showing such local magnetoelectric responses.

**10:15 AM \*EL11.04/EL14.06.01**

**New Developments in Transfer-Doped and Accumulation Channel Diamond Electronic Devices** [David A. Moran](#); University of Glasgow, United Kingdom

Transfer-doping of diamond has proven to be an attractive alternative to substitutional doping of diamond for the production of high-performance diamond electronic devices, such as Field Effect Transistors. The process, which relies in a low/negative electron affinity chemical termination of the diamond surface e.g. with hydrogen, combined with the application of a surface electron acceptor material of sufficiently high electron affinity, generates a high carrier density, shallow, sub-surface 2D hole gas that may be exploited as a conductive channel in several device applications.

Significant progress has been made recently in the further development of transfer doping processes in diamond, virtually eliminating previous issues such as inherent temperature and atmospheric sensitivity and associated instability. Through engineering of surface acceptor materials, charge mobility in the diamond has also seen significant improvement, leading to significant reduction in material resistivity. Alternative chemical surface terminations of diamond have also more recently demonstrated additional routes for the production of high performance electronic devices.

This presentation will attempt to provide an overview of these recent and exciting developments in the diamond electronic devices, and speculate on future directions and the potential impact of this accelerating area of research.

**10:45 AM EL11.04/EL14.06.02**

**MOSFETs on (111) Highly Oriented Polycrystalline 1-Inch Diamond Substrate** [Yukihiko Chou](#)<sup>1</sup>, Fuga Asai<sup>1</sup>, Kosuke Ota<sup>1</sup>, Atsushi Hiraiwa<sup>1</sup>, Yoshiaki Nishibayashi<sup>2</sup> and Hiroshi Kawarada<sup>1,1</sup>; <sup>1</sup>Waseda University, Japan; <sup>2</sup>Sumitomo Electric Industries, Ltd., Japan

We fabricated 2DHG diamond MOSFETs on a (111) highly oriented polycrystalline 1-inch diamond substrate and confirmed that the devices correctly functioned as a FET. The area of the 1-inch substrate is about 55 times larger than that of conventional 3mm square substrate. In this work, we fabricated 220 devices on the 1-inch diamond substrate, and the yield rate was about 95 percent. We found that the yield rate on the 1inch substrate tends to be much higher than that on the 3mm square substrate.

Diamond has outstanding characteristics as a semiconductor, such as wide band gap (5.5 eV), high thermal conductivity (22 W/cmK), and high breakdown field (10 MV/cm). Therefore, diamond is expected to be applied to the next generation's RF amplifier and power device. However, a problem in fabricating diamond devices is the low yield rate due to the small substrate size. In this work, we fabricated 2DHG diamond MOSFETs on the polycrystalline 1-inch diamond substrate, and we found that the yield rate was greatly improved.

The highly oriented (111) polycrystalline substrate was fabricated by Sumitomo Electric Industries, Ltd. All the devices on the 1-inch substrate are double-finger structure. Firstly, source and drain electrodes were deposited Ti/Pt/Au (20 nm/ 30 nm/ 90 nm). After H-termination and isolation, 200 nm of Al<sub>2</sub>O<sub>3</sub> was deposited as the gate insulator. After that, 300 nm of Al was deposited as the gate electrode. 80 percent of all the devices have the gate length L<sub>G</sub> = 5 μm and the others have L<sub>G</sub> = 2 μm. There are 3 kinds of source-drain length L<sub>SD</sub>, 10 μm, 15 μm, and 20 μm. Also, there are 3 kinds of total gate width W<sub>GT</sub>, 1 mm, 2 mm, and 3 mm.

The highest maximum drain current density was obtained from the device of L<sub>G</sub> = 2 μm, L<sub>SD</sub> = 10 μm, and W<sub>GT</sub> = 1 mm at V<sub>GS</sub> = -40 V and V<sub>DS</sub> = -40 V, and the result was 151 mA/mm. For all the devices that correctly functioned as a FET, the drain current density was in the range of 100 mA/mm to 150 mA/mm. The decrease in current density was observed as the gate width expanded, but it is assumed that the effect of the grain boundary on the devices is not serious. About 95 percent of yield rate was achieved in this work, and the distribution of the devices that did not function were impartial on the 1-inch substrate. This is because, thanks to the substrate size, photoresists uniformly coated the whole substrate in the fabricating process.

In this work, we fabricated 2DHG diamond MOSFETs on a (111) highly oriented polycrystalline 1-inch diamond substrate and confirmed that the devices correctly functioned as a FET. The highest maximum drain current density was 151 mA/mm, and the yield rate of devices on the 1-inch substrate was greatly improved. Fabricating 2DHG diamond MOSFETs on polycrystalline 1-inch diamond substrate is possible and it contributes to the yield rate improvement.

**11:00 AM DISCUSSION TIME**

**11:00 AM EL11.04/EL14.06.05**

**High Quality Al<sub>2</sub>O<sub>3</sub>/(111) (OH)-Terminated Diamond Interface for MOSFETs Fabrication** [Pietro Argenton](#)<sup>1</sup>, Martin Kah<sup>1</sup>, Marine Couret<sup>2</sup>, Nicolas Rouger<sup>2</sup>, David Eon<sup>1</sup> and Julien Pernot<sup>1</sup>; <sup>1</sup>University Grenoble Alpes, CNRS, Grenoble INP, Institut Néel, France; <sup>2</sup>Université de Toulouse, LAPLACE, CNRS, INPT, France

The efficiency of power devices is critical nowadays for the rise of renewable energy. Wide-bandgap semiconductors, such as silicon carbide (SiC) and gallium nitride (GaN), have advantages over silicon due to their high breakdown electric field and high-temperature operation. However, p-channel wide-bandgap FETs have poor performance compared with their n-channel counterparts due to low hole mobility, which leads to a high ON resistance and high conduction loss. This has constrained the production of complementary circuits with integrated n-channel and p-channel transistors. Diamond is a wide-bandgap material that has a bulk intrinsic hole mobility very high respectively to SiC and GaN, which makes it promising for use in high-mobility p-channel transistors. Due to the high optical phonon frequency and high acoustic phonon velocity of diamond, the number of phonons that participate in carrier scattering is small. Having all the others wide band gap semiconductors characteristics like high electric field, high breakdown voltage and high thermal conductivity also makes diamond attractive for power applications.

Most diamond power metal-oxide-semiconductor field-effect transistors (MOSFETs) have been fabricated using H-terminated diamond surfaces (and afterwards the surface transfer doping) with their unique properties of two-dimensional hole gas (2DHG). The downside of this concept comes from the close proximity of the negatively charged surface acceptors with the 2DHG, the carrier mobility is limited by surface impurities, and increasing the carrier concentration dramatically decreases the hole mobility. Moreover, the negative charges cause a positive shift in the threshold voltage, leading to normally ON characteristics.

In this work we try to find an alternative by realizing p-type OH-terminated diamond surface, taking advantage of the fact that applying a negative potential to a MOS stack leads to an accumulation regime of holes on the diamond surface. However, this happens only if the Fermi level is not pinned due to interface states. Therefore, a good interface quality between diamond and oxide is needed. We realized a p-type diamond with a boron concentration approximately 10<sup>17</sup> atom/cm<sup>3</sup> and a thickness of 0.5 μm on (111) EDP substrate followed by a OH-termination using a wet vapour annealing<sup>[1]</sup>. We have then realized some metal-oxide-semiconductor capacitors (MOSCAP) on top of it and studied their behaviour.

The frequency-dependent capacitance-voltage (C-V) characteristics were examined from depletion to accumulation regimes. The latter one was clearly observed with a very small leakage current. Moreover, we reached accumulation regime around 0V which can lead to a realization of a MOSFET with

normally OFF characteristics with very high current in ON state, thanks to the 2DHG. With these promising results, we finally fabricate MOSFETs using the same procedure as MOSCAPs.

In the first part of this presentation, the method will be described in details. Then, the C-V characteristics will be reported and deeply analysed. Lastly, we will show and discuss the first results obtained regarding the MOSFETs and comparing them with finite element simulation as well.

**Normally-Off Hydrogen-Terminated Diamond FET with High Temperature ALD Grown HfO<sub>2</sub>** Devansh Saraswat, Mohamadali Malakoutian, Kelly Woo and Srabanti Chowdhury; Stanford University, United States

Diamond is one of the best candidates for high-power, high-frequency applications due to desirable properties like high breakdown electric field (10 MV/cm), high carrier mobility (3800 cm<sup>2</sup> V<sup>-1</sup>s<sup>-1</sup> for holes and 4500 cm<sup>2</sup> V<sup>-1</sup>s<sup>-1</sup> for electrons) and high saturation velocity (>10<sup>7</sup> cm/s) [1].

Due to the difficulty in doping by conventional methods, the two-dimensional hole gas (2DHG) layer below the hydrogen-terminated diamond surface has been widely explored for fabricating field effect transistors. Prior studies have reported sheet density in the range of 10<sup>12</sup>-10<sup>14</sup> cm<sup>-2</sup> [2] and mobility of 50-200 cm<sup>2</sup> V<sup>-1</sup>s<sup>-1</sup> [3] for the 2DHG, including integrated CMOS operation at high temperatures[4]. For FET fabrication, it is essential to choose a dielectric that can minimize the gate leakage current as well as preserve the 2DHG in the channel. Various dielectrics such as Al<sub>2</sub>O<sub>3</sub>, ZrO<sub>2</sub>, AlN and MoO<sub>3</sub> have been used as a gate dielectric for diamond HFETs. HfO<sub>2</sub> is a widely used high-k dielectric material due its superior dielectric properties, high breakdown field and large band offsets ( $\Delta E_c=2.29$  eV and  $\Delta E_v=1.98$  eV) with respect to H-terminated diamond [5]. In this work, Al<sub>2</sub>O<sub>3</sub> and HfO<sub>2</sub> were compared as gate dielectric for HFETs. Normally off operation with two orders of higher current was achieved with high-temperature atomic layer deposition (ALD) grown HfO<sub>2</sub> in comparison with Al<sub>2</sub>O<sub>3</sub> counterpart, as the gate dielectric.

For device fabrication, a (100) CVD-grown diamond substrate was used. The sample was first oxygen terminated by boiling in a 3:1 mixture of H<sub>2</sub>SO<sub>4</sub> and HNO<sub>3</sub> at 200°C for 30 minutes. Then, hydrogen termination was performed in a microwave plasma CVD reactor at 850°C. This was followed by photolithography and oxygen plasma treatment for device isolation. Then, Ti/Pt/Au adhesion pads were deposited using e-beam evaporation. This was followed by gold deposition on hydrogen terminated regions to form the source and drain ohmic contacts. Subsequently, a 10 nm thick HfO<sub>2</sub> layer was deposited at 300°C using ALD. Then, Al/Au gate metal contact with a gate length (L<sub>G</sub>) of 1.5 μm was formed. The gate to drain distance (L<sub>GD</sub>) varied from 1.75 μm to 3.25 μm. Finally, source and drain contacts were opened using a 6:1 buffered oxide etchant (BOE) wet etch.

After device fabrication, DC output characteristics were measured using a probe station. A maximum drain output current of 2.05 mA/mm was achieved for a V<sub>GS</sub>=-4V. Gate leakage current ≤ 10<sup>-6</sup> mA/mm and a current on/off ratio of 10<sup>7</sup> were measured. A maximum transconductance (g<sub>m</sub>) of 2.06 mS/mm was obtained at V<sub>GS</sub>=-2V. The threshold voltage was determined to be -1.2V, indicating a normally-off performance. In contrast, our Al<sub>2</sub>O<sub>3</sub>-based FETs showed poor performance which requires further investigation.

The normally-off behavior in this device is likely due to the decrease in the upward band bending at the H-diamond surface. This is possibly a result of the desorption of acceptor species during the high-temperature ALD growth. Dielectrics grown at high temperatures are thermally more stable, making the device suitable for high-temperature applications. Further improvement in the device performance can be possible by exposing the substrate to a NO<sub>2</sub> gas environment and by using multiple dielectric layer stacks to improve the channel mobility. The current results show the potential of using high-temperature ALD grown HfO<sub>2</sub> for achieving normally-off behavior in diamond HFETs[6].

**Two-Inch High Quality Diamond Heteroepitaxial Growth on Sapphire** Seong-Woo Kim; Orbray Co, Ltd, Japan

Diamond semiconductors, owing to their superior properties compared to SiC and GaN, can be used to develop high-end applications, such as power devices, high frequency devices, quantum devices, and sensors. However, the inch-scaled diamond wafer is essential. In this study, Two-inch-diameter high-quality diamond (001) layers were grown on sapphire (11-20) A-plane misoriented substrate. Step-flow growth in diamond is realized thanks to misoriented substrate, and releases tensile strain in diamond layer. Consequently, even if microneedle technique<sup>[1]</sup> is not used, without breakage, diamond layer naturally was delaminated from the sapphire substrate. The FWHM of (004) and (311) X-ray rocking curves of the diamond layer grown on sapphire substrate misoriented by 7° towards [1-100] direction were 75 and 140 arcsec, respectively, the lowest ever.

In this study, results on 3 types of high-end applications will be discussed. One of them is the world largest diamond detector with the dimensions of 20 mm ' 20 mm ' 0.5 mm was fabricated from a 30 mm ' 30 mm heteroepitaxial diamond wafer. The device demonstrated a nuclide discrimination capability for <sup>133</sup>Ba, <sup>137</sup>Cs and <sup>60</sup>Co based on the pulse-height difference. The electrode was used as a cathode to apply -500 V bias voltage. The anode on another side was connected to a charge sensitive preamplifier. The anode was maintained at ground potential. The output signal from the preamplifier was acquired with a digitizer. A digital trapezoidal filter was applied to the waveforms to obtain pulse height spectra.

**Wide Bandgap Material Transfer as a Flagship Technology for Future High Power Devices** Julie Widiez, Guillaume Gelineau, Jérémie Chrétien, Cédric Masante, Alexandre Moulin, Vladimir Prudkovskiy, Nicolas Troutot, Emmanuel Rolland, Patrice Gergaud, Denis Mariolle, Sophie Barbet, Lucie Corbin, Vincent Amalbert, Pierrick Gilles, Frédéric Milesi, Frédéric Mazen and Lucie Le Van-Jodin; CEA-LETI, France

Today's environmental requirements for energy efficiency call for better management of electrical energy with minimum leakage at all levels: from DC phone chargers to power transmission via electrical vehicles. Wide bandgap (WBG) semiconductors are better suited for high-voltage and low-loss power devices than traditional Si-based power devices. The most commonly used are SiC, GaN and diamond with bandgap values of 3.2 eV, 3.4 eV and 5.5 eV respectively. However, the challenge of producing these competitive materials economically and efficiently remains. For example, the fabrication of SiC substrates is very energy-intensive, since it is carried out at 2400°C, i.e. 1000°C higher than for Si. To cite another example, the size of diamond substrates today is no more than a few square millimeters, while 300 mm Si wafers are on the market, limiting the appeal of such a material.

The ability to transfer only a thin layer of high-quality WBG material on a substrate that offers either the advantage of being less expensive or the advantage of its own function (thermal, electrical or insulating...) is therefore very interesting. The Smart Cut™ process combines an ion implantation with a bonding step and allows to create a structure that otherwise could not be made using deposition techniques. Relatively new direct covalent bonding techniques now make it possible to relax the draconian characteristics imposed on surfaces and substrates to enable such bonding with materials renowned for their outstanding properties. This opens up new possibilities in terms of assembly.

Significant improvements in electrical performance have been achieved by combining the advantages of a polycrystalline substrate with very low resistivity and a high-quality 4H-SiC transferred layer [1, 2]. However, the H<sup>+</sup> ion implantation used for the Smart Cut™ process leads to electrical deactivation and partially disorders the material. We report studies of healing and reactivation mechanisms of a transferred 4H-SiC thin film over a wide range of temperatures. After 950°C (splitting temperature), the thin SiC layer is still insulating. A 1300°C anneal allows the material to fully relax and reorganize with no further evolution beyond this temperature. The dopant reactivation takes place at higher thermal budgets. The transferred layer then recovers the donor doping level and electrical conductivity after 1700°C [3].

We also develop the transfer of IIa diamond onto larger and less expensive substrates [4]. The two key technological steps of the Smart Cut™ process (ion implantation and bonding) are studied:

A simplified process using a single ion implantation step at high temperature has been developed [5]. The diamond material after such implantation is studied in terms of sp<sup>2</sup>/sp<sup>3</sup> ratio (XPS), hydrogen concentration (SIMS) and exfoliation capability.

A wide range of bonding conditions are studied: direct bonding (manual, Surface Activated Bonding - SAB -), metal bonding (Ti, Au...) with a special care on bonding parameters (the flatness, the coefficient of thermal expansion and the roughness values). This part is particularly difficult because of the remarkable properties of diamond: its low coefficient of thermal expansion and its hardness make surface preparation and adhesion very challenging.

**Low-Temperature Direct Bonding of Diamond—Approach for Fabricating Low-Thermal-Resistance Widegap Devices** Naoteru Shigekawa<sup>1</sup>, Ryo Kagawa<sup>1</sup>, Jianbo Liang<sup>1</sup>, Yasuo Shimizu<sup>2</sup>, Yutaka Ohno<sup>2</sup> and Yasuyoshi Nagai<sup>2</sup>; <sup>1</sup>Osaka Metropolitan University, Japan; <sup>2</sup>Tohoku University, Japan

Characteristics of semiconductor electron devices such as output powers are limited by their temperature rise due to Joule heating in operation (self-heating effects). Device structures with the lowest thermal resistance are, consequently, one of the most important topics in R&D for advanced devices, especially for devices with widegap semiconductors that handle high output powers with high frequencies. Diamond is assumed to be the ideal material as heat spreader because of its high thermal conductivity and excellent electrical properties. In this presentation, we describe results that we obtained by directly bonding of diamond to Si and GaN and discuss the future prospective of direct bonding of diamond. We used surface activated bonding (SAB) technologies, in which two wafers are bonded after removing native oxides on their surfaces by irradiating them with fast atom beams of Ar (surface activation process). In SAB, bonding process is completed without heating bonded wafers in most cases, i.e., junctions of semiconductors with different coefficients of thermal expansion (CTE) can be fabricated.

We bonded a high-pressure high-temperature (HPHT) diamond (001) wafer and a Si (100) wafer using SAB. We found that the diamond//Si junction withstood a 1000-°C annealing in spite of a large difference in CTEs between diamond and Si. A high-resolution TEM observation revealed that a polycrystalline SiC intermediate layer was formed at the bonding interface after the annealing, which was assumed to play a role of reducing impacts of the difference in CTEs.

We prepared a GaN//diamond junction by bonding a GaN (0001) surface grown on Si (111) wafer to a diamond (001) wafer and removing the Si (111) wafer for the growth of nitride. We annealed the GaN//diamond junctions at temperatures up to 1000 °C and found that the junctions were also tolerant against such a high-temperature annealing.

Recently we transferred an AlGaIn/GaN epi layer to diamond using SAB and subsequently fabricated HEMTs. Ohmic contacts on nitride were formed by an annealing at 800-°C after bonding to diamond. The temperature rise of the GaN-on-diamond HEMTs was found to be lower than that of on-Si HEMTs with the same nitride structure. The results imply that direct bonding of diamond is promising for fabricating low-thermal-resistance semiconductor devices, especially after transferring active device layers to diamond wafers.

Diamond has unique material properties well suited for a broad range of quantum and electronic technologies. However, heterogeneous integration of

diamond with other materials remains a challenge, mainly due to limited heteroepitaxial growth of single-crystal diamond. Here, we discuss a directly bonded single-crystal diamond membrane technique that enables a wide variety of materials integration, including bonding diamond to silicon, fused silica, sapphire, thermal oxides, and lithium niobate. Our direct bonding process combines diamond overgrowth, membrane transfer, and dry surface functionalization, resulting in minimal contamination for high yield and scalable integration. We have demonstrated direct-bonded diamond membranes with thicknesses as thin as 10 nm, and observe a sub-nanometer interfacial region. We demonstrate the use case for integrating these direct-bonded membranes for high-quality nano-photonics, and total internal reflection fluorescence (TIRF) microscopy applications. The demonstrated process provides a key advance in the necessary toolkit needed to realize heterogeneous diamond-based hybrid systems for quantum and electronic technologies.

**Diamond Integration on GaN HEMTs: Overcoming the Challenges for Device-Level Thermal Management** Mohamadali Malakoutian, Rohith Soman, Kelly Woo, Anna Kasperovich, Jeongkyu Kim and Srabanti Chowdhury; Stanford University, United States

In the realm of higher frequency devices, where the gain is of utmost importance, the effective management of heat becomes crucial to maintain Power Added Efficiency (PAE) [1]. Ensuring efficient heat removal necessitates minimizing the thermal boundary resistance (*TBR*) between the heat source and the heat spreader, as well as establishing a low thermal resistance path to the heat sink [2]. The integration of diamond near the hot spot holds excellent potential due to its exceptional thermal properties. By incorporating diamond, heat can be effectively spread, thereby enhancing the heat transfer coefficient [3, 4]. The integration of diamond onto GaN HEMTs poses significant challenges, regardless of whether a diamond-first or device-first approach is employed.

In the diamond-first approach, the primary challenge lies in diamond surface roughness, which imposes a limitation on gate length  $< 2 \mu\text{m}$  through lithography, non-uniformity in the diamond etching, and contacts/pads damage after diamond etching. To address this issue, we have implemented a polishing technique through ion-milling, achieving a surface smoothness of less than 10 nm RMS roughness before carrying out E-beam lithography, and developed a more selective etching process using  $\text{O}_2/\text{SF}_6$  mixture in RIE. Additionally, a slanted etching technique was developed for rough diamond surfaces that starts with a  $2 \mu\text{m}$  opening at the top and achieves a gate footprint of less than 100 nm, suitable for X- to W-band applications.

In the device-first approach, two key challenges arise: gate dielectric leakage (2-10 mA/mm) and ohmic loss ( $R_c=1.4 \Omega\cdot\text{mm}$ ,  $R_{sh}=250 \Omega/\square$ ). To overcome gate leakage, we have modified the gate metal stack from Au/Ni to Mo and employed a low-temperature (LT) diamond growth technique at 350-400°C [5], effectively reducing the leakage to  $< 1 \mu\text{A}/\text{mm}$ . As for ohmic loss, we have successfully tackled it by incorporating a thicker  $\text{N}^+$  regrown region and using a 400°C diamond growth temperature ( $R_c=0.24 \Omega\cdot\text{mm}$ ,  $R_{sh}=225 \Omega/\square$ ). These combined measures have proven to be effective solutions in mitigating gate dielectric leakage and reducing the ohmic loss for higher current capabilities  $\sim 1 \text{ A}/\text{mm}$ .

We have successfully integrated LT diamond on GaN HEMTs using the above-mentioned approaches. By implementing the all-around diamond scheme and connecting the top diamond to the heat sink through diamond vias, the channel thermal resistance ( $R_{th}$ ) was reduced by 34% from 6.9 to 4.6 K $\cdot\text{mm}/\text{W}$ , realizing a higher heat transfer coefficient from the channel. This integration resulted in no dispersion (pulsed I-V at 400 ns gate pulse) and lower channel temperature ( $T_{ch}$ ) compared to the case without diamond. With low *TBR* (3-5  $\text{m}^2\text{K}/\text{GW}$ ) and high thermal conductivity ( $TC$ :300-1000  $\text{W}/\text{m}/\text{K}$  depending on the grain size and thickness), the average and peak  $T_{ch}$  dropped by 35% (200 to 130°C at 25  $\text{W}/\text{mm}$ , measured by I-V thermometry) and over 50% (120°C at 20  $\text{W}/\text{mm}$ , measured by thermoreflectance imaging), respectively [6]. Our technique not only addresses thermal management challenges for GaN-based power amplifiers but is also compatible with other technologies such as InP,  $\text{Ga}_2\text{O}_3$ , SiC, and Si. Proper thermal management can enhance the device's reliability and lifetime while providing a higher power at higher frequencies.

**Diamond/Graphene (carbon  $\text{sp}^3\text{-sp}^2$ ) Heterojunctions for Neuromorphic Electronic Devices** Kenji Ueda; Waseda University, Japan

Diamond/graphene (carbon  $\text{sp}^3\text{-sp}^2$ ) interfaces have attracted much attention because they are sources of various interesting electronic phenomena. Many theorists suggest hybrid structures of diamond and graphene exhibit interesting electronic characters, however there are only limited experimental reports on electronic characters of carbon  $\text{sp}^3\text{-sp}^2$  interfaces.

Recently, we newly found that diamond/graphene heterojunctions became photo-controllable memristors (photomemristors), which are optically controllable memory-resistors with both photo-switching and memory functions [1, 2]. The junctions also showed characteristic response to optical pulses, and brain mimic memory functions, that is, change of photomemory time from shorter to longer memory time depending on irradiated numbers of optical pulses [3]. These behaviors are analogous to transitions from short to long-term memory states of biological synapses. In addition, arrays using the diamond/graphene junctions can function as special types of image sensors which have selective memory function of optical information depending on the relative importance of the data as human brains perform.

These results suggest the diamond/graphene ( $\text{C sp}^3\text{-sp}^2$ ) junctions are promising for fabricating novel neuromorphic visual information processing systems that are modulated by specific interests.

**Diamond Material Pave the way for the Next Generation of Neuronal Implants** Lionel Rousseau<sup>1</sup>, Emmanuel S. Scorsone<sup>2</sup>, Gaëlle Lissorgues<sup>1</sup>, Patrick Poulichet<sup>1</sup>, Olivier Français<sup>1</sup>, Blaise Yvert<sup>3</sup>, Clement Hebert<sup>3</sup>, Serge Picaud<sup>4</sup> and Julie Zhang<sup>4</sup>; <sup>1</sup>Université Gustave Eiffel - ESIEE Paris, ESYCOM UMR 9007, France; <sup>2</sup>Université Paris-Saclay, CEA, France; <sup>3</sup>GIN, France; <sup>4</sup>Sorbonne Université/ INSERM UMR\_S968/ CNRS UMR 7210, France

Brain Computer Interface (BCI) offers a way to restore neuronal dysfunction due to degenerative diseases or accidents. Thus, it becomes possible to restore vision with retinal implant or to offer a way for tetraplegic to control a robot by thinking with electrodes implanted in the cortex and recently to do a digital bridge for paraplegic patient to stand-up and walk. But today these systems are limited by their insufficient stability. Neuronal implants require to operation during 10 years of lifetime, and collect data 24/7 and for 10 hours or more every day. But after several months of implantation, some modification can appear such as swelling of the passivation polymers thus inducing current leakage, or degradation of the electrode material.

With the last development of diamond growth process, it is now possible to integrate this material in micro and nano fabrication process as a standard material to produce sensors or neuronal implants. Diamond properties are very attractive for medical application. Diamond is a biocompatible material and it has no native oxide, so there is no degradation when the structure is placed in water or harsh environment. Diamond is also a high density material, so there are no species that can migrate inside diamond. In addition, conductive diamond, boron doped diamond (BDD) has a wide electrochemistry window that allow to give possibility to inject more current compare to classical metallic electrode.

We have developed a specific process to achieve a very thin full diamond implant combine conductive diamond for the electrode and intrinsic diamond as protective layer. With this structure we take advantages and strength of conductive and intrinsic diamond to achieve an hermetic implant. To validate our full diamond implant, we have done electrical characterizations impedance Spectroscopy and Cyclic Voltammetry. In-vivo experiments have been conducted on several set-ups to record Visual Evoked Potential and Auditory Evoked Potential, assessing the proper functionality of our implants.

To demonstrate their stability, we developed an accelerate long life set-up. The devices placed on PBS solution at a temperature of 77°C. Follow Arrhenius law, at this temperature acceleration factor is around 16, that means for one month in solution, is equivalent to one year and 4 months. This set up is composed of hotplate, and aluminum piece where we placed a hermetic containers with Phosphate Bovine Solution (PBS) and samples. To control integrity of samples an impedance meter is used to record periodically impedance. This type of set-up is also answer at ethical issue and reduce number of animal experimentation.

With this ageing setup, we compared InterDigited Electrodes (IDE) composed of metallic IDE covered with either intrinsic diamond or polymer like SU8. After 29 weeks (around 9 years), diamond is more stable with a variation of 3 % at 1 kHz (frequency of interest for neurons recording), compared to SU8 with 50 % of variation.

Therefore, intrinsic and doped diamond are very attractive for the next generation of neuronal implants.

SESSION EL14.02: Superconductive Diamond Devices

**Superconducting Diamond Microwave Resonators** Georgina M. Klemencic, Jerome Cuenca, Thomas Brien, Soumen Mandal, Scott Manifold, Simon Doyle, Adrian Porch and Oliver A. Williams; Cardiff University, United Kingdom

Superconducting microwave resonators form the foundation of an increasing number of superconducting technologies for quantum information processing<sup>1</sup> and radiation detection.<sup>2</sup> A specific example is the Kinetic Inductance Detector (KID), which uses a high-Q resonator as a photon detector for purposes ranging from astronomy to security.<sup>3</sup>

In a KID, radiation is detected when an incoming photon breaks a Cooper pair which decreases the frequency of the microwave resonator. The relative size of this shift increases with the penetration depth of the material. Noise in the form of random fluctuations in the resonant frequency can occur due to two-level systems (TLSs), generally ascribed to dangling bonds in amorphous oxides that form at the surface of metallic superconductors. For practical applications, optimising for both sensitivity and signal-to-noise ratio, the superconducting material used for a microwave resonator should ideally have a high penetration depth and a low population of TLSs.

Here, I will present our results on a detailed characterisation of a  $\lambda/2$  microwave resonator with a fundamental frequency of 409 MHz at 300 mK patterned from boron-doped nanocrystalline diamond (BNCD).<sup>4</sup> We compare the observed resonant frequency to simulations based on the device geometry alone and show that the frequency is reduced by more than half, indicating a very large penetration depth enabled by the granularity of the material. I will also present early measurements of the effect of noise on this resonator and make a comparison to a single crystal equivalent device.

Our data show that BNCD is a good candidate for fabricating microwave resonators requiring a high kinetic inductance fraction. Knowledge of the penetration depth of a material is also vital for the design of low-frequency superconducting devices, including SQUIDS. Our results, therefore, pave the way for more complex superconducting circuits based on BNCD.

**Reduction of Etching Damage and SQUID Operation of Single-Crystalline Diamond Josephson Junctions by Ridge Conduction Structure** Yutaro

Hashimoto<sup>1</sup>, Chiyuki Wakabayashi<sup>1</sup>, Yasuhiro Takahashi<sup>1</sup>, Yoshihiko Takano<sup>2</sup>, Minoru Tachiki<sup>2</sup>, Shuuichi Ooi<sup>2</sup> and Hiroshi Kawarada<sup>1,3</sup>; <sup>1</sup>Waseda University, Japan; <sup>2</sup>National Institute for Materials Science, Japan; <sup>3</sup>The Kagami Memorial Research Institute for Materials Science and Technology, Japan

Josephson junctions (JJs) are weak junctions between two superconductors and have been applied to various devices such as transmon qubits and superconducting quantum interference devices (SQUIDs). SQUIDs are extremely sensitive magnetic sensors. Typical materials for JJs, such as Nb and Al, are weak against oxidation and abrasion. In contrast, superconducting boron (B)-doped diamond has high resistance to oxidation and abrasion. So, it is expected to be applied to robust and highly resistant to degradation superconducting devices.

The first SQUID using superconducting B-doped diamond was reported by S.Mandal[1]. This SQUID using nanocrystalline diamond consists of JJs with 250 nm to 100 nm linewidth weak links. The operating temperature was 400 mK at low magnetic field and 40 mK at high magnetic field, and the maximum voltage modulations ( $V_{p-p}$ ) to magnetic field, which is a parameter related to magnetic sensitivity, was 0.35  $\mu$ V. While the first SQUID using single-crystalline diamond was constructed by JJs with a step edge structure[2]. Operating temperature and  $V_{p-p}$  of up to 2.6K and 1.1  $\mu$ V were reported for this type SQUIDs. Single-crystalline superconducting diamonds have different superconducting transition temperatures  $T_c$  depending on the growth orientation[3]. (001) B--doped diamond with low  $T_c$  (<4.2 K) grows on the step with 230 nm slope 50° produced by etching and regrowth of un-doped diamond, and the discontinuity with the heavily boron doped ( $B: 8 \times 10^{21} \text{cm}^{-3}$ ) (111) layer with high  $T_c$  (10 K) forms the step edge JJ. For operating temperatures above the liquid He temperature (4.2 K), it was necessary to fabricate JJs and SQUIDs using only the heavily B-doped (111) layer. SQUIDs consisting of trench-type JJs with the boundaries of discontinuous (111) sectors on trenches formed by focused ion beam (FIB) operated at 10 K and the maximum  $V_{p-p}$  was 4.0  $\mu$ V [4]. However, the trench shape formed by FIB was unstable, and it was difficult to obtain uniform JJs characteristics. Therefore, JJs with a single-step structure, consisting of a discontinuity in the heavily B-doped (111) layer deposited on top of a minute step of about 40 nm formed by reactive ion etching (RIE), has been proposed[4][5]. SQUID with single-step JJs is simple and highly reproducible, and operation at 9.5 K has been achieved. However, the  $V_{p-p}$  of single-crystal diamond SQUIDs was still small compared to SQUIDs made of other materials. Therefore, we have tried to improve  $V_{p-p}$  by increasing the normal resistance of JJs through JJ width miniaturization. For SQUIDs with single-step JJs,  $V_{p-p}$  increased significantly from 1.4  $\mu$ V to 47.7  $\mu$ V by miniaturizing JJs width from 15  $\mu$ m to 5  $\mu$ m. In the JJs miniaturized down to less than 5  $\mu$ m, however, the etching damage became prominent, and  $V_{p-p}$  could no longer be expected to improve with this type of miniaturization.

In this study, we propose a new JJ structure, the ridge conduction structure, which is unaffected by etching damage. In ridge conduction structure JJs, first a narrow ridge structure is formed on the undoped substrate by RIE, and then the heavily B-doped diamond has been grown along the ridge. JJs with a 40 nm step as in single-step JJs are formed on top of the ridge structure. The flow path of superconducting current can be restricted on the ridgelines of (111) surface, because growth sectors different from (111) sector show low  $T_c$  superconducting on sidewalls without etching the B-doped layer. As a result, we confirmed the operation of JJs and SQUIDs with a minimum JJs width of 3  $\mu$ m using this structure. Also, we confirmed that the ridge conduction structure reduces etching damage by reducing the residual resistance at 300 nm nanobridges with this structure.

**Diamond Quantum Devices: Surface Termination Characterization and Methods** Alastair Stacey; RMIT University, Australia

Diamond quantum devices are being increasingly explored for technological applications, with a common need being quantum defects - such as NV centres - very near to the diamond surface. These surfaces are known to host crystalline defects and a range of crystal termination chemistries, all of which can affect the near-surface defect centres in a variety of ways. In this talk we will present our efforts to quantify these defects, while simultaneously engineering the diamond surface with chemical and electronic functionalities.

3:45 PM EL14:03.02

**Environmental Control of Shallow Nitrogen-Vacancy Sensors in Oxygenated (100) Diamond Surface** Adam Gali<sup>1,2</sup>, Anton Pershin<sup>1,2</sup> and Peter Udvarhelyi<sup>1,2</sup>; <sup>1</sup>Wigner Research Centre for Physics, Hungary; <sup>2</sup>Budapest University of Technology and Economics, Hungary

Quantum sensing with nitrogen vacancy (NV) center in diamond is an emerging technology to detect nuclear spins and chemical species with nearly atomic resolution. This is achieved by translating the magnetic- and electric-field fluctuations from the respective sources directly to an optical signal, detected by a change in the fluorescence intensity of the NV center. In this work, we develop realistic models of the diamond-solvent interfaces to elucidate new sensing applications for the NV center, which are based on the reversible variations in the surface potential. More specifically, we show that aqueous diamagnetic electrolyte solutions such as sodium chloride can be sensed by an increase of the spin relaxation time of near-surface NV-center ensembles. Our first principles calculations combined with interface modeling identify a critical role of the interfacial band bending which leads to a stabilization of fluctuating charges at the interface of an oxygen-terminated diamond. In addition, we demonstrate that aqueous environment enables to recover a contrast in the optically detected magnetic resonance experiment for the shallow NV centers at cryogenic temperatures. Both predicted phenomena were directly confirmed in experiments by observing the optically detected magnetic resonance and spin relaxation times of the ensemble and single NV-centers.

This work was supported by the National Research, Development, and Innovation Office of Hungary (NKFIH) grant No. KKP129866 of the National Excellence Program of Quantum-coherent materials project and the Quantum Information National Laboratory supported by the Ministry of Innovation and Technology of Hungary, the QuantERA II MAESTRO project, and the Horizon Europe EIC Pathfinder QuMicro project (grant No. 101046911).

**Pick-Flip-And-Place Hybrid Integration of a Single-Crystal Diamond Nanobeam with an Ensemble of Nitrogen-Vacancy Centers** Ryota Katsumi<sup>1,2</sup>, Kosuke Takada<sup>1</sup>, Shun Naruse<sup>1</sup>, Kenta Kawai<sup>1</sup>, Daichi Sato<sup>1</sup>, Takeshi Hizawa<sup>1</sup> and Takashi Yatsui<sup>1,2</sup>; <sup>1</sup>Toyoashi University of Technology, Japan; <sup>2</sup>The University of Tokyo, Japan

Nitrogen-vacancy (NV) centers in single-crystal diamond have been intensively studied for various quantum applications such as quantum sensing, quantum communication, and quantum simulation. To accelerate advances in quantum technologies based on NV centers, implementing micro/nanostructures in diamonds is essential. Because of recent advancements in etching technologies for diamond photonics, various nanophotonic

structures, including photonic crystals, ring resonators, and disk resonators, have been successfully fabricated to date.

Combining color centers in diamond with well-developed integrated photonics using hybrid integration techniques such as transfer printing provides a powerful route toward large-scale and multifunctional quantum devices. However, the existing etching technology for diamond photonics is inherently not compatible with reported hybrid integration approaches. For example, the bottom of a diamond nanostructure fabricated using angled etching is a triangular shape that makes it difficult to place on other substrates using conventional pick-and-place techniques. Therefore, it is significant to develop hybrid integration techniques with high yields for scalable diamond quantum photonics, irrespective of the sample structure.

In this work, we propose “pick-flip-and-place” transfer printing for the hybrid integration of a diamond NV triangular nanobeam on chip in a deterministic manner. This approach provides a flat diamond-chip interface and allows for the integration of NV centers on chip with a near-unity success rate, irrespective of the width and shape of the diamond nanostructures. In experiment, we demonstrate that an integrated diamond nanobeam containing an ensemble of NV centers can function as a nanoscale quantum sensor. We believe that the proposed approach paves the way for the realization of scalable diamond quantum photonics assisted by cutting-edge integrated photonic technologies.

We describe the basic procedure for the proposed nanofabrication and hybrid integration processes based on transfer printing. First, triangular nanobeam containing NV centers with high density (300 ppb) were prepared via vertical dry etching of diamond substrate, followed by a diamond undercut process based on angled etching. We then used transfer printing to select a suitable diamond nanostructure from the processed diamond substrate using a polydimethylsiloxane (PDMS) film with weak adhesion. This “weak” PDMS was flipped to lift off the nanostructure from the flipped film using a PDMS film with strong adhesion. This process allows for a flat interface between the diamond nanostructures and photonic chip, which is necessary for high-yield integration. Finally, the transferred diamond nanobeam was integrated by slowly peeling off the film onto an SiO<sub>2</sub> substrate, which is a common low-refractive-index material in integrated photonics for efficient light confinement in a waveguide. It is notable that we can perform hybrid integration irrespective of device structure and target materials by using the proposed “pick-flip-and-place” integration approach, enabling us to combine diamond quantum photonics and state-of-the-art photonic integration technology.

To experimentally show that the fabricated device could function as a nanoscale quantum sensor, we performed optically detected magnetic resonance (ODMR) measurements on integrated NV centers. We confirmed an ODMR dip at a microwave frequency of 2.88 GHz with an ODMR contrast of ~0.006 and the linewidth of 7.8 MHz, which is comparable to those measured for bulk diamond. Therefore, we, for the first time, succeeded in the hybrid integration of a diamond nanobeam with an ensemble of NV centers on a chip for quantum sensing. The proposed approach based on transfer printing provides a deterministic route toward a scalable combination of diamond quantum photonics and cutting-edge integrated photonics technologies.

**Characterization of Nitrogen Aggregation in CVD-Grown Diamond** Eveline Postelnicu<sup>1</sup>, Christine Jilly-Rehak<sup>1</sup>, Lillian B. Hughes<sup>2</sup>, Simon Meynell<sup>2</sup>, Haoxue Yan<sup>1</sup>, Tri Nguyen<sup>1</sup>, Ania Bleszynski Jayich<sup>2</sup> and Kunal Mukherjee<sup>1</sup>; <sup>1</sup>Stanford University, United States; <sup>2</sup>University of California, Santa Barbara, United States

Understanding the mechanisms behind incorporation of dopants in chemical vapor deposition (CVD)-grown diamond is paramount to optimizing nitrogen vacancy (NV)-center based quantum devices and those for power electronics. The mechanism of nitrogen incorporation during CVD growth, and the resulting density and spatial distribution of the nitrogen are not well understood. In the context of limited incorporation of dopants such as nitrogen, there is evidence that features on the growth surface of diamond, like step bunching and hillocks, strongly segregate these impurities. A spatially resolved study of dopant distribution around these growth features would provide more insight into the impact on devices and point to strategies to obtain higher densities of dopants. To this end, we have studied nitrogen aggregation in hillocks formed in (100) homoepitaxial diamond grown via plasma-enhanced chemical vapor deposition (PECVD).[1] <sup>15</sup>N enriched nitrogen gas was utilized during growth to form a near-surface, 7 nm-thick delta-doped <sup>15</sup>N layer. Hillock growth has been studied extensively in diamond and has been attributed to a variety of mechanisms, including spiral growth on a screw dislocation core[2], heterogeneous nucleation at foreign crystallite sites[3] and penetration twins[4], as well as repeated 2D nucleation on miscut diamond substrates.[5] Meynell et al confirmed an inverse relationship between hillock density and substrate miscut and also observed nitrogen accumulation in hillock defects which correlated to a higher NV density.[6] Using panchromatic and spectrally resolved cathodoluminescence (CL) mapping, we observed greater NV emission from hillock edges in particular. We utilized nanoscale secondary ion mass spectrometry (nanoSIMS) to spatially resolve <sup>15</sup>N concentration (measured as the <sup>12</sup>C<sup>15</sup>N<sup>-</sup> ion) with ~50-70nm resolution, using a 20 pA Cs<sup>+</sup> ion beam and a mass resolution greater than 9000 to resolve nearby isobaric interferences. NanoSIMS confirmed <sup>15</sup>N aggregation in hillock edges, which we conclude directly correlates to an increase in NV center density. Previous broad-area SIMS measurements identified 2×10<sup>16</sup> cm<sup>-3</sup> <sup>15</sup>N density in the uniform regions of the delta-doped layer. By comparing the local <sup>12</sup>C<sup>15</sup>N<sup>-</sup> counts per volume in the hillock defect to that of the uniform regions, we identified <sup>15</sup>N density of 1.2×10<sup>18</sup> cm<sup>-3</sup> in the hillock defects, a nearly two order of magnitude increase compared to the delta-doped layer. We will show how volumetric SIMS scans using nitrogen as a tracer provide additional insight into the growth mechanism of these surface features. Understanding these can lead to future NV-based device applications that intentionally harness dopant aggregation.

**Two-Dimensional Spin Systems in PECVD-Grown Diamond with Tunable Density and Long Coherence for Enhanced Quantum Sensing and Simulation** Lillian B. Hughes<sup>1</sup>, Simon Meynell<sup>1</sup>, Zhiran Zhang<sup>1</sup>, Weijie Wu<sup>2</sup>, Emily Davis<sup>2</sup>, Zilin Wang<sup>2</sup>, Bingtian Ye<sup>2</sup>, Norm Yao<sup>2</sup>, Kunal Mukherjee<sup>3</sup> and Ania Bleszynski Jayich<sup>1</sup>; <sup>1</sup>University of California, Santa Barbara, United States; <sup>2</sup>Harvard University, United States; <sup>3</sup>Stanford University, United States

Solid-state spins constitute a powerful platform for quantum technologies. Dense ensembles of coherent spins provide a starting point for investigating strongly interacting spin systems in which novel, many-body states can arise with applications in both quantum simulation and sensing. Dimensionality plays a critical role in the nature of many-body states, with reduced dimensionality giving access to unique phases and phenomena such as interaction-driven localization or dipolar-driven spin squeezing. For sensing applications, a dense 2D layer of sensors in close proximity to a sensing target exhibits enhanced spatial resolution (set by the depth of the layer) compared to a 3D ensemble at the same volumetric density, while benefiting from either 1/√N classical sensitivity enhancements or entanglement-driven enhancements. Lastly, dense 2D ensembles could serve as a starting point for targeted, on demand formation of individual, optically resolvable defects at specific locations, such as inside nanostructures. Altogether, creating thin spin layers with

tunable density is of intense current interest but has been minimally explored in solid-state electronic spin systems to date.

Defects in diamond, such as nitrogen-vacancy (NV) centers and substitutional nitrogen (P1 centers), are particularly promising solid-state platforms to explore. However, the ability to controllably create coherent, two-dimensional spin systems and characterize their properties, such as density, depth confinement, and coherence has been an outstanding materials challenge. We present a refined approach to engineer dense ( $> 1 \text{ ppm} \cdot \text{nm}$ ), 2D nitrogen and NV layers in both (100) and (111) diamond using delta-doping during plasma-enhanced chemical vapor deposition (PECVD) epitaxial growth. We employ both traditional materials techniques, *e.g.*, secondary ion mass spectrometry (SIMS), alongside NV spin decoherence-based measurements to characterize the density and dimensionality of the P1 and NV layers. We present depth confinement of the spin layer down to  $< 4 \text{ nm}$ , high (up to 0.74) ratios of NV to P1 centers, and reproducibly long NV coherence times which are dominated by dipolar interactions between the engineered P1 and NV spin baths. Altogether, the results of our joint materials and qubit-based approach are key elements in the engineering of solid-state-spin systems for the next generation of quantum technologies.<sup>1,2</sup>

**Photophysics of the SnV Center in Diamond** Philipp Fuchs<sup>1</sup>, Soniya Nuchikkat<sup>1</sup>, Jan Fait<sup>1</sup>, Johannes Goerlitz<sup>1</sup>, Michael Kieschnick<sup>2</sup>, Jan Meijer<sup>2</sup> and Christoph Becher<sup>1</sup>; <sup>1</sup>Universität des Saarlandes, Germany; <sup>2</sup>Universität Leipzig, Germany

For many applications in the field of quantum information processing stationary qubits are required, providing long-lived spin coherence and suitable level schemes for coherent control and efficient optical read out. Color centers in diamond, more specifically the group-IV-vacancy centers, have emerged as promising candidates among solid state qubits. They exhibit favorable properties such as individually addressable spins with long coherence times and bright emission of single, close to transform limited photons. Recent experiments have shown that the negatively charged tin-vacancy center (SnV) [1] combines long spin coherence times at conveniently achievable cryogenic temperatures ( $> 1 \text{ K}$ ) [2,3] with truly lifetime-limited transition linewidths down to 20 MHz [1].

However, exploiting these properties requires active stabilization of the charge state, as the SnV center upon resonant laser illumination can be easily ionized to its double negative charge state (SnV<sup>2-</sup>) which is optically inactive [3]. To prevent ionization, illumination with a second light field in the blue spectral range is required. We find that the charge stabilization requires the presence of additional defects in the vicinity of the SnV center such as divacancies [3] in the bulk or sp<sup>2</sup> defects on the surface [4].

Here, we propose a simple rate equation model for the SnV center photophysics that includes this ionization process. We apply the model to an extensive set of measurements on different SnV centers, along with a thorough characterization of the efficiency of our measurement setup. We conclude that a charge-stabilized SnV<sup>-</sup> center is a nearly ideal single photon source in terms of quantum efficiency, since we can describe any reduced photon rate by ionization to the optically inactive SnV<sup>2-</sup> charge state without assuming other non-radiative decay channels. We further discuss the occurrence of fluctuating background emission, its suppression via thermal oxidation in air atmosphere and the role of surface defects in the charge transition cycle.

**Disposable Electrochemical Biosensor for Ultrasensitive Detection of Salivary Cortisol on a Non-Covalently Modified Laser-Induced Graphene Surface for Stress Monitoring** Atul Sharma, Alia Wolff, Ayanna Thomas and Sameer R. Sonkusale; Tufts University, United States

Monitoring stress indicators (such as cortisol) is crucial for understanding and managing the root cause of several cognitive, neurological, cardiovascular and endocrinological diseases. Cortisol negatively affects the regulation of various physiological processes such as carbohydrate metabolism and blood glucose levels. Long-term stress can disrupt homeostasis in the cardiovascular, renal, skeletal, and endocrine systems, leading to the development of chronic diseases [1,2]. Because of its central role, continuous monitoring of cortisol levels in the human body is critical for health and wellness. Current diagnostic techniques are complex and performed at centralized facilities by qualified specialists rather than at the site of therapy, which is critical for real-time monitoring. Electrochemical biosensors based on graphene's conductivity and flexibility are appealing in such contexts. Towards the goal of routine stress-level monitoring, this work realizes the design and development of an ultrasensitive and disposable immunosensor based on vertically aligned laser-induced-graphene (LIG) electrodes as a transducer surface for non-invasive salivary cortisol monitoring via differential pulse voltammetry (DPV) signal transduction mechanism. The LIG electrode was used due to its wide scalability, high electrochemical stability, increased number of reaction sites, efficient electrical conduction owing to the increased surface area and structurally more uniform alignment of the graphene layer conductivity, and low cost [3]. The LIG electrodes were fabricated using a laser ablation technique (in-house). Before use, the surface of the electrode was cleaned by cyclic voltammetry in 0.50 M sulphuric acid containing 0.10 M KCl as electrolyte. Later, the LIG electrode surface was chemically functionalized with a self-assembled monolayer of pyrene-NHS (1-Pyrenebutyric acid N-hydroxy succinimide) ester incorporating an NHS-activated functional group for the receptor (antibody) immobilization. Furthermore, a monoclonal antibody to salivary cortisol (mAb) was incubated on the Pyr-NHS-LIG electrode surface and

immobilized via peptide bond formation between the carboxyl terminal of the crosslinker and the amine terminal of the antibody. This step is followed by electrode passivation to incorporate an antifouling layer. LIG's structure and electrical conductivity were preserved by using the non-covalent functionalization of Pyr-NHS ester. Cortisol complexation with immobilized mAb-Cort resulted in ferri/ferro redox electrochemistry-mediated measurement. Under optimum experimental settings, the immunosensor performance exhibited a dynamic working range from 100 fg mL<sup>-1</sup> to 10.0 ng mL<sup>-1</sup> ( $R^2 = 0.9982$ ) with a detection limit of 10.0 fg mL<sup>-1</sup> for cortisol (n=3). The developed immunosensor was successfully deployed to assay human salivary cortisol and showed a strong correlation with established laboratory methods (e.g., ELISA). This offers great promise for point of care monitoring of diseases.

**Investigation of Intracellular Thermogenesis Dynamics using Mitochondria-Targeted Nanodiamond Quantum Thermometry** Yoobeen Lee<sup>1</sup>, Kiho Kim<sup>2</sup>, Dohun Kim<sup>2</sup> and Jin Seok Lee<sup>1</sup>; <sup>1</sup>Hanyang University, Korea (the Republic of); <sup>2</sup>Seoul National University, Korea (the Republic of)

Intracellular thermometry techniques provide valuable information into biological processes by detecting temperature variations within specific organelles under different physiological conditions. However, miniaturizing biocompatible thermometers to submicrometer sizes and attaching them to organelles pose significant challenges. In this study, we present a novel approach utilizing organelle-targeting nanodiamond quantum thermometry, using nitrogen-vacancy (NV) color centers, to monitor temperature changes during ATP generation within living human skin fibroblast cells. To enable this monitoring, we developed a microscopy system that integrates a coplanar waveguide-incubating chamber and a real-time particle tracking system, facilitating the tracking of nanodiamonds within cells while simultaneously measuring temperature. Using this system, we induced temperature rise based on the thermogenic response by inhibiting ATP synthesis, and measured the resulting changes in temperature within mitochondria, nucleus, and membrane. Our technique can achieve spatially resolved temperature measurements related to mitochondrial thermodynamic and gain insights into the distinct thermodynamic properties in specific organelles within cells.

**Homoepitaxial Diamond Growth Initiation on Smooth CMP Surfaces at Various Mis-Cut Angles** S M Asaduzzaman and Timothy A. Grotjohn; Michigan State University, United States

Homoepitaxial diamond growth by microwave plasma-assisted CVD is used to grow both doped and intrinsic epilayers of diamond for electronic and quantum applications. Often when different doping types or concentrations are desired, the deposition is done in different diamond deposition systems due to avoiding doping memory effects in the deposition system. This requires that the growth process be re-initiated when the sample is moved to a different deposition system. The initiation of the growth process has been shown to often have defects at the growth initiation boundary as evidenced by optical microscopy, photoluminescence and/or cathodoluminescence. This study aims to investigate the growth process at the initiation of the diamond deposition to improve the boundary between different doped epilayers. An objective in many applications is to have abrupt junction between diamond doped with different concentrations or types.

Experiments were performed on the growth initiation on single crystal diamond substrates with various mis-cut angles from the (001) surface. The mis-cut angle was varied from 0 to 4 degrees as determined by X-ray diffraction measurements. To prepare the smooth diamond surface before growth the substrates were chemical mechanical polishing (CMP) polished to achieve a surface roughness of less than 0.3 nm RA. The CMP process was done by polishing the diamond substrate with a slurry of boron carbide, potassium permanganate, and phosphoric acid at a rate of about 100 nm/hr. The surface roughness was measured with AFM. Prior to CMP the substrate was mechanically polished on a Scaife, and the surface was then plasma etched to remove about 2 μm of diamond that may have polishing damage.

The diamond deposition was performed with a hydrogen, methane, and carbon dioxide feed gas mixture that gives a growth rate of 2-6 μm/hr. The diamond deposition was done with only a short time between deposition system turn on and growth initiation. This short time is important to minimize any surface etching/roughening before the growth starts. The growth was allowed to proceed for short periods of time so that 1-2 μm of diamond or less were grown. When the short growth is finished the surface is examined with AFM, optical microscopy, and SEM to look for island growth and step-terrace growth features as a function of the mis-cut angle. Also diamond deposition runs are done under the same growth conditions for various times to see how the growth surface evolves at the start.

The work has observed the smooth surface getting rougher at the initiation of the growth. We will report on the evolution of the surface versus growth time and mis-cut angle. For small mis-cut angles island-like growth occurs and we will quantify the growth of the island size versus growth time. For larger mis-cut angles the transition to step-flow growth will be quantified in terms of terrace and step size evolution. The steps will also be analyzed in terms of step facet height and direction. We will also look at the implications of the growth initiation on doping spatial uniformity in the grown layer.

**Fabrication of Polymeric Microresonators Embedded with NV Color Centers in Nanodiamonds using Two-Photon Polymerization** Filipe A. Couto, Marcelo B. Andrade, Adriano Otuka, Sebastião Prata Vieira, Sérgio Muniz and Cleber Mendonca; São Carlos Institute of Physics, University of São Paulo, Brazil

The NV-color center in diamond is a fluorescent defect that shows great potential for quantum information technologies. It acts as a single-photon emitter at room temperature, offers optical spin state preparation and readout capabilities, and exhibits long coherence time and photostability. Integration of these emitters into photonic structures is essential for various applications and can be achieved through the use of nanodiamonds as a platform. Nanodiamonds enable the incorporation of these quantum emitters into a wide variety of host materials and structures. This work focuses on the fabrication of polymeric cylindrical microresonators embedded with NV color centers using the two-photon polymerization (2PP) technique on a nanodiamond-doped photoresist. The fabricated resonators are 50 μm tall, with radii ranging from 30 μm to 15 μm, and the average size of the nanodiamonds is 40 nm. The positions of the nanodiamonds are located using laser scanning microscopy (LSM), and a homemade confocal fluorescence setup is used to map and measure the spectra of the fluorescent spots. Different concentrations of nanodiamonds were tested, and it was observed that concentrations above 0.5 wt% of nanodiamonds in the photoresist made fabrication impossible. Fabrication was achieved for concentrations ranging from 0.1 wt% to 0.01 wt%, resulting in the identification of multiple fluorescent spots in the structures. However, the quality factors of the resonators were in the range of 10<sup>2</sup> to 10<sup>3</sup>. For a concentration of 0.002

wt%, resonators with quality factors in the range of  $10^4$  to  $10^5$  containing around three emitters per structure were successfully fabricated. Raman spectroscopy measurements were carried out on a previously mapped resonator, where the characteristic diamond peak at  $1332\text{ cm}^{-1}$  could only be observed in the spots where fluorescence was previously detected, confirming the presence of nanodiamonds at specific positions within the resonators. In summary, this work highlights the utilization of the 2PP technique to fabricate polymeric microresonators embedded with fluorescent nanodiamonds. Various characterization techniques were employed to analyze the position and fluorescence of the nanodiamonds. The findings pave the way for the fabrication of photonic devices integrated with nanodiamonds for applications in sensing and quantum optics.

#### 8:00 PM EL14.04.10

**Spin-Photon Interfaces based on Spin Defects in Diamond Coupled to an Optical Microcavity** [Andrea Corazza](#), Yannik Fontana, Viktoria Yurgens, Josh Zuber, Brendan Shields, Minghao Li, Mark Kasprczyk, Patrick Maletinsky and Richard Warburton; University of Basel, Switzerland

Optically-active spins in diamond attracted considerable attention as spin-photon interfaces to establish remote spin-spin entanglement among the nodes - a key building block in a quantum network. A prominent example of a highly coherent and optically addressable electron spin is the negatively charged Nitrogen-Vacancy (NV) center. However, its long radiative lifetime, the small branching ratio into the zero-phonon-line (ZPL) of the emitted photons (2.5-3%) and the inefficient photon extraction out of the diamond limit the entanglement rates and hence the scalability to a few network nodes. We demonstrate efficient selective coupling of the ZPL transition of a coherent NV center to the optical mode of an open Fabry-Perot optical microcavity, mitigating these problems. The coupling of a solid-state spin to a microcavity acts on its radiative lifetime via the Purcell effect, on its branching ratio via the cavity coupling and it efficiently funnels the coherent photons out of the diamond [1]. We present an improved NV creation protocol, carbon implantation post-fabrication, which yields to NV centers with excellent optical coherence even in membranes thinner than  $2\text{ }\mu\text{m}$ , with over 50% of the emitters showing optical linewidths below  $150\text{ MHz}$  [2]. We then embedded one of these diamond membranes ( $1.6\text{ }\mu\text{m}$  thick) in an open Fabry-Perot optical microcavity. The ZPL count rates are as high as  $140\text{ kcts/s}$  under off-resonant excitation, exceeding the state-of-the-art achieved for photonic interfaces based on solid-immersion lenses (SILs). The high photonic flux is achieved through a net Purcell enhancement of 1.8, increasing the fraction of ZPL photons from 3% to 44.7%, an improvement by a factor of 17.5 compared to the NV Debye-Waller factor of 2.55%. By efficient suppression of the resonant excitation, we measure resonance fluorescence from an NV for the first time without relying on time-bin filtering and extract an NV linewidth of  $159\text{ MHz}$ . In two-photon protocols for spin-spin entanglement, our platform would increase the entanglement success probability by more than an order of magnitude, and by more than two orders of magnitude with feasible system improvements.

Our versatile cavity design enables us to use any optically-active spin, which ideally combines excellent optical and long spin coherences. To this regard, the neutral charge state of the Silicon-Vacancy centre emerged as a promising defect in diamond and it exhibits cardinal properties required from an optically active solid-state spin such as long spin coherence and stable, strong optical transitions thanks to its high Debye-Waller factor of and its inversion symmetry which makes it insensitive to electric field noise. While the isolation and stabilization of the neutral SiV charge state has recently been made possible using Boron doping, the method is technologically challenging as it requires careful fine-tuning of the B concentration [3]. Using a versatile approach based on hydrogen surface termination, we demonstrate that the charge state of the SiV can be switched between SiV<sup>-</sup> and SiV<sup>0</sup> in a reliable way, even for diamond structures with low surface-to-volume ratios [4]. We present the method by creating single SiV<sup>0</sup> centres in  $0.5\text{-}3\text{ }\mu\text{m}$  thin diamond membranes. These structures can be readily integrated in optical microcavities, making them a promising spin-photon interface and an ideal host for a quantum memory. In conclusion, we propose two different approaches to manipulate coherently spin defects and to generate coherent single photons resonantly and with high probability, making our systems attractive spin-photon interfaces - an important step towards quantum networks based on spin defects in diamond.

**High Lateral Breakdown Field in Ib HPHT Diamond Substrates** [Pietro Argenton](#), Martin Kah, Danial Majidi, Marine Couret, Nicolas Rouger, David Eon and Julien Pernot; CNRS, France

The efficiency of power devices is critical nowadays for the rise of renewable energy. A great effort is being put into trying to optimize both energy dissipation and blocking capability. In the latter respect the goal is to increase as much as possible the voltage breakdown of devices in the off-state. Because the breakdown voltage increases with the semiconductor bandgap, Ib HPHT diamond substrate, with a bandgap of  $5.5\text{ eV}$ , is a candidate as the ultimate substrate for power devices. In particular Ib HPHT diamond substrates are widely used for lateral Field Effect Transistors (FET) thanks to its insulating properties at room temperature.

In this work, the blocking characteristics of diamond Ib nitrogen-doped substrates are investigated through the use of metallic contacts separated by different gap widths in order to apply large range of electric field (from  $\text{V/cm}$  to  $\text{MV/cm}$ ). Thanks to the electron beam lithography technique, several metallic structures separated by different gaps down to  $500\text{ nm}$  were deposited on an Ib HPHT diamond substrate. The I-V characteristics between two electrodes have been measured up to reach the breakdown voltage of each structure. In order to understand the breakdown mechanism underlying within the structure, electron beam induced current (EBIC) has been used in order to map the electric field between two successive electrodes. This experiment is particularly useful for voltages close to the breakdown voltage.

In the first part of this presentation, the method will be described in details. Then, the I-V characteristics for different breakdown voltages and fields up to  $10\text{ MV/cm}$  will be reported and compared with previous theoretical and experimental results. Finally, the mechanism causing the breakdown of the material will be discussed and compared with finite element simulation.

**Femtosecond Laser Writing Inside Diamond** [Patrick Salter](#)<sup>1</sup>, Pilar Villar<sup>2</sup>, Calum Henderson<sup>3</sup>, Marta Kruger<sup>1</sup>, Fernando Lloret<sup>2</sup>, Daniel Reyes<sup>2</sup>, Daniel Araujo<sup>2</sup> and Richard B. Jackman<sup>3</sup>; <sup>1</sup>University of Oxford, United Kingdom; <sup>2</sup>Universidad de Cadiz, Spain; <sup>3</sup>University College London, United Kingdom

Laser writing with pulses of duration less than a picosecond presents a diverse platform for the functionalisation of diamond, with a range of different modification regimes for internal structuring beneath the diamond surface. The laser is tightly focused beneath the surface where non-linear absorption leads to a perturbation of the diamond structure on a scale less than a micrometre, without any damage to the surrounding material or surface. At higher laser pulse energy, the light-matter interaction breaks down the diamond to create a graphitic phase. At lower laser pulse energy, a finer process is accessible which can yield a vacancy ensemble, without breakdown of the diamond lattice. These processing regimes are applied for the fabrication of a range of devices, ranging from detectors for harsh environments, through to quantum technology and security inscription within gemstones. We focus this talk on our new results for laser written vias passing through a diamond wafer, and the influence of laser dose on the electrical conductivity. Surprisingly, increasing the laser dose delivered to the sample causes a transition from a regime in which the written structures display ohmic conductivity into a regime in which they are insulating in nature. We show that a combination of these regimes can be achieved with laser over-writing to give asymmetric conduction characteristics for the vias. A high-resolution structural characterisation of the laser written features by transmission electron microscopy reveals a diverse range of carbon nanostructures embedded within the diamond, and can be used to explain some of these phenomenon

**Direct Laser Writing of Nanochannels Between Ultra-Thin Nanocrystalline Diamond Films and Glass Substrates** Stoffel D. Janssens, David Vázquez-Cortés and Eliot Fried; Okinawa Institute of Science and Technology Graduate University, Japan

The fabrication of nanofluidic devices, which have one dimension below the 100 nm cornerstone, is complex, expensive, and time-consuming due to the small length scales involved. Direct femtosecond laser writing of nanochannels might overcome the inherent challenges; however, progress in this field is limited. Still, encouraging developments have been made. For example, laser writing can produce nanocavities in thin nickel films [1]. Films with such cavities may offer a wide range of possibilities for magnetism-related research but are not transparent in the visible spectrum, which excludes optical microscopy for nanofluidic research. Laser writing can also produce nanochannels in fused silica substrates [2]. These channels are usually perpendicular to the surface of the substrates, have variable diameters, are open on one side, and are typically no more than ten micrometers long.

This talk presents a method for fabricating nanofluidic devices through the direct femtosecond laser writing of arbitrary long nanochannels between nanocrystalline diamond (NCD) films and glass substrates. Laser writing transforms a portion of the sample into a nanostrip, and the nanostrip is surrounded by two nanochannels generated by film delamination. For an NCD film with an as-deposited thickness of 300 nm, the mean height and the width of a nanochannel made in this way are on the order of 30 nm and 2  $\mu$ m, respectively, and are tunable to a certain extent by laser pulse energy. Experiments indicate that a nanostrip consists of NCD, non-diamond carbon, and glass particles, which might be mixed with carbon due to laser ablation. It is found that the expansion of the sample material shapes a nanostrip and causes delamination and nanochannel formation. Such an expansion happens, for example, during the transformation of diamond to carbon of other forms [3]. Since the pulse energy needed to ablate the bare glass substrate is much greater than those used for nanochannel writing, one can deduce that nanostrip formation is initiated in the NCD film near the film-substrate interface. The origin of this phenomenon might be the presence of low-quality NCD at that location, which is bound to absorb more light than high-quality NCD [4]. By fabricating a nanofluidic device and performing simulations, it is shown that the nanochannels fill with water through capillary action.

NCD is an appealing material for applications due to its biocompatible, chemical, mechanical, electrical, optical, and quantum properties. Low-cost diamond films can be achieved by plasma-assisted chemical vapor deposition with methane gas diluted in molecular hydrogen as a precursor mixture. With this deposition technique, NCD films are commonly synthesized on substrates seeded with nanodiamonds [5]. NCD can also be doped to make it electrically conductive, paving the way for various applications [6]. Being inexpensive, transparent, and chemically inert, glass is a natural choice for research in micro- and nanofluidics. The coefficient of thermal expansion can also be tuned towards that of other materials, allowing the fabrication of structures with relatively low residual stress. Since NCD films are inert to hydrofluoric acid (HF), NCD can act as an etch stop during the HF etching of glass [7]. Here, we rely on this property for fabricating the nanofluidic device.

#### 2:30 PM EL14:07.03

**Femtosecond Direct Laser Writing for Diamond NV Centers Placement** Cleber Mendonca<sup>1</sup>, Lucas Nolasco<sup>1</sup>, Filipe Couto<sup>1</sup>, Juliana Almeida<sup>2</sup>, Carlíe Oncebay<sup>3</sup> and Sergio Muniz<sup>1</sup>; <sup>1</sup>University of Sao Paulo, Brazil; <sup>2</sup>UFSCar, Brazil; <sup>3</sup>National University of Engineering, Peru

The integration of devices for applications in photonics and quantum information technologies requires the development of platforms combining basic elements, such as resonators and waveguides. One promising solid-state optically active systems currently studied for such applications is the nitrogen-vacancy (NV) center in diamond, which is usually produced by irradiating diamond with beams of electrons or nitrogen ions. NV centers can be optically initialized and read out, present long coherence times at room temperature and allows creating protocols to manipulate its spin-state by combining optical and magnetic methods. Furthermore, NV centers can also be used as quantum sensors to detect temperature and magnetic and electric fields. The controlled production and placement of NV centers in photonic structures is of high relevance to engineer devices.

In this direction, this work presents results obtained from our efforts to use of fs-laser pulses to generate active and spatially localized NV centers in CVD diamond, as well as the fabrication of polymeric optical microcavities, via two-photon polymerization, incorporated with nanodiamonds containing NV centers. Upon excitation of diamond using 150-fs pulses from a Ti:sapphire laser at 775 nm, with a repetition rate of 1 kHz, we have determined that active defects, with the least damage to the surface, can be generated using pulse fluence in the range of 11 – 34 mJ/cm<sup>2</sup>, as observed by the typical fluorescent emission of NV center. For fluences higher than 34 mJ/cm<sup>2</sup> the damage on the diamond's surface started to get too severe, also resulting in lower emission. Our results also revealed that the density of NV centers grows with the number of fs-pulses. The generation process, however, is stochastic. Furthermore, fs-pulse at ~800 nm (86 MHz repetition rate) were used to fabricate, via the two-photon polymerization (2PP), cylindrical resonators incorporated with nanodiamonds presenting centers. Even though the cavity quality factor (Q) decreases with the amount of nanodiamonds, for a cavity with 0.01 wt% of nanodiamonds Q ~10<sup>3</sup> is achieved. More interestingly, we were able to collect the NV-center emission from specific positions in such microvities, that display the typical features of the NV-centers. In summary, The results reported here demonstrate the use of fs-laser pulses to generate localized center in diamond by using 150-fs pulses (775 nm) with fluences higher than 11 mJ/cm<sup>2</sup>. Also 2PP was successfully used to fabricate microresonators containing nanodiamonds, with Q of about 10<sup>3</sup>. ## SESSION EL14.08: Florescent NanoDiamond and ND for Bio Applications

Session Chairs: Bohuslav Rezek and Stepan Stehlik

Tuesday Afternoon, November 28, 2023

Hynes, Level 2, Room 209

**3:15 PM EL14.08.02****Enhanced Photophysical Transition Dynamics of NV Centers in Nanodiamond on Structured Metamaterial Platforms** Peng Zheng and Ishan Barman; Johns Hopkins University, United States

While promising as photostable solid-state quantum emitters for biological sensing and imaging applications, nitrogen-vacancy (NV) centers in nanodiamond are limited by their intrinsically inefficient photon generation and extraction from excited NV centers, which restrict the achievable sensitivity and temporal resolution. To overcome these challenges, judiciously structured metamaterials are developed, which can support broadband Purcell enhancement and spatially extended local plasmonic fields for effective plasmon-NV centers coupling. With fluorescence lifetime imaging microscopy characterizations, a simultaneous amplification to the photophysical transition dynamics and emission intensity of NV centers are observed. We envision that the structured metamaterials pave the way for developing superior biological sensing platforms with enhanced sensitivity as well as augmented spatial and temporal resolution.

**3:30 PM \*EL14.08.03****High-Efficiency Tracible Nanodiamond-Mediated Gene Editing System Development and Application** Chia-Ching Chang<sup>1,1,2</sup>, Shih-Hwa Chiou<sup>3,1</sup> and Yonhua Tzeng<sup>4</sup>; <sup>1</sup>National Yang Ming Chiao Tung University, Taiwan; <sup>2</sup>Academia Sinica, Taiwan; <sup>3</sup>Taipei Veterans General Hospital, Taiwan; <sup>4</sup>National Cheng Kung University, Taiwan

Nanodiamonds (NDs) are biocompatible crystalline carbon nanomaterials for biomolecules or small molecules delivery into the target cells especially for NDs smaller than 5 nm. By conjugating NDs with red fluorescence protein, mCherry, the distribution of these nano-fluorescence nanoparticles (ND-mCherry) can be traced in the cells or tissues. Moreover, by conjugating linear DNA fragments with all the components of the CRISPR/Cas9 genome editing system, the NDs particles became a gene-editing device. X-linked retinoschisis (XLRs) is an inherited retinal disorder disease that leads to reduced visual acuity in affected persons. Genetic analysis indicated that XLRs is caused by mutations c.625T in the RS1 gene. Therefore, RS1 serves as a target for gene editing systems. The low transfection efficiency is one of the major challenges of conventional CRISPR/Cas9 genomic editing systems. In this study, we developed an ND-mCherry-CRISPR / Cas9 gene editing system (ND-mCherry-CRISPR / Cas9). The size of ND is approximately 3 nm, which contained both a target gene sequence and an extra green fluorescence protein gene as a gene expression reporter. This tracible ND-mediated gene editing system is not only delivered genes into hiPSCs and mouse retina but also mediates gene editing events. Therefore, the structure of the mouse photoreceptor layer was loose, and cone/rod cells were also found to be abnormal by the ND-mediated gene editing system introduced. The effective gene editing efficiency is about 10 times higher than conventional CRISPR / Cas9. Namely, ND-mediated gene editing systems can be used as a way to quickly establish animal models of hereditary diseases. Furthermore, by conjugating with the gene correction sequences and our system will be a potential medical device for disease treatment.

**4:00 PM EL14.08.04****Controlling the Interaction of Nanodiamond Surfaces with Physiologic Environments** Elisabeth Mayerhoefer<sup>1</sup>, Julia Puck<sup>2</sup>, Daniela Elena Costea<sup>3</sup>, Harsh Nitin Dongre<sup>3</sup> and Anke Krueger<sup>1</sup>; <sup>1</sup>Stuttgart University, Germany; <sup>2</sup>Wuerzburg University, Germany; <sup>3</sup>University of Bergen, Norway

The application of nanodiamond in quantum sensing, tissue engineering or drug delivery requires a highly defined interaction of the diamond surface with the surrounding medium. The uncontrolled formation of a protein corona is one of the major challenges. Furthermore, the denaturing of surface bound functional moieties as well as the attachment of serum components can lead e.g. to a loss of function, masking of functional moieties, the uncontrolled agglomeration of the particles as well as alteration in the uptake mechanism for the introduction of diamond nanoparticles into cells.[1] We have recently reported on the use of a complex zwitterionic moiety for the inhibition of the protein corona formation and the efficient uptake of such functionalized fluorescent nanodiamonds into cells.[2,3]

Here, we discuss the control of these undesired effect by the highly defined modification of the diamond surface using different zwitterionic moieties based on differently charged small peptides as well as crown ethers immobilized using short organic linker molecules.

The resulting nanodiamond conjugates have been investigated regarding their dispersibility, colloidal stability and inhibition of protein adsorption.

Uptake experiments and cell based assays confirm the low toxicity and high biocompatibility of these functionalized nanodiamonds and elucidate the efficient uptake and release into the cytosol without substantial agglomeration. The influence of differently charged surface moieties will be discussed. Such functionalized nanodiamonds are a promising tool for biomedical and sensing applications as the modular approach allows to introduce additional functional moieties, which can then be used to deliver drug molecules, provide specific interactions for targeting and tissue engineering.

Su and Chia-Liang Cheng; National Dong Hwa University, Taiwan

Nanodiamond (ND) has been considered as a biocompatible and feasible platform for efficient cancer drug delivery. Examples have been successfully demonstrated for various cellular and animal models. However, to date, very few or none studies had included the assessment on the effects and efficiency in a quantitative fashion; and the transportation of these ND-drugs to the cancer/tumor sites are still in a less understood state. In cancer therapy, drug resistance may arise due to intercellular microenvironment, cytoskeletal structure, and drug resistance genes causing limited therapeutic effect in cancer treatment.

In this study, we use nanodiamond (ND) as a carrier to improve drug delivery in the 3D cellular model which has been observed drug resistant characterization due to the structure of cellular model. The aim of this study is to compare the penetration ability of ND-drug complex and free anticancer drug treatment in 2D and 3D breast cancerous cells model (MCF-7 and MDA-MB-231). Several variations of the Multi cellular tumor spheroid (MCTS)

cocultures were used to examine the effect of the extra cellular matrix (ECM) to the drug delivery and drug entering mechanisms. ND-drug complex is formed by conjugating Human Serum Albumin (HSA) and doxorubicin (DOX) with ND. Cytotoxicity of the drug complex is determined by MTT assay and Quantitative analysis in 2D cellular model. Growth inhibition assay evaluated the drug efficacy in 3D cellular model. Results show that ND-complexes are more efficient to deliver the drug in 3D cellular model.

**Nucleation Layer Formation and Properties of 5 nm Hydrogenated Boron-Doped HPHT Nanodiamonds** Stepan Stehlik<sup>1,2</sup>, Katerina Dragounova Aubrechtova<sup>2</sup>, Ekaterina Shagieva<sup>2</sup>, Rostislav Medlin<sup>1</sup>, Petr Belsky<sup>1</sup>, Tomas Kovarik<sup>1</sup>, Evgeny Ekimov<sup>3</sup>, Stepan Potocky<sup>4</sup>, Bohuslav Rezek<sup>4</sup> and Alexander Kromka<sup>2</sup>; <sup>1</sup>New Technologies – Research Centre, University of West Bohemia, Czechia; <sup>2</sup>Institute of Physics, AS CR, Czechia; <sup>3</sup>Institute of High Pressure Physics, Russian Academy of Sciences, Russian Federation; <sup>4</sup>Faculty of Electrical Engineering, Czech Technical University in Prague, Czechia

Boron-doped diamond is an excellent electrode material due to its large potential window, robustness, and antifouling properties. While boron-doped diamond in the form of CVD-grown mono or polycrystalline diamond films is already a well-established material, reports on boron-doped nanodiamonds (BNDs) are rare, and BNDs are not broadly accessible. Yet, their potential is tremendous e.g. in (photo)catalysis and biomedicine. BNDs were at first obtained by delamination and milling of CVD films (10.1021/nm500573x), showing also some positive effect on conductivity when used for nucleation (10.1016/j.carbon.2014.07.048). A more scalable and promising technique for making of BNDs is a high-pressure high-temperature (HPHT) synthesis from organic molecular precursors. This process offers unprecedented control of the ND size, enables the dopant incorporation in a high concentration, and provides monocrystalline NDs (10.1021/acsbmaterials.0c00505). Here we investigate whether a nucleation layer from these HPHT BNDs, can potentially lead to better quality (morphology, electrical properties) of the thin (50-200 nm) boron-doped CVD diamond films compared to the standard nucleation with detonation nanodiamonds (DNDs).

We used the BNDs that were synthesized from borabicyclo[3.3.1]nonane dimer C<sub>16</sub>H<sub>30</sub>B<sub>2</sub> under HPHT conditions (8-9 GPa, 1250°C). The obtained black powder was analyzed by Raman and FTIR spectroscopies, which showed relatively high sp<sup>2</sup>-C content and an abundance of C-H<sub>x</sub> bonds. To obtain pure BNDs, the powder was boiled under reflux in a mixture of H<sub>2</sub>SO<sub>4</sub> and HNO<sub>3</sub> (3:1) for 6 hours until the bubbling of the mixture disappeared. Surprisingly, boiling in acids led to complete breakage of the interparticle bonds, and after the centrifugal acid removal, well-dispersed deep blue BND colloid was obtained just by gentle shaking of the sediment. Raman spectroscopy showed a spectrum typical for highly boron-doped diamond without any significant sp<sup>2</sup>-C content. FTIR and zeta potential analysis showed an oxidized surface (presence of C-O and C=O bonds and negative zeta potential of -31 mV). To determine the BND size we used small angle X-ray scattering (SAXS) that showed the mode particle size to be 5 nm. TEM analysis confirmed well-crystalline and well-dispersed BNDs. In order to reverse the zeta potential of the BNDs to become positive, the oxidized BNDs were lyophilized and then hydrogenated at 700°C for 3h. After hydrogenation, the zeta potential of BNDs indeed became positive (44 mV), i.e., similar to the intrinsic NDs after hydrogenation which is important for the achievement of densely seeded substrates with a negative zeta potential. The nucleation layer was created on Si substrates as well as on SiO<sub>2</sub>/Au interdigital electrodes. The morphology and density of the nucleation layers obtained with H-BNDs was investigated by AFM and SEM. Finally, boron-doped CVD diamond film was grown over the nucleation layer on both substrate types, and its morphology, structure, and electrical properties were characterized and compared to the standard nucleation obtained with DNDs.

#### 3:45 PM EL14.12.02

**Accuracy Estimation of All-Optical Thermometry Between 283–373 K using the NV-Center Zero-Phonon Line Spectrum of Diamond Microparticles** Taichi Shikama<sup>1</sup>, Takato Watanabe<sup>1</sup>, Masaya Zetsu<sup>1</sup>, Yoshikazu Hirai<sup>1</sup>, Mazin Jouada<sup>2</sup> and Masahiro Hasuo<sup>1</sup>; <sup>1</sup>Kyoto University, Japan; <sup>2</sup>Karlsruhe Institute of Technology, Germany

The temperature dependences of the intensity, peak wavelength, and width of the zero-phonon line (ZPL) spectrum from diamond nanoparticles have been used for all-optical thermometry of microscale objects [1-3]. The method is especially effective when it is challenging to apply the thermometry using the optically detected magnetic resonance [4-5]. However, the ZPL spectrum shape varies particle-to-particle due to presumably the difference in the particle shape [3], which produces a different magnitude of the strain in the diamond lattice, and the variation requires calibration of the particle dependence of the three parameters mentioned above. To establish the calibration procedure and estimate the accuracy of the all-optical thermometry, we measured the particle-to-particle variation in the ZPL spectrum between 283–373 K.

In the experiments, we used commercial diamond microparticles of 150 μm and 0.75 μm average diameters (Adamas Nanotechnologies). The microparticles were used instead of nanoparticles for the ease of particle-to-particle spectroscopy. Approximately 100 particles were dispersed on a silicon wafer mounted on a temperature-controlled stage of an epifluorescent microscope. 594 nm laser was used as an excitation light source, and the photoluminescence spectrum of each particle was measured using a spectrometer (1.5 nm resolution). In the measured spectra, a wavelength range near the ZPL was fitted using an analytical function based on the theoretical shapes of the ZPL and phonon side band spectra [6].

The three parameters were evaluated from the fitting result, and we made histograms of them at every 10 K between 283–373 K. Among the three parameters, the peak wavelength has the smallest variance compared with the temperature dependence suggesting that better accuracy of the thermometry can be obtained by using the peak wavelength. We found that particles with close ZPL spectrum shape at 293 K have close temperature dependences of the peak wavelength between 283–373 K. Thus, the calibration could be done at one temperature condition by sorting particles having close ZPL spectrum shapes.

#### 4:00 PM EL14.12.04

**Growth of Nanocrystalline Diamond Thin Films from Detonation and HPHT Nanodiamonds: Correlative Microscopy Study** Stepan Stehlik<sup>1,2</sup>, Katerina Dragounova Aubrechtova<sup>2</sup>, Ekaterina Shagieva<sup>2</sup>, Rostislav Medlin<sup>1</sup>, Petr Belsky<sup>1</sup>, Tomas Kovarik<sup>1</sup>, Alexander Kromka<sup>2</sup>, Stepan Potocky<sup>3</sup> and

Bohuslav Rezek<sup>3</sup>; <sup>1</sup>University of West Bohemia, Czechia; <sup>2</sup>Czech Academy of Sciences, Czechia; <sup>3</sup>Czech Technical University in Prague, Czechia

The nucleation layer formed by diamond nanoparticles (nanodiamonds, NDs) is nowadays probably the most common approach how to facilitate polycrystalline diamond growth on diverse substrates by chemical vapor deposition (CVD). Yet the formation of thin and ultrathin functional diamond films [Stehlik et al., doi 10.1021/acscami.7b14436] gives rise to numerous challenges in terms of adhesion, surface uniformity, layer density, sp<sup>2</sup>/sp<sup>3</sup> carbon phases, grain sizes, grain boundaries, etc. A recent study with oxidized nanodiamonds showed that the nanodiamond material quality (determined by origin and surface modifications) has a pronounced effect on the diamond CVD growth and resulting properties, including the brightness of SiV color centers [Zhang et al., doi 10.1039/d2tc01090a].

Thus, in this work we compare the effect of several types of hydrogenated nanodiamonds (being principally more suitable) for nucleation and growth of nanocrystalline diamond thin films with SiV centers. We employ detonation nanodiamond (DND) solutions from standard 4 nm DNDs and novel size-reduced 2 nm DNDs and 4 nm DNDs with reduced nitrogen content (< 0.05 at.%), all obtained from pre-production stock (OZM Research). We also employ HPHT NDs of 0-30 nm size (MSY30, Pureon) purified by annealing in air (450°C, 5h). All NDs were hydrogenated by annealing in a hydrogen atmosphere, providing them positive zeta potential and stability in a colloidal solution [Kolarova et al., doi 10.1016/j.diamond.2023.109754]. The nucleation solutions were prepared by sonication of 100 mg NDs in 20 mL water and subsequent centrifugation to remove larger aggregates. Nucleation layers were formed on Si substrates and Si self-sensing AFM probes which were immersed in the nucleation solution and sonicated for 10 min. We applied CVD diamond growth for 5-30 min (10 - 80 nm thickness) using microwave plasma SEKI SDS6K reactor with standard growth conditions (hydrogen 300 sccm, methane 15 sccm, 60 mbar, 3 kW, 800 °C).

We characterize the morphology, material, and functional properties of the nucleation layers and resulting CVD diamond thin films by correlative microscopy combining SEM, AFM, Raman, and photoluminescence measurements. We show the dependence of these features on the specific properties of the 4 types of employed nanodiamonds. The work has been supported by the Technology Agency of the Czech Republic (TACOM project) and the Czech Science Foundation.

**Fabrication of Q-Carbon Nanostructures and Subsequent Formation of High-Quality Diamond on  $\beta$ -Ga<sub>2</sub>O<sub>3</sub>** Pallab Kumar Sarkar, Saif Al Arafain Taqy and [Ariful Haque](#); Texas State University, United States

The ultrawide bandgap (UWBG) oxides and nitrides, particularly beta-gallium oxide ( $\beta$ -Ga<sub>2</sub>O<sub>3</sub>), are promising material systems for next-generation power devices in commercial and military applications. For most electronic and RF applications, UWBG semiconductor-based devices, including  $\beta$ -Ga<sub>2</sub>O<sub>3</sub>, can operate at much higher voltages, frequencies, and temperatures than commercially available options, including silicon carbide and gallium nitride. However, the remarkably low anisotropic thermal conductivity of  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> (11-27 Wm<sup>-1</sup> K<sup>-1</sup>) is a significant bottleneck for high-power device applications as it affects the device performance and results in self-heating effects (SHE), which severely limits output power density and maximum current flow of the circuit. To address this issue, the incorporation of a diamond layer that can operate as a heat spreader in Ga<sub>2</sub>O<sub>3</sub>-based devices has been investigated due to its extraordinarily high thermal conductivity (~ 2000 W/m/k). The deposition of high-quality diamond coatings onto non-diamond substrates, such as  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> films, is a complex task due to several inherent nucleation, growth, stress, and adhesion-related issues. The absence of carbon solubility in  $\beta$ -Ga<sub>2</sub>O<sub>3</sub>, a large mismatch in surface energies with a significant difference in thermal expansion coefficient between  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> and diamond, and unfavorable decomposition phenomena during CVD make it difficult to achieve uniform diamond layers with suitable adhesion and nucleation density. This study introduces a novel method for depositing diamond on  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> films using a diamond-like carbon (DLC) through pulsed laser deposition (PLD) and successive pulsed laser annealing (PLA) to form a quenched carbon (Q-carbon) layer, demonstrating improved precision and control in the synthesis of diamond coatings for optoelectronic and electronic devices. In this investigation, we have created strong Q-carbon/ $\alpha$ -carbon and Q-carbon/nanodiamond heterostructures on  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> films using laser annealing of amorphous carbon films with nanosecond laser pulses above the melt threshold. The energy density required for the PLA is calculated by modeling the laser-solid melt interaction, and a maximum melt regrowth velocity of 12.5 m/s is achieved at a laser energy density of 0.4 J/cm<sup>2</sup>. Raman studies and X-ray photoelectron spectroscopy (XPS) demonstrate the presence of a high sp<sup>3</sup> content of ~ 81% in the Q-carbon region. Nanodiamonds formed by the PLA process exhibit a distinct Raman peak at 1320 cm<sup>-1</sup>, with a red shift of approximately 12 cm<sup>-1</sup> due to the phonon confinement effect. This research reveals a considerable increase in the nucleation density during diamond deposition by hot filament chemical vapor deposition (HFCVD). A very high seeding density with high-quality delamination-free diamond film growth is possible on the Q-carbon region of the film due to the presence of densely packed diamond tetrahedra in Q-carbon which act as nucleation sites for diamond growth. The nucleation density, diamond quality, and stress values were compared for diamonds on Q-carbon coated  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> and uncoated  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> films. The incorporation of a Q-carbon intermediate layer significantly reduces the compressive stress in diamond films on  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> to 0.37 GPa, compared to 1.23 GPa for films deposited on uncoated substrates. The phase purity of the diamond can be measured by its FWHM of signature Raman peak, with a manually calculated value that matches the direct value obtained from the deconvoluted signal. The values obtained were obtained to be 11 cm<sup>-1</sup> and 16.66 cm<sup>-1</sup> for Q-carbon coated  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> and uncoated  $\beta$ -Ga<sub>2</sub>O<sub>3</sub>, respectively. Thus, this study addresses the critical challenges, i.e., poor adhesion and large thermal mismatch between diamonds and  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> films, which has tremendous implications in realizing efficient  $\beta$ -Ga<sub>2</sub>O<sub>3</sub>-based high power devices.

#### 9:00 AM \*EL14.13.04

**Current Status of Diamond Power Devices for High Voltage Applications - Prospects of Vertical Devices** [Mariko Suzuki](#); University of Cádiz, Spain

The global demand for energy savings through improved power conversion efficiency is creating a tremendous opportunity for high-performance power devices. Ultra-high-voltage and high-efficiency power devices will offer a significant reduction in size, weight, and cooling for power systems and grid-scale power conversion applications.

Diamond, an ultra-wide-bandgap semiconductor, is an ideal candidate for ultra-high-voltage devices due to its exceptional characteristics such as the high thermal conductivity, the mechanical strength, high carrier mobilities (both of electrons and holes), and the high dielectric breakdown strength. Diamond devices have been remarkably developed thanks to the establishment of microwave plasma chemical vapor deposition (MPCVD) growth techniques including doping control and characterization techniques. In this decade, several diamond power devices have exhibited excellent performances beyond other semiconductors based on the material advantages.

Vertical devices have advantages for high power devices, such as low on-resistance, high blocking voltage and high operation current. However, there are not many reports on vertical diamond power devices due to inadequate device fabrication techniques and difficulty in obtaining doped substrates especially

with high-quality.

In this talk, current status and prospects of diamond power devices will be introduced focusing on vertical devices.

**$10^6 \text{ cm}^2/(\text{V}\cdot\text{s})$  Carrier Mobility Measured in Ultra Pure Diamond by Time of Flight Electron Beam Induced Current** Alexandre Portier<sup>1,2</sup>, Fabrice Donatini<sup>2</sup>, Denis Dauvergne<sup>1</sup>, Marie Laure Gallin Martel<sup>1</sup> and Julien Pémot<sup>2</sup>; <sup>1</sup>University Grenoble Alpes, CNRS, Grenoble INP, LPSC-IN2P3, France; <sup>2</sup>University Grenoble Alpes, CNRS, Grenoble INP, Institut Néel, France

Diamond is a very promising material for various applications, and understanding its basic properties is key for the development of future devices. In particular, the low-field mobility of holes has never been measured below  $\sim 80$  K in ultra-pure diamond. In order to measure this mobility, we developed an innovative Time of Flight electron Beam Induced Current (ToF-eBIC) technique. A 1 ns pulsed electron beam was made to impact the diamond semiconductor, inducing charge carrier creation and motion through the 546  $\mu\text{m}$  thick bulk diamond, under the influence of an applied electric field. The resulting signal was analysed using the transient time technique. Thus, the velocity of electrons and holes was assessed as a function of the temperature from 13 to 300 K and as a function of the electric field with values ranging from 1.5 to 9200 V/cm. A low-field mobility value of  $1.03 \times 10^6 \text{ cm}^2/(\text{V}\cdot\text{s})$  was measured for holes at 13 K, demonstrating that diamond is a suitable material to transport charge carriers in a ballistic regime at a scale of ten micrometers.

**Electron Contact Strategies for Diamond Enabled with a Nitrogen Doped Nano-Carbon Interlayer** Gabriel B. Munro-Ludders, Saurabh Vishwakarma, David J. Smith, Robert J. Nemanich and Franz Koeck; Arizona State University, United States

Ohmic metal contacts to n-type diamond have historically posed a challenge to the fabrication of diamond devices, due to the formation of a rectifying Schottky barrier, which limits the practicality and scope of diamond devices. Nitrogen-doped nanoCarbon films have recently been explored as ohmic interface layers to enable low-resistance ohmic contact with N-type diamond [1]. In this work the electronic interface between nitrogen-doped nanoCarbon interlayers and metals is investigated using photoelectron spectroscopy and transmission electron microscopy, to determine the mechanism of ohmic contact.

Titanium and molybdenum layers were deposited on nanoCarbon films, and each respective metal/nanoCarbon interface was characterized via X-ray Photoelectron Spectroscopy (XPS) and Ultraviolet Photoelectron Spectroscopy (UPS). The n-type SBH was determined to be  $\Phi_B = 3.7$  eV and  $\Phi_B = 4.1$  eV for the titanium-nanoCarbon and molybdenum-nanoCarbon interfaces, which indicates a partial pinning of the fermi level. Characterization via TEM and electron energy loss spectroscopy reveal the presence of  $\sim 4$  nm diameter  $\text{sp}^3$ -bonded diamond grains surrounded by a matrix of  $\text{sp}^2$  bonded carbon, indicating a mixed phase material with non-crystalline states. Two models of the contact mechanism, contingent on the density of unfilled surface states after metal deposition, are proposed to understand the ohmic contact mechanism. A sufficiently low surface state density coupled with a high inter-bandgap density may reduce band bending and allow for flat-band contact by filling surface states, unpinning the fermi level. Alternatively, hopping-type conduction near the Fermi level through  $\pi^*$ -bonded states into the conduction band may also reduce the effective SBH.

Future work will investigate the electronic interface between nanoCarbon interlayers and n-type diamond substrates, to enable ohmic contact with n-type single-crystalline diamond. Switching between pinned and unpinned contact regimes through modulating the inter-bandgap state density via modifying morphology, doping concentration, and non-carbon chemical composition in the film also presents an avenue for future investigations.

**Fabrication of Diamond Membranes and Photonic Nanostructures for Integration of Color Centers** Julia Heupel, Lukas Wolfram and Cyril Popov; University of Kassel, Germany

Single-crystal diamond (SCD) in form of thin membranes with incorporated color centers, such as nitrogen-vacancy (NV) centers or silicon-vacancy (SiV) centers, has gained an ever-increasing interest over the years as a highly promising platform for photonic integrated devices or for envisioned applications in quantum information technologies (QITs). To achieve the desired long optical and spin coherence times for QIT applications, such membranes need to be free from lattice defects, paramagnetic impurities, and charge traps. This requires an initial removal of the damaged surface layers from the cut and polished starting material. Additionally, further processing of diamond by e.g., dry etching for fabrication of photonic structures, can lead to higher roughening of the surface due to a micro-masking effect from particles, originating from the polishing procedure. In our work we address the importance of the SCD surface preparation to overcome the above mentioned challenges, which affect the structuring process and critically influence the final quality of the membrane or structured photonic devices as well as their performance.

The fabrication process of SCD membranes with various diameters and thicknesses, exhibiting a low surface roughness down to 0.2 nm, applying inductively coupled plasma reactive ion etching (ICP-RIE) with Ar/Cl<sub>2</sub> and O<sub>2</sub> plasma will be demonstrated. By a variation of the major etching parameters, an enhanced planarization of the surface can be obtained, especially due to a low etch rate of a few nm/min and the Ar/Cl<sub>2</sub> chemistry. These planarized SCD membranes can be successfully bonded via van der Waals forces or via PMMA on plane cavity mirrors and optically characterized in a fiber-based Fabry-Pérot microcavity system regarding their mode structure and finesse. They can be also used as starting material for fabrication of 1D or 2D photonic crystal structures applying electron beam lithography (EBL).

The work is financially supported by the German Federal Ministry of Education and Research (BMBF) under the Project “Quantenrepeater.Link” (QR.X).

## 2:00 PM EL14.15.02

**The Highest Concentration NV Ensembles Formed by Heavily Nitrogen-Doping CVD System with Plasma Confinement and High Density Vacancy Formation by Focused Electron Beam Irradiation** Yudai Asano<sup>1</sup>, Kyosuke Hayasaka<sup>1</sup>, Mayu Ueda<sup>1</sup>, Kyotaro Kanehisa<sup>1</sup>, Kosuke Kimura<sup>2</sup>, Takashi Tani<sup>1</sup>, Shinobu Onoda<sup>2</sup>, Shinpei Enomoto<sup>3</sup> and Hiroshi Kawarada<sup>1,3</sup>; <sup>1</sup>Waseda University, Japan; <sup>2</sup>National Institutes for Quantum Science and Technology, Japan; <sup>3</sup>Waseda University, Japan

Highly concentrated NV ensembles are expected to be applied to magnetic sensing. Only method for high concentration of nitrogen above 10<sup>20</sup> cm<sup>-3</sup> in diamond is limited to CVD method, because the damage of heavily implanted diamond cannot recover easily. We have successfully fabricated diamond thin films with the world's highest nitrogen concentration of 8.0 × 10<sup>20</sup> cm<sup>-3</sup> [1] using a microwave plasma chemical vapor deposition (MPCVD) system that is specially designed to confine plasma to the thickness of a microwave waveguide. This method can also introduce 1 × 10<sup>22</sup> cm<sup>-3</sup> of boron, and diamond with the world's highest superconducting transition temperature has been synthesized. HPHT synthetic (111)-oriented diamond substrates were used. That's because (111) diamond substrate have the high impurity incorporation efficiency [2]. These CVD films exhibit extremely high crystallinity, as indicated by the Raman spectrum measurement (Laser 532nm), which shows a diamond peak FWHM of 8.6 cm<sup>-1</sup>, comparable to HPHT diamonds. After fabricating the films, we performed electron beam irradiation using a 300 keV TEM with an electron fluence of 10<sup>18-22</sup> cm<sup>-2</sup>, resulting in the world's highest NV concentration of 8.5 × 10<sup>18</sup> cm<sup>-3</sup> [3]. This method is necessary for electron irradiation for high density nitrogen above 1 × 10<sup>20</sup> cm<sup>-3</sup>. The quantification of NV concentration was done using the DEER (Double Electron-Electron Resonance) based on NV interactions. DEER is a method of measuring NV concentration from the magnetic dipole interaction strength between NV's four orientation groups by applying microwaves simultaneously to groups of each different resonance frequencies, so this method utilizes the fact that the decay rate of coherence time is proportional to the number of resonant NV groups in the concentration range of 8.5 × 10<sup>17</sup> ~ 1.7 × 10<sup>19</sup> cm<sup>-3</sup>, as confirmed by simulations and experiments [4]. By manipulating the number of resonant NV groups, we determined the NV concentration [3]. Previously, the concentration was estimated from the emission intensity, but when the NV concentration exceeded 10<sup>18</sup> cm<sup>-3</sup>, the saturation of NV concentration occurred without an increase in irradiation fluence. As a result, the estimated values from the emission intensity using the DEER method were higher than those estimated from the emission intensity. However, the obtained NV concentration of 1.0 × 10<sup>18</sup> cm<sup>-3</sup> is only about 1% yield relative to the nitrogen concentration. Understanding the behavior of nitrogen in CVD diamond could potentially lead to higher NV concentrations. Despite such a high nitrogen concentration, the T<sub>2</sub><sup>\*</sup> was 50 ns, and T<sub>2</sub> remained at 0.5 μs measured by Ramsey and Hahn echo, respectively. This value is long compared to experimentally reported values [5]. This is because many reports showed that coherence time is inversely proportional to nitrogen concentration between 2 × 10<sup>16</sup> and 1 × 10<sup>20</sup> cm<sup>-3</sup>. At the nitrogen concentration of our nitrogen-doped CVD diamond ([N] = 8.0 × 10<sup>20</sup> cm<sup>-3</sup>), the coherence time is calculated to be approximately 0.03 μs, which is much shorter than our measured value, suggesting that CVD diamond has advantages for high-density NV ensemble.

This work was supported by MEXT Quantum Leap Flagship Program (MEXT Q-LEAP) Grant Number JPMXS0118067395.

## 2:15 PM EL14.15.03

**Exploring Magnetism in Multiferroics with Scanning NV Magnetometry** Paul Stevenson<sup>1</sup>, Peter Meisenheimer<sup>2</sup>, Hongrui Zhang<sup>2</sup> and Ramamoorthy Ramesh<sup>3</sup>; <sup>1</sup>Northeastern University, United States; <sup>2</sup>University of California, Berkeley, United States; <sup>3</sup>Rice University, United States

Multiferroic materials hold great promise for next-generation devices, offering a route towards low-power, voltage-based control of magnetic ordering. Realizing this potential, however, requires understanding the coupling between magnetic and ferroelectric degrees of freedom. Using scanning NV magnetometry (SNVM), we are able to resolve the wide range of antiferromagnetic textures in the multiferroic BiFeO<sub>3</sub>, revealing previously hidden heterogeneity and allowing us to directly image the effect of applied electric fields.

We also show how SNVM can be used to image multiple field components simultaneously – without ambiguities normally present in reconstructions – by optimizing magnetic field conditions, and how local variations in the refractive index of BiFeO<sub>3</sub> can be imaged below the diffraction limit. These new capabilities demonstrate the broad utility of SNVM for exploring magnetic textures in multiferroic materials.

## 2:30 PM EL14.15.04

**Analysis of Ferro- and Antiferromagnetic Memory Bits by Scanning NV Magnetometry** Peter Rickhaus<sup>1</sup>, Vicent Borrás<sup>1</sup>, Robert Carpenter<sup>2</sup>, Sebastien Couet<sup>2</sup>, Liza Zaper<sup>1,3</sup>, Alexander Stark<sup>1</sup>, Mathieu Munsch<sup>1</sup>, Marco Nordmann<sup>1</sup>, Paul Lehmann<sup>3</sup>, Kai Wagner<sup>3</sup>, Christoph Adelman<sup>2</sup>, Oleksandr Pylypovskiy<sup>4</sup>, Paul van der Heide<sup>2</sup>, Denys Makarov<sup>4</sup> and Patrick Maletinsky<sup>3,4</sup>; <sup>1</sup>Qnami AG, Switzerland; <sup>2</sup>Imec, Belgium; <sup>3</sup>University of Basel, Switzerland; <sup>4</sup>Helmholtz-Zentrum Dresden-Rossendorf, Germany

Storing information in magnetic bits requires excellent control over their nanoscale magnetic properties. A prime example of this challenge are STT-MRAM (spin transfer torque magnetic random access memory) devices - which have rather high failure rates. In order to investigate the sources of potential failure, a technique that can resolve small magnetic fields with high spatial resolution is required. The request is even more urgent for next-generation magnetic memory materials, such as antiferromagnets, which generate even smaller magnetic signals. Scanning NV magnetometry (SNVM) is an emerging quantum sensing technique that offers the required sensitivity. Here, we will look at the local magnetic properties of bits in state-of-the-art STT-MRAM devices using scanning-NV magnetometry [1]. Furthermore, we will demonstrate magnetic images of a few hot candidate materials for future magnetic memory devices including antiferromagnetic chromia, BFO [2] and ultra-scaled CoFeB nanowires [3]. We will reveal magnetic textures that are undetectable with more standard characterization techniques and discuss implications on device fabrication.

**An Ultra-Sensitive Biosensor Based on Mid-Infrared Diamond Waveguide Spectroscopy** Pontus Forsberg and [Mikael Karlsson](#); Uppsala University, Sweden

In this presentation, our latest work in the development and the use of an ultra-sensitive biosensor based on diamond waveguides will be highlighted. We have during the last years been working on the design and fabrication of mid-infrared (MIR) diamond waveguides. The diamond MIR waveguides together with a broadband tunable quantum cascade laser (QCL), emitting in the so called molecular fingerprint region, are the two key elements in our newly developed label free MIR biosensor. In our approach MIR light is coupled into microfabricated diamond waveguide structures, which are purposefully designed to sustain single or multimode standing waves. The associated evanescent waves that are created at the waveguide surface will extend into the surrounding media and interact with the analyte thus provide the sensing volume. In existing commercial technologies, attenuated total reflection IR (ATR-IR) spectroscopy, IR light from a thermal emitter is coupled through a millimeter sized diamond crystal, with up to 10 internal reflections in the diamond crystal. This is a powerful technology and is today used for i.e. quality control in medical and food industry, protein analysis, forensics, etc. However, the relatively low sensitivity of this technique hinders its use in many applications. Our biosensor achieves unsurpassed sensitivity due to the large number of standing waves nodes created in our waveguides which roughly can be translated to the number of internal reflections per length unit is maximized. Moreover, the use of a bright QCL laser as a light source further increases the sensitivity of our biosensor – therefore an ultra-sensitive sensor is realized. Finally, the diamond waveguide material facilitates further functionalization by means of organic chemistry thus extending the capabilities of traditional silicon or gold based biosensor technologies, and we demonstrate here one possible route to fabricate selective affinity layers for protein fishing from complex mixtures.

Several designs of diamond waveguides are discussed, ranging from thin film diamond slab waveguides, rib waveguides, to microfabricated free hanging diamond waveguides. We have recently showed how AlN can be used as cladding layer to overcome earlier difficulties in guiding light at longer wavelengths (5-10  $\mu\text{m}$ ). We will also present how we significantly can increase the sensitivity of the diamond waveguide sensor by depositing a high index film on the diamond waveguide. Using silicon as the high index film also opens up for easy functionalization of the sensor.

The diamond waveguide sensor has been tested on different analytes, such as acetone and isopropanol, showing a very stable performance and very high sensitivity. We have therefore starting to work on “real-world” chemical sensing applications. Currently, we are analyzing different forms of the protein alpha-synuclein, which is relevant in understanding the mechanism behind Parkinson’s disease. We have previously shown that ATR-IR spectroscopy can be used to analyze the secondary structure of different alpha-synuclein aggregates. Moreover, it is also possible to see the difference in the IR-spectra between the native state and the neurotoxic misfolded state of the protein. However, the ATR element is impractical to functionalize and the sensitivity of the ATR-IR spectroscopy is too low to be used on relevant samples from patients. In contrast, our diamond waveguide biosensor exhibits the desired key properties to analyze the secondary structure of alpha-synuclein at biologically relevant concentrations. Future work includes the functionalization of the diamond waveguide sensor surface to selectively adsorb alpha-synuclein from cerebrospinal fluid, with the ultimate goal to detect Parkinson’s disease at an early stage.

### 3:45 PM \*EL14.16.02

**Electronic Properties and Memristive Behavior in Undoped Diamond Foils for Artificial Neurons-On-A-Chip Application** Adrian Nosek<sup>1</sup>, Adrian Olejnik<sup>2</sup>, Marc Bockrath<sup>3</sup> and [Robert Bogdanowicz](#)<sup>2</sup>; <sup>1</sup>University of California Riverside, United States; <sup>2</sup>Gdansk University of Technology, Poland; <sup>3</sup>The Ohio State University, United States

The electronic properties of chemical vapor deposited undoped polycrystalline diamond foils are investigated via continuous and pulsed mode measurements. In continuous mode, our diamond thin foil operates as a bipolar memristor with a variable onset voltage and internal nanobattery effect. We attribute the memristive properties to a filamentary redox-based resistive switching mechanism with ionic and electronic charge transport within our diamond foil. In order to explain the occurrence of this dip, we consider the hydrogen redox-based switching model. In this model, hydrogen ions are separated from the conductive filament and migrate towards the negatively charged electrode through atomic vacancies and produce a build-up internal nanobattery voltage. This diffusion process is accelerated by local high temperatures produced by the current carrying filament. While current compliance is not necessary for this effect to occur, it is certainly beneficial because a fixed part of the voltage drop occurs due to electrons travelling towards the positive electrode and the rest of the voltage drop occurs due to protons migrating and accumulating at the negative electrode. After the pulse is turned off, a current in reverse direction flows due to the build-up internal voltage as well as repulsion of accumulated positive charge carriers. In pulsed mode operation, our diamond foils exhibit synaptic behavior, similar to the interface between two neurons. Our memristors exhibits high retention times with high on/off ratios up to  $10^4$  required for logic operations. As an inorganic synapse, our foil exhibits sensory, short-term, and long-term memory effects according to a psychological human memory model. Spike-timing dependent plasticity supports our findings. Furthermore, we observe functionalities commonly found in neurons, such as a mimicked refractory period where our conductive filament corresponds to an axon. We anticipate that our study paves the way for future artificial-neurons-on-a-chip application. Our research findings constitute an important step towards artificial-neurons-on-a-chip application, as well as organic-inorganic brain-electronics interfaces.

### 4:15 PM EL14.16.03

**Rapid Measurement of Plasma Molecular-Targeted Drug Concentration with Boron-Doped Diamond Electrode** [Genki Ogata](#)<sup>1</sup>, Takuro Saiki<sup>2</sup>, Yasuo Saio<sup>2</sup>, Yasuaki Einaga<sup>1</sup> and Hiroshi Hibino<sup>3,4</sup>; <sup>1</sup>Keio University, Japan; <sup>2</sup>Niigata University, Japan; <sup>3</sup>Osaka University, Japan; <sup>4</sup>AMED, Japan

Compared to conventional cytotoxic anti-cancer drugs, molecular-targeted medications exhibit reduced toxicity. These drugs are administered to patients at fixed doses, without the need for adjustments based on biomedical indices such as body surface area. However, this therapeutic approach leads to considerable variability in plasma concentration among individuals, often resulting in significant adverse events that necessitate dosage reduction. Recent clinical studies have sought to quantify the correlation between drug concentration and clinical efficacy or toxicity. To enable personalized administration of molecular-targeted drugs, it is imperative to determine plasma concentrations directly at the clinical site. In recent years, advancements in medical

engineering have yielded various portable or wearable biosensors capable of rapid on-site monitoring. Nonetheless, the widespread utilization of these devices has been hindered by insufficient evaluation of accuracy using clinical samples, variability between sensors, and the need for complex and costly fabrication processes. To overcome these challenges, we propose a straightforward approach utilizing untreated boron-doped diamond (BDD), an electrochemical material known for its sustainability. As a proof-of-concept, we selected pazopanib, a molecular-targeting anticancer drug recommended for monitoring. By employing a BDD plate chip measuring approximately  $1 \text{ cm}^2$ , our sensing system accurately detected pazopanib concentrations in rat plasma samples within the clinically relevant range. Furthermore, the response of the chip remained stable throughout 60 consecutive measurements, demonstrating its excellent repeatability. When we examined plasma samples collected from orally administered healthy rats and cancer patients using our system, the measured concentrations closely matched those obtained through liquid chromatography with mass spectrometry. Additionally, we evaluated the reproducibility of the BDD chips. Finally, we constructed a portable system featuring a palm-sized sensor housing a chip to facilitate practical implementation. This setup successfully determined drug concentrations from approximately  $40 \mu\text{L}$  of whole blood obtained from dosed rats within a short turnaround time of approximately 10 minutes. By employing this "reusable" sensor-based approach, we can accelerate point-of-care drug monitoring, advance personalized medicine, and potentially reduce medical expenses.

#### 4:30 PM EL14.16.04

**Fabrication of Diamond/Metal Oxide Hybrid Structures: Towards Gas Sensors with Enhanced Sensitivity and Selectivity** Petr Ashcheulov<sup>1</sup>, Marina Davydova<sup>1</sup>, Andrew Taylor<sup>1</sup>, Neda Neykova<sup>1</sup>, Alexandr Laposa<sup>2</sup>, Jaromir Kopeček<sup>1</sup> and Pavel Hubík<sup>1</sup>; <sup>1</sup>FZU, Czechia; <sup>2</sup>CVUT, Czechia

The release of hazardous compounds such as NO<sub>x</sub>, SO<sub>x</sub>, CO, NH<sub>3</sub>, other nitrogen or sulfur-containing compounds, and volatile organic compounds (benzene, toluene, methanol, etc.) in the atmosphere is of significant concern for human health. Therefore, there is a rising demand for advanced chemiresistor sensors, which need to satisfy the following requirements: high sensitivity, selectivity, stability and reproducibility. In recent years, various metal oxides (e.g., ZnO, SnO<sub>2</sub>, CeO<sub>2</sub>) have been recognized as promising materials for the detection/sensing of toxic pollutants and hazardous gases. Yet, chemiresistor sensors based on metal oxides have exhibited rather poor selectivity (i.e., simultaneous sensitivity to reducing and oxidizing gases) along with the necessity of high temperature (> 300 °C) operation.

In this work we demonstrate fabrication of hybrid structures based on diamond (intrinsic and boron-doped) and metal oxides (MOx) for their application as active components in gas chemiresistor sensors. We investigate the effect of doping and the diamond structure (planar and/or 3D geometries) on the sensing characteristics of hybrid structures (e.g., sensitivity and selectivity) towards various gases. Fabricated diamond/MOx structures were characterized via various microscopic and spectroscopic techniques, and the effect of their electrical characteristics on the sensing properties is discussed. This work was supported by the Czech Science Foundation grant GACR 22-04533S.

**Normally-Off Vertical Diamond MOSFETs with Drain Current Density over 200 mA/mm using Oxidized Si Terminated Diamond Channel Formed by Si Molecular Beam Deposition Approaches** Kento Narita<sup>1</sup>, Kosuke Ota<sup>1,2</sup>, Yu Fu<sup>1</sup>, Chiyuki Wakabayashi<sup>1</sup>, Atsushi Hiraiwa<sup>1</sup>, Tatsuya Fujishima<sup>2</sup> and Hiroshi Kawarada<sup>1,2,3</sup>; <sup>1</sup>Waseda University, Japan; <sup>2</sup>Power Diamond Systems, Inc., Japan; <sup>3</sup>The Kagami Memorial Research Institute for Materials Science and Technology, Japan

For realization of high-power high-speed miniaturized complementary inverters [1], development of p-type field-effect transistors (p-FETs) corresponding to SiC or GaN n-FETs is essential. Normally-off operation with threshold voltages ( $V_{th}$ ) more negative than  $-3 \text{ V}$  are required for power devices with operating voltage above  $500 \text{ V}$ , but the conventional vertical diamond FETs are normally-on operation ( $V_{th}$ :  $+15 \sim +30 \text{ V}$ ) using hydrogen-terminated diamond (C-H) channel [2,3]. In contrast, we have fabricated (001) vertical diamond MOSFETs with oxidized Si terminated diamond (C-Si-O) channel by the reaction of chemical vapor deposition (CVD) SiO<sub>2</sub> with diamond and achieved the first normally-off operation ( $V_{th}$ :  $-9.0 \text{ V}$ ) in vertical diamond FETs with a maximum drain current density ( $I_{D,max}$ ) of  $108 \text{ mA/mm}$ [4]. In this study, by Si molecular beam deposition (MBD) method, we fabricated C-Si-O side-wall channel in vertical diamond MOSFETs for the first time. We obtained the  $V_{th}$  of  $-4.5 \text{ V}$  and the  $I_{D,max}$  of  $214 \text{ mA/mm}$ , which is the highest  $I_{D,max}$  among the normally-off vertical diamond FETs.

The C-Si-O channel formation method is as follows. After  $200 \text{ nm}$  regrown undoped layer was deposited by microwave plasma CVD, SiO<sub>2</sub> was deposited  $400 \text{ nm}$  as a mask by tetraethyl orthosilicate based plasma-enhanced CVD. A p<sup>+</sup> layer ( $[B]: 1 \times 10^{21} \text{ cm}^{-3}$ ) was selectively deposited by MPCVD after etching  $400 \text{ nm}$  of the SiO<sub>2</sub> mask and  $40 \text{ nm}$  of the regrown undoped layer by inductively coupled plasma reactive ion etching. After SiO<sub>2</sub> mask removal, the diamond surface was treated with hydrogen termination.  $0.5 \text{ nm}$ -silicon was deposited and followed by in-situ annealing at  $1193 \text{ K}$  for  $15 \text{ min}$  in the MBD apparatus. During the annealing in high vacuum, the reaction between C-H and Si occurred and C-Si- happened [5,6]. The C-Si- surface was naturally oxidized and transformed to C-Si-O after the C-Si- channel was exposed to air [7].

The vertical device dimensions for source-source length ( $L_{SS}$ ), effective channel length ( $L_{ch}$ ), trench width ( $W_T$ ), gate-drain length ( $L_{GD}$ ), trench depth ( $D_T$ ) and gate width ( $W_G$ ) are  $8 \mu\text{m}$ ,  $5.2 \mu\text{m}$ ,  $4 \mu\text{m}$ ,  $0.4 \mu\text{m}$ ,  $3 \mu\text{m}$  and  $25 \mu\text{m}$ , respectively. The  $I_{D,max}$  normalized by the  $W_G$  was  $214 \text{ mA/mm}$ , and the  $I_{D,max}$  normalized by the active area ( $L_{SS} \times W_G$ :  $2.0 \times 10^{-6} \text{ cm}^2$ ) was  $5350 \text{ A/cm}^2$  at  $V_{DS}$ :  $-45 \text{ V}$  and  $V_{GS}$ :  $-40 \text{ V}$ , and the on-resistance ( $R_{on}$ ) was  $8.1 \text{ m}\Omega\text{cm}^2$ . The on/off ratio was  $10^7$  and gate leakage current was less than  $10^{-5} \text{ mA/mm}$  at  $V_{DS}$ :  $-10 \text{ V}$ . The maximum transconductance ( $g_{m,max}$ ) was  $15 \text{ mS/mm}$ , and the maximum field-effect mobility ( $\mu_{FE,max}$ ) was  $68 \text{ cm}^2/\text{Vs}$ . The  $V_{th}$  was  $-4.5 \text{ V}$  at  $V_{DS}$ :  $-10 \text{ V}$ . As a result, we achieved the normally-off operation of  $|V_{th}| > 3 \text{ V}$ , and the  $I_{D,max}$  of over  $200 \text{ mA/mm}$ . The  $V_{th}$  shifted more than  $20 \text{ V}$  in the negative direction compared to conventional C-H channel vertical diamond FETs [2,3]. The negative electron affinity of C-Si-O surface ( $-0.25 \text{ eV}$ ) [7] is weaker than that of C-H surface ( $-1.3 \text{ eV}$ ) [8] and the negative fixed charge of Al<sub>2</sub>O<sub>3</sub> on the C-Si-O interface is less than that on the C-H interface. The large negative shift of  $V_{th}$  is due to the smaller band offset and the smaller band bending between diamond and Al<sub>2</sub>O<sub>3</sub> in the C-Si-O channel than in the C-H channel. In the near future, by introducing a p<sup>-</sup>-drift layer, and C-Si-O channel only on the sidewalls, we will realize vertical diamond devices with high breakdown voltage over  $1000 \text{ V}$  and normally-off operation.

**Atomic Hydrogen Effects on Chemical Bonding of Diamond-Like Carbon Films Prepared by Pulsed Laser Deposition** Takahiro Kawabata; Public University Corporation Toyama Prefectural University, Japan

##### 1. Introduction

Tetrahedral amorphous carbon (ta-C) films have been prepared by pulsed laser deposition (PLD) [1-4]. Stock et al. [1] reported that the  $sp^3$  carbon ratio [ $sp^3 C / (sp^3 C + sp^2 C)$ ] in the ta-C film prepared using an ArF excimer laser (198 nm) was 80% or more, which was higher than the  $sp^3$  ratio (~60%) in the film deposited using a KrF excimer laser (248 nm). Yoshitake et al. [2] reported that the ta-C film prepared in a hydrogen atmosphere had a higher  $sp^3$  ratio than the film deposited in an oxygen atmosphere. Cheng et al. [3,4] performed postdeposition-annealing of ta-C with atomic hydrogen irradiation and found that atomic hydrogen etching accelerated crystallization of micro/nano graphite as the annealing temperature rose. In this study, we have deposited diamond-like carbon (DLC) films by PLD using a KrF excimer laser and investigated atomic hydrogen effects on the chemical bonding of the DLC films. We clarified the optimum deposition conditions to promote  $sp^3$ -bonded carbon atoms in the films. The novelty of this study is that the hydrogen effects were investigated by varying the deposition parameters systematically.

##### 2. Experimental methods

DLC films were prepared on Si(100) substrates by PLD using a KrF excimer laser with a wavelength of 248 nm. The DLC film was deposited at a substrate temperature of RT, a laser repetition rate of 20 Hz, a laser intensity of 0.25 J/pulse using an atomic hydrogen source (hydrogen pressure: 0.01 Pa, tungsten filament current: 4 A) for 60 min as a standard sample. One of the substrate temperature, laser repetition rate, hydrogen pressure, and filament current was varied with the other parameters fixed. The  $sp^3$  ratio [ $sp^3 C / (sp^3 C + sp^2 C)$ ] was determined from C 1s core-level spectra obtained by X-ray photoelectron spectroscopy (XPS).

##### 3. Results and discussion

The DLC films prepared with atomic hydrogen irradiation had higher  $sp^3$  ratios than those prepared in a vacuum. Especially, the DLC film deposited at a filament current of 4 A exhibited the highest  $sp^3$  ratio. The hydrogen pressure at which the  $sp^3$  ratio reached a maximum was found to be 0.01 Pa. When the substrate temperature was increased from RT to 700 °C, the  $sp^3$  ratio decreased. It was found that the  $sp^3$  ratio in the film deposited at a repetition rate of 20 Hz was higher than that in the film deposited at 10 Hz. The maximum  $sp^3$  ratio of 57% was obtained in this study, which was close to that reported in Ref. 1, in which PLD using a KrF excimer laser was employed.

Yasui et al. [5] have reported that the amount of atomic hydrogen generated using a tungsten filament source increases with the filament temperature. C.-L. Cheng et al. [3] have shown that hydrogenated, disordered carbon films are deposited at RT, whereas the graphitization of the films occurs at substrate temperatures above 500 °C, which is facilitated by hydrogen etching. When the filament temperature and hydrogen pressure increase, the amount of atomic hydrogen increases, leading to the acceleration of the formation of C-H bonds and selective etching of  $sp^2$ -bonded carbons by atomic hydrogen. When the substrate temperature decreases or the repetition rate (the flux of C atoms) increases, the surface diffusion length of C atoms decreases. In this case, C atoms adsorbed on the surfaces are not able to arrive at stable sites, and the film becomes a metastable form of amorphous carbon.

##### 4. Summary

The maximum  $sp^3$  ratio of 57% was obtained when the hydrogen pressure, substrate temperature, laser intensity, and laser repetition rate were 0.01 Pa, RT, 0.25 J/pulse, and 20 Hz, respectively.

**All-Optical Modulation of Fluorescent Nanodiamonds for Practical Applications** Lingzhi Wang and Zhiqin Chu; The University of Hong Kong, Hong Kong

Because of ultrahigh photostability, nanoscale volume emitting strong fluorescent signal, and low cytotoxicity, fluorescent nanodiamonds (FND) containing nitrogen vacancy (NV) centers are regarded as promising fluorescent markers in various applications. Here, based on optical polarization-selective excitation phenomenon of NV centers, we provided FNDs with more useful functions, including orientation measurement and providing high-dimensional anticounterfeiting information. Particularly, our scheme showed two characteristics: 1) easy-to-implement solution; 2) useful functions. Specifically, our scheme can be conveniently achieved based on mature commercial sample and common microscope with slight modification. Utilizing the orientation measurement of FNDs, we provided the information for cell traction force in a new dimension (rotational dimension). Based on the 3D anticounterfeiting information from FNDs, we achieved physical unclonable function labels, well satisfying common commercial and anticounterfeiting requirements. In above application scenarios, our scheme has little negative influence due to all-optical manipulation.

**Room Temperature sub-THz (300 GHz) Plasma Wave Generation in p-Diamond TeraFET** Muhammad Mahmudul Hasan<sup>1</sup>, Nezhil Pala<sup>1</sup> and Michael Shur<sup>2</sup>; <sup>1</sup>Florida International University, United States; <sup>2</sup>Rensselaer Polytechnic Institute, United States

The growing demand for efficient and compact terahertz (THz) sources operating at room temperature is driven by their wide-ranging applications in spectroscopy, imaging, and communication systems. Hydrodynamic transport modeling of TeraFETs (Terahertz Field-Effect Transistors) has revealed that p-diamond is a promising material for sub-THz applications beyond 5G. P-diamond, characterized by its large carrier effective mass, exhibits longer momentum relaxation times compared to other semiconductor materials, rendering it advantageous for generating THz radiation at lower frequencies. This paper presents a comprehensive hydrodynamic modeling study of a p-diamond-based TeraFET acting as a THz source. Our simulations show that p-diamond TeraFETs could support channel carrier oscillations at THz frequencies below 1 THz at room temperature operating as THz sources enabled by the Dyakonov-Shur instability.

To investigate the performance of the p-diamond TeraFETs, we conducted a thorough numerical analysis using a 1D hydrodynamic model. This model incorporates viscosity effects and considers damping resulting from electron scattering by impurities and phonons. Our simulations conclusively demonstrate the efficacy of the p-diamond TeraFET in emitting resonant THz radiation at a frequency of 300 GHz at room temperature when biased by a DC current. We explored the dependencies of the resonant oscillations on the channel length, drift velocity, and gate bias. These dependencies guide precise tuning of the emitted THz radiation. Our analysis predicts the minimum drift velocity necessary to overcome the decay factor caused by scattering and viscosity effects, ensuring robust resonant oscillation. These findings shed light on the p-diamond TeraFET's operation and aid in optimizing its

performance as a sub-THz source.

#### 10:00 AM EL14.04.02

**Reliable Formation of Diamond p-Type Channel by Additional Negative Ions Formed from Corona Discharge** Xuezheng Jia<sup>1</sup>, Kento Narita<sup>1</sup>, Kosuke Ota<sup>1,2</sup>, Akira Takahashi<sup>1</sup>, Ryosuke Yamamoto<sup>1</sup>, Atsushi Hiraiwa<sup>1</sup>, Tatsuya Fujishima<sup>2</sup> and Hiroshi Kawarada<sup>1,2,3</sup>; <sup>1</sup>School of Fundamental Science & Engineering, Waseda University, Japan; <sup>2</sup>Power Diamond Systems, Inc., Japan; <sup>3</sup>The Kagami Memorial Laboratory for Materials Science and Technology, Waseda University, Japan

The hydrogen-terminated (C-H) diamond surface has been used in diamond MOSFETs for its p-type high conductivity[1][2]. So far, we have reported diamond MOSFETs using 2-dimensional hole gas (2DHG), which is induced by the surface dipole formed by hydrogen-carbon bonds. The negatively charged adsorbates are also considered to have an important role to obtain high surface conductivity[3]. In the fabrication of diamond MOSFETs, even if C-H surface is preserved, we noticed that the surface conductivity decreases after several device processing sequences, because of different ambient and high temperature processing condition. In this work, we developed the recovering method of conductivity by irradiating extra negative ions in air on the hydrogen-carbon (C-H) surface to enhance the current density of the C-H diamond surface. The low conductivity of C-H diamond substrate was improved successfully. This result indicates the necessity of negatively charged adsorbates on the C-H diamond surface. It also makes the fabrication of C-H diamond FET more reliable by intentionally introducing additional negative ion formed by corona discharge to the C-H diamond surface. In this study, the surface of (001) undoped diamond was hydrogen-terminated. Ti/Pt/Au (30nm/20nm/100nm) was evaporated as source/drain electrodes to define the channel length. Before introducing additional negative ion, the current density was 8 mA/mm at  $V_{DS} = 30$  V, with  $L_{ch} = 5$   $\mu$ m,  $W_{ch} = 70$   $\mu$ m, which is more than 1 order of magnitude below the current density of C-H diamond channel reported [4]. To increase the conductivity of C-H surface, we introduced a large amount of negative ion by corona discharge near the substrate surface to provide additional negative charge on the hydrogen-carbon surface for 30 min[5]. The change of current density over time was measured. With additional negative ion in the air, the current density increased rapidly from 9 mA/mm to 164 mA/mm in 30 min and saturated. Sheet resistance decreased from 656 k $\Omega$ /sq to 38k $\Omega$ /sq. The current density maintained the maximum for more than 3 days. All the experiment and measurement were performed in regular air. The increase of current density indicated the amount of negative charge on the C-H surface has a great influence on the density of polarization-induced 2DHG. The desorption of negatively charged adsorbates in the device processing probably leads to a low density of 2DHG, which results in low conductivity of hydrogen-terminated surface. It takes more than several hours for negatively charged adsorbates to cover the surface. This low conductivity issue can be simply improved by introducing additional negative ion to the C-H surface. This process only takes about 30 minutes in air without using toxic gas such as NO<sub>2</sub>. Introducing additional negatively charged adsorbates in the device fabrication process is recommended to secure the higher density of polarization-induced 2DHG, higher p-type conductivity and a higher yield of C-H diamond p-FET.

**Iodine Doping in Tetrathiafulvalene Twisted Crystals** St. John Whittaker, Merritt C. McDowell, Shin Kim, Bart Kahr and Stephanie Lee; New York University, United States

Tetrathiafulvalene (TTF), a workhorse of the organic electronics community since it's superconductor tetracyano-p-quinodimethane co-crystal was

discovered in 1973,[1] is an optically inactive centrosymmetric molecule that crystallizes in an optically inactive centrosymmetric space group *P*-1 when grown from the melt. We recently discovered that growth-actuated crystal twisting breaks this symmetry to render TTF twisted crystals optically active and thus promising candidates for chiroptoelectronics.[2] In this work, tetrathiafulvalene (TTF) banded spherulites comprising helicoidal fibrils are doped with iodine to improve their conductivity for (chir)optoelectronics. Within five minutes of exposure to iodine vapor, TTF film conductivity increased by six orders of magnitude, from 100 pA to 100  $\mu$ A, accompanied by a color change from pale yellow to dark red. Grazing incidence x-ray diffraction patterns also revealed a change in crystal structure upon iodine doping. The rate of iodine doping was found to depend on the local crystal face presented at the film surface, which alternates between faces as the crystalline fibrils twist about the growth direction, forming concentric "bands" surrounding the spherulite center. Crystal face-dependent iodine intercalation was observed by optical microscopy, light absorbance spectroscopy, and electron dispersive x-ray spectroscopy. Faces corresponding to fast iodine intercalation were previously identified as the 1-11 face.[3] Mueller Matrix imaging revealed that crystal twisting is not disrupted by iodine intercalation, with circular dichroism and birefringence retained after five minutes of film exposure to iodine vapor. Combined with the orders of magnitude improvement in electrical conductivity, optically active doped TTF banded spherulites will provide a platform to examine chiral-induced anisotropies in electron and photon interactions in molecular semiconductor twisted crystals.

**Blending Chiral Small Molecules to Achiral DPP-Based Conjugated Polymer to Induce Chiroptical Properties** Jeongwoo Beak, Yina Moon, Jeongjin Hong and Dong-Yu Kim; Gwangju Institute of Science and Technology, Korea (the Republic of)

Conjugated polymers have been developing due to their electrical and optical properties. Furthermore, the chiroptical properties with conjugated polymer have distinguished characteristics of selectivity based on handedness. There are many methods to induce chirality to conjugated polymers, but blending chiral small molecules to achiral conjugated polymers is one of promising and simple methods via supramolecular interactions. By utilizing this method, the induced chirality to conjugated polymer can be applied to optoelectronic devices for multiple signal due to differences in absorption depending on right or left circularly polarized light at the same wavelength.

In this study, diketopyrrolopyrrole(DPP) based polymers with charge transport, NIR absorption property, PDVT-10 is blended with chiral small molecules, (*R*)- or (*S*)-1,1'-Binaphthyl-2,2'-diamine(*R*)- or (*S*)-BN). The chiroptical characteristics are based on the blending ratio and opposite properties between (*R*)- and (*S*)-BN with PDVT-10 in solution. In thin films, the presence of (*R*)- or (*S*)-BN affects PDVT-10, leading to the emergence of a new peak in circular dichroism on near-infrared range and a peak shift in UV-Vis spectrometer. Moreover, it is possible to invert the absorption of circular dichroism and shift UV-Vis peaks through annealing condition. The formation of helical structures through supramolecular assembly on blended films is observed on AFM images and the chiral orientation of BN is transferred to the morphology of PDVT-10 confirmed by 2D-GIWAXS analysis. Moreover, a phototransistor based on an organic field-effect transistor (OFET) demonstrates difference sensitivity to right or left circularly polarized light with a wavelength of 850 nm in the near-infrared range. In particular, the optical activity of semiconductors in the near-infrared range, combined with chirality, is significantly important due to their ability for long-range optical communication, skin penetration, and night vision. In conclusion, this blending method could be proposed as a simple and straightforward approach to induce new chiroptical properties to achiral conjugated polymers.

**Twisted Hydrogen-Bonded Frameworks** Rochelle B. Spencer, Anna Yusov, Alexandra Dillon, Wantong Wu, Bart Kahr, Michael D. Ward and Stephanie Lee; New York University, United States

Directing the assembly of molecules within hydrogen-bonded frameworks is being extensively explored as a modular crystal engineering strategy to access novel molecular packing arrangements of target molecules. Crystal twisting, a common but little-known phenomenon in molecular crystals, of these frameworks provides an additional handle to not only interrogate crystal orientation-dependent properties but also to impart chirality for chiroptoelectronics. Here, we demonstrate crystal twisting in solution-processed bis(guanidinium) naphthalene-1,5-disulfonate ( $G_2$ )(1,5-NDS) films in which molecular assembly is driven by hydrogen bonding between guanidinium and sulfonate moieties. When deposited from ethanol in conditions that favor low nucleation densities but high branching rates, ( $G_2$ )(1,5-NDS) crystallizes as banded spherulites of helicoidal fibrils emanating radially from a single nucleation center and twisting in concert with one another about the growth direction. Scanning electron micrographs (SEMs) reveal tightly packed fibrils that alternate between flat-on and edge-on orientations with respect to the substrate surface with a twisting pitch of  $\sim 3 - 4 \mu\text{m}$ . 2D x-ray diffraction (XRD) patterns collected on ( $G_2$ )(1,5-NDS) banded spherulites confirm that the crystals adopt a bilayer packing motif with ethanol as guest molecules. These banded spherulites further exhibit band-dependent linear dichroism and birefringence, as well as circular dichroism and birefringence as a consequence of twist-induced loss of symmetry. Given the modular nature of these hydrogen-bonded frameworks to incorporate a broad range of molecular pillars and guests, combining hydrogen bond-directed assembly with crystal twisting will open unexplored avenues in the design of chiroptoelectronic materials.

**Chiral Organic Semiconductors – Lending a Hand in Photocatalysis** Aisha Mumtaz, Rebecca Ingle and Bob Schroeder; University College London, United Kingdom

Society's ever-growing energy demands and simultaneous rapid depletion of current greenhouse gas-emitting resources showcase the need to find clean, renewable alternatives. Generation of hydrogen through the combined action of sunlight, water and a photocatalyst, the water splitting reaction (WSR), offers a promising solution to this long-standing problem. However, the WSR suffers from uncontrolled spin alignment of OH radicals, producing hydrogen peroxide ( $\text{H}_2\text{O}_2$ ) as a by-product, which greatly hinders the efficacy and scalability of this process.[1] As chiral molecules are sensitive to electron spin orientation, due to the Chiral Induced Spin Selectivity (CISS) effect, they could behave as spin filters in photocatalysis, thus providing a unique pathway to cleaner energy by impeding hydrogen peroxide formation.[1],[2]

Conjugated polymers are a class of material that have gained increasing attention due to their applications in many electronic devices such as transistors, organic light emitting diodes (OLEDs) and flexible organic photovoltaics (OPVs). This is owing to their tuneable optoelectronic properties, intrinsic flexibility, solution-processability, low cost and abundance. Application of these features to photocatalysis, in combination with the spin selectivity of chiral molecules, could result in efficient, scalable production of hydrogen for clean energy resources.[2],[3]

This work focuses on the synthesis and spectroscopic characterisation of a series of novel, chiral conjugated polymers to generate the desired CISS effect for the suppression of  $\text{H}_2\text{O}_2$  in the WSR. Development of these systems relies on gaining a deeper understanding on how the nanoscale chirality impacts the overall chiral expression. We therefore investigate the effect of chiral centre positioning on the polymer microstructure. In addition to pursuing

renewable, cleaner energy for society, this work could also have a profound impact on our understanding between the interplay of chiral centres and polymer microstructure.

**Can We Still Measure Circular Dichroism with Circular Dichroism Spectrometers: Anisotropic Artifacts in Multiscale Hierarchically Structured Films from Magic-Sized Clusters** Thomas J. Ugras<sup>1</sup>, Yuan Yao<sup>1</sup>, Talisi Meyer<sup>1</sup>, Da Wang<sup>2</sup>, Arantxa Arbe<sup>3</sup>, Sara Bals<sup>2</sup>, Bart Kahr<sup>4</sup> and Richard Robinson<sup>1</sup>; <sup>1</sup>Cornell University, United States; <sup>2</sup>University of Antwerp, Belgium; <sup>3</sup>Spanish National Research Council, Spain; <sup>4</sup>New York University, United States

Chiral materials with strong linear anisotropies are difficult to accurately characterize with circular dichroism (CD) because of artifactual contributions to their spectra from linear dichroism (LD) and birefringence (LB). Recently, we have discovered that CdS magic-sized clusters (MSC) can self-assemble into ordered films that have a hierarchical structure spanning seven orders of length-scale [1]. Because of the small size of MSCs and because of their high organic-ligand/core ratio, these hybrid materials have “softer” inter-particle interactions, with access to a richer phase diagram beyond the classical close packed structures seen with larger nanoparticles, resulting in self-organization into anisotropic patterns. These films have a strong CD response, but the chiral origins are obfuscated by the hierarchical architecture and LDLB contributions. Here, we derive and demonstrate a method for extracting the “chiroptic” CD signal (CD generated by structural dissymmetry) from hierarchical MSC films and identify the chiral origin [2]. The theory behind the method is derived using Mueller matrix and Stokes vector conventions, making use of a second-order Taylor series expansion to extract the CD. The method is verified experimentally before it is applied to hierarchical MSC and nanoparticle films with varying macroscopic orderings. Each film’s extracted chiroptic CD shares a bisignate profile aligned with the exciton peak, indicating the assemblies adopt a chiral arrangement and form an exciton coupled system. Interestingly, linearly aligned MSC films possess one of the highest g-factors (0.05) among semiconducting nanostructures reported. Further, we derive an expression to model the measured CD using a third order Taylor series expansion which introduces “pairwise interference” contributions to CD spectra that, unlike LDLB contributions, cannot be averaged out of the signal. We find that the third order pairwise interference terms can make noticeable contributions to the simulated CD spectra. Using numerical simulations of the measured CD across a broad range of linear and chiral anisotropy parameters, the LDLB interactions are most prominent in samples that have strong linear anisotropies (LD, LB) but negligible chiral anisotropies, where the measured CD strays from the chiroptic CD by factors greater than  $10^3$ . Media with moderate-to-strong linear anisotropy are in great danger of having their CD altered by these effects in subtle manners. These experimental and theoretical studies provide a simple means to extract the chiroptic CD from spectra anisotropically structured samples and highlight the significance of considering distortions in CD measurements through higher order interference effects in highly anisotropic nanomaterials.

**Chirality-Induced Quantum and Topological Properties in 2D Tellurium** Chang Niu and Peide P. Ye; Purdue University, United States

Chirality is increasingly recognized as a critical property in various aspects of human life, spanning fields such as biological chemistry and physics. The disruption of chiral symmetry significantly influences the properties of matter, particularly in pharmaceuticals, biochemistry, and materials science. Thus, a comprehensive understanding and manipulation of chiral materials are crucial for advancing cutting-edge technologies, including chirality-based sensors, optical devices, and electronic systems.

Trigonal Tellurium (Te) possesses one of the simplest crystal structures, consisting of a unit cell where three Te atoms form a covalently bonded spiral chain. The chirality of the Te crystal is determined by the helicity of these atomic Te chains, classified into different space groups:  $P3_121$  (right-handed) and  $P3_221$  (left-handed). Recently, hydrothermally grown two-dimensional (2D) Tellurium (Te) with a thickness of about 10 nanometers has attracted considerable attention due to its excellent electrical, thermal, and optical properties. The chemical potential of 2D Te can be electrostatically tuned by applying a gate voltage, enabling systematic studies of the quantum and topological properties induced by chirality.

Under ambient pressure, the conduction band minimum and valence band maximum of Te are located at the  $H(H')$  point in the first Brillouin zone. Due to Te atoms' strong spin-orbit interaction and the unique chiral crystal structure characterized by three-fold screw symmetry, the conduction bands split and cross at the  $H(H')$  point, leading to a Weyl node. This node produces a radial-like spin texture in  $k$ -space, where spin polarization aligns parallel to the direction of electron momentum. This characteristic distinguishes it from the spin texture observed in Rashba semiconductors or the surface states of topological insulators, where the spin polarization is perpendicular to the electron momentum direction. Importantly, the spin polarization and charge of the Weyl nodes reverse in different enantiomers, a consequence of the mirror symmetry of left- and right-handed Te crystals.

Our investigations of the chirality-induced properties in 2D Te involved electrical and photoelectric responses. The chirality of 2D Te flakes was determined and verified using hot sulfuric acid etch pits and high-angle tilted high-resolution scanning transmission electron microscopy (HR-STEM). At low temperatures (0.3 K), we observed gate-tunable nonlinear electrical responses in 2D Te, including nonreciprocal electrical transport along the longitudinal direction and a nonlinear planar Hall effect along the transverse direction when subjected to a magnetic field. At room temperature, we discovered tunable chirality-dependent circular photogalvanic and photovoltaic effects, stemming from the interaction between circular-polarized light and the chiral crystal structure of 2D Te. These findings highlight the ability to control and manipulate the degree of chirality in materials.

**Nonlocal Spin Transport Property of Chemical Vapor Deposition - Grown Tellurium Crystal** Zixu Wang and Jian Shi; Rensselaer Polytechnic Institute, United States

Chiral crystalline materials have a unique and robust spin-momentum relation allowing the design of energy-efficient spintronic devices. For example, when electrons flow in chiral materials, the electron spin is polarized either parallel or antiparallel to the current direction. In this work, we report the nonlocal spin transport characteristics of chemical vapor deposition - synthesized single crystalline Te crystal. We apply inversion spin hall effect to measure the current-induced spin in Te crystal. We find that the spin polarization can transport several hundreds of micrometers at room temperature. This work provides resilient testbeds for future development of practical spintronic devices.

**2:45 PM EL15.02.03**

**Photoactive Electrically Switchable van der Waals Chiral Semiconductor NbOI<sub>2</sub>** Zhizhuo Liang and Jian Shi; Rensselaer Polytechnic Institute, United States

Basic understanding of the anisotropic and bilinear magnetoresistance (BMR) of GaAs is crucial for the design of spin-active devices. For BMR, it shows a linear dependence on the electric current and the magnetic field. BMR has been reported in topological insulators, two-dimensional electron gas, topological semimetals, 3D Rashba materials, etc. Here we report the observation of BMR in bulk n-type GaAs with a doping concentration of  $1 \times 10^{18} \text{ cm}^{-3}$ . We measure the anisotropic magnetoresistance and BMR at 2.4 K, 4 K, and 10 K. During measurement, we vary the magnetic field from -14 T to 14 T. Magnetoresistance dependency on the current intensity, the magnetic field strength, direction of the magnetic field, and angle between the magnetic field and the current are studied. The work suggests the existence of non-trivial BMR in bulk GaAs.

**Atomically Sharp Internal Interface in a Chiral Weyl Semimetal Nanowire** Nitish Mathur<sup>1</sup>, Fang Yuan<sup>1</sup>, Guangming Cheng<sup>2</sup>, Sahal Kaushik<sup>3</sup>, Inigo Robredo<sup>4</sup>, Maia G. Vergniory<sup>4</sup>, Jennifer Cano<sup>5,6</sup>, Nan Yao<sup>2</sup>, Song Jin<sup>7</sup> and Leslie Schoop<sup>1</sup>; <sup>1</sup>Princeton University, United States; <sup>2</sup>Princeton Institute for Science and Technology of Materials, United States; <sup>3</sup>Nordita, Stockholm University and KTH Royal Institute of Technology, Sweden; <sup>4</sup>Max Planck Institute for Chemical Physics of Solids, Germany; <sup>5</sup>Department of Physics and Astronomy, Stony Brook University, United States; <sup>6</sup>Center for Computational Quantum Physics, Flatiron Institute, United States; <sup>7</sup>University of Wisconsin--Madison, United States

Internal interfaces in Weyl semimetals (WSMs) are predicted to host distinct topological features that are different from the commonly studied external interfaces (crystal-to-vacuum boundaries). However, the lack of atomically sharp and crystallographically oriented internal interfaces in WSMs makes it difficult to experimentally investigate hidden topological states buried inside the material. In this talk, I will first discuss the presence of a unique internal interface known as *merohedral* twin boundary in chemically synthesized single-crystal nanowires (NWs) of CoSi, a chiral WSM of space group  $P2_13$  (No. 198). Secondly, I will show the material characterization techniques to confirm the nature of lattice symmetry breaking inside the CoSi NWs due to the presence of this internal interface. Finally, I will conclude with showing why these interfaces are topologically relevant and how these *merohedrally* twined NWs could be ideal material systems to probe unexplored topological properties associated with internal interfaces in chiral nanostructures.

## SESSION EL15.03: Creating Chirality in Nanomaterials and Assembled Structures

Session Chairs: Matthew Beard and Jian Shi

Tuesday Morning, November 28, 2023

Hynes, Level 2, Room 207

**8:00 AM \*EL15.03.01**

**Inorganic Chiral Nanoparticles—A Promising Chiral Trigger to Induce Homochirality** Zhifeng Huang; The Chinese University of Hong Kong, Hong Kong

Origin of homochirality is a fundamentally important but yet unanswered question. One of the keys to answer this question is to understand external chiral forces to trigger symmetry breaking, which has been believed to induce the homochirality. Diverse chiral forces have been proposed, but one is missing: inorganic chiral surfaces have an enantiospecific interaction with prochiral molecules, considering the fact when the Earth formed about 4.5 billion years ago, it was prebiotically composed of inorganic minerals, mostly crystalline in nature and some are chiral, followed by the existence of organic life. We are studying chiral forces contributed from inorganic atomically chiral surfaces.

We use glancing angle physical vapour deposition to fabricate inorganic chiral nanoparticles (or CNPs), which have adjustable optical activities in the UV-visible-near infrared region. Inorganic CNPs are made of diverse metals, alloys and oxides, and composed of chiral structures at the atomic scale, including chiral twisting of multi-layers of achiral facets, high-index chiral facets, and chiral defects. Inorganic CNPs enantiospecifically interact with prochiral molecules, leading to an enantiospecific amplification of molecular optical activity, an enantioselective photoinduced cyclodimerization of a prochiral anthracene derivative, and reliable manipulation of symmetry breaking of prochiral helicenes. Our works shed light on the origin of homochirality (or life) stemming from the atomically chiral surfaces of minerals through the enantiospecific interactions with prochiral molecules.

**8:30 AM EL15.03.02**

**Origins of Chirality in II-VI Semiconductor Nanoclusters via Symmetry Breaking** Chenjie Zeng; University of Florida, United States

Chiral semiconductor nanostructures have potential applications in chiral optoelectronics, spintronics, sensors, and catalysis. Compared to organic molecules, the origins of chirality in semiconductor nanomaterials are less understood due to many possible chiral geometries at hierarchical levels. Here, we unveil the intrinsic origins of chirality in II-VI semiconductor nanoclusters by achieving atomic precision in a tetrahedral-shaped CdSe nanocluster and X-ray crystallographic analysis. We show that the chirality emerges from the incorporation of tetrahedral coordination of individual ions into the icosahedral packing of the lattices, breaking the symmetry of the inorganic core from an achiral  $I_h$  to a chiral  $T$ . The chirality in the CdSe core further propagates to the metal-ligand interface, as manifested in the clockwise and counter-clockwise rotations of the interfacial coordination patterns. The asymmetric assembly of ligands on the tetrahedral facets further breaks the cluster symmetry from  $T$  to  $C_3$ . The left- and right-handed enantiomers are co-crystallized as a 1:1 racemic mixture. The resolved atomic structure of the chiral CdSe clusters shed light on the chiral structures observed in the larger

semiconductor nanocrystals and their assemblies.

**Inducing Chiral Photoluminescence in Single Photon Quantum Emitters using Chiral Induced Spin Selectivity Effects.** Suryakant Mishra, Jennifer Hollingsworth, Eric Bowes, Han Htoon and [Andrew C. Jones](#); Los Alamos National Laboratory, United States

Chiral quantum emitters or non-reciprocal single photon devices have the potential for playing a significant role in future quantum communication-based infrastructure. To date, the realization of circularly polarized quantum emitters generally requires complex and bulky experimental infrastructures such as high magnetic/electric fields and cryogenic-temperatures. One potential means of realizing chiral quantum emission in solid-state systems is Chiral-Induced Spin Selectivity (CISS). This effect is a well-known physical phenomena known to enable control over electronic spins via the asymmetric transport of electronic spins in chiral organic and inorganic systems. We have explored the utilization of CISS effects as a means of manipulating the circular polarization of photoluminescence from single quantum emitters. Here, cadmium selenide-quantum dots are immobilized on a chiral surface prepared using electrodeposition of aniline. We observe both the inducement a significant degree of circular polarized photoluminescence emission and a magnetization-dependent photoluminescence quenching by using a ferromagnet valve in the chiral substrate. These observations illustrate the potential of a CISS-based mechanisms for realizing chiral single photon emission sources in solid-state material devices. By further exploring the dependence of circularly polarized emission on the quantum dot shell thickness and the thickness of the chiral films, we develop and demonstrate a model for the energy transfer pathways experienced by differing spin orientations in this system.

#### 9:00 AM EL15.03.04

**Structure-Property Relationships of Electrospun CdS Quantum Dot Fibers with Mechanically Modulated Reversible Chirality** [Hansadi Jayamaha](#), Thomas J. Ugras, Tobias Hanrath, Richard Robinson and Larissa Shepherd; Cornell University, United States

Over the last three decades, electrospinning has gained increasing interest as a synthesis technique for micro and nano fibers due to its tunability and versatility. For the first time, electrospinning induced self-assembly of Cadmium Sulfide (CdS) magic sized clusters (MSCs) and their resulting chiroptical properties are discussed. The MSCs assemble into hexagonal mesophase during synthesis and the higher-level structures arise during the evaporation process. Through electrospinning, multiple hexagonal mesophase bundles are postulated to form twisted nanofibrils. These nanofibrils collectively constitute the microfiber as the result of self-assembly. Using Field emission scanning electron microscopy (FE-SEM), and atomic force microscopy (AFM) the morphology of the microfibers and the arrangement of the observed fibrillar structures are studied. The chiroptical properties of the fiber mats are extensively studied using Circular dichroism (CD) spectroscopy.

We improve the uniaxial fiber orientation, thereby synthesizing chiral microfibers with high dissymmetric factors ( $\sim 0.02$ ) and linear dichroism (LD), comparable to thin films of the same material. Reversible changes in CD signals and reduced electron dipole alignment (i.e., LD) occur on stretching of the fibers embedded in elastomeric films. To study the alignment of the mesophase filaments and inter-filament distance upon stretching, Synchrotron based small angle X-ray scattering (SAXS) was used. We confirm a 4-scan method for removing Linear Dichroism-Linear Birefringence (LD-LB) and photo elastic modulator contributions and isolating true CD is applicable for such fibrous webs. This work provides the groundwork for further study of electrospun chiral fibers by bringing forth new research questions regarding the assembly of MSCs into fibrous structures.

#### 9:15 AM EL15.03.05

**Room-Temperature Electrically Switchable Rashba-Dresselhaus Effect in a Van Der Waals Ferroelectric Crystal with Persistent Spin Helix** [Jian Shi](#); Rensselaer Polytechnic Institute, United States

Here we show the discovery of the persistent spin helix in an organic-inorganic hybrid ferroelectric halide perovskite whose layered nature makes it intrinsically like a quantum well. We demonstrate that the spin-polarized band structure is switchable at room temperature via an intrinsic ferroelectric field. We reveal valley-spin coupling through a circular photogalvanic effect in single-crystalline bulk crystals. The favoured short spin helix wavelength (three orders of magnitude shorter than in III-V materials), room-temperature operation and non-volatility make the hybrid perovskite an ideal platform for understanding symmetry-tuned spin dynamics, towards designing practical spintronic materials and devices that can resolve the control-relaxation dilemma.

#### 9:30 AM BREAK

#### 10:00 AM \*EL15.03.06

**Noncentrosymmetric and Chiral 2D Quantum Materials Through Screw Dislocations and Structural Tuning** [Song Jin](#); University of Wisconsin-Madison, United States

Rationally controlling the structures of two-dimensional (2D) layered materials allows us to tune the electronic structures and quantum states of matter, discover new physical properties, thus enable new applications. We show how the phase, layer stacking and thus physical properties of 2D  $\text{MX}_2$  materials can be influenced by screw dislocations. Noncentrmetry of these  $\text{MX}_2$  materials and 2D Ruddlesden-Popper (RP) lead halide perovskites could be enabled at the monolayer and bulk crystal structure level by structural tuning and screw dislocations. Furthermore, chiral microplates of  $\text{MX}_2$  and 2D RP perovskites can be produced via a screw dislocation growth mechanism and the resulting chiroptical properties of individual chiral objects are studied using fluorescence detected circular dichroism (FDCD) microscopy and other polarized spectroscopic/nonlinear optical techniques. Moreover, we achieved systematic interlayer twisting of  $\text{MX}_2$  spiral layers grown via screw dislocations due to mismatched geometry between Euclidean crystal lattices and non-Euclidean (curved) surfaces to form moiré superlattices, which could lead to novel quantum phenomena. The ability to enable and control noncentrosymmetry, chirality, and twisting of 2D materials open up new dimensions of quantum materials for the study of nonlinear and chiral optical properties, valleytronics and twistronics.

#### 10:30 AM EL15.03.07

**Enabling Chiroptical Properties in Achiral 2D Perovskites via Spiral Morphology** [Willa Mihalyi-Koch](#), Katherine Parrish, Randall H. Goldsmith and Song Jin; University of Wisconsin-Madison, United States

Chiral 2D halide perovskites are promising semiconducting materials for chiroptoelectronic and spintronic applications. Chirality is typically imparted into 2D perovskites through the incorporation of chiral ammonium spacer cations, resulting in a chiral crystal structure. However, the extent of chirality transfer from the chiral organic cations to the inorganic perovskite network remains debated. In this work, we present another approach to introduce chirality and chiroptical properties into 2D perovskites through nanostructure morphology. By tuning crystallization conditions at an air-water interface, a large family of 2D perovskites with achiral crystal structures can be directly grown into spiral microplates via a screw dislocation growth mechanism. We demonstrated the versatility of this method by synthesizing spiral microplates of 10 different 2D Ruddlesden-Popper lead halide perovskites with various spacer cations,

A-site cations,  $n$  number, and halide anions. The microplates can then be transferred to arbitrary substrates and characterization with atomic force microscopy clearly revealed the spiral centers. Fluorescence-detected circular dichroism (FDCD) microscopy was used to investigate the resulting chiroptical properties of individual chiral objects and large, spatially dependent  $g$ -factors on the order of  $10^{-3}$  were observed from  $(\text{BA})_2(\text{MA})_2\text{Pb}_3\text{I}_{10}$  spiral microplates. These results show that screw dislocation-driven growth can be used as a generally applicable method for enabling chirality and chiroptical properties in 2D perovskites without the need for chiral cations.

#### 10:45 AM EL15.03.08

**Ligand-Induced Chirality in Zig-Zag Topography of Two-Dimensional Iron Hydroxide for Spin-Polarized Photon Absorption Control** [Bumchul Park](#)<sup>1,1</sup>, [Sung-Chul Kim](#)<sup>2</sup>, [Dae Beom Lee](#)<sup>3</sup>, [Jun Lu](#)<sup>1,1</sup>, [Ji-Young Kim](#)<sup>1,1</sup>, [Sang Hyun Lee](#)<sup>1,1</sup>, [Young Keun Kim](#)<sup>3</sup> and [Nicholas A. Kotov](#)<sup>1,1</sup>; <sup>1</sup>University of Michigan–Ann Arbor, United States; <sup>2</sup>Korea Institute of Science and Technology, Korea (the Republic of); <sup>3</sup>Korea University, Korea (the Republic of)

Chromagnetic nanomaterials capable of combining magnetism and chirality are of the cutting-edge engineering for spin-polarized light-matter interaction because they can modulate circularly polarized light through a magnetic field or conversely modulate the excited state and spin state of a material with circularly polarized light. However, most chiral nanomaterials, including noble metals, semiconductors, and ceramics, have a strong chiroptical response but a weak net magnetic moment, limiting to induce strong coupling with the magnetic field of photons in polarized light-matter interaction. Transition metal oxides such as Co, Fe, Ni, and Mn can offer a strong magnetic dipole moment from the exchange coupling of 3d electron spins but rarely have optical activity in the UV-Vis range. Antiferromagnet has been marginalized in spin-polarized light modulation because the net magnetic moment is canceled out by antiparallel spin sublattice leading to negligible Zeeman effect. However, unlike ferromagnetism, which is usually limited to metals, antiferromagnets offer a much greater degree of freedom to control atomic topography and spin configuration. Here, we identified that previously unknown two-dimensional (2D) topography of iron oxyhydroxide enables the arrangement of low-dimensional antiferromagnet spin chains, which can be leveraged in a magnetically tunable spin-polarized photon absorption. We found a new type of nanoscale iron oxyhydroxide, layered ferric rust (LFR), with a monoclinic structure forming in the crystallization in the presence of acetate anion. The acid ligands coordinating iron atoms induce an unexpected zig-zag stacking of dimerized FeO octahedra, leading to a layered crystal structure with extended interlayer spacing. Topotactic intercalation of enantiomeric amino acids between the sheets breaks mirror symmetry in the crystal lattice and introduces screw axis symmetry, enabling transfer chirality of amino acid to LFR crystallization, producing chiroptical active LFRs. Achiral and chiral LFRs reserve low dimensional antiferromagnet spin chains where some portion of spins can be excited into parallel spin arrangement even under low external magnetic fields at room temperature. Therefore, the chiral LFR enables spin-polarized photon absorption in the UV-Vis wavelength range by the Zeeman effect in addition to the chiroptical activity contributed by the ligand-induced mirror symmetry breaking, as manifested by magnetic circular dichroism measurement. We believe our results would be a cornerstone for designing inorganic-organic hybrid two-dimensional nanomaterials for the various chiral spintronics, optoelectronics, and catalyst fields.

#### 11:00 AM EL15.03.09

**Exceptionally Large Chiroptic Dissymmetry Factors in Films of Supramolecular Magic-Sized Clusters** [Thomas J. Ugras](#), [Yuan Yao](#), [Reilly Lynch](#) and [Richard Robinson](#); Cornell University, United States

A key goal of optical materials science is to develop self-assembling hierarchical materials from nanoparticle building blocks with interesting properties. Understanding the structure-property relationships within these systems will enable the rational design of advanced optical devices. Recently, our group has discovered that CdS magic-sized clusters organize into hexagonal fibers which can self-assemble into ordered films that have a hierarchical structure spanning seven orders of length-scale[1]. These films have demonstrated strong linear and circular dichroism (LD, CD) responses originating from transition dipole alignment and cluster-to-cluster coupling, respectively, but further characterization of the optical properties using lab-based measurements are obscured by the samples' mixed linear and chiral anisotropies[2, 3]. In this work, we pair two synchrotron techniques, microfocussed small-angle x-ray scattering (SAXS) and synchrotron radiation Mueller Matrix polarimetry (MMP) mapping, to unravel the structural and optical anisotropies present in the self-assembled nanocrystal films. These studies have revealed local chiroptical properties stronger than previous measurements from lab instruments; in fact, our measured dissymmetry factors (i.e., absorption  $g$ -factor) are the largest reported for inorganic semiconductors, and only an order of magnitude smaller than the theoretical maximum limit of 2. The MMP mapping reveals that the self-organized films contain millimeter-scale domains with a constant CD magnitude and handedness, whereas isotropic films (non-self-assembled) present much smaller micron-scale domains. Further, MMP and SAXS measurements show that within self-assembled, anisotropic films the transition dipoles of the clusters are macroscopically oriented in the same direction as the nm-scale fibers. In summary, these experiments have revealed a relationship between the self-assembly process, the orientation of supramolecular nanocrystal fibers, and the handedness of a film's response. These results - anomalously large chiral anisotropy, orientational control of the clusters and their transition dipoles, and enantiomeric control of chiral domains within nanocrystal films - enable chiral light control for a range of emerging technologies.

#### 11:15 AM EL15.03.10

**Decomposition of Layered Double Hydroxides for Accessing Chiral Metal Oxides** [Áine Coogan](#)<sup>1</sup>, [Lucia Hughes](#)<sup>1,1,1</sup>, [Finn Purcell-Milton](#)<sup>1,2,3</sup>, [Seán Cardiff](#)<sup>1,1</sup>, [Valeria Nicolosi](#)<sup>1,1,1</sup> and [Yurii K. Gun'ko](#)<sup>1,3,1</sup>; <sup>1</sup>Trinity College Dublin, The University of Dublin, Ireland; <sup>2</sup>Technological University Dublin, Ireland; <sup>3</sup>University College Dublin, Ireland

In recent years, significant research efforts have been directed towards the development of chiral and chiroptically active inorganic nanomaterials, resulting in many new nanomaterials of various forms and morphologies, including quantum dots, nanowires, and tetrapods, among others.<sup>1-3</sup> Layered double hydroxides (LDHs) have emerged as a distinct class of ionic two-dimensional (2D) nanomaterials, renowned for their exceptional anion exchange properties, allowing for the incorporation of diverse species within their interlayer spaces, including chiral molecules. Surprisingly, despite this unique characteristic, there is a notable absence of reported studies exploring the utilisation of LDHs treated with chiral ligands to induce chiroptical activity. While chiral copper (II) oxide (CuO) nanostructures have previously been documented in literature, their synthesis often requires harsh, high-temperature synthetic conditions and the inclusion of expensive surfactants and symmetry-breaking agents to induce circular dichroism (CD) responses in the visible range.<sup>4-5</sup> Prior to this work, the room temperature synthesis of chiral CuO has remained un-explored to the best of our knowledge. Additionally, the potential for chirality transfer from chiral ligands to LDH-based nanostructures has not been reported. Herein, we present the unique facile approach to the synthesis of chiral CuO nanostructures through an alkaline room-temperature, aqueous treatment of carbonate-intercalated copper-aluminium LDHs (CuAl-CO<sub>3</sub> LDHs) with L- and D-Phenylalanine (L- and D-Phe). The resulting 2D CuO nanosheet bundles

display remarkable chiroptical activity, with  $g$ -factors up to 0.0035. Time-dependent circular dichroism (CD), powder X-ray diffraction (pXRD) and Fourier transform infrared spectroscopy (FT-IR) studies reveal that the initial chirality transfer arises from Phe coordination to the  $\text{Cu}^{2+}$  sites, leading to decomposition of the  $\text{CuAl-CO}_3$  LDH to  $\text{CuO}$ . Self-assembly of the Phe-functionalised  $\text{CuO}$  nanosheets results in enhancement of the chiroptical activity. This work represents a novel, facile route of accessing chiral metal oxides through decomposition of LDH precursors. The ease of synthesis and induction of strong chiroptical activity in the visible range (400-800 nm) highlights the significance of this work. The resultant new chiral metal oxides hold promise for potential applications in enantiomeric separation and asymmetric catalysis, paving the way for advancements in chiral nanomaterial research.<sup>6</sup>

**DNA-Templated Silver Nanoclusters with Strong Chiroptical Response in the Visible Spectral Region** Rweetuparna Guha, Anna Gonzalez Rosell, Malak Rafik and Stacy Copp; University of California, Irvine, United States

DNA can template the chemical synthesis of few-atom silver nanoclusters with defined chiralities and strong electronic circular dichroism (CD) response. These " $\text{Ag}_N$ -DNAs" have a diversity of sizes, shapes, and optical properties that are selected by the nucleobase sequence of their DNA ligands. Composed of just 10-30 Ag atoms and 1-3 short DNA oligomers, most studies of  $\text{Ag}_N$ -DNAs have focused on their bright visible to near-infrared fluorescence. The DNA sequence-selected chiroptical properties of  $\text{Ag}_N$ -DNAs are also of both fundamental and applied interest and have been far less studied. As an inherently chiral ligand, DNA selects for nanocluster chirality without the need for intensive separation techniques that are typically required for metal nanocluster enantiomer separation, such as chiral chromatography. The chiral properties of  $\text{Ag}_N$ -DNAs hold promise for biomolecular sensing and nanophotonics applications. However, studies of the chirality of  $\text{Ag}_N$ -DNAs prepared to atomic precision are limited to date, and few X-ray crystallographic structures have been reported.

To understand the chiral properties of  $\text{Ag}_N$ -DNAs, we investigated a large set of 19 different atomically precise  $\text{Ag}_N$ -DNA species with emission at the far red/NIR spectral border [1]. The molecular formula of each purified species is determined by high-resolution mass spectrometry and correlated to its optical absorbance, emission, and CD spectra. We find that these  $\text{Ag}_N$ -DNAs are either 6-electron clusters or 8-electron clusters (corresponding to the oxidation state of the silver nanocluster), with distinct absorbance and CD spectral features for these two classes of nanoclusters. 8-electron  $\text{Ag}_N$ -DNAs are stabilized by two DNA oligomer copies and display complex CD spectra with multiple distinct UV and visible transitions. The electron count of these "magic-sized" 8-electron nanoclusters suggests quasispherical geometries. 6-electron  $\text{Ag}_N$ -DNAs, which past studies support have rod-like shapes, exhibit three different ligand compositions, each with its own characteristic CD signatures.  $\text{Ag}_N$ -DNAs stabilized by two oligomer copies exhibit a distinct positive or negative monosignate CD signature aligned with the longest visible absorbance peak of the nanocluster, suggesting a chiral nanocluster core whose handedness is selected by the specific DNA template sequence.  $\text{Ag}_N$ -DNAs stabilized by three oligomer copies exhibit the same visible CD signature but distinct UV CD signatures, suggesting that DNA ligands adopt similar conformations around nanoclusters with three DNA ligands. Finally,  $\text{Ag}_N$ -DNAs stabilized by two oligomer copies and additional chlorido ligands exhibit significantly suppressed visible CD signatures, supporting that the additional atomic ligands suppresses nanocluster chirality. The distinct chiroptical signatures and compositions of these four classes of  $\text{Ag}_N$ -DNAs also correlate to distinct excited state emission properties, suggesting that nanocluster electron count and chirality influences both ground and excited state processes in these emitters. This study illustrates the diversity of structure-property relationships for NIR-emissive  $\text{Ag}_N$ -DNAs, which could be harnessed to precisely tune these emitters for applications that exploit their DNA sequence-selected chiral properties. Moreover, the results show that the chiroptical properties of  $\text{Ag}_N$ -DNAs are highly sensitive to nanocluster composition and ligand conformation.

#### SESSION EL15.04: Interaction Between Spin and Structural Chirality in Materials

Session Chairs: Matthew Beard and Hanyu Zhu

Tuesday Afternoon, November 28, 2023

Hynes, Level 2, Room 207

#### 1:30 PM \*EL15.04.01

**Magnetic Chirality** Sang Wook Cheong and Xianghan Xu; Rutgers University, United States

Chirality, which arises from the breaking of mirror symmetries combined with any spatial rotations, is a fundamental concept that plays a pervasive role in a wide range of phenomena from the functionality of DNA, vine climbing to the piezoelectricity of quartz crystals. It is worth noting that chirality does not always involve a twisting resembling a screw. In the context of magnetic systems, chirality refers to the presence of chirality in spin ordered states or mesoscopic spin textures. The term "chirality" has been extensively used in the physics community in recent years, often leading to confusion due to its various interpretations. To provide clarity, we define that in steady states, chirality ( $C$ ) remains unchanged under time-reversal operations, whereas chirality prime ( $C'$ ) represents the breaking of both time-reversal and mirror symmetries combined with spatial rotations. This colloquium aims to explore different examples of magnetic chirality and chirality prime, along with the emergent phenomena associated with them. These phenomena include self-inductance, directional nonreciprocity in magnetic fields, current-induced magnetization, chirality-selective spin-polarized current, Schwinger scattering, magneto-optical Kerr effect, and linear magnetoelectricity. While some of these exotic phenomena have been recently observed, many others still require

experimental confirmation in the future.

**Chiral States of Electrons and Spins and Their Electromagnetic Signatures** Joel Moore<sup>1,2</sup>; <sup>1</sup>University of California, Berkeley, United States; <sup>2</sup>Lawrence Berkeley National Laboratory, United States

Chiral crystal structures allow optical effects such as natural optical activity, which has long been used to identify chirality. While the symmetry analysis of structural chirality and optical response was carried out many years ago, the details of how microscopic electron wavefunctions generate observed chirality were not completely understood even in the linear case. Studies motivated by the experimental discovery of Weyl semimetals clarified the origin of chirality at low frequency in all chiral metals (the chiral or gyrotropic magnetic effects) and the importance of the orbital magnetic moment. Weyl semimetals are more unique in their *nonlinear* optical properties, where chiral Weyl semimetals show an exciting kind of quantization in their chiral photocurrent or chiral magnetic effect at the non-interacting level. The second part of the talk concerns how interactions between electrons or spins can lead to the spontaneous development of a chiral order parameter. The specific example discussed in detail is the behavior of triangular lattice Mott insulators, where a chiral spin liquid is shown numerically and analytically to be a competitive state arising near the Mott transition. Experimental signatures of this state, and the rapidly developing experimental situation of triangular lattice compounds, are discussed as an example of how new techniques allow greater understanding of correlated lattice problems.

**Chiral Magneto-Optical Properties and Chiral Spintronics Based on Chiral Halide Perovskites** Lan-Sheng Yang, Pei-Hsuan Lo, Chin-An Hsu, Yi-Hsiu Hua and Yu-Chiang Chao; National Taiwan Normal University, Taiwan

Chiral halide perovskites can be prepared by solution processing using a mixture of a lead halide and a chiral organic halide as a precursor. Examples of chiral organic halides are *R*- and *S*-methylbenzylammonium halide and *R*- and *S*-1-(2-naphthyl)ethylammonium halide. In this presentation, we will present the chemical composition, morphology, absorption, photoluminescence, quantum yield and carrier lifetime of chiral perovskite films prepared from precursor solutions with different stoichiometric ratios and different halide ratios. The chiral halide perovskite films exhibit chiroptical properties, such as circular dichroism and circularly polarized luminescence, in the absence of an external magnetic field. Symmetrical circular dichroism spectra were obtained. The energy level splitting induced by chiral molecules was estimated by using multiple Gaussian fitting. Once the magnetic field is applied, the magnetic field-induced CD features are superimposed on the intrinsic chirality-induced CD features. In addition, spin organic light-emitting diodes were realized by using chiral halide perovskite film as the spin-polarized hole transport layer. At room temperature, circularly polarized electroluminescence was observed from the spin organic light-emitting diodes in the absence of an external magnetic field.

### 2:45 PM EL15.04.04

**Evaluation of the Spin Splitting of Chiral Perovskites via Circular Photogalvanic Effect** Taishi Noma<sup>1</sup> and Daigo Miyajima<sup>1,2,3</sup>; <sup>1</sup>RIKEN, Japan; <sup>2</sup>The University of Tokyo, Japan; <sup>3</sup>The Chinese University of Hong Kong, China

In materials that exhibit spin splitting, a zero-bias photocurrent can be generated by circularly polarized light. This phenomenon is called circular photogalvanic effect (CPGE), and CPGE had been investigated exclusively in inorganic materials.<sup>[1]</sup> However, recently, CPGE has been observed also in chiral perovskites, where chiral organic molecules are incorporated into inorganic perovskite frameworks.<sup>[2,3]</sup> It is reported that the direction of the CPGE current in chiral perovskites is reversed depending on the chirality, which could provide novel functionalities for spintronic devices. Nevertheless, the CPGE of chiral perovskites has not been well investigated. The chirality-dependent CPGE of chiral perovskites originates from Dresselhaus effect, which is caused by the inversion asymmetry at crystal structures. However, Rashba effect, which is caused by the inversion asymmetry at surfaces or interfaces, can also occur in chiral perovskites with strong spin-orbit coupling (SOC). Rashba effect is promising for spintronic application because the strength of SOC can be tuned by external voltages. Therefore, it is of great importance to clarify the contribution of Rashba and Dresselhaus effects in the observed CPGE currents. In this study, we observe the CPGE of ((*R/S*)-(-)-1-cyclohexylethylamine (*R/S*-CYHEA))<sub>8</sub>Pb<sub>3</sub>I<sub>14</sub> single crystals possessing chiral-polar crystal structures (space group is *P*2<sub>1</sub>), and evaluate the contribution of Rashba and Dresselhaus effects.

To evaluate the contribution of Rashba and Dresselhaus effects, we compared the CPGE currents of (*R*-CYHEA)<sub>8</sub>Pb<sub>3</sub>I<sub>14</sub> and (*S*-CYHEA)<sub>8</sub>Pb<sub>3</sub>I<sub>14</sub>, generated along the nonpolar axis in the crystals. As reported in our previous work,<sup>[3]</sup> we observed the chirality-dependent CPGE current of the (*R/S*-CYHEA)<sub>8</sub>Pb<sub>3</sub>I<sub>14</sub> based on the Dresselhaus effect, by obliquely irradiating light in the incident plane parallel to the measurement direction of photocurrent. In our experiment, in theory, the CPGE current based on Dresselhaus effect can be generated regardless of the incident planes of light, whereas the CPGE current based on Rashba effect can be generated only in the direction perpendicular to the incident plane of light. Therefore, by obliquely irradiating light in the incident plane perpendicular to the measurement direction of photocurrent, it is possible that we can observe the CPGE current induced by both Rashba and Dresselhaus effects. Results showed that the CPGE of (*R*-CYHEA)<sub>8</sub>Pb<sub>3</sub>I<sub>14</sub> was negligibly small, whereas that of (*S*-CYHEA)<sub>8</sub>Pb<sub>3</sub>I<sub>14</sub> was significantly large. Importantly, the direction of the CPGE current based on the Rashba effect is identical regardless of the chirality, which is in contrast to that based on the Dresselhaus effect. Hence, it could be reasonable that the magnitudes of the CPGE currents of (*R*-CYHEA)<sub>8</sub>Pb<sub>3</sub>I<sub>14</sub> and (*S*-CYHEA)<sub>8</sub>Pb<sub>3</sub>I<sub>14</sub> were significantly different due to the contribution of both Rashba and Dresselhaus effects.

We investigated the contribution of Rashba and Dresselhaus effects to the CPGE of chiral perovskites. In the presentation, we will quantitatively discuss the contribution of Rashba and Dresselhaus effects.

**Chiral Discrimination and Dispersion Intermolecular Forces** Vladimiro Mujica<sup>1</sup> and Rafael Gutierrez<sup>2</sup>; <sup>1</sup>Arizona State University, United States; <sup>2</sup>Dresden University of Technology, Germany

Intermolecular London dispersion forces, responsible for van der Waals (vdW) interactions, are due to induced-electric dipole induced-electric dipole interaction. They can be affected by molecular chirality in an unexpected way that is connected to the Chiral-Induced Spin Selectivity (CISS) effect, which provides a physical mechanism for the onset of an effective vdW interaction that depends on the relative orientation of the two enantiomers associated to a chiral molecule. This argument provides a path for chiral discrimination, which plays a fundamental role in molecular recognition of bio-molecules and the

design of chiral material interfaces.

In this contribution, we will explicitly describe a simple model to explore the influence of the CISS effect in vdW forces, and the way this leads to molecular chiral discrimination.

**Theoretical Perspective on Chirality-Induced Spin Selectivity and Chiroptical Properties in Layered Halide Perovskites** Mikael Kepenekian<sup>1</sup>, Claudine Katan<sup>1</sup>, Simon Thébaud<sup>2</sup>, Jacky Even<sup>2</sup>, Shangpu Liu<sup>3</sup>, Felix Deschler<sup>3</sup>, Alexandre Abhervé<sup>4</sup> and Nicolas Mercier<sup>4</sup>; <sup>1</sup>University of Rennes, France; <sup>2</sup>INSA Rennes, France; <sup>3</sup>Heidelberg University, Germany; <sup>4</sup>University of Angers, France

3-dimensional (3D) halide perovskites  $AMX_3$  (A: organic cation, M: metal ion, X: halide) have shown spectacular results in optoelectronic devices. However, they offer limited choice of metals and organic cations, which limits the chemical design of optimal materials. This is not the case of lower dimensional materials, e.g. layered (2D) halide perovskites (LHPs) [1], that impose far less constraints over the organic spacer. It then become possible to associate the exceptional optoelectronic properties of halide perovskites with chiral cations to reach promising materials for chiroptical and magnetochiral applications [2].

Here, we report joint experimental and theoretical investigations of LHPs with exceptional (i) chiroptical, and (ii) magnetochiral properties. Firstly, the enantiopure  $3BrMBA_2PbI_4$  (MBA = methylbenzylammonium) perovskite thin films exhibit external photoluminescence quantum efficiency as high as 39% and circularly polarized photoluminescence up to 52%, at room temperature [3]. Next, we consider a series of chiral lead-bromide networks which crystallize in enantiomorphic polar space groups  $P4_12_1$  and  $P4_32_1$  for the R and S enantiomers, respectively [4]. Chirality-induced spin selectivity (CISS) effect measurements performed over those materials by magnetic conducting-probe atomic force microscopy (mc-AFM) reveal a spin polarization of about 40% [4].

We use a set of experimental characterizations (e.g. single-crystal x-ray diffraction), and theoretical tools (semi-empirical modeling and density-functional theory based calculations) to describe the chiral-related properties of these LHPs and help the cation engineering of efficient chiral halide perovskites.

**Spin Polarized Current Injection from Chiral Halide Perovskites into III-V LEDs** Matthew Hautzinger, Kirstin M. Alberi and Matthew C. Beard; National Renewable Energy Laboratory, United States

Spintronic applications integrating conventional group IV and III-V semiconductors suffer from a lack of efficient spin injection techniques. Most works rely on a ferromagnetic layer in combination with a tunnel oxide barrier, to avoid the conductivity mismatch, to inject spin polarized current into the semiconductor. These complicated interfaces are susceptible to defect chemistries inhibiting efficient spin polarized carrier injection. Here, we integrate semiconducting chiral halide perovskite,  $(R/S-MBA)_2PbI_4$  (MBA = alpha-methylbenzylammonium) with III-V AlGaInP LEDs. The semiconducting  $(R/S-MBA)_2PbI_4$  injects spin polarized current into the AlGaInP via the chirality induced spin selectivity effect. The spin polarized current produces circularly polarized electroluminescence, with efficiencies regularly achieved of 10 +- 3% at room temperature and no external magnetic field applied. This remarkable efficiency is due to the pristine semiconductor-semiconductor interface between the  $(R/S-MBA)_2PbI_4$  and AlGaInP which avoids the problematic conductivity mismatch of ferromagnetic-semiconductor interfaces. We characterized this interface with TEM, XPS, and cross sectional KPFM to show it has excellent interfacial properties with no unintentional barriers introduced. We further prove the circularly polarized emission is the result of spin polarized current injection by measuring the Hanle effect. We observe a decrease in circularly polarized light emission with the application of a magnetic field, as expected from spin polarized current injection. These results present a new method of spin polarized current injection, enabled by a semiconducting CISS layer, which can be applied to numerous spintronic applications.

**Structure-Property Tunability using Chirality and Symmetry Breaking in Hybrid 2D Perovskites** David B. Mitzi; Duke University, United States

Hybrid organic-inorganic perovskite (HOIP) semiconductors based on metal halide frameworks offer unprecedented opportunity to tailor structural and materials properties using the full flexibility afforded by the associated inorganic and organic components,<sup>1</sup> and such tunability offers wide-ranging potential for applications including solar cells, light-emitting devices, detectors, transistors and advanced computing devices. In this talk we will focus on examining the role that the organic cation can play in introducing or impacting chirality, symmetry breaking and associated phase transitions within HOIPs, as well as on the resulting chiroptical (e.g., circularly dichroism),<sup>2</sup> spin-selective charge transport (e.g., chirality-induced spin selectivity),<sup>3</sup> and electronic structure (e.g., spin splitting of the conduction band)<sup>4</sup> characteristics of these systems. Recent examples of such symmetry-related tunability highlight the promise of using the organic component to control light, charge and spin within the wide-ranging HOIP family.

**Proximity-Effect-Induced Remote Chirality Transfer in Halide Perovskites** Md Azimul Haque<sup>1</sup>, Roman Brunecky<sup>1</sup>, Junxiang Zhang<sup>2</sup>, Yifan Dong<sup>1</sup>, Matthew P. Hautzinger<sup>1</sup>, Steven P. Harvey<sup>1</sup>, Seth R. Marder<sup>2</sup>, Matthew C. Beard<sup>1</sup> and Joseph Luther<sup>1</sup>; <sup>1</sup>National Renewable Energy Laboratory, United States; <sup>2</sup>University of Colorado Boulder, United States

Hybrid organic/inorganic halide perovskites are intriguing chiral material systems owing to their excellent optoelectronic properties and potential to impart chirality with the organic A-site cation. Typically, chiroptical properties arise due to structural symmetry breaking from chiral A-site organic cation to the inorganic framework. In the present work, we demonstrate a proximity effect of remote chirality transfer to induce chirality in otherwise *achiral* 2D halide perovskites. A chiral organic ligand is introduced in the perovskite lattice without altering the structure, thus introducing chirality into existing 2D perovskites. Furthermore, we construct a chirality-composition library with varying the A, B, X-sites, along with the dimensionality, revealing the essential role of each atomic component in the perovskite structure. This approach of remote chirality transfer in halide perovskites could lead to new prospects in terms of composition, spin transport properties, and devices without extensive chemical modifications.

**The Real Origin of Apparent Circular Dichroism in Chiral Perovskites** Sunihl Ma<sup>1</sup>, Bumchul Park<sup>1</sup>, Sang Hyun Lee<sup>1</sup>, Jooho Moon<sup>2</sup> and Nicholas A. Kotov<sup>1</sup>; <sup>1</sup>University of Michigan–Ann Arbor, United States; <sup>2</sup>Yonsei University, Korea (the Republic of)

Chirality, a fundamental concept for matters that cannot be super-imposed with their mirror images, is ubiquitous in almost all branches of natural science. Due to significance of chirality and wide versatility of chiral materials, in recent years, the concept of chirality can be successfully expanded to variety of different material including quantum dots, liquid crystals, and organic-inorganic hybrid system. Especially, chiral perovskite materials have attracted unprecedented attention as a new type of chiral semiconductors since the first report of chiroptical response in 2017. Different from the inherent chiral organic materials, chirality transfer from chiral organic spacer to achiral inorganic frameworks should be preceded to achieve chiroptical activity in chiral perovskite. Although extensive studies have reported the circular dichroism (CD) in chiral perovskite, the origin of chiroptical response in chiral perovskite ambiguous. Furthermore, several groups reported CD sign inversion behavior when flipping thin films samples, implying that the observed CD signal from chiral perovskite thin films might be originated from linear effects. However, due to the poor understanding of CD mechanism and inherent limitation of commercial CD spectrometers, the macroscopic origin of apparent CD behavior has been incorrectly interpreted. From this point of view, we investigate the real origin of apparent and genuine CD response in chiral perovskite thin films by using our home-made Mueller matrix polarimeter (MMP). Interestingly, based on experimental results from MMP and theoretical decomposition of Mueller matrix parameters, we found that apparent CD behavior is primarily originated from linear birefringence (LB) effects rather than linear dichroism (LD) behavior which is attributed to microscopy preferred orientation of thin films. Furthermore, polarization optical microscopy confirmed that LB effect is closely related with second-order ferroelectric phase transition behavior. To the best of our knowledge, this is first systematic study to clarify the real origin of apparent CD behavior based on the decomposition of Mueller matrix parameter, which is different from the interpretation based on ambiguous LDLB effect. Our study unveils the importance of the LB effect on the CD behavior of thin films and provide an in-depth understanding between ferroelectricity and chiroptical response.

**Fluorinated Structural Isomers in 2D Chiral Perovskites Enabling Efficient Stable Spin-Dependent Oxygen Evolution Reaction** Jaehyun Son<sup>1</sup>, Sunihl Ma<sup>2</sup>, Hyungsoo Lee<sup>1</sup>, Gyumin Jang<sup>1</sup>, Chan Uk Lee<sup>1</sup>, Seongyeon Yang<sup>1</sup>, Subin Moon<sup>1</sup>, Junwoo Lee<sup>1</sup>, Wooyong Jeong<sup>1</sup> and Jooho Moon<sup>1</sup>; <sup>1</sup>Yonsei University, Korea (the Republic of); <sup>2</sup>University of Michigan–Ann Arbor, United States

Spin-dependent electrochemistry is introduced as an innovative concept for boosting overall photoelectrochemical (PEC) efficiency. Especially, the performance of oxygen evolution reaction (OER) can be improved by the chirality-induced spin-selectivity (CISS) phenomenon based on chiral materials. The CISS can effectively reduce the overpotential of the OER process by aligning the electron spins with specific directions. The parallel-aligned electron spins favor the generation of triplet oxygen (<sup>3</sup>O<sub>2</sub>), which is energetically more stable than the singlet oxygen state (<sup>1</sup>O<sub>2</sub>), while refraining from the formation of competitive by-product of hydrogen peroxide. In this regard, the chiral 2D organic-inorganic hybrid perovskites (OIHP) are considered as a promising spin filter due to their exceptional spin-polarization capability of over 80%. However, there are still underlying intrinsic obstacles to exploit chiral 2D OIHPs as spin filters for OER devices. The 2D OIHPs structures have poor conductivity along with out-of-plane direction where multiple spin-alignment occurs, which restricts further enhancement of OER performance. Such a problem stems from the multi-quantum well structures of OIHPs composed of two repeating building blocks, namely organic cations and inorganic frameworks. In addition, the vulnerability of 2D OIHPs to water is attributed to the hygroscopic nature of the organic cations, which becomes another hindrance to accomplishing the long-term operational stability of OER devices. Therefore, it is essentially necessary to develop groundbreaking materials that can promote electrical properties and moisture instability while maintaining the chirality of OIHPs.

Herein, we introduce chiral 2D OIHPs fluorinated methyl-benzylamine (F-MBA) chiral structural isomer cations, which have different structures according to the fluorine location of ortho-, meta-, and para- on the benzene ring. The chirality of the 2D OIHPs can be augmented according to the specific chiral cation structures originating from the intensified organic-inorganic halogen-halogen interactions. Moreover, the fluorinated chiral organic cations can not only endow hydrophobic characteristics to OIHP systems but also enhance the out-of-plane conductivity by reducing the exciton binding energy. As a result, we have implemented the fluorinated 2D OIHPs film on top of BiVO<sub>4</sub> photoanode for oxygen production. The fluorinated OIHPs spin filter dramatically reduces the overpotential with improved operational stability. Our results suggest a promising material design rule to fabricate stable and efficient chiral 2D OIHPs spin filter for spin-dependent applications.

#### 10:45 AM EL15.05.05

**Chiral Cation Doping for Modulating Structural Symmetry of 2D Perovskites** Yi Xie<sup>1,1</sup>, Jack Morgenstein<sup>1</sup>, Benjamin Bobay<sup>1</sup>, Ruyi Song<sup>1</sup>, Naidel Caturello<sup>2</sup>, Peter C. Sercel<sup>3</sup>, Volker Blum<sup>1,1</sup> and David B. Mitzi<sup>1,1</sup>; <sup>1</sup>Duke University, United States; <sup>2</sup>Federal University of ABC, Brazil; <sup>3</sup>Center for Hybrid Organic Inorganic Semiconductors for Energy, United States

Cation-mixing in two-dimensional (2D) hybrid organic-inorganic perovskite (HOIP) structures represents an important degree of freedom for modifying organic templating effects and tailoring inorganic structures. However, the limited number of known cation-mixed 2D HOIP systems generally employ a 1:1 ratio of cations for stabilizing the 2D perovskite structure. Achieving more general cation mixing ratios should allow greater control over accessing lower symmetry structures and therefore opportunities for modulating and enhancing emergent symmetry-sensitive properties. Here we demonstrated a chiral-chiral mixed-cation system wherein a controlled small amount (<5 %) of chiral cation S-2-MeBA (S-2-MeBA = (S)-(-)-2-methylbutylammonium)

can be doped into (S-BrMBA)<sub>2</sub>PbI<sub>4</sub> (S-BrMBA = (S)-(-)-4-bromo- $\alpha$ -methylbenzylammonium), modulating the structural symmetry from a higher symmetry (*C*<sub>2</sub>) to the lowest symmetry state (*P*<sub>1</sub>). This structural change occurs when the concentration of S-2-MeBA, measured by solution nuclear magnetic resonance, exceeds a critical level—specifically, for 1.4  $\pm$  0.6 %, the structure remains as *C*<sub>2</sub>, whereas 3.9  $\pm$  1.4 % substitution induces the structure change to *P*<sub>1</sub>. Atomic occupancy analysis suggests that one specific S-BrMBA cation site is preferentially substituted by S-2-MeBA in the unit cell, which rearranges the organic layer to break *C*<sub>2</sub> rotational symmetry. Density-functional theory calculations indicate that the spin splitting along different k-paths can be modulated by cation doping. A true circular dichroism band at the exciton energy of the 3.9% doping phase shows polarity inversion and a ~45 meV blue shift of the Cotton-effect-type line-shape relative to (S-BrMBA)<sub>2</sub>PbI<sub>4</sub>. A trend toward suppressed melting temperature with higher doping concentration was observed. The chiral cation doping system and the associated doping-concentration-dependent structural transition provide a material design strategy for controlling and enhancing symmetry-related properties, such as chiroptical, non-linear optical, spin-related, and ferroelectric properties.

#### 11:00 AM EL15.05.06

**Boosting Non-Centrosymmetric Distortion and Magnetic Properties in Chiral Metal Halide Perovskites** Sanghyun Nam<sup>1</sup>, Jaewook An<sup>2</sup>, In Hyeok Park<sup>2</sup> and Young Hoon Kim<sup>1</sup>; <sup>1</sup>Hanyang University, Korea (the Republic of); <sup>2</sup>Chungnam National University, Korea (the Republic of)

Control of spin-polarized currents and magnetic properties in materials are important to demonstrate various spintronic applications such as MRAM and spin LEDs. In conventional semiconductors and metals, spin polarization and magnetization occur by the application of external magnetic fields or fabrication of ultra-thin (<5 nm) layer of the materials, which complicate the fabrication process and device structure. Here, we report novel materials system, hybrid chiral metal-halide perovskites (MHPs), which can control the spin polarization and magnetic properties via simple solution process. MHPs consist of three different atoms or molecules in various crystal structures (representations are ABX<sub>3</sub> and A<sub>2</sub>BX<sub>4</sub> where A is an organic ammonium, B is a transition metal cation and X is a halide anion). First, we synthesize chiral lead (Pb)-based MHPs ((R-/S-MBA)<sub>2</sub>PbI<sub>4</sub> where MBA is methylbenzylammonium) and find that R-/S-MBA cations transfer the chirality to the inorganic metal-halide octahedra (PbI<sub>6</sub>) by the asymmetric electrostatic interaction between ammonium group in MBA and halide in inorganic octahedra. (R-/S-MBA)<sub>2</sub>PbI<sub>4</sub> polycrystalline thin films show circular dichroism (CD) signals with opposite directions which are dependent on the chiral direction of MBA. Furthermore, (R-/S-MBA)<sub>2</sub>PbI<sub>4</sub> show efficient spin selectivity > 80% without external magnetic fields by the chiral-induced spin selectivity (CISS) effect. Second, to solve the toxic problem in Pb-based MHPs, we synthesize Pb-free chiral MHPs that use palladium (Pd) in B site cation. Pd-based MHPs have 0-dimensional orientation of Pd-halide square-planar, where the direction of the orientation depends on the chiral direction in A-site cation, and increased CD signals when mixed halides are used in X-site (anisotropy g-factor ( $g_{CD}$ ) = 3.3  $\times$  10<sup>-3</sup> in pure chloride, 1.2  $\times$  10<sup>-2</sup> in pure bromide, 1.8  $\times$  10<sup>-2</sup> when Br<sub>0.5</sub>Cl<sub>0.5</sub>). We also measured the spin selectivity in Pd-based chiral MHPs. Third, to induce magnetic properties in MHPs in addition to the chirality, we synthesize iron (Fe)-based chiral MHPs with different Fe compositions. Fe-based chiral MHPs show CD signals in the absorption range of metal-halide tetrahedra, which clarify that R-/S-MBA transfers its chirality to the metal-halide tetrahedra. Furthermore Fe-based chiral MHPs exhibit paramagnetism at low temperature, which demonstrate the potential of future MHP materials which have both chirality and magnetic properties.

#### 11:15 AM EL15.05.07

**Highly Efficient Chiral 2D/3D Perovskite Artificial Leaf for Spin-Dependent Photoelectrochemical Overall Water Splitting** Hyungsoo Lee, Chan Uk Lee, Juwon Yun, Wooyong Jeong, Chang-Seop Jong, Jaehyun Son, Young Sun Park, Subin Moon and Jooho Moon; Yonsei University, Korea (the Republic of)

The intricate nature of the multi-step oxygen evolution reaction (OER) continues to pose a challenge in achieving bias-free photoelectrochemical water-splitting systems. Several theoretical and experimental studies have suggested that OER efficiency can be significantly improved in chiral material-based photoanodes by utilizing the chirality-induced spin selectivity (CISS) phenomenon. The final product at the photoanode is the oxygen molecules, where the spin alignment of intermediate radicals is favorable to the generation of triplet <sup>3</sup>O<sub>2</sub> (most stable molecular oxygen species). Considering the energy difference between a singlet <sup>1</sup>O<sub>2</sub> and triplet <sup>3</sup>O<sub>2</sub> (the energy of a singlet <sup>1</sup>O<sub>2</sub> is approximately 100 kJ mol<sup>-1</sup> higher than that of triplet <sup>3</sup>O<sub>2</sub>), spin-dependent chemical reactions combined with the CISS phenomenon can play a crucial role in facilitating the OER process. Especially, by promptly aligning the spin distribution of photo-generated charges within the absorber, it could effectively prevent the formation of hydrogen peroxide, leading to a dramatic reduction in overpotential. In this regard, the incorporation of a chiral spin-filter layer on top of the absorber has been recognized as a promising strategy to achieve a significant enhancement on the PEC performance of the solar-driven water splitting system.

Chiral 2D OIHPs have been conventionally employed as spin-filter layer with two distinct enantiomers, namely *R*- and *S*-methyl benzylamine (*R*- and *S*-MBA). Owing to the weak  $\pi$ - $\pi$  interaction of the MBA organic cation, however, the coupling effect between the  $\pi$ -electron and p-orbital of the halide in the inorganic framework is relatively weak in chiral 2D OIHPs. To reinforce the coupling effect of chiral 2D OIHPs, we utilized naphthyl ethylamine (NEA) capable of stronger  $\pi$ - $\pi$  stacking interaction between naphthalene rings. Moreover, the introduction of NEA organic cations can simplify the molecular arrangement of chiral 2D OIHPs, leading to enhanced film crystallinity and improved chiroptical properties. Herein, we demonstrated that the CISS phenomena can become a remarkable approach by adopting NEA-based chiral 2D OIHPs as a spin-filtering layer on the 3D OIHPs photoanode. Our chiral 2D OIHPs exhibited an impressive CISS efficiency of approximately 95%, indicating a remarkable achievement in spin controlling when compared to other chiral materials. Moreover, chiral 2D/3D OIHPs-based water-splitting device achieved enhanced oxygen evolution performance with a reduced overpotential of 0.2 V, high fill factor, and increased photocurrent of 22 mA cm<sup>-2</sup> at 1.2 V<sub>RHE</sub> compared to a device without a spin-filtering layer. For unbiased water splitting, a perovskite-based photocathode decorated with a spatially decoupled hydrogen evolution reaction catalyst was fabricated. This decoupled geometry was adopted to enable the physical protection of the perovskite layer from the electrolyte, thus allowing excellent stability for over 100 h. To implement the bias-free water splitting performance, this perovskite photocathode was connected in parallel with spin-filtering layer adopted 2D/3D OIHPs-based photoanode. Overall solar-driven water splitting was achieved using all the OIHP photoelectrodes, resulting in a remarkable unassisted solar-to-hydrogen efficiency of ~13% and a continuous 100 h stable operation.

**Leveraging Chirality for Extreme Control of Light** [Andrea Alu](#); City University of New York, United States

In this talk, I will discuss our recent progress in tailored broken geometrical symmetries to control the interaction of light with structured materials and

metasurfaces. In particular, I will discuss our theoretical and experimental work on nonlocal metasurfaces supporting chiral eigenstates, locally structured with subwavelength resolution. I will also discuss the unique opportunities that chirality and rotational broken symmetry enables in the context of polaritonic systems and time metamaterials.

#### 2:00 PM EL15.06.02

**Active Chiral Plasmonic Metasurfaces** Juhwan Kim, Jang-Hwan Han, Gyurin Kim and Hyeon-Ho Jeong; Gwangju Institute of Science and Technology, Korea (the Republic of)

Chiral plasmonics offers a powerful means to control light-matter interactions based on their unique polarization-sensitive chiroptical characteristics, enabling a wide range of applications, including molecular sensing, holographic encryption, and optical filters.[1] In order to fully exploit the potential of chiral plasmonics for industrial applications, it is crucial to develop their active system that can respond to external stimuli and thus allow us to dynamically control their chiroptical responses. However, such active chiral plasmonics are still in their early stages of development. Here, we present an active chiral plasmonic metasurface capable of dynamically controlling the chiroptical response through combinatorial modulation of both the state of light polarization and an external electrical input. The metasurface consists of a wafer-scale array of chiral nanohelices grown using a physical shadow growth technique, with a conductive polymer shell polymerized around the entire surface of helices. The intrinsic dissymmetry factor of this chiral plasmonic metasurface exceeds 0.1, leading to rich polarization-dependent colors. To achieve further extended color dynamics, we electrochemically control the redox state (i.e., refractive index) of the conductive polymer shell, thereby inducing changes in the plasmonically resonating colors of the nanohelices.[2] Remarkably, in conjunction with controlling the state of the light polarization, we achieve full-color dynamics from the single chiral plasmonic metasurface, driven by just input voltages of less than 1 V, highlighting its potential applications in electrochromic displays and filters. In this presentation, we will discuss the successful fabrication of these chiral plasmonic metasurfaces and provide a comprehensive characterization of their active chiroptical properties. The proof-of-concept applications will also be presented, featuring their impressive fidelity for active coloration.

#### 2:15 PM EL15.06.03

**Chirality Induced Second Harmonic Generation in Aligned and Enantiomer Enriched Carbon Nanotubes** Rui Xu<sup>1</sup>, Yuan Tian<sup>2</sup>, Jacques Doumani<sup>1</sup>, Andrey Baydin<sup>1</sup>, Weiran Tu<sup>1</sup>, Yohei Yomogida<sup>3</sup>, Fuyang Tay<sup>1</sup>, Jiaming Luo<sup>1</sup>, Jun Lou<sup>1</sup>, Kazuhiro Yanagi<sup>3</sup>, Riichiro Saito<sup>2</sup>, Junichiro Kono<sup>1</sup> and Hanyu Zhu<sup>1</sup>; <sup>1</sup>Rice University, United States; <sup>2</sup>Tohoku University, Japan; <sup>3</sup>Tokyo Metropolitan University, Japan

Aligned assemblies of single-chirality semiconducting carbon nanotubes (CNTs) are ideal materials for developing nanoelectronic, optoelectronic, and quantum photonic devices. Although left- and right-handed CNTs have identical properties in many aspects, enantiomer-dependent properties can manifest in magneto-transport, optical polarization selection, and nonlinear optics. For example, theoretical studies have predicted a large, resonance-enhanced second-order nonlinear optical susceptibility up to nm/V in perfect chiral CNT ensembles, but the value has never been experimentally verified due to mixed chirality components, poor alignment, and low densities. Here, we report the synthesis of centimeter-scale single-enantiomer, highly packed, and aligned (11,-5) CNT thin films using the controlled vacuum filtration method. We observed giant second harmonic generation (SHG) from the samples with effective second-order nonlinear optical susceptibility up to 70 pm/V, which corresponds to 350 pm/V for an enantiomerically pure, densely packed and perfectly aligned solid as predicted when the fundamental frequency resonates with the transition of the CNTs at 1000 nm. We confirmed that the SHG signal originates from the inversion symmetry breaking from the intrinsic chirality of the film, instead of surface defects, by angle and polarization dependent SHG measurements. Our findings provide a fast and scalable method for characterizing the alignment and enantiomer purity of CNT films, and establish them as an excellent material for nonlinear optical studies and applications.

**Chiral Materials from Perylene Diimide Building Blocks: Twistacenes and Helicenes** Colin Nuckolls; Columbia University, United States

This presentation will detail our efforts to create materials from contorted aromatic molecules. In particular, I will discuss how to create helicenes and twistacenes from perylene diimide building blocks. These materials have extraordinary properties as materials. The helicenes have the largest chiroptical response of any molecular species. The twistacenes helicity is dynamic and can be controlled by light and chemical/electrochemical reductions. These materials excel as photovoltaics, photodetectors, batteries, and pseudocapacitors. The presentation will discuss these opportunities.

#### 4:00 PM EL15.06.05

**Bringing Sensitive Circularly Polarized Luminescence Spectroscopy to the Time Domain** Antti-Pekka M. Reponen<sup>1</sup>, Marcel Mattes<sup>1</sup>, Winald Kitzmann<sup>2</sup> and Sascha Feldmann<sup>1</sup>; <sup>1</sup>Harvard University, United States; <sup>2</sup>Johannes Gutenberg-Universität, Germany

Materials capable of emitting circularly polarized light (CPL) are promising for breaking efficiency limits in existing optoelectronic applications and may enable entirely new photonic and spintronic technologies [1]. However, reliably detecting CPL with the necessary sensitivity to quantify low dissymmetry factors, while being able to identify and ideally circumvent artefacts arising from linear dichroism, linear birefringence or linearly polarized emitted or scattered light is experimentally challenging [2].

Here we report on our recent efforts to develop CPL detection with the additional dimension of time evolution to achieve broadband, calibration-free CPL spectroscopy with nanosecond time resolution [3]. This technique will serve as a powerful tool to study the dynamics of chiral emitters and to understand how chirality evolves in the excited state.

#### 4:15 PM EL15.06.06

**Twisting Photons with Chiral Metal-Halide Semiconductors** HaiPeng Lu; The Hong Kong University of Science and Technology, Hong Kong

Chiral metal-halide semiconductors (MHS) have recently developed as promising candidates for spin- and polarization-resolved optoelectronic devices. Although several chiral MHS with rich chemical and structural diversity have been reported lately, the fundamental mechanisms governing their chiroptical activity, namely, circularly polarized absorption and emission, remain elusive. In this talk, I will discuss our recent progress in understanding and tuning

the chiroptical activity in chiral MHS. I will first discuss how the chirality is transferred from organic to inorganic component through asymmetric covalent bonding interactions. Their endowed molecular chirality was then studied by circular dichroism (CD). However, we found that the previously reported "apparent" CD in chiral MHS thin films is not an intrinsic chiroptical property, but rather, arising from an interference between the film's linear birefringence and linear dichroism. We verify the presence of LB and LD effects in both one-dimensional and zero-dimensional chiral MHS thin films. We then establish spectroscopic methods to decouple the genuine CD from other spurious contributions, which allows a quantitative comparison of the intrinsic chiroptical activity across different chiral MHS. The relationship between the structure and the genuine chiroptical activity is then uncovered, which is well described by the chirality-induced spin-orbit coupling in the chiral structures. Meanwhile, we found that high CD signals do not necessarily lead to high circularly polarized luminescence as most of the current chiral MHS display very low photoluminescence quantum yields (PLQY). We will then discuss the reasons of low PLQY in these materials. Finally, we will show our strategies to turn on the circularly polarized luminescence by introducing extrinsic self-trapped excitons in a 0D chiral MHS, and by tuning the inorganic layer thickness in perovskite nanoplatelets.

**Twisted Organic Semiconductor Crystals for Chiroptoelectronics** Sehee Jeong, St. John Whittaker, Yongfan Yang, Akash Tiwari, Alexander Shtukenberg, Bart Kahr and Stephanie Lee; New York University, United States

We present crystal twisting, a common albeit little known phenomenon in molecular crystals, as a generalizable strategy to repurpose optically inactive organic semiconductors for chiroptoelectronics. This phenomenon is not limited to specific chemical structures or crystal space groups - twisting has been observed in inorganic, polymer, and small molecule crystals grown from vapor, solutions and melts. Because crystal twisting introduces repeating patterns of crystal orientations perpendicular to the substrate surface as crystals twist about the fast growth direction,  $\langle hkl \rangle$ -dependent material properties are likewise patterned on the microns to millimeter length scale. Twisting also imparts chirality - crystals twist either clockwise or counterclockwise about the growth direction - rendering them optically active. The commonality of crystal twisting enables potentially hundreds of centrosymmetric organic semiconductors designed over the past fifty years to be incorporated into devices that discriminately transmit, emit and detect circularly polarized light. Here we characterize the (chir)optoelectronic properties of several molecular semiconductors, including trisopropylsilyl ethynyl anthradithiophene (TIPS ADT) and tetrathiafulvalene (TTF), and test their performance in resistors, transistors and photodetectors.

#### 4:45 PM EL15.06.08

**Chiroptical Synaptic Heterojunction Phototransistors: Noise-Reduced Detection of Circularly Polarized Light via Self-Assembled Supramolecular Nanohelix of  $\pi$ -Conjugated Molecules** Jung Ah Lim<sup>1</sup>, Hanna Lee<sup>1</sup>, Changsoo Choi<sup>1</sup> and Eunji Lee<sup>2</sup>; <sup>1</sup>Korea Institute of Science and Technology, Korea (the Republic of); <sup>2</sup>Gwangju Institute of Science and Technology, Korea (the Republic of)

Chiroptical photodetectors have become increasingly important in a range of fields, including chiral imaging, spintronics, and quantum optics. To enable practical chiroptical optoelectronics, it is essential to develop high-performance chiroptical photodetectors with high responsivity, sensitivity, polarization direction identification, and device integration feasibility. This study presents the successful demonstration of high-performance chiroptical synaptic phototransistors utilizing heterojunctions comprising a self-assembled nanohelix of a  $\pi$ -conjugated molecule and a metal oxide semiconductor. In this work, heterojunction devices consisting of a chiral nanomaterial and semiconductor offer a promising strategy for developing high-performance chiral optoelectronic devices. To impart strong chiroptical activity, a novel diketopyrrolopyrrole-based, donor-acceptor type  $\pi$ -conjugated molecule decorated with chiral glutamic acid was newly synthesized, capable of supramolecular self-assembly through noncovalent intermolecular interactions. Through hydrogen-bonding-driven, gelation-assisted self-assembly, we obtained supramolecular nanohelix structure consisting of intertwining fibers with strong and stable chiroptical activity in solid-film form. Phototransistors based on interfacial charge transfer at the heterojunction from the chiroptical nanohelix to the metal oxide semiconductor exhibited exceptional chiroptical detection, with a high photocurrent dissymmetry factor and remarkable photoresponsivity. Interestingly, the chiroptical phototransistor displayed photonic synapse-like behavior, generating time-dependent photocurrents and persistent photoconductivity attributed to interfacial charge trapping. Leveraging the synaptic functionality advantage, a trained convolutional neural network achieved over 89 % accuracy in recognizing noise-reduced circularly polarized images of handwritten alphabetic characters.

#### 5:00 PM EL15.06.09

**Ionic Modified Cellulose Nanocrystals Chiral Structures for Electronics** Diana Gaspar<sup>1</sup>, Paul Grey<sup>2</sup>, Bruno Mendes<sup>2</sup>, Madalena Roque<sup>2</sup>, Rodrigo F. Martins<sup>2</sup> and Luis Pereira<sup>1,2</sup>; <sup>1</sup>AlmaScience, Portugal; <sup>2</sup>Cenimat@3N, School of Science and Technology (FCT-NOVA), Universidade NOVA de Lisboa and CEMOP/UNINOVA, Portugal

Many approaches exist in the quest for efficient, abundant, cheap and eco-friendly photonics that can be easily integrated with other platforms for practical applications.

Approaches using 3D metamaterials, mesoporous semiconductors, or plasmonics are promising. Nevertheless, these methods often involve complicated fabrication processes that need high energy consumption (such as vacuum and physical vapour deposition) to deposit these materials, which are often not so green, sustainable, typically expensive, and colour-limited.

Researchers have sought eco-friendly materials with similar performance and lower energy costs during the past few years, and Nature offers many examples of such materials for our innovation. Natural micro and nanostructures, such as the ones found in beetles or butterflies, have evolved over millions of years to produce periodic patterns that can reflect light. These structures served as inspiration to create artificial analogues using cellulose nanocrystals (CNCs), which can form a chiral nematic liquid crystalline phase when dispersed in water. The chiral order is preserved as the water evaporates, and solid films with 1D photonic crystal properties and iridescent colours are obtained. The intrinsic left-handedness of such structures can interact selectively with left and right-circular polarized light (LCPL and RCPL).

The pitch control and, therefore, the reflected colour is particularly interesting. This manipulation can be done using external stimuli such as magnetic and electric fields, drying processes with different interfaces or playing with the chemistry behind the acid hydrolysis. With this work, we demonstrate that CNC suspensions with low concentrations (~4-5wt.%) with proper evaporation-induced self-assembly conditions lead to the formation of films with interesting photonic properties with a left-handed twisted arrangement. The use of strong acid cation resins to mediate the counterion exchange on commercial CNCs. It was observed that adding different alkali salts to the CNCs anisotropic suspension results in a blue shift of the photonic bandgap with higher salt concentrations and proper distinction between LCPL and RCPL ( $\Delta\text{CPL} \approx 42\%$ ).

Combining the photonic character of the tailored CNC films, whose photonic bandgap can be matched with the bandgap of light sensitivity of semiconductors, it will be possible to create devices capable of discrimination between LCPL and RCPL signals in the blue region.

**Anisotropic Circular Photogalvanic Response in Chiral Weyl Semimetal RhSi** [Byunghoon Kim](#)<sup>1</sup>, Tyler Cochran<sup>1</sup>, Zi-Jia Cheng<sup>1</sup>, Gyu-Hee Kim<sup>2</sup>, Xian Yang<sup>1</sup>, Doo-Hyun Ko<sup>2</sup>, Prashant Padmanabhan<sup>3</sup> and M. Zahid Hasan<sup>1</sup>; <sup>1</sup>Princeton University, United States; <sup>2</sup>Sungkyunkwan University, Korea (the Republic of); <sup>3</sup>Los Alamos National Laboratory, United States

Weyl semimetals have been a hot topic in the condensed matter physics community due to their unconventional linear band crossing from the bulk characters. Breaking of time-reversal or inversion symmetry allows Dirac fermions to split into a pair of Weyl fermions with an opposite chirality at a non-high symmetry point in momentum space. The circular photogalvanic effect in which the incident helicity determines the generated current vector is direct evidence from the topology and band structure of the chiral Weyl semimetals. Notably, in optical transition near a Weyl node, it has recently been predicted that the magnitude of the CPGE is associated with its monopole charge. Since the nodes with opposite charges are nondegenerate, it also hints at the CPGE response stemming from the Berry monopole charge. Here, we explore the helicity-dependent optoelectronic response of the topological/Weyl semimetal RhSi via time-domain terahertz emission spectroscopy. The remarkable CPGE behavior in in-plane mode was experimentally demonstrated, whereas it did not exhibit notable signatures in out-of-plane mode. We further perform the photoemission measurement, together with optical simulation, to investigate the physical properties of chiral Weyl semimetal RhSi.

**8:00 PM EL15.07.02**

**Chiral Pyrrole-Based Polyaromatics** [Abdusalom A. Suleymanov](#) and Timothy M. Swager; Massachusetts Institute of Technology, United States

In recent years, there has been significant interest in incorporating heteroatoms into polycyclic aromatic hydrocarbons (PAHs). This exploration of heteroatom-doped variants of extended  $\pi$ -conjugated materials has revealed their distinct and enhanced electronic and photophysical properties. Among the various five-membered aromatic heterocycles, pyrrole stands out as the most electron-rich when compared to its isoelectronic counterparts, furan and thiophene. The synthetic versatility and strong redox activity of pyrrole enable the creation of synthetic frameworks with enhanced p-doping and other desirable material properties.

Our research has focused on the synthesis and characterization of novel chiral pyrrole-based PAHs. These include twisted azacoronenes and helicenes incorporating pyrrole units. We are currently investigating their chiroptical, electrochemical, and magneto-optical properties.

**8:00 PM EL15.07.03**

**Chiral Phonons in  $\alpha$ -HgS Nanocrystal** [Sang Hyun Lee](#), Bumchul Park and Nicholas A. Kotov; University of Michigan, Ann Arbor, United States

Chiral phonon is a quantized particle that represent collective atomic motions with broken reflection and inversion symmetries. Chiral phonons have gathered significant interest due to their unique properties observed in various types of materials such as two-dimensional (2D) materials, biomolecular complexes, and inorganic chiral crystals [1,2,3]. Here, we observe chiral phonons in mercury sulfide cinnabar ( $\alpha$ -HgS) nanocrystals with terahertz time-domain polarimetry (THz-TDP).  $\alpha$ -HgS has two enantiomeric crystal structure that belongs to space group P3<sub>1</sub>21 or P3<sub>2</sub>21 depending on the rotational direction of the helical crystal lattice. By employing phonon dispersion calculations, we identify the IR active phonon modes in  $\alpha$ -HgS that lies in the spectral range of 1 ~ 10 meV, specifically the A<sub>2</sub> (1.16 THz) and E modes (1.3 THz), which can be experimentally measured using THz-TDP. Mirror-symmetrically synthesized P/M  $\alpha$ -HgS nanocrystals show identical THz absorption (TA) peaks, while their THz circular dichroism (TCD)/THz optical rotary dispersion (TOR) signals exhibit opposite characteristics, corresponding to the A<sub>2</sub> phonon mode. This clearly proves the existence of chiral phonons in  $\alpha$ -HgS nanocrystals. Moreover, it is important to mention that strong TCD signals can be measured despite the substantial disparity in scales between the THz wavelength (~300  $\mu$ m) and  $\alpha$ -HgS nanocrystals (~20 nm). Chiral phonons of  $\alpha$ -HgS nanocrystals within the THz range not only provide new insights for THz photonics/phononics, but also bridges the gap between THz photonics and nano-engineering, opening a new door for various applications.

**8:00 PM EL15.07.04**

**Banded Spherulite Formation in Chiral Halide Perovskites** [Matthew Hautzinger](#), Qitong Ge and Matthew C. Beard; National Renewable Energy Laboratory, United States

Halide perovskites containing chiral organic moieties have been recognized recently for their remarkable chirality induced spin selectivity properties. Notably, the compounds exhibit chirality transfer from the chiral organic to the inorganic metal halide components. Here, we investigate the growth of the chiral halide perovskites as textured thin films containing banded spherulite structures. The compound, (S-NPB)<sub>2</sub>PbBr<sub>4</sub> in particular, exhibits robust banded spherulite formation when the processing conditions are optimized. These banded spherulites containing extrinsic chirality of helical twists in them leading to their mesoscopic structure. We show the temperature control over these structures during the growth and characterize the pitch and growth of the helical twists within these films. The results presented here have implications for the chirality induced spin selectivity of these materials, as the compound contains meta chirality, not only in the crystallographic structure, but also in the mesoscale banded spherulites formed.

**8:00 PM EL15.07.05**

**Growth-Actuated Twisting of Photochromic Crystals** [Merritt C. McDowell](#)<sup>1</sup>, Natercia Barbosa<sup>2</sup>, Helen Zardus<sup>1</sup>, Alexander Shuikenberg<sup>1</sup>, Johanna Brazard<sup>2</sup>, Bart Kahr<sup>1</sup>, Takuji Adachi<sup>2</sup>, St. John Whittaker<sup>1</sup> and Stephanie Lee<sup>1</sup>; <sup>1</sup>New York University, United States; <sup>2</sup>University of Geneva, Switzerland

1,2-bis(2-methyl-5-phenyl-3-thienyl)perfluorocyclopentene (BpFCP) single crystals grown from the vapor phase were previously discovered to dynamically twist and coil when irradiated with UV light due to mechanical strain associated with a reversible, light-induced ring closure [1]. Here, we form BpFCP twisted crystals through growth-actuated twisting during crystallization from the melt. At high undercoolings, i.e. large crystallographic driving forces, BpFCP forms banded spherulites comprising helicoidal fibrils that twist in concert with one another as they grow radially from the spherulitic nucleation center. As-crystallized films appear transparent when viewed using unpolarized light. When imaged between crossed polarizers, on the other hand, concentric bands of interference colors are visible due to continuously rotating refractive indices as the crystals twist about the growth direction. Upon irradiation with UV light to induce the photochromic ring closure, alternating bands in BpFCP spherulites turn dark blue, creating a vibrant stripe pattern. Local Raman spectroscopy on adjacent bands revealed this patterning to be a result of orientation-dependent dichroism of photocyclized crystals, as opposed to orientation-dependent photoreactivity. Film cracking upon UV light exposure suggests that fibrils experience internal stress from photoisomerization-induced shifts in crystal lattice parameters. Mueller Matrix imaging further revealed strong circular dichroism (CD) and birefringence (CB) in BpFCP banded spherulites, with local CD and CB signals changing dynamically during photocyclization. Because banded spherulites expose different crystal orientations at the film surface, they provide a unique opportunity to investigate orientation-dependent chiroptoelectronic properties in these dynamic crystals.

**Supramolecular Chirality Induced by Self-Assembly in Novel Quinoid Conjugated Molecules** Jeongjin Hong, Yeonsu Choi, yunseul Kim, Yina Moon, Jeongwoo Beak and Dong-Yu Kim; Gwangju Institute of Science and Technology, Korea (the Republic of)

Molecular assemblies with supramolecular chirality have been developed for decades due to their distinctive chiroptical properties. Among the versatile approaches to induce supramolecular chirality, self-assemblies using non-covalent interactions have considered as a great potential for applying biological field and chiroptical devices owing to their high tunability and controllability.

In this work, we designed and synthesized novel quinoid conjugated molecules QuEDOT-(S)-Cn and QuPheDOT-(S)-Cn employing enantiopure alkyl side chains. Quinoidal moieties are suitable for constructing supramolecular chirality through self-assembly due to their strong  $\pi$ - $\pi$  stacking property of highly planar structure. QuEDOT-(S)-Cn and QuPheDOT-(S)-Cn had different chiroptical properties in solution and film states depending on the external stimuli (solvents, temp) as well as different chemical structures. Then we conducted diverse analyses such as AFM, POM, SEM, CD, GIWAXS to determine the reason for the difference in anisotropic factors between two molecules. We will explain and discuss the relationship between the behavior of supramolecular chirality and chemical structures. These results suggest chemical designing strategies of organic semiconducting materials in forming supramolecular chirality using self-assembly.

#### 8:00 PM EL15.07.07

**Chiral-Induced Surface-Enhanced Raman Optical Activity on Nanoparticle-On-Mirror Substrate** Sung Gun Lee; Seoul National University, Korea (the Republic of)

Raman Optical Activity (ROA) has emerged as a valuable tool for characterizing stereostructural changes in both organic and inorganic compounds, offering complementary steric information to traditional spectroscopic methods. In particular, ROA has garnered attention as a chiral-selective method for analyzing biomolecules such as nucleic acids, and peptides, overcoming the limitations of conventional spectroscopy. However, due to the inherently low cross-section of ROA, which is three to five orders of magnitude lower than typical Raman, achieving sufficient signal sensitivity remains a challenge. To address this issue, efforts have been made to measure ROA signals using SERS, which utilizes plasmonic materials to enhance the Raman signal of analytes via the electric field concentrated around nanoparticles (SEROA). However, biomolecules typically have low Raman cross-sections and poor signal stability at high laser intensity and long measuring times, limiting the utility of SEROA. Recently, chiral-induced ROA has been proposed as a breakthrough, leveraging the "sergeants-and-soldiers" principle to induce chirality in a trace chiral compound, enabling the measurement of chirality with shorter measuring times and lower laser intensities.

This study demonstrates the possibility of a nanoparticle-on-mirror (NPoM) substrate and measurement configuration for ROA, which isolates hotspots from particle aggregation. To confirm the reliability of the NPoM configuration for ROA, chirality was induced in a self-assembled monolayer of 4-mercaptopyridine on a gold nanofilm surface.

### SESSION EL15.08: Tunable Structural Chirality in Materials

#### 9:00 AM \*EL15.08.01

**Bio-Enabled Chiral Flexible Nanomaterials—From Chiral Emitting Sources to Photonically-Assisted Multilevel Logic** Vladimir Tsukruk<sup>1,2</sup>;

<sup>1</sup>Georgia Institute of Technology, United States; <sup>2</sup>Institute for Human and Machine Cognition, United States

Bio-enabled hybrid nanomaterials represent a novel class of functional materials, which uses bio-derived materials, bioinspiration and biomimetic approaches to design functional nanomaterials and structures with co-assembled biological and synthetic components to bring best of two worlds: adaptive photonic functions and chiroptical activity, flexibility and mechanical strength, potential sustainability and scalability [1]. Here, we summarize our recent results on functional bio-derived chiral nematic polysaccharides co-assembled with graphene oxides, organic semiconductors, magnetic nanoparticles, and quantum dots for adaptive chiroptical materials, magnetic materials and photonic multi-value logic thin film electronics.

Firstly, we discuss robust photonic nanomaterials from cellulose nanocrystals and nanofibers decorated with highly photoluminescent organic dyes, quantum dots and quantum nanowires for tailored emission of linear and circular polarized light [2, 3]. Secondly, we present results on magnetically steerable uniform photonic organization of cellulose nanocrystals decorated with superparamagnetic nanoparticles to achieve uniform organization [4]. Assembly under weak magnetic field gradients enables transformation from helicoidal cholesteric to uniaxial nematic phase with near-perfect orientation order parameter was achieved across large areas, enhanced mechanical robustness, and fast actuation ability. Finally, we demonstrate biophotonic field effect transistors mediated by circularly polarized excitation with multi-valued logic elements for dramatically elevated encryption ability [5].

**Switching Chirality in Microarrays Enabled by Shape-Reconfigurable Spindle Microparticles** Mingzhu Liu, Xingyue Han, So Hee Nah, Tianwei Wu, Yuchen Wang, Liang Feng, Liang Wu and [Shu Yang](#); University of Pennsylvania, United States

Giant circular photo-galvanic effect has been realized in chiral metals when illuminated by the circularly polarized light. However, the structure itself is not reconfigurable nor can we tune the crystal chirality in the adjacent domains. Here we synthesize spindle-shaped liquid crystalline elastomer microparticles that can continuously change shape from prolate to spherical to oblate upon heating above the nematic to isotropic transition temperature. The shapes are reversed upon cooling. When arranged the microparticles in a honeycomb lattice, the lattice can be switched from a right-handed chiral state to achiral one, then to a left-handed chiral state, without breaking the translational symmetry. Accordingly, the sign of rotation of the polarized light passing through the lattices changes as measured by time-domain terahertz (THz) spectroscopy. Further, we can locally alter the chirality in the adjacent domains using near-infrared (NIR) light illumination. The ability to controllably create chiral states at the boundary of the achiral/chiral domains will allow us to explore complex structures through the interplay of symmetry and topology.

### 9:45 AM EL15.08.03

**Artificial Photosynthesis Empowered by PSII-Inspired Supramolecular Quantasomes with Chiral Architectures** [Marcella Bonchio](#)<sup>1,2,3</sup>; <sup>1</sup>University of Padova, Italy; <sup>2</sup>INSTM, Italy; <sup>3</sup>ITM-CNR, Italy

Being the natural-born photoelectrolyzer for oxygen delivery, Photosystem II (PSII) is hardly replicated with man-made constructs. In particular, the PSII organization in natural thylakoids sets key guidelines to rethink the molecular design of groundbreaking artificial photo-electrolysers. Building on the early "quantasome" hypothesis (*Science* 1964, 144, 1009-1011), PSII mimicry can be pared down to essentials by shaping a photocatalytic ensemble (from the Greek term "soma"= body) where light-quanta trigger water oxidation. We have recently reported on PSII-inspired nanodimensional quantasomes (QS) that readily self-assemble into hierarchical photosynthetic nano-stacks, made of bis-cationic perylenebisimides (PBI<sup>2+</sup>) as chromophores and deca-anionic tetraruthenate polyoxometalates (Ru4POM) as water oxidation catalysts (*Nature Chem.* 2019, 11, 146-153). A combined supramolecular and click-chemistry strategy allows to interlock the multi-lamellar architecture emerging from the perylene aromatic stacking in water, while installing tetraethylene glycol (TEG) cross-linkers thus enhancing water harvesting and transport in proximity of the oxygen evolving center (*J. Am. Chem. Soc.* 2022, 144, 14021-14025). *Our breaking new results deal with the introduction of sugar-based substituents as asymmetry effectors for the assembly of chiral quantasomes* evolving oxygen using low energy green photons ( $\lambda > 450$  nm, FEO<sub>2</sub> > 95 %). Action spectra, mass-activity, light-management, photoelectrochemical impedance spectroscopy (PEIS) together with Raman mapping of hydration shells, point to a key role of the supramolecular structure nano-arrays, where the interplay of hydrophilic, hydrophobic and chiral domains is reminiscent of PSII-rich natural thylakoids.

**A Multi-Functional Full-Polarized Light Emitting and Controlling Device** [Jiawei Lyu](#) and Ki Tae Nam; Seoul National University, China

Nanomaterials emitting polarized light directly without using the traditional polarizers are believed to simplify the design of polarization optics and afford higher efficiency, showing great potential in practical applications such as 3D display, hologram, anti-counterfeiting and light communication. While most efforts are focused on improving the polarized light emission performance of specific nanomaterials, of paramount importance is to interface these excellent materials with state-of-the-art industrial technology to make functional devices. Herein, we propose and demonstrate an efficient route to fabricate full-polarized emitting and controlling devices via integrating 3D printing technique with the (micro) LED display technology. We achieved an extraordinarily high degree of linearly and circularly polarized luminescence (CPL) through precise control of the nanomaterial assembly structure. Moreover, we realized efficient spatio-temporal modulation of various polarization states. These features enable multiple applications including a secured visible light communication (VLC) system and polarization-based multichannel displays.

### 10:45 AM EL15.08.05

**Solution Synthesis of Halide Chiral Crystal with Controlled Dimension and Morphology** [Zhihao Zhang](#); Rensselaer Polytechnic Institute, United States

Recently, there has been a surge of research interest in understanding the intriguing spin-related phenomena in chiral materials. In this work, we present a solution-based approach for growing ferromagnetic chiral halide crystal. By tuning the temperature, growth time and concentration, we optimize the growth morphologies. We use X-ray diffraction and Raman spectroscopy to characterize the crystal structure and phase. The chirality is investigated by circular dichroism spectroscopy. The integration of ferromagnetism and chirality in the same crystal provides a rich platform for understanding spintronic phenomena.

**Unprecedented Intrinsic Chirality in CsPbBr<sub>3</sub> Nanoplatelets Tunable Through Synthetic Conditions** [Progna Banerjee](#), Jia-Shiang Chen, Xuedan Ma and Elena Shevchenko; Argonne National Laboratory, Center for Nanoscale Materials, United States

This work reports on the intrinsic chiral behavior in colloidal ultrathin CsPbBr<sub>3</sub> nanoplatelets with unprecedented quantitative s-handed value as studied using circular dichroism measurements. Through adjusting various synthetic parameters, such as temperature, Cs and Pb reagent ratios, reaction solvents and stirring direction, we are able to tune the quantitative chiral properties in these nanomaterials. Additionally, the functional aspects such as the

handedness of these nanoplatelets can be tuned using brominated methylbenzylamines with suitable *r/s* chirality. We utilize the advantageous procedure of single particle photoluminescence studies to attain insights into the lifetimes and correlate them with the presence and the type of ligands. We reach qualitative arguments based on surface defects and Pb extraction through selected area electron microscopy, and rigorous x-ray diffraction accompanied with Rietveld refinement analyses- to explain the atomic arrangements at the surface of these nanoplatelets which can be tuned through synthetic factors. Optical characterization by absorption and circular dichroism extends these ideas into correlation with microscopy and diffraction results. These remarkable control of chiral parameters without external stimuli in untreated/as prepared nanoplatelets; and through choice of the ligation combinations hence accomplished highlight the suitability of these ultrathin CsPbBr<sub>3</sub> nanoplatelets for applications in a wide range of optical and mechanical applications including chiral superstructures.

**Tuning Chiroptical Properties of Chiral 2D Hybrid Organic-Inorganic Perovskites Through Mixing Halogen** Lan-Sheng Yang, Chun-Yao Huang and Yu-Chiang Chao; National Taiwan Normal University, Taiwan

Chiral 2D halide perovskites have attracted increasing attention due to their exceptional photoluminescence properties, tunable bandgap, and various crystallized structure. However, tuning chiroptical properties of chiral 2D hybrid halide organic-inorganic perovskites have not yet been extensively studied. Here, we report the chirality of chiral 2D halide perovskites through circular dichroism (CD) and circularly polarized photoluminescence (CPL). By varying the mixing ratio of chlorine, bromide, and iodide anions in S- or R-(MBA)<sub>2</sub>PbI<sub>4</sub>(1-x)Br<sub>4x</sub> or S- or R-(MBA)<sub>2</sub>PbBr<sub>4</sub>(1-y)Cl<sub>4y</sub>, the mixing of halide ions allows a tunable band gap of the chiral OIHPS, leading to a shift of the CD signal from 495 to 320 nm and the CPL signal from 530 to 485nm. Moreover, it is noticed that the CD signal ascends from x=0 to x=1 and descends from x=1 to x=4. Successively, the CD signal ascends from y=0 to y=4. This difference can be explained that the phase transition of the crystalline structure occurred. Chiral optical asymmetry (g-factor) at y=4 has a maximum value of 0.015 compared to other mixing ratios. The CPL signal becomes greatly small after the phase transition because of structural distortion in the inorganic framework and instability. Additionally, the CD sign conversion is discovered as well through mixing halogen. These properties can take advantage of the structural engineering of high-performance chiroptical materials for spin-polarized light-emitting devices. Spin organic light-emitting diodes were achieved by using chiral 2D hybrid halide perovskites film as the spin filter layer. Circularly polarized electroluminescence was observed at room temperature in the absence of an external magnetic field.

**11:30 AM EL15.08.09**

**Leveraging The Preferences in Transition Metal-P/Si Bonding to Design Novel Chiral Materials** Kirill Kovnir; Iowa State University, United States

Non-centrosymmetric chiral intermetallic compounds with antisymmetric spin-orbit coupling exhibit a plethora of emergent properties. Chemical bonding preferences in the transition metal silicon-phosphides TM-Si-P create the asymmetric environment around metal atoms resulting in high abundance of non-centrosymmetric chiral and polar crystal structures. The synthesis of those phases is hampered by inertness of TM and Si in contrast to high reactivity and vapor pressure of phosphorus. We developed a comprehensive synthetic strategy allowing to produce single crystals and phase-pure polycrystalline samples of metal tetrel-pnictides. The correlation between the crystal structure, chemical bonding, and optical and properties will be discussed with focus of earth abundant TM for applications.

SESSION EL15.09: Chiral Phonons and Structural Dynamics in Chiral Materials

**Chirality-Induced Spin Selectivity Effect in 2D Chiral Hybrid Perovskites: Chiral-Phonon-Activated Spin Seebeck Effect** Dali Sun; North Carolina State University, United States

The Chirality-Induced Spin Selectivity (CISS) effect, a unique ‘spin filtering’ effect arising from the structural handedness of organic compounds (i.e., chirality) and their assemblies that lack inversion symmetry [1]. It utilizes chirality to generate robust spin information from chiral (left- (S) or right-handed (R)) molecules without the need for common magnetic elements. The CISS effect provides a strong coupling between spin and electronic properties without the need for magnetic ordering. Recently, the CISS effect has been reported in 2D chiral hybrid perovskites (2D-chiral-HOIPs), a resurgent class of solution-processed hybrid semiconductors consisting of alternating layers of chiral organic compounds and inorganic framework of corner-sharing metal halide octahedra. Although considerable progress has been made in understanding many features of the CISS response in chiral-HOPs [2,3] and other chiral materials, an adequate quantitative description of (i) the CISS effect, (ii) its strong manifestation for spin selectivity at ambient temperatures, and (iii) its mechanistic origins, is still lacking. It comes to our attentions that angular momentum in condensed matter systems, including rigid rotation and elastic deformation, can be viewed as an information vector [4]. At the microscopic scale, the lattice vibrations, i.e., phonons, can carry angular momentum and mimic the well-known information-carrying photons [5]. This phonon angular momentum, i.e., *chiral phonon* displays a non-zero phonon angular momentum when the system is displaced from equilibrium, offering a high potential for producing the CISS effect at elevated temperatures. Here we show the observation of spin currents generated by chiral phonons in a 2D chiral HOIP implanted with chiral cations when subjected to a thermal gradient [6]. The generated spin current shows a strong dependence on the chirality of the film and external magnetic fields, of which the coefficient is orders of magnitude larger than that produced by the reported spin Seebeck effect. Our findings indicate the potential of chiral phonons for spin caloritronic applications and offer a new route toward spin generation in the absence of magnetic materials. Demonstration of the chiral-phonon-activated spin Seebeck effect in 2D chiral HOIPs may aid in solving the paradoxical diversity of CISS models, shedding light on CISS-related responses observed in a wide variety of chiral systems.

**Chiral Phonon-Induced Spin Polarization** [Hanyu Zhu](#), Jiaming Luo, Tong Lin, Junjie Zhang, Xiaotong Chen, Elizabeth Blackert, Rui Xu and Boris I. Yakobson; Rice University, United States

Controlling spins on very short time scales may enable novel non-equilibrium magnetic physics as well as ultrafast spintronics for energy-efficient information processing. Chiral phonons, where atoms rotate unidirectionally around the equilibrium position inside crystalline lattice, break time reversal symmetry and are expected to directly couple with magnetization. We excited chiral phonons using circular-polarized terahertz pulses and observed a prominent transient magneto-optic Kerr effect in rare-earth trihalides. The effective magnetic field needed to polarize the paramagnetic spins is on the order of 1 T under very moderate pump fluence of 0.2 mJ/cm<sup>2</sup>. The temperature dependence of the spin dynamics indicates the magnetic field indeed is generated by the phonons, as opposed to a pure electromagnetic inverse Faraday effect. Our result may open a new route to investigate spin-phonon interaction in ultrafast magnetism and chiral transport properties for quantum devices.

**Terahertz Excitation of Chiral Phonons to Induce Dynamical Multiferroicity** Megan Nielson, Enoch (Sin Hang) Ho, Aldair Alejandro, Matthew Lutz, Clayton Moss and [Jeremy A. Johnson](#); Brigham Young University, United States

Circular motion of ions in solid materials has been posited as a means to dynamically induce or control magnetic properties. This circular motion fundamentally requires the excitation of “chiral” phonon modes, and the ability to excite and control transient crystal chirality could have a significant impact on condensed matter physics.

Pairs of phonon modes in ferroelectric materials can be excited to create circular or elliptical motion of ions. Depending on the charge of the ions and magnitude of their motions, these ion loops with right or left handedness can induce a magnetic moment, even in originally non-magnetic materials. Therefore, exciting ion loops in ferroelectric solids to dynamically induce magnetic ordering, will make them transiently multiferroic.

We have recently had much success in controlling the waveform and polarization of high-field, broadband terahertz (THz) pulses. This waveform control is driven by the capability to perform two-dimensional (2D) THz spectroscopy, including the ability to create circularly polarized THz pump pulses. In this presentation, we report how we generated intense pulses of circularly polarized THz light to excite pairs of degenerate phonon modes. As the phonon modes are excited with proper relative phase (provided by the circularly polarized THz pulses), circular phonon motion results. The transient magnetic moment induced by these excited ions loops is then measured with the ultrafast Faraday effect.

To generate circularly polarized light, we combine two linearly polarized THz pulses with adjustable relative delay. A differential chopping scheme enables us to readily measure the sample response from a single (vertically polarized) THz pulse, the other individual (horizontally polarized) THz pulse, and the combined THz pulse with controllable polarization state, all in a succession of four laser shots; the probe response in the absence of a THz pump pulse is measured with the fourth laser shot.

To probe the sample response, we direct an 800-nm probe pulse through the excited region of the sample and measure the modification of the probe polarization with a transient birefringence detection scheme. This allows us to measure the transient Faraday effect to detect the creation of an ultrafast magnetic moment. However, it can also measure other ultrafast birefringence signals, like the THz Kerr effect. Fortunately, by controlling the relative polarization angles between THz and probe pulses, we can isolate the Faraday signal from the Kerr signal.

With circularly polarized THz pulses, we excite a z-cut sample of LiNbO<sub>3</sub>. The lowest frequency E symmetry phonon modes are doubly-degenerate with perpendicular mode effective charge vectors that can be driven with THz pulses polarized along the crystallographic x and y directions. Exciting pairs of E-modes with circularly polarized THz pump pulses induces ion-loop motion, leading to a transient magnetic moment in LiNbO<sub>3</sub>. While the chiral phonon motion takes place, a transient magnetic moment is induced that can be detected with the Faraday rotation of a probe pulse. We observe a transient signal persisting for ~3 ps, which is longer than the THz pump pulse duration (<1 ps), confirming that this isn't just the THz inverse Faraday effect. The magnetic moment signal also switches sign as the THz polarization and subsequent chiral phonon motion changes handedness.

In summary, using a 2D THz experimental setup, we can create high-field circularly polarized THz pulses. These circularly polarized THz pulses excite chiral phonon motion in LiNbO<sub>3</sub>, transiently inducing a magnetic moment that persists longer than the THz excitation pulses. Isolating the Faraday signal from the Kerr signal confirms that the excited chiral phonon motion, so-called ion loops, induces magnetic ordering in non-magnetic LiNbO<sub>3</sub>. The ability to use circularly polarized THz pulses to control chiral phonon motion will provide many new avenues in the study of condensed matter systems.

**Phonons and Phase Symmetries in Non-Symmorphic Twisted and Layered Materials** [Lucas Lindsay](#); Oak Ridge National Laboratory, United States

Structural complexity underlies a variety of novel quasiparticle behaviors that can have profound impacts on material functionalities. Here I will discuss the role of structural twisting and translational symmetries in determining the vibrational behaviors of non-symmorphic chiral and achiral materials and how these translate into spectral features and functionalities. We advance a dynamical theory that incorporates the various symmetries internal to the lattice unit cell directly into the description of the phonon frequencies and eigenvectors. This naturally elucidates phase conservation relations in twisted structures and layered materials. We apply this theory to build insights into vibrational dynamical structure factors and spectral observations from inelastic neutron and x-ray scattering experiments, and provide a fresh perspective on symmetry-enforced crossings, quasiparticle interactions, and band topologies.

**Towards Chiral Acoustoplasmonics** Beatriz Castillo Lopez de Larrinzar<sup>1</sup>, Chushuang Xiang<sup>2</sup>, Edson Rafael Cardozo de Oliveira<sup>2</sup>, Norberto Daniel Lanzillotti-Kimura<sup>2</sup> and [Antonio Garcia-Martin](#)<sup>1</sup>; <sup>1</sup>Instituto de Micro y Nanotecnología, CSIC, Spain; <sup>2</sup>Centre de Nanosciences et de Nanotechnologies (C2N), France

The possibility of creating and manipulating nanostructured materials encouraged the exploration of new strategies to control electromagnetic properties. Among the most intriguing nanostructures are those that respond differently to helical polarization, i.e., exhibit chirality.[1] Circularly polarized light can be used to probe and determine the chiral nature of a plasmonic structure, which is usually reflected as quantitative differences in the values of the absorption or scattering cross-sections. However, reaching maximum absorption and minimum scattering for one helicity, and the opposite for the other is not usually found to occur at the same wavelength.[2]

In the present work, we propose a simple chiral plasmonic structure based on crossed elongated bars where light-handedness defines the dominating cross-section absorption or scattering, as it identifies the two different enantiomers in a chiral structure which determine how the system interacts with its environment. The system is yet maintained simple enough to understand the actual nature of the response observed, be open to future developments, and warrant fabrication for future experimental verification [3,4]. Based on this structure, our work demonstrate that, not only through the interactions between different elements it is possible to make the absorption and scattering cross-sections radically and qualitatively different for the two circular polarizations, but also that the dominating cross-section can be switched from absorption to scattering by simply changing the polarization of the impinging beam. Also, we theoretically propose a simple pump-probe experiment using circularly polarized light. [5] In the reported structures, the generation of acoustic phonons is optimized by maximizing the absorption, while the detection is enhanced at the same wavelength -and different helicity- by engineering the scattering properties [6]. Thus, the presented results constitute one of the first steps towards harvesting chirality effects in the design and optimization of efficient and versatile acoustoplasmonic transducers.

### 3:45 PM EL15.09.06

**Preparation and Characterization of Chiral Mechanical Metamaterials** [Wenbing Wu](#) and Nicholas A. Kotov; University of Michigan, United States

Chirality of nanostructures and nanocomposites have been instinctively associated with their chiroptical activities, *e.g.*, circular dichroism and optical rotation. Chiral effects have also been predicted to exist in the mechanics of materials by theories more than 50 years ago.<sup>[1]</sup> Two key phenomena have been identified: 1) A chiral material can rotate the linear polarization plane of a transverse mechanical wave, analogous to the optical rotation of electromagnetic waves. 2) A moment is induced when a chiral solid is subjected to longitudinal stress. Notwithstanding the theoretical achievements, it has only been recently that a few experimental progresses have emerged, because challenges remain in both the preparation and characterization of such materials. The goal of this talk is to present our most recent work in addressing these two challenges.

Currently reported chiral mechanical structures were mostly created via 3D printing. We propose a material engineering strategy to fabricate chiral mechanical composites with helical inclusions. A variety of chiral nano- and micro-particles and assemblies can be obtained self-assembly methods.<sup>[2]</sup> The morphology of these particles, including their size and twisting pattern, can be tuned by the self-assembly process. The chiral particles are then included in an aerogel matrix of aramid nanofibers.<sup>[3]</sup> The micro-rotation of the particles, induced by external linear mechanical waves, transmits through the nanofiber network and couples into a collective macroscopic rotation, which can be experimentally measured.

In contrast to electromagnetics, there are few commercially available tools for the detection of the polarization of mechanical waves. We built up a digital image correlation (DIC) system that enables the measurements of the displacement vector of a surface with nanometer resolution.<sup>[4]</sup> A piezoelectric transducer, on which a chiral solid is mounted, produces a linear transverse mechanical wave up to 250 kHz. The DIC measurements are used to identify the polarization directions of the transverse waves on the piezoelectric transducer and the sample surface. The twisting angle between the two directions is an indication of the mechanical chirality of the solids. This presentation outlines our ongoing efforts on the preparation and characterization of chiral mechanical effects in self-assembled composite metamaterials.

**The Interplay Between Dopants and Charge Carriers in Organic Semiconductors** [Lambert Jan Anton Koster](#); University of Groningen, Netherlands

In order to make rational improvements of the charge transport properties of doped organic semiconductors, a thorough understanding of this rather complex process is needed. The efficacy of doping is governed by a multitude of steps, including the interactions between (ionized) dopants and charge carriers. In this contribution, we explore the effects of carrier-dopant and carrier-carrier interactions and strategies to mitigate them.

We use kinetic Monte-Carlo simulations to better understand the effects of carrier-dopant and carrier-carrier interactions. Such simulations predict that a larger host-dopant distance can result in a higher Seebeck coefficient for a given electrical conductivity. In order to realize such a system, we use amphiphatic side chains in an n-type donor-acceptor copolymer. The amphiphatic side chain contains an alkyl chain segment that acts as a spacer between the polymer backbone and an ethylene glycol type chain segment. The use of this alkyl spacer can not only reduce the energetic disorder in the conjugated polymer film but can also properly control the dopant sites away from the backbone, which minimizes the adverse influence of counterions. We find that this selectively increases the Seebeck coefficient and the power factor by a factor of ~ 5.

While it has been recognised that Coulomb interactions between dopants and charge carriers are important, carrier-carrier interactions—interactions among charge carriers—in doped organics have received less attention. In a doped organic semiconductor, however, the number of (free and bound) charge carriers equals the number of reacted dopants. As a result, both types of interactions are of importance for a proper description of the transport properties of doped organic semiconductors.

To study the transport properties in the presence of dopants and including both carrier-carrier and carrier-dopant interactions we once again use kinetic Monte-Carlo simulations. While the conductivity is indeed affected by carrier-dopant interactions, the effect of carrier-carrier interactions appears to be even stronger, especially so at high doping concentrations. Experimentally, we observe that the electrical conductivity of a large number of organic semiconductors shows a maximum: Upon increased doping levels the conductivity decreases. This type of behaviour is commonly attributed to changes in the microstructure as a consequence of doping. However, we find that even when using vapour doping, where there are no observable changes in the microstructure, this behaviour persists. The experimental findings match the Monte-Carlo data very closely, which suggests that the Coulomb interactions among charge carriers is at the root of the limited conductivity at high doping densities.

**11:00 AM \*EL16.01.02**

**Dopant-Carrier Coulomb Interactions in Organic Electronics: DOS Shape, Transport, and Carrier Screening** [Zlatan Aksamija](#); University of Utah, United States

Organic electronic materials, specifically conjugated polymers, are a cost-effective and environmentally friendly alternative to inorganics. However, they do not possess intrinsic free carriers, which means they must be doped to increase the number of free carriers and boost conductivity. Simultaneously, their low dielectric constant means electrostatic Coulomb interactions between free carriers and dopant counterions are poorly screened. These dopant-carrier interactions dramatically alter the energetics of the states available for transport as well as the dynamics of free carriers. The importance of Coulomb interactions and their impact on the density of states (DOS) via dopant-induced disorder is now well established. In this invited talk, I will discuss our results arising from coupling a model for modification of the electronic density of states (DOS) in the presence of dopants with a phonon-assisted carrier hopping simulation through those states. We expanded the model initially proposed by Arkhipov et al. to include the finite dopant size and minimum dopant-carrier separation, which limit the deepest traps in the tail of the DOS. We use the DOS model as input to the hopping transport simulation to analyze the transport properties of doped conjugated polymers and extract both conductivity and Seebeck coefficient at each doping concentration. We also vary the parameters of the dopants, including their size, energy level, and charge distribution on the dopant counterion to quantify their impact on conductivity.

However, previous studies of hopping transport within the Gaussian Disorder Model did not consider the role of screening the dielectric interactions by the carriers. In our work, we implement screening in the Debye-Hückel formalism and calculate dopant-induced disorder with the resulting electrostatic potential. For a point dopant, this gives the well-known Yukawa potential, which we generalize for dopant charge distributions other than the point charge. Then we solve Pauli Master Equation with Miller Abrahams hopping rates with states from the resulting screened DOS. Our results show that screening has a significant impact on the Seebeck coefficient and shape of the DOS. The thermoelectric power factor increases almost by a factor of 2 at higher doping. We also observe that the log slope of the Seebeck coefficient plotted against the electrical conductivity for different doping concentrations, which was previously thought to have a universal value (-1/4), increases for a more energetically disordered system. By including screening, we were able to reproduce and explain these curves obtained in measurements and connect the change in slope with the change in structure of the host polymer. We conclude that carrier screening of dopant Coulomb interactions plays an important role in transport and thermoelectric properties of polymers, especially at high doping concentrations. Our work refines the understanding of fundamental processes in doped polymers and enables their easier engineering for thermoelectric, photovoltaic and other applications.

**11:30 AM EL16.01.03**

**The Effects of Doping on Transport in Organic Electronics: Analyzing the Dopant-Induced Disorder** [Andrew Tolton](#) and Zlatan Aksamija; University of Utah, United States

Organic electronic materials, specifically conjugated polymers, are a cost-effective and environmentally friendly alternative to inorganics. However, their low intrinsic conductivity means they must be doped to increase the number of free carriers. Characterizing the effects of doping on organic thermoelectrics has proven to be a long-standing problem. Doping introduces both structural and energetic changes to the polymer, changing the shape of the electronic Density of States (DOS) through the creation of band tails and widening the DOS, resulting in a type of energetic disorder termed dopant-induced disorder (DID). The shape of the DOS resulting from doping can be captured through two parameters: the width of the DOS, termed energetic disorder, and the shape of the DOS, which is quantified by a shape parameter  $p$ , which can take on values of 1 for an exponential DOS to 2 for a Gaussian one. In our previous work, we showed that DID causes energetic disorder to increase while the  $p$  value simultaneously decreases from 2 to below 1 in heavily doped polymers, implying heavy tails. The resulting carrier mobility is impaired by the presence of heavy tails and the deep trap states in them. Doping then simultaneously increases DID, affecting the shape of the DOS, but fills the deepest tail states first, partially countering their effect.

To decouple the influences of each of these effects, we fix the shape of the DOS to simulate doping without DID. We then compute both conductivity and thermoelectric Seebeck coefficient at each DOS and carrier concentration using a numerical simulation of phonon-assisted carrier hopping between localized states. The simulation iteratively solves the Pauli master equation with Miller-Abrahams hopping rates. The iteration converges on an out-of-equilibrium distribution function, from which carrier and energy currents are computed, from which we extract conductivity and Seebeck coefficient, respectively. The Seebeck coefficient is a convenient and readily measurable proxy for the carrier concentration as it scales with the position of the Fermi level in the DOS. The Seebeck vs conductivity plot thus reveals the tradeoff induced by doping and captures the impact of the DOS on transport. We find distinct behavior of the Seebeck vs conductivity relation across doping regions, and these behaviors can be described in terms of carrier concentration in conjunction with the key parameters of the DOS: its width (energetic disorder) and shape parameter. The distinct regions on the Seebeck-conductivity curve come from surprisingly simple relationships between doping and several transport parameters, which also allow us to provide qualitative expressions for difficult-to-measure quantities like carrier concentration and carrier-dependent mobility. Ultimately, this analysis clearly displays the underlying effects of doping without the simultaneous obfuscation of DID, allowing us to gain a clearer understanding of the effects of both influences. This work will impact the design of polymer-dopant complexes for reaching higher carrier mobility in future organic electronics.

11:45 AM EL16.01.04

**A New Strategy to Greatly Improve The Seebeck Coefficient and Overall Thermoelectric Properties of Conducting Polymers** Jianyong Ouyang; National University of Singapore, Singapore

Conducting polymers emerge as the next-generation thermoelectric materials because of their merits including high conductivity, high mechanical flexibility, low cost and solution processability. However, their Seebeck coefficient is notably lower than inorganic thermoelectric materials by about one order in magnitude. The conventional methods to increase the Seebeck coefficient of conducting polymers including partial dedoping with a reducing agent or base and energy filtering. Nevertheless, these methods are not very effective, and the overall thermoelectric properties of conducting polymers are not very high. Here, I will present a new strategy to greatly improve the Seebeck coefficient and thus the overall thermoelectric properties of conducting polymers. The zT value can be comparable to the best inorganic thermoelectric materials at room temperature.

SESSION EL16.02: Carrier-Dopant Interactions in Organic Semiconductors—Design and Applications

1:30 PM EL16.02.01

**Doping-Enabled Photomultiplication in Narrowband Near-Infrared Organic Photodetectors for Enhanced Detectivity** Louis Conrad Winkler<sup>1</sup>, Jonas Kublitski<sup>2</sup>, Johannes Benduhn<sup>1</sup> and Karl Leo<sup>1</sup>; <sup>1</sup>Technische Universität Dresden, Germany; <sup>2</sup>Universidade Tecnológica Federal do Paraná, Brazil

Continuous monitoring of food quality, blood oxygen, or industrial processes requires high-throughput near-infrared photodetectors. Due to excellent properties like low-cost, flexibility, and narrowband response, organic photodetectors (OPDs) have vast market potential for such applications. In this work, we utilize the emerging absorption feature of a weakly doped C60 bulk for photo-responses above 1000 nm, circumventing the difficulties of obtaining molecules with a low optical gap and low molecular mass. The unavoidable increase of band-to-band recombination for low-gap systems, which is detrimental to the external quantum efficiency (EQE), is overcome by combining two mechanisms to achieve a strong photocurrent gain. Trap-assisted accumulation, realized by very low doping, and energetic blocking of holes, are utilized to achieve a spectral response (SR) of 15 AW<sup>-1</sup> at 1092 nm. Furthermore, spatial doping variations are implemented into the device to boost the absorption within the optical cavity, resulting in a narrow response of 18 nm. This approach allows easy tuning of the resonant wavelength by bulk thickness variations and thus allows spectrally highly resolved measurements. Contrary to OPDs working in the self-powered mode, this detector is optimized for operation under reverse bias. With its high spectral response, low-cost readout circuitry based on CMOS technology could be used for signal detection.

1:45 PM EL16.02.02

**Control of Resistance Temperature Change of Solution-Processed Conductive Polymers for Strain Sensor Applications** Yu Kato<sup>1</sup>, Kenjiro Fukuda<sup>2,2</sup>, Takao Someya<sup>1,2,2</sup> and Tomoyuki Yokota<sup>1,1</sup>; <sup>1</sup>The University of Tokyo, Japan; <sup>2</sup>RIKEN, Japan

Organic materials are used in flexible electronics due to their excellent flexibility and simple fabrication using solution processes. Because the resistance of organic materials changes with strain and temperature, flexible strain<sup>[1]</sup> and temperature<sup>[2]</sup> sensors using organic materials have been studied. In such sensors, control of conductivity and resistance temperature change is important. When the device is used as a strain sensor, the resistance temperature change needs to be small to make the sensor less susceptible to temperature. In contrast, when the device is used as a temperature sensor, the resistance temperature change should be large to increase sensitivity. Low conductivity makes the device more sensitive to electronic noise. In this study, we evaluated the influence of the fabrication conditions on the conductivity and temperature characteristics of devices using conductive polymers. Then, we selected a condition and applied it to a strain sensor.

Chromium and gold were evaporated on substrates as electrodes. Conductive polymers were spin-coated on the substrates followed by annealing under a nitrogen atmosphere. Conductive polymers consisted of a polymer material and a p-type dopant. The doping concentration in this experiment was 12%, which means that twelve dopant molecules were added per one hundred monomeric units of the polymer. The standard conditions in this experiment were P3HT for the polymer, BCF for the dopant, and 70 °C for the annealing temperature, and the effects of changing these conditions were evaluated. Temperature coefficient of resistance (TCR) is defined as the ratio of resistance change to temperature change. In this study, TCR was calculated using the resistances at 25 and 40 °C. When the device was applied to the strain sensor, a 1- $\mu$ m-thick parylene was deposited on the device as a passivation layer. A gauge factor, defined as a ratio of resistance change to applied strain, was measured.

By adding BCF to P3HT, the conductivity increased by four orders of magnitude, and the TCR changed from -1.3%/K to -0.9%/K. Increasing the annealing temperature from 70 to 150 °C reduced the conductivity by two orders of magnitude and changed the TCR to -2.0%/K. Similar results were obtained when F4-TCNQ was used as a dopant, indicating that the influence of the dopant type on the characteristics was small. When other polymers such as DPP-DTT, PTB7 and PBDTT-DPP were mixed with F4-TCNQ, the TCRs were -2.0%/K, -2.3%/K, and -2.7%/K, respectively. Subsequently, we fabricated a strain sensor using P3HT/BCF annealed at a low temperature, which was a condition that exhibited a small resistance temperature change and high conductivity. The gauge factor of the sensor was 5.9 when a tensile strain of 6.6% was applied. The sensor was attached to an arm and detected resistance change during arm bending.

**Interplay of Electrical and Mechanical Properties of Doped Conjugated Polymers** [Christian Müller](#); Chalmers University of Technology, Sweden

Chemical and electrochemical doping are widely used to modulate the electrical properties of conjugated polymers. Doping of thin films facilitates fundamental spectroscopic studies and, ultimately, is important for the operation of devices from transistors to solar cells. However, some applications such as thermoelectrics and wearable electronics require bulk materials, which complicates doping processes and mass transport, limiting the performance of devices. This talk will explore some of the fundamentals of doping of both thin films and bulk materials. The impact of doping on the electrical as well as mechanical properties will be discussed, and it is shown how doping can be used to tune both the conductivity and stiffness of conjugated polymers. Finally, strategies are explored that permit to decouple the effect of doping on the electrical and mechanical properties, which can be used to prepare a variety of conducting bulk materials, from stiff composites and foams to hydrogels and stretchable fibers.

**Role of Confinement in Enhancing Electrical Transport of Conducting Polymers** [K. S. Narayan](#), Sukanya Das and Chandan Pramanik; JNCASR, India

Confined conducting polymers (CPs) such as in nanocylinder geometries have been shown to exhibit enhanced conductance that is primarily attributed to factors such as chain alignment, increased crystallinity, and/or pi-pi stacking. We address the significance of these factors of polymers confined in alumina nanocylinders of diameters ranging from 20 nm to 100 nm and compare them with properties of bulk films. A conducting substrate of suitable work function and a common top contact was used to examine the macroscopic electrical transport of the CPs in these regularly patterned structures. Isolated nanopores were examined using conducting atomic force microscopy methods. A series of conducting polymers that include in-situ polymerized PEDOT:Tos, other forms of PEDOT from aqueous dispersion, and n-type doped polymers were examined. The enhanced vertical conductivity that is normally not observed in thick PEDOT films due to the transport barriers also points to the reduced degree of disorder. The difference in electrical charge transport of polymer blend PEDOT:PSS and polymer-monomer blend PEDOT:Tos in alumina scaffold in terms of  $\sigma$  as a function of  $\omega$  and  $T$  highlights the efficacy of this approach to reduce disorder in tailored systems. The high-resolution transmission electron microscopic technique illustrates the picture of structural disorder present in the nanochannels and the variation of connecting pathways between the ordered regions on an amorphous matrix in two types of CPs with similar electronic PEDOT backbone. The confinement facilitates microstructures as the in-situ polymerization of PEDOT:Tos proceeds. The utility of these geometry-induced properties is demonstrated in the context of photodetection and thermoelectric applications.

**A Close Look at Organic Magnetoresistance in Conjugated Polymers** [Zuchong Yang](#) and Emanuele Orgiu; Institut National de la Recherche Scientifique (INRS), Canada

Migratory animals in nature can amazingly sense Earth's extremely weak magnetic field (~50 micro-tesla) and use it as a compass for the precise navigation during their long-distance migration. It has been shown that this mysterious magnetoreception capability is closely related to the quantum spin dynamics of radical pairs from their magnetically sensitive proteins<sup>1</sup>. Intriguingly, some lab-synthesised organic semiconductors (OSCs) can also show a similar magnetic field response but to a much wider range (from sub-milli-tesla to tens of tesla), even at room temperature. The electrical current of organic-based devices can exhibit a noticeable variation when the latter ones are immersed in a magnetic field, which is called the organic magnetoresistance (OMAR). As OMAR is believed to be originated from bipolaron formation, which is intimately coupled with the charge transport, it represents an attractive playground for understanding the fundamental spin physics in OSCs and further exploring its potential for organic spintronics.

So far, most of the previous studies on OMAR have been based on limited kinds of model OSCs such as Alq<sub>3</sub>, polyfluorene with a relatively disordered charge transport, which also serve as the active layer in the organic light-emitting diode<sup>2</sup>. Compared with a diode, a 3-terminal field-effect transistor (FET) adds a powerful electrical knob to tune the charge density inside the semiconductor via electrostatic doping. Furthermore, by functionalizing with different self-assembled monolayers, the structure of additional semiconductor-dielectric interface can also have an impact on the charge transport and spin dynamics through van der Waals interaction. Thus, an extensive study on state-of-the-art OSCs and more importantly, from the perspective of FET, could provide insights for understanding the effect of magnetic field-dependent spin pair configuration on charge transport. Herein, we chose three high-performance semiconducting polymers with the microstructure ranging from semi-crystalline to semi-amorphous, and representative of p-, n-, and ambipolar-type, respectively. Exploiting the transistor configuration, we studied the magnetic field effect on charge transport in these conjugated polymers under both low (100 milli-tesla) and high magnetic field (up to 9 tesla). A systematic investigation of the temperature-, electric field-, and interface-dependent magnetoresistance will be presented in detail.

**Amorphous Poly-3-Hexylthiophene Thin Films via Electro Spray Deposition under High Vacuum** [Shubham Bhagat](#) and Ingo Salzmann; Concordia University, Canada

Conjugated polymers (CPs) are heavily explored for their application in flexible organic electronic devices such as organic photovoltaics, organic light emitting diodes, organic transistors and organic thermoelectrics. This interest in CPs mainly stems from their high flexibility and ease of processibility on the large-scale by using cost-efficient solution-based techniques. Moreover, unlike their inorganic counterparts, the materials class of organic semiconductors offers the striking advantage that their optoelectronic properties can be easily tuned by their chemical structure including the chain length. However, CPs are thermally fragile thus intrinsically inhibiting vacuum deposition by thermal evaporation. Therefore, CPs are typically processed by solution-based techniques only. There, however, the extent of polymer pre-aggregation and film growth is substantially influenced by the choice of the solvent and other difficult to control experimental factors. The resulting microstructure in CP films can, in addition, not be improved by processing at

elevated temperatures, which are largely inaccessible for common solvents. In contrast to conjugated organic molecules (COMs) that can be processed in-vacuo to form crystalline films of high coherence lengths, prototypical CPs such as regioregular poly(3-hexylthiophene) (P3HT) are semi-crystalline when grown from solution with the ratio of crystalline to amorphous film portion being hard to control. For CPs, molecular doping enables tuning the thin-film conductivity over orders of magnitude. However, the film crystallinity has huge impact on the charge carrier mobility in CP heterostructures as well as pristine and doped CP films, where it has been argued that amorphous and crystalline film portions react differently to dopant exposure. Due to the intrinsic semi-crystalline nature of CPs such as P3HT in thin films, information experimentally gained comprises superimposed signatures from the crystalline and amorphous regions of the CP. Therefore, preparing amorphous CP films represents the most straightforward experimental approach to disentangle this information. In contrast to *improving* the structural properties of semi-crystalline CP films, however, deliberately *reducing* their crystallinity and achieving *amorphous* films has not been achieved so far. Here, we demonstrate that room-temperature high vacuum electrospray deposition (HV-ESD) of P3HT enables reproducibly establishing such films and provide evidence for their amorphicity by synchrotron grazing-incidence X-ray diffraction (GIXRD). In addition to details of the experimental procedure of HV-ESD and the properties of pristine P3HT films established therewith, we will discuss their doping phenomenology with the strong electron acceptor 2,3,5,6-Tetrafluoro-tetracyanoquinodimethane (F4TCNQ).

**Tuning the Properties of Poly(3-alkylthiophene)s via Side Chain Engineering** Genevieve Sauve; Case Western Reserve University, United States

Regioregular poly(3-alkylthiophene)s (P3ATs) constitute an important class of conjugated polymers (CPs) for organic electronic applications. In particular, poly(3-hexylthiophene) (P3HT) is one of the most studied and accessible CPs due to its simple synthesis that enables kilogram scale production. One way to potentially tune CPs properties without affecting electronic properties is to introduce functional groups several carbons away from the conjugated backbone. However, such modifications can affect CPs self-assembly, crystallinity and  $\pi$ - $\pi$  stacking, making it challenging to optimize properties while maintaining good charge carrier mobility. It is thus essential to better understand how side chain modifications affect desirable properties. Here, we explore using side chain engineering to increase the relative dielectric constant ( $\epsilon_r$ ) and to improve the mechanical properties of P3ATs. Results give us guidelines to tune properties while maintaining favorable film morphology for charge carrier mobility.

Conjugated polymers typically have low  $\epsilon_r$  (3-4), which limits their application. Increasing  $\epsilon_r$  could enhance device performance by promoting exciton dissociation, reducing bimolecular charge carrier recombination, and enhance charge carrier mobility via charge screening. Here, we introduced highly polar methylsulfinyl and methylsulfonyl groups at the end of P3AT side chains. This placement should allow the polar groups to efficiently rotate and increase orientational polarization. High  $\epsilon_r$  values were achieved for these functionalized P3ATs based on an accurate capacitance measurement using a gold/semiconducting polymer/SiO<sub>2</sub>/n-doped Si configuration. The  $\epsilon_r$  at megahertz and room temperature increased from 3.8 for P3HT to 7.4 for the sulfinylated and 8.1-9.3 for sulfonylated P3ATs. These values are among the highest  $\epsilon_r$  reported for CPs. Grazing-incident wide-angle X-ray diffraction results showed that these polar groups decreased the crystallinity for the polythiophene backbones and interfered with the  $\pi$ - $\pi$  stacking in the crystalline structure, especially the methylsulfonyl groups. From this study, we conclude that the methylsulfonylated polymers may be promising to provide a balance between high  $\epsilon_r$  and preserving favorable  $\pi$ - $\pi$  stacking structure for device applications.

Like most CPs, P3ATs tend to be brittle, limiting their application. Interestingly, one of the polymers with high dielectric constant had unusual mechanical properties. We hypothesized that the improved properties were due to the ester group six carbon away from the backbone. To better understand the effect of ester groups on both mechanical and electronic properties, we synthesized two random copolymer series: poly(3-alkylthiophene-2,5-diyl)-*ran*-(3-(6-pentanoatehexyl)thiophene-2,5-diyl) where alkyl is either hexyl (P3HT series) or dodecyl (P3DDT series). In both series, the ester-functionalized side chain content was varied. The copolymer's optical, thermal, structural, electrical and mechanical properties were investigated. Optimal mechanical and electrical properties were obtained with 10% ester content, and the mechanical property improvements were maximized when the co-side chain was shorter (hexyl) than the ester-functionalized side chain. The best combination of robustness and charge carrier mobility was thus obtained for the P3HT random copolymer with 10% ester-functionalized side chain: a high fracture strain (29±6%) combined with a high tensile strength (3.9±0.6 MPa) was achieved while maintaining the same high charge carrier mobility than a similar MW P3HT (0.12±0.01 cm<sup>2</sup>/Vs). These exciting results demonstrate the feasibility of using ester-functionality in optimizing both mechanical and electrical properties of poly(3-alkylthiophene)s.

**Tuning Work Function and Device Efficiency in Nanostructured Organic Layered Interfaces—From Electrochemical Crosslinking to Hybrid Dendrimers** Rigoberto C. Advincula; The University of Tennessee/Oak Ridge National Laboratory, United States

The introduction of organic and polymer layers in bulk heterojunction solid-state devices, displays, and transistor devices, plays a central role in mediating device performance. It is often associated with thin-layered nanostructuring and control of energy/electron transport corresponding to mobility with the active layers. In this talk, we emphasize our studies in the use of nanostructuring methods and rational electrochemically active dendrimer synthesis to fine-tune the work function in organic semiconductor devices, i.e. to increase device performance and efficiency. Several examples of this approach in exploring the role of electro-active species include 1) synthesis and electrochemical crosslinking of precursor polymers, 2) grafting of polymer brushes and patterning, 3) utilizing surface plasmon resonance spectroscopy to probe transport phenomena, and 4) LED, PV and sensor device development.

SESSION EL16.03: Poster Session: Carrier-Dopant Interactions in Organic Semiconductors—From Fundamentals to Applications III

**Role of Polymer-Dopant Distance on Charge Transport in Amorphous and Crystalline Domains in Doped Conjugated Polymers** Michael Lu-Díaz<sup>1</sup>, Muhamed Duhandzic<sup>2</sup>, Subhayan Samanta<sup>1</sup>, Simon Harrity<sup>1</sup>, Zlatan Aksamija<sup>2</sup> and Dhandapani Venkataraman<sup>1</sup>; <sup>1</sup>University of Massachusetts Amherst, United States; <sup>2</sup>The University of Utah, United States

Conjugated polymers lack free carriers and thus need to be chemically doped to increase conductivity. This process, however, introduces energetic disorder and charge traps. Therefore, there is a compelling need to identify factors that affect dopant-polymer interactions and modify them suitably for improved charge transport. The effect of Coulomb interaction of charged polymer and dopant counterion is one such factor. In literature, some studies ascribe reduced Coulomb interactions to increased counterion size while others to increased molecular ordering. We resolve this apparent conflict by evaluating the

impact of doping the crystalline and amorphous domains on the density of states (DOS) and how each domain type contributes to charge transport. We measured Seebeck coefficient ( $\alpha$ ) and electrical conductivity ( $\sigma$ ) of gradually dedoping of regioregular and regiorandom P3HT films and their blends. We used wide angle X-ray scattering and UV-Vis-near IR spectroscopy to characterize the doped P3HT films and fitted data to a phonon-assisted hopping model of charge transport to extract the dopant-induced disorder from the calculated DOS. We show that the regiorandom and regioregular domains in the doped polymer simultaneously contribute to the charge transport with their individual contribution depending on their doping level. We also show that any observable impact of counterion size or paracrystallinity on charge transport can be correlated to polymer-dopant distance,  $R_s$ . Our two-DOS model of crystalline and amorphous regions connects well to the observed trends in the  $\alpha$ - $\sigma$  curves of regiorandom and regioregular P3HT blends. Our work shows the amorphous domain encounters a larger dopant-induced disorder and also contributes to charge transport significantly. Thus, it is important to take into account the effect of dopant-induced disorder on particular structural regions while designing polymers and dopants for improved charge transport.

**Enhancing the Power Factor of SWNT Thin Films for Organic Thermoelectrics** Sooyon Chang, Prithwish Biswas and Zhiting Tian; Cornell University, United States

Thermoelectrics are regarded as one solution that upcycles waste heat to convert it into a useful resource; electricity. A thermoelectric device utilizes the Seebeck effect across a p-type and n-type material to create a voltage difference from a temperature gradient. Unlike many developments in the area of p-type, many conventional n-type materials have been restricted to inorganics that are toxic and expensive. Here, we focus on organic n-type material through doping and post-treatment which allows us to tune the power factor (PF) even further. Organic single wall carbon nanotubes (SWNT) are known for their high electrical conductivity through electron hopping of valence electrons and have shown potential for thermoelectrics. We have fabricated micron-thick SWNT films using a surfactant to induce an n-type behavior and doped them to further increase the electrical conductivity. The films were measured over 3 months and retained a stable negative Seebeck coefficient, which proves as a promising candidate for long-term thermoelectric devices. We have found that the different annealing temperatures and doping times of the dopant resulted in a distinguished surface morphology where we could improve the electrical conductivity with no diminishing of thermopower.

#### 8:45 AM EL16.04.02

**Quasi-Instantaneous Doping Mechanism of Organic Semiconductors by a Strong Lewis Acid** Melissa Berteau-Rainville<sup>1</sup>, Shubham Bhagat<sup>2</sup>, Thomas Baumgartner<sup>3</sup>, Emanuele Orgiu<sup>1</sup>, Christopher Caputo<sup>3</sup> and Ingo Salzmann<sup>2,2</sup>; <sup>1</sup>Institut National de la Recherche Scientifique, Canada; <sup>2</sup>Concordia University, Canada; <sup>3</sup>York University, Canada

The doping of organic semiconductors (OSCs) is of crucial importance for applications in electronic devices, where it is used to alter the opto-electronic properties of OSCs. P-type doping is generally achieved via the admixture of strong electron acceptors, i.e. molecules that feature a high electron affinity, in order to remove a full electron from the OSC. Because of their typically conjugated nature such molecules tend to form supramolecular complexes with the organic semiconductor instead of promoting electron transfer, which quenches the efficiency of the dopant. Furthermore, control over structure in doped systems, which is paramount to performances in applications, is difficult to achieve because these molecules do not interact covalently.

In this light, trivalent group XIII Lewis acids (boron, aluminum centers) have been used as dopants, paired with OSCs that contain hard nitrogen atoms to which they can bind covalently. This resulted, for example, in the possibility to tune the bandgap of OSCs by employing acids of different strengths, but not in full electron transfer. In other systems where OSCs do *not* feature hard basic sites to which LAs can bind covalently, however, full electron transfers were reported, notably in the poly(3-hexylthiophene) (P3HT) - tris(pentafluorophenyl)borane (BCF) system. This came as a surprise as the electron affinity of BCF is thought to be insufficient to induce such electron transfers. As such, it was more recently proposed that this doping proceeds via a proton transfer that can be introduced by water traces even in inert environments, through a mechanism that was calculated to be highly endergonic.

Considering all these findings, we will report on the surprising observation that BCF can readily dope three different thiophene-containing OSCs of relatively low ionization energy in a quasi-instantaneous manner that is at odds with a highly endergonic mechanism. We investigated more closely the doping behavior of several Lewis acids analogous to BCF with P3HT in order to understand the factors determining the ability of Lewis acids to produce such doping. We performed supporting DFT calculations to assess the energetics involved in different possible mechanisms. Altogether, our data strongly suggest that this quasi-instantaneous doping is not mediated by a proton transfer alone, which we will discuss in the framework of the previously suggested doping processes known to be at work for organic semiconductors.

#### 9:00 AM \*EL16.04.03

**Adduct-Forming and Macromolecular Dopants for Semiconducting Polymers** Howard E. Katz, Jinfeng Han, Tushita Mukhopadhyaya, Connor Ganley and Paulette Clancy; Johns Hopkins University, United States

The traditional vision of the dopant-semiconductor interaction, including organic and polymeric semiconductors, is direct electron transfer between the two, leaving a charge carrier on the semiconductor in the form of a mobile radical ion and an oppositely charged counterion. In this presentation, we explore a two-step alternative doping mechanism, by which the dopant forms a covalent adduct with a conjugated polymer segment, and that adduct subsequently participates in the electron transfer that leads to the charge carrier generation. We investigated both p-type and n-type versions of this process, using tris(pentafluorophenyl)borane (TPFB) and fluoride anion (F<sup>-</sup>), respectively, as the adduct-forming species. Many structures of conjugated segments were used as models for the polymer segments that might form adducts with TPFB or F<sup>-</sup>. Evidence that adducts could serve as dopants was obtained from conductivity and Seebeck coefficient measurements, electron paramagnetic resonance (EPR) spectroscopy, optical absorbance spectroscopy, and Density Functional Theory calculations. Furthermore, we paired the F<sup>-</sup> dopant with a pyridinium polymer to create an n-type analog of PEDOT-PSS, where the charge transporter and dopant counterion in the conducting composition are both macromolecular, and the electronic conductivity was especially high compared to that obtained from single-molecule dopants.

#### 9:30 AM BREAK

**10:00 AM EL16.04.04**

**Inhomogeneous Dopant Distribution in Organic Semiconductors: Causes and Consequences for Charge Transport** Martijn Kemerink; University of Heidelberg, Germany

While the effect of the incorporation of dopant molecules on the microstructure of the host material has been intensely investigated, translating these results to electronic properties has received less attention. Here, we will show two case studies of inhomogeneous dopant distribution in organic semiconductors, for which we do a quantitative comparison between experimental data of dopant distributions and conductivity and numerical simulations thereof. For the latter we developed two intuitive tools to produce simplified yet realistic morphologies of doped organic polymers, accounting for the effects of (a) aggregation and phase separation in the semiconducting host material and of (b) diffusion and preferential incorporation in specific phases of the dopant. The created morphologies are then used as starting point for kinetic Monte Carlo simulations of charge transport. Importantly, the case studies can be generalized to design rules to achieve high conductivity at low dopant concentrations.

**10:30 AM EL16.04.05**

**Stable and Tunable Chemical Doping for Organic Semiconductors in Aqueous Solution under Ambient Conditions** Masaki Ishii<sup>1,2</sup>, Yu Yamashita<sup>1,3</sup>, Shun Watanabe<sup>3</sup>, Katsuhiko Ariga<sup>1,2,3</sup> and Jun Takeya<sup>1,3</sup>; <sup>1</sup>National Institute for Materials Science, Japan; <sup>2</sup>Tokyo University of Science, Japan; <sup>3</sup>The University of Tokyo, Japan

Doping levels in chemical doping of organic semiconductors are determined by semiconductor and dopant energy levels. While precise control of doping is required to fabricate advanced devices, as seen in silicon semiconductors, control in doping levels at a scale of thermal energy (25 meV) has been challenging for organic semiconductors. Most of dopants are unstable under ambient conditions owing to the reactivity with water or oxygen in air, which further decreases precision in doping levels. Low precision in doping levels and need for inert processing environment have been bottlenecks for developing and manufacturing advanced organic semiconductor devices employing chemical doping.

In this study, doping levels of organic semiconductors were controlled reproducibly and precisely in aqueous dopant solution under ambient conditions [1]. In our method, chemical doping is based on proton-coupled electron transfer (PCET) reactions that are widely observed in biochemistry, unlike conventional methods that employ single electron transfer reactions. Our aqueous dopant solutions contain dopant salts, pH adjusting agents and PCET-based redox couples. As a PCET-based redox agent, for instance, Benzoquinone/Hydroquinone (BQ/HQ) couple was employed. Through redox reactions, BQ gets transformed into HQ by accepting two electrons and two protons, where its redox potential depends on proton activity, pH, of the aqueous solution following the Nernst equation. A well-known p-type semiconducting polymer, poly[2,5-bis(3-tetradecylthiophen-2-yl)thieno[3,2-b]thiophene] (PBTTT), was doped by BQ/HQ doping solutions. PBTTT got oxidized when the redox potential of BQ/HQ exceeded the Fermi level of PBTTT in a low pH environment. The positive charge introduced into PBTTT was compensated by intercalation of anions in aqueous solution similarly to anion-exchange doping in organic solvents [2]. Bis(trifluoromethanesulfonyl)imide (TFSI) or bis(nonafluorobutanesulfonyl)imide (NFSI) was employed as dopant anion introduced into PBTTT, which would realize stable doped state owing to their closed-shell structures and hydrophobicity [3].

Doping level of PBTTT was controlled by the pH value of dopant aqueous solution, where the redox potential of BQ/HQ showed pH dependence of 59 mV/pH. According to the optical absorption and conductivity measurement, the doping level of PBTTT increases with decreasing solution pH. Tuning of doping levels were also confirmed by structural analysis based on X-ray diffraction and elemental analysis based on X-ray photoelectron spectroscopy measurements. Doping levels of one PBTTT film were modulated repeatedly by cycles of increase and decrease in solution pH, which demonstrates that both of oxidation and reduction of organic semiconductors take place in our system that develops chemical equilibrium. It was verified that one can control the Fermi level of organic semiconductors reproducibly with a high degree of precision, *ca.* thermal energy of 25 meV at RT, over a few hundred meV around the band edge. This is a critical range to control electronic properties of semiconductors.

Our PCET-based system provides a facile, scalable, precisely controlled, reproducible and reliable chemical doping method, which would lead to ambient processed organic electronics and bioelectronics.

**Effect of Dipolar Dopants on Charge Carrier Transport in Ordered Molecular Semiconductors with Order Parameters** Akira Ohno, Tsukasa Nakamura, Yukiko Takayashiki, Jun-ichi Hanna and Hiroaki Iino; Tokyo Institute of Technology, Japan

We have investigated the orientational and translational order effect of dipolar molecules on carrier transport. Random orientation of dipolar or polar molecules interacting with carriers provides static disorder in organic semiconductors. We examined the doping effect of dipolar dopants using liquid crystalline organic semiconductors, which provides us with a useful model system for examining the effect in both experiments and simulations: we doped molecules with electrostatic dipoles or molecular polarization in smectic liquid crystal, e.g., phenylanthracene derivatives, which show the layered structure and resulting 2D carrier transport. The dopants such as organic cyanides and ketones are controlled in their orientation and translational ordering in the smectic liquid crystals where they are either mixed in intralayer or microphase separated in the interlayer, while the others are inserted into the interlayer and behave in a three-dimensional random orientation and coordination in the alkyl chain of liquid crystal.

Obtained mobilities by time-of-flight experiments have characteristic temperature and field dependence and can be analyzed by Gaussian disorder formalism. These effects are successfully analyzed by using our theoretical model based on calculating the N-th moment of the total Coulomb potential contribution of dipoles for an ordered molecular alignment. We found that the dipole dopants degrade the carrier transport in the 2D-ordered layer structure and gave the additional energetic disorder  $\sigma_d$  proportional to a square root of the dipole concentration  $\sim C^{1/2}$ . Therefore, it should be noted that the carrier transport is less sensitive to the dipoles compared with that in the 3D conduction system. We also confirmed the phenomena by carrier transport simulation of kinetic Monte Carlo for a snap-shot of hopping sites decided by MD simulation with generated energetic disorder landscape.

This dependence shows us that the effect on carrier transport is limited in highly ordered materials, even if there is an origin that causes a large static disorder. This gives us an insight into why the behavior of carrier transport is different between crystal and semi-ordered phases such as liquid crystals or polymers. Intrinsic mobilities measured in various liquid crystalline (LC) materials reported in the last few decades, do not change much from material to material but do change much from mesophase to mesophase: for example, typical mobility is on the order of  $\sim 10^{-2}$ - $10^{-3}$  cm<sup>2</sup>/Vs in crystal B and E phases, of  $\sim 10^{-2}$ cm<sup>2</sup>/Vs in hexatic B phase, and  $10^{-3}$ cm<sup>2</sup>/Vs in smectic A and C phases [1] regardless chemical structures of liquid crystal. On the other hand, a wide variation of mobilities from  $10^{-3}$  to  $10$  cm<sup>2</sup>/Vs depending on chemical structures is often observed in crystals. It is true even for liquid crystalline molecules, benzothienobenzothiophene (BTBT) derivatives, such as Cn-BTBT and Ph-BTBT-Cn in crystalline phase: in fact, high mobility of over  $10$  cm<sup>2</sup>/Vs reported in their crystalline phase. [2]

These facts indicate a clear contrast in carrier transport between the ordered and semi-ordered phases. For investigating the origin of differences, we introduced the Gaussian disorder model restricted by the order parameters as static disorder into the charge transport model with the dynamic disorder. This model can be consistently applied for both crystalline and liquid crystalline phases and made it possible to discuss the difference in carrier transport between crystal and semi-ordered materials. These fundamental studies are very important for the functional design of organic semiconductors, especially for the operation of printable electronics.

**Minimizing Molecular-Dopant-Induced Disorder in Emerging Semiconductors** Keehoon Kang; Seoul National University, Korea (the Republic of)

Doping has been one of the most essential methods to control charge carrier concentration in semiconductors. Excess generation of charge carriers is a key route for controlling electrical properties of semiconducting materials and typically accompanies alteration of electronic structure by the introduction of dopant impurities, both of which have played pivotal roles in making breakthroughs in inorganic microelectronic and optoelectronic devices both at research and industrial levels, especially for Si-based technology. Molecular doping is a facile and effective doping method for various semiconducting materials since it is relatively non-invasive compared to high-energy implantation of ionic impurities used in Si. However, there are main challenges remaining in fully utilizing molecular doping in emerging semiconducting materials such as  $\pi$ -conjugated polymer semiconductors, two-dimensional materials and metal-halide perovskites due to the difficulties in preventing dopant-induced disorder effects while maintaining a high carrier mobility. This talk will introduce concepts that we have developed to minimizing the dopant-induced disorder [1, 2, 3] while mitigating current injection and doping stability issues in electronic devices [4, 5], and finally outline the future challenges remaining in the field to fully uncover the potentials.

**Self-Doped Conjugated Polymers and Copolymers - Feasibility and Advantages in Devices** Julian Hungenberg, Adrian Hochgesang, Florian Meichsner and Mukundan Thelakkat; University of Bayreuth, Germany

Mixed ionic-electronic conductors are widely studied for accumulation mode (undoped systems) or depletion mode (doped systems) devices. PEDOT:PSS has been established as the working horse for depletion mode organic electrochemical transistors (OECTs) as it consists of the conjugated polymer PEDOT<sup>+</sup> which is intrinsically doped and stabilized by PSS<sup>-</sup> counterions. It is neither soluble in water nor organic solvents, wherefore thin films are processed from aqueous dispersion. This results in a nonuniform film morphology consisting of doped PEDOT-rich domains surrounded by an insulating PSS matrix. This particular structure leads to several drawbacks such as long-term instability. Furthermore, its complex structure hampers the ability for chemical modification.

In contrast to PEDOT:PSS, most conjugated polymers are intrinsic (pristine or undoped) semiconductors and hence show very low electrical conductivities. Therefore, doping is necessary to increase the charge carrier density and thus the electrical conductivity. Upon molecular doping, active redox species are added to the OSC which can donate (n-type) or accept electrons (p-type) generating free charge carriers. For p-type doping, this means a transfer of electrons from the highest occupied molecular orbital (HOMO) of the OSC to the lowest unoccupied molecular orbital (LUMO) of the dopant. Issues here are the requirement of deep-lying dopant LUMO, thus stability against air/water, and the need for high amounts of dopants for charge carrier formation which ultimately disturbs the film morphology.

To address these challenges, our group took high efforts in the field of molecular doping of conjugated polymers. The first concept published takes advantage of HOMO-HOMO doping by mixing two donor materials (OSC-1 and OSC-2). OSC-2 is a chemically oxidized small molecule semiconductor namely Spiro-OMETAD(TFSI)<sub>2</sub> which is capable to oxidize the OSC PDPP[*T*]<sub>2</sub>-EDOT (OSC-1). Thereby, the doping takes place by an electron transfer from the HOMO<sub>OSC-1</sub> to the partly occupied HOMO<sub>OSC-2</sub>.<sup>1</sup> A second work extends this concept through the use of multielectron acceptor salts. For this, oxidized triphenylamines were linked to form multielectron acceptor dopants, which can accept up to four electrons per dopant. This strategy allows for significantly reducing the number of dopant molecules compared to common single electron acceptor dopants.<sup>2</sup>

Here, we present a novel synthetic strategy of a conjugated polyelectrolyte (CPE) based on a polythiophene-derivative toward a stable self-doped system which can be solution-processed from water as well as organic solvents. Our new CPE is intrinsically doped after synthesis, which is promoted by the stabilization of free charge carriers by its ionic side chains. We present self-doping as an elegant way to avoid the use of molecular dopants fully, while still maintaining high and stable conductivity. This was investigated by time-resolved spectroelectrochemistry in aqueous electrolytes, UV-vis spectroscopy in thin films in the dry state as well as conductivity measurements. We were furthermore able to employ our self-doped CPE as a mixed conductor and showed its application in a depletion mode OECT device with high transconductance and currents. By copolymerization with a comonomer, which is not self-dopable, we were able to tune the self-dopability and therefore to switch the transistor's mode of operation towards a well-performing accumulation mode device with a low threshold voltage.<sup>3</sup> These findings could help to study the self-doping processes and to develop new CPEs with low threshold voltages towards innovative device applications.

**Challenges in Doping of Organics: Small Molecules vs. Polymers** Karl Leo; IAPP, Germany

Controlling the charge carrier densities is a key feature of any semiconductor electronic device. In inorganic semiconductors, general understanding of doping has been achieved early on and research has concentrated on finding dopants in large-gap systems like nitrides. In organic materials, doping is now a routine technique for mass-produced OLED displays and organic solar cells. However, it is still far from a microscopic understanding. Furthermore,

doping in organic systems where both electronic and ionic transport happen has recently generated much interest. In this talk, I will address these two very different systems: I will discuss recent progress in understanding the doping in small-molecule semiconductors, touching new dopants and high mobility materials, allowing to realize devices like the first organic bipolar transistors. I will compare to recent work on the doping of organic electrochemical transistors (OECTs). These devices have recently been investigated broadly since they offer switching and sensing functionality in an electrolytic environment compatible with biological systems. The mixed electron-ion transport of the devices has consequences for the doping process, making it significantly different from the electrostatic doping of standard FET devices.

**Molecular Doping of Conjugated Polymers for Flexible and Printed Organic Thermoelectric Generators** Boseok Kang; Sungkyunkwan University, Korea (the Republic of)

Organic thermoelectric generators (OTEGs) have received significant attention as a promising independent energy harvesting solution in the era of the Internet of Things. The OTEG device is attached directly to the surface of heat energy sources and transforms waste heat energy into valuable electricity based on the principle of the Seebeck effect. Several attempts have been made to achieve high-efficiency solution-processed OTEG devices, but there still remains a challenge to improve the thermoelectric figure of merits and the solution processibility for the device fabrication. In particular, doping is essential for controlling the charge carrier concentration in the conjugated organic media and governing charge transport physics, resulting in optimized device performance. In this talk, I will discuss various doping and molecular design strategies for improving the thermoelectric efficiency and solution processibility of conjugated polymers for flexible and printed OTEGs.

**Enhancing Performance in DPP-based N-type Thermoelectrics for Molecular Doping Utilizing HSP Approach** Soyeong Jang<sup>1</sup>, Diego Rosas Villalva<sup>1</sup>, Guorong Ma<sup>2</sup>, Anirudh Sharma<sup>1</sup>, Andrew Bates<sup>2</sup>, Abdel H. Amwas<sup>2</sup>, Xiaodan Gu<sup>2</sup> and Derya Baran<sup>1</sup>; <sup>1</sup>Kaust, Saudi Arabia; <sup>2</sup>The University of Southern Mississippi, United States

The solubility of conjugated polymers (CPs) significantly determines their device performance. Consequently, understanding the relationship between the solubility of n-type host polymer-dopant-solvent systems and their electronic properties is vital within the CPs realm. This study delves into the impact of various halogenated solvents on the solubility and morphological properties of a novel pyridine-flanked DPP n-type polymer (2PyDPP-2CNTVT) and Tetrabutylammonium fluoride (TBAF) as the dopant system. We utilized Hansen Solubility Parameter (HSP) for the solubility study. We employed Grazing Incidence Wide Angle X-ray Scattering (GIWAXS) and Atomic Force Microscopy (AFM) to probe the doped polymer thin films' molecular structural disorders and surface morphology. Our findings indicate that Dichlorobenzene (DCB) solvent has superior solubility affinity for the polymer backbone and dopant. This affinity fosters improved host-dopant miscibility, excellent dopant accommodation, and enhanced film processibility. Consequently, this leads to increased electron mobility ( $\mu_e$ ) of 2.3 cm<sup>2</sup> V<sup>-1</sup> s<sup>-1</sup> and conductivity ( $\sigma$ ) of 2.64 S cm<sup>-1</sup> compared to films made with alternative halogenated solvents in this study. Additionally, our multidisciplinary experimental approach reveals an improved doping efficiency resulting from the lowest activation energy in the DCB system. These insights propose the DCB solvent as the optimal choice for achieving high  $\mu_e$  and electrical conductivity  $\sigma$  in TBAF-doped 2PyDPP-2CNTVT CP film. This work underscores the importance of selecting solvent based on HSP evaluation to maximize the potential of molecular doping into n-type DPP-based CP, mitigating the trade-off between  $\sigma$  and Seebeck coefficient (S).

**Advancements in Molecular Doping of Semiconducting Polymers: Applications in Organic Thermoelectrics** Shravyesh Patel; University of Chicago, United States

Molecular doping of semiconducting polymers holds significant promise for organic thermoelectrics, offering tunable electronic properties and ease of processability. In the first part of the talk, we delve into the fundamental structure-property relationships of sequentially doped thiophene-based polymers, shedding light on dopant segregation, microstructure, and their impact on conduction limits and stability. In the second part, we explore the potential of molecular doping in the development of functionally graded materials (FGMs) for organic thermoelectrics. Specifically, we demonstrate precise compositional control in thin film FGMs through sequential vapor doping of polythiophene derivatives with 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4TCNQ). Utilizing techniques such as grazing incidence wide angle X-ray scattering (GIWAXS) and Raman spectroscopy, we spatially resolve dopant compositional profiles within the FGM thin films. Additionally, we quantify the lateral distribution of electronic conductivity and Seebeck coefficient, providing insights into the spatial distribution of transport parameters. Our research advances the understanding of structure-transport properties and contributes to the development of efficient organic thermoelectric materials through sequential doping and functional grading.

**Enhancing Thermoelectric Properties and Optimization Through Coulombic Interactions and AI-Driven High-Throughput Experiments** Kedar Hippalgaonkar<sup>1,2</sup>; <sup>1</sup>Nanyang Technological University, Singapore; <sup>2</sup>Institute of Materials Research and Engineering, Singapore

Our studies propose a novel approach to enhance thermoelectric properties in conducting polymers by controlling coulombic interactions, without regulating morphology. We observe a significant three-fold enhancement in the thermoelectric power factor of OD-PDPP2T-TT compared to PBTIT-C12, attributed to improved counterion screening, verified experimentally by measuring the dielectric constant of the films, and explaining the enhancement through Boltzmann Transport Equations [1]. We establish a correlation between optical absorption signatures and thermoelectric properties, extracting carrier concentration and confirming the importance of charge mobility amidst structural disorder. Furthermore, we demonstrate the benefits of combining high-throughput experiments with machine learning for materials and process optimization, especially by consider optical signatures that directly provide information about doping [2]. Our automated setup enables rapid thin film preparation and characterization, achieving a >10x improvement in learning cycles. By combining regio-regular poly-3-hexylthiophene with carbon nanotubes, we identify optimal compositions achieving high electrical

conductivities [3]. This integrated approach offers insights into enhancing thermoelectric properties and accelerates materials optimization in organic thermoelectrics.

**Beyond Doping: Self-Induced Anisotropy Breaks the  $\sigma$ -S Coupling Towards High Performance N-Type Conjugated Polymer Thermoelectrics.** Diego Rosas Villalva<sup>1</sup>, Deniss Derewjanko<sup>2</sup>, Yongcao Zhang<sup>1</sup>, Ye Liu<sup>1</sup>, Andrew Bates<sup>3</sup>, Anirudh Sharma<sup>1</sup>, Soyeong Jang<sup>1</sup>, Xiaodan Gu<sup>3</sup>, Martijn Kemerink<sup>2</sup> and Derya Baran<sup>1</sup>; <sup>1</sup>King Abdullah University of Science and Technology, Saudi Arabia; <sup>2</sup>Heidelberg University, Germany; <sup>3</sup>The University of Southern Mississippi, United States

In recent years, there has been continuous progress in the development of N-type organic thermoelectrics (OTE) due to the synthesis of new conjugated polymers and dopants. The primary focus of most designs has been to enhance doping efficiency and increase electrical conductivity, resulting in values surpassing  $102 \text{ S cm}^{-1}$ . Although effective, doping encounters limitations because of the inherent inverse relationship between the properties that determine the figures of merit in thermoelectric materials. To advance the field further, alternative approaches are needed beyond optimizing doping efficiency and the host:dopant ratio. In this study, we propose the concept of self-induced anisotropy as a solution to overcome the inverse coupling between electrical conductivity and Seebeck coefficient in N-type OTEs. Previous research has suggested methods like rubbing and drawing to induce anisotropy in p-type OTEs based on thiophenes. In our work, we exploit the interactions between solvent, host, and dopant to induce a preferential orientation. This orientation increases the in-plane delocalization length, thereby improving electrical conductivity while maintaining the Seebeck coefficient. By adopting this approach, we have achieved promising results in the 2DPP-2CNTVT:N-DMBI system. At room temperature, we obtained a Power Factor of  $115 \mu\text{W m}^{-1} \text{K}^{-2}$  and a figure of merit of 0.17, which further increased to  $188 \mu\text{W m}^{-1} \text{K}^{-2}$  and 0.36, respectively, at 105 C. To explain the origin of self-induced anisotropy, we utilized Hansen Solubility Parameters and established guidelines for formulating solvent-host-dopant systems that can achieve a similar effect. This discovery opens new possibilities for advancing N-type OTEs.

### 3:45 PM EL16.05.06

**Elucidating Design Rules Towards Enhanced Solid-State Charge Transport in Oligoether-Functionalized Dioxythiophene-Based Alternating Copolymers** Abigail A. Advincula<sup>1,2,3</sup>, Amalie Atassi<sup>1</sup>, Shawn A. Gregory<sup>1</sup>, Karl Thorley<sup>4</sup>, James Ponder<sup>2,1,5</sup>, Guillaume Freychet<sup>6</sup>, Austin Jones<sup>1</sup>, Gregory Su<sup>7</sup>, Shannon Yee<sup>1,1</sup> and John R. Reynolds<sup>1,1</sup>; <sup>1</sup>Georgia Institute of Technology, United States; <sup>2</sup>Air Force Research Laboratory, United States; <sup>3</sup>ARCTOS Technology Solutions, United States; <sup>4</sup>University of Kentucky, United States; <sup>5</sup>UES, Inc., United States; <sup>6</sup>Brookhaven National Laboratory, United States; <sup>7</sup>Lawrence Berkeley National Laboratory, United States

Understanding solid-state charge transport in chemically doped, electrically-conductive conjugated polymers (CPs) is important to emerging applications which include organic thermoelectrics, transparent electrodes, and bioelectronics. The synthetic tunability of CPs, e.g., backbone or side chain modulation, affords high control over energy levels (i.e., ionization energy/electron affinity), doping processes, and microstructures, factors which influence the electrical conductivity of a given CP system.

This study investigates the solid-state charge transport properties of the oxidized forms of dioxythiophene-based alternating copolymers consisting of oligoether-functionalized 3,4-propylenedioxythiophene (ProDOT) copolymerized with different aryl groups, dimethyl ProDOT (DMP), 3,4-ethylenedioxythiophene (EDOT), and 3,4-phenylenedioxythiophene (PheDOT) respectively, to yield the copolymers P(OE3)-D, P(OE3)-E, and P(OE3)-Ph. At a dopant concentration of 5 mM FeTos<sub>3</sub>, electrical conductivities for these copolymers vary significantly (ranging between  $9 \text{ S cm}^{-1}$  and  $195 \text{ S cm}^{-1}$ ) with the EDOT copolymer, P(OE3)-E, achieving the highest electrical conductivity. UV-vis-NIR and X-ray spectroscopies show differences in both susceptibility to oxidative doping and extent of oxidation for the P(OE3) series, with P(OE3)-E being the most doped. Wide angle X-ray scattering measurements indicate that P(OE3)-E generally demonstrates the lowest paracrystallinity values in the series, as well as relatively small  $\pi$ - $\pi$  stacking distances. The significant (i.e., order of magnitude) increase in electrical conductivity of doped P(OE3)-E films versus doped P(OE3)-D or P(OE3)-Ph films can therefore be attributed to P(OE3)-E exhibiting both the highest carrier ratios in the P(OE3) series as well as good  $\pi$ - $\pi$  overlap and local ordering (low paracrystallinity values). Furthermore, these trends in extent of doping and paracrystallinity are consistent with the reduced Fermi energy level and transport function prefactor parameters calculated using the semi-localized transport (SLoT) model. Observed differences in carrier ratios at the transport edge ( $c_e$ ) and reduced Fermi energies [ $\eta(c)$ ] suggest a broader electronic band (better overlap and more delocalization) for the EDOT-incorporating P(OE3)-E polymer relative to P(OE3)-D and P(OE3)-Ph. Ultimately, we rationalize improvements in electrical conductivity due to microstructural and doping enhancements caused by EDOT-incorporation, a structure-property relationship worth considering in the future design of highly electrically conductive systems.

### 4:00 PM EL16.05.07

**Ion-Exchange Doping of Semiconducting Single-Walled Carbon Nanotubes** Angus Hawkey, Aditya Dash, Zhiyong Zhao, Anna Champ, Michael Zharnikov, Martijn Kemerink and Jana Zaumseil; Heidelberg University, Germany

Due to their unique electronic and thermoelectric properties, networks of purely semiconducting single-walled carbon nanotubes (SWNTs) are a promising material for thermoelectric generators, which convert a temperature difference produced by waste heat into an electrical current. Dense films of SWNTs can be deposited from dispersion (e.g., by printing) and are mechanically flexible. They reach high electrical conductivities upon p- or n-doping and retain a high Seebeck coefficient. To introduce the charge carrier densities relevant for thermoelectric applications, chemical doping is typically used. However, the remaining dopant counterions are often unstable and the impact of the counterion on the thermoelectric properties of the SWNTs is still not fully explored. The recently developed technique of ion-exchange doping provides a means to exchange the dopant counterion with anions or cations from a huge library of commercially available salts and ionic liquids that do not possess the redox potential to reduce or oxidize the SWNTs themselves. In this work, we fabricated thin film networks of polymer-sorted small and large diameter SWNTs (>99% semiconducting) and chemically p-doped them using ion-exchange doping with a range of dopant counterions at low and high doping levels. Optical and electrical measurements reveal the ion-exchange efficiency and the influence of the counterion size on the electrical and thermoelectric properties.

### 4:15 PM \*EL16.05.08

**The Influence of Counterion Structure and Doping Level on the Optical, Electronic, and Thermoelectric Properties of  $\pi$ -Conjugated Polymers** Kyle N. Baustert, Ashkan Abtahi, Joel H. Bombile, Ahmed Ayyash, Chad Risko, Augustine O. Yusuf and Kenneth R. Graham; University of Kentucky, United States

Many organic electronic devices use chemical or electrochemical doping to introduce charge carriers into  $\pi$ -conjugated polymers (CPs) and change their

optical and electronic properties. As these charge carriers are introduced into a CP, counterions are either created (chemical doping) or injected (electrochemical doping) into the CP to balance the charge associated with the polaron on the CP. The structure of these counterions can exert a pronounced influence on the properties of doped CPs. Understanding how dopants and counterions interact with CPs to influence their optical and electronic properties is thus critical to designing new dopants and electrochemically doped CPs. Here, we focus on the influence of counterion size on the optical, electronic, and thermoelectric properties of selected CPs, including P3HT derivatives and PDPP4T. At the small and large ends of the spectrum we use tetrafluoroborate ( $\text{BF}_4^-$ ) and tetrakis[3,5-bis(trifluoromethyl)phenyl]borate ( $\text{BArF}^-$ ), respectively, where  $\text{BArF}^-$  has a molar volume that is eight times larger than  $\text{BF}_4^-$ . We find that the electrochemical doping behavior and polaron absorbance of *regioregular*-poly(3-hexylthiophene), *rr*-P3HT, differs significantly depending on whether  $\text{BF}_4^-$  or  $\text{BArF}^-$  is the counterion. Through comparing *rr*-P3HT to *regiorandom*-P3HT, *rra*-P3HT, we attribute the counterion-dependent properties of *rr*-P3HT partly to the ability of the counterion to penetrate the crystalline regions. The large counterion  $\text{BArF}^-$  cannot penetrate the crystalline regions and as a result a higher potential is needed to oxidize *rr*-P3HT with  $\text{BArF}^-$ . Counterion distribution is not the only influential parameter, as the low energy polaron absorbance peak (P1) appears at lower energy with  $\text{BArF}^-$  for both *rr*- and *rra*-P3HT, which density functional theory calculations indicate is due to the larger size of  $\text{BArF}^-$  relative to  $\text{BF}_4^-$  and the resulting increased distance between the charged counterion and charged polaron. Through electron paramagnetic resonance (EPR) measurements we show that the smaller counterion  $\text{BF}_4^-$ , which can penetrate the crystalline regions, results in increased bipolaron formation relative to  $\text{BArF}^-$  as a counterion in *rr*-P3HT. Additionally, we find that the choice of counterion impacts both the electrical conductivity and Seebeck coefficient reached at a given charge-carrier concentration for P3HT derivatives and PDPP4T. These results highlight the influential interplay between counterion structure, polymer morphology, and resulting optical, electronic, and thermoelectric properties.

SESSION EL16.06: Design of Dopants and Polymers II

#### 8:30 AM EL16.06.01

**Changing the Charge Transport Mechanism in Conjugated Polymers via Post-Processing Side Chain Removal** James Ponder<sup>1,2</sup>, Shawn Gregory<sup>3</sup>, Amalie Atassi<sup>3</sup>, Abigail Advincula<sup>1,4</sup>, Joshua M. Rinehart<sup>3</sup>, Shannon Yee<sup>3</sup> and John R. Reynolds<sup>3</sup>; <sup>1</sup>Air Force Research Laboratory, United States; <sup>2</sup>UES, Inc., United States; <sup>3</sup>Georgia Institute of Technology, United States; <sup>4</sup>Arctos, United States

As the processability of electroactive conjugated polymers (CPs) is essential to their application in a range of devices, balancing solubility, processability, and film properties has become a key point of research. Solubilization of the conjugated backbone is typically achieved by introduction of relatively long branched hydrocarbon or oligoether side chains, which allows many degrees of conformational freedom. Such side chains, while enabling a wide range of processing conditions, reduce the relative fraction of active material in the film and obstruct  $\pi$ - $\pi$  intermolecular interactions, leading to increased localization of charge carriers and compromise many of the desirable properties of the material (such as electrical conductivity). To counteract the deleterious effects introduced by side chains, we report that post-processing side chain removal, exemplified here via ester hydrolysis, significantly increases the electrical conductivity of chemically doped CP films with a corresponding decrease in Seebeck coefficient. In a model alkyl ester functionalized 3,4-propylenedioxythiophene (ProDOT) system, we found that the electrical conductivity of oxidatively doped films increased 10-fold upon side chain removal via hydrolysis. A combination of X-ray photoelectron spectroscopy (XPS), profilometry, and grazing incidence wide angle X-ray scattering (GIWAXS) results show that improvement in electrical conductivity and reduced Seebeck values are not due to an increase in carrier ratio (i.e., number of charge carriers per repeat unit ring), but instead results from an increase in charge carrier density (i.e., number of charge carriers per unit volume) due to densification and increased ordering of active polymer backbone material following side chain removal. This increase in charge carrier density leads to a reduction in charge localization, thereby improving charge transport, as contextualized using the newly developed semi-localized transport (SLoT) model. Applying this method to 3,4-ethylenedioxythiophene (EDOT) copolymer and homopolymer structures, synthesized via direct arylation polymerization, significantly higher average electrical conductivities are attained, with values ranging from 450 to ~1200 S/cm, depending on the repeat unit structure, in thick (> 600 nm) films. In an all EDOT-based system, we observe a change in transport mechanism, from a low electrical conductivity and thermally activated (hopping-like) regime to a high electrical conductivity and thermally deactivated (metal-like) regime. Finally, these results are compared to those of matching oligoether functionalized polymers for a direct comparison of the differences in charge transport between these two reported methods of conductivity enhancement.

#### 8:45 AM EL16.06.02

**Maleimide-Substituted Polyacetylene: A New Highly Conductive n-Type Polymer** Harrison M. Bergman and Timothy M. Swager; Massachusetts Institute of Technology, United States

The development of highly conductive organic semiconductors has been a longstanding goal in materials science due to their chemical tunability, solution processability, mechanical flexibility, and other unique properties. Conjugated polymers are some of the most promising materials in this respect and have been widely employed in diverse device architectures such as organic field effect transistors (OFETs), organic light emitting diodes (OLEDs), and organic photovoltaics (OPVs). These applications generally require both n-type and p-type semiconducting materials, but the development of p-type conducting polymers has greatly outstripped that of n-type and ambipolar systems. Specifically, n-type materials generally display lower conductivities and mobilities in their doped states and are less stable due to oxidation under ambient conditions.

This bottleneck is largely synthetic. Stability against oxidation requires decreasing LUMO levels well below -4.0 eV, yet there are relatively few building blocks that are sufficiently electron withdrawing to achieve this. Furthermore, there are limited design strategies for assembling these building blocks into polymers that retain high backbone planarity and electron delocalization, which are both critical to high mobility and conductivity. Thus, the development of new polymer scaffolds is critical to closing the performance gap between n-type and p-type conjugated polymers.

Polyacetylenes (PAs) are attractive as high conductivity polymers, holding the record for highest reported conductivity in an organic semiconductor. However, they are inherently p-type materials. Although the introduction of strongly withdrawing groups to the PA core is straightforward conceptually, there are several practical challenges. Many standard withdrawing groups are too sterically bulky to preserve backbone planarity, and those that remain are generally incompatible with traditional PA syntheses.

We address this issue by developing a new class of PAs consisting of an alternating sequence of maleimide and vinylene units, dubbed maleimide-polyacetylene or mPA. This structure achieves high backbone planarity while still introducing a high density of strongly withdrawing groups, furnishing a

highly conductive polymer with a low LUMO of -4.2 eV. The maleimide unit is also a facile synthetic handle, which enables the introduction of diverse functionality without perturbing backbone conformation. These polymers were accessed via a new synthetic approach, where a nonconjugated precursor polymer was synthesized via ring opening metathesis polymerization (ROMP), followed by an efficient elimination to furnish the final polyacetylene. This strategy is scalable and efficient and enables the synthesis of low dispersity polymers with highly controllable molecular weights. Beyond mPA, it should be generalizable to a range of other electron-deficient polyacetylenes, opening the door to a new class of n-type organic semiconductors.

**Negative Polaron in an n-Doped Polymer Semiconductor: Energy Levels and Hubbard  $U$  Interactions** Dominique Lungwitz<sup>1</sup>, Syed Joy<sup>2</sup>, Ahmed E. Mansour<sup>3</sup>, Andreas Opitz<sup>3</sup>, Chamikara Karunasena<sup>4</sup>, Hong Li<sup>4</sup>, Naitik A. Panjwani<sup>5</sup>, Kartikay Moudgil<sup>6</sup>, Kan Tang<sup>7</sup>, Jan Behrends<sup>5</sup>, Stephen Barlow<sup>7,6</sup>, Seth R. Marder<sup>7,6</sup>, Jean-Luc Brédas<sup>4</sup>, Kenneth R. Graham<sup>2</sup>, Norbert Koch<sup>3,8</sup> and Antoine Kahn<sup>1</sup>; <sup>1</sup>Princeton University, United States; <sup>2</sup>University of Kentucky, United States; <sup>3</sup>Humboldt-Universität zu Berlin, Germany; <sup>4</sup>University of Arizona, United States; <sup>5</sup>Freie Universität Berlin, Germany; <sup>6</sup>Georgia Institute of Technology, United States; <sup>7</sup>University of Colorado Boulder, United States; <sup>8</sup>Helmholtz-Zentrum Berlin, Germany

Doping organic semiconductors leads to the formation of polarons, positive in the case of p-doping and negative for n-doping. The released carrier polarizes neighboring molecular sites and induces intra- and inter-molecular relaxation. In the traditional picture, the formation of a negative polaron results in two localized levels within the gap: a half-occupied level below the LUMO/CBM, and a doubly occupied level above the HOMO/VBM. Conversely, the formation of a positive polaron results in an empty level below the LUMO/CBM and a half-occupied level above the HOMO/VBM. Recent experimental and theoretical studies have challenged this original interpretation.[1-3] In the case of an added electron (hole), the new picture points to a half-occupied (empty) level below the semiconductor LUMO/CBM, split from an unoccupied (half-occupied) level positioned above (below) the LUMO/CBM (HOMO/VBM). The split corresponds to the intra-molecular Coulomb interaction, also known as Hubbard interaction  $U$ . In this work, we investigate n-doping of the polymer P(NDI2OD-T<sub>2</sub>) with the molecular dopants [RhCp\* $^+$ Cp]<sub>2</sub> and [N-DMBI]<sub>2</sub> as well as Cs, using ultra-violet and low-energy inverse photoemission spectroscopy (UPS, LEIPES) aided by EPR measurements and DFT computations.[4] The UPS data show that all three dopants induce the growth of a DOS in the former empty gap of the polymer while LEIPES shows an additional DOS above the polymer CBM. In agreement with the above-mentioned new interpretation, the additional DOS is assigned to the formation of the singly occupied and unoccupied levels, and allows the direct determination of the Hubbard  $U$ .

**The Role of Redox Doping in Organic Electronics and Opto-Electronics** Seth R. Marder; University of Colorado Boulder, United States

Organic semiconductors and hybrid/organic materials have attracted interest for electronic applications due to their potential for use in low-cost, large-area, flexible electronic devices. Here we will report on recent developments pertaining to n-dopants that could impact the charge injection/collection processes in organic light emitting diodes, organic field effect transistors, and organic photovoltaic and hybrid organic/inorganic perovskite devices. I will highlight the application of n-doping for the development of electron injection layers for organic light emitting diodes (OLEDs), and their use for doping of electron transport materials which result in high conductivities and in some cases good thermoelectric performance. In the case of OLEDs, it will be shown that photoactivation (as illustrated in the cartoon at the right) can lead to stable doping of materials (i.e. the doping induced conductivity remains relative constant over hundreds of hours) beyond the expected thermodynamic limit, which would be predicted based on an assessment of the effective reduction potential of the n-dopant and the reduction potential of the electron transport material. We will also highlight some of the differences between approaches based upon “dimeric” dopants, vs. hydride donor dopants.

#### 10:30 AM EL16.06.05

**Deprotonation-Based n-Doping of a New Acceptor-Acceptor Conjugated Polymer** Andreas Erhardt<sup>1,2</sup>, Adrian Hochgesang<sup>2</sup>, John Mohanraj<sup>2</sup> and Mukundan Thelakkat<sup>2</sup>; <sup>1</sup>Monash University, Australia; <sup>2</sup>University of Bayreuth, Germany

Doped organic semiconductors have proven to be viable materials for heat-to-electrical energy conversion (TE: thermoelectrics). For working large-scale thermoelectric generator devices, the synergistic use of p- and n-type components is necessary. However, as common for organic semiconductors, stable, n-doped polymers are sparse. Besides approaches to solve intrinsic stability issues of the doped acceptor towards ubiquitous oxidizing agents (H<sub>2</sub>O and O<sub>2</sub>), the choice and underlying mechanism of suitable n-dopants is an open field of research.

Our very recent works report the design and synthesis of an acceptor-acceptor low LUMO copolymer (“DPP-TPD”, [1]) in conjunction with bulk n-doping using Cs<sub>2</sub>CO<sub>3</sub>. [2] We present a novel acceptor-acceptor copolymer synthetic strategy using direct arylation polymerization and demonstrate excellent viability for n-doped systems for TE applications.

In contrast to previous reports about Cs<sub>2</sub>CO<sub>3</sub> n-doped systems, we elucidate the mechanism, that our copolymer is doped via a solid-state acid-base interaction between the polymer and the basic carbonate. The resulting increase of the backbone electron density by deprotonation of the thiophene moiety is accompanied by the formation of bicarbonate. The crucial role of the basicity was demonstrated by comparative doping studies of the host polymer with further organic and inorganic carbonates. The general viability of the concept was evaluated with the strong base n-butyl lithium, which, in agreement with our findings, induces outstanding electron conductivity after thermal annealing. Comparable to N-DMBI hydride/electron transfer, Cs<sub>2</sub>CO<sub>3</sub> proton abstraction doping shifts the polymer work function towards the LUMO. Thereby, the anionic doped state is resilient against O<sub>2</sub> but is highly susceptible to H<sub>2</sub>O. Based on GIWAXS, Cs<sub>2</sub>CO<sub>3</sub> is mainly incorporated into the amorphous region of the film with the help of hydrophilic side chains and has a minor impact on the crystallinity. Together, the synergy between Cs<sub>2</sub>CO<sub>3</sub> proton abstraction doping and acceptor-acceptor copolymer strategy creates an n-doped system with promising properties for thermal energy conversion, as evidenced by a remarkable maximum power factor of  $(5.59 \pm 0.39) \times 10^{-6} \text{ W m}^{-1} \text{ K}^{-2}$  in n-type thermoelectric element.

The main implications and novelty of our work are a: the viability of copolymers, following an acceptor-acceptor design principle, and b: the possibility to n-dope suitable copolymers via deprotonation reactions using simple carbonate dopants, opening a vast field of new n-type dopants.

**Factors Promoting or Inhibiting Charge Transfer in Doped Organic Semiconductors** Ingo Salzmann; Concordia University, Canada

To control the conductivity of organic semiconductors (OSCs) and their energy level alignment in heterostructures and at interfaces, OSCs are being electrically doped by introducing guest species into the semiconductor host. Common doping agents added to initiate electron transfer include strong molecular donors/acceptors and Lewis acids. Complementary to direct integer charge transfer between OSC and dopant to form ion pairs (the ultimate goal of doping OSCs), fractional charge transfer can occur forming ground-state charge transfer complexes instead via intermolecular orbital rehybridization of OSC and dopant, which is detrimental to the doping efficiency [1]. For OSCs including oligothiophenes of different chain length *p*-doped with strong electron acceptors [2, 3], I will discuss the role that (i) thin film structure plays for the respective doping scenario, (ii) that of the dopant strength, and (iii) of OSC conjugation length. These findings suggest exploiting steric hindrance to suppress CPX formation which we recently demonstrated for a non-planar *p*-dopant of 3D shape [4]. Finally, I will contrast above doping scenarios to those that have been proposed to be at work for the doping of OSCs using Lewis acids as alternative doping agents.

**11:15 AM \*EL16.06.07****Engineering Carrier-Dopant Interactions to Improve Charge Transport Properties in Highly-Doped Semiconducting Polymers** Kilwon Cho; Pohang University of Science and Technology, Korea (the Republic of)

Doping is a powerful technique that can easily tune the electrical properties of semiconducting polymers and hence, grant flexibility to their applications. Highly-doped semiconducting polymers with high electrical conductivity have found extensive use in thermoelectric materials and bioelectronics. However, the low dielectric constant of semiconducting polymers causes strong Coulomb interactions between carriers and dopants. As a result, carriers cannot be effectively transported through the host polymer network and tend to localize within a few monomer units or  $\pi$ -stacks. These limitations, distinct from those observed in conventionally doped inorganic semiconductors, necessitate novel engineering strategies to not only generate more charge carriers but also reduce unfavorable electrostatic interactions between carriers and dopants in doped semiconducting polymers. This talk will explore straightforward engineering methods to reduce Coulomb interactions between carriers and dopants in highly-doped semiconducting polymers. The corresponding reduction in charge localization and improved transport achieved through these methods will be discussed. Additionally, I will explore the effects of molecular structures that exhibit resilience to the energetic disorder caused by electrostatic carrier-dopant interactions on charge transport properties. Lastly, the talk will introduce the significant thermoelectric performance achieved in our research and discuss the potential of thermoelectric materials based on doped semiconducting polymers for the near future.

SESSION EL16.07: Understanding the Impact of Dopant-Carrier Interactions

Session Chairs: Nagarjuna Gavvalapalli and Mukundan Thelakkat

Wednesday Afternoon, November 29, 2023

Hynes, Level 2, Room 205

**1:30 PM \*EL16.07.01****Quantifying Polaron Populations in Sequentially Doped Conjugated Polymers** Adam J. Moule<sup>1</sup>, Tucker L. Murrey<sup>1</sup>, Melissa Berteau-Rainville<sup>2</sup>, Meghna Jha<sup>1</sup>, Ingo Salzmann<sup>3</sup> and Mark Mascal<sup>1</sup>; <sup>1</sup>University of California, Davis, United States; <sup>2</sup>Institut National de la Recherche Scientifique, Canada; <sup>3</sup>Concordia University, Canada

Conjugated polymers can be chemically tailored for a variety of electronic device applications. Sequential solution doping with high electron affinity (EA) molecular dopants is the processing technique that has produced molecularly doped polymeric films with the highest conductivity. In spite of numerous studies quantifying the conductivity of molecularly doped polymers as a function of processing conditions, there is no established method to quantify the charge density. The consequence is that the relationship between conductivity, mobility, and charge density is poorly understood, prohibiting meaningful quantitative comparisons between different polymers and dopants. Here we demonstrate a practical method to quantify the polaron density using the material density, molecular volumes, and optical measurements. Importantly, this method enables quantitative comparisons between multiple different polymer and dopant combinations as we demonstrate using P3HT and a series diketopyrrolopyrrole (DPP) co-polymers doped with a series of ultra-high EA cyano- and ester-substituted cyclopropane-1,2,3-triylidene-based dopants. The Langmuir isotherm is used to fit the solution concentration dependence of the film polaron mole fraction, which enables characterization of the sequential doping process using a single equilibrium constant. The saturated polaron mole fraction saturates with respect to the energetic driving force for doping, indicating that simply increasing the EA of the dopant is not an effective strategy for obtaining 100% ionization of the polymer monomers. To ground this thermodynamic model, we simulated the density of states (DOS) using Gaussian energy distributions. This DOS model predicts the experimental saturated doping level for every polymer/dopant pair within uncertainty. This data and model demonstrate conclusively that increasing the polaron density has a larger effect on increasing both conductivity and charge mobility than the polymer chemistry or structure.

**2:00 PM \*EL16.07.02****Considerations on "Double Doping" and an Enhanced *p*-Dopant Complex** Norbert Koch<sup>1,2</sup>; <sup>1</sup>Humboldt-Universität zu Berlin, Germany; <sup>2</sup>Helmholtz-Zentrum Berlin, Germany

The double ionization of molecular dopants enables the doping efficiency to rise above 100%. This means increased conductivity can be achieved with fewer dopant molecules, resulting in less disruption to the semiconductor film's structure. However, current models of doped organic semiconductors based on Fermi-Dirac statistics with two distributions that represent the host and dopant density of states, fail to explain double dopant ionization, and also the analogous situation of bipolaron formation on a host semiconductor polymer. This shortcoming is addressed by considering the energy level renormalization of the frontier molecular orbital levels upon electron transfer between host and *p*-dopant. Varying the model parameters host-dopant energy level offset, energetic disorder, reorganization energy, and Hubbard *U* sublevel splitting, robust trends in the fractions of doubly-ionized, singly-ionized, and neutral species are found.

The conventionally used *p*-dopants based on tetracyanoquinodimethane (TCNQ) and its derivatives feature limited oxidation strength especially for modern polymer semiconductors with high ionization energy (IE). These small molecular dopants also exhibit pronounced diffusion in polymer hosts. A facile

approach is presented to increase the oxidation strength of several TCNQ-derivatives by coordination with four tris(pentafluorophenyl)borane (BCF) molecules, using a single-step solution mixing process, resulting in bulky dopant complexes. Using a series of polymer semiconductors with IE up to 5.9 eV, the efficiency of doping using such complexes is found to be significantly higher compared to using either of the dopants alone. Additionally, the bulkier structure of the complexes is shown to result in a higher stability against dopant drift in thin films under an applied electric field. The simple approach of solution-mixing of readily accessible molecules thus offers access to enhanced molecular *p*-dopants.

**Unlocking the Full Potential of Electron Acceptor Molecules for Efficient and Stable Hole Injection into Organic Semiconductors** Taku Oono, Takuya Okada, Tsubasa Sasaki, Takahisa Shimizu and Hirohiko Fukagawa; Japan Broadcasting Corporation, Japan

Improving the hole injection property are of pivotal importance in the future development of organic optoelectronic devices. Electron acceptor molecules with high electron affinity (EA) are widely used in electronic applications, such as hole injection, p-doping and charge generation. Although p-doping and charge generation have generally been discussed in terms of matching the ionization energy (IE) of organic semiconductors with the EA of acceptor molecules, it has been demonstrated that the EA depends on the charged states of acceptor molecules in recent years [1,2].

In this study, we report a strategy to maximize the potential of acceptor molecules for efficient and stable hole injection into organic semiconductors [3]. This strategy has been developed based on the correlation between the HIL-dependent properties of OLEDs and the actual energy levels around the anodes as determined by both low-energy inverse photoemission spectroscopy and ultraviolet photoemission spectroscopy. Efficient and stable hole injection into an organic semiconductor with a relatively high IE of 5.8 eV is possible by stacking acceptor molecules with EAs of 4.3 and 5.0 eV. This superior hole injection property enables direct hole injection even into materials used as the emitting host for pure blue thermally activated delayed fluorescence (TADF) emitters with a large band gap. A pure blue TADF organic light-emitting diode (OLED) that has both a Commission internationale de l'éclairage (CIE) *y* coordinate of less than 0.10 and a low turn-on voltage of only 2.67 V was realized by employing a device architecture with no energy barrier in the OLED. The findings are expected to have a wide range of organic electronic applications, such as the efficient hole injection into materials with high IE used in perovskite LEDs, organic thin-film transistors, and organic semiconductor laser diodes.

### 3:45 PM EL16.07.04

**Imaging the Effect of Nanoscale Morphology on Molecular Doping Efficiency in Conducting Polymers** Sung-Joo Kwon<sup>1</sup>, Rajiv Giridharagopal<sup>1</sup>, Shinya Chen<sup>1</sup>, Ramsess Quezada<sup>1</sup>, Jiajie Guo<sup>1</sup>, Justin Neu<sup>2</sup>, Wei You<sup>2</sup> and David S. Ginger<sup>1</sup>; <sup>1</sup>University of Washington, United States; <sup>2</sup>University of North Carolina at Chapel Hill, United States

Understanding the mechanisms underpinning doping of conducting polymers (CPs) is critical for improving their performance in next-generation organic electronic devices. Although a number of studies have investigated molecular or electrochemical doping of conducting polymers, most work has focused primarily on understanding doping via device-level operation using macroscopic probes. Conducting polymers (CPs) are inherently nanostructured, with a mixture of crystalline and amorphous domains. Thus, understanding the underlying mechanisms behind doping can benefit from nanoscale real-space imaging. Here, we investigate the molecular and electrochemical doping on two CPs with very different reported doping efficiencies (# charges/ dopant molecules) using functional atomic force microscopy methods. Specifically, we compare the morphology dependence behind the well-known poly(3-hexylthiophene) (P3HT) polymer, with alkyl sidechains, to a more state-of-the-art polymer p(g<sub>3</sub>2T-TT) that has been reported to exhibit substantially higher doping efficiencies. We use scanning Kelvin probe microscopy and conductive AFM to investigate local doping and visualize the morphology-dependence of local dopant/counterion accumulation. We use these methods to provide a link between optical measurements of doping with spectroelectrochemistry and local work function variations for films that have been molecularly and electrochemically doped. These results show that doping efficiency is linked to the polymer's ability to accommodate the dopant in its three-dimensional structure, where P3HT exhibits significant surface aggregation of molecular dopants that limits its ultimate efficiency compared to p(g<sub>3</sub>2T-TT). We validate these results chemically via time-of-flight secondary ion mass spectrometry, providing a comprehensive view of the interplay between the local structure and ion ingress. This work provides guidance for optimizing future combinations of polymeric materials and molecular dopants to maximize conductivity

### 4:00 PM EL16.07.05

**Thermal Stability of Organic Hole Transport Layers** Stephanie A. Buchholtz, Tobias Antrack, Hans Kleemann and Karl Leo; Dresden Integrated Center for Applied Physics and Photonic Materials, Germany

The electrical conductivity of amorphous doped organic hole transport layers, as used in organic light-emitting diodes (OLEDs), solar cells, or photodetectors, increases with temperature due to the dominant hopping-like transport mechanism. However, the conductivity irreversibly breaks down at a certain temperature. For example, OLEDs and organic photovoltaics have operating temperatures up to 80°C and 145°C, respectively. In addition, the active layer of an organic solar cell is deposited on the hole transport layer and has to be annealed at temperatures up to 140°C for a higher efficiency. The reasons for this breakdown are unknown, impeding the development of more stable devices. Here, we show a relation between the breakdown of the conductivity and the glass transition of the small molecule host materials and find that the choice of the dopant and the doping concentration significantly affects the thermal stability of the layer. Based on our investigations, we develop different hypotheses about the cause of the breakdown. With our results, we devise strategies to improve the thermal stability of organic hole transport layers.

### 4:15 PM \*EL16.07.06

**Counterion Control and the Electronic Structure of Polarons and Bipolarons in Doped Conjugated Polymers** Benjamin J. Schwartz; UCLA, United States

When an electron is removed from a conjugated polymer, such as poly(3-hexylthiophene-2,5-diyl) (P3HT), the remaining hole and associated change in the polymer backbone structure from aromatic to quinoidal are referred to as a polaron. Bipolarons are created by removing the unpaired electron from an already-oxidized polymer segment. In electrochemically-doped P3HT films, polarons and bipolarons are readily observed, but in chemically-doped P3HT films, bipolarons rarely form. We explain this observation by studying the effects of counterion position on the formation of polarons, strongly coupled polarons, and bipolarons using both spectroscopic and X-ray diffraction experiments and time-dependent density functional theory (TD-DFT) calculations. The counterion positions control whether two polarons spin-pair to form a bipolaron or whether they strongly couple without spin-pairing. When two counterions lie close to the same polymer segment, bipolarons can form, with an absorption spectrum that is blueshifted from that of a single polaron. Otherwise, polarons at high concentrations do not spin-pair, but instead J-couple, leading to a redshifted absorption spectrum. The counterion location

needed for bipolaron formation is accompanied by a loss of polymer crystallinity, so that bipolarons can form only in disordered regions of conjugated polymer films. Our TD-DFT calculations of polarons and bipolarons predict absorption spectra that match well with experiment, providing strong evidence that TD-DFT is correctly capturing the electronic structure of the doped material. Several groups, however, who looked at the energies of the Kohn-Sham orbitals from (non-time-dependent) DFT calculations, have recently argued that the traditional band picture is incorrect for doped conjugated polymers. Instead, these non-time-dependent DFT calculations suggest that polaron creation causes only one unoccupied state to move into the band gap near the valence band edge while half-filled states in the conduction and valence bands bend downward in energy. To understand the discrepancy, we also performed an analysis using natural transitional orbitals (NTOs) that shows that our TD-DFT calculations indeed reproduce the traditional band picture of polarons and bipolarons. Taken together, our experimental and theoretical results argue that controlling the counterion location and using the properly level of theory is critical to understanding the electronic structure of polarons and bipolarons on doped conjugated polymers.

SESSION EL16.08: Applications of Doped Organic Semiconductors

**Electrical Doping Stabilizes Organic Nanoparticle Dispersions for the Eco-Friendly Fabrication of Solar Cells** Felix Manger, Jonas Armleder, Philipp Marlow, Karen Fischer, Holger Roehm, Christian Sprau and [Alexander Colsmann](#); Karlsruhe Institute of Technology, Germany

Nanoparticle dispersions allow the use of eco-friendly processing agents for the solution deposition of organic semiconductor thin-films for photovoltaic and other optoelectronic applications. Omitting surfactants, which are commonly used to stabilize dispersions, is essential to not jeopardize the solar cell performance. In this work, electrical doping is used to charge the organic nanoparticles. The resulting electrostatic repulsion between the nanoparticles stabilizes the dispersion. Different doping concepts are deployed, compared and their effect on the nanoparticle stabilization is explored. Preference is given to volatile dopants which evaporate from the nanoparticulate light-harvesting layer after thin-film deposition. Finally, using electrical doping and the corresponding electrostatic stabilization, novel surfactant-free nanoparticle dispersions from high-performance organic semiconductors are synthesized by nanoprecipitation, giving rise to record solar cell power conversion efficiencies beyond 10%.

#### 8:45 AM EL16.08.02

**Efficient N-Doping in Organic Semiconductors by Novel Approaches and Materials Design** [Antonio Facchetti](#); Northwestern University/Flexterra Inc, United States

In this presentation we will report new strategies to efficiently n-doped organic semiconductor films. Thus, starting from initial work investigating molecular n-doping of naphthalenediimide (NDI) and isomeric benzothiadiazole (isoBT) based polymers we explored how variations in polymer backbone composition, regiochemistry, thin-film processing, and doping affect major film morphology and charge transport characteristics in transistor and diode architectures. For instance, we showed that NDI-(TVT)<sub>x</sub>(TET)<sub>y</sub> [x+y=100%; TVT = thienyl-CH=CH-thienyl; TET = thienyl-CH<sub>2</sub>CH<sub>2</sub>-thienyl] charge transport in transistor has a unique dependence on the x,y values. Thus, we explored how charge transport is affected in diodes as well as how NDI-(TVT)<sub>x</sub>(TET)<sub>y</sub> (polymer acceptor) + polymer donor solar cells perform. Finally, we recently discovered new approaches to enhance doping efficiency and conductivity via 1, tuning film morphology by favoring molecule dopant penetration and, 2, using catalysts that promote the semiconductor+dopant reaction. The latter strategy enables excellent doping efficiencies and conductivities for several organic semiconductors.

**Models of Polymeric Mixed Ionic and Electronic Conductors** [Alessandro Troisi](#)<sup>1</sup>, [Alessandro Landi](#)<sup>2</sup>, [Colm A. Burke](#)<sup>1</sup> and [Hesam Makki](#)<sup>1</sup>; <sup>1</sup>University of Liverpool, United Kingdom; <sup>2</sup>University of Salerno, Italy

In organic polymeric materials with mixed ionic and electronic conduction (OMIEC), the excess charge in doped polymers is very mobile and the dynamics of the polymer chain cannot be accurately described with a model including only fixed point charges. Ions and polymer are comparatively slower and a methodology to capture the correlated motions of excess charge and ions is currently unavailable. Considering a prototypical interface encountered in this type of materials, we constructed a scheme based on the combination of MD and QM/MM to evaluate the classical dynamics of polymer, water and ions, while allowing the excess charge of the polymer chains to rearrange following the external electrostatic potential. We used this methodology to study the timescale for electronic charge rearrangement and the change in static and dynamic disorder as the doping level increase. We also propose a microscopic mechanism for reversible charging of OMIEC materials that can be used for designing new materials and rationalizing the current experimental observations.

#### 10:30 AM \*EL16.08.05

**MURI: Doping in Organic and Printed Electronics Center (DOPE Center)** [Wei You](#); University of North Carolina at Chapel Hill, United States

Doping of organic semiconductors plays an important and growing role in organic electronics, ranging from organic light emitting diodes and organic solar cells to thermoelectrics and bioelectronics. However, unlike Si, where parts per million dopant concentrations can significantly alter conductivity, doping organic semiconductors with molecular dopants typically requires a much higher concentration. Complex interplay between the microstructure, electronic structure and molecular interactions of the polymer and dopants has prevented systematic understanding. Progress is largely dependent on heuristically guided, slow, trial-and-error experimentation. Furthermore, only *p*-type doping has been widely implemented in organic semiconductors, and *n*-type doping has met with limited success. Thus, developing air-stable *n*-dopants is an important objective for the field of molecular dopants.

Supported by the DoD MURI program, the DOPE Center aims to transform the field of solution-processed, doped conducting polymers by 1) co-designing optimized *p*- and *n*-doped conducting polymer systems and achieving facile *n*-doping, 2) extending our recent, paradigm-changing discovery of photoredox doping in conjugate polymers, 3) accelerating the pace of data generation by collaborative workflow integration of robotic experimentation and machine learning (ML) and artificial intelligence (AI) approaches, 4) creating fundamental knowledge that informs novel materials synthesis and system optimization.

This talk will introduce the DOPE Center, and progress made up to this point. Importantly, the DOPE Center welcomes collaboration, and hopes to serve as a coalescing point to work with the large community to rapidly advance the field.

#### 11:00 AM \*EL16.08.06

**Nanomechanics of Materials used in Flexible Electronics** [Deepak Venkateshvaran](#) and Leszek J. Spalek; University of Cambridge, United Kingdom

Organic semiconductors are multifunctional soft electronic materials that play an impactful role in the flexible electronics industry. Their use spans printed electronic circuits, large area displays, flexible solar energy harvesters, and implantable bioelectronics. For their competitive optical, electronic, thermoelectric, and spin-based properties, these soft electronic materials attract significant academic engagement, seeding new technologies for the future. [1, 2, 3]

Although macroscopic flexibility on the centimetre to metre scale is a unique selling point for organic semiconductor technology, not much is known about their mechanical properties on the nanoscale. Quantification of these nanomechanical properties, together with an understanding of nanoscale stiffness tunability and homogenisation, holds significant potential for fundamental and applied science. [4, 5]

During the last decade, the development of high precision atomic force microscopes has made it possible to quantify the mechanical properties of organic polymers on the scale of a few polymer chains. Techniques such as higher eigen mode imaging make it possible to visualise molecular ordering on the nanoscale under ambient conditions with ease. These techniques allow one to correlate molecular ordering with the stiffness that such ordering manifests.

In this talk, the science and technology of precision nanoscale measurement of mechanics will be spotlight. The interrelation between molecular organisation and nanomechanical properties in high-performance polymers used for organic electronics will be shown. [6, 7] A quantification of differences in strain within organic nanocrystal polymorphs will also be demonstrated. The measurement techniques demonstrated in this talk are extendable to a wide variety of multifunctional materials with a broad range of elastic properties and have significant use in both academia and industry.

**MXene Synthesis – Pros and Cons of Various Methods** Yury Gogotsi; Drexel University, United States

MXenes (carbides, nitrides, oxycarbides and carbonitrides of early transition metals) are a very large family of 2D materials. They have a chemical formula of  $M_{n+1}X_nT_x$ , where M is a transition metal (Ti, Mo, Nb, V, Cr, etc.), X is either carbon and/or nitrogen ( $n=1, 2, 3$  or 4), and  $T_x$  represents surface terminations (O, OH, halogens, chalcogens). The large variety of structures and compositions, availability of solid solutions on M and X sites, and control of surface terminations offer a plethora of materials to produce and investigate.<sup>1</sup> Combining their plasmonic properties with ease in aqueous processing, high electronic conductivity (over 20,000 S/cm), biocompatibility, and excellent mechanical properties, which exceed other solution-processable 2D materials, MXenes have the characteristics enabling numerous applications. However, the properties of MXenes depend on their synthesis method. Selective etching of Al, Si or Ga in acidic electrolytes is the most common approach. However, the use of molten salts for selective etching has been gaining the momentum, as MXenes with uniform halogen surface terminations can be produced. Hydrothermal and electrochemical selective etching methods have been introduced. Finally, CVD synthesis and topochemical synthesis using graphene/graphite or metal oxide add a new dimension. A critical overview of various synthesis techniques will be provided.

**Progress in the Direct Synthesis of Two-Dimensional Transition Metal Carbides and Nitrides (MXenes)** Di Wang<sup>1</sup>, Chenkun Zhou<sup>1</sup>, Alexander S. Filatov<sup>1</sup>, Wooje Cho<sup>1</sup>, Francisco Lagunas<sup>2</sup>, Mingzhan Wang<sup>1</sup>, Young-Hwan Kim<sup>1</sup>, Suriyanarayanan Vaikuntanathan<sup>1</sup>, Chong Liu<sup>1</sup>, Robert F. Klie<sup>2</sup> and Dmitri V. Talapin<sup>1</sup>; <sup>1</sup>University of Chicago, United States; <sup>2</sup>University of Illinois at Chicago, United States

MXenes are a large family of two-dimensional (2D) transition metal carbides and nitrides with a general formula of  $M_{n+1}X_nT_x$  ( $n = 1-4$ ), where M stands for early transition metal (such as Ti, V, or Nb), X is C or N, and T is surface terminations (for example, -OH, -F, and -Cl). Their structures can be described as  $n+1$  close-packed M layers interleaved with  $n$  layers of X atoms, then sandwiched between surface groups. MXenes have been actively studied for their potential applications in energy storage, electromagnetic interference (EMI) shielding, and catalysis.

MXenes are typically synthesized from a series of non-van der Waals precursors (MAX phases, where A is typically Al) by selectively extracting A atoms with hydrofluoric acid-containing solutions. This process is relatively time-consuming and generates hazardous waste, both of which may limit the scalability of MXene manufacture.

We demonstrated two direct ways, bypassing the MAX phase intermediates, to prepare one of the most widely used MXenes,  $Ti_2CCl_2$ . One is based on the high-temperature reaction of a stoichiometric mixture of precursors. The other uses chemical vapor deposition (CVD), where gaseous reagents flow through a heated substrate to form a thin film of product. We even pushed MXene bottom-up synthesis to a new level by expanding the scope of MXene available through direct synthesis, tuning the morphology of MXene products from stacks to spheres. The direct synthesis routes save time and minimize hazardous waste production. Besides, these new routes offer synthetic modalities not compatible with traditional methods, especially in cases where corresponding MAX phases are not available. Considering the extensive possibility of element combinations, the direct synthesis method could substantially expand the variety of MXene family. These benefits are expected to improve the efficiency of scaling production and expedite converting lab-scale discoveries into industrial-level applications.

**Synthesis of Three Families of Titanium Carbonitride MXenes** Teng Zhang, Christopher E. Shuck, Kateryna Shevchuk, Mark Anayee and Yury Gogotsi; Drexel University, United States

Layered MAX phases and 2D MXenes derived from them are among the most studied materials due to their attractive properties and numerous potential applications. The tunability of their structure and composition allows every property to be modulated over a wide range. Particularly, elemental replacement and forming a solid solution without changing the structure allows fine tuning of material properties. While solid solutions on M (metal) site have received attention, the partial replacement of carbon with nitrogen (carbonitrides) has received little attention. By applying this concept, herein we report the synthesis of three families of titanium carbonitride  $Ti_{n+1}Al(C_{1-y}N_y)_n$  MAX phases and  $Ti_{n+1}(C_{1-y}N_y)_nT_x$  MXenes with one, two and three C/N layers. This greatly expands the variety of known MAX phases and MXenes to encompass 16 titanium carbonitrides with tunable X-site chemistries and different 2D layer thicknesses, including MXenes in the  $Ti_4(C_{1-y}N_y)_3T_x$  system, which have not been previously reported. We further investigated the relationship between the composition, structure, stability, and synthesis conditions of the MXenes and their respective Al-based MAX phases. This range of materials will enable fundamental studies of the N:C ratio effect on optoelectronic, electromagnetic and mechanical properties of MXenes, as well as tuning those properties for specific applications

**Synthesis Science Between MAX Phases and MXenes** Christina S. Birkel<sup>1,2</sup>, Rose Snyder<sup>1</sup> and Carina Büchner<sup>2,1</sup>; <sup>1</sup>Arizona State University, United States; <sup>2</sup>Technische Universität Darmstadt, Germany

The synthesis of MAX phases and their two-dimensional siblings MXenes, especially when pushing beyond Ti-based compounds, is far from trivial. Our group uses diverse preparation techniques to access new versions of these intriguing types of materials, recent examples include Cr<sub>2</sub>GaC in the shape of carbonaceous microwires,<sup>1</sup> hollow and full microspheres<sup>2</sup> as well as hitherto unknown carbonitride phases, such as Cr<sub>2</sub>GaC<sub>1-x</sub>N<sub>x</sub> and V<sub>2</sub>GaC<sub>1-x</sub>N<sub>x</sub>.<sup>3</sup> We specialize in non-conventional methods, such as sol-gel chemistry<sup>4-6</sup> and microwave heating<sup>7</sup> to synthesize the MAX phases.

In this talk, I will highlight two of our recent projects: (i) Our work on a unique "S14" MAX phase (Mo<sub>0.75</sub>V<sub>0.25</sub>)<sub>5</sub>AlC<sub>4</sub>, its structural investigation and transition to the respective MXene including its electrocatalytic properties. (ii) The transition from a MAX-like "221" compound Mo<sub>2</sub>Ga<sub>2</sub>C to the fully exfoliated MXene Mo<sub>2</sub>CT<sub>x</sub> as well as Mn-doped variants.

All materials are structurally characterized by diffraction and microscopy techniques and a deeper understanding of their chemical composition, formation mechanism and stability is obtained through spectroscopy and thermogravimetric methods.

**MXenes: Science, Applications and Hype** Michel W. Barsoum; Drexel University, United States

At this juncture there is no doubt that MXenes have captivated the world's interest and with good reason. The number of potential applications is quite numerous and diverse. The use, or addition, of MXenes can boost some properties sometimes to record levels; in other cases it allows for herewith new applications for 2D materials. Their chemical diversity is also a huge attractor. As MXenes - like other new materials - get more popular, they are accompanied by hype. With hype comes responsibility. Hying, or overpromising, is bad for the field in general and should be curtailed. In this talk I differentiate between work done in the name of science that has little chance of applicability and other work that may lead to applications. The fundamental, and quite difficult problem to solve, with MXenes is that because we are dealing with essentially a few - 2, 3, 4 - of highly reactive transition metals layers interleaved with C or N, it will be very difficult indeed to render them oxidation resistant. It follows that applications where MXenes are placed in *open*, aqueous-based systems will be few and far between. Hying such applications - while not simultaneously solving the stability conundrum for times commensurate with the time of use in said applications - is irresponsible since they fall under the purview of science. Another example of hype is work on MXene-based supercapacitors. To date, most of supercapacitor work on MXenes makes use of dilute aqueous-based electrolytes. We have shown that when using such electrolytes, such as sulphuric acid, the self-discharge rate is quite high which, in turn, would again greatly limit the scope of applicability of such devices. Other potential pitfalls will be discussed.

**2:00 PM DISCUSSION TIME**

**2:15 PM EL17.02.03**

**M<sub>5</sub>X<sub>4</sub>: A Family of MXenes** Marley Downes<sup>1</sup>, Christopher E. Shuck<sup>1</sup>, Robert Lord<sup>1</sup>, Mark Anayee<sup>1</sup>, Mikhail Shekhirev<sup>1</sup>, Ruocun (John) Wang<sup>1</sup>, Tetiana Hryhorchuk<sup>1</sup>, Martin Dahlqvist<sup>2</sup>, Johanna Rosen<sup>2</sup> and Yury Gogotsi<sup>1</sup>; <sup>1</sup>Drexel University, United States; <sup>2</sup>Linköping University, Sweden

MXenes are two-dimensional (2D) transition metal carbides, nitrides, and carbonitrides typically synthesized from layered MAX-phase precursors. With over 50 experimentally reported MXenes and a near-infinite number of possible chemistries, MXenes are the fastest-growing family of 2D materials. They offer a wide range of properties, which can be altered by their chemistry (M, X, T<sub>x</sub>) and the number of metal layers in the structure, ranging from two in M<sub>2</sub>XT<sub>x</sub> to five in M<sub>5</sub>X<sub>4</sub>. Only one M<sub>5</sub>X<sub>4</sub>T<sub>x</sub> MXene, Mo<sub>4</sub>VC<sub>4</sub>, has been reported. Herein, we report the synthesis and characterization of two new phase-pure M<sub>5</sub>AX<sub>4</sub> mixed transition metal MAX-phases, (TiTa)<sub>5</sub>AlC<sub>4</sub> and (TiNb)<sub>5</sub>AlC<sub>4</sub>, and their successful topochemical transformation into (TiTa)<sub>5</sub>C<sub>4</sub>T<sub>x</sub> and (TiNb)<sub>5</sub>C<sub>4</sub>T<sub>x</sub> MXenes. The resulting MXenes were delaminated into single-layer flakes, analyzed structurally, and characterized for their thermal and optical properties. This establishes a family of M<sub>5</sub>AX<sub>4</sub> MAX phases and their corresponding MXenes. These materials were experimentally produced based on guidance from theoretical predictions, opening the door to exciting new applications for MXenes.

**2:30 PM \*EL17.02.04**

**Tailoring of Vacancy Concentration and Pore Size in MXenes** Johanna Rosen; Linköping University, Sweden

MXenes show great prospects for surface-related applications owing to their large surface area and unique physical and chemical properties. MXenes with vacancies, whether ordered or randomly distributed, have shown a significant property enhancement, particularly in energy storage devices. Generally, randomly ordered vacancies in 2D monolayers have the possibility to conglomerate and form pores of different size. The performance can then be further enhanced, allowing interaction with various inorganic and organic species depending on the pore size. I will present a general experimental approach for tailoring vacancy concentration and pore size in a selection of well-known MXenes, inspired by theoretical calculations. The method is based on alloying of the parent MAX phases, where the concentration of the alloying element is directly correlated to the vacancy concentration (pore size) in the resulting MXene. The synthesized MXenes are shown to have a large surface area, and are further characterized with respect to structure, composition, and selected properties. The formation of pores is shown to significantly enhance the capacitance, and the materials are predicted to have selectivity towards inorganic and organic chemical species which can play an important role in molecular separation and energy related applications.

**MXenes for Solid-State Electrochemical Energy Storage** Masashi Okubo; Waseda University, Japan

Layered transition-metal carbides/nitrides (MXenes) are an emerging family of electrochemical energy storage materials. When used as an electrode material with a liquid electrolyte, MXenes exhibit Li<sup>+</sup> intercalation without large structural changes, which enables fast ion transport as well as dense charge storage in the open interlayer space between MXene nanosheets. It is well known that the Li<sup>+</sup> intercalation of MXene electrodes is significantly affected by liquid electrolytes. However, the charge storage using MXene electrodes in inorganic solid electrolytes has rarely been investigated. Especially, the strain-free property of MXene should be beneficial to maintaining solid-solid interface, which enabling long-term cycling of all-solid-state batteries.

In this work, we investigate the charge storage behavior of various MXene electrodes with solid electrolytes. After clarifying the strain-free charge storage mechanism through the MXene–solid electrolyte interface, we exploit it for the stable operation of a strain-free ASSB using MXene as a negative electrode material.

**4:00 PM EL17.03.02**

**Bringing Together Laser Treated MXene and Titania Nanotubes Towards Composite Electrode Material Active under Visible Light** Katarzyna Siuzdak<sup>1</sup>, Dujearic Kouao<sup>1</sup>, Miroslaw Sawczak<sup>1</sup>, Vit Stranak<sup>2</sup>, Petr Sezemsky<sup>3</sup>, Jan Hanus<sup>3</sup>, Ondrej Kylian<sup>3</sup> and Katarzyna Grochowska<sup>1</sup>; <sup>1</sup>The Szwalski Institute of Fluid-Flow Machinery Polish Academy of Sciences, Poland; <sup>2</sup>University of South Bohemia in České Budějovice, Czechia; <sup>3</sup>Charles University, Czechia

For the past 20 years, taking into account as the starting date the discovery of the extraordinary properties of a single layer graphene, finally the materials exhibiting 2D architecture have gained more attention. Among family of chalcogenides and boron nitrides that became so popular, the carbides and nitrides of transition metals became a rising star due to the attractive properties [1]. In MXene flake one can find a layer of transition metal and interlayer of carbon with some termination (O, OH, F or Cl) that are linked also to the metallic part. Most of known MXene synthesis routes involved fluoride-containing compounds, either aqueous or molten salts treatment of the MAX phase. Despite individual sheets are obtained they are still formed in a specific stack of several micrometers providing some problem when the composite with other materials should be achieved.

To overcome this problematic issue we propose laser treatment as an additional step in the fabrication route. The fabrication of Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> is performed in a quite typical way including mixing of MAX phase with HF and HCl solution and further delamination supported with NaCl. Microscopic investigation revealed that MXene sheets form agglomerates and additional efforts should be undertaken. Therefore, the MXene powder was frozen using liquid nitrogen and on such frozen material a liquid isopropanol was poured. Then beam of 1064 nm generated by pulsed Nd:YAG laser was irradiating frozen Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>. The interaction between laser and this material results in its ablation and its capture in a liquid medium. During the process the solution above the frozen material become grayish and such liquid was collected after different periods of time. Both the resonant peak at 120 cm<sup>-1</sup> and the out-of-plane vibrations at 736 cm<sup>-1</sup> of Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> are clearly visible on the Raman spectrum confirming the preservation of the MXene structure.

Finally, the material was used for the modification of surface provided by titania nanotubes obtained via anodization of Ti plates and Ti sputtered layer. The modification was carried out via treatment with TiCl<sub>4</sub>/Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> solution followed by thermal annealing. The SEM inspection revealed that the initially smooth and thin walls of titania were uniformly overgrown and more porous but any agglomerates clogging the tubular interior were not detected. Cyclic voltammetry curves recorded for the series of modified titania electrodes indicated enhanced photoresponse under both visible and UV-vis light. In a particular case when the electrode was exposed to visible light, almost 20 times higher photocurrent at 0 V vs. Ag/AgCl/0.1M KCl comparing to bare titania was reached.

Apart from the improved photoresponse, the electrochemical activity of modified titania in the cathodic range was significantly changed, namely the cathodic current was much higher than the one registered for bare titania. For example at -1.0 V, bare titania exhibits nearly 0.1 mA/cm<sup>2</sup> whereas for the modified substrate the recorded current equals 2.6 mA/cm<sup>2</sup>. It should be underlined that when the treatment of titania was carried out with TiCl<sub>4</sub> solution but without addition of laser treated MXene, such electrochemical response was not achieved. It indicated that the presence of MXene is crucial for greatly improved electrochemical and photoelectrochemical properties of the composite electrode material.

Summarizing we would like to show the unique laser treatment of 2D metal carbide material and its possible usage for formation of the composite with inorganic platform exhibiting promising electrochemical and photoelectrochemical properties being of high importance for development in the research area of water splitting and photoconversion.

**Investigation of Electrochemical Properties of Carbonitride MXenes with Different Nitrogen Contents** Chun-Pei Cho<sup>1,2</sup>, Teng Zhang<sup>2</sup>, Kateryna Shevchuk<sup>2</sup>, Ruocun (John) Wang<sup>2</sup> and Yury Gogotsi<sup>2</sup>; <sup>1</sup>National Chi Nan University, Taiwan; <sup>2</sup>Drexel University, United States

Carbonitride MXenes with different nitrogen-to-carbon ratios have been fabricated. As the nitrogen content increases, the plasmonic resonance and A<sub>1g</sub> characteristic peaks in the Raman spectra become weaker, indicating successful nitrogen substitution in the carbon (X) sublattice of MXene. An additional redox pair in the cyclic voltammetry (CV) curves further confirms the presence of nitrogen species in the carbonitride MXenes. When utilized as the anode material in a supercapacitor with a 3M aqueous sulfuric acid electrolyte, the highest specific capacitance achieved by a carbonitride MXene is approximately 370 Fg<sup>-1</sup> at a scan rate of 2 mVs<sup>-1</sup>. The fitting results of XPS spectra demonstrate the reduction in both carbide and nitride signals, and C-Ti-F becomes the dominant surface termination after electrochemical cycling. The carbonitride MXene with the highest nitrogen level exhibits the best rate capability but the worst cyclic stability. It also shows inferior Coulombic efficiency at lower scan rates. In contrast, the Lithium-delaminated Ti<sub>3</sub>C<sub>2</sub> material has the best cyclic stability. The results of Electrochemical Impedance Spectroscopy (EIS) align with the CV results for the carbonitride MXenes. It has been demonstrated by Staircase Potentiometric Electrochemical Impedance Spectroscopy (SPEIS) that, with a higher nitrogen content, a less negative applied potential is required to achieve smaller impedance and interlayer spacing.

**V<sub>2</sub>C and Nb<sub>2</sub>C MXenes: An Emerging Tunable Platform for Nanophotonics** Alexandra Boltasseva<sup>1</sup>, Jeffrey Simon<sup>1</sup>, Colton Fruhlin<sup>1</sup>, Stefano Ippolito<sup>2</sup>, Danzhen Zhang<sup>2</sup> and Yury Gogotsi<sup>2</sup>; <sup>1</sup>Purdue University, United States; <sup>2</sup>Drexel University, United States

MXenes, or transitional metal carbides, carbon nitrides, and nitrides, have recently emerged as a fascinating class of two-dimensional nanomaterials. These materials follow the chemical formula  $Mn+1XnTx$ . A prototypical MXene,  $Ti_3C_2Tx$  has been studied extensively over the past two decades demonstrating remarkable electrical and optical properties and utilized for linear optical devices such as broadband absorbers, and nonlinear devices like saturable absorbers in lasing cavities. Here, we expand upon our groups' previous work with  $Ti_3C_2Tx$  to new members in the MXene family, specifically  $V_2C$  and  $Nb_2C$ . By employing ellipsometry, we investigate the optical response of  $V_2C$  and  $Nb_2C$ . Our findings reveal a metallic transition for  $V_2C$  at longer wavelengths, while  $Nb_2C$  retains its dielectric nature due to the higher carrier concentration in  $V_2C$ . This transition from dielectric to metallic behavior is marked by the permittivity  $\epsilon$  crossing zero in a region known as epsilon-near-zero (ENZ), which holds significant implications for optical technology. Furthermore, our research demonstrates that the ENZ point can be manipulated by adjusting the film thickness of  $V_2C$ , thereby affecting both its linear and nonlinear properties. These findings lay the foundation for future device development utilizing various members of the MXene family, including the creation of layered metamaterials.

**Etching Mechanism of Aluminum Layers during 2D MXene Synthesis** Chi Won Ahn; NNFC, Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Understanding the etching mechanisms of MXene and obtaining direct insights into the influence of etchants on structural features and defects are of critical importance for improving MXene properties, optimization of etching protocols, and exploring new MXene compositions. Despite their importance, such studies have been challenging because of the monoatomic thickness of the A-element layers being etched and aggressive etchants that hinder in situ studies. Here, we visualize the etching behavior of the  $Ti_3AlC_2$  MAX phase in different etchants at the atomic scale using focused ion beam and electron microscopy. We also report on the structural changes in the  $Ti_3AlC_2$  phase as a function of etching time and etchant type ( $LiF/HCl$ ,  $HF$ , or  $NH_4HF_2$ ) to reveal the etching mechanism for the first time.

**Controlling the Interlayer Spacing of Two-Dimensional Titanium Carbide (MXene) Membranes for Selective Ion Separations in Water** Yaguang Zhu, Austin J. Booth, Kimberly Ventura-Martinez and Kelsey B. Hatzell; Princeton University, United States

MXenes are an emerging class of two-dimensional nanomaterials with promising applications in critical resource recovery, energy storage, and desalination. Specifically, MXene membranes are able to selectively separate cations based on charge and ionic radius<sup>1</sup>, with low permeation rates for large and/or multivalent cations but high permeation rates for alkali-metal cations such as  $Li^+$ . Fine-tuning of this ion sieving behavior could enable the energy-efficient recovery of lithium and other critical metals from wastewater. More recently, aluminum ions ( $Al^{3+}$ ) have shown the ability to "lock" the interlayer spacing of MXene membranes<sup>2</sup> via intercalation between MXene nanosheets, preventing other cations from intercalating and preserving the selectivity of these membranes over time. Other ions<sup>3</sup>, as well as water molecules<sup>4</sup>, can also readily intercalate between MXene layers; furthermore, intercalation can strongly affect water adsorption/desorption<sup>3</sup>.

The exchange rates and mechanisms of ions and water within these confined interlayer spaces remain poorly understood, yet understanding these mechanisms is critical to the use of MXenes for advanced ion sieving technologies. To explore these processes, we have examined the changes in MXene membranes' interlayer spacing in response to intercalation (and exchange after pre-intercalation) with a variety of metal cations, including hydrophilic ions such as  $Mg^{2+}$  as well as more hydrophobic cations such as  $Cs^+$ . We have also investigated the effects of water intercalation on interlayer spacing, especially the ability of hydrophilic cations to introduce additional layers of water between MXene nanosheets. Understanding how to reliably control the interlayer spacing (i.e., pore size) of MXene thin films will improve our ability to design selective ion sieves for metal recovery from water.

**Development of Rapid Synthesis Method of MAX Phase Composites by Combination of Induction Heating and Self-Propagating High-Temperature Synthesis** Daisuke Nishine, Ryosuke Numata, Riku Sawamura, Taro Shimomura, Mahito Yamamoto and Mitsuru Inada; Kansai University, Japan

MXene, a two-dimensional layered material, is expected to be applied in a wide variety of fields. Generally, MXene is prepared by etching MAX phase. Therefore, it is very important for MXene research to develop a low-cost and simple method to synthesize the MAX phase. In most cases, the MAX phase is synthesized by high-temperature heating at around 1500°C under high pressure. Hot-pressing, spark plasma sintering, and other methods are used to satisfy these synthesis conditions, but they are specialized, expensive, and sometimes require several hours to synthesize the MAX phase. Therefore, it is desirable to develop a simple, low-cost and rapid synthesis method.

We have developed an original, low-cost and simple MAX-phase synthesis equipment by combination of the induction heating (IH) and the self-propagating high-temperature synthesis method. The IH method can rapidly heat a sample in a carbon crucible up to about 2000°C. This rapid heating induces local chemical reactions. The heat of the chemical reaction then propagates throughout the sample and then the MAX phase is synthesized. We have tried to synthesize two types of MAX phases using this equipment. One is  $Ti_3AlC_2$  and the other is  $V_2AlC$ . XRD measurements and SEM observations showed that both MAX phases were successfully synthesized. It should be noted that this method can synthesize both in vacuum and in inert gas atmosphere. And it took less than a minute from the start of heating to the end of synthesis. These results indicate that this method is one of the candidates for a low-cost, simple, and rapid MAX phase synthesis method that can be applied to various types of MAX phase synthesis.

**8:00 PM EL17.04.04**

**Synthesis of MXenes via Dry Selective Extraction from MAX Phases** [Mark Anayee](#), Ervin Rems, Eiaara Fajardo, Robert Lord, David Bugallo and Yury Gogotsi; Drexel University, United States

MXenes are a rapidly growing family of two-dimensional (2D) transition metal carbides and nitrides which are promising for various applications, including energy storage and conversion, electronics, and healthcare. Hydrofluoric acid-based etchants are typically used for large-scale and high-throughput synthesis of MXenes. Herein, we present a computational thermodynamic model with experimental validations to explore the feasibility of fluorine-free synthesis of MXenes by dry selective extraction (DSE) from precursor MAX phases using iodine vapors at elevated temperature. A range of MXenes with iodine surface terminations are systematically screened using first-principles calculations to find candidates with high phase stability and low etching energy. We further demonstrate a thermodynamic model based on the CALculation of PHase Diagrams (CALPHAD) approach, using  $\text{Ti}_3\text{C}_2\text{I}_2$  as an example, to assess the Gibbs free energy of the reaction and the state of the byproducts (*e.g.*, gas or solid) as a function of temperature and pressure. Based on the assessment, the optimal etching temperature and vapor pressure are predicted, and further verified by experiments. This work opens an avenue for scalable, fluorine-free dry synthesis of MXenes with compositions and surface chemistries that are not accessible using wet chemical etching.

**8:00 PM EL17.04.05**

**Microwave-Assisted Hydrothermal Synthesis of MXene-Derived Bilayered Vanadium Oxides for Aqueous Zinc Ion Battery** [Shang-Tung Chiang](#) and Majid Beidaghi; Auburn University, United States

$\text{V}_2\text{O}_5$  shows great promise as a cathode material in zinc-ion batteries (ZIBs) due to its impressive theoretical capacity of 589 mAh/g, which is based on a two-electron transfer mechanism. However, its limited conductivity poses a significant challenge to its widespread application. In this study, we propose a universal approach to produce high-rate cathodes by creating heterostructures through a single-step process of ion intercalation and phase transition of MXene-derived hydrated vanadates. In our experiment, we introduced Zinc ions (using  $\text{ZnCl}_2$ ) into the  $\text{V}_2\text{C}$  MXene precursor to increase the spacing between layers, and then applied hydrothermal treatment using a microwave. This significantly reduced the synthesis time from several hours to 15 minutes while maintaining the excellent conductivity of MXene and the high theoretical capacity of  $\text{V}_2\text{O}_5$ . The resulting material, denoted as  $\text{Zn-V}_2\text{C-V}_2\text{O}_5$ , exhibits a high specific capacity of 352 mAh/g at 0.1 A/g and demonstrates remarkable cycling stability. These findings position  $\text{Zn-V}_2\text{C-V}_2\text{O}_5$  as a promising candidate for cathode materials in Zinc-ion batteries, offering a new approach for enhancing zinc ion storage in vanadium-based materials.

**8:00 PM EL17.04.06**

**Reaction Barrier and Desorption Energy Co-Determined  $\text{CO}_2$  Electroreduction Selectivity on  $\text{Mo}_2\text{C}$ -Based Catalysts by Modulating Terminations Species and Defects** [Caihong Liang](#), Zhonghan Zhang, Zheng Liu, Shuzhou Li and Yeng Ming Lam; Nanyang Technological University, Singapore

Using electrocatalysts to convert  $\text{CO}_2$  to useful products via  $\text{CO}_2$  reduction reaction ( $\text{CO}_2\text{RR}$ ) is one of the solutions to greenhouse gases problems. Recently, MXenes have been recognised as potential  $\text{CO}_2\text{RR}$  electrocatalysts for its efficiency and tunability. However, comprehensive understanding on the relationship between  $\text{CO}_2\text{RR}$  performance and terminations of MXenes still remains open. For the sake of rational design for effective catalysts,  $\text{Mo}_2\text{CT}_x$ , a widely applied type of MXenes, is used as the model to systematically investigate the effect for  $\text{CO}_2\text{RR}$  from terminations via density functional theory (DFT) calculations. In this study, it is verified that different terminations over  $\text{Mo}_2\text{CT}_x$  exhibit different  $\text{CO}_2\text{RR}$  performances. This work puts forward that the selectivity is co-determined by desorption energy and reaction barrier of each product. Slabs completely covered with -O- or -F are tended to produce HCOOH, while slab with full -OH coverage are inclined to generate CO. Furthermore, results from a reconstructed slab based on one published experimental work with mixture terminations of 5.5% F, 5.5% Vacancy, 33.5% O, and 55.5% OH shows good consistency for the major products (selectivity towards  $\text{C}_1$  products as  $\text{HCOOH} \gg \text{CO} \gg \text{CH}_4 \gg \text{CH}_3\text{OH}$ ). Additionally, this study predicts  $\text{CO}_2\text{RR}$  performance of  $\text{Mo}_2\text{CO}_2$  with 0%, 5.6%, 11.1%, and 100% oxygen vacancy (Ov). The models with 5.6% or 100% Ov are beneficial to generate more valuable final products - methanol or methane, respectively, while the model with medium Ov (11.1%) tend to produce CO. This work provides useful insight and guidance to future research that utilizing terminations of MXene to design  $\text{CO}_2\text{RR}$  electrocatalysts, especially for  $\text{Mo}_2\text{CT}_x$  systems.

**8:00 PM EL17.04.07**

**Broad-Wavelength Light-Driven Hybrid MXene/Molecular Crystal Actuators Actuated inside Tissue-Like Phantoms** [Dong Wook Kim](#)<sup>1</sup>, Yuki Hagiwara<sup>2</sup>, Hideko Koshima<sup>2</sup> and Metin Sitti<sup>1</sup>; <sup>1</sup>Max Planck Institute for Intelligent Systems, Germany; <sup>2</sup>Waseda University, Japan

Significant progress has been made in the research of molecular crystals that can undergo light-driven actuation. This progress has been achieved through the development of different molecules and the identification of driving mechanisms. However, the crystals that have been developed so far have primarily been driven by ultraviolet (UV) or blue light, and the use of red or near-infrared (NIR) light for actuation has not been explored. In this study, we have successfully created molecular crystals that can be actuated by light across a broad range of wavelengths, including UV, visible, and NIR light, using the photothermal effect. To achieve this, we incorporated titanium carbide ( $\text{Ti}_3\text{C}_2\text{T}_x$ ) MXene nanosheets into salicylideneaniline crystals. Unlike the original thin molecular crystals, which only exhibited slow bending under UV light due to photoisomerization, the addition of the MXene layer enabled rapid actuation of the molecular crystals at various thicknesses and wavelengths. The hybridization of MXene with molecular crystals not only provides strong biocompatibility but also allows for the bending of the hybrid crystals within agar phantoms that mimic biological tissue. Furthermore, we demonstrated that this MXene hybridization approach can be extended to other common molecular crystals, including different derivatives of salicylideneaniline and anisole.

**8:00 PM EL17.04.10**

**Enhancing The Ion Intercalation of MXene in Molecular Crowding Electrolytes** [Chaofan Chen](#), Albert de Kogel and Xuehang Wang; TU Delft, Netherlands

The charge storage mechanism and performance of the MXenes electrode are highly dependent on the electrode and electrolyte composition. For example,  $\text{Ti}_3\text{C}_2\text{T}_x$  has shown rapid pseudocapacitive (de)intercalation of protons and transformation between the oxygen surface groups (=O) and hydroxyl (-OH) groups in acidic aqueous electrolytes.<sup>1</sup> As a result,  $\text{Ti}_3\text{C}_2\text{T}_x$  exhibit an ultrahigh volumetric capacitance of  $1500 \text{ F cm}^{-3}$  in  $\text{H}_2\text{SO}_4$  electrolyte.<sup>2</sup> In less corrosive neutral aqueous electrolytes, the cation intercalation is accompanied by negligible charge transfer, leading to ultrafast charge storage.<sup>3</sup> Consequently, a moderate capacitance with superior cycling stability is reported in neutral electrolytes compared to acidic electrolytes. Compared to dilute aqueous electrolyte, which has a limited electrochemical stability window (ESW), the water-in-salt (WIS) electrolyte possesses a large ESW owing to the depressed activity of free water. Besides, the unique solvation structure of WIS electrolyte induces novel solvation-free  $\text{Li}^+$  intercalation and increases capacitance.<sup>4</sup> As a result, WIS electrolyte helps overcome the drawback of the low energy density of MXene in neutral aqueous electrolytes. We further explored the electrochemical behavior of 2D  $\text{Ti}_3\text{C}_2$  MXene in safe, low-cost, and environmentally benign polyethylene glycol (PEG)-based molecular crowding electrolytes (MCE). The addition of PEG-based molecular crowding agents can also widen the potential window of the MXene electrode up to 1.6 V due to the suppressed hydrogen evolution reaction. Additionally, a pair of redox peaks at -0.25 V/-0.05 V vs. Ag (cathodic/anodic)

emerged in cyclic voltammetry after adding the PEG, yielding an additional 25% capacitance. We used in-situ XRD to reveal the charge storage mechanism in MCE electrolytes. Interestingly, we observed the co-insertion of the molecular crowding agent PEG-400 during the  $\text{Li}^+$  intercalation process. As a result,  $\text{Ti}_3\text{C}_2\text{T}_x$  electrodes presented a large interlayer space change of 4.7 Å during a complete charge/discharge process.

**MXene Functionalized Kevlar Yarn via Automated Dip Coating** Lingyi Bi<sup>1</sup>, William Perry<sup>1</sup>, Robert Lord<sup>1</sup>, Ruocun (John) Wang<sup>1</sup>, Tetiana Hryhorchuk<sup>1</sup>, Alex Inman<sup>1</sup>, Oleksiy Gogotsi<sup>2</sup>, Vitaliy Balitskiy<sup>2</sup>, Veronika Zahorodna<sup>2</sup>, Ivan Baginskiy<sup>2</sup>, Stepan Vorotilo<sup>1</sup>, Genevieve Dion<sup>1</sup> and Yury Gogotsi<sup>1</sup>; <sup>1</sup>Drexel University, United States; <sup>2</sup>Materials Research Center, Ukraine

The rise of the Internet of Things (IoT) has spurred extensive research on integrating conductive materials into textiles to turn them into sensors, antennas, energy storage devices, and heaters. MXenes, owing to their high electrical conductivity and solution processability, offer an efficient way to add conductivity and electronic functions to textiles through simple dip coating. However, manual development of MXene-coated textiles restricts their quality, quantity, and variety. Here, we developed a versatile automatic yarn dip coater tailored for producing continuously high-quality MXene-coated yarns and conducted the most comprehensive MXene-yarn dip coating study to date. Compared to manual methods, the automatic coater provides lower resistance, superior uniformity, faster speed, and reduced MXene consumption. It also enables rapid coating parameter optimization, resulting in a thin  $\text{Ti}_3\text{C}_2\text{T}_x$  coating uniform over a 1 km length on a braided Kevlar yarn while preserving its excellent mechanical properties (over 800 MPa) and adding Joule heating and damage sensing to composites reinforced by the yarns. By dip-coating five different yarns of varying materials, diameters, structures, and chemistries, we gained new insights into MXene-yarn interactions. Thus, the automatic dip coating presents ample opportunities for scalable integration of MXenes into a wide range of yarns for diverse functions and applications.

#### SESSION EL17.05: MXenes Electrochemistry and Electrochemical Applications

**MXenes and Two-Dimensional Transition Metal Carbo-Chalcogenides as Electrocatalysts for Hydrogen Evolution Reaction** Elham Loni<sup>1</sup>, Ahmad Majed<sup>1</sup>, Kun Liang<sup>2</sup>, Anika Tabassum<sup>3</sup> and Michael Naguib<sup>1</sup>; <sup>1</sup>Tulane University, United States; <sup>2</sup>Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, China; <sup>3</sup>University of the District of Columbia, United States

MXenes are a group of two-dimensional (2D) materials composed of transition metal carbide, nitrides, and carbonitrides denoted as  $\text{M}_{n+1}\text{X}_n\text{T}_x$ ; M is an early transition metal, X is carbon/nitrogen, and  $\text{T}_x$  stands for surface terminations. These materials are created by selectively etching thin metal layers from layered ceramics. MXenes have shown great promise in various electrochemical energy storage and conversion applications. For instance,  $\text{Ti}_3\text{CNT}_x$  MXene demonstrated an onset overpotential of 53 mV and an overpotential of 148 mV at 10 mA/cm<sup>2</sup> when used as an electrocatalyst for the hydrogen evolution reaction (HER). Another class of 2D materials called transition metal carbo-chalcogenides (TMCCs) combines characteristics of MXenes and transition metal dichalcogenides on an atomic scale. They are synthesized via solid-state synthesis at ambient pressure, followed by intercalation and delamination in water without the use of surfactants. The conductive carbide core and catalytically active chalcogenides surface of TMCCs make them appealing as electrocatalysts. In this study, we will present the large-scale synthesis and characterization of various TMCCs (e.g.,  $\text{Ta}_2\text{Se}_2\text{C}$ ,  $\text{Ta}_2\text{S}_2\text{C}$ ,  $\text{Nb}_2\text{S}_2\text{C}$ , and their solid solutions:  $(\text{Ta}_y\text{Nb}_{1-y})_2\text{S}_2\text{C}$ ;  $y = 0.25, 0.5, \text{ and } 0.75$ ). Additionally, we will discuss the electrochemical performance of MXenes and TMCCs as electrocatalysts for the HER.

#### 8:30 AM EL17.05.02

**Tuning the Structure of MXene-Based Composites for Electrochemical Carbon Dioxide Reduction** Guangxin Sun<sup>1,2</sup>, Chunnian He<sup>3</sup>, Andrew B. Wong<sup>1,1</sup> and Elham Loni<sup>1</sup>; <sup>1</sup>National University of Singapore, Singapore; <sup>2</sup>The Joint School of NUS-TJU, China; <sup>3</sup>Tianjin University, China

The electrochemical  $\text{CO}_2$  reduction reaction ( $\text{CO}_2\text{RR}$ ) is a promising way to valorize  $\text{CO}_2$  and realize net-zero  $\text{CO}_2$  emissions. For  $\text{CO}_2\text{RR}$ , MXene is a good candidate that can adsorb  $\text{CO}_2$ . However, one of the critical challenges for  $\text{CO}_2\text{RR}$  is the control of selectivity. In our case, titanium carbide-based MXene materials were usually found to have high competing hydrogen evolution reaction (HER) performance, where HER is a competing reaction to  $\text{CO}_2\text{RR}$ . Therefore, to improve selectivity to  $\text{CO}_2\text{RR}$  products, we tuned the electronic structure of MXene to suppress HER and enhance the  $\text{CO}_2\text{RR}$  performance via a cations-alloying method. Through systematic investigations, we found that the MXene electronic structure can be tuned, which accompanies microstructure evolution, which is dependent on the reduction potentials of introduced cations. Additions of cations with lower reduction potentials, e.g.,  $\text{Na}^+$ ,  $\text{Co}^{2+}$ ,  $\text{Ni}^{2+}$ , did not change performance significantly, while  $\text{Cu}^{2+}$  and  $\text{Ag}^+$  have significant effects, which was confirmed by systematic characterizations.

Taking the *in-situ* reduced Ag nanoparticle decorated MXene as a model system, we demonstrate that these materials showed a significant improvement in  $\text{CO}_2\text{RR}$  performance. The ratio of  $\text{CO}$  to  $\text{H}_2$  in the product can be tuned in the range of 1:3 to 1:1 by changing the added amount of  $\text{Ag}^+$ . The result can be attributed to the change in electronic structure. With a moderate addition of cations and moderate redox reaction between MXene and cations, the electronic structure can be tuned while the MXene microstructure is maintained. Therefore, with the well-kept MXene structure, the electrons can be transferred from MXene to Ag nanoparticles, and the HER performance is suppressed. With much more cation addition, the MXene structure was degraded, which resulted in nearly 100% HER.

#### 8:45 AM EL17.05.03

**Rational Selection of Transition Metals in  $\text{M}_4\text{C}_3$  MXenes to Control the Electrocatalytic Hydrogen Evolution Reaction** Anupma Thakur, Nithin Chandran B S, Brian Wyatt and Babak Anasori; Indiana University-Purdue University Indianapolis, United States

2D MXenes have shown great promise as active materials in electrocatalytic hydrogen evolution reaction (HER). In this work, we present the selection of

transition metal elements (V, Nb, Ta) in three  $M_4C_3T_x$  MXenes ( $V_4C_3T_x$ ,  $Nb_4C_3T_x$ ,  $Ta_4C_3T_x$ ) to control their electrocatalytic performance for HER using an experimental approach. We synthesized  $V_4C_3T_x$ ,  $Nb_4C_3T_x$ ,  $Ta_4C_3T_x$  MXenes from their parent MAX phases via a selective etching route using hydrofluoric acid, followed by an organic intercalant (tetramethylammonium hydroxide)-assisted delamination. Further, we used an ion exchange process to modify the MXenes' surface chemistry and interlayer spacing by replacing ( $TMA^+$ ) with  $Li^+$  cations. By comparing the electrocatalytic HER performance of the resulting  $V_4C_3T_x$ ,  $Nb_4C_3T_x$ ,  $Ta_4C_3T_x$  MXenes, we demonstrate the role of exposed transition metals (V, Nb, Ta) on the basal plane. Notably,  $V_4C_3T_x$  MXenes exhibit the lowest HER overpotential of  $\sim 248$  mV at  $10$  mA/cm<sup>2</sup> under acidic conditions ( $0.5$  M  $H_2SO_4$ ), surpassing  $Nb_4C_3T_x$  ( $\sim 317$  mV at  $10$  mA/cm<sup>2</sup>) and  $Ta_4C_3T_x$  MXenes ( $\sim 426$  mV at  $10$  mA/cm<sup>2</sup>). This improved performance can be attributed to the catalytically active vanadium basal planes in  $V_4C_3T_x$ . Our findings provide insight into the design of efficient and cost-effective catalysts through the rational selection of transition metals in MXenes for application as HER catalysts and tailoring electrocatalytic properties of 2D materials for sustainable energy applications.

#### 9:00 AM EL17.05.04

**Elucidating the Interactions Between Different Transition Metal Cations and  $Ti_3C_2T_x$  MXene Through Intercalation Method for Electrochemical Applications** Shianlin Wee, Dario Gomez Vazquez and Maria Lukatskaya; ETH Zurich, Switzerland

MXenes, are a family of two-dimensional (2D) transition metal carbides, nitrides and/ or carbonitrides.[1] The intercalation of different metal cations and organic molecules into MXenes for tuning MXenes' electronic and electrochemical properties have been widely reported.[2][3][4] However, transition metals (TMs) which have distinct electrochemical behaviors[5][6] have not been explored in the literature of MXenes' intercalation. Therefore, we herein compared the intercalation effects of different TM cations including ( $Ni^{2+}$ ,  $Co^{2+}$ ,  $Zn^{2+}$ ,  $Mn^{2+}$ ) on  $Ti_3C_2T_x$ , for offering a general insight on the influences of multi-valent, redox-active TMs on MXenes. In particular, the changes on the physiochemical and electrochemical properties of MXenes were investigated using different in-situ and ex-situ methods, for a better understanding on the interfacial interactions between TM cations and MXenes in the confined environment of MXenes' multilayer structures. Additionally, we studied the TM-intercalated MXenes in hydrogen evolution reaction to further explore their electrocatalytic performances. This work serves as a foundation for the fine-tuning of MXenes' properties by utilizing a variety of TM cations intercalation for different electrochemical systems.

#### 9:15 AM EL17.05.05

**Electrochemical Charge Storage Process of  $Ti_3C_2T_x$  in Neutral Aqueous Electrolyte** Chaofan Chen<sup>1</sup>, Glenn Quek<sup>2</sup>, Albert de Kogel<sup>1</sup>, Ruipeng Li<sup>3</sup>, Xuehang Wang<sup>1</sup> and Guillermo Carlos Bazan<sup>2</sup>; <sup>1</sup>Department of Radiation Science and Technology, Delft University of Technology, Netherlands; <sup>2</sup>Departments of Chemistry and Chemical & Biomolecular Engineering, National University of Singapore, Singapore; <sup>3</sup>Brookhaven National Laboratory, United States

MXenes, a group of two-dimensional transition carbides/nitrides, have demonstrated remarkable performance as pseudocapacitive electrodes, owing to their unique transition metal oxide-like surface, large interlayer spacing and high electrical conductivity<sup>[1]</sup>. The charge storage behavior of MXene electrodes are strongly dependent on the interaction between MXene surface chemistry and the electrolyte solution<sup>[2]</sup>. In acidic electrolyte, the (de)intercalation of hydrated  $H^+$  (from) into  $Ti_3C_2T_x$  interlayer leads to a reversible conversion between =O and -OH surface groups, which is accompanied by the Ti valence change<sup>[3]</sup>. Consequently,  $Ti_3C_2T_x$  displays a pseudocapacitive behavior with a mirrored redox peaks emerged in the CV curve. In contrast,  $Ti_3C_2T_x$  electrodes typically exhibit EDL-like behavior in neutral aqueous electrolytes, with a rectangular CV and a sloping GCD curve within a narrow (ca. 1.2 V) potential window, resulting in a relatively lower capacitance ( $80 - 120$  F g<sup>-1</sup>)<sup>[4]</sup>. Recently, it has been found that the charge storage mechanism of MXene electrodes in different electrolytes can be elucidated through in-situ UV-Vis spectroscopy<sup>[5]</sup>.

Engineering the MXene electrode and optimizing the electrolyte composition have the potential to further enhance the pseudocapacitive performance of MXene. An extended potential window of 1.6 V can be obtained by employing water-in-salt electrolyte (WIS). Using WIS electrolyte also induces a novel intercalation process that fully solvated  $Li^+$  ions intercalate into MXene layer at positive potential<sup>[6]</sup>. Partially oxidizing  $Ti_3C_2T_x$  in the WIS electrolyte can further enhance the pseudocapacitance in the neutral aqueous electrolyte by activating a new surface redox reaction at  $< -0.2$  V. This is due to the higher valence of Ti (+2.86) in the partially oxidized  $Ti_3C_2T_x$ , which is more prone to be reduced than the Ti (+2.43) in the pristine MXene<sup>[7]</sup>.

In our recent research, we try to improve the electrochemical performance of  $Ti_3C_2T_x$  by employing PEG-based Molecular crowding electrolyte (MCE) and designing MXene-based heterostructure. By introducing PEG as the molecular crowding agent into dilute LiTFSI electrolyte, a 25% increase in capacitance ( $100.8$  F g<sup>-1</sup>) is obtained in MCE. The capacitance increase is possibly due to additional intercalation process of fully-solvated  $Li^+$ , accompanied by the co-insertion of the PEG molecules. Furthermore, We construct a  $Ti_3C_2@N$ aphthalenediimide (NDI) heterostructure, in which a n-type conjugated polyelectrolyte is incorporated with  $Ti_3C_2T_x$  MXene through a facial self-assemble process. Contributing from both the faradaic reaction from NDI and the pseudocapacitance from MXene, a high specific capacitance of  $126.1$  F g<sup>-1</sup> is obtained in  $1$  M  $NH_4Cl$  electrolyte, which is 1.5 times higher than that of pristine  $Ti_3C_2T_x$ . Benefiting from the unique structure,  $Ti_3C_2@NDI$  also showed a superior rate performance of  $102.8$  F g<sup>-1</sup> at  $10$  A g<sup>-1</sup> (81% capacitance retention of  $0.1$  A g<sup>-1</sup>) and a great cycling stability of 89% capacitance retention upon 10 000 cycles for  $NH_4^+$  storage.

**MXene Chemistry and Applications** Vadym Mochalin; Missouri University of Science and Technology, United States

A large family of two-dimensional transition metal carbides and nitrides (MXenes) raises interest for many applications due to their high electrical conductivity, mechanical properties [1], potentially tunable electronic structure [2], nonlinear optical properties [3], and the ability to be manufactured in the thin film state [4]. However, their chemistry that is key to development of these applications, still remains poorly understood [5,6]. In this presentation we will discuss recent progress in understanding fundamental MXene chemistry and harnessing it for suppressing unwanted reactions and prolonging stability of these materials.

For example, suppressing oxidation and hydrolysis at high pH was demonstrated as an effective way to prolong shelf-life and stability of MXene aqueous colloids [7]. Use of polyphosphate also has been shown to improve chemical stability of MXene aqueous colloids [8]. Other selected examples illustrating connections between understanding MXene chemistry and development of their applications will also be considered.

**Atomistic Insights into the Degradation Mechanism of  $Ti_3C_2T_x$**  Valentina Nesterova and Konstantin Klyukin; Auburn University, United States

Understanding the degradation mechanism at the molecular level is increasingly needed for a variety of clean energy applications, including membranes, batteries, and catalysts. MXenes, a family of 2D transition metal carbides and nitrides, demonstrate outstanding electrochemical performances and intriguing mechanical properties. However, the stability of MXenes remains a concern because of their fast degradation in water solution or air under ambient conditions. The mechanisms responsible for the oxidative degradation of MXenes remain elusive. In this work, we use ab initio molecular dynamics (AIMD) and density functional theory (DFT) simulations to resolve the atomistic mechanism of oxidative degradation of titanium carbide layers in the presence of water molecules and elucidate the role of surface chemistry on its stability. To reveal factors controlling the degradation rate, we correlate activation barriers of oxidation processes to chemical and physical traits of MXene surfaces.

**11:15 AM EL17.06.03**

**Effect of Synthesis Conditions on the Morphology, Stability and Electrochemical Properties of  $Nb_2CT_x$  MXenes** Yeonjin Baek and Majid Beidaghi; Auburn University, United States

MXenes have gained significant attention in recent years for their unique properties and potential applications. Among several compositions of MXenes synthesized so far, Niobium carbide ( $Nb_2CT_x$ ) MXene has shown promise for use in batteries, supercapacitors, photocatalysts, and fuel cells. However, despite many studies on the properties of this material, the effect of the synthesis process on the morphology, stability, and electrochemical properties of single-layer  $Nb_2CT_x$  MXenes, has not been extensively studied before. In this study, we have explored various etching and delamination processes for  $Nb_2CT_x$  and propose an improved synthesis process. Etching of the  $Nb_2AlC$  MAX phase was performed in two different etchants and followed by delamination with TBAOH or TMAOH. Our results show that the synthesis yield is highly dependent on the composition of the etchant. Also, the size and quality of the produced MXene can be tuned by adjusting the etching and delamination conditions. To evaluate the electrochemical properties of  $Nb_2CT_x$  synthesized using different methods, free-standing films of the MXene were fabricated and tested as supercapacitor electrodes. These studies also showed the dependence of the electrochemical properties and stability of produced MXenes on the synthesis condition.

**11:30 AM \*EL17.06.04**

**Hybrid Organic-Inorganic MXenes** Chenkun Zhou, Di Wang, Young-Hwan Kim and Dmitri V. Talapin; University of Chicago, United States

Two-dimensional (2D) transition-metal carbides and nitrides (MXenes) show impressive performance in applications, such as supercapacitors, batteries, electromagnetic interference shielding, or electrocatalysis. These materials combine the electronic and mechanical properties of 2D inorganic crystals with chemically modifiable surfaces, and surface-engineered MXenes represent an ideal platform for fundamental and applied studies of interfaces in 2D functional materials.

The comprehensive understanding of MXene surfaces is required for prescriptive engineering of their physical and chemical properties. We discuss general strategies to install and remove surface groups by performing substitution, reductive elimination and oxidative addition reactions. Successful synthesis of MXenes with oxo-, imido-, thio-, seleno-, or telluro- terminations, as well as bare MXenes (no surface termination), and hybrid organic-inorganic MXenes are demonstrated. The description of MXene surface structure requires a mix of concepts from the fields of coordination chemistry, self-assembled monolayers and surface science. MXene surface groups control biaxial lattice strain, phonon frequencies, electrochemical performance, the strength of electron-phonon coupling, making MXene surfaces not spectators but active contributors to conductivity, superconductivity, and catalytic activity.

**Bioelectronics and Beyond: MXenes for Sensing, Treating and Restoring Human Health** Flavia Vitale; University of Pennsylvania, United States

MXenes have sparked a rapidly growing interest for applications in biomedical research and medicine. Alongside with the remarkable combination of properties and scalable processability, the growing selection of tunable MXene species, and the increasing recognition of their broad biocompatibility are paving the way for the integration of MXenes in high-performance sensing and therapeutic platforms.

In this talk I will first highlight the most recent developments of MXene-based biomedical technologies, particularly in the areas of sensing, therapeutics, and regenerative medicine. Then, I will present our most recent work on  $Ti_3C_2T_x$  MXene-based wearable and implantable bioelectronics for recording and stimulating brain and muscle activity. Due to the combination of high conductivity and low electrochemical impedance, these human-scale MXene bioelectronics can establish highly conformable interfaces with the body without the need for any conductive adhesives and gels that are typically required with conventional metal-based electrodes. Furthermore, the low density and low magnetic susceptibility mismatch between  $Ti_3C_2T_x$  and biological tissues enable artifact-free clinical imaging with magnetic resonance (MRI) and computed tomography (CT), which is precluded when using metals such as Pt. Finally, we recently demonstrated that  $Ti_3C_2T_x$  films and devices can be effectively sterilized with clinical thermal and chemical sterilization processes, without any degradation of their properties and structure.

To illustrate the potential of  $Ti_3C_2T_x$  MXene bioelectronics, I will review examples of application in cognitive neuroscience research, clinical neurological monitoring, and neuromuscular rehabilitation. In conclusion of the talk, I will discuss the opportunities and challenges for clinical translation and commercialization of MXene-based medical technologies.

**2:15 PM EL17.07.02**

**3D Microporous  $Ti_3C_2T_x$  MXene for Electrochemical Sensing of Antibiotics in Tissue Engineered Scaffolds** Anand P. Tiwari, Katie Hixon and William J. Scheideler; Dartmouth College, United States

3D continuous mesoscale architectures of nanomaterials provide opportunities to enhance performance and integration of electrochemical biosensors through control over the distribution of active sites and facilitation of ion transport. We present 3D printed microporous electrochemical biosensors integrating biocompatible 2D  $Ti_3C_2T_x$  MXenes to monitor antibiotic drug release in tissue engineering scaffolds. The 3D microporous  $Ti_3C_2T_x$  MXene is synthesized by a simple deposition of MXene ink on a microscale 3D-printed polymer scaffold coated in conductive ZnO:Al. Due to the microporous hybrid structure of  $Ti_3C_2T_x$  MXene, direct electron transfer is facilitated and the 3D biosensors displayed efficient detection of common antibiotics such as gentamicin and vancomycin. The engineered 3D pore structure exposes more electrochemically active surfaces of MXene, resulting in remarkable sensitivity for detecting gentamicin concentrations from 10 nM to 1 mM and vancomycin concentrations from 100 nM to 1 mM, which are 1000 times more sensitive than planar 2D films of MXene. Additionally, this study characterized the suitability of these implantable sensors for bone tissue regeneration applications. Osteoblast-like (MG-63) cells are seeded on the microporous 3D MXene architectures for 3, 5, and 7 days. An increased concentration of cells is noted over the 7 days along both the edges and pores where MXene had been deposited, demonstrating biocompatibility and clinical translation potential. Based on these results, this combination of 3D scaffolds with biocompatible 2D  $Ti_3C_2T_x$  MXene materials can provide a platform for mediator-free biosensing, enabling new applications for *in vivo* monitoring of drug elution.

**2:30 PM EL17.07.04**

**Sustained Superlubricity in  $Mo_2TiC_2$  MXenes Facilitated by Tribocatalytic Reaction at The Sliding Interfaces** Sai Varun Sunkara<sup>1</sup>, Brian Wyatt<sup>2</sup>, Yuzi Liu<sup>1</sup>, Subramanian Sankaranarayanan<sup>1</sup>, Babak Anasori<sup>2</sup>, Andreas Rosenkranz<sup>3</sup> and Anirudha Sumant<sup>1</sup>; <sup>1</sup>Argonne National Laboratory, United States; <sup>2</sup>Purdue University, United States; <sup>3</sup>University of Chile, Chile

The materials community has witnessed remarkable progress over recent decades in exploring various attractive properties of MXenes due to their excellent, physical, chemical, and mechanical properties. These properties encompass its outstanding physical, chemical, and mechanical attributes, all of which have demonstrated exceptional potential across diverse application domains, ranging from energy storage, and electromagnetic shielding, to advancements in biological and medical technology. Recent interest in exploring their tribological properties is rooted in their layered structure and ability to shear easily coupled with their robust mechanical properties. While numerous studies have been published showcasing MXenes' promise as an additive under lubricated conditions or as a solid lubricant in dry environments, the critical factor of long-term stability as a reliable lubricant in either scenario has remained unproven, thereby constraining its full application potential within the lubrication industry.

In this current work, we study an ordered double transition metal MXene ( $Mo_2TiC_2$ ) and demonstrate its exceptional tribological performance in dry nitrogen atmosphere using macro-scale pin-on-disc tribo-testing. We demonstrate sustained superlubricity, with a friction coefficient as low as 0.005, persisting over the extensive course of linear sliding, spanning an astonishing distance of 86 kilometers, with no signs of failure and minimal wear rates. We will elucidate the intricate mechanisms governing wear and friction, which underpin such extraordinary tribological performance. Additionally, we explain the pivotal role played by tribo-catalytic reactions at the sliding interface, which yield a stable, lubricious tribolayer. This milestone achievement represents a game-changer across a spectrum of tribological applications and marks a significant leap forward in the development of innovative solid lubricants based on MXene.

*Work performed at the Center for Nanoscale Materials, a U.S. Department of Energy Office of Science User Facility, was supported by the U.S. DOE, Office of Basic Energy Sciences, under Contract No. DE-AC02-06CH11357.*

**2:45 PM EL17.07.05**

**Effect of 2D MXenes on The Densification and Stability of Boron Carbide- $Ti_3C_2$  Composites** Nithin Chandran B S<sup>1,2,3</sup>, Kartik Nemani<sup>2,1</sup>, Anupma Thakur<sup>2,1</sup> and Babak Anasori<sup>1,2</sup>; <sup>1</sup>Purdue University, United States; <sup>2</sup>IUPUI, United States; <sup>3</sup>Indian Institute of Technology Madras, India

MXenes are explored as additive materials for structural and high-temperature applications due to high temperature stability and two-dimensional (2D) layered morphology. Boron carbide ( $B_4C$ ) holds significance as a structural ceramic due to its superior hardness (up to 43 GPa) along with low density ( $2.52 \text{ g cm}^{-3}$ ), and high melting point ( $2763 \text{ }^\circ\text{C}$ ). However, poor sinterability of  $B_4C$  is attributed to the presence of strong covalent bonds between boron and carbon, the presence of nanoscale  $B_2O_3$  on the surface, and low self-diffusion coefficients. Incorporating 2D MXenes in the  $B_4C$  matrices can improve the fracture toughness. MXenes' layered morphology combined with colloidal stability due to their high negative zeta potential (-35 to -50 mV) allows additive-free self-assembly on ceramic grains, leading to their uniform distribution in the sintered ceramic composite. In this work, we demonstrate the preparation of green bodies of  $B_4C$  with nanometer-thin  $Ti_3C_2T_x$  MXene flakes via electrostatic self-assembly. The prepared green bodies of MXene-wrapped  $B_4C$ , up to 10 wt.% MXene, are sintered by pressure-assisted spark plasma sintering. We also discuss the effect of MXene flake concentration on the improvement of  $B_4C$  sinterability and mechanical properties. Our study presents the first use of MXene in  $B_4C$  manufacturing and MXenes effects on

the densification and stability of boron carbide sintered ceramics and offers insights into the potential of MXenes as sintering additives in ceramic systems.

### 3:30 PM \*EL17.08.01

**Applications of 2D Metal Carbides in Catalysis** Yue Wu; Iowa State University, United States

Many novel applications have been discovered for 2D metal carbides (MXenes), among which catalysis is a unique one. Due to their different crystal structures, MXenes behave differently from conventional bulk carbides. In this presentation, we will discuss the metal-support interactions observed in different MXene systems and how they alternate the catalytic reactions, including alkane dehydrogenation, methane coupling, and electrochemical reactions, from both experimental studies and theoretical modelings. These newly-discovered metal-support interactions could enable MXenes as exciting platforms for reactions important to petrochemical industry and low-carbon energy development.

### 4:00 PM EL17.08.02

**Environmentally Stable Organo-MXene Gas Sensors Based on Surface Chemical Functionalization** Seon Joon Kim; Korea Institute of Science and Technology, Korea (the Republic of)

The demand for low-power chemical sensing has been increasing due to the emergence of flexible, portable, and wearable devices. To achieve this, two-dimensional (2D) nanomaterials have drawn attention due to their high surface area, and high tunability, and room-temperature operation. Among them, MXenes especially show outstanding performance due to their simultaneous existence of high electrical conductivity and high-density surface functional groups. However, issues such as limited environmental stability need to be addressed for further utilization. Here, we introduce ligand-grafting surface chemical functionalization methods to develop organo-MXene gas sensors that have enhanced environmental stability over pristine MXene gas sensors. Based on the good dispersibility of organo-MXenes in organic solvents, a self-assembly method was designed and employed to fabricate nanometer-scale thin film gas sensors. Gas responses were greatly enhanced compared to that of pristine MXene where the modification of surface tail groups allowed tunable selectivity toward various VOC gases. Furthermore, organo-MXene gas sensors showed good stability in ambient environments for extended periods of time.

### 4:15 PM EL17.08.03

**Three-Dimensional MoS<sub>2</sub>/MXene Heterostructure Aerogel for Chemical Gas Sensors with Superior Sensitivity and Stability** Hamin Shin<sup>1</sup>, Seulgi Kim<sup>2</sup>, Jaewoong Lee<sup>1</sup>, Jihan Kim<sup>1</sup>, Dongju Lee<sup>2</sup> and Il-Doo Kim<sup>1</sup>; <sup>1</sup>Korea Advanced Institute of Science and Technology, Korea (the Republic of); <sup>2</sup>Chungbuk National University, Korea (the Republic of)

The concept of integrating diverse functional 2D materials into a heterostructure provides unparalleled platforms for exploring novel physics not accessible in a single 2D material. Here, physical mixing two 2D materials, MXene and MoS<sub>2</sub>, followed by freeze drying is utilized to successfully fabricate a 3D MoS<sub>2</sub>/MXene van der Waals heterostructure aerogel. The low temperature synthetic approach effectively suppresses significant oxidation of the Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> MXene, and results in a hierarchical, and freestanding 3D heterostructure composed of high-quality MoS<sub>2</sub> and MXene nanosheets. Functionalization of MXene with MoS<sub>2</sub> catalytic layer substantially improves sensitivity and long-term stability toward detection of NO<sub>2</sub> gas, and computational studies are coupled with experimental results to elucidate that the mechanism behind enhancements in the gas sensing properties is effective inhibition of HNO<sub>2</sub> formation on MXene surface, due to the presence of MoS<sub>2</sub>. Overall, this study has a great potential for expansion of applicability to other classes of two-dimensional materials as a general synthesis method, thus laying a foundation to be applied in future fields of catalysis and electronics.

### 4:30 PM EL17.08.05

**Mxene-Based Engineering for Photoelectrochemical Detection by Combining Nanozyme and Oxygen Reduction** Akhilesh B. Ganganboina; National Institute of Materials Sciences, Japan

Efficient photoelectrochemical (PEC) detection requires a deep understanding of the processes involved in generating, separating, and reacting photoinduced carriers at interfaces. However, slow interfacial reactions and the need for appropriate photoactive layers pose significant challenges to constructing advanced PEC platforms. In this study, platinum single-atom catalysts (Pt SACs) were integrated onto CuO<sub>2</sub> and two dimensional Mxene as a proof of concept, amplifying PEC signals by boosting oxygen reduction reactions. As a newly emerging class of 2D materials, Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> MXene was used as fantastic support to uniformly anchor Cu<sub>2</sub>O nanoparticles due to its electronegative surface. Pt SACs were also shown to exhibit efficient peroxidase-like activity, depressing PEC signals through Pt SACs-mediated enzymatic precipitation reactions. By utilizing the oxygen reduction and peroxidase-like activity of Pt SACs, a robust PEC sensing platform was successfully constructed for the sensitive detection of SARS-CoV-2. This research provides valuable insights into the use of SACs for sensitive PEC analysis.

SESSION EL17.09: Poster Session II

### 8:00 PM EL17.09.01

**The Adsorption Ability of Urea on Single 3d Metal Doped MXene (Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>) via DFT Calculations and Experiments** Caihong Liang, Zhihao Yen, Teddy Salim and Yeng Ming Lam; Nanyang Technological University, Singapore

Dialysis is a process used to remove excess urea toxins from the body through adsorption or conversion. Urea adsorption by emergent 2D materials such as MXenes is one probable approach. However, MXenes synthesized by the safer and easier MILD method (MILD  $\text{Ti}_3\text{C}_2\text{T}_x$ ) has lower affinity to urea, which can be improved by surface modifications. Density Functional Theory (DFT) studies indicate that oxygen-terminated  $\text{Ti}_3\text{C}_2\text{O}_2$ , which is the dominant species on MILD  $\text{Ti}_3\text{C}_2\text{T}_x$ , have a much better urea adsorption ability when introduced with Cu, Co, and Ni dopants and the corresponding adsorption energy ( $E_{\text{ads}}$ ) are  $-2.16$  eV,  $-1.91$  eV and  $-1.78$  eV respectively. These adsorption energies are much more favourable than the undoped one ( $E_{\text{ads}} = -0.52$  eV). Experimentally, the adsorption studies found that low concentration of Cu, Co, Ni on  $\text{Ti}_3\text{C}_2\text{T}_x$  showed a removal efficiency of 21.9 %, 6.0 % and 0.2 %, respectively, much better than 0 % removal efficiency of unfunctionalized  $\text{Ti}_3\text{C}_2\text{T}_x$ . Both DFT calculations and experiment showed that various metal functionalized MXenes has similar trend for urea adsorption, highlighting the feasibility of using computational approach to predict urea adsorption and further opening a new promising direction for the urea adsorption.

#### 8:00 PM EL17.09.02

**Langmuir-Like Adsorption Behavior of Amine Ligand for Surface Chemistry of MXene** Woojae Jeong, Hwansoo Shin and Tae Hee Han; Hanyang University, Korea (the Republic of)

Surface chemistry is important to comprehend the stability of oxidation and dispersion of MXene in different organic media, thereby expanding its potential applications. Amine ligands is a potential candidate to modify the surface of MXene nanosheets due to strong interaction between Amine functionalities and MXene surface. Among those, Oleylamine (OAm) is a promising ligand due to its amine functionalities and commercial availability. The OAm is grafting onto MXene by covalent bonds through nucleophilic reactions and hydrogen bonding at room temperature. Furthermore, the OAm develop monolayer on MXene surface behavior by Langmuir-like adsorption. It is finely confirmed by that the slope decreases as the OAm concentration ( $C_1$ ) increases in coverage vs  $C_1$ . The monolayer formation occurs in two distinct steps: a lying-down phase followed by an ordered monolayer. The OAm grafted MXene nanosheets (OAm-MX) represent highly stable dispersion in various organic solvents including non-polar solvents, as well as excellent oxidation stability. This be attributed to the hydrophobic properties and steric stabilization induced by the long alkyl chain of OAm on the MXene surface. Moreover, the OAm-MX nanosheets was facially assembled by solution process on the various substrate, demonstrating enhanced coating performance. Therefore, this study provides key comprehension of the adsorption behavior and interaction between amine ligands and MXene nanosheets for the surface chemistry of MXene.

#### 8:00 PM EL17.09.03

**High Performance Waste-Based Triboelectric Nanogenerators with Sulfur-Rich Polymer and MXene** Sungsu Kim<sup>1,1</sup>, Woongbi Cho<sup>1,1</sup>, Hyeonhoo Lee<sup>1,1</sup>, Minbaek Lee<sup>2</sup>, Tae Hee Han<sup>1</sup> and Jeong Jae Wie<sup>1,1,1</sup>; <sup>1</sup>Hanyang University, Korea (the Republic of); <sup>2</sup>Inha University, Korea (the Republic of)

Recently, we reported utilization of inverse-vulcanized sulfur-rich polymer (SRP) prepared by surplus annually generated 7 million tons during petroleum refining processes, as tribo-negative materials for a triboelectric nanogenerator (TENG). Since the TENG generates power by charge separation on friction surfaces, utilization of fluorine with the highest electronegativity induced excellent electron-withdrawing ability is widely used in the TENG. Previous studies employed F2 gas or fluorine-rich polymers to enhance SRP tribo-negative characteristics. However, F2 is toxic, and the TENG with fluorine-rich polymers requires higher output current to stably operate electronic devices. Herein, we introduce MXene as a filler for the reinforcement of SRP tribo-negative characteristics. MXene is a metallic 2D nanomaterial with a high electronic conductivity and specific surface area. Hence, the inclusion of minute amount of MXene can significantly improve the electric properties of composites. In a same area 12.5 cm<sup>2</sup>-sized, incorporating 0.4 wt% MXene into the SRP composite in the TENG without using toxic gas had shown output voltage and current 2-fold and 3-fold higher compared to the neat SRP. We believe that the SRP/MXene composites will contribute to the advancement of waste-based and self-powered devices in the form of the TENG.

#### 8:00 PM EL17.09.04

**Revolutionizing Greenhouse Gas Monitoring with Layered MXenes: Room-Temperature Chemoresistors** Niravkumar J. Joshi, Sachin T. Navale and Albert Romano-Rodriguez; University of Barcelona, Spain

Greenhouse gas (GHG) emissions, particularly carbon dioxide, methane, and nitrous oxide, are the primary cause of global warming and climate change. To effectively monitor the actual impact of emission of these gases, specialized gas measurement systems that are specifically adapted are necessary. Currently, National surveillance agencies rely on highly sensitive, selective, complex, bulky, and expensive systems to monitor the environment. These systems serve as reference units and are only installed in a few specific, mostly fixed, key locations. However, in order to achieve a more comprehensive monitoring approach and develop climate change models, it is essential to have a distributed network of sensing system. This can be achieved through the deployment and connection of numerous gas sensing systems enabled by the Internet of Things (IoT). These devices need to be sensitive, selective, and energy-efficient, although they may have lower accuracy and precision compared to the reference instruments. Existing commercial sensors do not meet all the necessary requirements, highlighting the need for new and enhanced functional nanomaterials and sensors. The objective of this research is to demonstrate the current state of development regarding advanced miniaturized gas sensing devices for monitoring GHG emissions. For this, we have developed a chemiresistive sensor platform that utilizes a layered structure of 2D MXenes, serving as an advanced sensing platform for detecting GHGs. The layered MXenes were synthesized using a chemical etching method involving a strong HF etchant, resulting in the formation of multilayered  $\text{Ti}_3\text{C}_2\text{TX}$  (MXene) sheets. These MXene sheets were then integrated onto a chip with interdigitated electrodes to form a microsensor. In this way, a low-cost gas-sensitive sensor for methane (CH<sub>4</sub>) was developed, which exhibited superior selectivity in front of other gases. Throughout this research, a comprehensive investigation of the synthesis and of greenhouse gas detection application of these 2D MXenes has been conducted. This study is expected to pave the way for the utilization of a broad range of MXenes as highly sensitive sensors for greenhouse gases.

SESSION EL17.10: MXenes Structures and Properties I

Session Chairs: Babak Anasori and Seon Joon Kim

Wednesday Morning, November 29, 2023

Hynes, Level 2, Room 208

#### 8:00 AM \*EL17.10.01

**Tailoring MXene Crystal Defects & Surface Terminations for Electronic and Energy Applications** Chong Min Koo; Sungkyunkwan University, Korea (the Republic of)

Surface chemistry and defect engineering play a crucial role in determining not only the physicochemical, electrochemical, and optoelectronic properties, but also environment stability and processability of 2D MXene nanomaterials. MXenes, transition metal carbides/carbonitrides/nitrides, are a very large

family of 2D materials with the general formula  $M_{n-1}X_nT_x$ , where M, X, T<sub>x</sub>, and n represent transition metal(s), carbon or nitrogen, surface terminal groups such as -OH, -O and -F, and integers ranging from 1 to 4, respectively. MXenes have been attracted in many electronic, electrochemical, and optoelectronic applications, due to their high electronic conductivity, and solution processability. However, achieving high quality MXenes with precise stoichiometry remains a challenge due to difficulties in controlling the oxygen substitution in both the precursors and final MXene products. Furthermore, the presence of complex oxidation states, surface terminal groups, and interactions with the environment pose obstacles to post-surface functionalization of MXenes. As a result, the establishment of robust surface chemistry and defect engineering protocols for MXenes is still in progress, impeding practical applications. This presentation will briefly demonstrate recent our progress in controlling the surface chemistry and crystal defects of MXenes.

#### 8:30 AM EL17.10.02

**The Effect of Carbon Compounds on MXene Surfaces** Yusuke Ogawa, Seiji Kawasaki, Yasuaki Okada and Takeshi Torita; Murata Manufacturing Co. Ltd., Japan

MXene can be used in a wide range of material applications because of its diverse material properties, derived from its various compositions and surface termination groups. Surface terminations, such as -F, -O, -OH, are introduced by the etching process, and many works related to surface terminations have already been published. One publication has already explored how surface terminations affect the resulting material properties, as well as how to control surface termination groups.<sup>[1]</sup>

However, in reality, MXene also captures carbon compounds spontaneously by electrostatic interaction. Therefore, we should also take these factors into account. XPS is a useful method for evaluating surface properties. Generally, we use Ar sputtering to remove contaminants on the sample surface, but sputtering also affects the inherent surface condition. In such case, gas cluster ion beam (GCIB) provides an alternative way to clean the sample surface, while causing less damage.<sup>[2]</sup> Accordingly, herein we present on GCIB treatment of MXene samples, and outline property differences before and after carbon compounds are removed from the MXene surface.

**Enhancing Heating Efficiency and Protection of MXene Through Graphene Skin** Dongjun Kang and Tae Hee Han; Hanyang University, Korea (the Republic of)

Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> MXene has outstanding characteristics of high electrical conductivity and facile processability in benign water solvents, and has been highlighted as a versatile Joule heating material with low-voltage operation with stable heating performance. However, MXene can be easily oxidized in warm and damp environments due to its plentiful hydrophilic functional groups on sheets. In addition, the high convective heat loss from the MXene surface limits their heating efficiency. Therefore, we tailored a multifunctional graphene skin (with a thickness of ~370 nm) for MXene, to protect the venerable surface properties of MXene. Both MXene and graphene layers have tortuous pathways with similar layered structures; however, the water impermeability of graphene was ~70 times higher than that of bare MXene due to narrow d-spacing and the hydrophobic nature of graphene skin. In addition, we found that the heat loss regulation effect of graphene skin increased the heating efficiency, indicating that the graphene skin is promising for developing adaptive heating materials. Our research has inspired a new hybrid skin strategy that exploits the full potential of materials for developing functional coatings for various applications.

#### 9:00 AM EL17.10.04

**Hybrid MXene-Polydopamine Nanocomposites for Targeted and Effective Photothermal Therapy** Igor Iatsunskyi<sup>1</sup>, Daniel Aguilar-Ferrer<sup>1</sup>, Maksym Pogorielov<sup>2,3</sup>, Oleksiy Gogotsi<sup>4</sup> and Emerson Coy<sup>1</sup>; <sup>1</sup>Adam Mickiewicz University, Poland; <sup>2</sup>University of Latvia, Latvia; <sup>3</sup>Sumy State University, Ukraine; <sup>4</sup>Materials Research Center, Ukraine

Hybrid MXene-Polydopamine (PDA) nanocomposites have emerged as a promising targeted and effective photothermal therapy (PTT) platform. PTT utilizes light-absorbing materials to convert light energy into heat, resulting in localized hyperthermia that selectively damages cancer cells. However, challenges such as limited photothermal conversion efficiency, inadequate tumor targeting, and potential side effects hinder the clinical translation of PTT. MXenes, a class of two-dimensional transition metal carbides/nitrides, possess exceptional optical absorption properties in the near-infrared (NIR) region, where biological tissues exhibit maximum transparency. The combination of MXenes with PDA offers synergistic advantages for enhanced PTT. MXenes serve as efficient photothermal agents, while PDA provides a versatile coating that promotes biocompatibility and allows surface functionalization for targeted therapy.

The hybrid MXene-PDA nanocomposites exhibit excellent photothermal conversion efficiency due to the strong light absorption of MXenes and efficient heat transfer facilitated by the PDA coating. The nanocomposites can be easily functionalized by targeting ligands or biomolecules, enabling selective accumulation and internalization in cancer cells. Moreover, the MXene-PDA nanocomposites can be further engineered to release therapeutic agents, such as chemotherapy drugs, in response to the photothermal effect, achieving combined photothermal-chemotherapy treatment.

This research highlights experimental results in developing MXene-PDA nanocomposites for targeted and effective PTT. The synthesis methods employed to fabricate the nanocomposites, including surface modification and functionalization, are discussed, along with their photothermal conversion efficiency and biocompatibility. We explored the effect of PDA layer thickness over MXene flakes on PTT. Antibodies for various types of cancers were used as targeting ligands. We demonstrated that the hybrid MXene-PDA nanocomposites are promising to advance PTT as a cancer treatment modality. Their unique properties, such as high photothermal conversion efficiency and surface functionalization capabilities, make them attractive candidates for targeted therapy.

#### 9:15 AM EL17.10.05

**Electrochemically Modulated Interaction of MXenes with Microwaves** Danzhen Zhang, Meikang Han, Christopher E. Shuck, Bernard McBride, Teng Zhang, Ruocun (John) Wang, Kateryna Shevchuk and Yury Gogotsi; Drexel University, United States

Controlling the reflection and absorption of incident electromagnetic waves at gigahertz frequencies in thin films is important for protecting electronics and humans. The ability to dynamically depress electromagnetic wave jamming is significant for enabling communication while protecting electronics. However, conventional electromagnetic interference (EMI) shielding materials don't offer this capability. MXenes, as a large family of two-dimensional transition metal carbides and nitrides, have shown a broad range of EMI shielding performance as well as different energy storage mechanisms from electric-double-layer capacitance to pseudocapacitive behavior. Herein, we report a method for active control of electromagnetic wave interactions with various MXene films, including Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>, Ti<sub>2</sub>CT<sub>x</sub>, V<sub>2</sub>CT<sub>x</sub>, V<sub>4</sub>C<sub>3</sub>T<sub>x</sub> and Nb<sub>4</sub>C<sub>3</sub>T<sub>x</sub>, leading to EMI shields with unprecedented bidirectional modulation of shielding capability. The reversible tunability of EMI shielding effectiveness was achieved by electrochemically driven ion insertion/desertion and charge

transfer in MXene layers with different electrolytes, accompanied by expansion and shrinkage of layer spacing, as well as a change in the oxidation state of the transition metal. An EMI shielding 'switch' was demonstrated through the electrochemical oxidation of MXene films. Our results offer opportunities to develop smart EMI protection with active modulation, which is different from conventional 'static' shielding and can adapt to demanding environments.

### 9:30 AM \*EL17.10.06

**Enhancing MXene's Heating Functionality Through Surface Modification** Tae Hee Han; Hanyang University, Korea (the Republic of)

MXenes are a class of two-dimensional materials with potential applications in fields such as thermal management and high-temperature materials. In this talk, I focus on two key aspects: the thermal evolution of  $Ti_3C_2Tx$  MXene during annealing and the grafting behavior of amine ligands for MXene surface modification. (1) The thermal decomposition behavior of MXene is explored using X-ray photoelectron spectroscopy (XPS) and two-dimensional correlation spectroscopy (2D-COS), providing insights into its structural changes, providing practical information for thermal applications of MXene. (2) Surface modification strategies are employed to enhance MXene's stability and dispersibility. Oleylamine (OAm) is grafted onto MXene nanosheets, resulting in improved oxidation and dispersion stability. The modified MXene exhibits excellent solution processability and coating performance. Additionally, the potential of OAm-MX as a heating element is investigated, leading to the development of a scalable electrothermal heating membrane with high efficiency. These advancements broaden the applications of MXene in thermal management and water desalination.

### 10:30 AM \*EL17.11.01

**Plasmonic Properties of 2D MXenes** Sarah B. King<sup>1</sup>, Joseph Spellberg<sup>1</sup>, Janek Rieger<sup>1</sup>, Calvin Raab<sup>1</sup>, Francisco Lagunas<sup>2</sup>, Robert F. Klie<sup>2</sup>, Di Wang<sup>1</sup>, Dmitri V. Talapin<sup>1</sup>, Jordan A. Hachtel<sup>3</sup> and Abdoulaye Djire<sup>4</sup>; <sup>1</sup>University of Chicago, United States; <sup>2</sup>University of Illinois at Chicago, United States; <sup>3</sup>Oak Ridge National Laboratory, United States; <sup>4</sup>Texas A&M University, United States

Despite their tremendous potential as plasmonic materials because of their 2D metallic properties, very little is known about the fundamental plasmonic resonances of MXenes. This is primarily due to irregularity in plasmonic responses from mixed surface terminations and varying material shape and thickness. In this talk I will discuss experimental methods we are using in my group to probe the nanoscale plasmonic response of MXenes, both traditional mixed-terminated  $Ti_3C_2Tx$  as well as singly terminated MXenes synthesized by both CVD and molten salt synthesis,  $Ti_2CCl_2$  and  $Ti_3C_2Cl_2$ . Leveraging the time-resolution and spatial-resolution of time-resolved photoemission electron microscopy we are investigating the evolution of plasmonic fields in MXenes in space and time. Using the (MAC)-STEM/EELS facility at ORNL we can directly image energy-resolved plasmonic resonances of MXenes, where we find that surface oxidation substantially decreases the plasmonic response of  $Ti_3C_2Cl_2$ . Together our experiments highlight the variation in nanoscale plasmonic properties of MXenes and opportunities for control.

### 11:00 AM \*EL17.11.02

**Ultrafast Photoexcitations in 2D MXenes** Lyubov V. Titova; Worcester Polytechnic Institute, United States

MXenes are 2D transition metal carbides and nitrides with electronic properties that can be tuned by their chemistry and structure. Metallic-like conductivity, flexibility, high optical damage threshold and ease of processing owing to their hydrophilicity, make MXenes candidates for a host of electronic and optical applications. We use ultrafast optical and THz spectroscopic techniques to investigate the nature and behavior of photoexcitations in MXenes of different chemistries. We show that electronic and optical properties of MXenes can be engineered by choices of the transition metals and their order as well as by controlling the intercalants in the interlayer gaps [1,2]. Furthermore, we demonstrate that MXenes with high free carrier density show promise as polarizers and tunable electromagnetic interference shields in the THz range [3,4].

### 11:30 AM EL17.11.03

**Stability of Pseudocapacitive Energy Storage in  $Ti_3C_2T_x$  MXene over Wide Temperature Range** Ruocun Wang, Mark Anayee, Teng Zhang, Yuan Zhang, Mikhail Shekhirev, Kateryna Shevchuk and Yury Gogotsi; Drexel University, United States

Pseudocapacitors have the potential to achieve high energy and high power density simultaneously, a holy grail for electrochemical energy storage. However, one obstacle facing pseudocapacitors is their shorter lifetime compared to commercial supercapacitors using the double-layer charge storage mechanism. In MXene-based pseudocapacitors, this concern is pronounced particularly at high temperatures due to the limited stability of the active material in contact with aqueous solutions, which can lead to oxidation and hydrolysis. This work shows that  $Ti_3C_2T_x$  MXene thin-film electrodes in 5 M  $H_2SO_4$  possess excellent rate capabilities from -50 °C to 100 °C but also a sufficient lifetime at 70 °C using a float test holding at -0.9 V vs.  $Hg/Hg_2SO_4$  reference electrode. Post-mortem characterization using X-ray photoelectron spectroscopy, Raman spectroscopy, and scanning electron microscopy with energy-dispersive X-ray spectroscopy showed no signs of oxidation in the bulk of the film. This work suggests sufficient electrochemical stability of  $Ti_3C_2T_x$  MXene as a negative electrode in protic aqueous electrolytes across a wide temperature range, making it promising for pseudocapacitor energy storage.

## SESSION EL17.12: MXenes Structures and Properties II

Session Chairs: Abdoulaye Djire and Seon Joon Kim

Wednesday Afternoon, November 29, 2023

Hynes, Level 2, Room 208

**1:45 PM \*EL17.12.01****High-Temperature Stability and Phase Transformation of 2D  $Ti_3C_2T_x$  and  $Mo_2TiC_2T_x$  MXenes** Brian Wyatt<sup>1</sup>, Kartik Nemani<sup>1</sup>, Matthew Boebinger<sup>2</sup>, Raymond R. Unocic<sup>2</sup>, Babak Anasori<sup>1</sup> and Nithin Chandran B S<sup>1</sup>; <sup>1</sup>Purdue University, United States; <sup>2</sup>Oak Ridge National Laboratory, United States

2D MXenes have a wide array of impressive properties due to their inherent transition metal carbide cores with abundant surface functionalities. While MXenes can be rapidly oxidized in air at high temperatures, they can be transformed into ultra-high temperature carbides when annealed under an inert atmosphere or vacuum. By annealing stacks of 2D MXene flakes, we can fabricate refractory carbides with controlled morphologies and crystal orientations. In this talk, we present our current understanding of the phase transformation of different MXenes, including  $Ti_3C_2T_x$  and  $Mo_2TiC_2T_x$ , by annealing them in the 600 °C to 2000 °C range under argon. We used a combination of ex-situ and in-situ characterization techniques and identified the effect of defects, such as vacancies and cation decorations, on phase stability and transformation of MXenes to refractory carbides. Our results suggest that MXenes can be used as nanosized building blocks for ultra-high temperature coatings or ceramic composite additives.

**2:15 PM DISCUSSION TIME****2:30 PM BREAK**

## SESSION EL17.13:MXenes Structures and Properties III

Session Chairs: Majid Beidaghi and Anupma Thakur

Wednesday Afternoon, November 29, 2023

Hynes, Level 2, Room 208

**3:30 PM \*EL17.13.01****Electroactive Soft Actuators Based on MXene-MOF Nanoarchitectures** Ilkwon Oh; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Electro-ionic soft actuators, capable of continuous deformations replacing non-compliant rigid mechanical components, attract increasing interest in the field of next-generation metaverse interfaces and soft robotics. Here, we report a novel MXene ( $Ti_3C_2T_x$ ) electrode anchoring manganese-based 1,3,5-benzenetricarboxylate metal-organic framework (MnBTC) for ultrastable electro-ionic artificial muscles. By a facile supramolecular self-assembly, the  $Ti_3C_2T_x$ -MnBTC hybrid nanoarchitecture forms coordinate bond, hydrogen bond, and hydrophilic interaction with the conducting polymer of poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS), resulting in a mechanically flexible and electro-ionically active electrode. The superior electrical and electrochemical performances of the electrode stem from the synergistic effects between intrinsically hierarchical nanoarchitecture of MnBTC and rapid electron transport behavior of Mxene, leading to fast diffusion and accommodation of ions in the ion-exchangeable membrane. The developed artificial muscle based on  $Ti_3C_2T_x$ -MnBTC is found to exhibit high bending displacement (12.5 mm) and ultrafast response time (0.77 s) under a low driving voltage (0.5V), along with wide frequency response (0.1 to 10 Hz) and exceptional stability (98% retention at 43,200 s) without any distortion of actuation performance. Furthermore, the designed electro-active artificial muscle was successfully used to demonstrate mimicry of eye motions including eyelid blinking and eyeball movement in a doll.

**4:00 PM EL17.13.02****Salt-Assisted Assembly of  $Ti_3C_2T_x$  Nanosheets on Arbitrary Polymers** Liang Zhao<sup>1</sup>, Lingyi Bi<sup>2</sup>, Jiayue Hu<sup>3</sup>, Guanhui Gao<sup>4</sup>, Danzhen Zhang<sup>2</sup>, Yun Li<sup>1</sup>, Aidan Flynn<sup>1</sup>, Ruocun (John) Wang<sup>2</sup>, Ling Liu<sup>3</sup>, Yury Gogotsi<sup>2</sup> and Bo Li<sup>1</sup>; <sup>1</sup>Hybrid Nano-Architectures and Advanced Manufacturing Laboratory, United States; <sup>2</sup>AJ. Drexel Nanomaterials Institute, Drexel University, United States; <sup>3</sup>Temple University, United States; <sup>4</sup>Shared Equipment Authority, Rice University, United States

MXenes are promising materials for next-generation flexible electronics and wearable systems due to their excellent conductivity, low infrared emissivity, and high mechanical properties. However, in a solution-based assembly process, hydrophilic MXenes are not compatible with many polymers, especially some high-performance polymers with inert and/or hydrophobic surfaces, such as Kevlar. Unlike many harsh surface treatment methods that induce dangling bonds on the polymer surface, we proposed a universal solution-processed salt-assisted assembly (SAA) strategy that enables ultra-thin and uniform  $Ti_3C_2T_x$  MXene coatings with high conductivity on diverse polymers without their modification. The salt added to the MXene aqueous solution neutralizes the charge, coagulates the colloid, and deposits MXene aggregates, leading to the ultrafast assembly of MXene on the solution on arbitrary polymer substrates. A library of salts has been demonstrated to be effective. Importantly, our method enables  $Ti_3C_2T_x$  assembly on high-performance thermally stable polymers such as Kevlar fabric. This SAA strategy may significantly broaden the applications of MXene coatings.

**4:15 PM EL17.13.03****Metal Ion-Driven Gelation in MXenes for Multiproperty and Multifunctional Hydrogels and Aerogels** Stefano Ippolito and Yury Gogotsi; Drexel University - Drexel Nanomaterials Institute, United States

To date, MXenes include over fifty different structures and compositions, with more than a hundred compositions predicted computationally (more than a thousand if surface terminations are also taken into account), being the largest known family of 2D materials. Owing to their extremely versatile structural and chemical composition, as well as surface chemistry, MXenes are one-of-a-kind materials in many research fields, embodying a true revolution in materials science. They introduce a large number of 2D building blocks in materials science, providing an exciting and wide-ranging portfolio of physicochemical properties and promoting the production of several MXenes-based hybrid systems for numerous applications. Here, we will discuss the production of all-MXene hydrogels and aerogels, where the gelation process is induced by metal ions. Taking advantage of the coordination chemistry between -OH groups on the surface of MXene flakes (resulting from the wet chemical etching steps) and metal ions, the gelation (in aqueous environment) is very fast (< 5 min) and the physicochemical properties of the resulting hybrid systems are strongly related to the nature of the MXene/metal ion dyad. Rheological measurements show a strong relationship between the metal ion and the loss tangent  $\tan\delta$  (equal to the ratio between

loss Modulus and storage Modulus, namely viscous modulus and elastic modulus) of the related hydrogel, where the main parameter seems to be represented by the charge density of the selected ion. Such a dependence is also observed in the surface area of corresponding aerogels (prepared from hydrogel by means of freeze-drying), where metal ions with higher charge density return lower surface area, glimpsing the chance to tune the latter parameter based on the envisaged final applications. In this regard, pore shape and aerogel structure are strongly affected by the chemical nature of the metal ions too, as a result of the different coordination geometry. Considering the extremely high versatility of such all-MXene hydrogels and aerogels (in terms of chemical and structural composition, as well as physicochemical properties), many different applications are being tested. For instance, the different and tunable electrostatic behavior of MXene aerogels could result crucial to produce gas and/or particle capture and sensing systems, whose regeneration *via* Joule heating might be possible because of their high electrical conductivity and versatile thermal properties. Also, the metal ions trapped within the MXene porous structure can be converted to metal clusters by simple thermal annealing (performed at 300°C, under Ar/H<sub>2</sub>), allowing the formation of ferromagnetic particles for electromagnetic sensing and other related applications. Moreover, due to their tunable porosity, mechanical properties, and composition, MXene aerogels are being tested for acoustic insulation/damping and sensing as well. Finally, thanks to the abovementioned gelation process, MXene hydrogels and aerogels can be shaped in many forms, including fibers that might be used for bioelectronics and sensing. Finally, this versatile approach can be employed for several metal ions and MXene structures, leading to the production of hybrid systems with tunable properties according to envisaged applications.

#### 4:30 PM EL17.13.04

**Developing Vitrimer-MXene Laminated Sheets for Stimuli-Responsive Coatings and Improved Composite Functionality** [Abigail A. Advincula](#)<sup>1,2</sup>, Justin Brackenridge<sup>3,1</sup>, Philip Barnett<sup>4</sup>, Christopher Muratore<sup>3</sup>, Madeline Buxton<sup>5</sup>, Vladimir Tsukruk<sup>5</sup>, Yury Gogotsi<sup>6</sup> and Dhriti Nepal<sup>1</sup>; <sup>1</sup>Air Force Research Laboratory, United States; <sup>2</sup>ARCTOS, United States; <sup>3</sup>University of Dayton, United States; <sup>4</sup>University of Tennessee Knoxville, United States; <sup>5</sup>Georgia Institute of Technology, United States; <sup>6</sup>Drexel University, United States

Organic-inorganic hybrid structures found in nature, e.g., nacre (“mother-of-pearl”), are often remarkably tough and exhibit multi-functional properties due to highly ordered arrangements of organic and inorganic components in such structures at the nanometer-to-micron length scale. Inspired by these hierarchical biological structures, this work details our efforts to fabricate a hybrid composite of ordered, alternating layers of organic vitrimer polymer and inorganic MXenes. Vitrimers, as a new class of polymers, ideally exhibit thermoset-like behavior at lower temperatures and thermoplastic-like reformability at higher temperatures due to their permanent yet dynamic polymer networks. MXenes, as a class of inorganic two-dimensional (2D) transition metal carbides and nitrides, exhibit excellent metallic conductivity, good transparency in the visible wavelength range, and high photon-to-phonon conversion efficiency.

In this work, we demonstrate the fabrication of highly ordered, ultra-thin (nearly single to a few layers) MXene films onto thin, free-standing sheets of vitrimer, yielding electrically conductive, highly transmissive vitrimer-MXene sheets for self-healing coatings and multi-functional composites. Large area (20 x 20 cm), thin (<65 μm) free-standing vitrimer sheets are first obtained utilizing industrially-relevant compression molding techniques. Thermomechanical testing (TGA, DSC, DMA, TMA, micro-indentation) indicates excellent spot-to-spot consistency in the fabricated sheets. Subsequently, a thin film of MXene is deposited onto the vitrimer sheet surface using an advanced deposition technique that leverages Rayleigh-Benard convection and the Marangoni effect. Surface morphology and mechanical properties of the vitrimer-MXene sheets are investigated at different length scales using micro-indentation testing and quantitative nanomechanical (QNM) analysis. UV-vis measurements and electrical conductivity measurements additionally indicate reasonably good transparency (>75 %T in the visible spectrum) and electrical conductivity values (~100 S/cm) for the vitrimer-MXene layers. Self-healing mechanisms of the vitrimer-MXene sheets in response to light are demonstrated, leveraging the high photon-to-phonon conversion efficiency of MXene. Finally, compression molding of multiple individual MXene-coated vitrimer layers together yields a hybrid composite with alternating ordered layers of vitrimer and MXene. DMA and tensile testing are subsequently used to evaluate modulus, creep resistance, and toughness. This work presents a novel approach to accessing composites with ordered layers of vitrimer and MXene, techniques useful towards further enhancing vitrimer functionality towards structurally robust electronic applications.

SESSION EL17.14: MXenes Structures and Properties IV

**MXetronics: Integrated Electronics using MXenes** [Husam N. Alshareef](#)<sup>1</sup>, Xiangming Xu<sup>1</sup>, Tianchao Guo<sup>1</sup>, Mrinal K. Hota<sup>1</sup> and Hala A. Al-Jawhari<sup>2</sup>; <sup>1</sup>King Abdullah University of Science and Technology, Saudi Arabia; <sup>2</sup>King Abdulaziz University, Saudi Arabia

This talk will focus on MXenes and their development for integrated electronic device applications. MXenes can be considered as 2D metal contacts with tunable conductivity and tunable work function which makes them in principle suitable for a variety of electronic devices. To realize electronic devices, we have been developing deposition processes, transfer techniques, interface engineering, surface functionalization, photolithographic and e-beam patterning, wet and plasma etching of MXenes. In this talk, I will discuss the various aspects of device fabrication methods to integrate MXenes in several types of electronic devices. The benefits and challenges of using MXenes in each device type will be discussed, with particular focus on the role of interface. Example devices that will be discussed include using MXenes as electrical contacts in thin-film electronics, quantum dot electronics, CMOS devices, GaN high electron mobility transistors (HEMT), memristors, and solar cells. We show that the device performance strongly depends on the quality of the interface between MXene and the semiconductor material, whose control is critical for achieving good device performance. We have also integrated MXene films as active materials for photodevices, photothermal devices, and sensors.

#### 8:30 AM EL17.14.02

**Structural Strategies of MXene-Based Materials for Thermoconductive Electromagnetic Interference Shielding Materials with Excellent Mechanical Flexibility** [Canh M. Vu](#); University of Chicago, United States

MXenes, which are a type of 2D transition metal carbides and nitrides, have shown great potential as electromagnetic interference (EMI) shielding materials owing to their properties of electrical conductivity, low density, and flexibility. However, the weak interfacial interaction and the low thermal conductivity of MXenes resulted in poor mechanical flexibility and heat-dissipating capability. In this study, we developed structural strategies of MXenes-based carbon nanomaterials to fabricate MXenes films with enhanced mechanical strength, electromagnetic interference (EMI) shielding, and thermal conductivity properties. Compared to MXene films, the resulting hybrid MXenes films exhibited significantly improved mechanical strength of over 270

MPa, a toughness of 5 MJ m<sup>-3</sup>, EMI shielding effectiveness of 70 dB, and an ultrahigh in-plane thermal conductivity of 110 W m<sup>-1</sup> K<sup>-1</sup>. This study presents a promising methodology for the development of high-performance materials that exhibit mechanical flexibility, electrical conductivity, electromagnetic interference shielding, and thermal conductivity properties.

**Development of Polymeric/MXene Composites Towards 3D Printable Electronics** Alejandra Salas Chavez<sup>1</sup>, Ignazio Roppolo<sup>1</sup>, Matteo Cocuzza<sup>1</sup>, Hanna Pazniak<sup>2</sup>, Jesus Gonzalez-Julian<sup>3</sup>, Stefano Bianco<sup>1</sup>, Julia Amici<sup>1</sup> and Thierry Ouisse<sup>2</sup>; <sup>1</sup>Politecnico di Torino, Italy; <sup>2</sup>Institut Polytechnique de Grenoble, France; <sup>3</sup>RWTH Aachen University, Germany

#### [Accepted Manuscript]

3D printing is an emerging technology for many applications, including electronics. On the other hand, to gather the applications' requirements with the possibility to produce complex 3-dimensional structures, the development of novel 3D printable materials is necessary. In this context, we studied the synthesis of 3D printable photocurable resins embedding Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>-MXenes, a class of 2D layered materials with outstanding electrical and electronic properties.

Starting from the pioneering works of Y. Gogotsi and M.W. Barsoum, MXenes envisage promising performances in different fields like energy storage[1], electromagnetic shielding[2], photodetectors[3], sensors[4] and electrocatalysis[5]. Nevertheless, their translation to devices nowadays is mainly limited to 2D configuration or conventional production processes.

Herein the motivation for this work stands for the development of stable polymeric inks suitable for Digital Light Processing (DLP) 3D printing technology using Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>-MXenes as functional fillers. Those were successfully synthesized using Ti<sub>3</sub>AlC<sub>2</sub> as a MAX phase precursor etched by a strong acid (hydrofluoric acid- HF) and using tetrabutylammonium hydroxide (TBAOH) as an intercalator, providing a few layered flakes presentation. Then, employed to fabricate complex 3D composite structures with high printing fidelity. To enhance the material's electrical conductivity, annealing treatments have been performed, followed by a complete characterization of the so obtained. The results show that objects with improved electrical conductivity have been successfully obtained. To this end, this achievement would open new perspectives towards developing complex 3-dimensional electronic applications.

**MXene and Their Surface Functionalization for the Development of Functional MXene Organic Inks** Tae Yun Ko; Korea Institute of Science and Technology, Korea (the Republic of)

Due to their unique metallic conductivity, transparency, and outstanding solution processability in water, MXenes have been attracted to many potential applications such as EMI shielding, energy storage, and electronic applications. However, oxidation instability of aqueous MXene dispersions and poor dispersion stability in organic solvents prevent the utility of MXenes in potential applications. Surface functionalization of MXene is critical for controlling the dispersion system, surface chemistry, processing, physicochemical properties, and applications. Herein, we designed and conceptualized various organic ligands that can improve oxidation stability and organic dispersibility of the functionalized MXene. The recently developed surface functionalization methods demonstrate a range of processes for synthesizing MXene organic inks into composites with different polymer and metal nanoparticles without chemical oxidation issues. Moreover, utilizing these functional inks as highly efficient electrodes, it is also possible to achieve fine patterning and direct writing on hydrophilic or hydrophobic substrates with excellent conductivity.

#### 9:15 AM EL17.14.05

**Controlling Aerosol-Jet Printed MXene Flakes Morphology for Neural and Energy Storage Applications** Javier Gutierrez Gonzalez<sup>1,2,3</sup>, Dahnán Spurling<sup>1</sup>, Tara McGuire<sup>2</sup>, Ke Li<sup>1</sup>, Ian Woods<sup>2,3</sup>, Adrian G. Dervan<sup>2</sup>, Valeria Nicolosi<sup>1,3</sup> and Fergal O'Brien<sup>2,3</sup>; <sup>1</sup>Trinity College, Ireland; <sup>2</sup>Tissue Engineering Research Group, Royal College of Surgeons in Ireland (RCSI), Ireland; <sup>3</sup>Advanced Materials Bio-Engineering Research Centre (AMBER, RCSI and TCD), Ireland

MXenes are a class of 2D layered materials consisting of carbides and nitrides of transition metals which has found application in a wide range of fields due to their excellent electrical conductivity, charge storage, and biocompatibility. Mainly used as aligned flakes, under certain processing conditions these 2D flakes can also fold in crumpled 3D structures. Despite being occasionally associated with faulty deposition, crumpled MXenes hold untapped potential, harboring intriguing properties that remain largely unexplored. Thus, the main goal of this study was to investigate the uncharted role that crumpled MXenes can play in both neural and energy storage applications.

In this work, the production of crumpled and aligned MXene (Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>) flake morphologies was systematically studied by using high-resolution Aerosol Jet 3D printing, while assessing their novel physical properties, such as roughness, conductivity, and optical properties. Furthermore, cell line -derived and primary neurons were plated on either morphology to examine the ability of both forms to support neuronal growth and development. In addition, to assess the potential utility of crumpled MXenes for energy storage applications, crumpled MXene flakes were used as a conductive spacer between aligned MXene layers for developing an all-MXene supercapacitor.

By modifying several 3D printing parameters, MXene flakes could both align and crumple at specific mass and sheath flow regimes, depending on the nozzle size, speed, and solvent mixture, while flake morphology was rapidly monitored using the in-built camera.

To assess biocompatibility, mouse neurons were seeded on printed crumpled and aligned MXene films, revealing distinct behavior depending on the flake morphology: crumpled MXene facilitated higher cell adhesion (as indicated by DNA count and immunostained cells), whereas neurons grown on aligned MXene films possessed longer neurite outgrowth. Further analysis using mouse primary neurons, resulted in healthy neuronal growth on both types of MXene for 8 days, while crumpled surfaces elicited decreased expression of GFAP, as observed in image analysis, suggesting reduced astrocytic reactivity.<sup>1</sup>

MXene supercapacitors were aerosol jet printed with the first layer being a highly conductive aligned MXene current collector, followed by alternating layers of crumpled and aligned MXene, resembling a *lasagne* structure. This hierarchical architecture effectively prevented excessive restacking of the

flakes by smartly combining both morphologies, preserving a nanoporous network and achieving up to 65 (F/g) gravimetric capacitance, 193 (F/cm<sup>3</sup>) volumetric capacitance and 88 (mF/cm<sup>2</sup>) areal capacitance.

Taken together, these results demonstrate that crumpled and aligned MXenes can be easily 3D printed with Aerosol Jet printing; both MXene morphologies exhibited unique characteristics when supporting neuronal growth, and also powered energy-dense *lasagne* structured supercapacitors. This study highlights the need for precise management of MXene deposition and customized flake design, encouraging material scientists to intensify the study of crumpled MXenes and other 2D materials, and their application in multiple fields including biomedicine, electronics and energy storage.

#### 9:30 AM EL17.14.06

**Understanding Light-Matter Interactions of MXene Family of 2D Materials** Hyunho Kim<sup>1,2</sup>, Danzhen Zhang<sup>1,2</sup>, Teng Zhang<sup>1,2</sup> and Yury Gogotsi<sup>1,2</sup>; <sup>1</sup>A.J. Drexel Nanomaterials Institute, United States; <sup>2</sup>Drexel University, United States

The MXene family, two-dimensional transition metal carbides, nitrides, and carbonitrides, have been the subject of extensive research activities for the past decade. Recent developments in the molten-salt route have enabled the engineering of MXenes' surface termination groups. For example, molten-salt route synthesized Ti<sub>3</sub>C<sub>2</sub>Cl<sub>2</sub> is found to have a vis-NIR absorption band centered at ~880 nm, which is red-shifted from 770~800 nm for the acid route prepared Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> with O, OH, and F terminations. The origin of this vis-NIR absorption band is yet to be understood, and the red-shift is difficult to explain by carrier density with the surface plasmon concept. Instead, we adapt an interband transition mechanism with consideration of light polarization to explain both UV and vis-NIR absorption bands of MXenes. The light-matter interactions of MXenes will be analyzed by using in-situ UV-vis spectroscopy under electrochemical modulation and Raman spectroscopy, and correlated with the literature on nonlinear optics, ultrafast terahertz spectroscopy, and pump-probe transient absorption. The important relationships between photons, electrons, and phonons in MXene, which are important for numerous applications of those materials, will be discussed.

**Application of Two-Dimensional Metal Carbides (MXenes) for the Removal of Emerging Contaminants from Water** Khaled Mahmoud; Hamad Bin Khalifa University, Qatar

Characteristic properties of two-dimensional (2D) transition metal carbides and nitrides (MXenes), such as high conductivity, hydrophilicity, and catalytic activity have led to a growing research interest in their use in environmental remediation and water treatment applications. The ability to process MXenes into flexible films with negative surface charge and hydrophilicity adds a possibility to control ion flux and biofouling by applying a small potential to the membrane. MXene shows a much higher antibacterial efficiency toward both Gram-negative and Gram-positive bacteria as compared with other 2D nanomaterials. Consequently, MXene membranes demonstrated outstanding water flux, and selective rejection of salts and organic molecules, which makes them ideal UF/NF membrane materials. Moreover, MXene has been successfully used for the efficient adsorption and removal of heavy metals such as Hg, and Cu. This talk summarizes the recent advances in the applications of MXenes as adsorbents, desalination membranes, electrodes for electrochemical deionization, and catalytic or antibacterial agents for water purification and other environmental remediation processes. The overview also features discussions on the computational attempts, biocompatibility, and environmental impact in the exploration of MXenes for water applications, highlighting the challenges and opportunities of these advanced 2D materials. The biocompatibility and cytotoxicity assessment of MXene and its impact on the environment will be highlighted.

#### 10:45 AM EL17.15.02

**The Effect of Lateral Size and Surface Functional Groups on Membrane Performance of the Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> MXenes** Kiandokht Pakravan and Majid Beidaghi; Auburn University, United States

The applications of MXenes in membrane-based separation technologies have been rapidly expanding in recent years due to their hydrophilicity, exceptional flexibility, superior thermal stability, high electrical conductivity, and large surface area. In this presentation, we demonstrate significant enhancement in the performance of MXenes (Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub>) membranes through understanding the effects of lateral sizes and surface chemistry of MXenes on the permeability and separation properties of the fabricated membranes. Single-layer Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> nanosheets with different lateral sizes were obtained by applying high-power sonication with varying times to MXene dispersion. The resulting MXene dispersions were used to fabricate membranes for studying the effect of lateral size on the membrane performance. Also, to investigate the effect of surface chemistry on membrane performance, Ti<sub>3</sub>C<sub>2</sub>T<sub>x</sub> was synthesized by two different methods. The first method was the conventional MXene synthesis based on the MILD etching method, where delamination and etching were performed in a single step using a mixture of LiF and HCl as the etchant. The second method used a mixed acid etchant (HF/HCl) followed by delamination with LiCl. The existence of HF in the mixed acid method results in a higher concentration of -F functional groups, which can decrease the hydrophilicity of MXene membranes. Our initial permeability measurements indicate that membranes fabricated using MXenes with smaller lateral sizes have higher permeability compared with MXenes membranes with larger flakes. Also, the permeability of the MXene membrane varies across different methods.

#### 11:00 AM EL17.15.03

**Highly Efficient Electrochemical Performance of MXene-Based Nanocomposites for Capacitive Deionization of Metals and Cations** Ruey-An Doong, Nai-Ying Wang and Thi Kim Anh Nguyen; National Tsing Hua University, Taiwan

MXenes, a promising 2D materials derived from MAX phases, have been potentially applied to energy storage devices and pollution purification systems including ion-sieving membranes and ion removal. MXene has also established its prospective as electrodes for capacitive deionization (CDI) application

for water purification and reuse due to the similar principle of charge storage in supercapacitors that uses the faradaic ion intercalation phenomenon. Electrode materials for asymmetric capacitive deionization, by combining carbonaceous materials with metal oxides, have emerged as a potential electrode material for CDI applications, which enable high ion removal capacity in comparison with devices containing only carbon materials. In this study, MXene based nanocomposites including  $\text{MoS}_2$ @MXene and Prussian blue analogues (PBA)@MXene have been fabricated to serve as the electrode materials for symmetric and asymmetric CDI applications. Results show that all the developed nanocomposites have a high surface area, suitable pore texture, and low electrical conductivity to accelerate the electron and ion transfer rate. The specific electrosorption capacities (SECs) of the MXene-based nanocomposites are in the range of 39.5 – 43.8 mg/g with a charge efficiency of > 82%. Additionally, the as-developed MXene nanosheet has an excellent selective adsorption capacity toward heavy metal and ammonium ions removal. The  $\text{Ti}_3\text{C}_2$  MXene can selectively electroadsorb  $\text{NH}_4^+$  with the SEC of 40 mg/g. When combining the vanadium aluminum carbide ( $\text{V}_2\text{AlC-OH}_x$ ) with activated biochar (AB), the asymmetric AB|| $\text{V}_2\text{AlC-OH}_x$  device exhibits a superior deionization performance for Cr(VI) removal. These results clearly demonstrate the superiority of the as-developed MXene nanocomposites and can pave a gateway for combining MXene materials with novel metal oxides for highly efficient deionization of salty water as well as toxic metal and inorganic ions in water and wastewater treatment.

**Operando Synchrotron Radiation X-Ray Diffraction Study on Phase Evolution of  $\text{Nb}_2\text{GaC}$  MAX during Molten Salt Etching** Changda Wang;  
University of Science and Technology of China, China

Lewis acidic molten salt method is a promising synthesis strategy to achieve MXenes with controllable surface terminations from numerous MAX materials. However, the molten salt etching strategy is not totally controllable and most experimental parameters are usually set empirically due to the unclear reaction process. Understanding the phase evolution chemistry and time-dependency during etching and post-processing is highly desirable, but still a key challenge due to the lack of operando characterizations and the complexity of the reaction process. Herein, we introduce an operando synchrotron radiation X-ray diffraction (SRXRD) technique to unveil the phase evolution process of  $\text{Nb}_2\text{GaC}$  MAX under molten-salts ambient. Several critical steps are demonstrated, including ultra-fast evolution from  $\text{Nb}_2\text{GaC}$  to  $\text{Nb}_2\text{CuC}$ , quick extraction of Cu atoms to form  $\text{Nb}_2\text{CT}_x$  MXene, and interlayer expansion caused by Cl grafting. Accordingly, we propose a controllable synthesis of  $\text{Nb}_2\text{CT}_x$  through precise temperature-controlling and time-adjusting. Afterward, the phase structure of  $\text{Nb}_2\text{CT}_x$  is also successfully tailored from hexagonal to amorphous by the time-dependent subsequent persulfate oxidation. The amorphous  $\text{Nb}_2\text{CT}_x$  with well-patterned morphology and numerous chloride terminations exhibits highly improved specific capacity, rate, and long cycling capability in lithium-ion batteries (LIBs). In conclusion, the operando SRXRD with online devices is promising for the dynamic study of the Lewis acid molten salt etching process such as phase evolution, lattice change, and etching time scale, which could not be provided by ex-situ methods.

#### 8:15 AM \*EL17.16.03

**MXene Label-Free Detection and Immune-Based Applications** Lucia G. Delogu<sup>1,2</sup>, Laura Fusco<sup>1,3,4</sup>, Arianna Gazzi<sup>1</sup>, Christopher E. Shuck<sup>3</sup>, Marco Orecchioni<sup>5</sup>, Sènan Mickael D'Almeida<sup>6</sup>, Darawan Rinchai<sup>4</sup>, Eiman Ahmed<sup>4</sup>, Leeat Keren<sup>7</sup>, Davide Bedognetti<sup>4</sup> and Yury Gogotsi<sup>3</sup>; <sup>1</sup>University of Padua, Italy; <sup>2</sup>New York University Abu Dhabi, United Arab Emirates; <sup>3</sup>A.J. Drexel Nanomaterials Institute, United States; <sup>4</sup>Sidra Medicine, Qatar; <sup>5</sup>La Jolla Institute for Allergy and Immunology, United States; <sup>6</sup>Flow Cytometry Core Facility, School of Life Sciences Ecole Polytechnique Fédérale de Lausanne (EPFL), Switzerland; <sup>7</sup>Department of Molecular Cell Biology, Weizmann Institute of Science, Israel

Two-dimensional (2D) transition metal carbides, nitrides, and carbonitrides (MXenes) are rapidly growing as nanoplatforms in biomedicine.[1-3] Considering the central importance of the immune response for any clinical translation of nanomaterials, we explored the potential biomedical applications of MXenes and their immune impact exploiting our expertise on the biological effects of 2D materials.[1-4] To satisfy a critical unmet need to detect 2D materials at the single-cell level while measuring multiple cell and tissue features, we proposed the “Label-free sINgle-cell tracKing of 2D matERials by mass cytometry and MIBI-TOF Design” (LINKED) strategy, enabling nanomaterial detection while surveying a high degree of information from single samples.[5] This strategy is based on single-cell mass cytometry (CyTOF) and ion-beam imaging by time-of-flight (MIBI-TOF). MXenes ensured mass detection within the cytometry range while avoiding overlap with more than 70 available tags. We demonstrated their detection in 15 human immune cell populations. We used mass cytometry to capture MXene biocompatibility and cytokine production after their uptake. *In vivo* biodistribution experiments using a mixture of MXenes in mice confirmed the versatility of our strategy and revealed MXene accumulation in the main organs.

In addition, envisaging future MXene-based biomedical nanotools and drug nanoformulations we further explored MXene immune modulation and antiviral activity taking SARS-CoV-2 as a model.[6,7] We analyzed four SARS-CoV-2 genotypes. When viral inhibition was tested *in vitro*,  $\text{Ti}_3\text{C}_2$  was able to reduce infection in SARS-CoV-2/clade GR-infected Vero E6 cells. Among the other MXenes tested,  $\text{Mo}_2\text{Ti}_2\text{C}_3$  also showed antiviral properties. Proteomic and functional annotation analysis revealed that MXene-treatment exerts specific inhibitory mechanisms. The immune impact of MXenes was evaluated on human primary immune cells by flow cytometry and CyTOF on 17 distinct cell subpopulations. Moreover, 40 secreted cytokines were analyzed by Luminex technology. MXene immune profiling revealed i) the excellent bio and immune compatibility of the material, as well as the ability of MXene ii) to inhibit monocytes and iii) to reduce the release of pro-inflammatory cytokines, suggesting an anti-inflammatory effect elicited by MXene. Finally, we considered that although vanadium-based metallodrugs have been recently explored for their effective anti-inflammatory activity, they frequently cause undesired side effects. Therefore, we hypothesized that vanadium immune properties could be extended to MXene compounds.[8] Therefore, we synthesized  $\text{V}_4\text{C}_3$ , evaluating its biocompatibility and immunomodulatory effects. By combining multiple experimental approaches, we investigated the effects on hemolysis, apoptosis, necrosis, activation, and cytokine production. We demonstrated the ability to inhibit T cell-dendritic cell interactions, evaluating the modulation of CD40-CD40 ligand interaction, two key co-stimulatory molecules for immune activation. We confirmed the biocompatibility at the single-cell level on 17 human immune cell subpopulations by single-cell mass cytometry. Finally, we explored the molecular mechanism underlying  $\text{V}_4\text{C}_3$  immune modulation, demonstrating a MXene-mediated downregulation of antigen presentation-associated genes. Our findings set the basis for further  $\text{V}_4\text{C}_3$  investigation as a negative modulator of the immune response in inflammatory and autoimmune diseases. Taken together, our results provide a compendium of knowledge on the biocompatibility of MXenes for the safe development of multi-functioning nanosystems in biomedicine.

**The Influence of Hydration on the Mixed Charge Conduction of Conjugated Polymer Films** [Sahika Inal](#); King Abdullah University of Science and Technology, Saudi Arabia

Organic mixed (ionic and electronic) charge conductors and electrochemical phenomena at the solid-liquid interface have garnered significant attention for applications in bioelectronics, electrochromics, energy storage/generation, neuromorphic computing, and thermoelectrics. These devices operate in electrolytes that render ions mobile in the film, making the coupling between electronic and ionic charges crucial. An example of such a device is the organic electrochemical transistor (OECT), a high-gain transducer commonly used to monitor bioelectronic signals. In this talk, I will show that the ions entering the semiconducting polymer channel are hydrated, and the water they bring inside the channel significantly affects OECT performance, which can be traced back to changes in the overall structural order. I will show the generality of this phenomenon with p and n-type materials. I will demonstrate how the amount of water the film takes governs its dielectric constant and the polaronic species formation. I will introduce one synthetic method and one postprocessing approach that can limit the water uptake of the film during device operation. These approaches enhance the mixed conductivity of polymers while preventing material degradation with oxygen, leading to OECTs with longer shelf life and operational stability.

### 11:00 AM EL18.01.02

**Are Existing OECT Models Broad Enough? The Role of the Counter Ion and Ionic Contact Blocking** Sapir Bitton and [Nir Tessler](#); Technion-Israel Institute of Technology, Israel

OECTs have many advantages making them a promising technology for the future of electronics and bio-electronics. They have high transconductance which leads to a high sensitivity [1], and low operating voltage [2]. They can be fabricated on flexible substrates, [3] are scalable, and cost-effective for mass production. [4] The above attributes make them suitable for various applications, including healthcare (biosensors, drug delivery devices), robotics (sensors and actuators), and flexible electronics (e-skins, displays). However, they have limitations and challenges, such as stability and reversibility issues, manufacturing complexity, and the need for further optimization in certain applications. [5]

In our study, we simulated an OECT with PEDOT: PSS as the semiconductor layer. At the ON state, no cations are present in the bulk, resulting in a hole current within the PEDOT: PSS bulk. Conversely, at the OFF state, cations penetrate the bulk, depleting it and causing a significant drop in current. The above is well-known and detailed modeling has already revealed the importance of the ions' distribution with the semiconducting layer. [6,7]

Here we expand on previous studies using the industry-standard device simulator Sentaurus by Synopsys. Using the ion ("hydrogen") diffusion module allows for self-consistent simulation of the ionic electronic conduction as well as the contact phenomena. The first new observation to report is that, like in some memory technologies, ion accumulation close to the contact interface blocks the contact injection. In fact, this contact blocking plays an important role in obtaining low enough off currents.

Next, since the counterions (anions) are explicitly incorporated into the model, we report their influence on the OECT's conductance. We will present hole, cation, and anion distributions in the electrolyte and semiconductor for ON and OFF states under three scenarios: (1) Anions can move freely in the

electrolyte but are blocked by the semiconductor, (2) Anions can move freely in the electrolyte and penetrate the semiconductor, and (3) Anions are static in the electrolyte (as in solid electrolytes). We identify the scenario resulting in the highest transconductance and demonstrate the potential role of the electrolyte's counter ions (anions) in achieving best-performing OECTs.

We will discuss how our new findings suggest that the models used abundantly to describe OECT's performance may not be general enough. [8]

**Ion-Associated Charge Transport in Conjugated/Non-Conjugated Polymer Layers for Wet and Dry Electronic Devices** Takeo Suga; Waseda University, Japan

Electro-active organic polymers (*i.e.* p-conjugated polymer conductors/semi-conductors) have attracted increasing interest for organic electronics applications, such as solar cells, field-effect transistors, and batteries, because of their facile integration to soft/flexible device configurations, and environmentally benign/sustainable feedstock compared with rare metals, etc. Non-conjugated, redox-active polymers such as radical polymers have also attracted research attention to their utilization as an electrode-active material for rechargeable batteries and a charge-transport layer for electronic devices. Any of these applications, the role of associated ion transport is indispensable for efficient charge injection, transport, and storage. Here we take three examples: a) stable charge-storage in radical/conducting polymers, b) modulated charge-transport in the radical-containing resistive memory, and c) efficient charge collection through polymer semiconductors in the perovskite solar cells, and discuss each role of ions for charge-transport in electro-active polymers.

**Asymmetric Side-Chain Engineering of Thiophene-Based Polymers for Organic Electrochemical Transistor Applications** Preeti Yadav and Christine Luscombe; Okinawa Institute of Science and Technology Graduate University, Japan

Conjugated polymers with mixed ion-conducting properties have recently gained considerable attention due to their potential applications in various emerging technologies spanning from bioelectronics to energy harvesting and storage. The soft and biocompatible nature of conjugated polymers coupled with their mixed conduction properties has been leveraged to develop many organic bioelectronic devices including organic electrochemical transistors (OECTs), neural probes, organic electronic ion pumps, and conducting polymer actuators. Among these, an OECT device comprising of a redox-active organic semiconductor layer interfacing a source, a drain electrode, and an electrolyte solution is capable of directly transducing small ionic fluxes into electrical signals making it ideal for sensing biomolecules. To achieve a high-performing OECT device, carrier mobility, and ion transport should be balanced in such a way that maximum transconductance is achieved, highlighting the crucial role played by crystallinity and morphology in mixed conduction. Therefore, it is important to establish an in-depth understanding of the chemical structure of the semiconducting polymer, charge transport, and morphology for designing high-performance OECT materials. In this work, we have synthesized polythiophene derivatives and explore how the polymer morphologies will affect carrier mobility and ion transport. The fundamental design idea is to obtain a highly planarized polymer structure by enhancing the side-chain organization through the incorporation of asymmetric side chains. Specifically, we investigate the effect of the enhanced side-chain organization on film morphologies, carrier mobility, and ion transport. Thiophene monomer is synthesized using Stille coupling and subsequently polymerized using Kumada catalyst transfer polymerization. The obtained polymer is characterized using NMR, MALDI, DSC, TGA, UV-vis absorption spectroscopy, and cyclic voltammetry. The morphologies and microstructure of the polymer films are examined using AFM and GIWAX followed by OECT device fabrication and characterization.

#### 1:45 PM \*EL18.02.02

**Operando Studies of Organic Mixed Ionic-Electronic Conductors: Structure, Composition and More...** Jonathan Rivnay; Northwestern University, United States

Organic mixed ionic-electronic conductors (OMIECs) have gained considerable interest in bioelectronics, power electronics, circuits and neuromorphic computing. These organic, often polymer-based semiconductors rely on a combination of ionic transport, electronic transport, and high volumetric charge storage capacity. Despite recent progress and a rapidly expanding library of new materials, a full understanding of fundamental processes of OMIECs remains largely unexplored. Critically, useful studies require us to probe these systems in device-relevant conditions, fully considering the effects of ions and solvent on microstructure and transport. To this end, we report on recent efforts towards structure/composition-property relations in high performance organic mixed conductors using ex-situ, in-situ, and operando scattering and spectroscopic techniques. We use a combination of GIWAXS, GISAXS, XPCS, E-QCMD, UV-Vis, XRF, as well as device measurements to explore kinetics, composition, and structural evolution during electrochemical operation. Importantly, these findings provide insights into materials design for enhancing device performance and stability.

#### 2:15 PM EL18.02.03

**Probing Polarons in Mixed Conductors via the Photoinduced Stark Effect** Christopher Grieco, Abdul Rashid Umar and Austin Dorris; Auburn University, United States

Conjugated polymers are promising candidates for high performance bioelectronics due in part to their ability to conduct ions and charge carriers simultaneously. However, the fundamentals of mixed ion and charge transport, including their complex dependence on polymer structural dynamics occurring *in operando*, remain unclear due to limited characterization methods. Using ultrafast transient absorption spectroscopy, we demonstrate a new approach to probing the nature and local environment of polarons in a mixed conducting, electrochromic polymer, 3,4-propylenedioxythiophene-*co*-3,4-ethylenedioxythiophene (ProDOT-*co*-EDOT).[1] Selectively photoexciting hole polarons via the P1 and P2 polaronic transitions causes spatial separation of the hole from its counterion during thermalization. The resulting electric field, which induces a Stark shift of the bandgap transition of nearby polymer chains, creates signals in the transient spectrum that reflect the electronic structure and environment of the charge carrier. As a first step, we show how this optical spectroscopy method, which effectively senses polarons in both amorphous and crystalline domains, can be implemented in spectroelectrochemical measurements to elucidate mixed conduction mechanisms.

### 2:30 PM EL18.02.04

**Swelling of Side Chain Free Polymers upon Electrochemical Cycling** Lucas Flagg<sup>1</sup>, Lee Richter<sup>1</sup>, Jiajie Guo<sup>2</sup>, David S. Ginger<sup>2</sup> and Jianguo Mei<sup>3</sup>; <sup>1</sup>NIST, United States; <sup>2</sup>University of Washington, United States; <sup>3</sup>Purdue University, United States

Organic mixed ionic-electronic conductors (OMIECs) are an exciting class of new materials with a range of potential applications including biosensors, electrochromics, and neuromorphic computing. For many of these applications the performance of n-type materials trails p-type materials by at least an order of magnitude. Recently, a pair of side-chain less polymers have been demonstrated as promising n-type OMIECs. These materials challenge the existing understanding of this class of materials, where polar (often ethylene glycol) side chains enable electrolyte and ion ingress, which subsequently enables volumetric doping. Here, we seek to understand the swelling during electrolyte contact and during redox cycling of these side chain less materials using *in-situ* GIWAXS. These measurements reveal drastic differences in how the two polymers swell in response to applied bias. In water-based electrolytes, BBL shows a redox induced swelling upon first passage, and remains swollen during subsequent doping cycles. In contrast, PBDF does not show any lattice expansion when in contact with water regardless of doping state. However, in propylene carbonate electrolyte PBDF shows a reversible melting during dedoping to the point where all diffraction peaks disappear. Upon electrochemical redoping, the crystallinity returns to its original level. Additionally, in the partially doped state the lattice spacing depends strongly on the exact doping state. We investigate this melting/recrystallization and swelling phenomena in relation to conductivity of the system. Overall, this work provides insights into the role of swelling in side-chain less OMEIC materials which can inform design rules moving forward.

Monday Afternoon, November 27, 2023

Hynes, Level 1, Room 111

### 3:15 PM \*EL18.03.01

**Electronic and Ionic Conduction in Radical-Containing Small Molecules and Polymers** Bryan W. Boudouris; Purdue University, United States

Optoelectronically active small molecules and polymers have made critical inroads in many solid-state electronic devices (e.g., organic field-effect transistors), and excitingly, organic molecules capable of providing mixed electronic and ionic conduction offer unique opportunities in many application areas including bioelectronic devices. Here, we describe electronic and ionic conduction in both low molecular weight and polymeric materials containing stable open-shell sites. While the chemical nature of the two classes of materials differs, the key premise is that controlling the spatial distance between the radical groups is critical for electronic transport and that the redox behavior of open-shell species allows for facile ion transport if it is controlled appropriately.

First, we demonstrate how control of the local structure in radical-containing small molecules and polymers impacts charge transport in these materials. In one example, we implement radical polymers, which are macromolecular materials that have flexible polymeric backbones and pendant groups that bear stable open-shell moieties. In contrast to almost all other optoelectronically-active polymers, radical polymers lack backbone conjugation and are completely amorphous in the solid state. Despite this shift in macromolecular design archetype, we demonstrate that the solid-state electrical conductivity of a designer radical polymer exceeds  $20 \text{ S m}^{-1}$ , and this places this nonconjugated polymer conductor in the same regime as many grades of common commercially-available, chemically-doped conjugated conducting polymers. Thus, this work presents an alternate design paradigm for next-generation organic electronic materials. In a second example, small molecules that bear stable radical groups and form macroscopic single crystals are evaluated. Specifically, we quantified the electrical conductivity in two organic radical single crystals and demonstrated that a subtle change in atomic connectivity drastically alters the macroscopic electronic properties of the materials. One radical-based crystal had an electrical conductivity of  $\sim 3 \text{ S m}^{-1}$ , which is the highest value for nonconjugated radical conductors over a  $1 \mu\text{m}$ -scale reported to date. However, the other radical crystal has a 1,000-fold lower conductivity despite their extremely similar molecular structures. The temperature-dependent conductivity follows the variable range hopping mechanism for both radical crystals, and the difference in effective charge mobility is the reason for the conductivity difference. These results present a clear picture of the design rules and charge transport mechanism for radical-based materials.

Next, we describe how a blend of a common conjugated polymer, poly(3-hexylthiophene) (P3HT), and a radical polymer (i.e., a macromolecule with a nonconjugated backbone and with stable open-shell sites on its pendant groups), poly(4-glycidyoxy-2,2,6,6-tetramethylpiperidine-1-oxyl) PTEO, allows for the creation of high-performance organic electrochemical transistors (OECTs) through a unique mixed conduction mechanism. Second, we will discuss how this type of archetype can be translated to biomedical device applications through a practical demonstration of a stretchable and flexible polymer-based biosensor. This bioelectronic device is inkjet-printed atop a commercial soft contact lens in a high-throughput manner, and our electroretinogram (ERG) sensor shows performance that is superior to current clinical gold standards in human subjects. In this way, we couple the materials science mixed organic electronic conductors to translational performance to demonstrate clear patient impact.

### 3:45 PM EL18.03.02

**Generalised Framework for Controlling and Understanding Ion Dynamics with Passivated Lead Halide Perovskites** Tomi Baikie<sup>1</sup>, Philip Calado<sup>2</sup>,

Krzysztof Galkowski<sup>1</sup>, Samuel D. Stranks<sup>1</sup> and Piers R. B. Barnes<sup>2</sup>; <sup>1</sup>University of Cambridge, United Kingdom; <sup>2</sup>Imperial College London, United Kingdom

Metal halide perovskite solar cells have gained widespread attention due to their high efficiency and high defect tolerance. The absorbing perovskite layer is as a mixed electron-ion conductor that supports high rates of ion and charge transport at room temperature, but the migration of mobile defects can lead to degradation pathways. We combine experimental observations and drift-diffusion modelling to demonstrate a new framework to interpret surface photovoltage (SPV) measurements in perovskite systems and mixed electronic ionic conductors more generally. We conclude that the SPV in mixed electronic ionic conductors can be understood in terms of the change in electric potential at the surface associated with changes in the net charge within the semiconductor system. We show that by modifying the interfaces of perovskite bilayers, we may control defect migration behaviour throughout the perovskite bulk. Our new framework for SPV has broad implications for developing strategies to improve the stability of perovskite devices by controlling defect accumulation at interfaces. More generally, in mixed electronic conductors our framework provides new insights into the behaviour of mobile defects and their interaction with photoinduced charges, which are foundational to physical mechanisms in memristivity, logic, impedance, sensors and energy storage.

#### 4:00 PM EL18.03.03

**Ion- and Charge Transport in Dense Films of Semiconducting Single-Walled Carbon Nanotubes** Daniel Heimfarth, Merve Balci Leinen, Xuqiang Xu and Jana Zaumseil; Heidelberg University, Germany

Dispersions of purely semiconducting single-walled carbon nanotubes (SWCNTs) can be sorted and purified by polymer-wrapping and subsequently printed into thin or thick SWCNT films that are suitable for various electronic devices. Here, we demonstrate that these porous composites of conjugated polymer and semiconducting nanotubes enable mixed ionic and electronic transport with high charge carrier mobilities in electrochemical transistors with different electrolytes. The ionic transport and hence also the effective volumetric capacitance of the nanotube network can be increased substantially by changing from a hydrophobic polyfluorene copolymer with alkyl sidechains to one with tetraethylene glycol sidechains, thus reaching over  $200 \text{ Fcm}^{-1}\text{V}^{-1}\text{s}^{-1}$  as the product of carrier mobility and volumetric capacitance (*ACS Appl. Mater. Interfaces* 2022, 14, 8209). We find that the maximum transconductance for hole transport in SWCNT networks also depends on the size of the electrolyte anions, suggesting a direct impact on the delocalization of charge carriers along the nanotubes. Furthermore, we monitor the ion movement and thus charge carrier concentration within a nanotube network by spatially resolved in-situ Raman- and photoluminescence spectroscopy and explore the role of the network morphology and density for both charge and ion transport. Finally, we demonstrate the direct sensing of cupric ions and indirectly of glyphosate in water-gated transistors with polyfluorene copolymer-wrapped nanotubes (*Nanoscale* 2022, 14, 13542).

#### 4:15 PM EL18.03.04

**Controlling Mixed Ionic-Electronic Conducting Polymer Properties with Amphiphilic Chemical Design Strategies** Nicholas D. Siemons; Imperial College London, United Kingdom

Semiconducting polymers bearing hydrophilic glycol side chains can transport aqueous electrolytes through their bulk, allowing for the simultaneous movement of electronic and ionic charges during electrochemical doping (therefore called organic mixed ionic-electronic conductors, or OMIECs). Their mixed charge transport properties, chemical tuneability and easy synthetic scalability make them attractive materials for bioelectronic devices such as transistors [1] and charge storage devices [2]. While hydrophobic alkylated polythiophenes have demonstrated favourable charge transport properties [3] and the ability to operate stably in devices such as field-effect transistors, upon glycolation (making them into OMIECs) some of these favourable properties are deteriorated. For example, heavily glycolated polythiophenes have shown to excessively swell when electrochemically doped in the presence of an aqueous electrolyte [4], damaging their operational stability and charge transport properties. We explore how amphiphilic chemical design strategies can be leveraged to design OMIECs that retain their operational stability and high charge transport properties. We explore two strategies – 1) the random copolymerisation of alkylated and glycolated repeat units together and 2) using homopolymers with both alkyl and glycol moieties on their side chains. In the first case we find that a small level of alkylation leads to a large increase in the electrochemical cycling stability of the OMIEC, while leaving the electrochemical doping characteristics broadly unchanged. When using homopolymers with mixed alkyl/glycol side chains, we show how the size of the alkyl group on the side chain can control the polymer backbone conformation, impacting its electronic transport properties. Through a joint experimental/theoretical approach we identify the underlying microstructural mechanism behind both the inhibited swelling in alkyl/glycol copolymers and the effect on the backbone morphology in amphiphilic homopolymers. We identify the driving forces causing them to adopt their particular microstructure and draw parallels between the formation of micelles and vesicles in surfactants. Identifying these mechanisms and their driving forces in OMIEC systems will aid in the design of future polymers which optimise the transport of both ionic and electronic charges, while having high operational stability and charge transport properties.

#### 8:00 PM EL18.04.01

**Enhanced Thermoelectric Performance of PEDOT:PSS-Based Composites by Constructing Sequential Energy-Filtering Interfaces and Energy Barriers** Siqi Liu<sup>1</sup> and Chaobin He<sup>1,2</sup>; <sup>1</sup>National University of Singapore, Singapore; <sup>2</sup>Institute of Materials Research and Engineering, Singapore

Among all reported organic thermoelectric materials, poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) has drawn extensive attention owing to its high electrical conductivity. However, the Seebeck coefficient of PEDOT:PSS needs to be enhanced without sacrificing electrical

conductivity. As one approach, modulating the energy filtering effect at the component interfaces can enhance the Seebeck coefficient with only a slight reduction in electrical conductivity. In this presentation, I will report an effective strategy to significantly enhance the thermoelectrical properties of PEDOT:PSS by integrating core-shell PEDOT/polypyrrole (PPy) nanowires to form multiple sequential interfaces and enabling more effective energy filtering process in between. By tailoring the energy barriers among PEDOT/PPy/PEDOT:PSS interfaces, the Seebeck coefficient of the PEDOT:PSS composites was increased by ~46% with only a slight decrease in electrical conductivity. As a result, a significant improvement of over 85% in power factor was achieved compared with pristine PEDOT:PSS.

#### 8:00 PM EL18.04.02

**Textile-Embeddable Fibriform Organic Electrochemical Diodes with Rectifying, Complimentary Logic and Transient Voltage Suppression Function for Wearable E-Textile Circuits** Kwang-Hun Choi<sup>1,2</sup>, Soo Kin Kim<sup>1,2</sup>, Ho Won Jang<sup>2,2</sup>, Changsoo Choi<sup>1</sup>, Hyunsu Ju<sup>1</sup> and Jung Ah Lim<sup>1,3</sup>; <sup>1</sup>Korea Institute of Science and Technology, Korea (the Republic of); <sup>2</sup>Seoul National University, Korea (the Republic of); <sup>3</sup>Korea University of Science and Technology of Korea, Korea (the Republic of)

Electronic textile (E-textile) are considered ideal wearable platforms for human-machine interaction due to their flexibility and flexible, comfortable-wearing textile properties. For realization of a multi-functional, fully integrated E-textile circuit system, fibriform electronic devices become a key component that can merge a multifunctionality of integrated circuits and a textile nature. Here, we propose a fibriform electrochemical diode (fOED) as a building block for E-textile circuits. The fOED is fabricated by twisting metal/polymer semiconductor/ion gel coaxial microfibers and microfiber electrodes. The fOED exhibits a prominent asymmetrical current flow similar to that of the diode, with a rectification ratio of over  $10^2$ . From the fundamental studies on the electrochemical interaction between polymer semiconductors and ions, we reveal that the faradaic current by electrochemical reaction originates an abrupt current increase under a forward bias. Then, the threshold voltages of devices are determined by the redox potential of the polymer semiconductor. The fOED exhibit great bending and washing robustness, and was embeddable on the textile platform by its one-dimensional architecture (diameter < 300  $\mu\text{m}$ ). It also could be expanded to integrated circuit systems by simply merging the electrode threads, the full-wave rectifiers and logic gates (AND/OR) could be easily accomplished on textiles. Furthermore, it was also confirmed that fOED could be utilized as a protection diode, a fOED integrated electrocardiogram monitoring system could be protected from circuit damage by instant transient voltages. Our approach offers a new form factor for electrochemical diodes and we believe that this work will contribute to the development of next-generation wearable E-textile circuit systems.

#### 8:00 PM EL18.04.03

**Aerosol Jet Printed Organic Electrochemical Transistors using n-Type Naphthalene Dimide-Based Small-Molecule Organic Mixed Ionic-Electronic Conductor** Seongdae Kang<sup>1</sup>, Paul Lavryshyn<sup>1</sup>, Jiaxin Fan<sup>2</sup> and Manisha Gupta<sup>1</sup>; <sup>1</sup>University of Alberta, Canada; <sup>2</sup>Polytechnique Montréal, Canada

Organic semiconductors are capable of transporting both the ionic and electronic charges representing a new class of material: organic mixed ionic-electronic conductor (OMIECs). OMIECs have been used for a variety of organic electronics, including organic electrochemical transistors (OECTs) and energy conversion/storage devices. Most reported OMIECs are hole-transporting p-type polymeric material, such as PEDOT:PSS and polythiophene derivatives. In contrast, electron-transporting n-type OMIECs are less reported and often have poorer performance and stability, despite their need in fabricating complementary circuits or biosensors that require electron transfer. Compared to polymeric OMIECs, small-molecule mixed conductors offer significant potential thanks to their mono-dispersity and synthesis simplicity.<sup>1)</sup>

We recently reported the first naphthalene-diimide-based n-type small-molecule organic mixed ionic-electronic conductors and their utilization as a channel material in accumulation mode organic electrochemical transistors. The glycolated naphthalene diimide n-type OMIEC, gNDI-Br<sub>2</sub>, was characterized for its electrochemical behaviour and used to fabricate an OECT via a simple drop-casting technique. The gNDI-Br<sub>2</sub> OECT operated as an n-type accumulation mode and showed a maximum transconductance ( $g_{m, \text{max}}$ ) of  $814 \pm 124.2 \mu\text{S}$  and a mobility capacitance product ( $\mu\text{C}^*$ ) of  $0.23 \pm 0.04 \text{ F cm}^{-1} \text{V}^{-1} \text{s}^{-1,2)}$

The transconductance of the OECT is affected by its intrinsic material figure-of-merit ( $\mu\text{C}^*$ ) and channel geometry.<sup>3)</sup> Drop-casted gNDI-Br<sub>2</sub> devices pose a challenge for practical applications due to their unpredictable channel geometry and hence their repeatability. To resolve this issue, we fabricated gNDI-Br<sub>2</sub> OECTs using an aerosol-jet 3D printing technique with the Optomec Aerosol Jet 5X 3D printer. This method creates the sub-micron size aerosols using ultrasonic atomization which are deposited onto the substrate via a nozzle.<sup>4)</sup> Owing to the AJ5X 3D printing system, we were able to manipulate the OECT channel geometry and fabricate repeatable OECT devices.

Additionally, for the aerosol jet printing, the gNDI-Br<sub>2</sub> solution with low evaporation rate was required while transitioning to an aerosol. By using low-volatile solvent for the solution and aerosol-jet 3D printing, the gNDI-Br<sub>2</sub> molecules were evenly distributed onto the substrate, resulting in higher crystallinity as compared to the drop-casted OECTs. This resulted in an improved performance of the gNDI-Br<sub>2</sub> OECT ( $g_{m, \text{max}} = 1.12 \text{ mS}$ ,  $\mu\text{C}^* = 0.75 \text{ F cm}^{-1} \text{V}^{-1} \text{s}^{-1}$ ). Moreover, we achieved a fully printed n-type OECT by printing other component, including metal electrodes onto flexible polymer substrates. Using this gNDI-Br<sub>2</sub> OECT, we were able to fabricate aerosol-jet printed complementary logic circuit with a PEDOT:PSS p-type counterpart.

**Ionic Liquid Driven Enhancements in the Electromagnetic Interference Shielding Capabilities of Carbon-Based Polymer Composites** Paul Al Malak<sup>1,2</sup>, Cedric Vancaeyzeele<sup>1</sup>, Pierre-Henri Aubert<sup>1</sup>, Frédéric Vidal<sup>1</sup>, Giao T.M. Nguyen<sup>1</sup>, Paolo Bondavalli<sup>2</sup> and Cédric Plesse<sup>1</sup>; <sup>1</sup>CY Cergy-Paris Université, France; <sup>2</sup>Thales Research & Technology, France

Electromagnetic interference (EMI) has emerged as a crucial problem in the modern world because of the rapid proliferation of electronic and telecommunication systems, which emit electromagnetic radiation that may perturb the performance of electronic devices on one hand, and could be harmful to the human body on the other [1]. As a result, considerable endeavors have been devoted to the development of efficient materials for EMI shielding/absorption. Polymers and polymeric composites with a wide array of fillers, especially carbon-based fillers have been widely used as promising candidates in the development of commercially viable EMI shielding materials. Lately, extensive research efforts have been put forward, towards effective dispersion of the fillers throughout the matrix. Ionic liquids have emerged as a promising dispersing agent for CNTs through non-covalent functionalization by interacting with the CNTs surface through  $\pi$ - $\pi$ , cation- $\pi$  or even Van der Waals interaction [2]. They have been also used as fillers in metamaterial structures, where they actively engage in attenuating the electromagnetic wave thanks to their polarity [3]. Accordingly, it would be really interesting to develop a shield where we can take advantage of the already proven excellent EMI shielding capabilities of carbon based composites and in exploring the

capabilities of ionic liquids in a more active manner in a polymer matrix.

Here, we demonstrate the use of carbon-based nanomaterials (MWCNT, Graphene derivatives) incorporated in ionogels as effective EMI shields. These ionogels combine the unique properties of ionic liquids and their ability to attenuate the electromagnetic wave through dipole reorientation and translational motion (movement of the ions). The structural support is provided by the gel matrix, which also aids in matching the impedance of the shield with the surrounding environment, while the presence of carbon-based nanomaterials not only facilitated the formation of conductive pathways but also introduced interfacial polarization and dipole polarization between them and the ionic liquid-gel matrix. The ionogels exhibited remarkable performances across a wide frequency range, where the presence of the ionic liquid led to an enhanced absorption of the electromagnetic wave, with over 97% attenuation, of which over 55% is by absorption. Morphological characterizations revealed the homogeneous envelopment of the CNTs by the ionic liquid enhancing the interfacial polarization. The electrical conductivity measurements confirmed the conductive behavior of the carbon-based nanomaterial incorporated ionogels, which is essential for effective EMI shielding.

#### 8:00 PM EL18.04.05

**Elucidating the Role of Side-Chain Polarity of Conjugated Polyelectrolytes by Doping Through Organic Electrochemical Transistor** Sung Hyun Lee<sup>1</sup>, Changwha Jung<sup>1</sup>, Hyunho Jeong<sup>1</sup>, Chaeyeon Park<sup>2</sup>, Soonyong Lee<sup>2</sup>, Han Young Woo<sup>2</sup> and Hyunjung Lee<sup>1</sup>; <sup>1</sup>Kookmin University, Korea (the Republic of); <sup>2</sup>Korea University, Korea (the Republic of)

Conjugated polyelectrolytes (CPEs) exhibit a novel structure composed of electron or hole conducting  $\pi$ -conjugated backbone and ion conducting pendant ionic functionalities. Anionic narrow-band-gap CPE named poly[2,6-(4,4-bis-potassium butanysulfonate-4H-cyclopenta-[2,1-b;3,4-b0]-dithiophene)-alt-4,7-(2,1,3-benzothiadiazole)] (PCPDTBTSO3K, or CPE-K) is well known for self-doped property which is fabricated as a channel material for organic electrochemical transistor (OECT).

In this work, electronic and ionic transport is studied by OECT system. Different types of polarity of side chain attached to the same backbone that contains an alternating D-A units of cyclopentadithiophene (CPDT) and benzothiadiazole (BT) were synthesized. The affect of different polarity was examined as a channel material by using gel-type ionic liquid electrolyte (1-Ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide or [EMIM]<sup>+</sup>[TFSI]<sup>-</sup>) which allows wider range of gate voltage and constant measurement conditions etc. All three channel materials each showed ON and OFF state both in accumulation and depletion mode only by changing the polarity of gate and drain voltage. Ion transport mechanism was compared through OECT system by measuring transfer/output curve,  $\mu\text{C}^-$  value and response time etc. Our work allows for maximizing doping effect through ion penetration and utilize as a dual mode switching system.

#### 8:00 PM EL18.04.06

**Study on the Impact of Ions Uptake on the Thermoelectric Performance in Organic Electrochemical Transistors** Hyunho Jeong<sup>1</sup>, Changwha Jung<sup>1</sup>, Sung Hyun Lee<sup>1</sup>, Chaeyeon Park<sup>2</sup>, Soonyong Lee<sup>2</sup>, Han Young Woo<sup>2</sup> and Hyunjung Lee<sup>1</sup>; <sup>1</sup>Kookmin university, Korea (the Republic of); <sup>2</sup>Korea University, Korea (the Republic of)

The aim of our research is to explore the effects of penetrated ions in the polymer matrix by electrochemical doping on the thermoelectric performance in organic electrochemical transistors (OECTs). Controlling the Seebeck coefficient and electrical conductivity values of organic thermoelectric (TE) materials has been widely studied. However, earlier works were primarily conducted based on the chemical doping method. In terms of controlling the TE performance, the electrochemical doping method has the advantage of finely tuning doping levels by changing the applied gate voltage ( $V_g$ ). Anions or cations from ionic liquid penetrate the polymer matrix depending on the sign of applied gate voltage and modulating the conductivity. This method provides an easy way to study the TE performance of organic TE materials.

Generally, the focus is on the doped organic TE materials by penetration of mobile ions, and penetrated ions induced Seebeck coefficient is seldom considered. The temperature gradient causes not only the potential difference created by the polymer film but also the potential difference due to ions in the ionic liquid moving by the Soret effect. Thus, it is essential to clarify the contribution of ions to TE performance for further application.

Here, we demonstrate the influence of the uptake of mobile ions in an electrolyte (1-Ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide, ([EMIM]<sup>+</sup>[TFSI]<sup>-</sup>)) on TE performance using different polarity side chain polymers. We characterize the time-dependency of the potential difference between the cold side electrode and the hot side electrode based on the OECT system to investigate the ionic and electronic induced Seebeck coefficient separately.

**Molecular Design for Tunable Ionic Thermopower with High Stretchability** Minju Park; Korea Research Institute of Chemical Technology, Korea (the Republic of)

Wearable and stretchable electronics have attracted tremendous attention due to their wide applications in various areas. However, the lack of efficient, light-weighted and environmental friendly power sources has been the bottleneck that hinders the wide applications of wearable technologies. One of the attractive solutions is the thermoelectric generators (TEGs), which can directly convert waste heat from human body or environment into electricity. Though great development has been achieved with conventional TEGs, present inorganic thermoelectric materials still suffer from rigid properties and low Seebeck coefficient (several hundred  $\mu\text{V}/\text{K}$  scale), which requires an integration of hundreds of elements. To overcome these challenges, ionic thermoelectric materials utilizing ionic transport open up new possibilities for the recuperation of waste heat due to their enormous Seebeck coefficient, which can operate supercapacitors by energy harvesting.

Herein, we introduce intrinsically stretchable acrylamide based polymers (PAM) as the ion conductive materials comprising graphene derivatives, which possess high stretchability and excellent thermoelectric performance. Interestingly, ionic conductivity and thermopower could be tunable according to the molecular structure of graphene-based additives. Chemical structure of graphene-based additives was successfully modified by covalent functionalization with phenylsulfonic acid (SGO) and amine species (NGO), resulting in strong positive and negative charged graphene nanosheets, respectively. Induced charge could significantly affect to Coulombic interaction between ion and polymer, or ion and solvent, rendering in large difference in ion concentration under temperature gradient. As a result, the proposed materials exhibit excellent and tunable Seebeck coefficient (up to 39.7 mV/K) as well as remarkable stretchability. The ionic thermoelectric performance was sustained during multiple stretch-release cycles (50% strain, 1000 cycles), which demonstrates high durability under severe deformation. Furthermore, we fabricate ionic thermoelectric supercapacitors (ITESC) with ionogels, demonstrating the heat-to-electricity conversion was successfully established. These findings show a promising strategy to obtain multifunctional ionic thermoelectric materials by engineering the molecular structures, and demonstrate the great potential of ionogels for harvesting low-grade heat in human-comfortable humidity environments.

**Pyrene Dianhydride Condensation Ladder Polymer: Synthesis and Film Characterization.** Katherine Johnston, Emma Mikita and Julia A. Schneider; Fordham University, United States

Organic materials that display mixed-conductance—the ability to conduct both ions and electrons—are actively sought after for their possible use in organic electrochemical transistors and sodium-ion batteries, among many other applications. Of only a few n-type polymers reported to display mixed-conductance, poly(benzobisimidazobenzophenanthroline) (**BBL**) is the most promising to date. Its conjugated ladder structure makes it very environmentally stable and its ability to maintain a planar backbone when swelling in ionic media has led to high capacitance and electron mobility. The success of **BBL** in terms of its mixed-conductance has renewed interest in the study and development of n-type ladder polymers. We will present the synthesis of a new mixed-conducting material, a pyrene-based ladder polymer, poly(benzimidazobenzophenanthroline) ladder (**BPpL**), formed from the polycondensation reaction between our pyrene dianhydride monomer unit and 1,2,4,5-tetraaminobenzene tetrahydrochloride (**TAB.4HCl**). The larger aromatic core of **BPpL** vs. **BBL** influences the packing of the polymer, and therefore, how well the polymer can form films and perform in electronic devices. We will study and present how **BPpL** and **BBL** differ in regard to their film making abilities using spectro-electrochemical analysis, UV-Vis, and TEM. The capacitance of **BPpL** will also be measured and reported.

Through our synthesis of the pyrene dianhydride monomer, two isomers are produced. We will present the synthesis and characterization of each isomer in its diimide forms. The pyrene diimide units themselves and their spectral and electrochemical properties are useful to study for future incorporation into conjugated polymers. Pyrene is impactful as a core for these molecules due to its unique fluorescence property: excimer formation. Excimer formation causes a shift in fluorescence when the molecule is close to a neighboring molecule and can be a useful way to visualize the molecule's ability to stack or congregate. Determining the monomers' ability to form excimers can help with determining their ability to pack when in the polymer form. The synthesis of both pyrene diimide isomers will be presented with their fluorescence spectrum, which demonstrate excimer formation at higher concentrations.

**8:00 PM EL18.04.10**

**Enhancing Adhesion of PEDOT Coatings on Metal Electrodes: A Promising Approach** Sara Ebrahimi, Fabio Ciccoira and Sadaf Khoomortezaei; Polytechnique Montreal, Canada

The use of electrodes as biomedical devices in healthcare is undergoing innovative advancements, employing novel techniques that bridge the gap between biological systems and electronics. Nonetheless, traditional metallic electrodes encounter a substantial hurdle in the form of impedance, impeding the smooth transmission of electrical signals within living tissues. To tackle this challenge, recent breakthroughs suggest the utilization of poly(3,4-ethylene dioxithiophene) (PEDOT), an organic conducting polymer, as a solution to overcome the impedance obstacle [1]. PEDOT exhibits favourable qualities that make it an excellent candidate for bioelectronic devices. These desirable characteristics include its ability to maintain low impedance, high conductivity, excellent electrochemical stability, and biocompatibility, rendering it an optimal material for such applications [2]. When left uncoated, copper electrodes are susceptible to rapid oxidation, which challenges their direct compatibility with a PEDOT coating. To address this limitation, we propose applying nickel-phosphorus and gold/nickel-phosphorus layers onto the copper electrodes (Au/Ni-P/Cu). This coating approach helps overcome the oxidation issue and enhances the compatibility between the electrodes and the PEDOT material [3]. Afterward, the process involves depositing PEDOT onto the surface of the electrodes. The primary goal is to develop cutting-edge biomedical electrodes that exhibit enhanced conductivity, minimized impedance, and improved mechanical adhesion to the underlying metal substrate. However, it has been observed that PEDOT does not adhere adequately to the metal substrates [4]. In this work the main strategy employed for enhancing adhesion is etching the substrate.

The Ni-P/Cu electrodes were prepared through electroless plating, and applied gold and PEDOT layers onto the Cu electrodes. The deposition of PEDOT onto the electrodes was achieved using galvanostatic chronopotentiometry (CP) electropolymerization, gradually transforming the electrodes into a dark blue colour. The chronoamperometric method yielded PEDOT films that were uniform and consistent across the electrodes. To analyze and characterize the PEDOT coatings on both Ni-P/Cu and Au/Ni-P/Cu electrodes, several techniques were employed, including electrochemical impedance spectroscopy (EIS) and cyclic voltammetry (CV) in a phosphate-buffered saline solution (PBS), X-ray photoelectron spectroscopy (XPS), and scanning electron microscopy (SEM). The adhesion of the coatings to the substrate was evaluated through sonication and a tape test, demonstrating their robustness and strong adherence. Furthermore, the electrochemical and mechanical stability of the PEDOT material, doped with LiClO<sub>4</sub>, on the metal electrodes was successfully demonstrated by optimizing the conditions of the electro-polymerization process and pre-treatments of the substrates.

**8:00 PM EL18.04.11**

**Advanced in Operando Atomic Force Microscopy Studies of the Gating Mechanisms at Metal Oxide Ion-Gated Transistors** Luan P. Camargo<sup>1,2</sup>, Lariele C. Neres<sup>1,3</sup>, Martin S. Barbosa<sup>4</sup>, Ramin Karimi<sup>1</sup>, Jose R. Herrera<sup>1</sup> and Clara Santato<sup>1</sup>; <sup>1</sup>Polytechnique Montreal, Canada; <sup>2</sup>State University of Londrina, Brazil; <sup>3</sup>State University of São Paulo (UNESP), Brazil; <sup>4</sup>Federal University of Goias, Brazil

Characterization of interfaces by advanced techniques *in operando*, including Atomic Force Microscopy (AFM), are gaining significance in the scientific investigation of electrochemical devices since they permit to follow materials' dynamics, which in turn are linked to device performance.

Ion-Gated Transistors (IGTs) enable the modulation of electronic conductivity in a semiconducting channel upon the application of an electrical bias between the channel material and the gate electrode, through an ionic medium. Metal oxides such as WO<sub>3</sub> and TiO<sub>2</sub> as channel materials interfaced with ionic liquids, such as 1-ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide ([EMIM][TFSI]), shows great promise for low-power, large-area electronics but also, at the fundamental level, the study insulator-to-metal transitions. The presence of Li<sup>+</sup> ions in the ionic liquid can enhance the versatility of IGTs in terms of the degree of doping and time response<sup>1,2</sup>.

The doping mechanisms establishing the effectiveness of the ion gating mechanism are not well understood. Gaining insight into the structure of the electric double layer (EDL) forming at the channel ionic medium interface is expected to advance such understanding.

We report on a nanoscale study at interfaces between WO<sub>3</sub> and TiO<sub>2</sub> films and ionic liquids, possibly including Li ions, by AFM, force-distance profiling. The aim of the study is to shed light on phenomena and processes such as ion layering, ion packing density and shrinking, and ion reorientations. Scanning probe studies have been paralleled by computational efforts (Molecular Dynamics, MD). AFM force-distance profiling in conjunction with simulation methods, allows the characterization and understanding of the structure of the EDL and its evolution with the applied bias, thus permitting optimizing device performance.

**8:00 PM EL18.04.12**

**Investigating Doping/Dedoping Processes in Electropolymerized Organic Mixed Ionic-Electronic Conductors** Meijing Wang<sup>1,2</sup>, Janine Mauzeroll<sup>2</sup> and Fabio Cicoira<sup>1</sup>; <sup>1</sup>Polytechnique Montréal, Canada; <sup>2</sup>McGill University, Canada

Organic electrochemical transistors (OECTs) based on organic mixed ionic-electronic conductors (OMIECs), which possess both electronic and ionic transport capabilities, have shown promising application potentials in bioelectronics. <sup>1</sup> OECTs utilize the reversible doping/dedoping properties of active OMIEC channel materials by applying a gate voltage across the electrolyte to modulate the channel conductance. <sup>2</sup> Although there has been extensive research to understand the working principle which involves mixed ionic and electronic transport, the study on the fundamental understanding of ionic transport and injection/ejection is still limited. For example, in one of the model OMIECs, poly(3,4-ethylenedioxythiophene) (PEDOT) doped with organic polyanions poly(styrenesulfonate) (PSS), the dedoping mechanism is believed to be mainly due to the insertion of cations from the electrolyte to the PEDOT:PSS film. However, when small anion-based dopants, such as ClO<sub>4</sub><sup>-</sup> and BF<sub>4</sub><sup>-</sup>, are used in the PEDOT system, the anions may be released from the material to the electrolyte. <sup>2</sup> The doping/dedoping mechanisms are therefore becoming more complicated. To better understand these doping/dedoping processes, we utilized an *in situ* film fabrication method, electropolymerization, to prepare PEDOT-based films with various dopants, such as PSS<sup>-</sup>, ClO<sub>4</sub><sup>-</sup> and BF<sub>4</sub><sup>-</sup>. This approach allows the material properties to be readily adjusted by controlling the dopant type, dopant concentration, and other electropolymerization parameters <sup>3</sup>. The polymer films were deposited on the source and drain electrodes and grow gradually to cover the gap in between. The effects of dopant type, concentration, and deposition time on the performance of OECTs were systematically studied. Next, the electrochemical quartz crystal microbalance (EQCM), which can monitor the mass exchange between the film and electrolyte, was incorporated to explore the doping/dedoping behavior. Our work contributes to a deeper understanding of the ionic charge transport in small anion-doped OMIECs and the working mechanism of corresponding OECTs.

**The Role of Alky Spacers and Functionality in Polar Carboxylated Functionalized Polythiophene for High-Performance Organic Electrochemical Transistors** Zeyuan Sun<sup>1</sup> and Brian Khau<sup>2</sup>; <sup>1</sup>Lehigh University, United States; <sup>2</sup>The University of Chicago, United States

Side chain engineering of polar hydrophilic substituents on the mixed conductor backbones has been proved as a successful strategy in developing robust bioelectronic devices, including organic electrochemical transistors (OECTs). However, prevailing design principles rely heavily on the ethylene glycol moiety, limiting the ability to tailor chemistry to serve the vast application space for OECTs. In this work, we report a family of carboxylic acid functionalized polythiophenes, poly [3-(4-carboxyalkyl) thiophene-2,5-diyl], processing with a varying carboxyalkyl chain lengths (propyl, butyl, and pentyl) as a novel hybrid alkyl-polar side chain moiety. With the aid of a fully aqueous processing strategy, this family of material provides an opportunity for a comprehensive evaluation of both the length effect of alkyl spacer and the impact of carboxylic acid functionality on the electrochemical characteristics in aqueous environment. Our results show that longer alkyl spacers in carboxylic acid functionalized side chain yield disadvantages for achieving higher volumetric capacitance (C<sup>\*</sup>), however, significantly reducing detrimental swelling, with P3C(Pe)T exhibiting a thickness change upon passive swelling of only +1.9%. By integrating these high-performance mixed conductors into planar OECT architectures, it has been found that polymer bearing with butyl spacer exhibits the highest performance ( = 128.6 5.5 ), which render them as one of the best performing conjugated polyelectrolytes. By integrating these high-performance mixed conductors into both interdigitated and planar OECT architectures, material dependent properties were evaluated, including device performance and stability as well as geometry dependent effects. Furthermore, *in-situ* Raman spectroscopy and spectroelectrochemistry studies are also conducted which provide meaningful insights into structural reorganization and optical progression upon electrochemical doping/de-doping, yielding a molecular level understanding toward ionic-electronic coupling and device operation upon varying side chain length. Overall, through these extensive and methodical investigations, we were able to uncover distinct properties associated with the increased alkyl length in these carboxylated polythiophenes. Our study highlights that even minor alterations and structural variation in the side chain can have a significant impact on electrochemical, optical, microstructural, and electrical properties of a polymeric mixed conductor.

**8:00 PM EL18.04.15**

**High-throughput microfluidic-assisted machine learning to investigate vertical phase separation of small molecule:polymer blend** Jun Hee Woo and Steve Park; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Solution-based thin-film processing has been deemed as a promising technology that enables the fabrication of various devices such as field-effect transistors (FETs), solar cells, and sensors in a cost-efficient, facile, and scalable manner. One key feature of solution-based processing is the tunability of the ink formulation, through which the thin-film coating process and device performance can be controlled. Also, blending solutions containing different solutes has been shown to significantly improve the performance of the resulting devices compared to that of their unmixed counterparts. When small molecule organic semiconductor is mixed with insulating polymer, bilayer structure can be formed by the induction of vertical phase separation during drying process, which yields drastically improved charge transport properties, and hence the transistor performance. Despite the advantage of having controllability of ink formation, there also exists the critical challenge of finding the ideal ink composition that yields optimum device performance amongst numerous possible compositions. To generate a thin-film large enough to conduct device testing, several to hundreds of microliters of solution is required. However, since precisely controlling the ink formulation at this volume is difficult, several milliliters of solution is typically prepared. Therefore, ink formula optimization is inevitably a highly time-consuming and resource-intensive process. Added on top of this issue is the fact that the coating process parameters (e.g., substrate temperature, coating speed) also changes the thin-film properties and therefore the device performance, resulting in orders of magnitude increase in the number of possible combinations of experimental parameters (e.g., different combinations of ink composition, substrate temperature, coating speed) that need to be tested. The sheer number of combinations renders it impractical to test all combinations. Hence, researchers typically resort to iterative experiments based on intuition and heuristic approach, which limits or prolongs the optimization process and results in poor understanding of process-performance correlations. Resolving this challenge involves addressing two important questions. Firstly, how can thin-films of varying combinations of experimental parameters (i.e., various experimental conditions, where condition refers to a set of specific values of parameters under which thin-film was formed) be made in a time-efficient and resource-efficient manner so that data can be collected rapidly and economically? Secondly, how can the correlation between experimental parameters and device performance be systematically analyzed without reliance on human intuition? In this work, microfluidic screening-embedded thin-film processing technique is developed, through which thin-films of varying ratios of small molecule semiconductor:polymer blend were simultaneously generated and screened in a time- and resource-efficient manner. The vertical phase separation of C8-BTBT and PS blend solution was demonstrated, and was shown to have relatively high transistor performance, owing to the high intrinsic mobility of C8-BTBT and high viscosity of PS-added solution. Moreover, utilizing the thin-films of varying combinations of experimental parameters,

machine learning models were trained to predict the transistor performance. Gaussian Process Regression (GPR) algorithms tuned by Bayesian optimization showed the best predictive accuracy amongst the trained models, which enables narrowing down of the combinations of experimental parameters and investigation of the degree of vertical phase separation under the predicted parameter space. Our technique can serve as a guideline for elucidating the underlying complex parameter-property-performance correlations in solution-based thin-film processing, thereby accelerating the optimization of various thin-film devices in the future.

**Vertical-Structure Improves The Strain Limit of OMIEC-Transistors** Shilei Dai, Zhongrui Wang and Shiming Zhang; The University of Hong Kong, Hong Kong

Organic mixed ionic-electronic conductors (OMIECs), also known as organic mixed conductors, such as PEDOT:PSS, are becoming increasingly important materials in various applications. One typical application is the development of organic electrochemical transistors (OECTs), which enable high sensitivity at low power consumption. PEDOT:PSS OECTs find significant applications in diverse fields, including brain-machine interfaces and ubiquitous wearable biosensing.

To enhance the robustness for skin-integrated applications, stretchable OECTs (sOECTs) have been developed [1]. However, most sOECTs require OMIECs films to possess good mechanical properties, which limit their use in this emerging area.

In this study, we introduce the design of vertical sOECTs [2]. The unique vertically sandwiched structure between the source, OMIEC channel, and drain electrodes enables significantly higher stretchability, surpassing the strain limit of OMIECs. sOECTs developed with this design can be stretched in arbitrary directions, making them suitable for a wide range of skin-interfaced bioelectronic applications.

**Dual Gate Electrochemical and Transistors and Inverters based on WO<sub>3</sub> for Improved Transconductance and Dynamic Response** Luis Pereira<sup>1,2</sup>; <sup>1</sup>FCT NOVA, Portugal; <sup>2</sup>AlmaScience, Portugal

Electrolyte-gated transistors (EGTs) and electrochemical transistors (ECTs) have received special attention over the last decade due to their advantages, deriving from using electrolytes as gate dielectrics. These include low operating voltages, printability and solution processability, low contact resistances, and the possibility of fabricating new device architectures. High driving currents due to electric double layer (EDL) capacitance (C<sub>DL</sub>) in EDL transistors (EDLTs) or 3D-channel formation in ECTs, complement the list and open routes for their application in biosensors, electrochemical logic gates, wearable electronics, or low-power consumption and flexible devices..

This work shows a novel architecture of ECTs based on the electrochromic material WO<sub>3</sub>. Introducing a fourth electrode behind the channel (Back-electrode -BE) stabilized drain current, as electrons can be channeled into the active layer for electrochemical reactions. Additionally, control over the ion movement in the channel and the electrolyte and, consequently over the occurring redox reactions is possible. As a consequence thereof, it was found that V<sub>on</sub> can be controllable through the applied voltage at the BE (V<sub>BE</sub>) and that V<sub>on</sub> can be shifted from any negative V<sub>G</sub> up to 0 V and possibly beyond. The devices can be 'programmed' to work in normally-off (enhancement) or normally-on (depletion) mode. On-Off ratios of 10<sup>5</sup> and transconductances of 0.35 mS were achieved. Dynamic characterization with an asymmetric square (V<sub>G</sub> between -6 and 4 V) wave potential demonstrated On-Off ratios of 4 orders of magnitude for frequencies up to 1 Hz. Data suggests that the cut-off frequency lies way beyond that value. It was demonstrated that with precise control over V<sub>on</sub>, electrochemical logic inverters with two identical devices are feasible, presenting very high and controllable gains. The possibility of keeping load and driver transistors respectively at normally-on and normally-off makes transistor sizing redundant. Further, with this transistor architecture, problems like small logic swings or small noise margins, usually related to enhancement-load inverters, can be counteracted.

**Unraveling The Critical Hydration Effect on Size-Dependent and Ion-Specific Ion Pairing Inside Sub-1nm Graphene Nanoslits** Fan Feng, Zhe Liu and Dan Li; The University of Melbourne, Australia

The intriguing phenomena of ion pairing and salt aggregation inside two-dimensional nanoslits have recently been reported in experiments and numerical simulations, leading to the anomalous gate-voltage modulated ion transport and memoresistive properties. An in-depth grasp of the intricate mechanisms governing this ion pairing effect is imperative for engineering advanced materials with specific functionalities and heightened performance. Nevertheless, despite extensive investigations into the dielectric properties of confined water and its confining medium, a unified understanding of how ion-pairing effects are governed by the interplay of hydration effect and nanoconfinement has remained elusive.

This study delves into the ion pairing effect within sub-1nm graphene nanoslits and offers a novel insight into the mechanisms driven by hydration effects. Conducting atomic-level molecular dynamics (MD) simulations of alkali ion electrolytes within multilayered graphene membranes, we unveil a nuanced dependence on slit size and ion-specific behaviors influencing the ion pairing phenomenon, which are confirmed in our experiments. Furthermore, we conclude that the complicated dehydration and renormalization processes primarily determine the propensity for nanoconfined ion-pairing effects, by displaying a comprehensive analysis of the structural and energetic characteristics of water molecules within the hydration shells. We validate this mechanism by elucidating both slit-size and ion-specific effects: as the slit size decreases from 1nm to 7 Å, the structure of the hydration shell becomes increasingly ordered, resulting in a corresponding reduction in entropic free energy; on the other hand, the ion-specific effect is driven by distinct enthalpic changes associated with the formation of larger ion clusters, rather than the mere presence of individual ion pairs.

**Ultrafast Dynamics of n-Type Organic Mixed Ionic-Electronic Conductors for Photoelectrochemical Transistor Applications** Christopher E. Petoukhoff<sup>1</sup>, Victor Druet<sup>1</sup>, Latifah Almullah<sup>1</sup>, Nisreen Alshehri<sup>1</sup>, Catherine De Castro<sup>1</sup>, Sophie Griggs<sup>2</sup>, Maryam Alsufyani<sup>2</sup>, Iain McCulloch<sup>2</sup>, Sahika Inal<sup>1</sup> and Frederic Laquai<sup>1</sup>; <sup>1</sup>King Abdullah University of Science & Technology (KAUST), Saudi Arabia; <sup>2</sup>University of Oxford, United Kingdom

Conjugated polymer-based organic mixed ionic-electronic conductors (OMIECs) have been widely employed as the active materials in the channel of organic electrochemical transistor (OECT) devices, which are ideal for electronic devices in aqueous media. Due to their ease of chemical functionalization, tunable softness, and flexibility, polymer OMIECs are uniquely suited for biological applications, where OECT devices are expected to play a major role. Although the photosensitivity of conjugated polymers has been widely studied and applied for solar cells, photodetectors, and photocatalysts, the light-sensitivity of polymer OMIECs has been largely underexplored in OECT devices. While there have been several reports on light-sensitivity of organic photoelectrochemical transistors (OPECTs) employing OMIECs, these have largely relied on incorporation of additional light-

sensitive inorganic materials at the gate terminal. Very recently, we have demonstrated that a single *n*-type OMIEC can serve as the photoactive material in OPECT devices, without additional materials in the gate terminal [1]. We then demonstrated for a variety of different *n*-type OMIEC polymers that the intrinsic photosensitivity of the polymer is critically important for achieving large open circuit potentials, which must be balanced against the transconductance for the best performance of OPECT devices [2].

In this breaking news contribution, we discuss the origin of the photosensitivity of five different OMIECs. We combine doping-induced absorption (DIA), femtosecond transient absorption (TA), time-resolved photoluminescence (TRPL), and time-resolved THz (TRTS) spectroscopies to investigate the excited state dynamics. We compare the photoexcited species in dry, intrinsic OMIEC films and demonstrate that the instantaneous formation of intramolecular charge transfer (ICT) excitons is largely responsible for facilitating charge dissociation at interfaces, such as either at the ITO or electrolyte interface. We demonstrate that the exciton lifetime plays a critical role in determining the open-circuit potential of photoelectrochemical cells. However, the responsivity of OPECT devices is balanced by the dark transconductance, which is orders of magnitude larger for self-doped polymers, having conductivities on the order of 190 ohms-per-cm. Finally, we show that the exciton-to-charge conversion process is faster when the OMIEC is immersed in electrolytic solutions, which we attribute to the increased dielectric constant of the medium.

**Navigating The Complex Hole-Transport Material Additive Cocktail: Doping Methodologies for Small-Molecule HTMs** Benjamin Vella, Madeleine McRoberts, Graeme Cooke and Pablo Docampo; University of Glasgow, United Kingdom

Most organic molecular hole transporters used in perovskite solar cells require effective doping to reach conductivity values necessary to achieve maximum device efficiencies. This is typically achieved by incorporating a cocktail of additives including tert-butylpyridine, ionic salts (LiTFSI, Zn(TFSI)<sub>2</sub>) and metal complexes (FK209) which results in the partial oxidation of the semiconducting material, introducing additional free holes within the HTL and thus providing effective hole transport. However, a detailed study of the relationship between doping level and the quantity of free holes within the matrix has not been carried out. Indiscriminately adding the same additive cocktail to different HTM systems can lead to sub-optimal doping and an excess of reactive substances within the film that can catalyse degradation mechanisms. In this study, we investigate a range of HTMs possessing amide or imine linker groups. Our research highlights that oxidation and doping are not synonymous, and while oxidation generally leads to doping, this is not always the case. In addition, we reveal the intricate relationship between the different additives and the doping mechanism as a function of the chemical structures used. We conclude that a 'one size fits all' approach to HTM doping can lead to the misdiagnosis of effectively oxidised molecules, and therefore propose spectroscopic techniques to monitor the efficacy of doping, promoting rational HTM design and expediting the characterisation of new HTMs.

#### 8:00 PM EL18.04.21

**Regioregularity Effects on Mixed Conduction in a Glycolated Polythiophene** Dilara Meli<sup>1</sup>, Ella Kelly<sup>2</sup>, Joshua Tropp<sup>1,3</sup>, Ruiheng Wu<sup>1</sup> and Jonathan Rivnay<sup>1,1</sup>; <sup>1</sup>Northwestern University, United States; <sup>2</sup>Kalamazoo College, United States; <sup>3</sup>Texas Tech University, United States

Organic mixed ionic/electronic conductors (OMIECs) are a versatile class of materials that have found use in a wide variety of applications, from bioelectronics to neuromorphic computing. Much effort has been devoted in recent years to improve OMIEC performance, primarily focusing on systematic side chain and backbone engineering. Usually, novel OMIECs are characterized in organic electrochemical transistor (OECT) test beds from which the figure of merit,  $\mu C^*$  (mobility  $\times$  volumetric capacitance), is extracted.  $\mu C^*$  is an attractive metric for comparison, as it scales with device dimensions. However, care must be taken to emphasize that  $\mu C^*$  is not only dependent on synthetic chemistry, but also processing conditions and operating electrolyte environments.

Most prominent high-performing OMIECs synthesized to date are only available at the lab scale, leading to large batch-to-batch variability. Such issues of replicability further hinder systematic structure-property studies. To this extent, we herein study a commercially available glycolated polythiophene OMIEC, P3MEEET. Previous work on this polymer has revealed strong dependence of  $\mu C^*$  on operating electrolyte environment, an effect found to also be molecular weight dependent. It was shown that doping occurred with cation expulsion in KTFSI electrolytes, but via traditional anion uptake in NaCl electrolyte. This had dramatic impacts on charge percolation, which ultimately resulted in large observed differences in mixed conductivity.

To further probe the interplay between microstructure and electrolyte choice, we study regiorandom (RRa) and regioregular (RR) P3MEEET operated in two model electrolytes, aqueous KCl and KTFSI. Surprisingly, we observe little difference in  $\mu C^*$  for as-cast microstructures between the RRa and RR polymers. GIWAXS of as-cast RRa films reveals strong lamellar diffraction and DSC shows distinct side-chain melting. RRa P3MEEET is found to preferentially order edge-on, while the RR polymer shows more distinct face-on scattering. We further conduct electrochemical quartz crystal microbalance (EQCM) measurements to probe doping kinetics in both polymers.

Studies of post-processing treatments on other RR glycolated polythiophenes, in particular annealing, have previously been shown to dramatically affect swelling and thus mixed conduction. Here, we find strong dependence of  $\mu C^*$  on structural changes when operated in KCl electrolytes, whereas in KTFSI electrolytes  $\mu C^*$  appears relatively unchanged given the same post-processing conditions. In particular, annealed RRa polymers in KCl show improved performance, whereas RR polymers exhibit a decrease in  $\mu C^*$ . For the RRa polymer, this enhancement is primarily driven by an increase in  $C^*$  due to annealing, which is in contrast to the RR polymer which experiences a decrease in  $C^*$ .

In summary, we find that post-processing tunes mixed conductivity differently given differences in polymer regioregularity. However, these effects are also dependent on electrolyte environments, further emphasizing that  $\mu C^*$  must be treated as a system figure of merit.

SESSION EL18.05: Characterizing Mixed Ionic-Electronic Conductors

**Magnetic Resonance Studies of Highly Doped Polymeric Semiconductors** Tarig Mustafa, Dionisius Hardjo Lukito Tjhe, Ian Jacobs, Xinglong Ren, Yao Fu, Clare P. Grey and Henning Sirringhaus; University of Cambridge, United Kingdom

Doped organic semiconductors have proved attractive for future device applications such as thermoelectrics, bioelectronics and spintronics. At low doping levels, coulombic trapping of intercalated counter ions is believed to limit charge transport while at high doping levels conductivity is limited by disorder in the material.<sup>1</sup> However, a more detailed understanding of the couplings between the charge/spin carrying polarons of these materials and their environment remains sought after. Work has been done to understand such interactions in undoped materials by means of field induced Electron Spin Resonance (ESR) and has yielded valuable insight into the intimate couplings between charge, spin and structural dynamics.<sup>2</sup> Here, we extend that work to the study of systems systematically doped in-situ by means of an electrochemical transistor architecture and investigate the effects of interactions between polarons and with the counterions as function of temperature and varying doping levels. We complement the ESR measurements with Nuclear Magnetic Resonance (NMR) characterisation which has been shown to be a powerful technique for characterising ion dynamics in polymeric semiconductors.<sup>3</sup> We therefore use NMR to understand ionic motion and interactions in these systems and explore how they could impact the electronic properties of the material.

**Mixed Electron-Ion-Solvent Transfer in Conjugated Polymers Monitored using Quartz Crystal Microbalance with Dissipation Monitoring** Ratul Thakur and Jodie Lutkenhaus; Texas A&M University, United States

Conjugated polymers have promising applications in electronics and energy storage due to the polymer's tunable conductivity and redox activity. For example, the conductivity of poly(3-hexylthiophene) (P3HT) is heavily dependent upon the doping level and the dopant type. This feature becomes especially important when considering P3HT or similar conjugated polymers for devices that require switching between electronic states (conductive vs insulating). In this study, the mechanism of mixed ion-electron transfer studied using electrochemical quartz crystal microbalance with dissipation monitoring (EQCM-D) is discussed for P3HT and poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS). During cyclic voltammetry and galvanostatic charge-discharge experiments, the mass change of the polymer film is monitored in real time. Distinct mass transfer regions are quantified as a function of doping level and potential, which are then correlated to changes with *in situ* conductance and spectroelectrochemical response. To identify the time scale at which the doping reaction transitions from kinetic to diffusion control, electrochemical impedance spectroscopy is coupled with EQCM-D. Combining these insights with an electron and mass balance on the process, the number of solvent molecules per ion are estimated. This work gives valuable insight into the nature of mixed ion-electron transfer, including its time scale, as it relates to the electronic properties of conjugated polymers.

**Ion Trapping and Induced Ordering of Regiorandom Poly(3-hexylthiophene) upon Repeated Electrochemical Doping** Seth Jackson, Rand Kingsford, Garrett Collins and Connor G. Bischak; University of Utah, United States

Conjugated polymer organic mixed ionic electronic conductors (OMIECs) are promising materials for bioelectronics and other organic electronic devices. How these materials behave with repeated electrochemical doping matters for the stability and longevity of these devices. In this work, we employ a combination of grazing incidence wide-angle X-ray scattering (GIWAXS), UV-vis spectroelectrochemistry, and nanoscale imaging of the ions with photoinduced force microscopy (PiFM) to monitor film morphology changes in regiorandom poly(3-hexylthiophene) (RRa P3HT) when exposing the polymer film to various aqueous electrolytes upon repeated electrochemical doping. When using potassium bis(trifluoromethanesulfonyl)imide (KTFSI) as our electrolyte, we see increased ion trapping and an increase in crystalline order in RRa P3HT, as well as the crystallization of TFSI<sup>-</sup> ions, upon repeated electrochemical doping. Upon thermal annealing at 120 °C after continuous doping of RRa P3HT with TFSI<sup>-</sup>, we see a significant increase in lamellar stacking intensity compared to the film without thermal annealing. When comparing less chaotropic ions to TFSI<sup>-</sup>, we see these ions do not order RRa P3HT to the same extent as TFSI<sup>-</sup>. Overall, this study shows that both ion trapping and structural reorganizations occur in disordered conjugated polymers upon repeated electrochemical cycling.

**Improvement of the Electrical, Mechanical and Adhesive Properties of PEDOT:PSS** Jianyong Ouyang; National University of Singapore, Singapore

Poly(3,4-ethylenedioxythiophene):Polystyrene sulfonate (PEDOT:PSS) is a popular mixed ion-electron conductor, and it can have important application many areas. However, its electrical, mechanical and adhesive properties must be greatly improved for the practical application in some areas. Here, I will present some of our methods to significantly improve the electrical, mechanical and adhesive properties. We also demonstrate their application in wearable/flexible electronics.

**11:00 AM EL18.06.02**

**Tailored Design of Mixed Ionic-Electronic Conductors for both P-Type and N-Type OECTS** [Mukundan Thelakkat](#)<sup>1,2</sup>, Adrian Hochgesang<sup>1</sup>, Andreas Erhardt<sup>1</sup>, Gert Krauss<sup>1</sup>, Florian Meichsner<sup>1</sup> and Philip Schmode<sup>1</sup>; <sup>1</sup>University of Bayreuth, Germany; <sup>2</sup>Bavarian Polymer Institute, Germany

Mixed ionic electronic conductors (MIECs) were designed by various strategies of polymer architecture. For all materials, Cyclic voltammetry (CV), spectroelectrochemistry (SEC), ultraviolet photoelectron spectroscopy (UPS), Ultraviolet-Visible (UV-Vis) absorption spectroscopy, and organic field effect transistor (OFET) characterization were carried out and these properties demonstrate the suitability for OECT (organic electrochemical transistor) devices.

For p-type OECTs, conjugated polyelectrolytes and their copolymers based on polythiophene family was first designed and studied [1-2]. The concept was extended to hydrophilic polythiophenes carrying different oligoethylene glycol (OEG) substituents [3]. The advantage of the latter class is that no crosslinking is necessary to prevent the thin films from delamination. The concept of OEG substitution and the required degree of OEG substitution was further applied in the class of poly(diketopyrrolopyrrole) copolymers using different comonomers [4]. For this, four Polydiketopyrrolopyrroles (PDPPs) with increasing ethylene glycol (EG) content and varying nature of comonomer were synthesized. The studies of these hydrophilic PDPPs in NaCl electrolyte-gated OECTs reveal that a high amount of OEG on the DPP moiety is essential for MIEC. The PDPP containing 52 wt.% EG exhibits a high volumetric capacitance of 338 F cm<sup>-3</sup> (at 0.8 V), a high hole mobility in aqueous medium (0.13 cm<sup>2</sup>V<sup>-1</sup>s<sup>-1</sup>) and a  $\mu C^*$  product of 45 F cm<sup>-1</sup>V<sup>-1</sup>s<sup>-1</sup>. OECTs using this polymer retained 97 % of its initial drain-current after 1200 cycles (90 min of continuous operation). In cell-growth medium, the OECT-performance was fully maintained as in NaCl electrolyte. In vitro cytotoxicity and cell viability assays reveal the excellent cell compatibility of these novel systems, showing no toxicity after 24 h of culture. Due to the excellent OECT performance with a considerable cycling stability for 1200 cycles and an outstanding cell compatibility, these PDPPs render themselves viable for in vitro and in vivo bioelectronics.

For the n-type OECTs, two different classical acceptor motifs diketopyrrolopyrrole (DPP) and thienopyrrolodione (TPD) are copolymerized to yield the acceptor-acceptor polymer, Poly(DPP-TPD) [5]. The fundamental design idea is to maximize the electron affinity, thus increasing the ambient stability of the reduced state against oxygen and water while ensuring high ion compatibility through the incorporation of hydrophilic oligoethylene glycol N-substituents. Additionally, a highly planarized polymer structure is anticipated, due to the extended non-covalent interactions (conformational locking) between the carbonyl oxygen and the thiophene protons. The acceptor-acceptor system poly(DPP-TPD) for n-type devices exhibit high electron affinity (EA), and good electron mobility ( $\mu_{e(OFET)}$ ), in addition to the electrochemical reduction of polymer films in aq. electrolyte. In n-type OECTs, poly(DPP-TPD) demonstrates a moderate threshold voltage of  $V_{th} = 0.58$  V, and an outstanding  $\mu C^*$  value of 7.62 F cm<sup>-1</sup> V<sup>-1</sup> s<sup>-1</sup>. Cycling studies consisting of pulsed on- and off-switching of the device at gate voltages between  $V_g = 0.6 - 0.8$  V in the saturation regime reveal high stability for more than 2700 cycles with rapid switching kinetics.

**11:15 AM EL18.06.03**

**Mechanically Adaptive Mixed Ionic-Electronic Conductors Based on a Polar Polythiophene Reinforced with Cellulose Nanofibrils** [Youngseok Kim](#)<sup>1</sup>, Mariza Mone<sup>1,2</sup>, Sozan Darabi<sup>1,2</sup>, Sepideh Zokaei<sup>1</sup>, Lovisa Karlsson<sup>1</sup>, Mariavittoria Craighero<sup>1</sup>, Simone Fabiano<sup>3,4</sup>, Renee Kroon<sup>3,4</sup> and Christian Müller<sup>1,2</sup>; <sup>1</sup>Chalmers University of Technology, Sweden; <sup>2</sup>Wallenberg Wood Science Center, Chalmers University of Technology, Sweden; <sup>3</sup>Linköping University, Sweden; <sup>4</sup>Wallenberg Wood Science Center, Linköping University, Sweden

Conjugated polymers with oligoether side chains are considered as one of the promising active materials for organic electrochemical devices due to their ability to facilitate mixed ionic-electronic conduction in the electrolyte. However, they tend to have a low glass transition temperature and, consequently, a low elastic modulus, which prevent their use if mechanical robust materials are required. Carboxymethylated cellulose nanofibrils (CNF) are found to be a suitable reinforcing agent for a soft polythiophene with tetraethylene glycol side chains. Dry nanocomposites feature a Young's modulus of more than 400 MPa, which reversibly decreases to 10 MPa or less upon passive swelling through water uptake. The presence of CNF results in a slight decrease in electronic mobility but enhances the ionic mobility and volumetric capacitance, with the latter increasing from 164 to 197 F cm<sup>-3</sup> upon the addition of 20 vol% CNF. Overall, organic electrochemical transistors (OECTs) feature a higher switching speed and a transconductance that is independent of the CNF content up to at least 20 vol% CNF. Hence, CNF reinforced conjugated polymers with oligoether side chains facilitate the design of mechanically adaptive mixed ionic-electronic conductors for wearable electronics and bioelectronics.

**11:30 AM EL18.06.04**

**Engineering Response Time and Synaptic Behavior of Organic Ion-Gated Transistors Through Structural Modifications** Ramin Karimi<sup>1</sup>, [Zhaojing Gao](#)<sup>1</sup>, Afzal-Ahmed Dar<sup>1</sup>, Lariel C. Neres<sup>1,2</sup>, Patrick Dang<sup>1</sup> and Clara Santato<sup>1</sup>; <sup>1</sup>Polytechnique Montreal, Canada; <sup>2</sup>State University of São Paulo (UNESP), Brazil

The von Neumann architecture was designed for processing tasks serially. The amount of data produced in the present *intelligent* era renders this architecture unable to keep up. As a result, new solutions, such as neuromorphic parallel computing, are being developed to increase data storage and processing speed. There are concerns, however, about the sizes of the chips composed of synaptic transistors and their parallel computing capacity. In this work, we present the effect of poly (3-hexylthiophene) (P3HT) film thickness on the synaptic behavior and response time of ion-gated transistors (IGTs) based thereon. The P3HT films' thickness varies from 50 to 300 nm. The drain-source current,  $I_{ds}$ , and charge carrier mobility increase with thickness, likely due to an increased degree of crystallinity in the films with the thickness. The presence of crystalline domains is expected to increase the de-doping time (time to remove the anions from the p-type P3HT channel). In turn, this increases the transistor response time and permits to achieve transition from short-term plasticity (STP) to long-term plasticity (LTP). Further, increasing the thickness of the channel increases the plasticity and paired-pulse facilitation (PPF) index.

The molecular weight (MW) is another parameter that we consider to control synaptic functions and response time. The XRD patterns of films obtained from three different MW, low (ca. 24 kDa), intermediate (ca. 42 kDa), and high (ca. 91 kDa), show that the degree of crystallinity decreases with increasing MW. This is expected to strongly affect ion permeability, and therefore the advancement of doping and redistribution time of anions. In conclusion, we propose a methodology to control the response time and synaptic functions of IGTs with changing P3HT MW at constant film thickness or varying the thickness of channel fixing MW.

**11:45 AM EL18.06.05**

**Surface Functionalization for High-Performance and Water-Stable PEDOT:PSS Thin Films for Bioelectronics** [Peter O. Osazuwa](#), Abigail Nolin, Chun-Yuan Lo, Xu Feng, Charles Dhong and Laure V. Kayser; University of Delaware, United States

Organic mixed ionic-electronic conductors such as poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) have attracted attention as materials for the fabrication of organic electrochemical transistors (OECTs) for bioelectronics. The PEDOT:PSS dispersions are typically blended with (3-glycidyloxypropyl)trimethoxysilane (GOPS) before spin-coating to ensure strong adhesion of the films to device substrates and maintain their long-term stability in aqueous solutions. However, blending with GOPS changes the morphology of PEDOT:PSS films, affecting their electrical properties and significantly reducing the performance of OECTs. Here, we functionalized the surface of the substrates with GOPS to introduce a silane monolayer with epoxy groups before spin-coating PEDOT:PSS. The resulting films were compared to those obtained by blending and showed similar long-term stability in aqueous solutions under passive conditions and electrochemical cycling. However, the surface functionalization approach led to increased electronic conductivity ( $2650 \pm 467 \text{ S cm}^{-1}$ ), higher transconductance ( $24 \pm 4 \text{ mS } \mu\text{m}^{-1}$ ), and  $[\mu C^*]$  value ( $376 \pm 74 \text{ F cm}^{-1} \text{ V}^{-1} \text{ s}^{-1}$ ) in OECT devices, and larger volumetric capacitance ( $109 \pm 5 \text{ F cm}^{-3}$ ). Detailed characterization using time of flight secondary ion mass spectrometry (TOF-SIMS), atomic force microscopy (AFM), and X-ray photoelectron spectroscopy (XPS) confirmed that the silane crosslinker was not present in the bulk of the film which allowed an increased phase separation between PEDOT and PSS, and the formation of enlarged PEDOT-rich domains. We expect that this study will strengthen the case for the functionalization of substrates with GOPS instead of the conventional blending approach for the development of stable films in water and high-performance organic mixed ionic-electronic conductors for biological interfaces.

SESSION EL18.07: Theory and Simulations for Mixed Ionic-Electronic Conductors

Session Chairs: Laure Kayser and Micaela Matta

Tuesday Afternoon, November 28, 2023

Hynes, Level 1, Room 111

1:30 PM EL18.07.01

**Operando Experiments and Continuum Modeling of Mechanical Breathing and Multiphysics Coupling in Organic Mixed Ionic-Electronic Conductors** [Kejie Zhao](#); Purdue University, United States

Organic mixed ionic-electronic conductors (OMIECs) are the core functioning component in electrochemical devices such as organic electrochemical transistors (OECTs) and bioelectronics owing to their unique capability of mixed conduction. In electrochromic polymers, the cyclic redox reaction is associated with a mechanical breathing strain, which deforms the OMIECs and degrades the device reliability. We measure the breathing strain, the evolution of the mechanical properties of electrochromic thin films, and mechanical damage using customized environmental nanoindentation. Further, we formulate a continuum theory following the thermodynamics framework to describe the concurrent transport of charge carriers, mechanical swelling, and phase separation in the OMIEC. The free energy consists of contributions from the deformation of the polymer chains, the mixing of the polymer with salts and solvents, the electrostatic field, and the two-phase interfaces. We implement the theory into a finite element model and study the mechanics and electrochemistry of the OMIEC channel in an electrolyte-gated OECT. The computational model replicates the electrochemical performance of an OECT which agrees well with the experiments. Overall, this work provides a basic understanding of electrochemical and mechanical behaviors of organic mixed conductors.

1:45 PM EL18.07.02

**Modelling the Performance of a Novel Mixed Ionic-Electronic Conductor Based on  $\text{SmCoO}_3$**  [Nora H. de Leeuw](#); University of Leeds, United Kingdom

One of the main challenges facing solid oxide fuel cell (SOFC) technology is the need to develop materials capable of functioning at intermediate temperatures (500-800°C), thereby reducing the costs associated with SOFCs. Here, a novel SOFC cathode material is presented, predicted through a holistic approach of a combination of complementary computational techniques to optimise the material properties. This approach is transferrable to any material optimisation problem and allows the effect of A/B-site doping to be understood, on the scale of the individual property, but also the device as a whole. The electronic, magnetic, and physical properties as well as the thermal behaviour of  $\text{Sm}_{0.75}\text{A}_{0.25}\text{Co}_{1-x}\text{Mn}_x\text{O}_{2.88}$  (A = Ca, Sr; x = 0.125, 0.25) is systematically described, showing important trends and correlations that are directly coupled to its potential practical application in sustainable energy generation. The magnetic and electronic structures of these materials were directly coupled to the electronic conductivity, a finding that is applicable to other perovskite systems and to the wider energy materials community. Furthermore, evaluating the ionic conductivities of  $\text{Sm}_{0.75}\text{A}_{0.25}\text{Co}_{1-x}\text{Mn}_x\text{O}_{2.88}$  (A = Ca, Sr; x = 0.125, 0.25), a distinct improvement is identified in comparison to both  $\text{SmCoO}_3$  and the traditional cathode material strontium-doped lanthanum manganate. By coupling the electronic and ionic conductivity properties to the thermal expansion coefficients, we have shown that this material is compatible with traditional SOFC electrolytes. Combining all these insights from density functional theory calculations and molecular dynamics simulations strongly suggests that  $\text{Sm}_{0.75}\text{A}_{0.25}\text{Mn}_{0.25}\text{Co}_{0.75}\text{O}_{2.88}$  possesses the necessary properties that are desirable in an efficient intermediate temperature SOFC cathode material.

**Proton and Small Polaron Association and Migration in  $\text{H}_x\text{V}_2\text{O}_5$ ,  $\text{H}_x\text{Ta}_2\text{O}_5$ ,  $\text{H}_x\text{MoO}_3$ ,  $\text{H}_x\text{WO}_3$**  [Pjotr Zguns](#) and Bilge Yildiz; Massachusetts Institute of Technology, United States

Neuromorphic computing based on electrochemical random access memory (ECRAM) enables low-energy computing and nanosecond timescale operation [1–3]. The nanosecond switching relies on fast proton and small polaron diffusion in the working channel materials, transition metal oxides. Here we investigate the fundamental limit of mixed proton–polaron diffusion in  $\text{H}_x\text{V}_2\text{O}_5$ ,  $\text{H}_x\text{Ta}_2\text{O}_5$ ,  $\text{H}_x\text{MoO}_3$ , and  $\text{H}_x\text{WO}_3$  by means of first-principles calculations. We apply the DFT+*U* method to describe the electronic structure and polaron localization in the host oxide lattice. By investigating various spatial arrangements of these defects, we identify the ground state configuration of the proton–polaron. We probe microscopic factors that control carrier mobility, *viz.* the migration barriers and proton–polaron association energy (*i.e.*, the energy required to break the pair). Our results indicate that the polaron migration barrier is comparable to the association energy (in  $\text{V}_2\text{O}_5$ , on the order of 0.1 eV–0.2 eV), highlighting that the attraction between polarons and protons plays an important role in diffusion. Altogether, these computations will help us to identify the most suitable oxide for nanosecond switching of ECRAM devices.

**Influence of Chemical Structure on Properties of Mixed Conducting Conjugated Polymer Electrodes** Jenny Nelson<sup>1</sup>, Nicholas D. Siemons<sup>1</sup>, Hang Yu<sup>1</sup>, Iona Anderson<sup>1</sup>, Sachetan Tuladhar<sup>1</sup> and Alexander Giovannitti<sup>2</sup>; <sup>1</sup>Imperial College London, United Kingdom; <sup>2</sup>Chalmers University, Sweden

Organic mixed electronic and ionic conductors based on conjugated polymers with polar side chains are attractive candidates for electrodes in electrochemical devices. Their electrochemical and redox properties can be tuned through choice of polymer backbone and side chain [1, 2] while the processible nature of the polymer materials facilitates both manufacture and recycling. When applied as electrodes in electrochemical energy storage devices, conjugated polymer electrodes show excellent charging and discharging rates, high coulometric efficiency and compatibility with simple aqueous electrolytes. However, their specific capacity and their operational stability need to be improved [3]. In this work, we use electrochemical measurements and modelling to investigate the relationship between polymer chemical structure and the redox properties, charging behaviour and cycling stability of the polymer electrodes. We focus on the effect of side chains, since small changes in side-chain composition or structure can significantly influence the electrode properties. We use molecular dynamics simulations for series of polymers, to investigate how the side chain polarity influences polymer packing [4]; how the composition of mixed polar and non-polar side chains influences film swelling and stability; how backbone and side-chain structure influence electronic transport properties; and how polymer-ion interactions depend on the ion type. Finally, we consider design strategies for enhancing specific capacity. The findings can help to develop chemical designs for improved conjugated polymer electrodes for aqueous environments.

**In-Plane Orientation of Organic Mixed Ionic-Electronic Conductors to Enhance Charge Transport Properties** Isabelle Holzer<sup>1</sup>, Demetra Tsokkou<sup>1</sup>, Shubhradip Guchait<sup>2</sup>, Badr Jismy<sup>2</sup>, Martin Brinkmann<sup>2</sup>, Nicolas Leclerc<sup>2</sup> and Natalie Banerji<sup>1</sup>; <sup>1</sup>University of Bern, Switzerland; <sup>2</sup>CNRS University of Strasbourg, France

Organic mixed ionic-electronic conductors (OMIECs) are perfectly suited to interface biology and electronic devices as they enable both ionic and electronic transport; feature mechanical flexibility; can be successfully fabricated in versatile processing conditions; and are synthetically tunable.<sup>1</sup> While most recent progress in bioelectronics has been focused on device fabrication and comparing performance of different materials, there is still a lack of a more in-depth understanding of the fundamental processes occurring in functioning OMIECs.<sup>2</sup> The charge transport is happening mainly on the  $\pi$ -conjugated backbone of the organic semiconductor, while ions penetrate the bulk material. In PBT<sup>3</sup>TT, a polymer with high charge-carrier mobility, ion uptake in the polymer matrix can be facilitated by incorporating alkyl side chains with an ether group, further improving the performance.<sup>3,4</sup> Therefore, in this study we use high temperature rubbing to orient PBT<sup>3</sup>TT-<sup>8</sup>O films helping to unravel the fundamental processes of both the charge and ion transport. For comparison the same experiments were carried out with an OMIECs model material P3HT, which was already characterized by multiple different research groups.<sup>5</sup>

Combining electrochemical and chemical doping with spectroscopic techniques and chronoamperometry the oxidation behavior of the OMIECs was investigated. Foremost, with *in-situ* terahertz (THz) spectroscopy we can detect the scattering frequencies of charge carriers in semiconductors, this allows us to get the intrinsic nanoscale conductivity and short-range mobility of the studied OMIECs, which is not affected by any grain boundaries or electrodes. The analysis of the complex THz conductivity unveils the mobility and density of charges altogether. We were able to get conductivities of more than 1000 S<sup>cm</sup><sup>-1</sup> for P3HT and PBT<sup>3</sup>TT-<sup>8</sup>O for electrochemical doping. Furthermore, with chemical doping conductivities of more than 2000 S<sup>cm</sup><sup>-1</sup> were obtained and band like transport behavior was observed for PBT<sup>3</sup>TT-<sup>8</sup>O, showing the large effect of high in plane orientation of OMIECs.

#### 3:30 PM EL18.08.03

**Influence on the Performance of Organic Electrochemical Transistors of PEDOT:PSS Blends with Polyethylene Oxide of Different Molecular Weight** Chun-Yuan Lo<sup>1</sup>, Lucas Flagg<sup>2</sup> and Laure V. Kayser<sup>1</sup>; <sup>1</sup>University of Delaware, United States; <sup>2</sup>National Institute of Standards and Technology, United States

The addition of polyethylene oxide (PEO) to organic mixed ionic-electronic conductors, such as PEDOT:PSS, is commonly done to increase biocompatibility, hydrophilicity, or stretchability. In particular, when blended with PEDOT:PSS, PEO has been shown to change the microstructure of the thin films. In this study, we were interested in the effect of PEO on mixed ionic-electronic transport properties, particularly when the films are immersed in aqueous solutions such as for organic electrochemical transistors (OECTs). PEO is water soluble and therefore could easily be leached out of the films when immersed in water or an aqueous electrolyte. We studied PEO of two different molecular weights (MW), 400 Da (low MW) and 20,000 Da (high MW), in

PEDOT:PSS:PEO blends at 5 wt% PEO in solution, and crosslinked with GOPS. We monitored the composition of the spin-coated films by X-ray photoelectron spectroscopy (XPS) over a period of 4 hours of immersion in water. We found that most, if not all low MW PEO is removed from the films after 2 hours of immersion, while for high MW PEO, nearly 50% was still present in the films with a stable concentration after 1-2 h. In both cases, we noted the removal of excess PSS in the films, which is common for PEDOT:PSS immersed in water. The removal of PEO and PSS following water immersion was also confirmed by a significant reduction in film thickness, as measured by profilometry and atomic force microscopy. We then performed transconductance measurements on OECT devices to extract the mobility-capacitance product,  $[\mu\text{C}^*]$ , of our PEDOT:PSS formulations. In all cases, without PEO, or with low or high MW PEO, the transconductance increased significantly after immersion in water, consistent with the removal of insulating material. What was more surprising, however, was a much higher  $[\mu\text{C}^*]$  when low MW PEO was used as an additive and then removed by soaking in water. The  $[\mu\text{C}^*]$  values obtained, which have yet to be validated externally, are higher than those obtained when doping with ethylene glycol and close to that of previously reported crystalline PEDOT:PSS obtained by sulfuric acid treatment. We are still exploring the exact reasons for this increase, but it seems to stem from both an increase in the charge mobility and volumetric capacitance (up to  $129 \pm 22 \text{ F cm}^{-3}$ ). GIWAXS measurements did not indicate a change in film crystallinity, but spectroelectrochemistry revealed a higher charge density which is consistent again with the removal of PSS and PEO from the films. This study provides an avenue towards improving the performance of PEDOT:PSS electrodes without using sulfuric acid. We also hope to encourage others to study the fate of polymeric additives and small molecules in devices operating under aqueous conditions.

**Phase Separation in Mixed Ionic and Electronic Conductors for Information Storage** [Yiyang Li](#); University of Michigan, United States

Mixed ionic and electronic conductors (MIECs) enable vast changes in chemical composition induced by electrochemical currents and voltages. This electrochemically-induced change in chemical composition enables a substantial chemical capacitance, which can be harnessed for energy storage and emerging microelectronic devices. This change in composition can yield phase transformations and spinodal decomposition in MIEC materials due to materials thermodynamics. In this presentation, we show how this phase separation in metal oxide MIECs enables the coexistence of multiple physical states that are identical in energy. By switching between these physical states, we can provide a thermodynamically nonvolatile form of information storage. We demonstrate this phenomenon in two types of memory cells: resistive memory and electrochemical memory. We anticipate that phase separation can be broadly generalized to other forms of MIECs.

**Understanding the Disparity Between Doping and Dedoping Kinetics in Organic Electrochemical Transistors with Operando Optical Microscopy**

Jiajie Guo<sup>1</sup>, Shinya Chen<sup>1</sup>, [Rajiv Giridharagopal](#)<sup>1</sup>, Connor G. Bischak<sup>1,2</sup>, Jonathan W. Onorato<sup>1</sup>, Kangrong Yan<sup>3</sup>, Ziqiu Shen<sup>3</sup>, Chang-Zhi Li<sup>3</sup>, Christine Luscombe<sup>4,1</sup> and David S. Ginger<sup>1</sup>; <sup>1</sup>University of Washington, United States; <sup>2</sup>The University of Utah, United States; <sup>3</sup>Zhejiang University, China; <sup>4</sup>Okinawa Institute of Science and Technology, Japan

Organic electrochemical transistors (OECTs) operate via electrochemical doping, where an applied gate potential in an aqueous electrolyte modulates the channel conductivity through counterion injection into and expulsion from the semiconducting polymer. This doping process, and the resulting current in OECT devices, is far from instantaneous and exhibits significant disparity between doping and dedoping kinetics. Existing models of device operation cannot explain the experimental observations that turn-off times are generally much faster than turn-on times in accumulation mode OECTs, yet this difference in kinetics has significant practical implications for devices where designing for optimal switching times is critical. We address this shortcoming through operando optical microscopy, where we directly image the local doping level of the transistor channel (in real time) in combination with device measurements to present a comprehensive view of the physical process. We use these microscopy data to show that device turn-on occurs in two stages, while turn-off occurs in one stage. We attribute the faster turn-off to a combination of engineering as well as physical and chemical factors including channel geometry, differences in doping and dedoping kinetics, and carrier density-dependent mobility. We further show that ion transport is limiting the device operation speed in our model devices. Our study provides insights into the asymmetric kinetics in OECTs and gives practical guidelines for rationally engineering faster OECTs.

**Application Guided Design of Conjugated Polymers Towards Next-Generation Iono-Electronic Devices** [Aristide Gumyusenge](#); Massachusetts Institute of Technology, United States

Conjugated polymers, particularly organic mixed ionic-electronic conductors (OMIECs), continue to shine as promising conductors for applications requiring coupled conduction, particularly in bioelectronics. However, only a few mixed conductors are implemented in functional devices to date and a one-material-fits-all bottleneck continues to hamper rapid advancements. The challenge lies in the lack of a cross-disciplinary design approach for high-performance materials. Establishing the needed balance between the two antagonistic modes of transport (ion permeability and electronic charge transport) to yield high performance devices has not only become an exciting field of fundamental research, but also a conduit towards advanced electronics. My research group at MIT (the laboratory of organic materials for smart electronics, OMSE Lab) employs polymer modularity to design novel iono-electronic semiconductors. We employ an application-guided approach and create tailored structures for integrating into devices. In this talk, I will share our ongoing efforts in designing new semiconductors with varying degrees of ion-responsiveness and the scope of applications enabled by their molecular tuning. We utilize copolymerization as a facile route to yield a library of mixed conductors enabling a variety of applications ranging from rapidly switching electrochemical transistors to high-fidelity artificial synapses. We have shown that by systematically tethering polar side groups onto known excellent electron conductors, we can probe the contribution from both ionic and electronic conduction to the resulting device performance and determine suitable applications. We have also studied a hybridization strategy between different polymer components to yield extrinsic properties especially environmental robustness. This hybridization strategy has also shown effective for widening the scope of target analytes toward which our mixed conductors can respond, thus enabling new electronic designs.

### 2:15 PM EL18.09.03

**In-Situ Characterization of Ordering/Disordering in Electrochemically Doped Oligo-Ether Sidechain Modified Polythiophenes** [Lee Richter](#)<sup>1</sup>, Lucas Flagg<sup>1</sup>, Maximilian Moser<sup>2</sup>, Iain McCulloch<sup>2</sup>, Jonathan W. Onorato<sup>3</sup> and Christine Luscombe<sup>4</sup>; <sup>1</sup>National Institute of Standards and Technology, United

States; <sup>2</sup>University of Oxford, United Kingdom; <sup>3</sup>University of Washington, United States; <sup>4</sup>Okinawa Institute of Science and Technology, Japan

Organic mixed ionic and electronic conductors (OMIECs) are a novel material class, emerging as potential enablers for devices as diverse as actuators, biosensors and neuromorphic computing. In an OMIEC, volumetric doping (gating) of the active material is achieved through ingress of electrolyte ions, under potential control. This opens unique transduction modalities due to the mixed (ionic and electronic) modes of conduction. However, the complex changes in film structure: swelling by both electrolyte and counter ion coupled with electrochemical doping, requires in-situ and in-operando measurements to develop quantitative process-structure-function relationships. Side-chain modification, typically by the introduction of oligoethylene glycol (oEG) units, of traditional semiconducting polymers, has emerged as a powerful paradigm for OMIEC material design. We have applied in-situ grazing incidence X-ray diffraction (GIXD) to the study of 3 oEG modified polythiophenes, p3MEEMT[1], p(g3T2) and p(g1t2-g5t2).[2] All are regio-regular, but differ in terms of the length of the oEG side chain (2 units for P3MEEMT, 3 units for p(g3T2), and up to 5 units for p(g1T2-g5T2)) and in repeat unit symmetry. While the optoelectronic properties of these polymers are similar, consistent with the common backbone, the swelling behavior of the polymers were notably distinct. With moderate thermal annealing, all polymers exhibit semicrystalline behavior, typical of polythiophenes, with an edge-on habit of pi-stacked lamella. When characterized in-situ we find a remarkable disordering of the p(g3T2) in the neutral, dedoped state. Effectively no diffraction can be observed. However, a degree of order comparable to that observed ex-situ (dry) is obtained upon doping. This severe doping induced ordering is similar to that observed in doped regio-random P3HT[3] and is consistent with the enhanced pi-pi interaction (evidenced by a decrease in the interchain separation) typically observed for doped polythiophenes. This electrolyte induced “melting” is also present in the asymmetric sidechain p(g1T2-g5T2) but is absent in the shorter side chain polymer. While significant effort has been placed on characterization of swelling in OMIECs, the observation of nominal melting of semicrystalline material has not been extensively discussed and may limit the oEG content. In general, order within the polymer is considered important to electronic transport [4] thus the doping induced ordering may be essential to the final device performance.

## 2:30 PM BREAK

### 3:30 PM \*EL18.09.04

**Tailoring Organic Semiconductors for Mixed Ionic and Electronic Transport** Christian Nielsen; Queen Mary University, United Kingdom

The emerging research field of organic bioelectronics has developed rapidly over the last few years and elegant examples of biomedically important applications including for example in-vivo drug delivery and neural interfacing have been demonstrated.

The organic electrochemical transistor (OECT), capable of transducing small ionic fluxes into electronic signals in an aqueous environment, is an ideal device to utilise in bioelectronic applications. Initially, nearly all OECTs were fabricated with commercially available PEDOT:PSS, heavily limiting the variability in performance. We have previously shown that tailor-made semiconducting polymers are fully capable of matching the performance of PEDOT:PSS and over the last few years the library of mixed ionic-electronic conductors for OECT applications have expanded significantly. To capitalise on this development and the versatility of the organic chemistry toolbox, further materials development is needed. In my talk I will discuss our recent work in this area covering examples of both molecular and polymeric semiconducting materials and their performance in organic electrochemical transistors.

### 4:00 PM EL18.09.05

**Nanoscale Mapping of Ions, Polarons and Bipolarons in Organic Mixed Conductors** Seth Jackson, Garrett Collins and Connor G. Bischak; The University of Utah, United States

Organic mixed ionic-electronic conductors have emerged as promising materials for biosensors, bioelectronics, neuromorphic computing, and electrochromics. These technologies all operate based on electrochemical doping of organic mixed ionic-electronic conductors, which are most commonly conjugated polymers. The locations of ions, polarons, bipolarons directly impact how electronic charge carriers move through the OMIEC matrix. Using photoinduced force microscopy (PiFM) with visible, near-infrared, and infrared wavelengths, we generate maps of ion, polaron, and bipolaron densities with ~10 nm spatial resolution. In poly(3-hexylthiophene), we demonstrate using a combination of UV-vis spectroelectrochemistry, grazing incidence wide angle X-ray scattering (GIWAXS), nanoscale stiffness mapping, and PiFM, that ions and polarons reside preferentially in crystalline regions. We extend these initial studies to other OMIEC polymers with oligo(ethylene glycol) side chains to visualize the arrangement of ions, polarons, and bipolarons in the polymer matrix.

### 4:15 PM \*EL18.09.06

**Effect of Backbone Linearity on Mixed-Conductance in New Pyrene Dianhydride-Based Conjugated Ladder Polymers** Julia A. Schneider, Katherine Johnston, Emma Mikita and Emil Jaffal; Fordham University, United States

We report the synthesis of a new organic n-type ladder conjugated polymer, poly(benzimidazobenzod(e,f)phenanthrene-dione) (**BPyl**), for applications utilizing mixed ionic-electronic semiconductors. This pyrene-based ladder polymer is an exciting core-expansion of the high performing naphthalene-based polymer, poly(benzimidazobenzophenanthroline) **BBL**, but unlike **BBL**, it allows for structural variety in the conjugated backbone. Electronic charge transport and ion diffusion in organic conjugated polymers are both dependent on interchain interactions, yet maximizing these processes equally is a significant challenge toward achieving mixed conductance. The crystalline assemblies necessary for charge transport can often limit ion diffusion and hinder the capacitance of the material. While studies have shown that amorphous films perform better due to uniform swelling by the electrolyte, the insertion of conjugation-break spacers or hydrophilic side chains leads to decreased charge transport. With **BPyl**, we present a new approach for controlling polymer crystallinity by tuning backbone linearity using “linear” and “bent” isomeric monomers. We have synthesized two isomers of pyrene dianhydride for the polycondensation with 1,2,4,5-tetraaminobenzene tetrahydrochloride (TAB.4HCl) into conjugated ladder polymers. By tuning the ratio of pyrene comonomers we can impact film-formation ability and performance. We will present comparisons of **BBL** and **BPyl** (linear and bent) via spectro-electrochemical analysis, TEM imaging, electrochemical characterization, and organic electrochemical transistor (OECT) devices.

### 4:45 PM EL18.09.07

**Revealing The Microstructure of Hydrated Conjugated Polymers using Cryogenic Electron Microscopy** Masoud Ghasemi and Enrique Gomez; The Pennsylvania State University, United States

Organic mixed ionic-electronic conducting (OMIEC) polymers have attracted a tremendous amount of attention due to their easy tunability and potential for various applications, such as neuromorphic computing and biosensing. Among different OMIECs, poly(3,4-ethylenedioxythiophene):polystyrene

sulfonate (PEDOT:PSS) is the most widely used polymeric system due to its commercial availability and ease of processibility as an aqueous dispersion. PEDOT is a p-type conjugated polymer with poor solubility in both polar and nonpolar solvents, hence it is usually processed along with PSS which also serves as a dopant to induce positively charged electronic carriers in PEDOT. It has been shown that both the electronic and mechanical properties of PEDOT:PSS can be modulated through post-processing or the application of different additives. Despite its wide range of applications the underlying mechanisms behind the improvement in the mechanical properties of PEDOT:PSS in the presence of additives remains poorly understood. In this work, we use cryogenic electron microscopy (Cryo-EM) to investigate micro- and nano-structure of PEDOT:PSS in different hydrated and swollen states. Our results suggest that in a hydrated state PSS rich regions of the PEDOT:PSS swell while the PEDOT-rich phases maintain an interconnected network which highlights the importance of a charge percolation pathway as well as the amorphous phase connectivity to achieve high mobility and stretchable OMIECs. Our findings may pave the way to a deeper understanding of OMIECs and their structure-function relationships.

**Monolithic Integration of Single-Crystalline 2D Standalone Circuitry Enabled by Ultra Low Temperature Growth** [Jeehwan Kim](#); Massachusetts Institute of Technology, United States

It is necessary to find a strategy obtain single-crystalline TMDs on a Si wafer without transfer for seamless integration of TMDs for CMOS technologies. However, so far, epitaxial methods has been an only way to obtain single-crystalline TMDs which requires a single-crystalline hexagonal substrate and transfer them onto the Si wafer. Here my team at MIT has succeeded to directly grow single-crystalline MoS<sub>2</sub> and WSe<sub>2</sub> on a HfO<sub>2</sub>-coated Si wafer without needing to have an epitaxial seeding. We geometrically confine the growth of the first set of nuclei by defining selective growth trenches before the second set of nuclei is introduced. By utilizing the edge of trenches as a heterogeneous nucleation site, we were able to grow TMDs as low as at 380 oC which will enable monolithic integration of logic devices on various circuitry. Also, such low temperature direct non-epitaxial single-crystalline growth methods lay foundations to finally obtain vertically stacked complementary FETs by monolithic integration of MoS<sub>2</sub> nMOS on top of WSe<sub>2</sub> pMOS.

### 11:00 AM EL19.01.02

**Area-Selective Atomic Layer Deposition on a 2D Monolayer Lateral Superlattice** [Jeongwon Park](#)<sup>1</sup>, [Seung Jae Kwak](#)<sup>2</sup>, [Won Bo Lee](#)<sup>2</sup>, [YongJoo Kim](#)<sup>3</sup> and [Kibum Kang](#)<sup>1</sup>; <sup>1</sup>Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of); <sup>2</sup>Seoul National University (SNU), Korea (the Republic of); <sup>3</sup>Kookmin University, Korea (the Republic of)

Recently, area-selective atomic-layer-deposition (AS-ALD), which allows the direct deposition of target materials on the desired area using a deposition barrier, has emerged as an advanced patterning process. In conventional AS-ALD (CAS-ALD), various barriers, including self-assembled monolayers, surface terminations, and inherent selectivity in metal-insulator combinations, have been deployed. Nevertheless, these barriers have not yielded satisfactory results when confronting highly reactive ALD precursors or when handling diverse materials in AS-ALD. Furthermore, CAS-ALD, which selectively deposits materials in predefined regions through top-down patterning, has not successfully reduced pattern sizes beyond the resolution of optical lithography.

In this research, we report a novel superlattice-based AS-ALD (SAS-ALD) using a 2D lateral superlattice as a patterning template. The lateral superlattice is grown by coherent lateral epitaxy of monolayer MoS<sub>2</sub> and MoSe<sub>2</sub> with chemical vapor deposition (CVD) process. Due to the unique feature of lateral growth in 2D materials, the superlattice is composed of linear patterns of MoS<sub>2</sub> and MoSe<sub>2</sub>. Interestingly, we have discovered that when various materials (Al<sub>2</sub>O<sub>3</sub>, HfO<sub>2</sub>, Ru, Te, Sb<sub>2</sub>Se<sub>3</sub>, and TiN) are deposited via ALD on the MoS<sub>2</sub>-MoSe<sub>2</sub> lateral superlattice, they selectively deposit only on the MoSe<sub>2</sub> regions, resulting in linear patterns of target materials.

Since the width of linear pattern is determined by the duration time of gaseous CVD precursors, a scaling down is significantly easier compared to conventional patterning methods. As a result, we patterned target materials on the lateral superlattice template with a sub-10 nm half pitch size. Furthermore, unlike CAS-ALD, which controls the chemisorption of ALD precursors, SAS-ALD has a completely new mechanism that utilizes physisorption

differences and diffusions. Through molecular dynamics (MD) simulations and density functional theory (DFT) calculations, we confirmed that the adsorption energy of ALD precursor on 2D transition dichalcogenides (TMDs) is influenced by local strain and curvature of TMDs. Importantly, we observed that the most stable adsorption of the precursors occurs on the compressed MoSe<sub>2</sub> valley region, which has compressive strain and concave surfaces. The computational results were further supported by experimental evidence showing initial nucleation of ALD materials on the compressed MoSe<sub>2</sub> valley region. Based on the physisorption differences and diffusion of ALD precursors, SAS-ALD has been able to selectively deposit various materials such as Al<sub>2</sub>O<sub>3</sub>, HfO<sub>2</sub>, Ru, Te, Sb<sub>2</sub>Se<sub>3</sub>, and TiN. Additionally, we successfully achieved Al<sub>2</sub>O<sub>3</sub> AS-ALD using a trimethyl aluminum, the highly reactive precursor, and this was possible even at a few nanometer scales.

SAS-ALD, based on a novel mechanism, allows for patterning of target materials in a linear shape using a 2D lateral superlattice template. From a patterning perspective, the width is controlled by the duration time of CVD precursor, making scaling down very easy. In addition, in terms of AS-ALD, we were able to effectively fabricate various materials in very narrow patterns. This technology is expected to have even greater potential when combined with guide patterns created through photolithography for precise positioning. Additionally, since SAS-ALD utilized 2D TMDs as pattern templates, we anticipate that various 2D/3D hybrid structures can be created.

**Reconfigurable Mixed-Kernel Heterojunction Transistors for Personalized Support Vector Machine Classification** Justin Qian<sup>1</sup>, Xiaodong Yan<sup>1</sup>, Jiahui Ma<sup>2</sup>, Aoyang Zhang<sup>2</sup>, Stephanie Liu<sup>1</sup>, Matthew Bland<sup>1</sup>, Kevin Liu<sup>1</sup>, Xuechun Wang<sup>2</sup>, Vinod K. Sangwan<sup>1</sup>, Han Wang<sup>2</sup> and Mark C. Hersam<sup>1</sup>; <sup>1</sup>Northwestern University, United States; <sup>2</sup>University of Southern California, United States

The continual increase in the volume of data generated by sensors, robots, and mobile devices poses a challenge for cloud computing centers in terms of power costs, efficiency, accessibility, and scalability. In particular, artificial intelligence (AI) based classification has shown tremendous potential in a variety of applications such as signal processing and image recognition but often has huge data and energy costs due to the underlying von Neumann architecture of complementary metal-oxide-semiconductor (CMOS) chips. In contrast, the use of edge computing to locally analyze and process data has the potential to alleviate the burden on large data centers, while also improving latency, security, and privacy. Because edge computing resources are often limited, edge-based hardware needs to be more power-efficient than conventional graphics processing units (GPUs), application-specific integrated circuits (ASICs), or field programmable gate arrays (FPGAs).

This presentation will discuss edge computing at the device level using a highly reconfigurable mixed-dimensional dual-gated MoS<sub>2</sub>/carbon nanotube (CNT) van der Waals heterojunction device achieved in a self-aligned manner. By tailoring the degree of electric-field screening through control over CNT density and overlapping heterojunction area, the heterojunction device is shown to generate tunable Gaussian, sigmoid, and mixed Gaussian/sigmoid functions. These heterojunction-generated functions are then used as kernels for support vector machine (SVM) based arrhythmia detection from electrocardiogram (ECG) signals. For a single device, mixed kernels were found to outperform purely Gaussian and purely sigmoid kernels. Bayesian optimization was further used to determine the optimal Gaussian/sigmoid hyperparameters and mixing ratio for a full mixed-kernel library that was generated from the integration of two devices, resulting in exceptionally high classification accuracies. Compared to existing literature on Gaussian transistors and CMOS circuits, our mixed-kernel heterojunction (MKH) transistors show unprecedented tunability in a compact four-terminal geometry with close to two orders of magnitude fewer circuit elements. In this manner, CNT-MoS<sub>2</sub> MKHs have the potential to be widely applicable to SVM classification in diverse wearable and edge applications. <!--[endif]-->

#### 11:30 AM \*EL19.01.04

**Hexagonal and Amorphous Boron Nitride Thin Films** Hyeon Suk Shin; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Hexagonal boron nitride (hBN) is a promising two-dimensional (2D) material owing to its unique optical properties in the deep-UV region, mechanical robustness, thermal stability, and chemical inertness. hBN thin films have gained significant attention for various applications, including nanoelectronics, photonics, single photon emission, anti-corrosion, and membranes. Thus, wafer-scale growth of hBN films is crucial to enable their industrial-scale applications. In this regard, chemical vapor deposition (CVD) is a promising method for scalable high-quality films. To date, considerable efforts have been made to develop continuous hBN thin films with high crystallinity, from those with large grains to single-crystal ones, and to realize thickness control of hBN films by CVD. However, the growth of wafer-scale high crystalline hBN films with precise thickness control has not been reported yet. The hBN growth is significantly affected by substrate, in particular the type of metals, because the intrinsic solubilities of boron and nitrogen depend on the type of metal. In this talk, state-of-the-art strategies adopted for growing wafer-scale, highly crystalline hBN are summarized, followed by the proposed mechanisms of hBN growth on catalytic substrates [1]. Furthermore, various applications of the hBN thin films are demonstrated, including a dielectric layer, an encapsulation layer, a wrapping layer of gold nanoparticles for surface enhanced Raman scattering, a proton-exchange membrane, a template for growth of other 2D materials or nanomaterials, and a platform of fabricating in-plane heterostructures. In addition, amorphous BN (aBN) as a counterpart of crystalline hBN is introduced [2]. Detailed structural characterisation indicates that a-BN is sp<sup>2</sup>-hybridised, with no measurable crystallinity, and mechanically robust, with excellent diffusion-barrier characteristics. The aBN thin film shows ultra-low dielectric constant (< 2.5), indicating great potential for its applications in Cu interconnects of integrated circuits.

#### SESSION EL19.02: Advances in the Assembly of Van der Waals Heterostructures

Session Chairs: Andrew Mannix and Hyeon Jin Shin

Monday Afternoon, November 27, 2023

Hynes, Level 3, Room 309

#### 1:30 PM \*EL19.02.01

**Ultraclean Layer Transfer and Atomic Reconstruction in Twisted TMD Lattices** Roman Gorbachev; University of Manchester, United Kingdom

Layer-by-layer assembly of van der Waals (vdW) heterostructures underpins new discoveries in solid state physics, material science and chemistry. Despite successes, all current assembly techniques use polymeric supports which limit their cleanliness, ultimate electronic performance, and potential for optoelectronic applications. In the first part of the talk, I will introduce a polymer-free platform for heterostructure assembly using re-usable flexible silicon nitride membranes. This approach enables production of heterostructures with interfaces free from interlayer contamination and correspondingly excellent (opto)electronic behaviour. In addition, eliminating polymeric supports allows new possibilities for vdW heterostructure fabrication: assembly at temperatures up to 600°C, and in different environments including ultra-high vacuum (UHV) and liquid submersion. We demonstrate UHV heterostructure

assembly for the first time and show the reliable creation of moiré superlattices with over x10 improvement in homogeneity.

In the second part of the talk, I will review our recent progress on twisted bilayer TMDs bilayers in the reconstruction regime. I will discuss their atomic structure observed in STEM, which is strikingly different for aligned (R) and anti-aligned (H) TMD monolayer orientations. This difference gives rise to correspondingly different optoelectronic properties, with ferroelectric domains arising in the former case and piezoelectric charge texturing in the latter. I will report our recent investigation of sliding ferroelectricity, and its switching behaviour observed in double gated structures using the electron channelling contrast SEM.

#### 2:00 PM \*EL19.02.02

**More Magic with Atomic Crystals** [Jiwoong Park](#); University of Chicago, United States

Atomically thin crystals, that are grown, combined, and integrated in large scale, can enable novel properties previously unimaginable. Such "magical" properties can span functional dimensions that go beyond widely-explored electronic phenomena, resulting in extreme thermal, photonic, and mechanical properties. In this talk, I will discuss latest examples with such magical properties realized with atomic crystals. First, we demonstrated three atom thick photonic waveguides, named delta-waveguide, that can generate light plane waves that propagate freely along the waveguide plane but confined along the out-of-plane direction. This enables integrated two-dimensional photonics and seamless mode matching with free-beam optics. Second, we demonstrated the fabrication and measurements of wafer-scale atomic crystal membranes on water that behave like a freestanding mechanical film. We discover that these membranes are not flat; instead they self-wrinkle with the wrinkle morphologies following a universal scaling law, as shown by continuum mechanics theory. This enables a tuning of their mechanical moduli over multiple orders of magnitude.

**Exploring the Inter-Layer Interactions of 2D Materials with Sub-Angstrom Resolution Modulated Nanoindentation** [Ryan Khan](#), Daniel Vizoso, Frank Delrio and Remi Dingreville; Sandia National Laboratories, United States

As the field of 2D materials continues to grow, more intriguing and complex structures will be discovered, increasing the demand for techniques to properly characterize the local nanoscale mechanical properties of any and all varieties of materials. While traditional nanoindentation can measure the in-plane modulus of suspended films over holes, the technique fails to accurately determine the out-of-plane modulus, requiring such large indentation depths that substrate effects cannot be distinguished. We employ modulated nanoindentation with Angstrom resolution (MoNI/ÅI), a novel technique that enables non-destructive measurements of the out-of-plane elasticity of ultra-thin materials with sub-angstrom level indentation depths. With such high resolution, even atomically thin materials can be examined in their most practical state on any underlying substrate, without erroneous contributions from the substrate. MoNI/ÅI has been previously used to explore local pressure induced phase transformations only possible in few layer 2D materials. In our work we explored the multi-layer stiffness dependence of deposited graphene and uncovered a peak transverse stiffness in bilayer graphene that was previously unknown. We complemented these findings with MD simulations and other characterization techniques to further elucidate this phenomenon providing a deeper insight of the inter-layer forces and interactions in graphene and other 2D materials.

#### 3:15 PM \*EL19.02.05

**Electronic and Electrochemical Properties of Moiré Superlattices** [Daniel K. Bediako](#); University of California, Berkeley, United States

The formation of moiré superlattices alters the electronic band structure in a manner that is systematically dependent on the interlayer twist angle, but spontaneous strain relaxation has considerable impact on the resulting physics. This talk will focus on the use of four-dimensional scanning transmission electron microscopy measurements to map lattice relaxation in bilayer and trilayer moiré superlattices and how these structural perturbations impact both the correlated electron physics of the materials as well as their interfacial electrochemical behavior measured by scanning electrochemical cell microscopy.

#### 3:45 PM \*EL19.02.06

**Introduction to the MonArk NSF Quantum Foundry** [Hugh Churchill](#); University of Arkansas, United States

The MonArk Quantum Foundry is an NSF program jointly led by Montana State University and the University of Arkansas with a mission to accelerate two-dimensional materials research for quantum technologies. The rapid prototyping and characterization capabilities of the foundry will be used to serve a broad range of collaborators and users interested in the development of 2D materials and devices for quantum technologies. In this talk I will provide an introduction to the goals and capabilities of MonArk, which are centered on robotic and AI-assisted creation, identification, and fabrication of 2D quantum materials and devices. I will provide a status report on the development of these capabilities and an outlook for the collaborator and user program that will begin in 2024.

#### 4:15 PM \*EL19.16.07

**Upconversion Electroluminescence in Plasmonic Van der Waals Tunnel Diodes** [Goki Eda](#); National University of Singapore, Singapore

Plasmonic tunnel junctions comprising van der Waals semiconductor are an attractive platform where the interplay between inelastically tunneling electrons, surface plasmons, and excitons is expected to give rise to novel light emission phenomena. Here, we report observation of peculiar upconversion electroluminescence in van der Waals tunnel diodes comprising a monolayer transition metal dichalcogenide (TMD) in the electron tunneling pathway. The device exhibits bimodal electroluminescence with a broad low energy band and a narrow high energy band. Interestingly, the high energy emission, which is attributed to the TMD ground exciton, is found to turn on at applied biases significantly lower than the threshold defined by its emission energy, whereas the low energy emission, which arises from plasmonic emission, strictly obeys the quantum cut-off. We examine several possible model and show that momentum-indirect excitation of high energy carriers enabled by inelastic electron tunneling is a key component enabling the apparent energy gain.

SESSION EL19.03: Poster Session I: 2D Materials—Liquid-Phase Deposition and Growth

**Scalable Solution Synthesis and Photocatalytic Activity of Layered ZnO and MoS<sub>2</sub> Heterostructures** [Maria Sushko](#), Lili Liu, Libor Kovarik, Jun Liu and Xin Zhang; Pacific Northwest National Laboratory, United States

Numerous inorganic materials have been identified as potential candidates for high-performance photocatalysts. However, their solar-to-energy conversion efficiencies still fail to meet commercial requirements. The main hurdle is the rapid recombination of photoexcited electrons and holes in single-phase materials. A viable predicted approach to suppress charge recombination is coupling two materials to form a two-dimensional (2D) heterostructure that physically separates photoinduced electrons and holes in different layers. In this work, the heterostructure-based paradigm was tested and a scalable solution synthesis of epitaxial ZnO-MoS<sub>2</sub> heterostructure was developed. A 2D ZnO-MoS<sub>2</sub> heterostructure was synthesized under hydrothermal conditions by stabilizing intermediate Zn-hydroxide states on a functionalized MoS<sub>2</sub> surface. Detailed characterization showed the formation of multilayer heterostructure with MoS<sub>2</sub> flakes intercalated between large size ZnO plates. The performance of this heterostructure was evaluated using photocatalytic degradation of rhodamine B. A degradation efficiency of 70% was measured within 90 minutes of visible light irradiation, almost doubling the efficiency of the corresponding single-phase materials or their physical mixtures.

**8:00 PM EL19.03.04**

**Electrochemically Exfoliated BCN-Cu Nanosheet Electrocatalysts for Efficient Green Hydrogen Evolution: Tuning the Intermolecular Electron Transfer** [Nageh K. Allam](#); American University in Cairo, Egypt

The search for materials with superior electrocatalytic performance has attracted attention during the past few years aiming to identify a convenient material that works at a low overpotential with long-term stability. Herein, we introduce an innovative technique to fabricate two-dimensional BCN heterostructure nanosheets with various Cu:BCN weight ratios. The fabricated composites showed unique electrocatalytic properties for hydrogen evolution reaction (HER). The morphology and structure of the electrocatalysts were characterized using field emission scanning electron microscopy, Raman, Fourier transform infrared spectroscopy, and X-ray photoelectron spectroscopy techniques. Remarkably, this study reveals the effect of electrochemical chronopotentiometry on facilitating electrochemical exfoliation and hence enhancing the catalytic activity of the fabricated nanosheets. This effect was further confirmed via density functional theory (DFT) calculations, unveiling the effect of the formed oxide layer on the charge transfer process. The overpotential of the 0.125 Cu-BCN composite at a current density of -10 mA/cm<sup>2</sup> vs RHE is 50% lower than that of pristine BCN. These findings were also affirmed by the DFT calculations, which showed that incorporating copper on BCN has significantly reduced the  $G_{H^+}$  value of the HER and subsequently accelerates the kinetics of the reaction and the overall catalytic activity of the material.

**8:00 PM EL19.03.05**

**Predicting Mechanical Properties of Nanocomposites Embedded with Carbon-Based Low Dimensional Materials** [Abigail L. Eaton](#), Marco Fielder and Arun K. Nair; University of Arkansas, United States

Carbon-based low dimensional materials, such as 1D carbyne and 2D cyclo[18]carbon (C18), offer a broad range of material properties that may be beneficial for the development of metal-matrix nanocomposites. However, the interface properties of these carbon-based materials with metal matrix could affect the nanocomposite mechanical properties. Thus, it is important to study the interface properties and perform mechanical testing of the nanocomposites embedded with carbon-based low dimensional materials to determine the most efficient material combinations to improve the mechanical properties.

Using molecular dynamics and density functional theory methods, we develop and study the interface properties of carbon-based materials embedded in Cu metal matrix. We focus on the use of 1D carbyne, 2D C18, and 2D C18-carbyne hybrids due to their low dimensionality and range of strength and elasticity. We then conduct uniaxial tensile testing of the nanocomposites to determine if the nanomaterials improve their mechanical properties when compared to single crystal Cu. From the mechanical property prediction and interface analysis, it is possible to determine the nanocomposite that would be most compatible for future development and applications.

**8:00 PM EL19.03.07**

**Synthesis of Layered Conducting Polymer Electrode for Superior Ultracapacitor Performance** [Duy Pham](#); Kennesaw State University, United States

Ultracapacitors (UCs) are electrochemical energy storage (EES) devices that provide fast charge-discharge capabilities and large storage capacity. UCs are comprised of two electrodes that house an electrolyte solution with a porous separator. Electrochemical double layer capacitors (EDLC) that are comprised of carbon-based materials such as activated carbons have an electrostatic charge storage mechanism, also known as non-Faradic charge transfer. The other well-known UCs are pseudocapacitors that are comprised of conducting polymers or metal oxides and have a redox charge storage mechanism, known as Faradic charge transfer. Currently, pseudocapacitors are thoroughly researched, however, the role of conducting polymer structure and property as a function of the deposition method currently remains limited. In this work, conducting polymer electrodes, polypyrrole (PPy) are synthesized using electrochemical depositions with controlled cycles and their performance is investigated. The UCs will be tested using cyclic voltammetry (CV), electrochemical impedance spectroscopy (EIS), and galvanostatic charge/discharge (GCD) to understand the role between deposition cycles and electrochemical performance. Material characterization such as XRD and FT-IR with surface morphology such as SEM are analyzed to give more insights into this charge kinetics between these variations of cycles.

**8:00 PM EL19.03.08**

**Graphene Based Nanofibrous Scaffold for Embedding Bacteriorhodopsin for Bioengineered Memory Application** [Philip Byrne](#), Evan McCarthy and Isaac Macwan; Fairfield University, United States

The photoactive protein, Bacteriorhodopsin (bR), is being implemented into optical memory applications, most notably for its photochemical and thermal stability. Due to this photochemical stability, bR can remain in one of two stable photostates, bR (ground state) and Q (elevated state), which are used to designate binary bits '0' and '1'. The challenge with this phenomenon is that the Q photo state has a low quantum yield, meaning that bR will not absorb enough photons to undergo photoisomerization. To increase the quantum yield of the photocycle, a molecular dynamics simulation involving graphene monolayer and crystal structure of the bR protein was performed to study the adsorption and preservation of the photostates of bR, where it was found that graphene has a potential to increase the quantum yield. However, a major challenge is to have a porous surface with even distribution of graphene nanoparticles to employ it as a scaffold to anchor the bR protein. The porosity of the surface would help anchor the protein onto the surface and the distribution of graphene nanoparticles would ensure proper chemical interactions. Such a porous surface is achieved through electrospinning where nanofibrous scaffold of poly vinyl alcohol (PVA) with graphene nanoparticles is utilized to immobilize the bR protein. Four different scaffolds on aluminum and Indium Titanium Oxide (ITO) surfaces are fabricated with and without graphene having PVA as a common matrix with optimized electrospinning parameters including flow rate, nozzle collector distance, voltage between nozzle and collector, viscosity of the polymer solution and type and configuration of the collector. It is found that the synthesized nanofibers have average diameters of ~200nm with graphene monolayers embedded within the nanofibrous scaffolds. The resulting scaffolds are characterized using scanning electron microscopy (SEM), profilometry and electrochemical impedance spectroscopy (EIS) to quantify its physical and electrical properties and are compared to the control PVA-bR scaffolds without graphene. The

distribution of the purple membrane discs containing bR embedded within the nanofibers is also quantified based on the fiber diameter, porosity and collector surface. The synthesized scaffolds are also tested using lasers with wavelengths ranging from 380nm to 640nm to drive the bR molecules to the branched photostates to demonstrate their use as a bioengineered memory device.

#### 8:00 PM EL19.03.09

**Faradaic and Non-Faradaic Charge Transfer Mechanism for Energy Storage Systems** Ben McKinney, Sonnett Kowalski, Ashish Aphale and Duy Pham; Kennesaw State University, United States

Faradaic and non-Faradaic charge transfer mechanisms play an essential role in energy storage and conversion processes. The faradaic charge transfer mechanism involves electrochemical reactions that result in the exchange of electrons between the electrode and the electrolyte. Whereas the non-faradaic charge transfer mechanism involves charge storage without significant chemical reactions at the electrode-electrolyte interface. In this work we report a hybrid nanocomposite material operating on both Faradaic and non-Faradaic mechanisms simultaneously. The hybrid electrodes containing conducting polymer and graphene oxide were synthesized using electropolymerization process and the effects of graphene oxide (GO) on polypyrrole were studied. Details of electrode synthesis, electrochemical testing, and fabrication of device as a button cell will be discussed. Polypyrrole and graphene oxide (PPy/GO) films were tested using electrochemical methods such as cyclic voltammetry (CV), Electrochemical Impedance Spectroscopy (EIS), and Galvanostatic Charge Discharge (GCD) to assess electrode performance. The results generated from such tests will provide insights into the ohmic, non-ohmic, and Warburg resistances along with specific capacities and charge discharge behavior of the electrodes. These insights will be discussed and compared with electrodes with different levels of graphene oxide.

#### 8:00 PM EL19.03.10

**Solar Assisted Expansion of Graphite Flakes for an Effective Exfoliation of Graphene Sheets** Shanavas Shajahan<sup>1,†</sup>, Rami A. Elkaffas<sup>1</sup> and Yarjan Abdul Samad<sup>1,1,2</sup>; <sup>1</sup>Khalifa University of Science and Technology, United Arab Emirates; <sup>2</sup>University of Cambridge, United Kingdom

Synthesis of scalable monolayer or few-layered graphene sheets is challenging due to the complex production processes [1-3]. Liquid phase exfoliation is considered as one of the most feasible techniques to produce industrially scalable [1] defect-free graphene sheets [4,5]. In ultrasonic exfoliation techniques, long exposure (up to 48 hours) [6] of graphene sheets to the ultrasonic waves considerably decreases its lateral size [7], which limits the mechanical and electrical properties of produced graphene [8]. In this study, we successfully achieved the preparation of graphene sheets with high (4-5 mm) lateral sizes by pre-expanding the graphite through solar-assisted expansion process [9]. The graphite flakes with a lateral size of about 600  $\mu\text{m}$  are intercalated with the perchloric acid ( $\text{HClO}_4$ ) at 120  $^\circ\text{C}$  for 30 min to prepare stage II intercalated graphite ( $\text{S}_2\text{IG}$ ). In the  $\text{S}_2\text{IG}$ ,  $\text{HClO}_4$  is intercalated in between every two layer of graphene sheets, which can be confirmed through Raman analysis [10]. The  $\text{S}_2\text{IG}$  is expanded by focusing sunlight on its surface using a simple magnification lens (diameter = 75 mm, focal length = 10 cm). The solar expansion process (SEP) resulted in the formation of expanded graphite with an expansion ratio of about 1:240 (graphite: solar expanded graphite) and lateral size of solar expanded graphite is about 400  $\mu\text{m}$ , which is similar to the intercalated graphite flakes. The solar expanded graphite is exfoliated through probe sonication (500-watt, 20 kHz) for 20 min to obtain few-layer graphene sheets [11]. Raman analysis confirms the formation of defect-free solar expanded graphite as well as few-layer graphene sheets. The obtained results clearly show that the lateral size of graphene sheets can be enhanced by pre-expanding the graphite sheets through solar irradiation before the probe sonication process.

**First-Principles Study of Electronic Structure and Nonlinear Optical Responses of Novel Two-Dimensional Materials and Moiré Superlattices** Alex Strasser and Xiaofeng Qian; Texas A&M University, United States

Janus two-dimensional (2D) materials and moiré superlattices exhibit rich physical properties and novel fundamental effects. In addition, the recent discovery and synthesis of  $\text{MA}_2\text{Z}_4$  2D materials prompt further exploration of a new family of van der Waals materials, as well as their Janus counterparts. We investigate and compare the electronic structure and nonlinear optical responses in transition metal dichalcogenides (TMDCs) and Janus TMDCs,  $\text{MA}_2\text{Z}_4$  and Janus  $\text{MABZ}_4$  ( $\text{M} = \text{Mo}, \text{W}$ ;  $\text{A}, \text{B} = \text{Si}, \text{Ge}$ ;  $\text{Z} = \text{N}, \text{P}$ ), as well as twisted multilayer graphene systems. Using first-principles density functional theory, we show that the Janus structuring of TMDCs and  $\text{MABZ}_4$  leads to out-of-plane nonlinear responses in both second harmonic generation and shift current, enabling applications for nonlinear electronics and optoelectronics. Furthermore, phosphorous-based  $\text{MA}_2\text{Z}_4$  2D crystals exhibit enhanced nonlinear response in both low- and mid-frequency of second harmonic generation and shift current, comparable to and beyond that of 2D transition metal dichalcogenide  $\text{MX}_2$  materials. These phosphorous materials present strong Rashba spin splitting as evidenced in spin texture. Finally, a Wannier tight-binding model of twisted multilayer graphene is used to calculate nonlinear optical response, including k-point resolved shift vector. The data reveal

intense shift current in twisted bilayer graphene on hexagonal boron nitride. In summary, our theoretical results suggest that 2D Janus materials and twisted moiré superlattices offer significant opportunities for the design and manipulation of optoelectronic responses and devices.

#### 8:00 PM EL19.04.02

**Long-Lived Charge Separation in Large-Area, Single Crystal MoS<sub>2</sub> Monolayers Interfaced with Non-Fullerene Acceptor Y6** Christopher E. Petoukhoff, Zheng Yang, Shahidul Alam, Nisreen Alshehri, Jose P. Jurado Carlin, Catherine De Castro, Vincent Tung and Frederic Laquai; King Abdullah University of Science & Technology (KAUST), Saudi Arabia

Semiconductor heterojunctions based on 2D transition metal dichalcogenides (TMDs) have displayed record thickness-normalized current densities and absorption coefficients, particularly when interfaced with organic semiconductors [1]. As such, 2D TMDs have been employed as both charge transport layers in organic [2] and perovskite photovoltaics [3], as well as the active layer in mixed dimensional organic-2D heterojunctions [4]. MoS<sub>2</sub> and WS<sub>2</sub> have been demonstrated as alternative hole transport layers in high-efficiency organic photovoltaics (OPVs), leading to devices having greater than 17% power conversion efficiencies [5,6]. However, these works have focused on either mechanically-exfoliated, single-crystal TMDs or liquid-phase exfoliated films, which either limit the size or the homogeneity of the resulting devices. There have not yet been works incorporating large-area, single crystal TMD monolayers as hole transport layer materials for OPVs.

In recent years, the advancement of OPV efficiencies has largely been driven by the development of non-fullerene acceptor materials, such as the molecule BTP-4F (i.e., Y6). This molecule has sub-units of electron donating (D) and accepting (A) groups, in the form of A-DA'D-A structure, which give rise to large exciton delocalization with excitons having charge-transfer-like character. In fact, there has been growing evidence that neat Y6, unlike most neat organic semiconducting materials, can generate charge-separated states even without a donor/acceptor interface typical for OPVs.

In this work, we investigate the charge generation, transfer, and separation processes that occur when neat Y6 is interfaced with large-area, single crystal MoS<sub>2</sub> monolayers. We explore these processes using femtosecond transient absorption (TA) and time-resolved photoluminescence (TRPL) spectroscopies. Our results demonstrate that MoS<sub>2</sub>/Y6 interfaces lead to long-lived charges in both the MoS<sub>2</sub> and Y6 layers. We will compare the impact of MoS<sub>2</sub> on charge separation in neat Y6 compared to a typical donor:acceptor blend, PM6:Y6. These results demonstrate the viability of using MoS<sub>2</sub> as an effective hole transport layer in high-efficiency solar cells, particularly for single component OSCs fabricated from Y6-type materials.

Keum<sup>3,3</sup>, Miguel Fuentes-Cabrera<sup>3</sup>, Raymond R. Unocic<sup>3</sup>, Kunlun Hong<sup>3</sup>, Ilia Ivanov<sup>3</sup>, Christopher M. Rouleau<sup>3</sup>, Feng Gang<sup>1</sup>, Kai Xiao<sup>3</sup>, Jihua Chen<sup>3</sup>, Yumeng Li<sup>2</sup> and Bo Li<sup>1</sup>; <sup>1</sup>Villanova University, United States; <sup>2</sup>University of Illinois at Urbana Champaign, United States; <sup>3</sup>Oak Ridge National Laboratory, United States

Ultrathin and mechanically robust structures and devices with nanoscale dimension resolution are critical for miniaturized nanoelectromechanical systems (NEMS) and integrated circuit (IC). It is extremely challenging to achieve such structures from hybrid inorganic-organic systems because the lack of controllability of depositing/assembly organic structures. The attainment of precise fabrication control and comprehension of atomic-level interactions stands as the principal objectives of this research. Here, we propose the utilization of monolayer two-dimensional (2D) materials, such as graphene and MoSe<sub>2</sub>, synthesized through chemical vapor deposition (CVD), as 2D atomic templates to induce the epitaxial assembly of orthorhombic polyethylene (PE) crystals. By meticulously regulating the assembly temperature and time, the growth of PE lamellar crystals can be modulated, ranging from a few nanometers to hundreds of nanometers with an accuracy of sub-nanometer resolution. Adding PE will not only increase the mechanical robustness of 2D materials in fabricating the suspended structures, but also create a dielectric layer with controlled thickness to realize ultrathin device fabrication. The incorporation of polymer nanocrystals, monolayer graphene, and MoSe<sub>2</sub> yields a pioneering category of hybrid nanostructures, wherein the crystalline architectures of both constituents are highly controlled, thereby potentially reshaping the paradigm for manufacturing superior materials and devices with precisely engineered structures and properties.

**2D Materials Junction-Templated Photoelectrochemistry** Radha Raman<sup>1,2,3</sup>, Ya-Ping Hsieh<sup>2</sup> and Mario Hofmann<sup>3</sup>; <sup>1</sup>National Central University, Taiwan; <sup>2</sup>Academia Sinica, Taiwan; <sup>3</sup>National Taiwan University, Taiwan

In recent years, the development of lateral junctions between 2D materials has enabled a new class of nanostructures with precise transitions in electronic structure. In this study, we have utilized the unique carrier transport properties of lateral junctions to conduct electrochemistry with unprecedented spatial resolution and dynamic controllability. By electrostatically confining electrons within the junction, we were able to localize electrochemical reactions with nanometer precision in their lateral position. We have also developed a scalable process for the formation of graphene pn-junction networks that is compatible with various materials and techniques, including dielectrophoretic deposition. The high spatial selectivity of the deposition process allowed us to create complex 1D fractal-shaped nanostructures with ultrahigh Raman enhancement.

Furthermore, we have extended our study to utilize MoS<sub>2</sub> junctions to photo-deposit gold nanoparticles. The incorporation of MoS<sub>2</sub> lateral junctions facilitated the deposition of gold nanoparticles with high spatial resolution. The resulting nanostructure morphology can be used for various applications including surface-enhanced Raman spectroscopy and nanoelectronics.

These results offer exciting possibilities for the assembly of a new type of neural network based on axon-like guided growth of interconnected neurons. Such a network could have significant applications in the development of evolvable, brain-like future electronics. The potential of this technology highlights the importance of continued research in the field of photoelectrochemically deposited nanostructures on 2D material lateral junctions.

#### 8:00 PM EL19.04.05

**Exploring Two-Dimensional Indium Oxide for Memristive Switching: Fabrication, Characterization and Potential Applications** Kuan-Hung Chen<sup>1</sup>, Chang Hsun Huang<sup>1</sup>, Chen-Yuan Weng<sup>2</sup>, Chen-Chih Hsiang<sup>1</sup>, Yi-Hsiang Yen<sup>1</sup> and Yi-Chia Chou<sup>1</sup>; <sup>1</sup>Nation Taiwan University, Taiwan; <sup>2</sup>National Yang Ming Chiao Tung University, Taiwan

Since its groundbreaking discovery in 2004, graphene has captivated the scientific community[1], igniting an unprecedented interest in the exploration of

two-dimensional materials (2DMs). These materials have garnered immense attention due to their exceptional properties resulting from their reduced dimensions, charge carrier confinement, and dangling-bond-free surface. Their distinctive van der Waals nature holds tremendous potential for applications in the scaling era of semiconductor[2], propelling researchers into a realm of innovation. In particular, liquid indium and its alloys have emerged as highly promising candidates in the realm of printed electronics, owing to their low melting point, high stability and remarkable conductivity. A novel top-down technique called liquid metal printing (LMP) has ushered in a new era for the production of 2D metal-oxide films, operating at lower temperatures and simplifying the fabrication process compared to traditional deposition methods. By skillfully tailoring the temperature and oxidation time during LMP, researchers can fashion films of varying thicknesses while preserving their 2D attributes. The striking electrical behavior observed in liquid indium-based metals, stemming from their oxide interfaces, has paved the way for exciting prospects in electronic device design. Among these devices, memristors stand out, offering an array of advantages including rapid operation speed, low power consumption, and the ability to retain multiple memory states. This study embarks on an exploration of the untapped potential of two-dimensional indium oxide ( $\text{InO}_x$ ) as a medium for memristive switching, a territory that has thus far remained relatively unexplored. We successfully extracted  $\text{InO}_x$  from liquid indium and adeptly transferred it onto a  $\text{SiO}_2/\text{Si}$  substrate utilizing the LMP technique. The resultant  $\text{InO}_x$  showcased a considerable area coverage along with an ultra-thin atomic thickness, emphasizing its remarkable properties. A thorough analysis validated the presence of high-quality, structurally stable  $\text{InO}_x$ . To expand the horizons of this investigation, the fabrication process encompassed the creation of  $\text{InO}_x$  memory device, revealing distinct memristive characteristics. Delving further into the intricacies of the relationship between defect and fabrication temperature, we uncovered a direct correlation between oxygen vacancies and temperature, thereby influencing the memristive behavior of  $\text{InO}_x$ . To elucidate the switching mechanism, an elaborate model was constructed, unraveling the indispensable role played by preferential oxygen segregation along the grain boundaries. Besides, the memristor exhibited outstanding performance in terms of low power consumption and retention, holding its on/off ratio over multiple operating cycles with remarkable stability. Furthermore, the  $\text{InO}_x$  memristor showcased the ability to assume multi-level states under specific conditions, highlighting its potential for diverse applications. An intriguing revelation emerged from this study: the behavior of oxygen vacancies within the  $\text{InO}_x$  memristor exhibited a resemblance to the behaviors observed in ion migration within bionic neurons. This striking similarity opens up new vistas for the application of  $\text{InO}_x$  devices in constructing artificial neural network. This discovery holds immense significance as it enhances our understanding of the precise characteristics of oxygen defects and our ability to control the oxygen vacancies in atomically thin oxide films. Moreover, it carries substantial implications for the field of memory technology.

**Spontaneous Enthalpy-Uphill Exciton Dissociation at Organic/2D Heterostructures** Fatimah H. Rudayni<sup>1,2</sup>, Kushal Rijal<sup>1</sup>, Neno Fuller<sup>1</sup> and Wai-Lun Chan<sup>1</sup>; <sup>1</sup>The University of Kansas, United States; <sup>2</sup>Jazan University, Saudi Arabia

Bound interlayer excitons (IXs) at type-II transition-metal dichalcogenide (TMD) heterostructures are usually stable against thermal dissociation because of their large binding energy. In this work, we show that by combining TMD with organic molecules, IXs can dissociate spontaneously into free carriers despite it is an enthalpy-uphill process. Time-resolved photoemission spectroscopy is used to probe the exciton dynamics at the fluorinated zinc phthalocyanine ( $\text{F}_8\text{ZnPc}$ )/monolayer- $\text{WS}_2$  heterostructure. It is found that bound IXs can gain an energy of 240 meV in 50 ps without any external driving force. We attribute this anomalous enthalpy-uphill process to the entropy-driven IX dissociation. The face-on orientation of  $\text{F}_8\text{ZnPc}$  molecules on TMD allows the electron within the IX to delocalize along a direction perpendicular to the interface. This geometry reduces the density of bound IXs and enhances the entropic driving force. This kind of organic/2D heterostructures is advantageous to applications that require the generation of free carriers from bound excitons.

#### 8:00 PM EL19.04.07

**The Electrical, Optical, Structural and Chemical Properties of Molybdenum Ditelluride Film ( $\text{MoTe}_2$ ) using Ion-Beam Assist Magnetron Sputtering for the Device Application of Phototransistor** Hyeong Gi Park<sup>1</sup> and Jae-Hyun Lee<sup>2</sup>; <sup>1</sup>Ajou Kiuri Research Center, Korea (the Republic of); <sup>2</sup>Ajou University, Korea (the Republic of)

In this study, we investigate transition metal dichalcogenide materials as active layers for heterojunction phototransistors and optimize their physical properties through numerical simulation programs. Numerical analysis was performed using the AFORS-HET 1D program, and we optimized the parameters of  $\text{MoTe}_2$ ,  $\text{WS}_2$ , and other materials for the active layer along with Si, SiC, and GaAs substrates to improve the external and internal quantum efficiency. We deposited the  $\text{MoTe}_2$  by ion-beam assisted magnetron sputtering. Tuning of the Fermi level in  $\text{MoTe}_2$  leads to phototransistors with excellent electrical, structural, chemical and optical properties. Specifically, we investigated the different parameters such as power, pressure, temperature and gas atmosphere by sputtering process. Subsequently, we illuminated n-type  $\text{MoTe}_2$  sample with ion-beam source under Ar, oxygen ( $\text{O}_2$ ) and nitrogen ( $\text{N}_2$ ) gas environment and then transversed the carrier type into p- $\text{MoTe}_2$ . However, unveiling of the doping mechanism effect on various thicknesses using ion-beam is still challenging. In addition, we investigated the photoresponse of  $\text{MoTe}_2$  after illumination of ion beam. After that, the phenomenon of carrier modulations and photoresponse paves the way for wide applications of  $\text{MoTe}_2$  in optoelectronic devices.

#### 8:00 PM EL19.04.08

**Two-Dimensional Transition Metal Dichalcogenide Nanosheets for Therapeutic Drug Monitoring of Human Blood Samples** Tae G. Lee<sup>1</sup>, Sunho Joh<sup>1</sup>, Hee-Kyung Na<sup>1</sup>, Jin Gyeong Son<sup>1</sup>, Jaekak Yoo<sup>1,2</sup>, A Young Lee<sup>1</sup>, Cheol-Hee Ahn<sup>3</sup>, Da-Jeong Ji<sup>3</sup>, Jung-sub Wi<sup>4</sup>, Mun Seok Jeong<sup>5</sup> and Sang-Guk Lee<sup>3</sup>; <sup>1</sup>KRISS, Korea (the Republic of); <sup>2</sup>Sungkyunkwan University, Korea (the Republic of); <sup>3</sup>Yonsei University College of Medicine, Korea (the Republic of); <sup>4</sup>Hanbat National University, Korea (the Republic of); <sup>5</sup>Hanyang University, Korea (the Republic of)

Two-dimensionally layered transition metal dichalcogenides (TMDs) have been widely used in various biomedical applications such as biosensing and cancer therapy due to their characteristics including UV absorbance, photoinduced thermal effect, tunable bandgap and photoluminescence.<sup>1</sup> However, their applications in therapeutic drug monitoring, which is essential for individualizing drug dosage regimens, is rarely reported. In this regard, we exemplarily present a facile platform for rapid quantitative determination of therapeutic drugs and biomarkers that can satisfy clinical diagnostic demands. Two-dimensionally layered TMDs including tungsten disulfide ( $\text{WS}_2$ ), tungsten ditelluride ( $\text{WTe}_2$ ) and molybdenum ditelluride ( $\text{MoTe}_2$ ) were fabricated by chemical exfoliation and incorporated as matrices for laser desorption/ionization mass spectrometry (LDI-MS) to promote the ionization efficiency of the analytes. The  $\text{WS}_2$  nanosheet allowed for a sensitive detection of commonly prescribed immunosuppressive drugs including cyclosporine A and tacrolimus in the blood of organ transplant patients by LDI-MS, up to nanomolar concentration with a good linear response within the therapeutic concentration range.<sup>2</sup> Quantification of antiepileptic drugs in human blood was achieved using  $\text{WTe}_2$  and  $\text{MoTe}_2$  nanosheets, while they also facilitated the concentration determination of vitamin D3, which is a well-known biomarker for osteoporosis, Parkinson's disease, and cancers.<sup>3</sup> The validity of our method was further verified by performing statistical agreement assessment to compare our results with those of conventional analytical techniques such as liquid chromatography tandem mass spectrometry. The contribution of the physicochemical properties of TMDs to the ionization efficiency was studied by performing density function theory (DFT) calculations. The results of DFT calculations indicated that the  $\text{WTe}_2$  and  $\text{MoTe}_2$  tend to assist the ionization of

small molecules more efficiently by yielding greater proton affinities for the anti-epileptic drugs, suggesting that the metallic nature of telluride is one of the contributing factors. It is anticipated that our LDI-MS based method would expand the applicability of TMDs in diagnostic medicine, while it can also provide the evidences to elucidate their roles in ionization properties under laser irradiation.

**Evolution of Bandgap in WS<sub>2</sub> from Monolayer to Multilayer** Xu He, Jimpeng Tian, Saïen Xie and Antoine Kahn; Princeton University, United States

Transition metal dichalcogenides (TMDs) are 2D van der Waals materials with a chemical formula MX<sub>2</sub>, where M represents a transition metal such as tungsten (W) or molybdenum (Mo) and X represents a chalcogen atom such as sulfur (S) or selenium (Se). TMDs are layered compounds and can be stacked from mono- to multi-layer films. Unlike graphene, which has a zero gap, TMDs are more versatile in their applications in electronics due to their sizable electronic gaps, tunable with composition and thicknesses. Many theoretical works have been done to study and predict the electronic structures of these materials. It is now a consensus that TMD electronic gaps decrease as the number of layers increases. However, no experimental study has been completed to show how the electronic gap evolves from monolayer to multilayer structures.

In this work, we explore the evolution of optoelectronic properties such as energy level positions, electronic gap ( $E_G$ ), and exciton binding energy ( $E_B$ ) using ultraviolet and inverse photoelectron spectroscopies (UPS / IPES), complemented with Raman spectroscopy and photoluminescence (PL) measurements. High-quality large-scale monolayer and multilayer continuous films of WS<sub>2</sub> are grown by chemical vapor deposition on p-Si (with a native SiO<sub>2</sub> layer). Raman spectroscopy and PL help differentiate between mono- and multi-layer films. UPS and IPES are used to measure occupied and unoccupied states and determine valence band maximum (VBM), conduction band minimum (CBM), Fermi level position, and associated ionization energy, electron affinity, and  $E_G$ . We find that the valence (conduction) states shift toward (away from) the vacuum level from mono- to multi-layer films, decreasing the electronic gap from 2.29 eV to 1.61 eV. The optical gap ( $E_{OPT}$ ) measured by PL for the monolayer film is 1.96 eV. Finally, by subtracting  $E_{OPT}$  from  $E_G$ , we determine  $E_B$  for the monolayer film to be ~0.33 eV. Further studies are being conducted on other TMDs, including WSe<sub>2</sub>, to confirm our findings. These experimental studies will shed light on understanding TMDs bandgap evolution, making predictions on bandgap and energy levels possible for new TMD materials. This will help better decide on TMDs for appropriate band alignments in devices such as LEDs and solar cells where suitable energy levels are of essential importance.

**High Drift Velocity in Multilayer Indium Selenide at High Electric Fields** Yongwook Seok<sup>1,2</sup>, Hanbyeol Jang<sup>2</sup>, YiTaek Choi<sup>2</sup>, Heungsoon Im<sup>2</sup>, Kenji Watanabe<sup>3</sup>, Takashi Taniguchi<sup>3</sup>, Junghyo Nah<sup>4</sup> and Kayoung Lee<sup>1</sup>; <sup>1</sup>Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of); <sup>2</sup>Gwangju Institute of Science and Technology (GIST), Korea (the Republic of); <sup>3</sup>National Institute for Materials Science, Japan; <sup>4</sup>Chungnam National University, Korea (the Republic of)

Creating a high-frequency electron system demands a high saturation velocity ( $v_{sat}$ ). Herein, we report high-field transport properties of multilayer van der Waals indium selenide (InSe). The InSe is on a hexagonal boron nitride substrate and encapsulated by a thin, non-continuous indium layer, resulting in an impressive electron mobility that approaches 3000 cm<sup>2</sup>/Vs at room temperature. Along with the high mobility, the temperature dependence characteristics of the insulating state reveals the presence of minimal disorder and impurities in our InSe. By utilizing four-terminal pulsed measurements, the drain current ( $I_{DS}$ ) at high drain bias ( $V_{DS}$ ) was accessed, reaching up to 3.8 mA at 8 V.  $I_{DS}$  vs  $V_{DS}$  was measured at different carrier densities and temperatures, which are converted into electron drift velocity ( $v_d$ ) vs electric field ( $F$ ).  $v_d$  vs  $F$  data allow us to extract  $v_{sat}$  values, which are as high as  $1.8 \times 10^7$  cm/s at room temperature, superior to those of other gapped 2D semiconductors. Finally, we suggest an optical phonon emission model modified for parabolic dispersion to explain the current saturation, and determine the optical phonon energy of InSe as 22.9 meV, which is close to the theoretically expected value of monolayer InSe.

**Applications of Ambipolar Molybdenum Disulfide with Van der Waals Contacts** Jungi Song<sup>1</sup>, Suyeon Lee<sup>1</sup>, Yongwook Seok<sup>1</sup>, Yeonghyeon Ko<sup>1</sup>, Hanbyeol Jang<sup>2</sup> and Kayoung Lee<sup>1</sup>; <sup>1</sup>KAIST, Korea (the Republic of); <sup>2</sup>Gwangju Institute of Science and Technology, Korea (the Republic of)

Two-dimensional (2D) materials are promising to replace silicon because they do not exhibit performance degradation when scaled down to the nanoscale. However, their high contact resistance and Fermi-level pinning hinder the modulation of a single 2D semiconductor into n-type and p-type, and restrict their potential applications. To overcome those limitations, ambipolar transistors, which can dynamically switch the type of majority carriers, have been proposed. However, a few semiconductors with small bandgaps, such as graphene, black phosphorus, and tungsten diselenide, have shown ambipolar properties. Achieving ambipolar characteristics in 2D materials with a relatively large bandgap remains challenging. Here, we show ambipolar molybdenum disulfide (MoS<sub>2</sub>) transistors by employing van der Waals contacts. MoS<sub>2</sub> shows great potential for the future semiconductor industry, thanks to its sufficient bandgap (1.2–1.9 eV), decent mobility, stability, and mature large-area growth technology. Our devices achieve outstanding ambipolar current characteristics, with both PMOS and NMOS On/Off current ratios > 10<sup>6</sup> and two-point hole mobility > 23 cm<sup>2</sup>/V\*s. By utilizing the ambipolar current characteristics, we have designed a new multifunctional electronics that is reconfigurable between an ambipolar transistor, an n-type transistor, a rectifier (rectification ratio of ~10<sup>6</sup>), a reversible negative breakdown diode (On current of ~0.1 mA), and a photodetector. The talk will be concluded with a brief discussion regarding our demonstration of a complementary inverter based on ambipolar MoS<sub>2</sub> homojunction.

#### 8:00 PM EL19.05.02

**Modification of Mono-layer MoS<sub>2</sub> Through Post-Deposition Treatment and Oxidation for Enhanced Optoelectronic Properties** Jonathan Rommelfangen<sup>1</sup>, Marco A. Gonzalez-Angulo<sup>2</sup>, Devendra Pareek<sup>2</sup>, Levent Gütaý<sup>2</sup>, Phillip J. Dale<sup>1</sup> and Alex Redinger<sup>1</sup>; <sup>1</sup>University of Luxembourg, Luxembourg; <sup>2</sup>Carl von Ossietzky University of Oldenburg, Germany

Atomic layer deposition is a great tool for growing large-scale high-quality mono-layer (ML) MoS<sub>2</sub> and with a dedicated high temperature post-deposition treatment the amount of sulfur vacancies can be controlled. Sulfur-containing atmospheres, such as H<sub>2</sub>S, lead to MoS<sub>2</sub> with low number of sulfur vacancies and increased stability against oxidation in air, whereas post-annealing treatments in N<sub>2</sub> increase the number of vacancies and the material is more prone to oxidation. Post-deposition annealing treatments thereby offer a great possibility to tune the properties of the 2D layer.

Here we show that the sulfur vacancy-rich ML MoS<sub>2</sub> films oxidize already at room temperature, which strongly affects the photoluminescence yield, the MoS<sub>2</sub>-Al<sub>2</sub>O<sub>3</sub> substrate interaction and the structural integrity of the films. We used X-ray photoelectron spectroscopy to monitor the formation of MoO<sub>3</sub> and possibly MoS<sub>2-x</sub>O<sub>x</sub> after exposure to air and to quantify the number of sulfur defects in the films. Atomic force microscopy (AFM) measurements allow us to pinpoint the exact regions of oxidation and to develop a dedicated low temperature heating procedure to remove the oxidized species, leading to MoO<sub>3</sub>-free MoS<sub>2</sub> films. Interestingly, AFM and Kelvin probe force microscopy show that the MoS<sub>2</sub>-Al<sub>2</sub>O<sub>3</sub> substrate coupling is changed, which also affects the ML MoS<sub>2</sub> work function significantly (variations by approximately 300 meV). In addition, the reduction in MoS<sub>2</sub>-substrate coupling leads to a 10-fold increase in the PL intensity, and the ratio between trions and neutral excitons is changed.

Our work highlights the importance of oxidized sulfur vacancies and provides useful methods to measure and manipulate the number of vacancies on MoS<sub>2</sub>. Furthermore, the changes in the MoS<sub>2</sub>-substrate interaction via sulfur vacancies and oxidation offer a new pathway to tune the optoelectronic properties of the 2D films.

#### 8:00 PM EL19.05.03

**Band Alignment Tunability of 2-Layer MoS<sub>2</sub>/SiO<sub>2</sub> Interface with The Use of Inorganic Salts in Liquid-CVD Sulfurization** Alessio Lamperti<sup>1</sup>, Pinaka Pani Tummala<sup>1,2,3</sup>, Alessandro Cataldo<sup>1</sup>, Sara Ghomi<sup>1,4</sup>, Christian Martella<sup>1</sup>, Valeri Afanas'ev<sup>2</sup> and Alessandro Molle<sup>1</sup>; <sup>1</sup>IMM-CNR Agrate Brianza, Italy; <sup>2</sup>KU Leuven, Belgium; <sup>3</sup>Università Cattolica del Sacro Cuore, Italy; <sup>4</sup>Politecnico di Milano, Italy

Among two-dimensional (2D) transition metal dichalcogenides (TMDs), molybdenum disulfide (MoS<sub>2</sub>), in the semiconducting 2H phase, is one of the most extensively studied, because of its stability, versatility, and applicability in several fields, such as electrochemistry, optoelectronics, and microelectronics [1, 2]. To achieve sustainable exploitation of 2D-MoS<sub>2</sub>, a scalable synthesis over large macroscopic areas is required. In this respect, chemical vapor deposition (CVD) is a versatile and cost-effective method to address the deposition of high-quality few-to-single layers MoS<sub>2</sub> with controlled thickness, uniformity and defectivity up to the wafer scale and with satisfactory carrier mobility [3]. Having 2D-MoS<sub>2</sub> based microelectronic devices as target, the electron band alignment at MoS<sub>2</sub>/SiO<sub>2</sub> interface is a key-parameter dictating the electrostatic properties of the stacks such as built-in voltages, transistor thresholds, as well as the tunneling barrier heights. Therefore, the electrostatic control of the MoS<sub>2</sub>/SiO<sub>2</sub> interface, entailing the energy barrier height at the junction and the emergence of interface dipoles, is essential to overcome parasitic or undesired short-channel effects in ultra-scaled field-effect transistors (FETs) based on MoS<sub>2</sub> [1], or to fabricate compliant stacks in ultra-steep sub-threshold slope tunneling FET [4]. Despite previous attempts proved that the use of inorganic salts, such as NaCl, is effective in promoting selective extended 2D-MoS<sub>2</sub> growth [5], no attention has been put on the electrical properties at the MoS<sub>2</sub>/SiO<sub>2</sub> interface. Here, we performed internal photoemission (IPE) spectroscopy, a method successfully applied to 2D layered materials interfacing [6], on large-area (cm<sup>2</sup>) bi-layers MoS<sub>2</sub> directly grown on SiO<sub>2</sub>/Si substrates via liquid precursor CVD (L-CVD) sulfurization, where the ammonium heptamolybdate (AHM) Mo precursor, is provided via solution deposition with inorganic salts (NaCl, NaOH, KCl, KI) spun over the substrate, to assess any possible effect of these inorganic molecules on the MoS<sub>2</sub>/SiO<sub>2</sub> interface properties, in particular to determine the energy band alignment of MoS<sub>2</sub> with SiO<sub>2</sub>. We measured IPE thresholds from 3.9 to 4.2 eV, depending on the type of inorganic salt in solution, which in any case disagrees with the 3.6 eV value obtained in CVD grown MoS<sub>2</sub> from MoO<sub>3</sub> and S powders with the assistance of organic perylene-3,4,9,10-tetracarboxylic acid tetra-potassium salt (PTAS) [7]. To in-depth elucidate the origin of such discrepancy, we performed structural, morphological, and chemical analysis (SEM, AFM, Raman, XPS). For the case of NaOH, we revealed the presence of Na and OH residuals. Our findings are consistent with the emergence of Si-OH dipoles at the interface that individually dependent with each surface treatment in use, thus explaining the observed 0.6 eV energy widening in the IPE threshold.

Our study evidence the impact of the junction characteristics, and thus the need to consider them, on the real electrical behavior of devices integrating 2D materials, with critical implications on proposed models and reported values so far. We also report a relatively easy route to tune the band alignment at 2D-MoS<sub>2</sub>/SiO<sub>2</sub> interface, a fundamental property to consider in the perspective of direct integration of 2D materials in the process flow for microelectronic devices.

This study was supported by the Government of Italy through Ministero dell'Università e della Ricerca (MUR) under the PRIN projects "aSTAR", n. 2017RKWTMY and "PHOTO" n. 2020RPEPNH.

**Galvanic Displacement Across Single-Layer Graphene for The Deposition of Metal Nanoparticles** Isabelle Cunitz and Rohit Karnik; Massachusetts Institute of Technology, United States

This work aims to advance the scientific and engineering understanding of galvanic displacement reactions as buffered by a monolayer of graphene, specifically by investigating palladium deposition on graphene on a copper foil substrate via galvanic displacement between the copper and palladium (II) ions in solution. To understand palladium nanoparticle deposition and determine how this process can be controlled, electrochemical thermodynamics and classical nucleation theory are first synthesized into a thermodynamic model of the system. Next, scanning electron microscopy is used to characterize palladium deposition on the graphene/copper surface after galvanic displacement. Copper etch pits are observed to form during the reaction, maintaining contact between the deposition solution and the copper and thereby ensuring that the reaction is not self-limiting under the conditions studied. Palladium is observed to preferentially deposit along atomic steps in the copper foil, at graphene defects where the copper is exposed to the deposition solution, and at etch pits. The effects of varying palladium concentration and graphene/copper surface treatments are characterized, and these results are synthesized to propose a mechanism of palladium deposition via galvanic displacement through graphene. Finally, galvanic displacement is investigated in a novel engineering application, as a method of sealing graphene defects for the synthesis of centimeter-scale nanoporous atomically thin membranes. Palladium nanoparticles deposited on the graphene surface are observed to largely survive graphene transfer to a support membrane substrate, as well as mounting and

use in aqueous diffusion cell experiments. However, diffusion experiments show that graphene treated via galvanic displacement has higher leakage than untreated graphene, indicating that under the reaction conditions studied here, galvanic displacement has a net effect of graphene defect enhancement rather than defect sealing. This work contributes new insights regarding galvanic displacement as a method of modifying monolayer graphene, as well as exploring this method in the novel application of membrane separations. With further development, this simple, quick, and inexpensive technique for the fabrication of 2D material/nanoparticle composites may have a myriad of applications relevant to sustainability and beyond.

**Substrate Effects on Spin Defects in Two-Dimensional Hexagonal Boron Nitride** Chi-Che Wu and Elizabeth M. Lee; University of California, Irvine, United States

Two-dimensional (2D) hexagonal boron nitride (hBN) is a single atom thick wide band gap semiconductor with high thermal conductivity and chemical stability. Negatively charged boron vacancies ( $V_B^-$ ) in hBN have recently emerged as a promising platform for quantum sensing and quantum information science applications, owing to their long spin coherence times even at room temperature. Here, we investigate electronic structure properties of  $V_B^-$  in 2D hBN on top of solid-state substrates using density functional theory calculations and *ab initio* molecular dynamics simulations. By using substrates ranging from metals (e.g., copper) to insulators (e.g., silica), we discuss how the substrates and their surface chemistry can greatly impact the electronic and mechanical stability of  $V_B^-$ . Our results suggest ways to control the spin defect properties for 2D materials using substrate engineering and surface modification.

#### 8:00 PM EL19.05.06

**Synthesis of V-Doped WTe<sub>2</sub> Nanolayers and Single Crystals** Vera M. Gospodinova<sup>1</sup>, Dimitre Dimitrov<sup>1,2</sup>, Peter Rafailov<sup>2</sup>, Nikola Malinowski<sup>1</sup>, J.F. Sierra<sup>3</sup> and Sergio Valenzuela<sup>3</sup>; <sup>1</sup>IOMT-BAS, Bulgaria; <sup>2</sup>ISSP, Bulgaria; <sup>3</sup>Catalan Institute of Nanoscience and Nanotechnology (ICN2), Spain

The discovery of 2D topological insulator in monolayer 1T'-WTe<sub>2</sub> indicates great potential for novel electronic, spintronic, and quantum metrology. Theoretically, the interaction between the topological states and the magnetic ordered states of Td-WTe<sub>2</sub> enables the modulation of Weyl semimetal states by an external magnetic field and potentially the creation of a quantum anomalous Hall phase [1-3]. However, currently, ferromagnetism in layered 1T'-WTe<sub>2</sub> is still not observed. We are attempting to synthesize nanolayers/flakes of 1T'-WTe<sub>2</sub> with vanadium doping in order to induce magnetism. V-doped WTe<sub>2</sub> nanolayers/flakes were synthesized in an atmospheric pressure CVD (APCVD) quartz tube reactor with three independent thermal zones. LP (liquid precursors) method based on ammonium metatungstate hydrate (AMT) and ammonium metavanadate (AMV) or vanadium(IV) oxide sulfate (VOSO<sub>4</sub>) with addition of PTAS was used for the synthesis. The obtained nanolayers/clusters/flakes were studied by optical microscopy and Raman spectroscopy. In addition, we are reporting growth of V-doped WTe<sub>2</sub> single crystals by using flux (high-temperature solution) method. Particularly the self-flux method was used for crystal growth, and tellurium was used as a solvent (flux). The grown crystals were studied by XRD, XPS and Raman spectroscopy and the typical for WTe<sub>2</sub> X-ray diffraction patterns and Raman modes were observed. Vanadium incorporation (1.8 at. %) in the crystal structure was detected by XPS measurements. The estimated overall elemental composition in at. % confirms the presence of vanadium.

**Photogeneration at a Dirac/Charge-Compensated Semimetal Heterojunction based on Graphene and WTe<sub>2</sub>** Farima Farahmand, Ao Shi and Nathaniel Gabor; University of California, Riverside, United States

The unique photocurrent characteristics of pure semimetal heterojunctions composed of atomically thin materials remains a new frontier in optoelectronics. A novel pairing of a Dirac semimetal and a charge-compensated semimetal provides an opportunity to investigate photogeneration when photo-thermoelectric, photovoltaic, and other important photogeneration effects coexist. We employ near-infrared scanning photocurrent microscopy to investigate the dynamics of photoexcited electrons that control the electrical and optical conductivities at the interface to clarify the heterojunction band alignment between WTe<sub>2</sub> and graphene, which have charge compensated electron-hole bands and a Dirac point, respectively. Our findings highlight the important role that the photo-thermoelectric effect plays in the photocurrent distribution, alongside other phenomena such as the photovoltaic effect that have been seen earlier in p-n junctions. Our measurements not only define the essential photocurrent and band alignment characteristics of this combined Dirac-Weyl system but also provide valuable insights for the design and enhancement of highly sensitive infrared sensors based on van der Waals heterostructures. These discoveries pave the way for exciting advancements in the field of quantum optoelectronics.

#### 8:00 PM EL19.06.02

**Atomic Reconstruction of Large-Lattice-Mismatched Transition Metal Dichalcogenides Heterobilayers into Strained-Commensurate Structures** Seongchul Hong<sup>1</sup>, Ji-Hwan Baek<sup>1</sup>, Yuneong Chang<sup>1</sup>, Hong M. Nguyen<sup>2</sup>, Changheon Kim<sup>1</sup>, Yeonjoon Jung<sup>1</sup>, Hyoengseok Lee<sup>1</sup>, Kenji Watanabe<sup>3</sup>, Takashi Taniguchi<sup>3</sup>, Jangyup Son<sup>4</sup>, Hyeonsik Cheong<sup>2</sup>, Miyoung Kim<sup>1</sup> and Gwan-Hyoung Lee<sup>1</sup>; <sup>1</sup>Seoul National University, Korea (the Republic of); <sup>2</sup>Sogang University, Korea (the Republic of); <sup>3</sup>National Institute for Materials Science, Japan; <sup>4</sup>Korea Institute of Science and Technology, Korea (the Republic of)

Moiré superlattices between vertically stacked van der Waals (vdW) layers with twist angle or lattice mismatch generate periodic moiré potentials, which induce renormalization of electronic band structures and corresponding modulation of electrical and optical properties of moiré crystals. In addition, lots of attentions have been paid for spontaneous atomic reconstruction of small-mismatched vdW layers into periodic commensurate domains separated by incommensurate boundaries because of unprecedented physical properties of these unique vdW layers. Unlike small-mismatched vdW layers, the spontaneous reconstruction has not been observed in large-mismatched vdW layers owing to their large formation energy of commensurate structures. Here, we report thermally induced atomic reconstruction of a large-mismatched MoS<sub>2</sub>/MoSe<sub>2</sub> heterobilayer (lattice mismatch = 3.88%) into a strained-commensurate (SC) heterostructure that has angle- and lattice-matched commensurate domains separated by saddle point (SP) structures through hBN-

encapsulation annealing. We verified that the SP structure has large dilatational and shear strains of 4% and the SC structure exhibited splitting of the intralayer excitons owing to the inhomogeneous strain distribution. Our work verifies that even hetero-bilayers with large lattice mismatches can transform into lattice-aligned heterostructures regardless of twist angle and expands our understanding for electrical and optical properties of vdW heterostructures with new stacking sequences.

#### 8:00 PM EL19.06.03

**A High- $\kappa$  Wide-Gap Layered Dielectric for Two-Dimensional Van der Waals Heterostructures** [Aljoscha Söll](#)<sup>1</sup>, Edoardo Lopriore<sup>2,3</sup>, Asmund Ottesen<sup>2,3</sup>, Jan Luxa<sup>1</sup>, Gabriele Pasquale<sup>2,3</sup>, Jiri Sturala<sup>1</sup>, František Hájek<sup>4</sup>, Vítězslav Jarý<sup>4</sup>, David Sedmidubský<sup>1</sup>, Kseniia Mosina<sup>1</sup>, Andras Kis<sup>2,3</sup> and Zdenek Sofer<sup>1</sup>; <sup>1</sup>University of Chemistry and Technology, Czechia; <sup>2</sup>Institute of Electrical and Microengineering, Switzerland; <sup>3</sup>Institute of Materials Science and Engineering, Switzerland; <sup>4</sup>Institute of Physics of the Czech Academy of Sciences, v.v.i., Czechia

Van der Waals heterostructures of two-dimensional materials have opened up new frontiers in condensed matter physics, unlocking unexplored possibilities in electronic and photonic device applications. However, the investigation of wide-gap high- $\kappa$  layered dielectrics for devices based on van der Waals structures has been relatively limited. In this work, we demonstrate an easily reproducible synthesis method for the rare earth oxyhalide LaOBr, and we exfoliate it as a 2D layered material with a measured static dielectric constant of  $\epsilon_{0,1} \approx 9$  and a wide bandgap of 5.3 eV. Furthermore, our research demonstrates that LaOBr can be used as a high- $\kappa$  dielectric in van der Waals field-effect transistors with high performance and low interface defect concentrations. Additionally, it proves to be an attractive choice for electrical gating in excitonic devices based on 2D materials. Our work demonstrates the versatile realization and functionality of 2D systems with wide-gap and high- $\kappa$  van der Waals dielectric environments.

#### 8:00 PM EL19.06.04

**Synthesis and Characterization of (3D/2D)  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>/Graphene Heterostructure for Application as a Toxic Gas Sensor** [Ariadne C. Catto](#)<sup>1</sup>, Luis F. da Silva<sup>1</sup>, Eduard Llobet<sup>2</sup> and Elson Longo<sup>1</sup>; <sup>1</sup>Federal University of Sao Carlos, Brazil; <sup>2</sup>Universitat Rovira i Virgili, Spain

Metal semiconducting oxides (MOXs) have been widely employed in gas sensors due to their potential features, such as high sensitivity, selectivity, rapid gas detection, and stability. N-type MOXs (e.g. SnO<sub>2</sub>, WO<sub>3</sub>, ZnO, and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>) have been successfully applied as sensing elements in gas sensor devices for the detection of a variety of toxic gases, such as NO<sub>2</sub>, NH<sub>3</sub>, O<sub>3</sub>, and H<sub>2</sub>S. Among the n-type MOXs, hematite ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>) nanostructures have gained attention due to their high oxygen ion mobility at the material surface, excellent chemical and thermal stability under ambient atmosphere, and low cost. Despite its advantages, few studies have investigated the sensing activity of hematite. Therefore, efforts have been paid to improving the sensing performance of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> by using distinct strategies, such as combination with other components including noble metals, semiconductors, and carbon-based materials. Among these, graphene has received considerable attention due to its unique two-dimensional (2D) structure, high electron conductivity and mobility, and high surface area. Also, various MOXs may be combined with GO and/or rGO resulting in a self-assembled heterostructure with unique properties for the most diverse applications. Regarding gas sensing applications, hydrophobic graphene-based materials have been cited as an effective way to be employed in gas sensor devices leading to high sensitivity and selectivity even in high humidity conditions. Motivated by these considerations, we report here a versatile approach towards the production of advanced materials based on (3D/2D)  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>/graphene sheets heterostructure to be applied as a resistive NO<sub>2</sub> gas sensor. The effect of different amounts of addition ratios of graphene on the sensing performance has been studied. The  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>/Gr heterostructures were obtained by hydrothermal method and the crystalline phase, morphological, and surface properties were studied by XRD, FESEM, TEM and XPS techniques. Additionally, we successfully combined experimental and DFT calculations to understand the role played by the heterointerface and the chemical environment along the exposed surfaces  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>/Graphene sheets in the sensing properties towards NO<sub>2</sub> gas. The gas sensing experiments show that the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>/graphene heterostructure gas sensor has better sensing performance for NO<sub>2</sub> than the pristine graphene, such as high response, excellent selectivity, and low detection limit. The effects of temperature and moisture on the NO<sub>2</sub> sensitivity of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>/graphene heterostructures were also investigated. The optimal operating temperature for the highest gas response is around 150 °C, and the formation of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>/graphene heterostructure improved the NO<sub>2</sub> sensitivity against moisture. Furthermore, the selectivity was also evaluated by exposing the heterostructures to different gases such as O<sub>3</sub>, NH<sub>3</sub>, and CO. These findings show that (3D/2D)  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>/Graphene sheets heterostructures have a remarkable potential for practical applications as NO<sub>2</sub> gas sensor in environmental monitoring devices.

#### 8:00 PM EL19.06.05

**High-Performance Self-Powered UV Photodetector Based on NGQD/Graphene Schottky Diode** [Muhammad Shehzad Sultan](#)<sup>1</sup>, Wojciech Jadwisieniczak<sup>2</sup>, Alejandra P Flores Rivera<sup>1</sup>, Brad Weiner<sup>1</sup> and Gerardo Morell<sup>1</sup>; <sup>1</sup>University of Puerto Rico at Río Piedras, United States; <sup>2</sup>Ohio University, United States

Nitrogen doped graphene quantum dots (GQDs) have been widely used for various optoelectronic devices as a photoactive material due to their high absorption coefficient and tunable bandgap. However, the low mobility of NGQD films results in poor charge collection and device performance. By combining NGQDs with graphene into hybrid NGQD/Graphene photodetectors, photocarriers from NGQDs are transferred to graphene, improving charge collection and transport, and drastically increasing the photoresponsivity. In this study, we report the preparation of a NGQD/Graphene heterostructure in order to investigate the effect of NGQD on the photoactive response of graphene. Using UV-vis absorption and photoluminescence (PL) spectra, the optical properties of NGQD/Graphene heterostructure were measured. Moreover, to investigate their electronic and charge transfer properties, we fabricated the photodetectors with pristine graphene quantum dots and NGQD/Graphene heterostructure to analyze and compare their photoactive electrical properties. Under illumination, NGQD/Graphene PD showed an increase in both current and carrier mobility as compared to NGQD PD. The increased current and carrier mobility of NGQD/Graphene PD is due to the presence of a large number of photoexcited charge carriers. This is explained by NGQDs' n-type doping effect on graphene, which reduces the accumulation of holes in the active p-channel near the insulating layer and causes charge to be transferred from the NGQDs to the graphene. As a result, we discovered a charge transfer effect in the NGQD/Graphene heterostructure, which could be used in optoelectronic devices.

SESSION EL19.07: 2D Semiconductors—Quantum Emitters and Dopants  
Session Chairs: Kibum Kang and Andrew Mannix  
Tuesday Morning, November 28, 2023  
Hynes, Level 3, Room 309

#### 8:30 AM EL19.07.01

**Macroscopic Transition Metal Dichalcogenides Monolayers with Uniformly High Optical Quality** [Qiuyang Li](#), Adam Alfrey, Jiaqi Hu, Nathaniel Lydick, Eunice Paik, Bin Liu, Haiping Sun, Yang Lu, Ruoyu Wang, Stephen R. Forrest and Hui Deng; University of Michigan, United States

The unique optical properties of transition metal dichalcogenide (TMD) monolayers have attracted significant attention for both photonics applications and fundamental studies of low-dimensional systems. TMD monolayers of high optical quality, however, have been limited to micron-sized flakes produced by low-throughput and labor-intensive processes, whereas large-area films are often affected by surface defects and large inhomogeneity. Here we report a rapid and reliable method to synthesize macroscopic-scale TMD monolayers of uniform, high optical quality. Using 1-dodecanol encapsulation combined with gold-tape-assisted exfoliation, we obtain monolayers with lateral size  $>1$  mm, exhibiting exciton energy, linewidth, and quantum yield uniform over the whole area and close to those of high-quality micron-sized flakes. We tentatively associate the role of the two molecular encapsulating layers as isolating the TMD from the substrate and passivating the chalcogen vacancies, respectively. We demonstrate the utility of our encapsulated monolayers by scalable integration with an array of photonic crystal cavities, creating polariton arrays with enhanced light-matter coupling strength. This work provides a pathway to achieving high-quality two-dimensional materials over large areas, enabling research and technology development beyond individual micron-sized devices.

#### 8:45 AM EL19.07.02

**Unraveling the Role of Dopant Clustering in Magnetic Impurity Doped Monolayers of Transition Metal Dichalcogenides** Rehan Younas, Guanyu Zhou and Christopher L. Hinkle; University of Notre Dame, United States

Efforts to achieve above room temperature ferromagnetism in monolayers of transition metal dichalcogenides (TMDs) through substitutional doping with magnetic impurities are actively being pursued for energy-efficient logic and memory devices. However, the current limitations stem from phase separation and multi-layered growth at heavy doping levels, restricting the doping in monolayers to levels well below the threshold established by density functional theory (DFT) for above room temperature Curie temperature. On the other hand, room temperature magnetism has been frequently observed at significantly lower doping levels (0.1-1%), but this magnetism arises from a combination of substitutional dopants, point defects, contaminants, interstitials, or edge states. As a result, the origin of purely substitutional doping-induced ferromagnetism remains a subject of debate. Towards this end, this study employs molecular beam epitaxy to achieve up to 30% substitutional doping of vanadium (V) and iron (Fe) in a monolayer of tungsten diselenide, surpassing the doping requirements ( $>15\%$ ) indicated by DFT for room temperature ferromagnetism. Magnetometry measurements, however, reveal the absence of ferromagnetism down to a temperature of 4 K in these phase-pure films, with only the phase-separated films exhibiting any room temperature ferromagnetic behavior at Fe doping levels exceeding 30%. Structural characterization utilizing plan-view transmission electron microscopy reveals significant dopant clustering, even at modest doping levels ( $\sim 5\%$ ), which serves as the primary factor responsible for the absence of ferromagnetism in phase-pure films. Remarkably, these observations align with DFT calculations, which predict a low formation energy for dopant clustering, leading to a weakened exchange interaction that subsequently suppresses ferromagnetism. The insights gained from this exploratory study offer a promising pathway to attain high doping densities in monolayer TMDs while emphasizing the influence of dopant clustering on the magnetic properties of the films.

**Structure-Property Relations of Quantum Emitters in 2D Materials** Su Ying Quek; National University of Singapore, Singapore

Quantum emitters in the form of point defects in 2D materials are of interest as scalable single photon sources for photonics-based quantum technologies. It is important to know the optical signatures of intrinsic defects, but also critical to be able to controllably synthesize quantum emitters with desirable and known optical properties. In this work, we use state-of-the-art first principles calculations to elucidate the structure-property relations of quantum emitters in the wide-band-gap hexagonal boron nitride (hBN) layer, as well as in transition metal dichalcogenide (TMD) monolayers. Defects in hBN can be controllably created by carbon implantation and electron or ion bombardment. We present the photophysical properties of defects derived from boron vacancies and carbon impurities [1], as well as preliminary results on other point defects created by the electron or ion bombardment process. Comparisons are made with recent experiments. In the second part of the talk, we discuss the optical properties of unintended oxygen-related defects and intentional substitutional defects in TMDs. We find that chalcogen vacancies in  $WSe_2$  are readily passivated by oxygen, and oxygen interstitials are a possible source of single photons in  $WSe_2$  [2]. For both Re [3] and Nb dopants in  $WS_2$ , we present theoretical and experimental evidence of optical defect-to-bulk state transitions that partially preserve the valley polarization. We will also touch on preliminary results on THz quantum emitters in TMDs.

#### 9:30 AM EL19.07.04

**Magnetic Fluctuations in V-Doped  $WSe_2$**  Dinh Loc Duong<sup>1,2</sup>, Lan-Anh T. Nguyen<sup>3</sup>, Jinbao Jiang<sup>4</sup>, Tuan Dung Nguyen<sup>3</sup>, Philip Kim<sup>5</sup>, Min-kyu Joo<sup>6</sup> and Young Hee Lee<sup>3</sup>; <sup>1</sup>Department of Physics, Montana State University, United States; <sup>2</sup>Montana State University, United States; <sup>3</sup>Center for Integrated Nanostructure Physics, Institute for Basic Science, Korea (the Republic of); <sup>4</sup>National University of Defense Technology, China; <sup>5</sup>Harvard University, United States; <sup>6</sup>Sookmyung Women's University, Korea (the Republic of)

Vanadium-doped tungsten dichalcogenide (V-doped  $WSe_2$ ) reveals ferromagnetic order at room temperature, which can be controlled by a gate bias. In this presentation, we report electrically tunable magnetic fluctuations associated with RTNs in V-doped  $WSe_2$  at a low doping concentration using vertical tunneling graphene/V- $WSe_2$ /graphene devices. We identify bistable magnetic states from discrete Gaussian peaks of the RTN histogram, which were further confirmed by  $1/f^2$  features in the noise power spectrum. Three fluctuation categories in the resistance change were detected: small changes from the intralayer coupling between magnetic domains at high temperatures, anomalous large resistance changes over a wide range of temperatures, and persistent large resistance changes originating from magnetic interlayer coupling at low temperatures. We demonstrate the switching of the bistable state and further modulate the cut-off frequency of RTNs with bias. The observed electrical switching of a tunable bistable state in magnetic 2D materials can be utilized for low-power spintronics.

#### 9:45 AM EL19.07.05

**Elucidating Ferromagnetic Properties of Fe-Doped  $MoS_2$ ,  $WSe_2$  and  $WS_2$  at Various Temperatures** Mengqi Fang<sup>1</sup>, Hee Suk Chung<sup>2</sup>, Jae Hyuck

Jang<sup>2</sup>, Chunli Tang<sup>3</sup>, Wencan Jin<sup>3</sup> and Eui-Hyeok Yang<sup>1</sup>; <sup>1</sup>Stevens Institute of Technology, United States; <sup>2</sup>Korea Basic Science Institute, Korea (the Republic of); <sup>3</sup>Auburn University, United States

Transition metal-doped transition metal dichalcogenides (TMDs) have attracted significant attention due to their potential for spintronic and magneto-optical applications [1, 2]. By introducing transition metal dopants, such as vanadium [3], rhenium [4], and iron [5, 6], into TMDs, it is possible to create new electronic and magnetic properties, leading to the emergence of diluted magnetic semiconductors (DMS). These DMS materials combine the advantages of semiconductors with ferromagnetic behavior, enabling the development of spintronic devices for efficient information storage and processing [7, 8].

In this study, we present the synthesis and characterization of Fe:MoS<sub>2</sub>, Fe:WSe<sub>2</sub>, and Fe:WS<sub>2</sub> to elucidate their magnetic properties. The Fe-doped TMD materials were synthesized using contact-growth, of which detailed synthesis methods are reported elsewhere [5, 9]. To determine the ferromagnetic properties of synthesized materials, various techniques were employed: The structural and morphological characterizations were carried out using techniques such as optical, atomic force microscopy (AFM), and scanning transmission electron microscopy (STEM), confirming their successful synthesis and the presence of desired structural features. Furthermore, vibrating sample magnetometry (VSM) measurements were performed to determine the macroscopic magnetic properties, including coercivity and saturation magnetization. These measurements indicate that Fe:WSe<sub>2</sub> displays a more pronounced ferromagnetic signal than that from Fe:MoS<sub>2</sub>. Further investigation is needed to gain deeper insights into the underlying mechanisms responsible for these observations.

This research may pave the way for developing novel TMD materials with tailored magnetic properties for low-power spintronics applications and quantum information science.

**Controlling Quasiparticle Excitations in 2D Solids Through Atomically Precise Heterostructures** Alexander Weber-Bargioni and John C. Thomas; Lawrence Berkeley National Laboratory, United States

In this presentation, we investigate how atomically defined heterostructures, such as 2D stacks, 1D boundaries within a 2D material, and 0D vacancies and substitutes in 2D materials, localize new protected states that host quasiparticle excitations. Quasiparticles are emergent excitations in condensed matter systems that behave like particles, but are not elementary particles like electrons or protons. In 2D solids, a wide variety of quasiparticle excitations can be experimentally accessed, including localized electrons, excitons, superconducting states, and polaritons, as well as more exotic systems like Tomonaga Luttinger liquid. Each specific quasiparticle excitation is a result of a specific crystalline symmetry. By inducing atomically defined 0D, 1D, and 2D heterostructures, it is possible to localize, protect, and create novel quasiparticle excitations.

We demonstrate how to engineer heterostructures into 2D Transition Metal Dichalcogenides and visualize the resulting electronic structure using Scanning Tunneling Microscopy. We discuss the resulting quasiparticle excitations that we directly capture using Scanning Tunneling Microscopy, as well as Time Resolved optical Spectroscopy. We show how 0D heterostructures or defects in 2D MoSe<sub>2</sub> and 2D WS<sub>2</sub> carry intrinsic point defects that substantially modify electronic properties. For instance, individual S vacancies create two-level systems within the band gap with extremely high spin-orbit coupling, and can mediate single photon emission via optical or electric stimulation. We also demonstrate how C-H for S or Se substitutes in 2D WS<sub>2</sub> and 2D WSe<sub>2</sub> form locally charged hydrogen-like states. Upon deprotonation, the localized carbon radical hosts a deep in-gap state with a net spin and electron-phonon coupling that is similar to NV color centers in diamond, but with atomistic control. Furthermore, individual Chalcogen Vacancies can be decorated with a variety of different adatoms, creating new types of 0D heterostructures, such as Co-S substitutes that could become relevant for Quantum Information Science.

In 1D heterostructures, such as Mirror Twin Boundaries in MoSe<sub>2</sub> or WS<sub>2</sub>, we discovered atomically thin metallic conductors that undergo a quantum phase transition at low temperature to form a Tomonaga Luttinger Liquid (TTL). TTLs are correlated electron systems, where electrons couple to form a bosonic system, and that can foster partial electron and spin transport.

As a 2D heterostructure, we explore WS<sub>2</sub>/WSe<sub>2</sub> stacks, where we study the formation and recombination channels of interlayer excitons formed in WS<sub>2</sub>/WSe<sub>2</sub> stacks, which may relate to the recently reported formation of excitonic Bose-Einstein condensates. Another fascinating area of research is coupling quasiparticles to form new quasiparticles. By stacking 2D WSe on linear plasmonic cavities, we were able to couple excitons to plasmons, creating plexitons. We use techniques such as photo low-temperature Scanning Tunneling Microscopy, near-field optical microscopy, and low-temperature time-resolved optical spectroscopy to investigate the properties and behavior of these quasiparticle excitations.

### 11:00 AM \*EL19.07.07

**Moiré Minibands, Interlayer Coupling and Hybridization in vdW Stacks from Optical Spectroscopies** Ursula Wurstbauer; University of Münster, Germany

Two-dimensional (2D) materials exhibit unique properties due to their atomically thin structure and weak van der Waals (vdW) coupling between layers. This vdW nature allows for the precise engineering of 2D quantum systems through stacking, twisting, and inducing defects. External stimuli, such as electric or magnetic fields and charge doping, enable in-situ control of these systems.

In this study, we employ advanced optical spectroscopy methods to characterize interlayer coupling, interfacial quality, interlayer hybridization, and miniband formation in twisted vdW homo- and heterobilayers prepared from semiconducting transition metal dichalcogenides (TMDCs) such as MoSe<sub>2</sub> and WSe<sub>2</sub>. Photoluminescence and spectroscopic imaging ellipsometry (SIE) provide insights into the hybridization of band-edge and higher-lying interband transitions [1,2]. Non-resonant Raman spectroscopy is used to study the phonon fingerprint, which is sensitive to interlayer coupling, strain, and doping [3-

4].

Resonant Raman spectroscopy (RRS) is found to be highly sensitive to exciton-phonon coupling [5,6], and electronic Raman known as resonant inelastic light scattering (RILS) allows spectroscopy of Moiré mini-bands by probing collective electronic inter-miniband excitations [7]. Our research aims to deepen our understanding of the interplay between interlayer coupling, hybridization, and mini-band formation in 2D materials. These findings have implications for the design and development of novel quantum devices and applications.

We acknowledge funding by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under projects Wu 637/4- 1, 4 – 2, 7-1 and SPP 2244.

**Overcoming Industrial Challenges in Implementing 2D Materials in CMOS** Byun Kyung-Eun, Minsu Seol, Junyoung Kwon, Alum Jung and Min Seok Yoo; Samsung Advanced Institute of Technology, Korea (the Republic of)

Two-dimensional (2D) transition metal dichalcogenides (TMDs) have received great attention for their potential role as the channel material in electronic devices. Although 2D materials have demonstrated exceptional promise in academic research, significant industrial challenges must be confronted to integrate them into next-generation Complementary Metal-Oxide-Semiconductor (CMOS) technologies. In this talk, we highlight the significant challenges that the industry faces in implementing 2D materials into current semiconductor devices. These include issues related to material synthesis with high-throughput, fast and nondestructive characterization, proper integration processes for TMDs. We'll present the ongoing research about growth, characterization and integration. We demonstrate high-throughput production of 8-inch wafer-scale MoS<sub>2</sub> and WS<sub>2</sub>. Utilizing our TMD, we have successfully achieved the TMD FETs on an 8-inch wafer scale through a conventional CMOS process, demonstrating consistent electrical performance with a high yield of over 99%. Through our research on TMD FET structures, we have achieved remarkable advancements in device performance. We're also accelerating the Lab to Fab transition by using artificial intelligence (AI), which proves beneficial in predicting material behaviors and optimizing processing parameters. The talk will provide insights into the extensive efforts companies are making to navigate these challenges.

SESSION EL19.08: 2D Semiconductors—Synthesis I

**Unconventional vdW Heterostructures Assembled from Bespoke 2D Atomic and Molecular Lattices** Thomas J. Kempa, Reynolds Dziobek-Garrett, Ona Ambrozaite, Yifei Zhu and Dara Weiss; Johns Hopkins University, United States

Quantum materials have the potential to revolutionize sensing, analytical instrumentation, information processing, and energy conversion. Unconventional vdW superlattices assembled from precisely tailored 2D atomic and molecular lattices encode heterointerfaces which can provide an unprecedented control over charge, exciton, and spin states leading to unique artificial quantum solids. Realizing such superlattices requires not only rational, mechanism-driven chemical synthesis of atomically-precise 2D crystals, but also careful optical spectroscopy and device studies for rigorous determination of fundamental properties and intrinsic limits. In this talk I will discuss our key prior achievements and emerging results towards the assembly of these unconventional superlattices. First, we show that innovative surface-treatments and precursor chemistries can dramatically alter the dimensionality, morphology, and defect level of 2D transition metal dichalcogenides (TMD) grown by chemical vapor deposition (CVD). Second, we demonstrate the promise of gas-phase methods for the synthesis of single monolayer 2D molecular lattices (e.g., metal-organic frameworks), and also demonstrate their response to chemical, optical, and electrical stimuli through device transport and scanning probe measurements. Finally, we show that the merger, through direct CVD deposition or exfoliation and transfer, of these 2D crystals yields unique heterointerfaces that can elicit photon upconversion, modulation of lattice phonons, and control of exciton dynamics. Ultimately, the unprecedented array of chemical, dielectric, and mechanical potentials that such superlattices can support open unique opportunities for breakthroughs in optics, sensing, information processing, and sustainability.

**Metalorganic Chemical Vapor Deposition of Epitaxial MoS<sub>2</sub> and WS<sub>2</sub> on Group III-Nitrides** Shalini Kumari, Dorota Kowalczyk, Chen Chen, Nicholas Trainor, Seung H. Lee, Tim Mirabito, Nicholas D. Redwing and Joan M. Redwing; The Pennsylvania State University, United States

Scalable vapor phase deposition methods are rapidly developing enabling epitaxial growth of transition metal dichalcogenides (TMDs) monolayer and few-layer films on wafer-scale substrates. C-plane sapphire has been the primary substrate used so far for TMD epitaxy as it is crystallographically compatible with the hexagonal TMD lattice, is thermally stable at high temperatures and is available in large area at low cost. However, the direct lattice mismatch between the TMDs and sapphire is large and while there is commensurability which reduces the effective mismatch, the lattice off-sets lead to translational line defects between coalescing domains. In contrast, the group III-nitrides (GaN and AlN) are nearly directly lattice matched to MoS<sub>2</sub> and WS<sub>2</sub> making them intriguing substrates for TMDs epitaxial growth. WS<sub>2</sub> and MoS<sub>2</sub> have a lattice mismatch of only 1.1 % and 0.8 % to the lattice parameter of GaN, whereas WS<sub>2</sub> and MoS<sub>2</sub> have a lattice mismatch of only 1.3 % and 1.6 % to the lattice parameter of AlN respectively. In addition, direct growth of TMDs on GaN opens up prospects for novel 2D/3D heterostructures for bipolar and hot electron transistors and optoelectronics.

In this work, we present the growth, structural, and optical properties of fully coalesced MoS<sub>2</sub> and WS<sub>2</sub> monolayer to few layer films grown on GaN and AlN epitaxial templates on sapphire via Metalorganic Chemical Vapor Deposition (MOCVD). Molybdenum hexacarbonyl (Mo(CO)<sub>6</sub>), tungsten hexacarbonyl (W(CO)<sub>6</sub>) and hydrogen sulfide (H<sub>2</sub>S) were used as precursors in a N<sub>2</sub> and H<sub>2</sub> carrier gas for the growth of MoS<sub>2</sub> and WS<sub>2</sub> on 1 x 1 cm<sup>2</sup> GaN and AlN substrates. The relative thermal and chemical stability of GaN and AlN can significantly affect the epitaxial growth of TMDs. For example, in the

absence of  $\text{NH}_3$ , GaN begins to decompose at elevated temperatures in  $\text{H}_2$  while AlN remains relatively stable. Therefore, for TMD growth on GaN, the samples were heated in  $\text{N}_2$  to prevent decomposition and the growth temperature and flow rate/growth rate were tuned to prevent GaN decomposition and pit formation before the  $\text{MoS}_2/\text{WS}_2$  covers the surface. In this study, the growth temperature was varied from 900 to 1000 °C, growth time from 10 to 25 minutes, and molybdenum and tungsten precursor flow rates from 0.0006 to 0.003 sccm whereas the  $\text{H}_2\text{S}$  flow rate was maintained at 400 sccm. All the growths were done with a moderate reactor pressure of 50 Torr using  $\text{N}_2$  and  $\text{H}_2$  as the carrier gas. AFM and FESEM were carried out to characterize the surface coverage and morphology of the layers. Spatially resolved Raman and photoluminescence spectroscopy were used to investigate the uniformity of the growth across the sample. The TMD films were continuous with thicknesses of mono- to few layers although pits were present in films grown on GaN at elevated temperature and reduced growth rate. The presence of  $A_{1g}$  and  $E_{2g}$  Raman modes for  $\text{MoS}_2$  and  $\text{WS}_2$  were observed at room temperature. The  $\text{MoS}_2$  and  $\text{WS}_2$  films exhibit strong photoluminescence at room temperature centered around 1.9 eV and 2 eV respectively. The structural, microscopic, and optical properties of the  $\text{MoS}_2$  and  $\text{WS}_2$  monolayers on GaN and AlN will be discussed in detail in the meeting. We emphasize the opportunities for the compatible integration of 2D/3D TMDs/III-V nitrides heterostructures without any transfer process by a fine-tuned deposition, which can have wide implications for the performance of future electronic and optoelectronic devices.

**Multiscale Structural Analysis of Epitaxially Grown 2D Layers using Four-Dimensional Scanning Transmission Electron Microscopy** [Hanako Okuno](#), Djordje Dosenovic, Samuel Dechamps, Matthieu Jamet and Alain Marty; CEA-Grenoble, France

Epitaxial growth is a route to achieve highly crystalline continuous 2D layers. In recent years, large scale epitaxial growth of graphene and various transition metal dichalcogenides (TMDs) have been demonstrated by many research groups. However, high quality layer production with expected electrical properties is still challenging due to the imperfection of nucleation control. For instance, slight misalignment and symmetrical crystal inversion in neighbouring nucleation sites result in domain junctions, at the stage of coalescence, containing a large number of atomic defects and which drastically degrades material quality. The presence of polymorphs, such as 2H and 1T' in the TMDs, also modifies their electronic properties. In order to control growth process and to predict intrinsic properties of grown material up to wafer scale as a patchwork of defect structures, multiscale structural analysis should be accessible in routine way. X-ray diffraction (XRD) gives a precise information on material quality regarding the crystallinity and the angular distribution at mm scale, while scanning transmission electron microscopy (STEM) imaging offers today the capability to study the detailed local atomic structures such as vacancies, grain boundaries as well as the associated chemical composition at atomic scale. However, these techniques do not reveal complete material characteristics because of the gap in scale between the information obtained by different techniques. Four dimensional (4D)-STEM is a new acquisition technique allowing to simultaneously record 2D images in real and reciprocal spaces. Multiple information, from structure to electric field, at different scales can be reconstructed from signals appearing in diffraction pattern acquired at each pixel of the beam scan. In this work, we demonstrate an analytical process using 4D-STEM to study epitaxial 2D materials grown in both laboratory and industrial scales. Orientation, polarity and phase maps in various TMD monolayers, such as  $\text{WSe}_2$  and  $\text{WS}_2$ , are reconstructed at micron scale from 4D-diffraction datasets and directly correlated with both large scale XRD analysis and related atomic defect structures revealed by STEM imaging. This structural mapping technique allowed the localization of various domain junctions as well as quantitative information on their density. In addition, the technique was also applied in epitaxial vdW heterostructures for mapping local twist angles. The results show the capacity to construct structural overview of synthesized materials from large scale down to atomic scale, which provides reliable information necessary to develop high quality 2D materials and further to enable theoretical prediction of material properties basis on large-scale realistic structure models.

**Understanding Salt-Promoted Metal Organic Chemical Vapour Deposition of Transition Metal Dichalcogenides** Jinfeng Yang, Ryo Mizuta, Ye Fan, Vitaly Babenko and [Stephan Hofmann](#); University of Cambridge, United Kingdom

Scalable integrated process pathways remain a key challenge for ultrathin 2D device materials particularly for potential opto-electronic device applications. For transition metal dichalcogenides (TMDC), the use of salts to enhance chemical vapour deposition (CVD) has become widespread, yet the underpinning understanding remains limited. We employ operando scanning electron microscopy (SEM) and environmental X-ray photoelectron spectroscopy (XPS) to systematically study the role of salt-based growth promoters. We focus on  $\text{WS}_2$  as a model system and explore surface-based mechanisms linked to sodium tungstates, NaOH and NaCl on  $\text{SiO}_2$  and sapphire substrates in conjunction with widely used gaseous (MO)CVD precursors. We report various hot salt substrate corrosion phenomena that lead to the substrate spreading of W intermediates and significantly influence the growth mechanisms. We can directly resolve the formation and wetting behaviour of liquid droplets and show that the growth scenario particularly for mono-layers is not following a vapour-liquid-solid (VLS) model. Holistic calibration of SE contrast allows us to reveal  $\text{WS}_2$  nucleation and in-plane growth kinetics. Our discussion brings together the wider literature including mechanisms of 1D TMDC nanotube formation.

**Modified Self-Flux Synthesis of Centimeter-Scale Transition Metal Dichalcogenides** [Luke Holtzman](#), Madisen Holbrook, Nicholas Olsen, Xiaoyang Zhu, Abhay Narayan Pasupathy, James Hone and Katayun Barmak; Columbia University, United States

Two-dimensional transition metal dichalcogenides (TMDs) are a highly attractive class of materials due to their novel electronic and optoelectronic properties and the ability to use them as a platform for assembling heterostructures. Self-flux crystal growth of TMDs has been shown to grow bulk TMDs with the lowest defect densities of any synthesis technique, maximizing the ability to study their unique, intrinsic phenomena [1-3]. However, the current self-flux crystal growth method produces TMD crystals smaller than  $1 \text{ mm}^2$  on average, making monolayer-exfoliation difficult and limiting applications to single devices. Additionally, these crystals are too small to use macroscopic exfoliation techniques such as gold-assisted exfoliation, which require crystals greater than 2 mm in diameter and can isolate entire monolayers from every layer of a bulk crystal. [4] In this work, we use a modified flux-synthesis thermal cycle containing an optimized dwell temperature and temperature cycling Ostwald ripening to increase the crystal area of ultralow defect density TMDs by more than ten-fold. The crystal growth kinetics as a function of temperature are determined, enabling increased cooling rate steps and shorter synthesis times. An additional post-processing self-flux recrystallization step is added and further increases the crystal size of TMDs and reduces the defect density. Lastly, gold-assisted exfoliation is used to isolate several centimeter-long monolayers from one modified self-flux synthesis  $\text{MoSe}_2$  crystal, displaying monolayer yields per crystal more than five orders of magnitude greater than traditional scotch-tape exfoliation techniques. These self-flux synthesis modifications provide a route towards reproducibly exfoliating ultralow defect density TMD monolayers at the centimeter scale with high yields, greatly increasing the scalability of high-quality self-flux TMD bulk crystals for mass production.

### 3:30 PM EL19.08.07

**Wafer-Scale Fabrication of Extremely Narrow Nanowires of 2D Materials** Quynh Sam<sup>1</sup>, Qishuo Tan<sup>2</sup>, Mehrdad Kiani<sup>1</sup>, Xi Ling<sup>2</sup> and Judy Cha<sup>1</sup>; <sup>1</sup>Cornell University, United States; <sup>2</sup>Boston University, United States

Many van der Waals (vdW) layered two-dimensional (2D) materials host exotic transport phenomena such as topologically protected surface states<sup>1</sup> and quantum Hall effects<sup>1</sup> which exhibit strong size dependence at nanoscale dimensions.<sup>2</sup> When formed into 1D nanowires, additional materials property engineering via lateral confinement can be achieved.<sup>3</sup> The tunability of 2D materials with nanowire morphology makes them an attractive platform for studying fundamental physics and for use in next generation microelectronics; however, reliable fabrication methods that can produce narrow nanowires with high aspect ratios are currently lacking.<sup>1</sup>

Here, we report the thermomechanical nanomolding (TMNM) of bulk vdW layered materials to make nanowires with consistent crystal orientation, narrow widths under 40 nm, and high aspect ratios. In TMNM, elevated temperatures and pressures are used to extrude a material through a nanoporous mold to form nanostructures.<sup>4</sup> Until now, TMNM has been reported for metallic glasses and 3D crystalline materials to form 1D nanowires.<sup>4</sup> We demonstrate the use of this technique to successfully fabricate nanowires with widths ranging from 10 – 120 nm of four vdW layered materials: Te, In<sub>2</sub>Se<sub>3</sub>, Bi<sub>2</sub>Se<sub>3</sub>, and Bi<sub>2</sub>Te<sub>3</sub>. Atomic resolution scanning transmission electron microscopy (STEM) imaging shows the high crystalline quality of the molded nanowires. While the molding direction was perpendicular to the layer planes in the bulk crystal, crystal rotation occurs during TMNM such that the layers consistently lie along the growth axis of the molded nanowire. We find that the length of the nanowires increases with decreasing width during molding, suggesting that interfacial diffusion along the pores of the mold is the growth mechanism. This work expands the capabilities of TMNM as a straightforward approach to fabricate nanowires of 2D materials with uniform morphology and crystallographic orientation. Furthermore, lateral confinement of the nanowires afforded by TMNM provides an additional tuning knob for materials properties.

### 3:45 PM EL19.08.08

**Effects of Nucleation Temperature on the Properties of Wafer-Scale Epitaxial WS<sub>2</sub> on Sapphire Grown by Metalorganic Chemical Vapor Deposition** Chen Chen<sup>1</sup>, Nicholas Trainor<sup>1,1</sup>, Shalini Kumari<sup>1,1</sup>, Nicholas D. Redwing<sup>1,1</sup>, Yuxi Zhang<sup>1,1</sup>, Anuj Bisht<sup>1</sup>, Stephen Revesz<sup>2</sup>, Synda Labidi<sup>2</sup>, Meghan E. Leger<sup>1,1</sup>, Thomas V. McKnight<sup>1,1</sup>, Andrew R. Graves<sup>1</sup>, Hebin Li<sup>2</sup>, Nasim Alem<sup>1,1</sup> and Joan M. Redwing<sup>1,1</sup>; <sup>1</sup>The Pennsylvania State University, United States; <sup>2</sup>Florida International University, United States

Wafer-scale epitaxial growth of single crystal TMD monolayers is of significant interest to advance 2D device applications. MOCVD is a promising approach for TMD growth on c-plane sapphire as it enables the use of high substrate temperatures (800-1000°C) and chalcogen/metal ratios (10<sup>3</sup>-10<sup>5</sup>) which are beneficial for epitaxy. Previously we reported a multi-step process for MOCVD growth of WS<sub>2</sub> on sapphire which involves nucleation, ripening and lateral growth. The nucleation temperature was found to be crucial for achieving single orientation domains and coalesced layers with minimal inversion domain boundaries. In this study, we report the effects of nucleation temperature and film microstructure on the resulting optical and electrical properties of the monolayers.

Coalesced WS<sub>2</sub> monolayers were grown on 2" diameter c-plane sapphire in a cold-wall horizontal MOCVD reactor with an inductively heated graphite susceptor with gas-foil wafer rotation. W(CO)<sub>6</sub> was used as the metal precursor while H<sub>2</sub>S was the chalcogen source with H<sub>2</sub> as the carrier gas at 50Torr reactor pressure. The multi-step process consisted of a 30sec nucleation at temperatures ranging from 800°C to 950°C followed by 10min ripening in H<sub>2</sub>S, and then lateral growth for 20min at 1000°C, which gives rise to a coalesced monolayer across the entire 2" wafer. After growth, the substrate was cooled in H<sub>2</sub>S to 300°C to inhibit the decomposition of the obtained WS<sub>2</sub> films.

A coalesced monolayer of WS<sub>2</sub> was achieved on 2" c-plane sapphire over the nucleation temperature ranges from 800°C to 950°C. AFM indicates that the WS<sub>2</sub> monolayers are fully coalesced, with a bilayer coverage of less than 20%. Interestingly, stripe-pattern contrasts due to variations in the adhesion of the WS<sub>2</sub> monolayer to the underlying sapphire were observed under FESEM and the density of stripes increased as the nucleation temperature was raised from 800°C to 950°C. In-plane XRD *phi*-scans confirm that the films are epitaxially oriented with respect to the sapphire over the nucleation temperatures from 800°C to 950°C with the (11-20) of WS<sub>2</sub> aligned with the (11-20) of  $\alpha$ -Al<sub>2</sub>O<sub>3</sub>. The FWHM of both the *phi*-scan peak and *2theta*-scan peak of WS<sub>2</sub> decreased as the nucleation temperature was reduced. The sample nucleated at 800°C demonstrated the lowest FWHM of  $\sim 0.26^\circ$  in the *phi*-scan peak, indicating larger crystalline domains and reduced in-plane rotational misorientation of the WS<sub>2</sub> domains compared to the higher temperature samples. Room temperature photoluminescence measurements of the films on sapphire reveal an increase in the PL peak position from 1.9eV to 2.0eV as the nucleation temperature was increased from 800°C to 950°C.

The variations in the structural and optical properties of the WS<sub>2</sub> films with nucleation temperature are attributed to differences in the extent of coupling of the WS<sub>2</sub> to the underlying sapphire. The WS<sub>2</sub> grown at 800°C nucleation temperature exhibits the strongest coupling to the underlying sapphire as evidenced by the narrow FWHM of the in-plane XRD *phi*-scan peak, the lack of stripe contrast from buckling in the FESEM image and the red-shift in the PL peak indicating residual strain in the layer. In contrast, the WS<sub>2</sub> grown at 950°C nucleation temperature exhibits weaker coupling consistent with buckling contrast in the FESEM image, a broader FWHM for the XRD *phi*-scan peak and a PL peak at 2.0eV. To test this hypothesis, the films were transferred from the growth substrates and onto sapphire to remove the coupling arising from epitaxy. For the transferred WS<sub>2</sub> film grown at 800°C, a substantial increase in the PL intensity and a blueshift in the PL peak position to 1.95eV were observed, indicating a reduction in strain within the film after the transfer process. Additional results correlating the structural and optical properties of the WS<sub>2</sub> monolayers to the transport properties of field-effect devices will be reported.

**Large-Area Epitaxial Hexagonal Boron Nitride for Hydrogen Generation by Radiolysis of Interfacial Water** Johannes Binder, Aleksandra Dabrowska, Mateusz Tokarczyk, Katarzyna Ludwiczak, Rafal Bozek, Grzegorz Kowalski, Roman Stepniewski and Andrzej Wyszomolek; Faculty of Physics, University of Warsaw, Poland

Hydrogen is an important building block in global strategies toward a future green energy system. To make this transition possible, intense scientific efforts are needed, also in the field of materials science. Hexagonal boron nitride (h-BN) is a very promising candidate for such applications, as it has been demonstrated that micrometer-sized flakes are excellent barriers to molecular hydrogen. However, it remains an open question whether large-area layers

fabricated by industrially relevant methods preserve such promising properties.

We address this issue and show results on the growth of epitaxial h-BN on 2-inch sapphire wafers by metalorganic vapour-phase epitaxy (MOVPE) [1-5], which is currently regarded as one of the most promising growth techniques. This technique allows to grow hBN layers, with thicknesses of tens of nm [1,3], and can serve as a substrate for the direct growth of van der Waals heterostructures on the wafer-scale [4].

In this work, we show that electron-beam-induced splitting of water creates hBN bubbles that effectively store molecular hydrogen for weeks [5]. The bubble formation can be observed in-situ in a scanning electron microscope, giving us the unique possibility to visualize the hydrogen generation process. Raman spectroscopy proves the presence of molecular hydrogen and experiments with heavy water provide evidence that hydrogen generation is triggered by the radiolysis of water captured at the van der Waals interface. By performing a stress test we could also demonstrate that H<sub>2</sub> remains in the bubble even after extreme wear and deformation (over 500 cycles of deflation and inflation by changing the ambient pressure), highlighting the suitability of our large-area epitaxial material for possible hydrogen storage applications.

Our findings show that epitaxial h-BN by MOVPE is not only a potential candidate for the growth of large-area van der Waals heterostructures and hydrogen storage but also holds promise for the development of unconventional hydrogen production schemes [5].

**2D-3D Heterostructures for Low Power Logic and Memory Devices** [Deep M. Jariwala](#); University of Pennsylvania, United States

The isolation of a growing number of two-dimensional (2D) materials has inspired worldwide efforts to integrate distinct 2D materials into van der Waals (vdW) heterostructures. While a tremendous amount of research activity has occurred in assembling disparate 2D materials into “all-2D” van der Waals heterostructures and making outstanding progress on fundamental studies, practical applications of 2D materials will require a broader integration strategy. I will present our ongoing and recent work on integration of 2D materials with 3D electronic materials to realize logic switches and memory devices with novel functionality that can potentially augment the performance and functionality of Silicon technology. First, I will present our recent work on gate-tunable diode and tunnel junction devices based on integration of 2D chalcogenides with Si. I will extend that work to synthesizing high quality, homogenous phase 2D materials at back end of line compatible temperatures for logic applications. Following this I will present our recent work on non-volatile memories based on Ferroelectric Field Effect Transistors (FE-FETs) made using a heterostructure of MoS<sub>2</sub>/AlScN and also introduce achieving ambipolarity and low contact resistance with a highly polar ferroelectric material.

**Surface Modifications and Hydrophilic Transformations of Hydrophobic InSe 2D Materials for Biological Applications** [Shreyasi Sengupta](#)<sup>1</sup>, Swapnil B. Ambade<sup>1</sup>, Tana L. O’Keefe<sup>2</sup>, Christy L. Haynes<sup>2</sup> and Zeev Rosenzweig<sup>1</sup>; <sup>1</sup>UMBC, United States; <sup>2</sup>University of Minnesota Twin Cities, United States

Nanosheets are solid, layered two-dimensional nanostructures having properties unique and different from their bulk precursors, due to which they find potential applications in various fields. Our material of interest is InSe due to its many advantages, especially because it is an emerging material for electronic applications and is a direct bandgap semiconductor with high photoresponsivity. Usage of InSe and other 2D materials is expected to increase exponentially in the next decade. However, their unique morphology and ability to produce reactive oxygen species (ROS) can be detrimental to the environment. To address this environmental concern, our studies aim to understand the impact of surface chemistry modifications on the stability and interactions of these 2D materials with model membranes and bacterial organisms relevant to human health and the environment. Initially hydrophobic InSe nanosheets are synthesized by a facile kinetically controlled semi-bottom-up approach and are subsequently made hydrophilic and suitable for biological studies by surface modifications with different molecular ligands having varying toxicity via physisorption or chemisorption. A comparative study of the toxicity profiles of the differently modified hydrophilic InSe nanosheets is performed on *Shewanella oneidensis* MR-1, an environmentally relevant gram-negative bacterium. The goal is to understand the post-use fate of these materials on their disposal to the natural aqueous environment and design surface modification strategies to make them safer and sustainable for extensive environmental use. From a fundamental science perspective, this study should increase the molecular-level understanding of the interactions between hydrophobic 2D materials and their hydrophilic adsorbates.

#### 8:00 PM EL19.09.03

**Physical Adsorption and Oxidation of Ultra-Thin MoS<sub>2</sub> Crystals** [Yingchun Jiang](#), Zihan Liu, Huimin Zhou, Anju Sharma, Jia Deng and Changhong Ke; Binghamton University, The State University of New York, United States

The oxidation mechanism of atomically thin molybdenum disulfide (MoS<sub>2</sub>) is critical to its nanoelectronics, optoelectronics and catalytic applications as these devices dissipate Joule heating and often operate in oxidative environments. Herein, we systematically investigate the oxidation of mono- and few-layer MoS<sub>2</sub> flakes in air with temperature of 23–525 °C and relative humidity of ~10–60% using atomic force microscopy (AFM), Raman spectroscopy and X-ray photoelectron spectroscopy. Our study reveals the formation of a uniform nanometer-thick physical adsorption layer on the surface of MoS<sub>2</sub>, which is attributed to the adsorption of ambient moisture. This physical adsorption layer acts as a thermal shield of the underlying MoS<sub>2</sub> lattice to enhance its thermal stability and can be effectively removed by an AFM tip scanning in contact mode or annealing at 400 °C. Our study also shows that high-temperature thermal annealing and AFM tip-based cleaning result in chemical adsorption on sulfur vacancies in MoS<sub>2</sub>, leading to p-type doping. Our study

highlights the importance of humidity control in ensuring reliable and optimal performance for MoS<sub>2</sub>-based electronic and electrochemical devices and provides crucial insights into the surface engineering of MoS<sub>2</sub>, which are also relevant to the study of other two-dimensional transition metal dichalcogenide (TMD) materials and their applications.

#### 8:00 PM EL19.09.05

**Graphene Origami: Evolution of the Morphology of Free-Standing Few-Layer Graphene in Plasma Synthesis** Claudia-F. Lopez Camara, Paolo Fortugno, Markus Heidelmann, Hartmut Wiggers and Christof Schulz; University of Duisburg-Essen, Germany

Since discovered, graphene has shown to be a very versatile material due to its unique properties, which makes it suitable to multiple applications, ranging from sensing to batteries. Even though free-standing graphene flakes have traditionally been synthesized using exfoliation techniques, interest on gas-phase synthesis is on the rise due to its suitability for process scale-up and for generating graphene with very low oxygen content. Yet, the growth of free-standing few-layer graphene (FLG) during plasma synthesis leads to a variety of morphologies, such as turbostratic graphene (typically less than ten graphene layers), and the growth mechanism is essentially unknown.

Using spatially resolved thermophoretic sampling directly from the area of the graphene formation zone for transmission electron microscopy (TEM) analysis, we studied the morphology of graphene flakes in different growth stages. Single-layer and few-layer graphene were observed, and a morphology pattern evolution was discerned depending on time and reaction conditions. Based on these investigations, we propose a folding-based growth and structure formation process, leading to a conceptual mechanism of few-layer graphene formation and growth, starting from initial round single-layer graphene to, eventually, carbonaceous nanoparticles. The edges resulting from the folding have also been investigated, revealing that graphene does not seem to break at the bends but fold similar to rolling up carbon nanotubes and without opening new reactive sites for further growth.

#### 8:00 PM EL19.09.06

**Breathable MOFs Layer on Atomically Grown 2D SnS<sub>2</sub> for Stable and Selective Surface Activation** Ji-Soo Jang; Korea Institute of Science and Technology, Korea (the Republic of)

Two-dimensional (2D) materials (MoS<sub>2</sub>, SnS<sub>2</sub>, MXene, black phosphorus (BP), and graphene oxide) with intriguing physicochemical properties such as abundant reactive edge-sites, tunable electrical properties, and mechanical flexibility, have been developed for broad applications in chemical sensing, electrocatalysis, filtration membrane, and energy storage system.[1] Among various 2D materials, SnS<sub>2</sub> (IV-VI A group), which is a semiconducting layered structure with a large bandgap of ~2.2 eV and has many advantages (low-cost, nontoxic, and environmental friendly properties), can be catered well into the broad applications.[2] Based on these interesting material properties of SnS<sub>2</sub>, 2D SnS<sub>2</sub> is widely used as active surface reactor with rapid, sensitive, and selective surface reactivity to various molecules including ions, gases, and biomolecules. Even though the outstanding and exceptional characteristics of SnS<sub>2</sub> has been proved in many previous studies, its poor stability due to oxidation and degradation issues under the ambient operation conditions limits the practical usage of SnS<sub>2</sub>.

In this work, we newly developed 'Sandwich' like hybrid materials platform, 2D SnS<sub>2</sub> layer covered by uniformly porous ZIF-8, employing in-situ growing methods. First of all, the 2D SnS<sub>2</sub> layer (1st layer) was directly grown on the Si based sensor substrate through ALD method, and as such, strong bonds between active material (SnS<sub>2</sub> in this case) and the sensor substrate are able to be formed. Then, the in-situ growing of ZIF-8 was followed on the heterogeneous SnS<sub>2</sub> layers, so the defect free ZIF-8 covered the whole SnS<sub>2</sub> layers. The top-side of ZIF-8 membrane and bottom-side SnS<sub>2</sub> play critical role for molecular sieving and chemical detection, respectively. Due to the uniform pore distribution of ZIF-8 layer on the SnS<sub>2</sub> sensing layer, H<sub>2</sub>O molecules can be reliably blocked by ZIF-8 breathable layer, while target NO<sub>2</sub> molecules can selectively penetrate through the ZIF-8 layer. Therefore, our hybrid materials exceptionally showed high stability and selective surface activity from the chemical sensing case study and the underlying mechanisms were further investigated in the atomistic level using theoretical calculations.

**High-Throughput Production of an Atomically Thin Nano-Dot Array for Enhanced Exciton-Exciton Interactions** Jeongin Yeo<sup>1</sup>, Seungjae Lim<sup>2</sup>, Taewan Kim<sup>2</sup>, Jae-Ung Lee<sup>2</sup> and Joonki Suh<sup>1,1</sup>; <sup>1</sup>Ulsan National Institute of Science and Technology, Korea (the Republic of); <sup>2</sup>Ajou University, Korea (the Republic of)

Monolayer transition metal dichalcogenides (TMDs) are an appealing material platform for investigating and manipulating excitonic properties in the atomically thin limit due to their intrinsic strong Coulomb interactions and alleviated screening effects. To date, a number of such studies have been conducted to determine the excitonic physics or control their dynamics by diverse experimental approaches including electrostatic gating, magnetic field manipulation and strain engineering. However, physically confined excitonic transport through nanostructuring is not handled yet. Herein, we introduce a high-throughput nanofabrication of laterally confined monolayer TMDs in a hexagonal array. The fabricated nanodots of monolayer TMDs are approximately 20 nm wide far below typical exciton diffusion length of monolayer TMDs. We then investigated their photoluminescence (PL) characteristics by performing a series of power, wavelength (2.25~2.82 eV), and temperature dependent measurements. We observed the unconventional emission in sub-20 nm WS<sub>2</sub> nanodots, which is presumably associated with the physically confined excitonic transport behavior and reconstructed band structure. This platform is suitable tool for understanding of confined quasi-particle transport behavior and size-dependent PL study, providing a broader insight for fundamental excitonic many-body interactions and related dynamics.

#### 8:00 PM EL19.09.08

**A Practical Hydrogenated Graphene Gas Sensor for CO<sub>2</sub> Monitoring** Solimar Collazo<sup>1,1</sup>, Samuel Escobar<sup>1,2</sup>, Brad Weiner<sup>1,1</sup> and Gerardo Morell<sup>1,1</sup>; <sup>1</sup>University of Puerto Rico at Río Piedras, Puerto Rico; <sup>2</sup>National Institute of Standards and Technology, United States

The development of a practical gas sensor is of great interest for monitoring toxic and non-toxic gases that might endanger our safety and wellbeing in different settings. Here, we present a gas sensor based on hydrogenated graphene for monitoring carbon dioxide (CO<sub>2</sub>). Hydrogenated graphene was synthesized using a single-step method directly onto an insulating substrate plated with gold. The material was characterized using Raman spectroscopy, X-ray photoelectron spectroscopy (XPS), and X-ray diffraction (XRD). The interaction of the hydrogenated graphene with CO<sub>2</sub> was systematically studied at different parts per million (PPM) to determine the detection limits of the sensor. Our results show that the hydrogenated graphene-based sensor is capable of sensing CO<sub>2</sub> at mid-PPM levels with a CO<sub>2</sub> responsivity of -176.21. The biosensor was also found to detect CO<sub>2</sub> at low ppm values, making it suitable for use as a biosensor for aerobic cellular respiration and regular CO<sub>2</sub> emission sensing. We have successfully developed a versatile and practical gas sensor based on hydrogenated graphene for CO<sub>2</sub> monitoring. The sensor's detection limits, and responsivity make it suitable for a wide range of applications, including monitoring of CO<sub>2</sub> emissions and aerobic cellular respiration. The simplicity of the synthesis method used also makes it a promising candidate for large-scale production.

SESSION EL19.10: Poster Session IV: 2D Materials—Epitaxial and Van der Waals Heterostructures

**Van der Waals Heterostructures Containing Group-III Chalcogenides** Michael Altwater<sup>1,2</sup> and Nicholas Glavin<sup>1</sup>; <sup>1</sup>Air Force Research Lab, United States; <sup>2</sup>UES, Inc., United States

The group-III chalcogenides are an emerging class of van der Waals semiconductors with potential for applications in electronics, optoelectronics, and photonics. Further, material properties such as work function and band gap vary dramatically as the material is thinned toward the 2D limit. In this talk, we present experimental studies of the electronic and optical properties of van der Waals heterostructures containing the layered group-III chalcogenides. We analyze the effect of charge transfer within the structure as a function of layer thickness and compare the electronic performance with the more common TMD-based heterostructure devices.

**8:00 PM EL19.10.02**

**Self-Catalyzed Vapor-Liquid-Solid Growth of GaS Nanobelt** Yukihiko Endo, Yoshiaki Sekine and Yoshitaka Taniyasu; NTT Basic Research Laboratories, Japan

Among group-III chalcogenides, which are atomic-layered semiconductors, GaS shows a large layer-number-dependent bandgap energy from 2.5 eV (bulk) to 3.4 eV (monolayer) corresponding to blue and ultraviolet light wavelengths, respectively [1]. This unique property makes it a promising material for photonic devices and water-splitting photocatalysts [2, 3] and also an important component for group-III chalcogenide heterostructures. Furthermore, 1D structures of 2D layered materials, nanobelt or nanoribbon, would enable novel quantum devices and nanodevice integration. In this work, we demonstrate the synthesis of GaS nanobelt by means of self-catalyzed vapor-liquid-solid (VLS) growth.

GaS was grown on a sapphire wafer by metalorganic chemical vapor deposition (MOCVD). Triethylgallium (TEGa) and diethylsulfide (DES) were used as Ga and S sources, respectively. VLS growth of 1D GaS-nanobelts occurs from Ga clusters, which can be formed under a Ga-rich surface growth condition obtained at high [TEGa]/[DES] supply ratios, while 2D GaS layers are grown at low [TEGa]/[DES] supply ratios. Thus, the dimension of the GaS structure can be controlled by MOCVD growth conditions.

To evaluate the optical quality of the GaS nanobelt, we fabricated a photodetector (width: 900 nm, thickness: 100 nm, channel length: 2  $\mu\text{m}$ ). A photocurrent was generated under light irradiation with photon energies larger than 2.5 eV (wavelengths shorter than 500 nm), corresponding to the bandgap energy of GaS. The dark current was lower than the detection limit of our measurement system. A high ON/OFF ratio (> 1000) at a wavelength of 400 nm was obtained at the applied voltage of 10 V. This good photoresponsivity indicates that the VLS-grown GaS nanobelt has a high enough quality for device operation. The development of high-quality 1D GaS nanobelt synthesis on a wafer opens up opportunities for group-III chalcogenide nanodevice applications as well as the exploration of novel quantum phenomena.

Fuchs<sup>8</sup>, Christian Schueller<sup>8</sup> and P. C. Christianen<sup>3</sup>; <sup>1</sup>Universidade Federal de São Carlos, Brazil; <sup>2</sup>Universidade Federal do Ceará, Brazil; <sup>3</sup>Radboud University, Netherlands; <sup>4</sup>Wroclaw University of Science and Technology, Poland; <sup>5</sup>University of Exeter, United Kingdom; <sup>6</sup>Brazilian Center for Research in Energy and Materials (CNPEM), Brazil; <sup>7</sup>University of Antwerp, Belgium; <sup>8</sup>Universität Regensburg, Germany

Twisted van der Waals (vdW) heterostructures exhibit periodic variations, leading to a new type of in-plane superlattice known as moiré superlattice/pattern which modifies considerably the optical properties of excitons in transition metal dichalcogenides (TMD) vdW heterostructures. Here, we report on optical and magneto-optical properties of WS<sub>2</sub>/MoSe<sub>2</sub> heterobilayers with twist angles around 0° and 60° under out-plane magnetic fields up to 20 T [1]. We observed two neutral exciton peaks in the PL spectra: the lower energy one exhibits a reduced g-factor relative to that of the higher energy peak, and much lower than the recently reported values for interlayer excitons in other vdW heterostructures such as WSe<sub>2</sub>-MoSe<sub>2</sub>. In addition, similar values of g-factors are obtained for samples with twist angles of approximately 0° and 60° which indicates a weak hybridization between the intralayer and interlayer excitons for this heterostructure. Furthermore, time resolved PL experiments reveal that the lifetimes of the moiré exciton emission peaks are much shorter (< 50 ps) than the values reported in the literature for the interlayer excitons in other TMD heterostructures ( $\approx$  2 ns), which also indicates a weak exciton hybridization. The observed reduction of the g-factor value for the moiré exciton was explained by the quantized center-of-mass momentum of the moiré-confined exciton resulting in a exciton momenta value away from the exciton band edge. In general, our experimental and theoretical results provide evidence that such a discernible g-factor stems from the spatial confinement of the exciton in the potential landscape created by the moiré pattern, due to lattice mismatch and/or inter-layer twist in heterobilayers [1].

**8:00 PM EL19.10.05**

**Fabrication of Graphene/WC/SiC Heterostructures and its Electronic Properties** Kohei Otsuka<sup>1</sup>, Takahiro Ito<sup>1</sup>, Akira Endo<sup>2</sup> and Wataru Norimatsu<sup>3</sup>; <sup>1</sup>Nagoya University, Japan; <sup>2</sup>University of Tokyo, Japan; <sup>3</sup>Waseda University, Japan

Graphene can be grown by thermal decomposition of SiC and other carbides, which means that we can easily fabricate graphene/carbide heterostructure [1]. In this study, we focus on tungsten carbide (WC) as the carbide. Recently, it is found that Hexagonal WC is one of the topological semimetals, and it has attractive properties such as Fermi-arc surface states, negative magnetoresistance, and dHvA oscillations [2,3]. In graphene/topological semimetal heterostructures, nonlocal resistance originating from spin-polarized carriers has been observed, which is expected to be applied to spintronics [4]. Therefore, fabrication of graphene/WC heterostructures is expected to enable us to observe new electronic properties.

In this study, we fabricated graphene/WC/SiC heterostructure and investigate the electronic properties. Highly crystalline WC thin films were formed on 4H-SiC single-crystal substrates by pulsed laser deposition (PLD). Then, graphene was fabricated by thermal decomposition of the films. The fabricated graphene/WC/SiC samples were characterized by some measurements. The electronic state of the samples was measured by angle-resolved photoemission

spectroscopy (ARPES). Transport measurements of WC/SiC and graphene/WC/SiC samples were also performed at low temperatures.

4H-SiC (000-1) single crystal substrate ( $5 \times 5 \text{ mm}^2$ , on-axis, CREE) was used as a substrate. The WC thin film was fabricated by the PLD method. Then, the substrate was heated at  $1100^\circ\text{C}$  for 10 minutes. The resulting WC thin film was heated at  $1750^\circ\text{C}$  for 10 minutes in a vacuum to fabricate graphene. Reflection high-energy electron diffraction (RHEED), atomic force microscopy (AFM), Raman spectroscopy, X-ray photoelectron spectroscopy (XPS), transmission electron microscopy (TEM), ARPES, and low-temperature transport measurements were performed on the prepared samples.

From the High-resolution TEM images after WC deposition, we observed a WC thin film deposited on the SiC substrate with a thickness of about 7 nm. Analysis of the electron diffraction showed that the relationship of the orientation between hexagonal WC and SiC substrate was  $(0001)_{\text{WC}} // (000-1)_{\text{SiC}}$  and  $[11-20]_{\text{WC}} // [11-20]_{\text{SiC}}$ .

ARPES measurements of the graphene/WC/SiC sample showed band dispersions of graphene and bulk WC. Furthermore, we observed a band near the  $\Gamma$  point of WC, which we cannot explain by the band structure of graphene and bulk WC. We think the band originate from the surface state of WC or the interface interaction between graphene and WC.

Transport measurements indicate that superconductivity of WC/SiC and graphene/WC/SiC sample. We estimated the transition temperature ( $T_c$ ) of WC/SiC is about 1.8-2.2 K. We found that graphene/WC/SiC has smaller  $T_c$  than WC/SiC.

##### Quasi Van der Waals Epitaxy of Cadmium Telluride on 2D Materials Enguerrand Tourard; CEA Leti, France

Cadmium telluride is a key material for many technologies, such as energy production or infrared sensing, which makes the growth of free standing (strain free) layers of CdTe of particular interest. In 2017, Kim et al demonstrated that it is possible to guide the growth of a material through one or few monolayers of 2D material, given that the polarity of the substrate below the 2D material is strong enough. This technique, called “remote epitaxy”, has been applied successfully to a wide range of III-V / 2D systems, such as the epitaxial growth of GaN on hBN / GaN substrate, or GaAs on Graphene / GaAs substrate. Epitaxially grown layers are then easily transferred and the 2D coated substrate can be re-used for future growths. Despite this great success with III-V materials, remote epitaxy of II-VI semiconductors hasn’t been studied much. From a purely theoretical point of view, CdTe with its higher ionicity than GaAs or GaN should be a good candidate for remote epitaxy. However, a transfer step is required to obtain 2D coated substrates, with its lot of difficulties (polymeric contamination, degradation of the 2D surface, oxidation of the substrate...), whereas high quality surface and interface are required to perform remote epitaxy.

Another approach to bypass the need of 2D material transfer would be to perform epitaxy on a reconstructed passivated surface. It has been proven recently (Jovanovic et al, 2020) that sapphire could act as a quasi van der Waals substrate for such a growth of CdTe via the in-situ formation of a monolayer of tellurium at the interface. In such a case, the substrate surface, free from dangling bonds, allows for an easy transfer of the epitaxially grown CdTe membrane. But, unlike with “remote epitaxy”, growth is not seeded by the polar substrate, and one can ask what is the impact on the crystalline quality of the epilayer?

In this communication, we will present the results of MBE grown CdTe film on both sapphire and graphene wet-transferred onto CdZnTe. The crystalline quality of the grown CdTe film is discussed based on SEM, AFM and X-ray diffraction. Graphene quality is checked out prior and after epitaxy based upon Raman spectroscopy. Additional XPS analysis were performed to evaluate substrate oxidation and graphene cleanliness. Results of CdTe layer removal and manipulation will also be presented.

##### Edge-Contacted In-Plane Mixed-Dimensional Heterostructures from Monolayer MoS<sub>2</sub> and Low-Dimensional Mo/Te Compounds Hyeonkyeong Kim, Young Chul Kim, Yeong Hwan Ahn and Youngdong Yoo; Ajou University, Korea (the Republic of)

Mixed-dimensional heterostructures formed by combining 2D materials and other dimensional (0D, 1D, and 3D) materials have attracted attention due to their hybrid structures. However, in-plane mixed-dimensional heterostructures have been rarely investigated. Here, we report a novel sequential chemical vapor deposition method for synthesizing in-plane mixed-dimensional heterostructures composed of monolayer MoS<sub>2</sub> and low-dimensional molybdenum/tellurium (Mo/Te) compounds. The composition, dimension, and phase of the Mo/Te compounds interfaced with the monolayer MoS<sub>2</sub> were determined by adjusting the Te flux and growth time. While in-plane 2D/1D MoS<sub>2</sub>/Mo<sub>6</sub>Te<sub>6</sub> and 2D/2D/1D MoS<sub>2</sub>/2H MoTe<sub>2</sub>/Mo<sub>6</sub>Te<sub>6</sub> heterostructures were synthesized with a low Te flux, in-plane 2D/2D MoS<sub>2</sub>/mixed 2H-1T' MoTe<sub>2</sub> and 2D/2D MoS<sub>2</sub>/2H MoTe<sub>2</sub> heterostructures were obtained with a high Te flux. We performed scanning photocurrent microscopy measurements for studying the transport properties and the electronic band structures of the devices fabricated with in-plane mixed-dimensional 2D/2D/1D MoS<sub>2</sub>/2H MoTe<sub>2</sub>/Mo<sub>6</sub>Te<sub>6</sub> heterostructures. The composition-, dimension-, and phase-controlled synthesis method developed in this study will allow large-scale controlled fabrication of edge-contacted mixed-dimensional in-plane heterostructures.

#### 8:00 PM EL19.10.08

##### Atomic-Layer-Deposited Wide Bandgap Metal Oxide Buffer Layers on the Eco-Friendly Thin Film Photovoltaics Cheng-Ying Chen<sup>1</sup>, I-Jui Hsieh<sup>2</sup> and Pochun Chen<sup>2</sup>; <sup>1</sup>National Taiwan Ocean University, Taiwan; <sup>2</sup>National Taipei University of Technology, Taiwan

In this work, atomic layer deposition (ALD) is conducted for growing Wide Bandgap Metal Oxides (ZnSnO) as buffer layers on p-type selenium (Se) absorbers, which was used in the first solid-state solar cell in 1883 and has a high absorption coefficient and mobility, making it a p-type absorber for wide energy gap (~1.8~2.0 eV) thin film solar cells. In addition, direct bandgap, earth-abundance, simple composition, non-toxicity, low melting point and environmental stability make Se inexpensive and developable for solar cells. However, in the n-type buffer layer perspective, so far, has not been found a suitable buffer layer for modulating conduction band offset (CBO) between n-type buffer layers and p-type Se absorbers.

The benefit for using ALD growth ZnSnO can be summarized the as following points: (1) ZnSnO is wide band gap material (~3.2eV); (2) Controllable of Zn and Sn ratio, which can intentionally modulate the CBO become spike type (i.e.,  $0 < \text{CBO} < 0.5 \text{ eV}$ ); (3) ALD can effectively growth larger scale of thin-film and precisely control the thickness. Finally, the result presented the Zn<sub>1-x</sub>Sn<sub>x</sub>O ( $x=7\%$ ) under the optimization of ZnO and SnO ratio, the power conversion efficiency can be achieved at about 2.68%.

#### 8:00 PM EL19.10.09

##### Coherently Stacked Van der Waals Semiconductor Heterostructures Jong Yun Choi<sup>1,2</sup>, Hyun Je Cho<sup>1,2</sup>, Suk-Ho Lee<sup>1,2</sup>, Geonho Mun<sup>1,2</sup>, Heon-Su

Ahn<sup>1,2</sup>, Hwang-Jung Chang<sup>1,2</sup>, Hyunjin Jung<sup>2,3</sup> and Moon-Ho Jo<sup>1,2</sup>; <sup>1</sup>Center for Van der Waals Quantum Solids, IBS (Institute of Basic Science), Korea (the Republic of); <sup>2</sup>Pohang University of Science and Technology, Korea (the Republic of); <sup>3</sup>Center for Artificial Low Dimensional Electronic Systems, Institute for Basic Science (IBS), Korea (the Republic of)

We report atomically coherent layer-by-layer epitaxial growth of MoS<sub>2</sub>/WS<sub>2</sub> van der Waals (vdW) heterostructure with metal-organic chemical vapor deposition (MOCVD) which enables vertical stacking of atomically thin semiconductors without interlayer atomic mixing. Engineering the miscut angle of c-plane sapphire substrate, we first achieved the epitaxial growth of single crystalline WS<sub>2</sub> monolayer (ML) template as base layer. Single crystalline texture was confirmed by microscopies and transmission electron microscope (TEM) studies. Moreover, low energy electron diffraction (LEED) measurements at several different points perfectly exhibited 3-fold symmetry without any angle deviation. We also demonstrated coherent ML-by-ML epitaxial growth of MoS<sub>2</sub> on top of single crystalline WS<sub>2</sub> film. VdW epitaxy is kinetically controlled in the near-equilibrium limit, resulting in the tunable two-dimensional (2D) vdW electronic systems. Coherent monolayer stacking was verified by transmission electron microscope studies and optical characterization. Our AA'(2H) and AB(3R) stacked MoS<sub>2</sub>/WS<sub>2</sub> heterostructures showed strong interlayer coupling. Furthermore, electronic and optoelectronic properties of coherent vdW heterostructures were obtained. Our work suggests synthetic material platform of various 2D coherent heterostructures for future application in electronic and photonic nano devices.

**Metalorganic Chemical Vapor Deposition of Wafer-Scale Transition Metal Dichalcogenide Monolayer and Heterostructures** [Joan M. Redwing](#); The Pennsylvania State University, United States

Wafer-scale synthesis of transition metal dichalcogenide (TMDs) monolayers is of significant interest for device applications to circumvent size limitations associated with the use of exfoliated flakes. Metalorganic chemical vapor deposition (MOCVD) has emerged as a promising technique for scalable synthesis of TMD films as it enables growth at high temperatures and chalcogen overpressures which are beneficial for epitaxy and provides good control over precursor flux which is necessary for the synthesis of heterostructures.

Our work has focused on MOCVD growth of epitaxial semiconducting TMDs (MoS<sub>2</sub>, WS<sub>2</sub> and WSe<sub>2</sub>) on 2" diameter c-plane sapphire substrates. Metal hexacarbonyls (Mo(CO)<sub>6</sub>, W(CO)<sub>6</sub>) and hydrides (H<sub>2</sub>S, H<sub>2</sub>Se) are used as precursors with H<sub>2</sub> as the carrier gas in cold-wall MOCVD reactor geometries. Pre-annealing the sapphire surface in H<sub>2</sub>S or H<sub>2</sub>Se modifies the nucleation behavior of TMDs on sapphire which is attributed to passivation of dangling bonds on the sapphire surface. Passivation of step terraces can drive nucleation to occur preferentially at step edges on sapphire leading to unidirectional domains and a concomitant reduction in mirror twin defects. In situ spectroscopic ellipsometry is demonstrated to be an effective real time monitor of TMD growth even at the sub-monolayer level which can be exploited to track surface coverage as a function of time under varying growth conditions. The ability to precisely control and modulate precursor flux during growth is used to synthesize in-plane heterostructures that enable localized exciton confinement and emission.

#### 9:00 AM EL19.11.03

**Growth of Width-Controlled Single Atomic Layer TMD Nanoribbons** [Xufan Li](#) and Avetik R. Harutyunyan; Honda Research Institute USA Inc., United States

Controlling the width of single atomic layer transition metal dichalcogenides (TMDs) offers additional degree of freedoms for engineering their properties aiming applications in fields for next generations of optoelectronics, quantum computing, communication, and sensing. However, direct width-controlled synthesis of TMD nanoribbons, especially for the appealing width range below 30 nm, remains challenging. Therefore, developing facile methods for their direct and controllable synthesis is of central importance. We present a new growth method for single and double atomic layer of TMD nanoribbons with width down to sub-10 nm. Nanoribbons are grown via precipitation from the pre-deposited nanoparticles via vapor-liquid-solid mechanism in which the nanoparticle diameter also controls the width of nanoribbon. We also present the evolution of electrical and optical properties of the nanoribbons with their width reduction due to the corresponding dimension confinement and the results of their performance in the quantum electronics, particularly as a single electron transistor and single photon emitter.

#### 9:15 AM \*EL19.11.04

**The Impact of Boron and Nitrogen Isotopes on the Properties of Hexagonal Boron Nitride** [James H. Edgar](#), Eli Janzen and Thomas Poirier; Kansas State University, United States

Hexagonal boron nitride (hBN) is a two-dimensional dielectric material prized for its potential electronic, optoelectronic, and nanophotonic device applications. Here we describe how its properties are affected by changing its boron and nitrogen isotopes. hBN consists of 20% <sup>10</sup>B and 80% <sup>11</sup>B, and 99.6% <sup>14</sup>N and 0.4% <sup>15</sup>N when it is synthesized from sources with the natural distribution of isotopes (hBN<sup>nat</sup>). Isotopic disorder is greatly reduced when hBN is synthesized using an isotopically enriched boron source, either <sup>10</sup>B or <sup>11</sup>B. Consequently, the phonon polariton propagation length and lifetimes are increased by factors of eight and four times in monoisotopic hBN crystals. Due to reduced phonon scattering, the thermal conductivity is also increased, by as much as 50% to 650 Wm<sup>-1</sup>K<sup>-1</sup> for h<sup>10</sup>BN at room temperature. Reducing the density of nuclear spin density motivates the synthesis of hBN with the <sup>15</sup>N isotope: <sup>14</sup>N and <sup>15</sup>N have nuclear spins of 1 and ½ respectively. Thus, the DC sensitivity of the boron vacancy V<sub>B</sub><sup>+</sup> to magnetic fields is increased by a

factor of four with  $h^{10}B^{15}N$  over  $hBN^{nat}$ .

These hBN crystals with controlled isotope concentrations were grown at atmospheric pressure from molten metal solutions of nickel, chromium, and enriched boron in contacted with nitrogen gas at 1550 °C. By slow cooling (1-4 °C/h), hBN is synthesized and its crystals precipitate on the surface of the metal. This technique produces high quality hBN crystals, as indicated by their narrow  $E_{2g}$  Raman peak widths ( $<3 \text{ cm}^{-1}$  for  $h^{10}BN$ ) and strong photoluminescence intensities at energies great than 5.75 eV. This is a versatile, scalable technique for making high quality, large area, hBN single crystals with low residual impurity concentrations.

#### 10:15 AM EL19.11.06

**High Crystalline Quality  $PtSe_2$  Films for High Frequency Optoelectronics** Pierre Legagneux and Eva Desgue; Thales Research & Technology, France

Transition metal dichalcogenides (TMDs) are very attractive two-dimensional materials for optoelectronic applications, due to their various and tunable bandgaps, to the strong light-matter interaction per 2D layer and to the possibility to transfer and integrate these 2D materials on CMOS or photonic platforms.

While the most well-known TMDs ( $MoS_2$ ,  $WSe_2$ , ...) exhibit a bandgap in the visible range,  $PtSe_2$  is an original and remarkable TMD particularly adapted for optoelectronics in the infrared (IR) domain. It exhibits a bandgap varying from 1.2eV (monolayer) to 0.2eV (bilayer) and becomes semi-metallic from few layers to bulk. Thus,  $PtSe_2$  absorption can be easily tuned to absorb IR light by varying its thickness from two to multilayers.

$PtSe_2$  is air stable and particularly adapted for high-frequency optoelectronics with a very high theoretical ( $4000 \text{ cm}^2/\text{V.s}$ ) and a high experimental (e.g.  $\sim 200 \text{ cm}^2/\text{V.s}$ ) carrier mobility at room temperature (Note that larger mobilities are reported in the literature which remain however difficult to measure due to the difficulty to estimate actual carrier concentration in semimetal multi-layered  $PtSe_2$ ).

Due to its high intrinsic qualities,  $PtSe_2$  is studied to fabricate high frequency photodetectors operating at the 1.55  $\mu\text{m}$  telecom wavelength. Based on transferred thin  $PtSe_2$  films grown by CVD, 17 GHz bandwidth photodetectors have been fabricated on a  $SiO_2/Si$  substrate and 35 GHz bandwidth waveguide photodetectors have been realized on a silicon nitride platform.

High frequency optoelectronics requires both efficient photodetection and high-speed transport and thus materials exhibiting high crystalline quality.  $PtSe_2$  has been synthesized by mechanical exfoliation, CVD, thermally assisted conversion and molecular beam epitaxy (MBE). To evaluate  $PtSe_2$  crystalline quality, most groups have studied the full width at half maximum (FWHM) of the in-plane Eg Raman peak and shown that thinner is the Eg peak, higher is the crystalline quality and the electrical conductivity.

Here, we have studied the growth of high quality  $PtSe_2$  by MBE on sapphire, which is a low cost, insulating substrate and have fabricated high frequency optoelectronic devices on 2 inches sapphire substrates. We show 8-nm thick  $PtSe_2$  films exhibiting average FWHM Eg values as low as  $3.7 \text{ cm}^{-1}$  and electrical conductivities as high as 1.5 mS. Integrated in a coplanar wave guide, we demonstrated 1.55  $\mu\text{m}$  photodetectors with a 60 GHz bandwidth and optoelectronic mixers exhibiting a flat response between 1 and 30 GHz. Optoelectronic mixing is a key technical enabler for future broadband and multifunctional RF systems such as radio-over-fiber communication systems, radar systems, and satellite payloads.

To further increase  $PtSe_2$  crystalline quality, we are studying two methods: step-guided epitaxy and van der Waals epitaxy. Step-guided epitaxy on sapphire consists in growing on dedicated vicinal surfaces to favor the oriented nucleation of the crystals at the step edges (this method has been demonstrated by other groups for  $MoS_2$  and  $WS_2$  on sapphire). We will also show first results targeting van Der Waals (vdW) epitaxy of  $PtSe_2$  on h-BN.

#### 10:30 AM EL19.11.07

**Reproducible Synthesis of Ultrahigh-Quality Graphene by Oxygen-Free Chemical Vapor Deposition** Xingzhou Yan<sup>1</sup>, Jacob Amontree<sup>1</sup>, Christopher DiMarco<sup>1</sup>, Pierre Levesque<sup>2</sup>, Tehseen Adel<sup>3</sup>, Madisen Holbrook<sup>1</sup>, Christian Cupo<sup>1</sup>, Dihao Sun<sup>1</sup>, Kenji Watanabe<sup>4</sup>, Takashi Taniguchi<sup>4</sup>, Cory Dean<sup>1</sup>, Angela R. Hight Walker<sup>3</sup>, Katayun Barmak<sup>1</sup>, Richard Martel<sup>2</sup> and James Hone<sup>1</sup>; <sup>1</sup>Columbia University, United States; <sup>2</sup>Université de Montréal, Canada; <sup>3</sup>National Institute of Standards and Technology, United States; <sup>4</sup>National Institute for Materials Science, Japan

Progress in translating advances in the growth of graphene films by chemical vapor deposition (CVD) to applications has been hindered by challenges in quality and reproducibility, as well as the lack of a simple model of growth kinetics. Here we show that eliminating trace oxygen leads to fast and highly reproducible CVD graphene growth. The dependence of growth rate on growth time, temperature, and  $CH_4$  pressure follow straightforward trends, while previously unobserved behavior is seen for  $H_2$  pressure. A compact kinetic model is constructed to describe the graphene growth behavior, which can be used to guide graphene synthesis. We confirm that ppm-level oxygen disrupts growth by etching the graphene edges, and map the boundary between growth and etching in the presence of  $H_2$ . We demonstrate that trace oxygen causes two major sources of disorder in CVD-grown graphene: pinholes and amorphous carbon deposition. Finally, we grow epitaxial graphene on sapphire-supported  $Cu(111)$  films. The graphene shows few wrinkles, no evidence of amorphous carbon, and an ultra-low defect density. After dry transfer and device assembly, this graphene shows electrical transport behavior virtually indistinguishable from that of exfoliated graphene, both at room temperature and at low temperature.

#### 10:45 AM \*EL19.11.08

**In-Situ TEM of Atomic Reconstructions in 2D Transition Metal Dichalcogenides** Yichao Zhang<sup>1</sup>, Chia-Hao Lee<sup>1</sup>, Ji-Hwan Baik<sup>2</sup>, Huijie Ryu<sup>2</sup>, Gillian Nolan<sup>1</sup>, Gwan-Hyong Lee<sup>2</sup> and Pinshane Y. Huang<sup>1</sup>; <sup>1</sup>University of Illinois at Urbana-Champaign, United States; <sup>2</sup>Seoul National University, Korea (the Republic of)

Scanning transmission electron microscopy (STEM) provides uniquely powerful tools to study the interfacial structure and transformations of 2D materials up to atomic resolution. Here, we utilize 2D multilayer stacks to create nanoscale laboratories for studying the atomic structure, structural transformations, and properties of 2D interfaces inside the STEM. We utilize graphene encapsulation in combination with a MEMS-based heating holder to conduct in-situ studies of solid-solid phase transformations and interfacial restructuring in 2D transition metal dichalcogenides. The graphene encapsulation protects the 2D materials from the vacuum environment of the STEM, enabling high temperature studies up to 1000°C. We use these structures to directly visualize the layer-by-layer phase transformation of  $MoTe_2$  and the lattice reconstruction of 2D moiré.

First, we study the interfacial reconstruction mechanisms of twisted bilayer transition metal dichalcogenides ( $MoSe_2$  and  $WSe_2$ ) using *in situ* aberration-corrected STEM and dark-field transmission electron microscopy (DFTEM). We discover a new mechanism of local reconstruction from moiré patterns to parallel (3R) and/or antiparallel (2H) domains in twisted bilayer 2D transition metal dichalcogenides (TMDCs). Unlike previous reports, where the twist angle is altered by the rotation of a whole flake, we observe the nucleation and growth of commensurate domains through the formation and migration of grain boundaries. We capture the dynamic process of nucleation and growth of the aligned structure through a series of atomic resolution STEM images combined with atom-tracking analysis. These results provide new insights into the mechanisms of interlayer rotation at the atomic scale and potential methods for engineering the structure of moiré superlattices.

Second, we examine the atomic mechanisms of phase transitions of  $MoTe_2$ .  $MoTe_2$  exhibits multiple structural and electronic phases at room temperature (2H, 1T', and  $T_d$ ) that can be easily manipulated with different stimuli, making it a promising candidate for phase-change memories, high-performance transistors, and broadband photodetectors. We combine dark-field TEM and aberration-corrected STEM to image the phase transitions of few-layer  $MoTe_2$

*in situ* from the micro- to atomic scales. We find that  $T_d$ -to-2H phase transitions initiate at the phase boundary at temperatures as low as 200-225 C, much lower than previously thought. The 2H- $T_d$  interfaces propagate primarily along the b-axis of the  $T_d$  grain, producing an anisotropic, layer-by-layer phase transformation. These results should lead to new methods to manipulate the quantum and electronic properties within individual atomic layers.

#### SESSION EL19.12: Quantum Applications of 2D Materials

Session Chair: Andrew Mannix

##### 1:30 PM EL19.12.01

**Giant Magnetoresistance of Dirac Plasma in High Mobility Graphene** Alexey Berdyugin<sup>1,2</sup>, Na Xin<sup>1</sup>, James Lourebam<sup>1</sup>, Piranavan Kumaravadeivel<sup>1</sup>, Alexander Kazantsev<sup>1</sup>, Zefei Wu<sup>1</sup>, Ciaran Mullan<sup>1</sup>, Julien Barrier<sup>1</sup>, Alexandra Geim<sup>1</sup>, Irina Grigorieva<sup>1</sup>, Artem Mishchenko<sup>1</sup>, Alessandro Principi<sup>1</sup>, Vladimir Falko<sup>1</sup>, Leonid Ponomarenko<sup>3</sup> and Andre Geim<sup>1</sup>; <sup>1</sup>The University of Manchester, United Kingdom; <sup>2</sup>National University of Singapore, Singapore; <sup>3</sup>The University of Lancaster, United Kingdom

The most recognizable feature of graphene's electronic spectrum is its Dirac point, around which interesting phenomena tend to cluster. At low temperatures, the intrinsic behaviour in this regime is often obscured by charge inhomogeneity but thermal excitations can overcome the disorder at elevated temperatures and create an electron-hole plasma of Dirac fermions. The Dirac plasma has been found to exhibit unusual properties, including quantum-critical scattering and hydrodynamic flow. However, little is known about the plasma's behaviour in magnetic fields. Here we report magnetotransport in this quantum-critical regime. In low fields, the plasma exhibits giant parabolic magnetoresistivity reaching more than 100 per cent in a magnetic field of 0.1 tesla at room temperature. This is orders-of-magnitude higher than magnetoresistivity found in any other system at such temperatures. We show that this behaviour is unique to monolayer graphene, being underpinned by its massless spectrum and ultrahigh mobility, despite frequent (Planckian limit) scattering. With the onset of Landau quantization in a magnetic field of a few tesla, where the electron-hole plasma resides entirely on the zeroth Landau level, giant linear magnetoresistivity emerges. It is nearly independent of temperature and can be suppressed by proximity screening, indicating a many-body origin. Clear parallels with magnetotransport in strange metals and so-called quantum linear magnetoresistance predicted for Weyl metals offer an interesting opportunity to further explore relevant physics using this well defined quantum-critical two-dimensional system.

##### 1:45 PM EL19.12.02

**Two-Fold Anisotropic Superconductivity in Bilayer  $T_d$ -MoTe<sub>2</sub>** Zizhong Li<sup>1</sup>, Apoorv Jindal<sup>2</sup>, Alex Strasser<sup>3</sup>, Yangchen He<sup>1</sup>, David Graf<sup>4</sup>, Wenkai Zheng<sup>4</sup>, Kenji Watanabe<sup>5</sup>, Takashi Taniguchi<sup>6</sup>, Luis Balicas<sup>4</sup>, Xiaofeng Qian<sup>3</sup>, Abhay Narayan Pasupathy<sup>2</sup> and Daniel A. Rhodes<sup>1</sup>; <sup>1</sup>University of Wisconsin Madison, United States; <sup>2</sup>Columbia University, United States; <sup>3</sup>Texas A&M University, United States; <sup>4</sup>National High Magnetic Field Laboratory, United States; <sup>5</sup>NIMS, Japan; <sup>6</sup>Kyoto University, Japan

Non-centrosymmetric 2D superconductors offer an opportunity to explore superconducting behaviors with large values of anisotropy. Among the non-centrosymmetric families,  $T_d$ -MoTe<sub>2</sub> is a representative material because of its rich phases. Notably,  $T_d$ -MoTe<sub>2</sub> is the first 2D materials that demonstrated a coupling between ferroelectricity and superconductivity, and this ferroelectric switching can be simply controlled by electrical gating. Here, we will present on the superconducting behavior in bilayer  $T_d$ -MoTe<sub>2</sub> under the application of an applied magnetic field along different directions in-plane and under differing displacement fields and doping densities. Importantly, we find that bilayer  $T_d$ -MoTe<sub>2</sub> has two-fold symmetric superconducting behavior as a function of in-plane magnetic field angle that maximizes along the a-axis, parallel to the mirror plane. The two-fold anisotropy is preserved in the entire superconducting region, even with the interaction of strong Rashba spin-orbit coupling, and we find that the two-fold symmetric superconductivity exists after the ferroelectric switching. Our findings generally agree with previously observed results in multilayer and monolayer  $T_d$ -MoTe<sub>2</sub> and the expected spin-orbit enhanced upper critical fields as found in DFT calculations.

##### 2:00 PM \*EL19.12.03

**Few-layer 2M and  $T_d$ -TMDs: Topologically Nontrivial States, Superconductivity and Ferroelectricity** Apoorv Jindal<sup>1</sup>, Amartyajyoti Saha<sup>2</sup>, Zizhong Li<sup>3</sup>, Yangchen He<sup>3</sup>, Takashi Taniguchi<sup>4</sup>, Kenji Watanabe<sup>4</sup>, James Hone<sup>1</sup>, Turan Biroli<sup>2</sup>, Rafael Fernandes<sup>2</sup>, Cory Dean<sup>1</sup>, Abhay Narayan Pasupathy<sup>1</sup> and Daniel A. Rhodes<sup>3</sup>; <sup>1</sup>Columbia University, United States; <sup>2</sup>University of Minnesota, United States; <sup>3</sup>University of Wisconsin - Madison, United States; <sup>4</sup>National Institute for Materials Science, Japan

I will discuss our most recent results on superconductivity in bilayer  $T_d$ -MoTe<sub>2</sub>. For bilayer  $T_d$ -MoTe<sub>2</sub> the influence of an electrostatic gate allows us to identify a unique superconducting state that relies on Fermi surface nesting between hole and electron pockets. As a result, we show that the superconducting state can be completely quenched by an electrostatic gate. Concomitant to this effect, ferroelectricity resulting from interlayer sliding is also present in bilayer  $T_d$ -MoTe<sub>2</sub>, resulting in a hysteretic behavior of superconductivity with respect to an applied out-of-plane electric field. This behavior allows for the first investigations of how internal polarization might conflict with or enhance superconductivity in the two-dimensional limit. Time allowing, I will discuss our results on a similarly structured TMD in the few-layer limit, the topologically nontrivial 2M-WSe<sub>2</sub>.

##### 2:30 PM BREAK

##### 3:30 PM EL19.12.04

**Van der Waals Josephson Junctions for 2D Superconducting Qubits** Jesse Balseley<sup>1</sup>, Xuanjing Chu<sup>1</sup>, Jinho Park<sup>1</sup>, Ethan Arnault<sup>2</sup>, Martin V. Gustafsson<sup>3</sup>, James Hone<sup>1</sup> and Kin-Chung Fong<sup>3</sup>; <sup>1</sup>Columbia University, United States; <sup>2</sup>Massachusetts Institute of Technology, United States; <sup>3</sup>Raytheon BBN Technologies, United States

State-of-the-art superconducting qubits currently face numerous materials-limited roadblocks to increasing coherence times for fault-tolerant computing while shrinking form factors for scalability. Two-dimensional van der Waals (vdW) materials offer an ideal platform to circumvent these issues owing to their single-crystallinity, low defect density, and lack of dangling bonds. In particular, the vdW semiconductor WSe<sub>2</sub>—whose band gap is ~5x smaller than that of vdW insulator hBN—can exhibit tunneling through ~10 layers, enabling Josephson junctions with exceptional tunnel barrier homogeneity and lower loss compared to deposition-grown junctions by confining fields in ultra-clean vdW interfaces while achieving 100x smaller qubit area. We characterize the electronic properties of vdW Josephson junctions with ultra-high-purity WSe<sub>2</sub> barriers and discuss their potential in small-footprint, long-coherence-time superconducting qubits.

**3:45 PM EL19.12.05**

**Field-Free Superconducting Diode Effect in Fe(Se,Te) Van der Waals Josephson Junctions** Gang Qiu<sup>1,2</sup>, Hung-Yu Yang<sup>1</sup>, Lunhui Hu<sup>3</sup>, Huairuo Zhang<sup>4</sup>, Chi-Yen Chen<sup>5</sup>, Yanfeng Lyu<sup>6</sup>, Peng Deng<sup>1</sup>, Sergiy Krylyuk<sup>4</sup>, Albert V. Davydov<sup>4</sup>, Ruixing Zhang<sup>3</sup> and Kang L. Wang<sup>1</sup>; <sup>1</sup>University of California, Los Angeles, United States; <sup>2</sup>University of Minnesota, United States; <sup>3</sup>The University of Tennessee, Knoxville, United States; <sup>4</sup>National Institute of Standards and Technology, United States; <sup>5</sup>National Sun Yat-sen University, Taiwan; <sup>6</sup>Nanjing University of Posts and Telecommunications, China

Iron-based high-Tc FeTe<sub>x</sub>Se<sub>1-x</sub> (FTS) has been proposed to host unconventional superconductivity. Recent scanning probe and ARPES experiments imply spontaneous time-reversal symmetry breaking in FTS systems. In this work, we report the field-free superconducting diode effect in FTS van der Waals Josephson junctions (vJJ). Non-reciprocal superconducting critical current can be observed in the absence of external magnetic field, which directly manifests spontaneous time-reversal symmetry breaking in FTS systems. The polarity and efficiency of the diode effect are also stochastic, which can be randomly reset by performing a thermal cycle above the superconducting critical temperature T<sub>c</sub>. This suggests the time-reversal symmetry breaking ordering is closely tied to the superconducting states. The stochasticity also provides insights into ferromagnetic domain behaviors of superconducting surface states.

**4:00 PM EL19.12.06**

**2D-Material-Based Superconducting Quantum Devices** Xuanjing Chu<sup>1</sup>, Jesse Balgley<sup>1</sup>, Jinho Park<sup>1</sup>, Ethan Arnault<sup>2</sup>, Martin V. Gustafsson<sup>3</sup>, James Hone<sup>1</sup> and Kin-Chung Fong<sup>3</sup>; <sup>1</sup>Columbia University, United States; <sup>2</sup>Massachusetts Institute of Technology, United States; <sup>3</sup>Raytheon BBN Technologies, United States

Two-dimensional van der Waals (vdW) materials are promising platforms for superconducting quantum devices due to their single-crystallinity, low defect density, and lack of dangling bonds. Additionally, vdW materials offer a novel knob of gate-tunable electronic properties, including carrier density and superconducting gap energy, and can be readily combined into quantum device heterostructures such as Josephson junctions (JJs). JJs made from vdW materials can boast homogeneity across large (~1000 μm<sup>2</sup>) areas making them practical as novel sub-THz JJ emitters whose frequency can be tuned with a gate voltage as opposed to changing the bias current. We characterize the dc and microwave electronic properties of vdW materials and show they are compatible with high-quality-factor superconducting quantum devices. We also present numerical calculations of the emitting properties of gate-tunable Josephson junctions based on vdW superconductors and semiconductors and show that they can meet desirable performance criteria, including narrow linewidths < 1 MHz and appreciable output power at the microwatt level.

**4:15 PM \*EL19.12.07**

**Probing Complex Many-Body Interactions in 2D Heterostructures** Jyoti Katoch; Carnegie Mellon University, United States

Two-dimensional (2D) materials provide unprecedented opportunity to engineer their physical properties by modification to the electronic structure utilizing external perturbations- strain, gating, adsorbates, defects, twist-angle, and interface engineering. This is expected to cause changes to the Hamiltonian describing the system and has resulted in exotic phenomena such as superconductivity, bound quasiparticles, topological states as well as magnetic phases, with implications for novel electronics and spin-device applications. In this talk, I will present our work on directly visualizing (without any assumption) the electronic structure of atomically thin systems utilizing *in-operando* angle-resolved photoemission spectroscopy with nanoscale spatial resolution (nanoARPES) on 2D heterostructures and their fully functional devices. I will present the experiments which demonstrate on-demand tuning of the electronic band structure in atomically thin systems, such as transition metal dichalcogenides (TMDs) and graphene, by varying the twist-angle between the atomic layers and external dopants. Specifically, I will discuss the electric field tuning of the electronic interactions that result in van Hove singularity and flat bands in twisted bilayer graphene and twisted double bilayer graphene heterostructures. In addition, I will discuss our results where we observe the formation of quasiparticle polarons due to many-body interactions in graphene/TMDs heterostructures.

**4:45 PM EL19.12.08**

**Polymer-Free Assembly of Van der Waals Heterostructures** Wendong Wang<sup>1,2</sup>, Nicholas Clark<sup>1,2</sup> and Roman Gorbachev<sup>1,2,2</sup>; <sup>1</sup>National Graphene Institute, United Kingdom; <sup>2</sup>The University of Manchester, United Kingdom

2D heterostructures present an optimal approach for the synthesis of novel materials with highly adjustable properties, including electron topology and correlation effects. Currently, the prevailing method for constructing van der Waals heterostructures involves the "tear and stack" technique, wherein individual 2D layers are stacked using a polymer stamp. However, this approach easily traps contaminants at the heterostructure interface, leading to limitations in atomic cleanliness and electronic performance of the resulting heterostructures. To address this issue, we have developed a novel polymer-free stacking method that employs flexible, transparent, and thermally stable metallized silicon nitride membranes (SiN). These SiN membranes enable precise and rapid transfer of 2D flakes to desired locations in various environments, including air, argon glovebox, and ultrahigh vacuum, at elevated temperatures of up to 300°C. The elevated temperature during the fabrication process facilitates the removal of surface-adsorbed contaminants from the 2D heterostructure interfaces. To showcase the merits of this polymer-free transfer technique, we successfully fabricated and assessed distinct heterostructures. In initial experiments, we achieved hBN/graphene/hBN heterostructures exhibiting remarkably bubble-free regions, accompanied by mobility values reaching 3×10<sup>6</sup> cm<sup>2</sup>V<sup>-1</sup>s<sup>-1</sup>. Moreover, we demonstrated the fabrication of a more intricate LED structure with a bubble-free area 25x30 μm, completed within a mere 10-minute timeframe. Furthermore, a twisted monolayer/bilayer graphene on an hBN substrate displayed minimal variation in twist angles, with deviations of merely 0.016° over a length of 10 μm. Lastly, the SiN membrane method enables the large-scale transfer of 2D materials synthesized via chemical vapour deposition (CVD) from the growth substrate, devoid of any polymer involvement.

SESSION EL19.13: Poster Session V: 2D Materials—Characterization

Session Chairs: Sanjay Behura and Andrew Mannix

Wednesday Afternoon, November 29, 2023

Hynes, Level 1, Hall A

**8:00 PM EL19.13.03**

**Interface Structure of Fe-Intercalated Graphene/SiC (0001) Revealed by Atomic-Resolution Electron Microscopy** Ryotaro Sakakibara<sup>1</sup>, Tomoo Terasawa<sup>2,3</sup> and Wataru Norimatsu<sup>4</sup>; <sup>1</sup>Nagoya University, Japan; <sup>2</sup>Japan Atomic Energy Agency, Japan; <sup>3</sup>The University of Tokyo, Japan; <sup>4</sup>Waseda University, Japan

Thermal decomposition of SiC (0001) yields highly crystalline single-oriented graphene at the wafer scale [1]. There is a so-called buffer layer (BL) at the

graphene/SiC interface, which is a reconstructed carbon layer on SiC (0001). It is possible to convert this BL to quasi-freestanding monolayer graphene by intercalation of a foreign element [2]. In this method, foreign atoms enter the BL/SiC interface to terminate the interfacial Si atoms, and the BL is decoupled from the substrate. The intercalated atoms are thus arranged in two-dimension and covered by graphene. The intercalation of the ferromagnetic element Fe can manifest intriguing physical properties such as perpendicular magnetic anisotropy and spin injection to graphene. Meanwhile, due to the affinity of Fe with Si and C, its intercalation is challenging. So far, several studies are reporting Fe intercalation in graphene/SiC [3]; however, the direct observation of its interface structure is missing. Here, we performed a uniform Fe intercalation and observed its interface structure at the atomic scale with cross-sectional transmission electron microscopy (TEM).

The uniform BL sample was prepared by annealing a single crystalline 4H-SiC (0001) substrate at 1500°C in an Ar atmosphere. Fe intercalation was carried out by vacuum deposition of Fe with a thickness of about 10 nm at room temperature, followed by annealing at around 660°C. The samples thus obtained were characterized by Raman spectroscopy ( $\lambda=532$  nm), X-ray photoemission spectroscopy (XPS,  $h\nu=1486.6$  eV), and TEM. The TEM observations were performed using a JEM-ARM200F-type microscope at an accelerating voltage of 200 kV. The thin specimen for TEM was prepared by the conventional Ar-ion thinning method.

From the Raman spectra of the sample, the BL was successfully converted to monolayer graphene. The Fe 2p spectrum of XPS suggests the presence of metallic Fe or Fe silicide on the sample surface, even after air exposure. A high-resolution TEM (HRTEM) observation of this sample revealed a layered contrast of graphene on the substrate surface. More importantly, uniform atomic layers of Fe were identified at the graphene/SiC interface by a high-angle annular dark field scanning TEM (HAADF-STEM) observation and energy dispersive X-ray spectroscopy (EDX) analysis. The number of these Fe layers was two to four over a wide range of observations. The interlayer distance between the first and second layers of Fe was  $\sim 2.4$  Å. Such a structure has not been reported for Fe, Fe-oxide and Fe-silicide in their bulk form. In this Fe-intercalated graphene/SiC, modulation of the magnetic structure of Fe and spin injection to graphene can be expected.

#### 8:00 PM EL19.13.04

**Second-Harmonic Generation Imaging Microscopy with Ps Pulsed Lasers** Bitia Rezanian, Volker Buschmann, Christian Oelsner and Maria Loidolt-Krueger; PicoQuant GmbH, Germany

Second harmonic generation (SHG) imaging microscopy is a nonlinear optical imaging technique that uses SHG as a contrast mechanism to produce high-resolution images. SHG occurs in materials with non-centrosymmetric crystal structures. Therefore, SHG imaging has been applied for characterization of 2D semiconductors, transition-metal dichalcogenides (TMDs) such as WS<sub>2</sub> and MoSe<sub>2</sub>, lithium niobate crystals, PZT thin films, graphene, lanthanides, and even biological tissues. It provides information on the crystal lattice, assesses crystal quality and maps grain boundaries, defects, and mechanical strain. Furthermore, SHG imaging reveals the number of stacked layers as well as their orientation with respect to each other.

SHG imaging is commonly performed with a confocal laser scanning microscope using a high-power fs pulsed laser for excitation. In this study, we establish the use of high power ps pulsed lasers instead, with the aims of decreasing laser safety issues as well as reducing microscope complexity and cost. In addition, ps lasers offer high flexibility and tunability in terms of pulse duration, repetition rates, output power and external triggering.

We investigated two different 2D materials namely WSe<sub>2</sub> and MoS<sub>2</sub> on PDMS utilizing MicroTime 100 time-resolved confocal microscope. Reflection images and SHG images were acquired using a VisIR-1064 laser with 1064 nm wavelength, dimmed to laser class 3B and time-resolved photoluminescence (TRPL) images with 640 nm excitation.

The results set prove that ps pulsed lasers can replace fs lasers for SHG imaging. Moreover, the combination of ps lasers enables the collection of complementary datasets including reflection, SHG, TRPL and even two photon excitation (TPE) images collected from the same region of the sample using a single microscope setup. Thus, the optical properties of the materials can be characterized locally with several techniques to obtain a comprehensive understanding.

#### 8:00 PM EL19.13.05

**Imaging of Hyperbolic Plasmon-Phonon Polaritons in Twisted Double Bilayer Graphene** Anna Li<sup>1</sup>, William Wilson<sup>2</sup>, Danial Haei<sup>2</sup> and Yue Luo<sup>2</sup>; <sup>1</sup>University of California, Berkeley, United States; <sup>2</sup>Harvard University, United States

Complex van der Waals heterostructures can be assembled, layer-by-layer, via the deterministic transfer of selected two-dimensional layered materials. The transfer method used offers a significant degree of control and precision enabling assembly of new composite materials with engineered optical properties. Here, we have fabricated twisted double bilayer graphene using a new transfer system with far greater spatial resolution (20 nm) than the previous stamps at Harvard. We transferred mechanically exfoliated graphene and hexagonal boron nitride (hBN) with this transfer system (which uses a polymer stamp consisting of Polydimethylsiloxane (PDMS) and polycarbonate (PC)) to form hBN encapsulated, twisted double bilayer graphene at very small ( $\sim 0.03$  degrees) twist angles. The top capping layers of hBN was between 5–10nm thick, as verified using atomic force microscopy, and the bottom layers ranged from 10–20nm thick. These stacks were subsequently imaged using scanning near field microscopy in the mid-infrared range to observe the interference fringes from the system's "mixed" hyperbolic plasmon-phonon polaritons. Excited with a tunable QCL laser, we were able to study the dispersion relation and propagation behavior of the hybridized polaritons in twisted double bilayer graphene.

#### 8:00 PM EL19.13.06

**Measurement of Thermoelectric Properties of Semimetallic Polycrystal PtSe<sub>2</sub> Film with Temperature Dependence** Jae Won Choi, No-Won Park, Gil-Sung Kim, Min-Sung Kang, Yunho Kim, Seungwon Yang and Sangkwon Lee; Chung-Ang University, Korea (the Republic of)

Hardness of measuring thermoelectronic properties of nm-scale thickness thin film structure is one of the obstacles to research TMDC materials. We used a suspended bridge-type method and a strain gauge-controlled suspend platform to observe in-plane thermal conductivity and Seebeck coefficient of large-area platinum diselenide (PtSe<sub>2</sub>) thin film. We founded influence about thermoelectric properties differency with thickness and cristallity changes. We observe the greatly suppressed in-plane thermal conductivity for 11-nm-thick polycrystalline PtSe<sub>2</sub> film as compared to that of exfoliated similar-thick in-plane single-crystalline PtSe<sub>2</sub> layer at 300 K. This reduction is attributed to the enhanced phonon scattering in polycrystalline PtSe<sub>2</sub> thin film. Our finding can pave the way toward an effective strategy for promising large-area TE energy harvesting devices with a high figure of merit in 2D semimetallic

transition metal dichalcogenide materials.

#### 8:00 PM EL19.13.07

**Investigating the Trap-State Emission of CdTe Nanoplatelets** [Tasnim Ahmed](#) and Justin R. Caram; University of California, Los Angeles, United States

Recently, two-dimensional II-VI semiconductor nanoplatelets (NPLs) have gained tremendous attention due to their exceptional photophysical properties including sharp emission spectra, tunable absorption and emission, large absorption cross section and giant oscillator strength etc. With the advancement of synthetic strategies, these NPLs now can be synthesized with controlled thickness even down to atomic precision. But while most of the progresses have been made with CdSe NPLs, the controlled synthesis of CdTe NPLs still remains challenging; even the detailed photophysics involving them remain unexplored. Here in this work we aim to synthesize CdTe NPLs with controlled thickness and decipher their carrier dynamics in single particle and ensemble level. With this aim we synthesized three monolayer NPLs which interestingly show a distinct excitonic emission and a broad emission band which can be related to trap states emission. The time resolved photoluminescence study reveal two distinct PL decay behavior when monitored at different probe wavelengths. The prolonged PL decay (>30ns) of the broad emission also suggests that it is related to trap emission. To dig deep into the mechanistic pathways of the photogenerated charge carriers, temperature dependent photoluminescence, single particle photoluminescence imaging and ultrafast pump-probe measurements are employed. Understanding the trap states nature will help us to find a key to manipulate them and these long lived trap states carriers can be utilized for their potential applications such as in photocatalysis.

#### 8:00 PM EL19.13.08

**Manipulating Charge Density Wave States in Lanthanum Tri-Telluride through Lithium Intercalation** [Natalie Williams](#)<sup>1</sup>, Shiyu Xu<sup>1</sup>, Saif Siddique<sup>1</sup>, Ratnadwip Singha<sup>2</sup>, Judy Cha<sup>1</sup> and Leslie Schoop<sup>2</sup>; <sup>1</sup>Cornell University, United States; <sup>2</sup>Princeton University, United States

The rare earth tri-tellurides belong to a group of two-dimensional (2D) materials that possess intriguing quantum characteristics, including magnetic ordering, superconductivity, spin-density waves, and charge density waves (CDWs).<sup>1</sup> These properties hold significant potential for controlling electronic phases, making them appealing for applications in electronics and spintronics with specific advantages in memory devices and supercapacitors.<sup>2</sup>

Lanthanum tri-telluride, where lanthanum is the first element in the rare-earth series, exhibits a unidirectional CDW along the c-axis at room temperature. Here, we modulate the CDW order of lanthanum tri-telluride by electrochemically intercalating lithium into the gaps of the exfoliated flakes of lanthanum tri-telluride. Lithium intercalation imparts strain and electron doping to the host material, inducing changes in materials properties and even phase transformations.<sup>3,4</sup> We utilize in-situ Raman spectroscopy to investigate the structural alterations and CDWs of lanthanum tri-telluride flakes as consequence of lithium intercalation. These intercalation experiments hold the potential to uncover novel insights into the understanding of CDW states in rare earth tri-tellurides.

**Tuning the Fermi Level of Graphene by Two-Dimensional Metals for Raman Enhancement** [Na Zhang](#)<sup>1</sup>, Kunyan Zhang<sup>2,3</sup>, Wei Hu<sup>4</sup>, Rinu A. Maniyara<sup>1</sup>, Timothy Bowen<sup>1</sup>, Jonathon Schreengost<sup>1</sup>, Arpit Jain<sup>1</sup>, Da Zhou<sup>1</sup>, Chengye Dong<sup>1</sup>, Zhuohang Yu<sup>1</sup>, He Liu<sup>1</sup>, Noel Giebink<sup>1</sup>, Joshua A. Robinson<sup>1</sup>, Shengxi Huang<sup>5</sup> and Mauricio Terrones<sup>1,1,1</sup>; <sup>1</sup>The Pennsylvania State University, United States; <sup>2</sup>Lawrence Berkeley National Laboratory, United States; <sup>3</sup>University of California, Berkeley, United States; <sup>4</sup>Qilu University of Technology, China; <sup>5</sup>Rice University, United States

Graphene-enhanced Raman scattering (GERS) offers great opportunities to achieve optical sensing with high uniformity and superior molecular selectivity. The GERS mechanism relies on the charge transfer between molecules and graphene, which is difficult to precisely manipulate through varying the band alignment between graphene and molecules. In this work, we leveraged a few atomic layers of metal termed 2D metal to precisely and deterministically modify the graphene Fermi level. Using CuPc as a representative molecule, we demonstrated that the Fermi level tuning can significantly improve the enhancement and molecule selectivity of GERS. Specifically, aligning the Fermi level of graphene closer to the highest occupied molecular orbital (HOMO) of CuPc results in a more pronounced Raman enhancement. Density functional theory (DFT) calculations of the charge density distribution reproduce the enhanced charge transfer between CuPc molecules and graphene with a modulated Fermi level. Extending our investigation to other molecules such as Rhodamine 6G, Rhodamine B, crystal violet, and F<sub>16</sub>CuPc, we showed that 2D metal-enabled Fermi level tuning can preferentially improve the GERS for molecules with better band alignment with graphene, contributing to an enhanced molecule selectivity. This underscores the potential of utilizing 2D metals for precise control and optimization of GERS applications, which will benefit the development of high sensitivity, specificity, and reliability sensors.

**Structural Phase Patterning of MoS<sub>2</sub>** [Christopher A. Barns](#)<sup>1</sup> and Scott Dietrich<sup>2</sup>; <sup>1</sup>West Chester University, United States; <sup>2</sup>Villanova University, United States

Finding ways to protect our technology from intellectual theft has become increasingly needed in recent years. While most people think of technology security in terms of software, many neglect the need to bolster the protection of our hardware. With the U.S. pushing towards being a lead innovator in metal-oxide semiconductor field-effect transistors (MOSFETs), our innovations must have built-in protection to negate any chance of being stolen through reverse engineering. To aid this endeavor, we propose an alternative method of making MOSFETs by utilizing the structural phases of molybdenum disulfide (MoS<sub>2</sub>). Using a 30kV electron beam at 500pA, we expose MoS<sub>2</sub> flakes mounted on an SiO<sub>2</sub> substrate to a variety of electron beam doses to create patterns of its 1T metallic phase surrounded by the rest of its 2H semiconductor phase. Through this method, di-material logic gates are possible which will substantially fortify device security as a result.

**Spectrally-Resolved Polarization-Resolved Multiphoton Fluorescence and Second Harmonic Imaging in Low-Dimensional Materials** Tolulope Ajuwon, Arik Ahmed and [Steve Smith](#); South Dakota School of Mines and Technology, United States

Low-dimensional materials, especially two-dimensional (2D) materials, can have significantly enhanced nonlinear optical coefficients. In particular, the second-order nonlinear polarizability  $\chi^{(2)}$ , an important materials parameter for the generation of entangled photon pairs via parametric downconversion, can be notably enhanced in monolayer materials. The relationship between this nonlinear susceptibility and multi-layer stacking, orientation and material

defects can be revealed by spectroscopic, polarization-resolved imaging. A spectrally-resolved multi-photon induced fluorescence (MPIF) and second harmonic generation (SHG) imaging system, based on a closed loop piezoelectric stage, a transmission grating and an EMCCD is used to examine the nonlinear optical properties of low-dimensional materials. From the spectrally-resolved multiphoton emission, we form ratiometric images of select spectral bands, reducing sensitivity to variations in intensity caused by scattering or attenuation of the excitation beam. We visualize the spectrally-resolved MPIF and SHG in the two-dimensional (2D) material WSe<sub>2</sub> and demonstrate the correlation between the symmetry-induced suppression of SHG for even-numbered layers, where inversion symmetry is established, and the presence of edge and localized defect states on the finite-sized 2D flakes, revealed by variations in the MPIF. The polarization-resolved SHG in the single and multi-layer 2D material identifies the symmetry and orientation of the layers. The application of the methods to determine  $\chi^{(2)}$  in other low-dimensional materials is also described.

**Multimodal Raman, Photoluminescence & SHG Imaging of 2D Materials** Stuart Thomson; Edinburgh Instruments Ltd., United Kingdom

Transition metal dichalcogenides (TMDCs) are exciting next-generation 2D semiconductors with versatile layer-dependent optoelectronic properties. The spatial characterisation of lab-grown TMDCs is crucial to understanding their unique optoelectronic properties and optimising film growth conditions. In this work, we present a multimodal imaging platform that combines optical widefield, Raman, photoluminescence and second harmonic generation imaging for the characterisation of 2D materials.

The imaging platform was used to characterise CVD grown WSe<sub>2</sub> crystals. Using Raman imaging, the presence of both monolayer and multilayer WSe<sub>2</sub> could be identified through a change in the intensity and peak position of the E<sub>1g</sub>/A<sub>1g</sub> phonon modes. Photoluminescence imaging confirmed the presence of monolayer WSe<sub>2</sub> with exciton emission at 780 nm, and identified two distinct multilayer regions in the centre of the crystal through changes in the photoluminescence wavelength and intensity. Finally, second harmonic generation imaging with femtosecond laser excitation was used to obtain the relative layer orientation of the multilayer domains in the WSe<sub>2</sub> flake.

**Exploring the use of Earth-Abundant Layered Materials in 2D-Based Studies: From Natural Mines to Van der Waals Applications** Ingrid Barcelos<sup>1</sup>, Raphaela de Oliveira<sup>1</sup>, Yara Galvão Gobato<sup>2</sup>, Raul Freitas<sup>1</sup>, Helio Chacham<sup>3</sup>, Bernardo R. Neves<sup>3</sup>, Christiano J. de Matos<sup>4</sup> and Alisson R. Cadore<sup>5</sup>; <sup>1</sup>Brazilian Synchrotron Light Laboratory, Brazil; <sup>2</sup>Universidade Federal de São Carlos, Brazil; <sup>3</sup>Universidade Federal de Minas Gerais, Brazil; <sup>4</sup>Universidade Presbiteriana Mackenzie, Brazil; <sup>5</sup>Brazilian Nanotechnology National Laboratory (LNNano), Brazil

Phyllosilicates minerals are an emerging class of naturally occurring layered insulators with large bandgap energy that have gained considerable attention from the scientific community. This class of materials has been explored recently at the ultrathin two-dimensional level due to their specific mechanical and optoelectronic properties, which are crucial for engineering novel devices. Phyllosilicates have lamellar structures and can be embedded into van der Waals heterostructures (vdWHs) due to the possibility of exfoliation down to monolayers and easy handling. Here, we will present a high throughput characterization of some naturally occurring layered phyllosilicates by employing several experimental techniques, first-principles calculations, and will demonstrate that these layered materials can be mechanically exfoliated down to their monolayer limit and combined in the different vdWHs[1-5]. Due to these properties, phyllosilicates minerals can be considered as promising low-cost nanomaterials for electronics, photonics, and optoelectronics future 2D-based device applications. We will also present features of these nanomaterials that are relevant to their use in potential 2D-based applications, discussing the major challenges in working with them. Consequently, our results establish the basis of further studies tuning phyllosilicates properties to desired studies. Therefore, we expect our work to stimulate further exploration of layered phyllosilicate materials and provide the foundation for novel nanotechnological applications.

#### 8:00 PM EL19.14.02

**Energy Harvesting using Few-Layer 2D Galena (galenene)** R. Karthik<sup>1</sup>, Appu Singh<sup>1</sup>, P. R. Sreeram<sup>1</sup>, Preeti L. Mahapatra<sup>1</sup>, Douglas S. Galvao<sup>2</sup> and Chandra S. Tiwary<sup>1</sup>; <sup>1</sup>Indian Institute of Technology, India; <sup>2</sup>State University of Campinas, Brazil

Radiofrequency (RF) energy harvesting using 2D materials is receiving increased attention. In this work, we have demonstrated RF energy harvesting using 2D galena (galenene). Galenene was obtained from liquid exfoliation of bulk galena crystals (PbS), which is one of the naturally abundant metal chalcogenides, the primary ore of lead. Several characterization analyses, such as X-ray diffraction, atomic force microscopy, Raman spectroscopy, and XPS, were carried out to determine the physicochemical properties of the 2D galena structures. A galenene-based Schottky diode was fabricated, and the energy harvesting was demonstrated using a handheld radio transceiver with a carrier frequency of 140–170 MHz. The device extracts RF energy and produces an output DC voltage of a maximum of 1.8 volts and a corresponding output power of 38 mW at 150 MHz, and lights up an LED within a range of 100 cm. At 150 MHz, the device's power conversion efficiency was found to be 19%. DFT simulations were used to gain further insight into the galenene RF energy harvesting mechanism and support the experimental interpretations [1].

**Monolayer Amorphous Carbon as a 2D Barrier** Ugur Karadeniz, Artem K. Grebenko, Zhang Hongji, Lucas M. Sassi, Alena A. Alekseeva, Chee-Tat Toh and Barbaros Oezylmaz; National University of Singapore, Singapore

Monolayer amorphous carbon (MAC) have emerged as a highly promising 2D material with exceptional properties. As the first amorphous 2D material, MAC possess a single atomic layer thickness and large area continuity over wafer scale. MAC can be synthesized conformally over a wide range of substrates at low temperatures (<300 °C). Its structure consists of complete in-plane sp<sup>2</sup> bonding and is free-standing at monolayer thickness. These unique attributes give MAC a range of properties that set it apart from its crystalline counterpart, graphene, and make it a compatible material for barrier applications.

This study presents research on the structural characterisation and barrier properties of atomically thin MAC films. By using laser-assisted chemical vapor deposition (LCVD), we successfully grew monolayer and multilayer MAC films, with precise control of the number of layers. By using Raman spectroscopy, X-ray photoelectron spectroscopy (XPS), and atomic resolution transmission electron microscopy (TEM), we show that MAC amorphous layered structure remains identical regardless of thickness. Multilayer MAC were found to be fully sp<sup>2</sup> bonded and lacked long-range order, exhibiting a distribution of 5-9-member carbon rings.

In our investigations, we explore the potential applications of MAC across various fields as a 2D barrier layer. The direct conformal growth of MAC onto the target substrate ensures defect-free, continuous coverage over large areas. Combined with the absence of reactive grain boundaries, this gives MAC films its exceptional chemical and mechanical stability despite their sub-nanometer thickness. The stability of MAC films is highly advantageous for barrier applications, where materials must remain structurally intact and free from degradation despite being sub-nanometer thick. We demonstrate the use of MAC films as ultrathin barrier films for copper interconnects in integrated circuits to impede metal ion diffusion. The findings of this study highlight the exceptional properties of atomically thin amorphous materials to overcome existing material bottlenecks. Together with its technologically relevant growth conditions, there is immense potential for enhancing device performance and addressing prevalent technological challenges.

#### 8:00 PM EL19.14.04

**Rational Design of Two-Dimensional Reduced Siloxene Metal-Free Semiconductor for Enhanced Photocatalytic Performance** Nav Deepak, Shobha Shukla and Sumit Saxena; IIT Bombay, India

This study investigated the photocatalytic properties of Reduced siloxene nanosheets for the removal of organic pollutants from wastewater. Reduction of Siloxene resulted in a decreased band gap from 2.7 to 2.3 eV, allowing for better absorption of visible light, and quenched photoluminescence, indicating increased efficiency in the utilization of absorbed light energy for photocatalytic reactions. The catalytic activity of the Reduced siloxene nanosheets was examined through the degradation of Methylene Blue (MB), following a pseudo-second-order model, and exhibited an adsorption capacity of 9.6 mg/g for MB. The results demonstrate that reduced siloxene nanosheets have significant potential as an efficient and effective catalyst for removing organic pollutants from wastewater. The reduction process induced changes in the band gap and photoluminescence quenching that contributed to a 78% increase in catalytic activity compared to the pristine Siloxene material (53%).

#### 8:00 PM EL19.14.05

**Large Area Phase Selection in Silicene by Interface Engineering** Daya Sagar Dhungana<sup>1</sup>, Simona Achilli<sup>2</sup>, Chiara Massetti<sup>3</sup>, Christian Martella<sup>1</sup>, Carlo Grazianetti<sup>1</sup>, Guido Fratresi<sup>2</sup> and Alessandro Molle<sup>1</sup>; <sup>1</sup>Consiglio Nazionale delle Ricerche, Italy; <sup>2</sup>Università degli Studi di Milano, Italy; <sup>3</sup>Università degli Studi di Milano-Bicocca, Italy

The synthesis of two-dimensional (2D) silicene by direct growth on Ag(111) substrate is usually qualified by the formation of multiple phases and domains, posing severe constraints on the spatial charge conduction towards a technological transfer of silicene to electronic transport devices. Here we engineer the silicene/silver interface by two different schemes, namely through decoration with Sn atoms, forming an 2D Ag<sub>2</sub>Sn surface alloy (surface decoration scheme), or through an epitaxially grown silicene-stanene heterostructure with stanene buffering the substrate (heterostructure scheme) [1]. Based on in situ low energy electron diffraction (LEED) we observe that phase selection is obtained via the two interface engineering schemes. In details, a 4×4 and √3×√3 single silicene phase are selectively stabilized in the surface decoration and heterostructure scheme, respectively. The two selected phases in both case separately, are well-distinguished by characteristic phase-sensitive Raman spectra taken after top encapsulation of silicene with a sequentially grown nanoscale Al<sub>2</sub>O<sub>3</sub>, and upon probing the surface by positional LEED and Raman scanning, they prove to be extended all over the whole growth area, namely on the cm<sup>2</sup> scale. Interface engineering by surface decoration also stabilizes the ordered growth of a √3×√3 phase in the multilayer range, featuring a single rotational domain instead of the multiple domain formation upon direct growth. Theoretical *ab initio* models are used to investigate low-buckled silicene phases (4×4 and a competing √13×√13 one) and various √3×√3 structures, supporting the experimental findings [2]. Interface engineering with the heterostructure scheme is also functional to design an all-around encapsulation of silicene, entailing the top and the bottom face of silicene [3]. This processing step is structurally preparatory to extract the silicene from its native Ag substrate with no occurring environmental degradation (e.g. oxidation). Stabilization of Ag-free silicene is explained in terms of the sacrificial role played by the bottom stanene layer. Based on close Raman spectroscopy monitoring, we are able to certify the endurance of the silicene in the monthly scale.

Interface engineering of silicene as reported in Ref. [2] provides new and promising technology routes to manipulate the silicene structure by controlled phase selection and single-crystal silicene growth on a wafer-scale, and enables us to develop an encapsulation scheme for the silicene preservation when its native Ag substrate is stripped off so as to create the condition for a full exploitation of silicene in durable operational devices like transistors and piezoresistors [4].

**Synthesis and Properties of Atomically-Thin Width-Controlled TMD Quantum Nanoribbons** Xufan Li<sup>1</sup>, Samuel Wyss<sup>2</sup>, Baichang Li<sup>3</sup>, Emanuil Yanev<sup>3</sup>, Yang Liu<sup>3</sup>, Yongwen Sun<sup>4</sup>, Zhiying Wang<sup>3</sup>, Matthew C. Strasbourg<sup>2</sup>, Raymond R. Unocic<sup>5</sup>, Yang Yang<sup>4</sup>, James Hone<sup>3</sup>, Nicholas J. Borys<sup>2</sup>, P. James Schuck<sup>3</sup> and Avetik R. Harutyunyan<sup>1</sup>; <sup>1</sup>Honda Research Institute USA Inc., United States; <sup>2</sup>Montana State University, United States; <sup>3</sup>Columbia University, United States; <sup>4</sup>The Pennsylvania State University, United States; <sup>5</sup>Oak Ridge National Laboratory, United States

Width confinement and effect of edge structure add new freedoms for exploring exotic properties for already rich atomically-thin materials. Unique properties have already been discovered in graphene nanoribbons with width less than 5 nm. However, for transition metal dichalcogenides (TMDs), the effects by width confinement and edge structure have only been predicted in theoretical calculation due to challenges in synthetic methods to obtain nanoribbons with width less than ~30 nm. We develop a synthetic strategy to directly grow TMD nanoribbons with controllable width (down to sub-10 nm) and layers (single or double layer), from the pre-deposited seed nanoparticles. Width-dependent Coulomb blockade oscillation in the electron transfer behavior in the nanoribbons suggests formation of quantum-dot-like electronic states due to width confinement. Furthermore, combination of width confinement with strain engineering through sharp bending generates highly localized states in TMD nanoribbons, which is responsible for high purity, deterministic single photon emissions. The TMD nanoribbons add a new family of materials to the reservoir for future quantum electronics and photonics.

**8:00 PM EL19.15.04**

**On the Structural and Morphological of Graphene Layers Grown on Pt/Ti/SiO<sub>2</sub> by Hot Filament Chemical Vapor Deposition** Angela Luis Matos<sup>1</sup>, Tej B. Limbu<sup>2</sup>, Ivan Castillo<sup>1</sup>, Balram Tripathi<sup>1</sup>, Brad Weiner<sup>3</sup> and Gerardo Morell<sup>1</sup>; <sup>1</sup>University of Puerto Rico at Río Piedras, Puerto Rico; <sup>2</sup>University of Houston-Clear Lake, United States; <sup>3</sup>University of Puerto Rico-Río Piedras, Puerto Rico

Herein, we report large area single and bilayer graphene growth on Pt/Ti/SiO<sub>2</sub> substrate by hot filament chemical vapor deposition (HFCVD) with and without the assistance of Cu foil. The quality and the number of graphene layers deposited on the substrate were assessed by Raman spectroscopy, and X-rays photoelectron spectroscopy (XPS) analysis. Atomic force microscopy (AFM) was used for assessing the surface topography of the graphene films grown on the Pt/Ti/SiO<sub>2</sub> substrates. The microstructure and elemental analysis have been performed by Scanning electron microscopy (SEM), and Energy dispersive spectroscopy (EDS). Our results show that bilayer layer graphene growth is facilitated by the presence of a copper foil placed nearby Pt/Ti/SiO<sub>2</sub> substrate, or by a relatively high filament temperature in the HFCVD reactor. Monolayer graphene grows only when no copper foil was placed nearby the Pt/Ti/SiO<sub>2</sub> substrate at a low filament temperature. Our approach paves a novel pathway towards the layer-controlled growth of graphene on Pt/Ti/SiO<sub>2</sub> substrate by HFCVD reactor for frontier applications.

**8:00 PM EL19.15.05**

**Low Pressure Chemical Vapor Deposition of 1T-TaS<sub>2</sub> Films on Sapphire for Controllable Charge Density Wave Phase Transitions** Nicholas D. Redwing<sup>1</sup>, Nicholas Trainor<sup>1</sup>, Gabriel Martinez<sup>2</sup>, Daniela R. Radu<sup>2</sup> and Joan M. Redwing<sup>1</sup>; <sup>1</sup>The Pennsylvania State University, United States; <sup>2</sup>Florida International University, United States

Metallic two-dimensional (2D) transition metal dichalcogenides such as TaS<sub>2</sub> can host charge density waves (CDWs), periodic modulations of electron density that arise in systems with strong electron-phonon coupling. CDWs can break crystal symmetry, mediate metal-insulator phase transitions and coexist with superconductivity. Furthermore, transitions between CDW phases can be tuned via strain, electric fields, etc. which can potentially be exploited for devices. Crystal disorder can inhibit CDWs, consequently, studies are typically carried out utilizing single crystal flakes exfoliated from bulk TMD crystals. Techniques to deposit large area, high crystal quality TaS<sub>2</sub> films are therefore needed to advance the field toward practical applications.

In this study, we report the synthesis and characterization of 1T-TaS<sub>2</sub> films on c-plane sapphire using low pressure chemical vapor deposition (LPCVD). The growths were carried out at 100 Torr in a horizontal hot wall CVD reactor using TaCl<sub>5</sub> and sulfur powder as sources in a 5% H<sub>2</sub>/Ar carrier gas mixture. The sulfur powder was placed upstream of the substrate in the quartz tube and was maintained at 150 °C. The TaCl<sub>5</sub> powder was contained within a stainless steel bubbler external to the reactor that was heated to 80 °C and maintained at a pressure of 110 Torr. The TaCl<sub>5</sub> was transported to the reactor by passing the H<sub>2</sub>/Ar carrier gas at a flow rate of 100 sccm through the bubbler and was introduced downstream of the sulfur boat in the reactor via a separate quartz injector tube. The effects of reactor temperature, gas flow rates and reactor pressure on the uniformity, deposition rate and properties of the films were investigated. Temperatures greater than ~800 °C and low reactor pressures (100 Torr) were required to decompose the TaCl<sub>5</sub> via reaction with H<sub>2</sub> and minimize pre-reactions upstream of the substrate. AFM, Raman spectroscopy and X-ray photoelectron spectroscopy were used to characterize the films after growth. The Raman spectrum of films grown at 900 °C and 100 Torr and cooled rapidly after growth exhibited Raman modes at ~90, ~240 and ~380 cm<sup>-1</sup>, consistent with the 1T phase of TaS<sub>2</sub>. Variable temperature Raman measurements are underway to investigate CDW phase transitions in the films.

**8:00 PM EL19.15.06**

**Epitaxial Monolayer Growth of 2D ReS<sub>2</sub> via MOCVD** Heewon Park<sup>1,2</sup>, Yeon-Jeong Jang<sup>1,2</sup> and Moon-Ho Jo<sup>1,2</sup>; <sup>1</sup>IBS, Korea (the Republic of); <sup>2</sup>POSTECH, Korea (the Republic of)

We report monolayer growth of epitaxial van der Waals semiconductor ReS<sub>2</sub> on sapphire substrate. ReS<sub>2</sub>, a member of transition metal dichalcogenide (TMDC), exhibits unique 1T' structure with large anisotropy. Metal-organic chemical vapor deposition (MOCVD) enables the synthesis of atomically thin semiconductor by precisely controlling vapor pressure. ReS<sub>2</sub> film and crystal could be obtained on sapphire substrate depending on the growth condition. Growth parameters such as temperature, pressure, and precursor supply affect the result of MOCVD growth. Material characterizations including Raman spectroscopy, atomic force microscopy (AFM), and x-ray photoelectron spectroscopy (XPS) were conducted to verify the quality of film and triangular crystals. Also, field effect transistors were fabricated to assess the mobility of polycrystalline ReS<sub>2</sub> film. We discuss polycrystalline nature of ReS<sub>2</sub> grown on insulating substrate due to its low in-plane symmetry and weak interlayer coupling between layers.

**8:00 PM EL19.15.08**

**Barium Titanate Thin Film Remote Epitaxy using Graphene** Temazulu S. Zulu, Larissa Little and Julia Mundy; Harvard University, United States

Barium titanate (BTO) thin films present exciting opportunities for use in photonics due to their high refractive index (~ 2.4) and wide bandgap (> 3 eV). We can integrate these films onto silicon to make scalable and efficient optical devices. In order to integrate the films onto silicon, we use remote Molecular Beam Epitaxy (MBE). In our process, we grow BTO films on a strontium titanate (STO) substrate with a graphene intermediate layer and then transfer the BTO films onto a silicon substrate. We first transfer graphene onto an STO substrate, then grow the BTO directly on the graphene layer. The weak Van Der Waals bond between graphene and the BTO thin film allows us to remove the film from the substrate and transfer it to a silicon substrate.

We propose this as an alternative to growing directly on silicon using an oxide layer, which requires careful control of oxygen pressure to maintain epitaxial growth. Our method allows the barium titanate to grow in a single epitaxial orientation since we have a nearly lattice matched oxide substrate, and allows us to reuse the substrates. We propose that this could be a potentially straightforward, scalable, and efficient method for the nanofabrication of integrated barium titanate films on silicon.

#### 8:00 PM EL19.15.10

**Promoting Growth of Two-Dimensional Semiconductors by Preloaded Precursors** Minsu Kim<sup>1</sup>, Minkyun Son<sup>2</sup>, Ki-Seok An<sup>2</sup> and Soonmin Yim<sup>2</sup>;  
<sup>1</sup>Kyonggi University, Korea (the Republic of); <sup>2</sup>Korea Research Institute of Chemical Technology, Korea (the Republic of)

The recent implementation of alkali metal halide catalysts in the context of chemical vapor deposition (CVD) for synthesizing transition metal dichalcogenides (TMDs) has facilitated impressive growth of two-dimensional (2D) TMDs. However, there remains a need for further investigation into process development and growth mechanisms in order to amplify the impact of catalysts and comprehend the underlying principles. In this regard, a novel approach is proposed that involving the concurrent introduction of a metal source (MoO<sub>3</sub>) and a salt (NaCl) through thermal evaporation. This technique yields notable growth behaviors, including enhanced 2D growth, regional selective growth, and expanded possibilities for diverse target materials. Employing a combination of sequential spectroscopy and morphological analyses, a comprehensive reaction pathway for MoS<sub>2</sub> growth is unveiled. Within this pathway, NaCl and MoO<sub>3</sub> react independently to generate intermediate compounds; Na<sub>2</sub>SO<sub>4</sub> and Na<sub>2</sub>Mo<sub>2</sub>O<sub>7</sub>. These intermediates play a crucial role in creating a conducive environment for 2D growth, characterized by augmented source availability and a liquid medium. Subsequently, through a self-assembly process, minute equilateral triangular grains amalgamate atop the liquid intermediates, culminating in the formation of substantial monolayer MoS<sub>2</sub> grains.

This investigation is poised to become a fundamental point of reference, offering insights into the principles underpinning salt catalysis and the evolution of CVD techniques for producing 2D TMDs.

#### 8:00 PM EL19.15.11

**Direct Synthesis of Twisted WSe<sub>2</sub> Multilayers by B<sub>2</sub>O<sub>3</sub>-Assisted Chemical Vapor Deposition** Jinwoo Kim and Gwan-Hyoung Lee; Seoul National University, Korea (the Republic of)

Moiré superlattices of stacked 2D layers have attracted a great attention, offering a unique platform for investigation of unprecedented quantum phenomena, such as superconductivity in twisted graphene bilayer and moiré excitons in twisted transition metal dichalcogenides (TMDs) bilayers. However, fabrication of twisted TMD bilayers still relies on a manual transfer process, which probably contaminates the interface of stacked layers and makes it difficult to precisely control the twist angle. Here, we present a direct synthesis method of twisted WSe<sub>2</sub> bilayers using chemical vapor deposition. We mixed small amount of B<sub>2</sub>O<sub>3</sub> with the source materials to promote growth of WSe<sub>2</sub>. In contrast to the WSe<sub>2</sub> grains produced by conventional CVD process, the WSe<sub>2</sub> grains grown in this work show the overlapping of neighboring grains, forming twist bilayer regions with various twist angles. Low-frequency Raman spectra of the twisted WSe<sub>2</sub> bilayers clearly shows the twist-angle-dependent layer breathing mode (LBM) and B<sub>2g</sub> mode, indicating that the twisted bilayers have atomically clean van der Waals interface and no contamination. Our work shows a way to directly synthesize a large number of the twisted bilayers with different twist angles and provides a platform to investigate the twist-angle-dependent electrical and optical properties of the twisted bilayers.

#### 8:00 PM EL19.15.12

**Van der Waals Epitaxially-Grown Molecular Crystal Dielectric  $\alpha$ -Sb<sub>2</sub>O<sub>3</sub> for 2D Electronics** Hyunjun Kim<sup>1</sup>, Huijie Ryu<sup>2</sup> and Gwan-Hyoung Lee<sup>1</sup>;  
<sup>1</sup>Seoul National University, Korea (the Republic of); <sup>2</sup>Samsung Advanced Institute of Technology, Korea (the Republic of)

In the forefront of nanoelectronics, two-dimensional (2D) materials have garnered substantial attention as prospective channel materials. This is due to their surface properties featuring free-dangling bonds, along with their exceptional mobility and the capacity for precise gate control at the atomic layer level. Nevertheless, the advancement of 2D electronics faces a hurdle in creating a seamless van der Waals interface, particularly in the direct growth of a high-k dielectric with a high degree of crystallinity on a 2D channel material. Here, we report van der Waals epitaxial growth of the molecular crystal dielectric  $\alpha$ -Sb<sub>2</sub>O<sub>3</sub> on graphene. The  $\alpha$ -Sb<sub>2</sub>O<sub>3</sub> nanosheets show a high breakdown field of 18.6 MV/cm for bilayers of 1.3 nm and decrease of the breakdown field with increasing thickness. We achieved equivalent oxide thickness (EOT) of 0.77 nm for 3L-Sb<sub>2</sub>O<sub>3</sub> and as low leakage current as the DRAM limit of  $1 \times 10^{-7}$  A/cm<sup>2</sup> at a gate voltage of 1 V. The epitaxially grown Sb<sub>2</sub>O<sub>3</sub> on graphene has two dominant orientation so that two types of grain boundaries (GB) with orientation angles of 0° and 60° are generated between aligned grains. The 0°-GB with well-stitched boundary shows higher electrical and thermal stabilities than 60°-GB with disordered boundary. Our work shows a method to epitaxially grow the molecular crystals on 2D materials and a great potential of molecular crystals for van der Waals dielectric in 2D electronics.

Light-matter interactions in anisotropic layered and two-dimensional semiconductors such as black phosphorus enables exploration of novel optical confinement phenomena at the atomic scale. Active polarization control, which has diverse applications in optical imaging, sensing, and computing, arises from the electrically tuneable crystalline anisotropy of black phosphorus (BP) which creates a mechanism for polarization modulation. I will discuss metasurfaces combined with van der Waals heterostructures incorporating twisted BP layers which open up further degrees of freedom in polarization conversion, and increases the polarization state tuning range to nearly half the Poincaré sphere. In other recent work, we discovered that certain edges of monolayer black phosphorus act as sites for localization and quantum confinement of quasi-1D excitons, resulting in discrete edge excitonic spectral emission lines with a nearly 10x reduction in linewidth relative to the surrounding 2D bulk. Integration of edge excitons into a gate-tunable heterostructure revealed a highly symmetric gate-dependence, enabling voltage-controlled turn-on/turn-off of polarized radiative emission.

**9:00 AM EL19.16.02**

**Tunable Interlayer Excitons in Organic-Inorganic Van der Waals Heterostructures** Aurelie Champagne<sup>1,2</sup>, Olugbenga Adeniran<sup>3</sup>, Tomojit Chowdhury<sup>4</sup>, Mengyu Gao<sup>4</sup>, Jiwoong Park<sup>4</sup>, Zhenfei Liu<sup>3</sup> and Jeffrey B. Neaton<sup>1,2,5</sup>; <sup>1</sup>Lawrence Berkeley National Laboratory, United States; <sup>2</sup>University of California, Berkeley, United States; <sup>3</sup>Wayne State University, United States; <sup>4</sup>The University of Chicago, United States; <sup>5</sup>Kavli Energy NanoScience Institute, United States

Interfacing transition metal dichalcogenides (TMDs) into van der Waals heterostructure bilayers with type-II level alignment has led to recent reports of interlayer excitons with large binding energies, long lifetimes, and signatures of exciton condensation at elevated temperatures [1–4]. Atomically flat two-dimensional molecular crystals (MC) on TMD monolayers is an emerging interfacial quantum materials platform with tunable level alignment, exciton binding energies, and photoluminescence, given the heightened sensitivity of the organic layers to their environment [5]. In addition to non-local adsorbate/substrate screening, free charge carrier screening is particularly relevant in MC-TMD bilayer heterostructures, and controllably altering these distinct modes of screening can lead to new phenomena. Using a dielectric embedding ab initio GW plus Bethe-Salpeter equation (GW-BSE) approach [6], we compute energy level alignment as well as neutral excitations at MC-TMD interfaces (MC = PDI or PTCDA; TMD = MoS<sub>2</sub> or WS<sub>2</sub>), exploring new emergent optical transitions, such as those associated with interlayer excitons characterized by electrons and holes separated between the MC adsorbate and the TMD, respectively. Combining the GW-BSE approach with a new model we have developed that reduces computational cost with no loss of accuracy [7], we further explore how the presence of free charge carriers can screen the electron-hole interactions and modify the quasiparticle energy level alignment and interlayer excitons.

**Extremely Anisotropic Few-Atom-Thick Organic-Inorganic Bilayers with Wafer-Scale Uniformity** Tomojit Chowdhury<sup>1</sup>, Fauzia Mujid<sup>1</sup>, Aurelie Champagne<sup>2</sup>, Ce Liang<sup>1</sup>, Patrick Knüppel<sup>3</sup>, Nathan Guisinger<sup>4</sup>, Jeffrey B. Neaton<sup>2</sup>, Kin Fai Mak<sup>3</sup> and Jiwoong Park<sup>1</sup>; <sup>1</sup>University of Chicago, United States; <sup>2</sup>Lawrence Berkeley National Laboratory, United States; <sup>3</sup>Cornell University, United States; <sup>4</sup>Argonne National Laboratory, United States

Thin films featuring extreme optical anisotropy are an ideal platform that enables efficient light sensing, harvesting, and display functionalities. However, realizing large-scale thin films with controllable and predictable optical anisotropy remains a major challenge due to two formidable experimental hurdles. First, the non-triviality of producing high-quality large area thin films while preserving their global anisotropic response. Second, the lack of direct experimental evidence linking the films' structures and their anisotropic properties. In this talk, we introduce large-scale and highly crystalline few-atom-thick organic-inorganic bilayers (BL) comprising single-layer two-dimensional molecular crystals (2DMC) atop transition metal dichalcogenide (TMD) monolayers. By leveraging the design flexibility in non-covalent molecular crystals, we grow diverse BLs that exhibit fully deterministic linear dichroism, which is tunable within a 50% range as we vary the 2DMC structures. Through comprehensive optical and high-resolution scanning probe microscopies and analyses, we establish a direct correlation between the molecular unit cells' structures and the observed optical anisotropy. Intriguingly, temperature-dependent polarized optical imaging and spectroscopy unveil the existence of a highly anisotropic excitonic species in the BL, which is distinct from both the pristine molecular and TMD excitons, even under the substantial dielectric screening by the TMD monolayer.

To gain insights into the nature of this anomalous excitonic species, we employ ab initio GW Bethe-Salpeter equation (BSE) calculations, which reveal a strong correlation between the electrons and the holes within the BL. This correlation gives rise to an anisotropic and significantly delocalized Wannier-like interlayer exciton that exhibits high sensitivity to the structure and composition of the 2DMC. These results underscore the potential of our organic-inorganic BL as an excitonically rich platform enabling the discovery of novel light-matter interactions beyond the confines of traditional covalent 2D materials. We will conclude this talk with an outlook on the prospects of creating exotic hybrid 2D systems, that includes the molecular analogue of the moiré superlattice.

**9:30 AM BREAK****10:00 AM EL19.16.04**

**Interfacial Optical Sensing of Ferroelectricity in Freestanding Perovskite Oxides with Monolayer WSe<sub>2</sub>** Jaehong Choi<sup>1</sup>, Kevin Crust<sup>2</sup>, Lizhong Li<sup>1</sup>, Jae Pil So<sup>1</sup>, Kenji Watanabe<sup>3</sup>, Takashi Taniguchi<sup>3</sup>, Harold Y. Hwang<sup>2</sup>, Jie Shan<sup>1</sup>, Kin Fai Mak<sup>1</sup> and Gregory Fuchs<sup>1</sup>; <sup>1</sup>Cornell University, United States; <sup>2</sup>Stanford University, United States; <sup>3</sup>National Institute for Materials Science, Japan

Two-dimensional (2D) transition-metal dichalcogenides (TMDs) can be easily integrated with other functional materials such as ferroelectric materials due to their lack of dangling bonds. Also, owing to their atomic thickness, electronic and photoluminescence (PL) properties of 2D TMDs can be modulated by external perturbations, which opens new avenues for quantum sensing and tunable optoelectronic devices. In this work, we integrate monolayer WSe<sub>2</sub> with a free-standing BaTiO<sub>3</sub> (BTO) membrane and studied the ferroelectricity induced PL modulation in WSe<sub>2</sub>. Perovskite oxide BTO has strong spontaneous polarization and moderate coercive field, but their epitaxial mother substrates often limit the range of device structures. Recent studies showed that BTO can be separated from its substrate by using a sacrificial oxide layer. By using this method, BTO is released from the substrate and transferred to a Si-based substrate. We pick up BTO membranes with an appropriate size by using a stamping method and fabricate a field effect device where the BTO polarization can be switched and sensed simultaneously with monolayer WSe<sub>2</sub> in-situ. We observe that the relative density of charge carriers in changes as the polarization switches, and this gives rise to the PL intensity modulation. The relative emission intensity of neutral excitons and trions show gate dependent hysteresis, which confirms that WSe<sub>2</sub> senses and optically reads out the ferroelectricity in BTO.

**Low-Power Optical Control of Two-Dimensional Magnets** Ti Xie<sup>1</sup>, Jierui Liang<sup>1</sup>, Hasitha S. Arachchige<sup>2</sup>, David Mandrus<sup>2</sup> and Cheng Gong<sup>1</sup>; <sup>1</sup>University of Maryland, United States; <sup>2</sup>The University of Tennessee, Knoxville, United States

A magnetic material, while dressed with different spin configurations, can host a variety of emergent phenomena such as chiral domain walls, skyrmions, and Majorana fermions. Traditional preparation of various spin textures in magnetic films by transforming an already established spin pattern demands

intensive energy to cause spin flipping or domain wall motion. In contrast, engineering the phase transition kinetics potentially opens up new avenues to achieve desired spin configurations. The two-dimensional (2D) layered magnets, owing to the ultra-thinness, allow the magnetism control by various external stimuli, among which optical approaches promise non-destructive manipulation, both locally and globally. In this talk, I will introduce how we demonstrated a low-power optical control of 2D magnets. By perturbing the phase transition kinetics, we found that optical incidence on the order of tens of microwatt per micrometer can effectively control magnetic domain formation, and the orientation of the magnetic domain is highly dependent on optical helicity. Our low-power optical operation paves the new avenue to efficiently engineer 2D spin textures for a plethora of emergent quantum phenomena.

#### SESSION EL19.17: Scalable Processing for 2D Materials

**Manufacturing 2D Materials at Large Scale and High Spatial Selectivity** [Zakaria Al Balushi](#); University of California, Berkeley, United States

The multitude of 2D materials in regard to composition, crystal structure and layer thickness leads to a variety of material properties covering all of the components necessary to address voltage, interconnect, energy, and dimensional scaling issues in a variety of applications. For 2D materials to be technologically competitive, it is imperative to develop manufacturable materials deposition protocols at low temperatures and at any location on demand without wafer transfer processing. In this talk, a low temperature spin coating process will be discussed to form transition metal dichalcogenides at low temperatures using a modified spin coating technique from low decomposition temperature molecules. Furthermore, to achieve spatial selectivity of grown 2D materials, this talk will also describe a novel process to spatially measure and modulate the surface energy of van der Waals surfaces at growth temperatures to achieve selective area growth of 2D materials into a variety of form factors.

#### 2:00 PM EL19.17.02

**Light Emission from Megasonically Solution-Processed MoS<sub>2</sub> Nanosheet Films** [Vinod K. Sangwan](#), Sonal V. Rangnekar, Mengru Jin, Maryam Khalaj, Beata M. Szydłowska, Anushka Dasgupta, Lidia Kuo, Heather Kurtz, Tobin J. Marks and Mark C. Hersam; Northwestern University, United States

Electroluminescence (EL), the conversion of an electrical current into light, is the basis of ubiquitous technologies including lighting, displays, and data communication. Recently, two-dimensional (2D) monolayer semiconductors have been widely studied in the context of electroluminescent devices due to their tunable photonic and electrical properties. Specifically, transition metal dichalcogenides (TMDs) show a direct band gap at the monolayer scale, strong light-matter interactions, tightly bound excitons, trions, and multi-excitons that can be controlled by strain and doping. Layered TMDs are also amenable to solution-processibility for printed optoelectronics with high carrier mobility and mechanical flexibility in printed active layers. Furthermore, stacking arbitrary 2D materials in van der Waals heterojunctions has enabled a variety of light-emitting devices, including lateral p-n homojunctions, vertical p-n heterojunctions, and quantum well structures. On the other hand, a light-emitting capacitor (LEC) achieves light emission through bipolar carrier injection using an alternating-current (AC) gating scheme that avoids stringent materials selection for matching contact metals and is less sensitive to morphological nonuniformity in the semiconductor. However, challenges in isolating optoelectronic-grade monolayer TMDs using scalable liquid-phase exfoliation have thus far precluded the realization of large-area EL devices.

Here, we overcome these challenges and demonstrate EL in large-area solution-processed molybdenum disulfide (MoS<sub>2</sub>) nanosheet films. Monolayer-rich MoS<sub>2</sub> ink is produced through electrochemical intercalation followed by megasonic exfoliation (i.e., sonication at megahertz frequencies) that has recently been shown to yield high-performance visible and near-infrared photodetectors.<sup>[1,2]</sup> The MoS<sub>2</sub> ink is used to produce large-area, percolating nanosheet films for AC-gated transient-EL devices in a metal-insulator-semiconductor-metal geometry. Characteristic monolayer MoS<sub>2</sub> photoluminescence (PL) and EL spectral peaks at 1.88-1.90 eV are observed in thick MoS<sub>2</sub> films with the emission intensity increasing with film thickness over the range of 10-70 nm. A vertical LEC geometry produces highly uniform EL in large-area devices, thus confirming that megasonically exfoliated MoS<sub>2</sub> monolayers retain their direct bandgap character in electrically percolating thin films. This work establishes the potential of megasonicated 2D monolayer inks as an additive manufacturing platform for flexible, patterned, and miniaturized light sources.

#### 2:15 PM EL19.17.03

**A Scalable Route for Composition-Tunable Transition Metal Dichalcogenide Nanosheets** [Rebekah Wells](#)<sup>1</sup>, Nicolas Diercks<sup>1</sup>, Victor Boureau<sup>1</sup>, Simon Nussbaum<sup>1</sup>, Marc Esteve<sup>1</sup>, Marina Caretti<sup>2,1</sup>, Hannah Johnson<sup>2,1</sup> and Kevin Sivula<sup>1</sup>; <sup>1</sup>Ecole Polytechnique Federale de Lausanne, Switzerland; <sup>2</sup>Toyota Motor Europe, Belgium

The alloying of 2D TMDs is an established route to robust semiconductors with continuously-tunable optoelectronic properties. However, a major obstacle in commercializing large-area, thin devices based on alloyed TMD nanosheets is their large-scale production.<sup>1</sup>

In this presentation we describe major advances that address this issue. Firstly, we describe a new powder-based, solution processable method to produce high quality 2D TMD nanosheets using a pre-annealing step and electrochemical intercalation/exfoliation.<sup>2</sup> Compared to traditional methods (i.e., ultrasonication), 2D TMD nanosheets produced using our method show ameliorated optoelectronic properties owing to high aspect ratios and low defect densities. Next, we demonstrate how this innovative method can be adapted to afford production of ternary (Mo<sub>0.5</sub>W<sub>0.5</sub>S<sub>2</sub>, Mo<sub>0.5</sub>W<sub>0.5</sub>Se<sub>2</sub>, MoSSe, WSSe) and quaternary (Mo<sub>0.5</sub>W<sub>0.5</sub>SSe) alloyed TMD nanosheets from commercially available, pure-phase bulk TMD powders. We provide evidence of the atomic mixing within the nanosheets using atomic resolution scanning transmission electron microscopy (STEM) in combination with integrated differential phase contrast (iDPC) for the metal and chalcogenide atoms, respectively. Furthermore, we show that control over the final composition of the nanosheets can be exerted by tuning the feed ratios of the TMD powders. Accordingly, we examine the unique optoelectronic properties that arise as a function of the chemical composition of the alloy. Notably, the phenomena observed are consistent with nanosheets produced *via* chemical vapor deposition (CVD) and related methods, suggesting that this versatile method is an economically viable solution for making alloyed 2D TMD nanosheets. Indeed, the ability to

produce controllably alloyed TMD nanosheets in large quantities is critical for the inexpensive production of next-generation, large-area optoelectronic devices.

In order to transform our exfoliated materials into large-area, thin films, we report the further advancement of our preparation methods toward a continuous roll-to-roll deposition of TMD-based thin films from nanosheet dispersions using a liquid-liquid self-assembly technique.<sup>3</sup> We demonstrate reproducible printing of 100mm wide TMD nanosheet films on plastic substrates. Thus, the advances presented here represent a comprehensive route towards large-area, tunable, and fully solution-processable 2D TMD-based devices.

**Permeation Mechanisms Through 1 nm Thin Carbon Nanomembranes** Andrey Turchanin; Friedrich Schiller University Jena, Germany

Molecular thin carbon nanomembranes (CNMs) synthesized by electron irradiation induced cross-linking of aromatic self-assembled monolayers (SAMs) are promising 2D materials for the next generation of filtration technologies [1, 2]. Their unique properties including ultimately low thickness of ~1 nm, sub-nanometer porosity, mechanical and chemical stability are attractive for the development of innovative filters with low energy consumption, improved selectivity and robustness. However, the permeation mechanisms through CNMs resulting in, *e.g.*, an ~1000 times higher fluxes of water in comparison to helium have not been yet understood [1]. Here we report a study of the permeation of He, Ne, D<sub>2</sub>, CO<sub>2</sub>, Ar, O<sub>2</sub> and D<sub>2</sub>O using mass spectrometry in the temperature range from room temperature to ~120 °C. As a model system, we investigate CNMs made from [1",4',1',1]-terphenyl-4-thiol SAMs. We found out that all studied gases experience an activation energy barrier upon the permeation which scales with their kinetic diameters. Moreover, their permeation rates are dependent on the adsorption enthalpy on the nanomembrane surface. These findings enable us to rationalize the permeation mechanisms and establish a model, which paves the way towards the rational design not only of CNMs but also of other organic and inorganic 2D materials for energy-efficient and highly selective filtration applications [3].

## 3:15 PM DISCUSSION TIME

### 3:30 PM EL19.17.06

**Production and Characterization of Phosphorene Nanoribbons (PNRs)** Eva Aw<sup>1</sup>, Loren Picco<sup>2,3,4</sup>, Oliver D. Payton<sup>2,3,4</sup>, Stacy R. Moore<sup>3</sup>, Fengfei Zhang<sup>1</sup>, Adam J. Clancy<sup>1</sup>, Thomas S. Miller<sup>1</sup> and Christopher A. Howard<sup>1</sup>; <sup>1</sup>University College London, United Kingdom; <sup>2</sup>Bristol Nano Dynamics Ltd., United Kingdom; <sup>3</sup>University of Bristol, United Kingdom; <sup>4</sup>Active Nano Mapping NNUF, United Kingdom

In our fast-paced technological world, the demand for more powerful yet smaller devices has fueled the need for nanomaterial innovation. To meet this demand, precise chemical doping techniques can be employed to tailor the properties of low-dimensional materials and facilitate their integration into functional films, electrodes, and spin-based electronics.

Phosphorene nanoribbons (PNRs), a newly synthesized nanomaterial by our research group at UCL [1], are predicted to exhibit exotic properties, including the Seebeck effect, tunable layer-dependent electronic, optical and ionic transport properties. Recent experiments have demonstrated room-temperature magnetism [2] in PNRs and their ability to enhance hole mobility in solar cells [3]. By combining the flexibility and unidirectional properties of nanoribbons with the high surface area and anisotropic properties of 2D phosphorene sheets, PNRs are expected to exhibit high conductivity due to the 2D confinement of electronic movements and edge effects.

My talk focuses on the synthesis of PNRs using a two-step method. Firstly, black phosphorus is intercalated with alkali metal ions, followed by exfoliation to form stable liquid dispersions of PNRs with few-layer thicknesses and 4-50 nm widths uniform along their lengths [4]. This scalable approach allows us to isolate high quality individual PNRs from bulk black phosphorus. In collaboration with Bristol Nanodynamics Ltd., I am using a recently developed conductive high-speed atomic force microscopy (HS-AFM) to characterise the local charge distribution of PNRs [5].

HS-AFM is an advanced characterization technique which allows for high-resolution data acquisition and real-time video observations across large surface areas. This technique enables simultaneous topography and conductivity measurements, providing valuable insights into the spatial maps of conductivity. By analyzing these maps, we can derive insights on how the electronic band structure of PNRs varies with the number of layers and bifurcations.

### 3:45 PM \*EL19.17.07

**Routine Defect Characterization and Creation of Single Photon Emitters in Two-Dimensional Materials with Atomic Force Microscopy** Matthew R. Rosenberger; University of Notre Dame, United States

Two-dimensional materials (2DM) are atomically thin materials with extraordinary mechanical, electrical, and chemical properties that make them

promising for next generation technologies in quantum communications, sensing, flexible and transparent electronics and optoelectronics, and energy conversion. The behavior of these materials depends on nanoscale details, such as intrinsic point defects and strain fields. In this talk, I will discuss the use of atomic force microscopy (AFM) for characterizing and manipulating 2DM at the nanoscale. First, I will describe our recent work on developing AFM-based techniques for rapid and routine point defect quantification in transition metal dichalcogenides (TMDs). Through direct comparison of conductive AFM and scanning tunneling microscopy (STM), we show that conductive AFM identifies the same defects as STM, validating conductive AFM as a standard defect quantification technique. I will also demonstrate that lateral force microscopy (LFM) can visualize point defects in both TMDs and hexagonal boron nitride. Since LFM is a mechanical technique, it does not require a conductive pathway, which is a significant advantage compared to conductive AFM and STM. In the second part of this talk, I will discuss our work on using AFM tips to write strain profiles into TMDs with nanometer-scale precision. Briefly, we use the AFM tip to indent 2DM placed on top of a thin polymer layer, which results in strain texturing. We use this technique to deterministically place single photon emitters (SPEs) in WSe<sub>2</sub>. We find that electrical gating can improve the purity of SPEs created with this method.

#### SESSION EL19.18: Advances in Novel 2D Material Synthesis

Session Chairs: Sanjay Behura and Andrew Mannix

Friday Morning, December 1, 2023

Hynes, Level 3, Room 309

#### 8:00 AM EL19.18.01

**Correlated SKPM and TERS Imaging of Janus MoSSe Monolayers and MoSSe-MoS<sub>2</sub> Vertical Heterostructures** Tianyi Zhang<sup>1</sup>, Andrey Krayev<sup>2</sup>, Hongwei Liu<sup>1,3</sup> and Jing Kong<sup>1</sup>; <sup>1</sup>Massachusetts Institute of Technology, United States; <sup>2</sup>HORIBA Instruments Inc, United States; <sup>3</sup>The Hong Kong University of Science and Technology, Hong Kong

We report correlated scanning Kelvin probe microscopy (SKPM) and tip enhanced Raman scattering (TERS) imaging of Janus MoSSe monolayers and MoSSe-MoS<sub>2</sub> vertical heterostructures (VHS) obtained by replacing the top sulfur layer of monolayer MoS<sub>2</sub> with selenium atoms via a plasma-assisted room-temperature atomic-layer substitution (RT-ALS) approach. MoSSe crystals were transferred to gold to improve the efficiency of TERS measurements. Unlike their conventional Raman counterparts, TERS spectra of MoSSe featured a strong A<sub>1</sub><sup>2</sup> mode, possibly due to the preferential enhancement of the out-of-plane modes favored in the gap-mode TERS. We observed a sharp drop of the intensity of A<sub>1</sub><sup>2</sup> mode in the VHS of MoSSe-MoS<sub>2</sub> that naturally occurred during the Janus conversion of multilayer islands sporadically occurring in larger monolayer MoS<sub>2</sub> crystals. The work function of these vertical heterostructures is drastically different from the monolayer Janus MoSSe material which makes SKPM technique an excellent tool for visualizing VHS. Besides, rather unexpectedly, we observed splitting of the A<sub>1</sub><sup>1</sup> mode of MoSSe both in the Janus monolayers and in their VHS, we will discuss possible reasons for this splitting.

SKPM imaging of multiple crystals confirmed high microscopic uniformity of the S-Se substitution and the lack of damage to the original MoS<sub>2</sub> crystals except for occasional etching of the grain boundaries in twin symmetry crystals. At the same time, TERS imaging revealed that the width and the spectral position of A<sub>1</sub><sup>2</sup> peak may vary drastically at the nanoscale which implies local nanoscale variations of the stoichiometry of Janus material.

Finally, in this study we found that 785 nm excitation provides the strongest TERS response on Janus MoSSe when compared to 633 nm, 671 nm or 830 nm excitations. This observation should be very helpful for future TERS studies on Janus TMDs and their vertical heterostructures.

#### 8:15 AM EL19.18.02

**Characterization and Engineering of 2D vdW Magnets Hosting 1D Magnetic Chains using Scanning Transmission Electron Microscopy (STEM)** Eugene Park<sup>1</sup>, John Philbin<sup>2</sup>, Joshua Sanchez<sup>1</sup>, Connor Occhialini<sup>1</sup>, Hang Chi<sup>1</sup>, Zhigang Song<sup>3</sup>, Alexandre Foucher<sup>1</sup>, Joachim D. Thomsen<sup>2</sup>, Julian Klein<sup>1</sup>, Zdenek Sofer<sup>4</sup>, Prineha Narang<sup>2</sup> and Frances M. Ross<sup>1</sup>; <sup>1</sup>Massachusetts Institute of Technology, United States; <sup>2</sup>University of California, Los Angeles, United States; <sup>3</sup>Harvard University, United States; <sup>4</sup>University of Chemistry and Technology Prague, Czechia

Van der Waals 2D magnetic materials have emerged as a novel platform that offers unique optoelectronic, magnetic, and quantum properties.<sup>1</sup> Such low-dimensional spin systems have vast potential in applications such as spintronics and nanoscale magnetic devices. The ability to engineer the structure and defects with respect to magnetic, optical, and electronic properties is critical. For example, using individual spins to encode many-body Hamiltonians can allow quantum simulation to be carried out on vdW heterostructures composed of 2D magnets. Out of the wide range of 2D van der Waals magnets, 2D magnets with high structural anisotropy are relatively unexplored, making such materials intriguing and helpful for both fundamental research and device design. For instance, the highly anisotropic character could deliver additional degrees of freedom like 1D magnetism that we can harvest in 2D vdW materials.

Here, we examine the structural properties of two kinds of 2D magnets hosting 1D chains of magnetic atoms. Using scanning transmission electron microscopy (STEM), we characterize structural properties such as the alignment of magnetic chains between layers with atomic resolution. We also explore the nature of defects and the possibility of controlling defect location using the STEM electron beam.<sup>2,3</sup> To reduce beam damage when imaging few layer materials, the sample was encapsulated in graphene to constrain the movement of atoms. By parametrizing a model spin-Hamiltonian based on density functional theory calculations, we predict the spin structure that develops from the chain arrangement of the magnetic atoms in this material. We discuss measurements to verify theoretical calculations using instruments such as vibrating sample magnetometry and photoluminescence. Lastly, we engineer the 2D magnet via electron beam irradiation to modify the structure of 1D spin chains and predict magnetic properties and spin structure using atomistic magnetic simulation.

**Hybrid Pulsed Laser Deposition Growth of Group IVB Dichalcogenides** Mythili Surendran, Huandong Chen, Shantanu Singh, Amir Avishai, Boyang Zhao, Yu-Tsun Shao and Jayakanth Ravichandran; University of Southern California, United States

Group IVB transition metal dichalcogenides (TMDCs) ( $\text{MX}_2$ ; M=Ti, Zr, Hf and X =S, Se, Te) have high calculated room temperature electronic mobilities (5-10 times higher than  $\text{MoS}_2$ ) making them promising materials for electronic applications<sup>1</sup>. However, they remain as the least explored amongst all the layered TMDCs largely due to the synthesis challenges to achieve large area high-quality thin films. TMDC thin films are mostly grown using chemical vapor deposition, although molecular beam epitaxy, metal-organic vapor deposition, pulsed laser deposition (PLD)<sup>2,3</sup> and several other techniques have been exploited. High temperatures of about 1000°C are typically required to grow group IVB TMDCs as they consist of refractory metals such as Zr and Hf, resulting in high defect densities in these films. Moreover, they have a high propensity to oxidize at these high temperatures, thus affecting the electronic properties.

Here, we report a hybrid PLD approach wherein we employed organo-sulfur precursors as sulfur source (as an alternative to  $\text{H}_2\text{S}$ ) to grow chalcogenide thin films. To demonstrate the efficacy of this approach, we have demonstrated epitaxial growth of Group IVB TMDCs such as  $\text{TiS}_2$  (semimetallic),  $\text{ZrS}_2$  and  $\text{HfS}_2$  (semiconducting)<sup>4,5</sup>. Structural and electrical characterization, along with low temperature transport studies reveal low defect densities and high carrier mobilities in these thin films. The synthesis challenges during the realization of refractory metal-based chalcogenides will be discussed in detail. This novel method enables growth temperatures as low as 500°C and opens up new opportunities to investigate the fundamental properties of Group IVB chalcogenides and realize the predicted electronic and optoelectronic applications.

**Electrically Driven Ion Dynamics with Negative Differential Resistance in Alkali Ions Intercalated 2D-Layered Metal Oxide** Gichang Noh<sup>1,2</sup>, Jeongho Kim<sup>2</sup>, Han Beom Jeong<sup>3</sup>, Yooyeon Jo<sup>1</sup>, Min-kyung Jo<sup>2</sup>, Eoram Moon<sup>2</sup>, Mingyu Kim<sup>2</sup>, Eunpyo Park<sup>1</sup>, In Soo Kim<sup>1</sup>, Chul-Ho Lee<sup>4</sup>, Hu Young Jeong<sup>3</sup>, Kibum Kang<sup>2</sup> and Joon Young Kwak<sup>1</sup>; <sup>1</sup>Korea Institute of Science and Technology, Korea (the Republic of); <sup>2</sup>Korea Advanced Institute of Science and Technology, Korea (the Republic of); <sup>3</sup>Ulsan National Institute of Science and Technology, Korea (the Republic of); <sup>4</sup>Seoul National University, Korea (the Republic of)

Ion-based electronics provide a platform to explore unique physical properties and have extensive applications in the design of bio-nano interface and biomimetic devices. 2D-layered materials, thanks to their ability to easily accommodate ions between their layers, emerge as an ideal choice for these ion-based electronic platforms. To realize systematic ion control in 2D-layered materials, it's crucial to ensure stable spatiotemporal reactions of ions on demand. However, substantial hurdles persist during device fabrication and operation based on ion intercalation, including the need for external force during the intercalation process, the challenge of maintaining thermodynamic stability with ions, and the management of structural distortions during ion migration. Here, we introduce the intrinsic stable potassium ion ( $\text{K}^+$ ) intercalated 2D-layered  $\text{MnO}_2$  (2D K- $\text{MnO}_2$ ) by the metal-organic chemical vapor deposition (MOCVD) method. Thermodynamically, the layered structure of  $\text{MnO}_2$  with the intercalated potassium ion and  $\text{H}_2\text{O}$  has the lowest Gibbs free energy among the other phases, resulting in spontaneous intercalation during the growth process. Potassium ions intercalated into the van der Waals gap of layered  $\text{MnO}_2$  can easily move under the external bias, and this electrical-driven ion movement causes the reversible phase transition to  $\text{Mn}_3\text{O}_4$ . Especially, the phase transition of  $\text{Mn}_3\text{O}_4$  and the lattice distortion by over-concentrated potassium ions form a high Schottky barrier that presents dominant negative differential resistance (NDR). We designed a device with multi-channels of the 2D K- $\text{MnO}_2$  to apply simultaneous signals with various conditions and successfully proved that the spatial and temporal potassium ion controls the gradual conductance changes with NDR behavior. Moreover, we imitated the biological voltage-gated potassium channels based on NDR-related conductance change and applied the long-term & short-term plasticity to the associative learning. Our approach to NDR-based ionic motion of 2D K- $\text{MnO}_2$  shows not only a new concept of the dynamics of ion devices but also the high applicability for ionic activities in the human body.

**Electrical Detection of the Flat Band Dispersion in Van der Waals Field-Effect Structures** Gabriele Pasquale<sup>1</sup>, Edoardo Lopriore<sup>1</sup>, Zhe Sun<sup>1</sup>, Kristians Cernevics<sup>1</sup>, Fedele Tagarelli<sup>1</sup>, Kenji Watanabe<sup>2</sup>, Takashi Taniguchi<sup>3</sup>, Oleg Yazyev<sup>1</sup> and Andras Kis<sup>1</sup>; <sup>1</sup>EPFL, Switzerland; <sup>2</sup>Research Center for Functional Materials, National Institute for Materials Science, Japan; <sup>3</sup>International Center for Materials Nanoarchitectonics, National Institute for Materials Science, Japan

The emergence of the field-effect transistor transformed contemporary technologies. Of paramount significance to the effective operation of such devices is the minimal current leakage between the source and gate electrodes. These currents have traditionally been considered detrimental, hindering the flow of electrical charge through the channel. Consequently, for more than seven decades, leakage currents were perceived as lacking any valuable insights beyond their role in improving performance and transistor design. This research delves into the examination of gate leakage currents, specifically tunneling

currents, in field-effect devices utilizing thin layers of InSe channels. InSe, known for its exceptional electrical and optical properties, as well as its distinctive band structure, exhibits a flat-band dispersion at the valence band edge, which may give rise to emergent phenomena [1]. However, determining the energy position of the flat band in a field-effect device has traditionally required costly and impractical methods. Therefore, our study focuses on analyzing tunneling currents in gated structures composed of a few layers of InSe and their relationship with ambipolar transport and photoluminescence measurements. Notably, we observe a shift in tunneling mechanisms due to the presence of the van Hove singularity at the flat band. To validate our findings, we explore tunneling currents as a reliable means of determining the position of the flat band, even at room temperature. Our study offers a fresh outlook on the enduring enigma, presenting an alternative framework for comprehending leakage currents in field-effect devices.

**2D Materials Integration with Silicon as 2D-3D Heterostructure Architecture Enabled by Quantum Tunneling** [Tara Jabegu](#), Ningxin Li, Aisha A. Okmi and Sidong Lei; Georgia State University, United States

In-line with the concept of three-dimensional (3D) hybrid integration, the combination of silicon-based circuits with two-dimensional (2D) material-based device architectures has emerged as an appealing topic. This fusion holds the promise in innovative electronics and optoelectronics with novel functions, higher integration level, fast speed, and many other benefits that are intangible in conventional designs. Nonetheless, the integration of silicon and 2D materials in a 3D configuration encounters a problem of substantial contact resistance. Earlier investigations suggested that the presence of van der Waals gap and in-gap states could be responsible for the poor contact. In this study, we present an alternative approach to enhance contact quality. In essence, instead of eliminating the van der Waals gap between silicon and 2D materials, we treat the gap as a quantum tunneling barrier and manage to increase the quantum tunneling efficiency. By tuning the Fermi-surface alignment and minimizing the charge carrier momenta mismatch, we effectively reduce the contact resistance between silicon and graphene achieving nearly ideal ohmic contact. Furthermore, we characterize the phonon-assisted inelastic transport process on this silicon-graphene interface and demonstrate its positive effects in enhancing the contact conductivity. This research provides a feasible and versatile approach for high-quality 3D-2D contact fabrication towards the hybrid integration of dissimilar materials with advanced functionalities in the field of electronics and optoelectronics.

**2D Single-Atom Switching Materials and Applications in Electronics and 6G Communication Systems** [Deji Akinwande](#); The University of Texas at Austin, United States

This presentation focuses on the nonvolatile resistance switching memory effect in 2D materials, aka, atomristors. Nonvolatile memory devices based on 2D materials are an application of defects and is a rapidly advancing field with rich multiphysics that can be attributed to vacancies combined with metal adsorption. The energetics of the defects are discussed and emerging applications such as zero-power switches in RF, 6G, and THz connectivity systems are presented. These memory devices offer high-energy efficiency and fast switching that may benefit mobile systems, cloud computing and data centers towards reduced energy consumption worldwide

**Impact of Thermal Annealing on the Interaction of Monolayer MoS<sub>2</sub> on Au** [Stephanie D. Lough](#)<sup>1</sup>, Jesse Thompson<sup>1</sup>, Darian Smalley<sup>1</sup>, Rahul Rao<sup>2</sup> and Masahiro Ishigami<sup>2</sup>; <sup>1</sup>University of Central Florida, United States; <sup>2</sup>Air Force Research Laboratory, United States

We have investigated the impact of thermal annealing on the interaction of single layer MoS<sub>2</sub> and Au using Raman Spectroscopy. Au-assisted exfoliation results in single layer MoS<sub>2</sub> which has weakly- and strongly-coupled regions where the strongly-coupled regions are n-doped and relatively unstrained while the weakly-coupled regions are p-doped and tensile strained. The observed nanoscale inhomogeneities may result in Au contacts having a large variability in performance. Our data also show that monolayer MoS<sub>2</sub> starts to decouple from Au at above 100 °C, becoming fully decoupled above 200-250 °C. This indicates that monolayer MoS<sub>2</sub> produced by Au-assisted exfoliation may be more easily transferred off Au at high temperatures. Our results also show that the overall areal coverage of strongly-coupled regions does not increase by thermal annealing while the degree of hybridization becomes more inhomogeneous at annealing temperatures above 100 °C.

**Photoluminescence Quenching in N-Heterocyclic Carbene Functionalized Tungsten Dichalcogenide Mixed-Dimensional Heterostructures** [Anushka Dasgupta](#)<sup>1</sup>, Rafael López-Arteaga<sup>1</sup>, Iqbal B. Utama<sup>1</sup>, Tumpa Sadhukhan<sup>2</sup>, S. Carin Gavin<sup>1</sup>, Xi Wan<sup>1</sup>, Wei Wang<sup>3</sup>, Brendan Kerwin<sup>1</sup>, Riddhi Ananth<sup>1</sup>, Albert Vong<sup>1</sup>, Nathaniel Stern<sup>1</sup>, George Schatz<sup>1</sup>, Xuedan Ma<sup>3</sup>, Emily Weiss<sup>1</sup> and Mark C. Hersam<sup>1</sup>; <sup>1</sup>Northwestern University, United States; <sup>2</sup>SRM Institute of Science and Technology, India; <sup>3</sup>Argonne National Laboratory, United States

Two-dimensional (2D) transition metal dichalcogenides (TMDs) are promising candidates for quantum optoelectronic devices due to their pronounced valley physics and excitonic properties. One approach to modulate these properties is to modify 2D TMDs with carbon-based ligands.<sup>1</sup> Among carbon-based ligands, the strong  $\sigma$ -donor character, stability, and structural tunability of N-heterocyclic carbenes (NHCs) has prompted investigations of NHC coordination to various atomically flat metal surfaces and metal nanoparticles. Here, we discuss the optical properties of WS<sub>2</sub> and WSe<sub>2</sub> monolayers functionalized with NHCs via a solvent-free route and an air-stable precursor. The deposition of NHCs on the 2D TMDs results in a significant room-temperature photoluminescence (PL) quenching. Moreover, low-temperature PL measurements (T = 3.9 K) show quenching of the WS<sub>2</sub> and WSe<sub>2</sub> excitonic emission and a shift of the defect bands to lower energies. The extent of both effects is tunable by altering the N-substituents of the NHCs as well as the thickness of the deposited organic layer. The resulting mixed-dimensional heterostructures are further characterized by X-ray photoelectron spectroscopy, atomic force microscopy, and time-of-flight secondary ion mass spectrometry to elucidate the nature of the functionalization process. The observed PL quenching is consistent with a charge transfer process from defect states introduced by chalcogen vacancies to midgap states introduced by the carbene layer, as predicted from first-principles density functional theory calculations. Overall, these results demonstrate that carbene functionalization is an effective pathway for modifying the optical properties of 2D TMDs.

### 2:00 PM EL19.20.03

**Computational Design of Plasma Process for High Purity Layer Thinning of 4-In MoS<sub>2</sub>** Muyoung Kim<sup>1</sup>, Changmin Kim<sup>1</sup>, Hyeong-U Kim<sup>1</sup>, Daewoong Kim<sup>1</sup>, Taesung Kim<sup>2</sup> and Woo Seok Kang<sup>1</sup>; <sup>1</sup>Korea Institute of Machinery and Materials, Korea (the Republic of); <sup>2</sup>Sungkyunkwan University, Korea (the Republic of)

Two-dimensional molybdenum disulfide (MoS<sub>2</sub>) has attracted huge attention for next-generation nanoelectronics due to its unique physical and chemical properties. Among the fascinating characteristics of MoS<sub>2</sub>, a tunable bandgap according to the thickness is necessary for on-demand engineering of future electronics. In this respect, the precise layer control of MoS<sub>2</sub> has been a long-standing desire, but prior studies encountered critical challenges such as poor scalability, surface roughening and impurities. This work aimed to achieve ultrahigh purity and precision in wafer-scale layer thinning of MoS<sub>2</sub> by plasma processes: plasma-enhanced chemical vapor deposition (PECVD) and reactive ion etching (RIE). The 4-inch MoS<sub>2</sub> was synthesized by PECVD, and the as-deposited layers were peeled off by RIE with a computationally screened gas mixture. For the computational screening, the plasma-induced surface chemistry was explored using first-principles calculations that offered atomic insights on reaction energetics and the associated orbital interaction. Through the process optimization, layer-by-layer thinning of MoS<sub>2</sub> was confirmed in 4-inch wafer, where mono- or bilayer was evenly removed for each RIE cycle. Additionally, there were no damages in atomic structure and chemical impurities. The combined computational screening-experimentation accelerates the process development and provides concrete understanding on underlying physics in manufacturing process.

### 2:15 PM EL19.20.04

**Plasma Electron Irradiation Etching (PEIE) of Two-Dimensional Materials** Yunjo Jeong<sup>1</sup>, Jong-Bae Park<sup>2</sup>, Eunjin Choi<sup>1</sup>, Dae Chul Kim<sup>2</sup>, Sukang Bae<sup>1</sup>, Young-Woo Kim<sup>2</sup> and Jangyup Son<sup>1</sup>; <sup>1</sup>Korea Institute of Science and Technology, Korea (the Republic of); <sup>2</sup>Korea Institute for Fusion Energy, Korea (the Republic of)

Two-dimensional layered materials (2DLMs) have garnered significant interest due to their versatility and the potential for investigating practical applications such as flexible electronics, molecular filters, etc. In maximizing the versatility of 2DLMs, various attempts have been made to tailor their properties for desired applications, such as inducing mechanical deformation, modifying their surface chemistry, and investigating the change in their thickness-dependent properties such as bandgap energy, mechanical strength, and optical transmittance. Although significant progress has been made in maintaining control over mechanical or chemical states of 2DLMs, precise control over their thickness remains a challenge. Currently, most research has focused on mono- or few-layer 2DLMs; however, while such research allows for a thorough understanding of the various properties of 2DLMs, practical application of 2DLMs is contingent upon achieving capacity for arbitrary manipulation of their thickness at the multilayer scale. Conventional approaches to control over the thickness of 2DLMs include bottom-up approaches such as chemical vapor deposition and top-down approaches such as chemical etching via plasma, wet etchants, etc. Although such approaches are relatively effective, they inherently exhibit tradeoffs such as defects and sample contamination. Here, we introduce a novel approach to achieving precise etching of two-dimensional materials at the nanometer scale. A modified plasma electron annealing method, originally designed for the recrystallization of amorphous Si [1], was employed to achieve highly precise control over the vertical dimension of exfoliated BN crystals. Characterization via Raman spectroscopy and atomic force microscopy (AFM) confirm successful thinning of BN, and an in-depth investigation via AFM of the surface roughness of the BN after the plasma electron treatment reveals that the remaining BN lattices remain undamaged. This work paves new potential for the investigation of 2DLMs at the multilayer level, opening up novel opportunities for their industry-friendly applications.

### 2:30 PM BREAK

### 3:00 PM \*EL19.20.05

**Interface Band Engineering for High-Performance 2D Field-Effect Transistors** Chul-Ho Lee; Seoul National University, Korea (the Republic of)

Two-dimensional (2D) semiconductors such as transition metal dichalcogenides (TMDs) have emerged as promising materials for implementing beyond-CMOS electronics due to excellent gate coupling and immunity to short-channel effects at the ultimate scaling. In addition, owing to a van der Waals layered structure, they hold great potential for non-conventional electronics capable of heterogeneous integration and deformation. To achieve high-performance 2D field-effect transistors (FETs), it is highly required to control the electronic states and energy band profiles at various heterointerfaces among the semiconductor channel, the gate dielectric, and metal electrodes. In this talk, I will present two types of proof-of-concepts 2D FETs enabled by interface band engineering: 1) modulation-doped FETs (MODFETs) and 2) metal-semiconductor FETs (MESFETs). In a MODFET, we demonstrated remote modulation doping in the type-II band-modulated channel, enabling us to achieve high mobility by suppressing dopant-induced charge impurity scattering. The 2D MESFETs were also demonstrated using the Fermi-level pinning-free metal Schottky gate, whose device characteristics approach the Boltzmann switching limit.

### 3:30 PM \*EL19.20.06

**Tailoring Localized Excitons and Their Light-Matter Interactions with Nanoscale Structure in 2D Semiconductors** Nicholas J. Borys<sup>1,2</sup>; <sup>1</sup>Montana State University, United States; <sup>2</sup>MonArk NSF Quantum Foundry, United States

Strain-induced localization of excitons is important for many conventional and quantum optoelectronic devices that are based on layered two-dimensional (2D) semiconductors. For example, single-photon emitters in single-layer WSe<sub>2</sub> (1L-WSe<sub>2</sub>), which are potential platforms for solid-state quantum light sources, occur in nanoscale regions of localized tensile strain that produce excitonic potential energy wells. In these regions and the surrounding vicinity, excitons funnel to the strained region of lowest energy. The resulting interplay between reducing the energy, spatially localizing, and hybridizing the exciton with defect states is hypothesized to be integral to the formation of quantum emitters. Understanding these phenomena and their roles in the formation of quantum emitters necessitates investigations that directly probe the intrinsic nanoscale structure-property relationships of strain-localized emitters and identify systematic differences between emitter populations of different systems. The latter focus is crucial to quantitatively assess how different approaches to generate the local strain such as random nanobubbles, deposition on nanofabricated pillars, or nanoindentation affect the quality and properties of the resulting quantum emitters.

This talk will highlight two recent studies by our group of strain-localized emitters in 2D semiconductors. In the first, nanobubbles of 1L-WSe<sub>2</sub> and 1L-WSe<sub>2</sub> on gold films are found to provide a unique background-free system in which to correlate strain-localized states with nanoscale structure. Using room-temperature steady-state and time-resolved spectroscopy, individual localization centers within single nanobubbles can be identified and counted. The occurrence of single or multiple emitters within an individual nanobubble correlates with its structure, demonstrating that strain-engineering of exciton localization in 2D materials necessitates nanoscale precision. Ongoing work is extending these correlated measurements to cryogenic temperatures to probe

how the number of localization sites correlates with the number of quantum emitters formed. In the second study, we statistically compare the steady state properties and excited state dynamics of localized exciton-based quantum emitters formed in a variety of systems of 1L-WSe<sub>2</sub> that vary the generation of local strain, the defect density in the 1L-WSe<sub>2</sub>, and the surrounding dielectric environment. Of the systems probed arrays of metallic stressors with high-quality flux-grown 1L-WSe<sub>2</sub> are found to systematically produce the most homogeneous quantum emitter populations. Combined, the two studies uncover key structure-property relationships for 2D semiconductor quantum emitters and aim at identifying which combination of strain generation, surrounding dielectric environment, and nanophotonic engineering is best suited to optimize emitter performance.

#### 4:00 PM EL19.20.08

**Rapid Detection of Atomically Thin Semiconductors using Automated Photoluminescence Mapping** [Juri G. Crimman](#)<sup>1</sup>, Moritz N. Junker<sup>1</sup>, Yannik M. Glauser<sup>1</sup>, Nolan Lassaline<sup>1,2</sup>, Gabriel Nagamine<sup>1</sup> and David J. Norris<sup>1</sup>; <sup>1</sup>ETH Zurich, Switzerland; <sup>2</sup>Technical University of Denmark, Denmark

Transition metal dichalcogenides (TMDs) are two-dimensional (2D) layered semiconductors that have been studied for various applications, ranging from transistors to single-photon emitters. While multilayered TMDs have an indirect band gap and are commonly used in electronics, TMD monolayers are integrated in optoelectronics since their direct band gap enables efficient light emission. Such atomically thin sheets are often obtained through mechanical exfoliation, followed by manual inspection using a brightfield microscope. However, this process is time-consuming, relies on user experience, and is prone to human error. Here we report a fully automated approach for identifying TMD monolayers using photoluminescence microscopy. Our technique reduces the time spent per sample by more than a factor of 20 and identifies WSe<sub>2</sub> and MoS<sub>2</sub> monolayers with close to 100 % accuracy. We anticipate that our approach will improve fabrication efficiency and enhance the quality of atomically thin optoelectronic devices such as photovoltaics, photodetectors, and light-emitting diodes.

SESSION EL19.21: Virtual Session I

Thursday Morning, December 7, 2023  
EL19-virtual

#### 8:00 AM EL19.21.02

**Large-Area Epitaxial Growth of  $\alpha$ -In<sub>2</sub>Se<sub>3</sub> and its Layer-Dependent Nonlinear Optical Properties** [Lei Xu](#), Xiaotian Zhang, Zhenhua Wu and Mingtao Yan; Shanghai Jiao Tong University, China

Non-volatile memories based on ferroelectric materials is one of the most competitive next-generation memories due to its low power consumption, fast read and write speed, non-volatility, and compatibility with CMOS manufacturing processes. However, the critical dimensions of conventional ferroelectric thin films as well as the depolarization and leakage current in conventional ferroelectric dielectrics limit the development of ferroelectric memories. On the other hand, recent development of field effect transistors based on two-dimensional ferroelectric semiconductors offers great potential to outperform conventional ferroelectric memories, in which the polarization states are stored in the semiconducting channels to bypass the limitations of conventional ferroelectric materials. Among all phases of In<sub>2</sub>Se<sub>3</sub>, two-dimensional  $\alpha$ -In<sub>2</sub>Se<sub>3</sub> with non-centrosymmetric structure possesses both intercoupled in-plane (IP) and out-of-plane (OOP) ferroelectricity in monolayer, which exhibits great application prospects such as non-volatile memories devices, memristors, and artificial intelligence synapse. However, the coexistence of multiple phases during the growth of In<sub>2</sub>Se<sub>3</sub> thin films remains as a challenge to growing uniform and pure  $\alpha$  phase In<sub>2</sub>Se<sub>3</sub> in a large area and meeting the requirements of large-scale integration. Herein, we demonstrate the synthesis of large-area  $\alpha$ -In<sub>2</sub>Se<sub>3</sub> monolayer and multilayer films via both chemical (CVD) and physical (PVD) vapor deposition methods. Characterization techniques such as Raman spectroscopy, piezo-force microscopy (PFM), high-resolution transmission electron microscopy (TEM) and second harmonic generation (SHG) were carried out to identify the single phase and high crystallinity of the films. In particular, we notice that the SHG signal intensity of PVD-grown  $\alpha$ -In<sub>2</sub>Se<sub>3</sub> decrease gradually with the increase of layers, which is the opposite trend to CVD-grown  $\alpha$ -In<sub>2</sub>Se<sub>3</sub>. This indicates a homostructure of  $\alpha$ -In<sub>2</sub>Se<sub>3</sub> films was formed in our CVD process compared to the vertical heterostructure of  $\alpha/\beta$ -In<sub>2</sub>Se<sub>3</sub> generated from our PVD process. We test the durability of our ferroelectric films. The  $\alpha$ -In<sub>2</sub>Se<sub>3</sub> films maintained the polarization for more than 30 minutes under PFM measurement and the films remained active after 2 months exposure to the air. Finally, we transfer the sample onto Au/Si substrate to study the polarization switching behavior of CVD and PVD- $\alpha$ -In<sub>2</sub>Se<sub>3</sub> under external electric field by conduct atomic force microscope (CAFM).

#### 8:15 AM EL19.21.04

**Intercalation-Exfoliation of MoS<sub>2</sub> with Evaporable Stabilizer to Obtain High-Yield Monolayers Inks for Printable Photodetectors** [Barbara Y. Martin](#)<sup>1</sup>, Tyler Davidson-Hall<sup>1</sup>, Nathan Yee<sup>1</sup>, Nicholas Wilson<sup>2</sup>, Teri Siu<sup>2</sup>, Manila Ozhukil Valappil<sup>2</sup>, Michael Pope<sup>2</sup>, Jianying Ouyang<sup>1</sup>, Neil Graddage<sup>1</sup> and Jianping Lu<sup>1</sup>; <sup>1</sup>National Research Council Canada, Canada; <sup>2</sup>University of Waterloo, Canada

Photodetectors are electronic devices which convert light into an electrical signal. Printable, flexible and low-cost photodetectors are in high demand as these devices can be used in a variety of applications such as cameras for smartphones, medical sensors, night vision or even ambient light sensors. Transition Metal Dichalcogenides (TMDs) possess strong light emission and absorption in the visible and near-infrared wavelength range, making them very attractive materials for optoelectronic applications. Molybdenum disulfide (MoS<sub>2</sub>) is a multilayer 2D material that can be exfoliated to obtain monolayers, this material is also characterized by multiple crystalline phases. With this variety of structures, it is possible to adjust the band gap of MoS<sub>2</sub> from an indirect band gap at 1.29eV to a direct band gap at 1.8eV. Moreover, metallic or semi-conductor monolayers can also be obtained. Chemical vapor deposition can be used to produce semi-conductor monolayer TMDs with controllable synthesis. However, large scale, and low-cost production is very difficult with this technique. Intercalation followed by liquid-phase exfoliation is a powerful technique to produce defect-free monolayers in large-quantities. However, reproducible printable inks with high concentration of TMD monolayers are more difficult to achieve. Another challenge to obtaining good quality TMD inks for printable photodetectors is the necessary to use a large amount of insulating stabilizer (such as PVP or ethyl cellulose).

Our work focuses on the development of highly concentrated MoS<sub>2</sub> inks for printable photodetectors. This ink was made by a new intercalation-exfoliation process, an easily evaporable stabilizer was used to replace PVP, and a cascade centrifugation step was added to the process to achieve a highly efficient monolayer size selection (90% of the flakes have less than 3 layers).

#### 8:30 AM EL19.21.08

**Potential, Scope and Limitations of Liquid Interface Assembly as a Technique for Synthesizing 2D Thin Films** [Medini Padmanabhan](#) and Nicholas Weber; Rhode Island College, United States

Solution fabrication of large-area thin films with 2D materials is an active field of study. In this work, we disperse natural graphite and MoS<sub>2</sub> flakes at a heptane-water interface. Individual flakes spread out and arrange themselves as a thin film at the interface, which is then transferred to a glass substrate. This technique allows us to combine the light absorbing properties of MoS<sub>2</sub> with the high conductivity of graphite to make composite films which exhibit photoconductivity. We observe that the flakes like to arrange themselves in a single layer and resist stacking. The conductivity of the resulting film is correlated with its porosity, much like a percolation network of resistors. We find that the technique, while very effective in spreading out these 2D materials into a single layer, does not help with exfoliation at the atomic scale.

### 8:35 AM EL19.21.09

**Mechanical Nanomanipulation of Water Confined in a Naturally Occurring Water-Hybrid 2D System** [Raphaela de Oliveira](#)<sup>1,2</sup>, Alisson R. Cadore<sup>2</sup>, Helio Chacham<sup>1</sup>, Raul Freitas<sup>2</sup>, Klaus Krambrock<sup>1</sup>, Angelo Malachias<sup>1</sup> and Ingrid Barcelos<sup>2</sup>; <sup>1</sup>UFMG, Brazil; <sup>2</sup>CNPEM, Brazil

Water is the matrix of life and its confinement in nanocavities and flow through nanocapillaries are central topics from geophysics to nanotribology. Water in nanoscale media can show distinct elastic and viscosity behaviors, presenting exquisite properties such as low dielectric constant [1]. A more recent development in the emergence of nanofluidics is the ability to fabricate artificial nanocapillaries for water transport through van der Waals (vdW) assembly of atomically-thin two-dimensional (2D) materials, such as hexagonal boron nitride and graphene [2]. Although the engineering of these nanocapillaries can be beneficial in controlling specific properties, there is plenty of natural water-based heterostructures barely explored so far. These water-hybrid 2D systems intercalate water layers in the lamellar structure of naturally occurring vdW materials that can show unprecedented and highly tunable properties for nanotechnology applications.

Hydrous minerals act as natural nanocavities for water transport on Earth, which is essential to biochemical processes with cycling of nutrients and elements. In this scenario, phyllosilicate minerals emerge as an abundant class of hydrous minerals that are wide band gap insulators. They can be exfoliated down to monolayers due to their lamellar structure that stacks silicon oxide tetrahedral layers with (Al,Mg)-octahedral layers with O/OH at the vertices [3]. Some specimens of phyllosilicates can be pillared by ions, such as clays, or further octahedral layers, such as chlorites. They present the unique ability to absorb water by confining water layers in the interlamellar space, being water-hybrid 2D systems of natural occurrence.

Theoretical studies suggest that the electrostatic charge distribution due to the presence of substitutional ions in the structure of phyllosilicates modulates how water confines between its layers [4]. Within the barely explored group of chlorite phyllosilicates, we can identify clinocllore as the specimen that favors higher incorporation of interlamellar water due to its more complex structure. In a previous works, we observed a contribution about 14%wt attributed to the presence of water/hydroxyl ions in clinocllore by quantitative analysis [5]. This expressive water-related amount suggests clinocllore as one of the most suitable natural platforms for water confinement in 2D systems among phyllosilicate minerals. However, the hydration of phyllosilicates by interlamellar water intercalation is not a well understood process besides its importance in several fields.

In the forefront of advancing our understanding of nanoconfined water in 2D systems, we will present the nanoimaging of interlamellar water in ultrathin exfoliated clinocllore by infrared scattering-type scanning near-field optical microscopy. We observed a striation pattern for the nanoconfined water capillaries in clinocllore that changes the overall dielectric properties of the system and, consequently, its surface potential probed by Kelvin probe force microscopy. As a unique result, we performed the nanomanipulation of confined interlamellar water in clinocllore by atomic force microscopy in contact mode. By applying a constant local force between the tip and the sample during the scanning, it was possible to drain practically all the fluid from the analyzed area in a controlled manner, changing the clinocllore surface potential. This pioneering result allows the multifunctionalization of these natural water-hybrid 2D system for catalytic applications, sensing, microfluidic devices, and patterning of biomolecules in 2D systems.

**Effect of Several Growth Parameters on Graphene Growth on Four Types of Supported Cu Films using Cold Wall CVD and Perspective on Growth Mechanism of Graphene from Scaling Functions of Graphene Island Size Distribution** [Shantanu Das](#)<sup>1,2</sup>; <sup>1</sup>Intel Corporation, United States; <sup>2</sup>Arizona State University, United States

In this work, I will present results from a series of studies using a custom-automated LabVIEW controlled graphene growth method in a custom-modified multi-chamber UHV chamber transformed into a cold wall CVD system. The controlled experimental approach allowed careful study of effect of several growth parameters on graphene growth on Cu. A systematic, in depth study of graphene in industrially preferred cold wall CVD has potential to shed light on studies of other single layer 2D materials.

Graphene growth was explored on solid electrodeposited, recrystallized, sputter deposited and liquid Cu films supported on W or Mo refractory substrates under ambient pressure using Ar, H<sub>2</sub> and CH<sub>4</sub> mixtures. Among these films, electrodeposited Cu film was chosen to study the effect of total flow rate, CH<sub>4</sub>:H<sub>2</sub> ratio and dilution of the CH<sub>4</sub>/H<sub>2</sub> mixture by Ar at a fixed substrate temperature of 1000 °C and total pressure of 700 Torr, on the nucleation density and average size of graphene crystallites. The resulting morphological changes correspond with those that would be expected if the precursor deposition rate was varied at a fixed substrate temperature for physical deposition using thermal evaporation. The evolution of graphene crystallite boundary morphology with decreasing effective C deposition rate indicates the role of edge diffusion of C atoms along the crystallite boundaries, in addition to H<sub>2</sub> etching on graphene crystallite shape. The results indicate that graphene grown on Cu films using cold wall CVD follows a classical two-dimensional nucleation and growth mechanism. Following nucleation at the earliest growth stages, isolated crystallites grow, impinge and coalesce to form a continuous layer. During the pre-coalescence growth regime, the size distributions of graphene crystallites exhibit scaling which is a function of island area, graphene coverage, average island area and areal density. For graphene grown on Cu surfaces that have been annealed in a reducing Ar+H<sub>2</sub> ambient, excellent data collapse onto a monotonically decreasing universal Avrami scaling function is observed irrespective of graphene coverage, surface roughness or Cu grain size. This result is interpreted to indicate attachment limited growth and desorption of C-containing species. Graphene grown on Cu surfaces that were annealed in a nonreducing environment exhibits a qualitatively different bimodal scaling function indicating diffusion-limited growth with a lower attachment barrier combined with C detachment from the graphene edges.

Graphene growth on molten Cu films supported on custom-designed Mo substrates demonstrate a similar 2D nucleation and growth mechanism. The study also explores the orientation of graphene islands on molten Cu. The roles of temperature gradient, chamber pressure and rapid thermal heating in C precursor-rich environment on graphene growth morphology on thin sputtered Cu films are explained. A comparison of graphene growth on electrodeposited Cu vs recrystallized Cu is also shown.

The growth process and the observed results are instructive for the burgeoning graphene industry. Due to the similarities between the growth mechanism of graphene synthesis using cold wall CVD and hot wall CVD, the considerable knowledge base relevant to hot wall CVD can be exploited for graphene growth using the relatively less-explored cold wall CVD. I also anticipate that applying the study of pre-coalescence size distribution method to other 2D material systems may be useful for elucidating atomistic mechanisms of film growth that are otherwise difficult to obtain.

**10:30 AM \*EL19.22.01**

**How's Your Interface?** Rodney S. Ruoff; Ulsan National Institute of Science and Technology, Korea (the Democratic People's Republic of)

The type of interface(s) formed between adjacent materials **A** and **B** can vary depending on **A** and **B** and parameters such as temperature and pressure—among others. Qualitative terms such as “chemisorption” (covalent bonding) and “physisorption” (van der Waals bonding and perhaps including H-bonding for some but not others) are used to describe bonding present at the interface. I will discuss several interfaces that interest me and my team—and how I think about these interfaces as providing opportunities for the growth of certain types of carbon and related (such as BN) materials. *We appreciate support from the Institute for Basic Science (IBS-R019-D1).*

**11:00 AM \*EL19.22.02**

**Three Theory Insights in 2D Growth, and Two Ideas in 2D Ferroelectrics** Boris I. Yakobson; Rice University, United States

(1) Why the 2D transition metal dichalcogenides grow better if salt is added to the mix? First-principles calculations of the atomistics behind-the-scenes, from the eutectic effect to gas-phase chemistry, reveal the mechanisms and suggest ways to better “cooking recipes” [Z. Liu et al. *Nature*, 2018: **556**, 355 || *JACS Nano*, 2021: **15**, 10525 || *JACS*, 2022: **144**, 7497]. (2) How to ensure that the produced 2D-layers are coveted single crystals and not a patchwork of inverted domains, disrupted by the grain boundaries? Vicinal plane substrates’ surface steps dictate the direction of 2D nucleation by virtue of edge-epitaxy. Theory reveals the key role of structural complementarity [*Nano Lett.* 2019: **19**, 2027], and thus predicts which substrates work best, e.g. for h-BN [T.-A. Chen et al. *Nature*, 2020: **579**, 219 || *Appl. Mater. Today*, 2023: **30**, 101734]. (3) This edge-step epitaxy offers a way to produce free, weakly-bonded borophene on insulator [*ACS Nano*, 2021: **15**, 18347], a potential breakthrough in the field, if experimentally realized.

(1<sup>+</sup>) We explore with DFT a hetero-bilayer of realistic 2D components: ferroelectric  $\text{In}_2\text{Se}_3$  and the  $\beta$ -Sb (known for its strong spin-orbit coupling). The  $\pm P$  of the  $\text{In}_2\text{Se}_3$  induces distinctly different electronics in the bilayer: if  $P$  points “inward”, it is a trivial insulator; switched “outward”, its state is nontrivial topological,  $Z_2 = 1$  — inviting future multifunctional devices’ applications [*Nano Lett.* 2021: **21**, 785].

(2<sup>+</sup>) In another example, the often-overlooked (blocked by the substrate) flexibility of 2D materials leads to unexpected behavior of the ferroelectrics. Introduced “ferro-flexo” coupling  $\sim P \times k$  in the Ginzburg-Landau-Devonshire  $J^4$ -energy, allows one to predict the spontaneous curvature  $k_s$  and the rise of Curie temperature, domain wall width, etc. for InP,  $\text{CuInP}_2\text{S}_6$  and  $\text{In}_2\text{Se}_3$ . Polarization switches do bend the layer, converting electrical signal to movement as an actuator, with efficient work-cycle [*ACS Nano*, 2023: **17**, 5121].

Tuesday Morning, November 28, 2023  
Hynes, Level 3, Room 301

**11:00 AM EL20.01.02**

**Thermodynamic Origin of Nonvolatility in Resistive Memory** [Jingxian Li](#) and Yiyang Li; University of Michigan, Ann Arbor, United States

Resistive memory or memristor is a highly potential memory and computing unit for next-generation information storage, in-memory computing, and neuromorphic computing. Valence change memory (VCM) is a promising memristor that stores information through the distribution of oxygen vacancy point defects in transition metal oxides.

The ability to store and retain information is a critical function of nonvolatile memory. It is widely believed non-volatility in resistive memory is a result of the slow diffusion kinetics of oxygen vacancies. In this work, we combine materials characterization, device measurements, ab initio, and continuum modeling and show instead that information retention results from phase separation that results from materials thermodynamics. We definitively show for the first time that the amorphous refractory metal oxides undergo spinodal decomposition into two phases with different metal to oxygen ratios. Moreover, the stability of this spinodal decomposition controls whether a resistive memory cell will be able to retain information over time.

By applying phase separation, a foundational principle of materials science, to the field of resistive memory, we explain for the first time why these materials are able to function as nonvolatile memory. We further highlight the critical importance of considering nonideal thermodynamic interactions such as phase separation for future electronic materials dominated by point defects.

**11:15 AM EL20.01.03**

**Fully Transient Simulation of Filament-Type Switching Operations in Unipolar and Bipolar Memristors by Combining Electrothermal and Phase-Field Models** Dongmyung Jung<sup>1</sup>, Chanhoo Park<sup>1</sup>, Ki-Ha Hong<sup>2</sup> and [Yongwoo Kwon](#)<sup>1</sup>; <sup>1</sup>Hongik University, Korea (the Republic of); <sup>2</sup>Hanbat National University, Korea (the Republic of)

Transient simulation of memristors where conductive filaments (CFs) dynamically evolve according to an electric field and temperature is a challenging subject. In the case of the valence change mechanism (VCM), the matrix and CFs can be regarded as two distinct phases, the high and low resistance phases (HRP and LRP), respectively. The HRP is stable. On the other hand, the LRP with a uniform concentration of defects is metastable. Therefore, the LRP spontaneously goes back to the HRP after some time, which explains the data retention. In many simulations of the memristor device, the defect migration was described by drift and diffusion (DD). In this case, a CF with a high defect concentration should start to dissolve immediately after forming or set because there is no electromigration at zero electric field and only diffusion by concentration gradient exists. Also, the closer to the outer part of the CF, the lower the defect concentration. In other words, the DD equation alone cannot explain the existence of the LRP with a uniform defect concentration. Phase-field model (PFM) is the most efficient to deal with a system where two distinct phases, LRP and HRP, are spatially mixed. We coupled the PFM with the electrothermal model along with defect generation and annihilation dynamics and successfully established a fully transient simulation of the forming, reset, and set operations of the VCM-based memristor. Using our model, both unipolar and bipolar switching can be simulated for the same active material by just changing boundary conditions that are bias conditions and interface properties with an electrode. It was shown that in the case of unipolar switching a CF evolves mainly by the generation and annihilation of defects whereas in the case of bipolar switching a CF evolves mainly by the electromigration of defects.

In our I-V curve simulation, the higher compliance current, the thicker CF as experimentally observed. Note that our simulation does not define any specific filament region in the model geometry. Only initial defects are randomly assigned. Also, the successive pulse operations were simulated for synapse applications. Most interestingly, the effects of the interval length between pulses could be observed. The CFs can evolve for the time when no pulse is applied, which is to reduce the interface energy for total energy minimization. As a result, a longer pulse interval resulted in better linearity in the long-term depression curve. More details and the results of our simulation will be shown in the actual presentation.

**Fusion of Solid-State Ionics and Electronics to Advance Neuromorphic Technology** [Kazuya Terabe](#), Takashi Tsuchiya and Tohru Tsuruoka; NIMS, Japan

For the further development of today's information society, hardware-oriented artificial intelligence (AI) systems, such as terminal equipment and brain computers that operate with low power consumption and small size, are expected to be developed. To realize such software-independent AI hardware, devices that realize various functions and performances, such as memristive and neuromorphic characteristics, are required. To this end, it is important to actively develop not only conventional semiconductor devices with properties suitable for digital arithmetic processing, but also new-concept devices operating on different principles. One of these is a new group of devices developed by fusing solid-state ionics and electronics. These devices operate by controlling the transport of ions and vacancies as well as electrons and holes in solids. Consequently, the transport of ions (vacancies) and the associated electrochemical phenomena can be used to control the local composition of device materials and even reconstructing the hetero-interface structure at will. In other words, it is the device nanoarchitectonics that is achieved by controlling ion transport. (named ionic nanoarchitectonics)<sup>[1]</sup>. This ionic nanoarchitectonics enables the control of various physical properties of device materials, and this control can create interesting devices with new functions and performance not found in conventional semiconductor devices. To date, we have created many devices with diverse functions using ionic nanoarchitectonics<sup>[1-4]</sup>. These devices include atomic switches, decision-making devices, artificial synaptic devices<sup>[5]</sup>, solid-state electrical double-layer transistors, artificial vision<sup>[6]</sup>, physical reservoir devices<sup>[7]</sup> and so on. Ion nano-architectonics, based on the fusion of solid-state ionics and electronics, is a promising method to enhance neuromorphic technology.

**Memristors and Arrays for Analog Computing with High Precision** J. Joshua Yang; University of Southern California, United States

The analog data deluge issue nowadays call for multipurpose analog computing platforms with great reconfigurability and efficiency, namely, field programmable analog arrays (FPAAs).[1] FPAAs as the analog counterpart of field programmable digital arrays (FPGAs) open opportunities for fast prototyping analog designs as well as efficient analog signal processing and neuromorphic computing. Memristors may be the ideal building blocks for FPAAs if they are truly analog with many conductance levels, not just for lab-made devices, but more importantly, devices fabricated in foundries. We have recently demonstrated 2048 conductance levels, a record among all types of memories, achieved with memristors in fully integrated chips with 256x256 memristor arrays monolithically integrated on CMOS circuits in a standard foundry.[2] We have unearthed the underlying physics that previously limited the number of distinguishable conductance levels in memristors and developed electrical operation protocols to circumvent such limitations. These results reveal insights into the fundamental understanding of the microscopic picture of memristive switching and provide approaches to enable high-precision memristors for various applications.

**Valence Change Memristive Devices for Bio-Inspired Information Pathways** Anna Linkenheil, Jonas Schneegaß, Benjamin Spetzler, Zhansong Geng, Kristina Nikiryu, Tzvetan Ivanov, Frank Schwierz and Martin Ziegler; Technische Universität Ilmenau, Germany

Memristive devices have attracted considerable attention in the electronic device community due to their inherent memory effect, which allows them to mimic the function of biological synapses. As such, they are a key building block for realizing artificial neural computing schemes in hardware, so-called neuromorphic systems. However, there are various neuromorphic architectures with different requirements for memristive devices, requiring optimization of electrical properties and materials as well as the technological framework for each specific application.

This talk will discuss the challenges and prospects of memristive devices for neuromorphic computing in general and several selected examples. Valence-change-based memristive devices are presented, and it will be discussed how their properties can be tailored by systematic design variations for applications in neuromorphic computing architectures. Furthermore, it is shown how the resistance change of memristive devices affects the dynamics of networks and how network dynamics influence network connectivity. Important requirements for memristive devices will be discussed, and it will be shown how a new way of information processing beyond current approaches can open a new bio-inspired pathway toward the construction of cognitive electronics.

This work was partially funded by the Carl-Zeiss Foundation via the Project MemWerk and the German Research Foundation (DFG) through the Collaborative Research Centre CRC 1461 "Neurotronics – Bio-Inspired Information Pathway".

### 3:00 PM EL20.02.05

**Electroforming-Free Threshold Switching in Polycrystalline ErMnO<sub>3</sub> Films Based Two-Terminal Devices** Rong Wu<sup>1,2</sup>, Florian Maudet<sup>1</sup>, Thanh Luan Phan<sup>1</sup>, Wassim Hamouda<sup>1</sup>, Veeresh Deshpande<sup>1</sup> and Catherine Dubourdieu<sup>1,2</sup>; <sup>1</sup>Helmholtz-Zentrum Berlin, Germany; <sup>2</sup>Freie Universität Berlin, Germany

Rare-earth hexagonal manganites h-RMnO<sub>3</sub> (R=Y, Er, Ho to Lu) have been extensively studied as multiferroic materials in the last 15 years. The study of non-volatile unipolar resistive switching behavior in polycrystalline YMnO<sub>3</sub> was reported, indicating that h-RMnO<sub>3</sub> may be promising candidates for memristive devices owing to their intriguing ferroelectric domain pattern - vortex lines where six-fold domains merge [1], [2]. In this work, we report the first demonstration of volatile resistive switching behavior observed in polycrystalline ErMnO<sub>3</sub> thin films. The devices exhibit a repeatable unipolar threshold switching behavior. To fabricate the devices, 60 nm-thick ErMnO<sub>3</sub> thin films were deposited on Pt-coated Si wafers using RF sputtering. Subsequently, a post-deposition annealing process was carried out at 750 °C in N<sub>2</sub>, resulting in the formation of polycrystalline ErMnO<sub>3</sub> thin films with mixed orthorhombic and hexagonal crystalline phases. Further engineering was realized through a subsequent thermal treatment at 400 °C in air. Top Pt electrodes were then patterned. The two-terminal Pt/ErMnO<sub>3</sub>/Pt devices exhibit high endurance (>10<sup>4</sup> cycles) and low variability. To gain a clear understanding of the physical origin of the threshold switching and to open a path for potential applications, a detailed structural study (X-ray diffraction, Raman spectroscopy, X-ray photoelectron spectroscopy, scanning electron microscopy) and extensive electrical characterization (current-voltage and voltage-current measurements including as a function of temperature, conductive atomic force microscopy) were performed. We propose a physical model to explain the observed threshold switching effect and current controlled negative-differential resistance behavior. Our model involves trap-assisted and thermally-activated Poole-Frenkel conduction, along with local Joule heating effects. We will discuss how the engineering of the microstructure, specifically the inclusions of minor orthorhombic phase within the hexagonal phase, plays a crucial role in achieving the threshold switching behavior. These devices hold great promise as candidates for building spiking neurons in leaky integrate-and-fire (LIF) neuron circuits [3].

**Oxygen Tracer Diffusion in Substoichiometric Hafnium Oxide for Resistive Memory** Dongjae Shin<sup>1</sup>, Jingxian Li<sup>1</sup>, Karsten Beckmann<sup>2</sup>, Anton V. Ievlev<sup>3</sup> and Yiyang Li<sup>1</sup>; <sup>1</sup>University of Michigan, United States; <sup>2</sup>State University of New York Polytechnic Institute, United States; <sup>3</sup>Oak Ridge National

Laboratory, United States

Resistive memory are highly promising candidates for neuromorphic computing due to their ability to retain a constant resistance state over time. Hafnium oxide-based memristors in particular have shown exceptional retention stability, exceeding 10 years at 85°C. It is believed that this retention stability is a result of slow oxygen vacancy migration; however, there exists substantial discrepancy between the experimentally measured device retention time and the characteristic oxygen diffusion time of HfO<sub>2</sub>. In this work, we measure the oxygen <sup>18</sup>O tracer diffusion of different HfO<sub>x</sub> thin films with different metal-to-oxygen ratios. We found that sub-stoichiometric hafnium oxide exhibits ~1-3 orders of magnitude lower diffusivity compared to stoichiometric HfO<sub>2</sub>. We show that the retention time of Hafnia memristors can be approximated by the diffusion time when we use this lower oxygen diffusivity of the substoichiometric oxide, resolving the question of why Hafnia memristors are able to retain state.

### 3:30 PM \*EL20.02.07

**New Mechanism in Ohmic VCM Devices - Prospective and Challenges** Shaochuan Chen<sup>1</sup>, Teng Zhang<sup>2</sup>, Heinrich Hartmann<sup>3</sup>, Astrid Besmehn<sup>3</sup>, Yuchao Yang<sup>2</sup> and Iliia Valov<sup>3,4</sup>; <sup>1</sup>RWTH Aachen University, Germany; <sup>2</sup>Peking University, China; <sup>3</sup>Research Center Juelich, Germany; <sup>4</sup>Institute of Electrochemistry and Energy Systems, Bulgaria

Functionalities, properties and stability of memristors are determined by three main factors – physico-chemical processes materials and operation scheme, where the first two factors are inherently related. It is a of highest priority of the ongoing research to improve memristors in several important aspects including multi-functional use, variability, state stability and degenerative processes. A way to progress in fundamental aspect understandings and applications is to achieve understanding and control over the physical processes involved in the formation of different resistive states and based on this knowledge to design reliable materials system being with predictable and adjustable properties. Several important aspects of the operation principles have been relieved, such as effects of protons and ambient moisture, interface interactions, migration of cations believed to be immobile, nanobattery effect, influence of the capping layers and film thicknesses etc.

In this work, we present a new mechanism observed in ohmic oxide memristors that allows for significant improvement of the device characteristics and stability. The switching performance depends on materials used for electrodes, their electrochemical activity and redox potential. We found that not Schottky barrier is necessary to switch the devices and reach reliable operation. *In situ* TEM analysis have shown that contribution of different ionic species is responsible for two distinctive switching mechanisms that in turn determine the performance. Based on this knowledge we were able to design devices showing multiple functionalities and with significantly improved characteristics.

### 8:00 PM EL20.03.01

**Flexible and Disposable Paper-Based Optoelectronic Physical Reservoir Devices** Hiroaki Komatsu, Norika Hosoda and Takashi Ikuno; Tokyo University of Science, Japan

Wearable sensor devices that use physical probes such as light and electric potential to monitor health conditions are widely used in the biomedical field. To classify and predict health conditions, the acquired data needs to be transmitted to an AI system in the cloud. The communication of such a large amount of data involves issues such as network load and communication speed. One of the methods to solve these issues is that we allow the sensor itself to have AI functions, such as physical reservoir (PR) devices. We believe that in-sensor optoelectronic PR device, which has (1) response times that match the time scale of biological signals (0.1-100 s), (2) flexibility, and (3) disposability, is one of the ideal frameworks to realize intelligent sensors. However, because the response times of the optoelectronic PR devices reported so far are several tens of milliseconds, it difficult to handle biological signals [1,2]. Moreover, flexibility and disposability have also not been addressed.

In this study, we fabricated an optoelectronic PR device that satisfy three requirements mentioned above. Our device is composed of ZnO nanoparticles (NPs)-embedded cellulose nanofiber (CNF) freestanding film. The film was prepared by spray deposition of CNF aqueous solution dispersed with ZnO NPs (average diameter: 25 nm)[3]. Patterned Au electrodes were formed on the film surface. We demonstrated a pattern recognition using ultraviolet (UV) light input pulses. To verify that it works as a PR device, the film was exposed to UV pulsed light encoded with 4-bit patterns (pulse width: 50-500 ms, wavelength: 365 nm), and the photocurrent was measured.

Under the UV pulsed light irradiation, the film showed the rise and decay time constants of 6.4 s and 3.4 s, respectively, indicating that our films have a time scale compatible with biomedical applications. Furthermore, the maximum photocurrent was increased with increasing the number of pulses when the UV light was repeatedly irradiated. This phenomenon indicates that our films exhibit the short-term memory required for reservoir devices. To demonstrate the AI performance, handwritten digit recognition was conducted using MNIST databases. Our device showed accuracy of 88%. Therefore, it was demonstrated that our films can be used as a PR device. In addition, handwritten digit recognition using our film with a bending radius of 9.5 mm and 16.1 mm showed almost no change in accuracy compared to the flat condition. Thus, it was demonstrated that our film can be used in the bent state. In this session, we will describe the results of pattern recognition in the bent state and introduce the possibilities of disposability.

**Organic Neuromorphic Electronics for Emulating and Interfacing Biological Systems** Paschalis Gkoupidenis; Max Planck Institute for Polymer

Research, Germany

Harnessing the exceptional efficiency of the brain in information processing at the technological level can be condensed in the terms “artificial intelligence” and “neuromorphic computing”. A popular approach in artificial intelligence is the representation of information processing aspects found in biological systems with artificial neural networks (ANNs). This approach is based on executing algorithms, that loosely represent the function of the nervous system, on traditional computer architectures. Over the last decade, the field of artificial intelligence (AI) has demonstrated an enormous potential for complex processing and efficient computing. However, concepts of AI are mainly based on digital operating principles, while being part of an analogue world with great diversity in signaling. Moreover, AI still lacks the efficiency and computing capacity of biological systems. Alternatively, neural functions can be directly emulated with non-conventional devices, circuits and architectures. This hardware-based paradigm of brain-inspired processing is known as neuromorphic electronics.

In this talk, various neuromorphic devices will be presented that are based on organic mixed conductors, materials that are traditionally used in bioelectronics. A prominent example of a device in bioelectronics that exploits mixed ionic-electronic conductivity phenomena is the organic electrochemical transistor (OECT). Organic neuromorphic electronics based on OECTs have the ability to emulate efficiently and with fidelity a wide range of bio-inspired functions including synaptic plasticity and neuronal dynamics. The presence of a global electrolyte in an array of devices also allows for the homeostatic control of the array. Global electrical oscillations can be used as global clocks that phase-lock the local activity of individual devices in analogy to the global brain oscillations. Moreover, “soft” interconnectivity through the electrolyte can be defined, a feature that paves the way for parallel interconnections between devices with minimal hard-wired connections. Finally, practical demonstrations will be shown, highlighting the potential of organic materials in robotics, neuromorphic sensing and biointerfacing.

**Proton-Based Electrochemical Random Access Memory using Nickel (Oxy)Hydroxide** [Andrew J. Jalbert](#) and Yiyang Li; University of Michigan, United States

In-memory computing using analog resistive memory cells can be substantially more efficient than digital computing. Electrochemical random-access memory (ECRAM) using protons or oxygen vacancies are a highly promising solution. Nickel Hydroxide is an electrochromic material that can be switched between two phases: Ni(OH)<sub>2</sub> (Hydroxide) and NiOOH (Oxyhydroxide) upon the insertion or removal of protons. In this work, we investigate the use of Nickel (Oxy)Hydroxide as a proton-based ECRAM material. We show that this material is able to switch resistance states in a linear and analog fashion by electrochemically shuttling protons through an alkaline electrolyte media at room temperatures. Importantly, this ECRAM cell is also able to retain information over time, providing the potential for long-term, nonvolatile, and analog information storage.

**Investigation of Drain Bias Stress Effect on IGZO TFTs Based Charge Storage Neuromorphic Circuits** [Ung Cho](#), Minseung Kang, Jaehyeon Kang, Hyeongjun Seo and Sangbum Kim; Seoul National University, Korea (the Republic of)

Charge storage type neuromorphic synapse circuits such as 2T0C, 3T1C and 6T1C have recently emerged as alternatives to nonideal nonvolatile memories for on-chip training of deep neural networks, particularly in terms of linear and symmetric weight updates [1]. Utilizing amorphous InGaZnO (a-IGZO) thin film transistors as update transistors instead of traditional Si CMOS enables long data retention and low power consumption due to their superior low leakage characteristics [2]. However, the reliability of the IGZO TFTs remains a critical challenge, particularly regarding oxygen vacancies in the active channel, gate insulator, and channel/gate insulator interface [3]. While previous research has extensively studied stability problems under positive bias stress (PBS), negative bias stress (NBS), and hot carrier stress (HCS), investigations on the impact of drain bias stress (DBS) on IGZO TFTs are limited. During the off-state, where no programming occurs and weights are maintained in the storage capacitor, the update transistors are exposed to drain and off-state gate bias stress. The off-state accounts for the majority of time in the operational scenario in charge storage type neuromorphic circuits, thus highlighting the significance of DBS stability analysis. This study focuses on investigating the effect of DBS at the transistor level, modeling degradation and unveiling its mechanisms. Furthermore, the impact of DBS on IGZO TFTs based charge storage neuromorphic circuits was assessed using the proposed model.

Electrical measurements were conducted to assess the reliability at the unit transistor level. The evaluation of gate bias stress, including both PBS and NBS, revealed little degradation in terms of threshold voltage ( $V_{th}$ ), subthreshold swing (SS), and on-current. On the other hand, during the evaluation of drain bias stress,  $V_{th}$  and SS demonstrated little change, while a noticeable on-current degradation was observed. Additionally we simulated the off-state by applying both drain bias and negative gate bias simultaneously, it was observed that the greater the negative bias, the more significant on-current degradation occurred. Complementary measurements, including capacitance-voltage measurements and the evaluation of transistors with various dimensions, were performed in order to elucidate degradation mechanisms and indicate the physical meaning of degradation through a stretched exponential model. The degradation model parameters, such as the time constant of electron trapping and the saturation point of current degradation, demonstrate an increased degradation with more negative gate bias. Using the proposed degradation model, the weight change of 3T1C neuromorphic circuits after cycling endurance could be successfully predicted. Furthermore, the impact of DBS on training and inference accuracy was investigated. Leveraging the knowledge gained from this study enables the design of more reliable IGZO TFTs based neuromorphic circuits and their operation, advancing the development of robust and efficient neuromorphic systems.

**Electrolyte and Neurotransmitter Dependency of Long-Term Plasticity in Biohybrid Synapses** [Francesca Santoro](#); Forschungszentrum Jülich/RWTH Aachen University, Germany

The replication of neural information processing in electrical devices has been extensively studied over the years. The paradigm of parallel computing,

which allows information to be simultaneously detected, processed and stored, is required for numerous applications in many fields. In the case of brain-computer interfaces, another important requirement is the suitability of the device for communication with cells. Organic electrochemical transistors (OECTs) based on PEDOT:PSS are used for this purpose due to their ionic-to-electronic signal transduction and biocompatibility [1]. Many works have demonstrated the reproduction of neural plasticity mechanisms, such as short-term facilitation and long-term potentiation. In each device, the physical mechanism of transduction may be different, but it is known that the electrolyte plays a key role in the functioning of these devices, as it provides the ions responsible for the chemical transmission of information. Focusing on long-term memory, this can be reproduced in the OECTs with the oxidation of the neurotransmitter, as in the case of the biohybrid synapse [2]. It is crucial to understand the influence of the electrolyte composition on the memory effect of the device, as long-term modulation is based on a change in the ionic balance between the electrolyte and the organic polymer. For this reason, the influence of some of the most used electrolyte compositions on neurotransmitter-mediated long-term plasticity was analyzed in this work. The interaction of electrolytes with dopamine oxidation was investigated by means of the cyclic voltammetry technique, and the effect on channel conductance was studied by applying pulses of different amplitude and duration as gate voltage of the transistors. It was shown that long-term memory can be hidden under certain conditions, such as the presence of  $Mg^{2+}$  and  $Ca^{2+}$  in the electrolyte. This electrolyte-dependency plasticity should be considered when the OECT is used in a biological environment in which a large number of molecules of a different nature, in addition to neurotransmitters, are present. The next step in this analysis involves the effect of the electrolyte in more neurotransmitter-sensitive OECTs, with micrometer-sized channel area.

**More is Different: Physical Computing Discovery** Elliot J. Fuller; Sandia National Laboratories, United States

The heterogenous integration of novel materials with existing technology is critical to beyond Moore computing paradigms. Digital computation based upon silicon has relied heavily on a reductionist hierarchy, wherein the system can be reduced to simple rules and elements can be designed separately. However, this hierarchy collapses when novel materials are integrated into physics-based compute paradigms due to the twin difficulties of complexity and scale. Physical compute systems must be co-designed. In 1972, the physicist Philip W. Anderson coined the term, “more is different” to describe emergent phenomena that occur in complex systems where entirely new properties appear, especially where symmetries are broken<sup>1</sup>. Here I will discuss experimental work on building complex physical systems that execute computational kernels, for example outer product updates<sup>2</sup>, and how these systems are “different” from their digital counterparts. Next, I will demonstrate how models can be used to predict the evolution of simple neuromorphic learning systems when operated under certain constraints<sup>3</sup>. These models break down when phase transformation (or symmetry breaking) occurs and the collective behavior of an ensemble of interacting elements is expected to exhibit emergent phenomena. Finally, I will discuss the development of a computing discovery platform to study emergent materials behavior, wherein rapid synthesis, characterization, and integration of new materials into compute arrays enables studying compute outcomes at scale (>1,000 interacting elements).

#### 10:45 AM EL20.05.02

**CMOS-Compatible Electrochemical Synaptic Transistor Arrays for Deep Learning Accelerators** Jinsong Cui<sup>1</sup>, Fufei An<sup>1</sup>, Yuxuan Wu<sup>1</sup>, Jiangchao Qian<sup>1</sup>, Saran Pidaparthi<sup>1</sup>, Jian-Min Zuo<sup>1,2</sup> and Qing Cao<sup>1,2</sup>; <sup>1</sup>University of Illinois, United States; <sup>2</sup>University of Illinois at Urbana-Champaign, United States

In-memory-computing architectures based on memristive crossbar-arrays can enhance the computing efficiency for deep-learning with massive parallelism. However, to fulfill their potential, the core memory devices must be capable of providing high-speed and symmetric analog programming with small variability, compatible with silicon technology, and scalable into nanometer-size footprint. We present an electrochemical synaptic transistor, built with CMOS-compatible metal oxides and operating by shuffling protons within a symmetric gate stack, to meet all these stringent requirements. It can be monolithically integrated with silicon transistors to form pseudo-crossbar arrays where parallel, precise, and symmetric programming of the channel conductance can be executed with gate-voltage pulses. High-speed programming with frequency approaching megahertz, endurance above 100 million read-write pulses, and device critical dimensions down to  $150 \times 150 \text{ nm}^2$  have all been realized.

#### 11:00 AM EL20.05.03

**Nonvolatile Electrochemical Random Access Memory using Phase Separation** Virgil J. Watkins, Diana Kim, Laszlo Cline and Yiyang Li; University of Michigan, United States

Analog neuromorphic computing can decrease the energy consumption of data-intensive tasks like machine learning by orders of magnitude through conducting matrix vector multiplication using Ohm's and Kirchoff's Laws. Electrochemical random access memory (ECRAM) stores and switches analog resistance states by electrochemically modulating the concentration of oxygen vacancies in a transition metal oxide. Unfortunately, most ECRAM devices are volatile and revert to equilibrium, with retention times orders of magnitude lower than the typical 10 year, 85C requirement. In our work we develop a nonvolatile ECRAM cell using tantalum oxide. Our core innovation is the use of phase separating materials in the miscibility gap. In this configuration, all resistance states have the same chemical potential, thereby eliminating the driving force for volatility. This result not only exceeds the expected 10 year lifetime, but can provide a memory cell with potentially indefinite retention at elevated temperatures.

#### 11:15 AM EL20.05.04

**Electric Field Regulated High Thermal Rectification Ratio using Ferrocenyl Terminated Molecular Junction** Xingfei Wei and Rigoberto Hernandez; Johns Hopkins University, United States

Conventional silicon-based electronic devices have electron conductance rectification ratios greater than . This magnitude was achieved in molecular electric diode composed of ferrocenyl (Fc) terminated self-assembly monolayers (SAMs) developed by the Nijhuis group [*Nature Nanotech* 12, 797–803 (2017)]. Perhaps surprisingly, the largest thermal rectification ratio reported so far in materials and devices is at the magnitude of near 1. Applying the same electrostatic attraction mechanism seen by the Nijhuis, we have found in atomistic simulations that ferrocenyl terminated molecular junctions can also achieve high thermal rectification ratio. In the forward bias case, the top electrode is negatively charged, the Fc group is positively charged, and the strong electrostatic force drag the Fc group closer to the top electrode and thereby enhances thermal conductance. In the backward bias case, the Fc group is charge neutral, and the electrostatic force between the Fc groups and the top electrode is weak and thereby reduces thermal conductance. We will report the distance between the two electrodes, the partial charge on the Fc group, the electric field magnitude, and the number of SAM molecules affecting heat transfer. The implications of this work for developing next-generation phononic devices will also be discussed.

**Volatile and Non-Volatile Memristive Technologies Implementing Tunable Dynamic and Relaxation for Spiking Neural Networks** Sabina Spiga; CNR-IMM, Italy

Hardware spiking neural networks (SNNs) are currently attracting an increasing interest towards low-power computing systems for edge applications, such as the ones relying on smart analysis of sensory signals in real time. Taking inspiration from brain computation, which processes information with temporal structure, it is desired that also neuromorphic chips compute with dynamics, encompassing devices and circuits able to compute and elaborate information over multiple time scales. In current CMOS-based neuromorphic chips, the integrative functions and temporal dynamics are mainly implemented by capacitors. Anyway, they hardly provide in the system time constants over ms or tens of ms, and their capacitance density is difficult to be scaled-up without occupying large silicon area. Within this framework, memristive technologies have recently shown great promise to substitute or complement CMOS circuits in hardware SNNs, with key role in providing novel and compact dynamical elements which can mimic the neuronal and synaptic features, and are able to extend the time domain of the computing system.

Our work focuses on memristive technologies capable of exhibiting tunable dynamics, integrative functions and relaxation effects which can span up to seconds or longer, up to the non-volatile behavior. The devices are based on the structure Ag/SiO<sub>x</sub>/Pt or Ag/Al<sub>2</sub>O<sub>3</sub>/SiO<sub>x</sub>/Pt stacks and the switching mechanism relies on the formation and dissolution of a silver-based filament shorting the two electrodes. The filament can be unstable and exhibits a relaxation behavior once the programming voltage is removed. In the ON, low resistance state, it is also possible to achieve conductance modulation as a function of the input stimuli. We will show that the devices show dynamic behaviors over multiple time scales which originate from an interplay of accumulation and relaxation effects, and the overall features can be controlled by programming conditions and material engineering.

**Enhancing Memory Retention of FAB Compatible ECRAM Devices using an Ion Blocking Layer** Nir Tessler<sup>1</sup>, Seonuk Jeon<sup>2</sup> and Jiyong Woo<sup>2</sup>;

<sup>1</sup>Technion-Israel Institute of Technology, Israel; <sup>2</sup>Kyungpook National University, Korea (the Republic of)

Traditionally, the only ions allowed or welcomed by the microelectronic industry are those that act as fixed dopants. The issue of mobile ions became welcome primarily due to the memristor technology however, thin film transistor technologies benefit from them too. The electrochemical (transistor) random access memory (ECRAM) is emerging as a promising building block for multi-level neuromorphic computing. Using FAB-compatible materials we construct the ECRAM using CuOx as the gate and ions source (Cu+). The morphology of the HfOx gate insulator layer is finetuned to render it ion transporting such that it can act as a uniform electrolyte layer. Lastly, the channel material is WOx with tungsten metal as the source/drain contact.

While there are several reports of ECRAM devices, the operation mechanisms are not fully known/understood thus withholding progress of this field. Using the Sentauros device simulator by Synopsis, including the hydrogen diffusion module, we simulate the mixed ionic electronic operation of the device. We have recently reported that by fitting the simulation to the device performance we could identify the potentiation mechanism (i.e., insulator charging) and the occurrence of copper plating that takes place under high Cu+ ion flux (as in fast charging of Li batteries).[1]

In the first part of the talk, we will expand on the chemical-physics details of the ECRAM device mentioned above. Next, we will present a new device architecture where an ion-barrier layer is introduced and is shown to enhance memory retention. The third device structure is where we remove the WOx layer and study the ionic-electronic conduction of a modified HfOx layer.

Using the above three device architectures in conjunction with the mixed ionic-electronic device simulation we reveal the role of the two memory mechanisms: a) Electric field-activated ion transport and b) Structure-induced trapping by ion-barrier layers.

**Probabilistic Computing using Metal Nanoparticles-Embedded Mott Threshold Switches for True Random Number Generator** Yewon Seo, Yunkyu Park and Junwoo Son; Pohang University of Science and Technology, Korea (the Republic of)

VO<sub>2</sub> threshold switch, which undergoes a insulator-to-metal transition above a threshold voltage, shows promise as a candidate for stochastic switching due

to its capacity to determine the overall electrical transition in devices through the percolative formation of metallic filaments [1]. However, geometric evolution of the switchable (metallic or insulating) domains significantly influences the stochastic switching in VO<sub>2</sub>; the performance of VO<sub>2</sub> based stochastic devices (e.g., true random number generators) could be tuned by the evolution of metallic domains in the insulating matrix and random formation of conducting filaments [2].

Here, we achieve drastic enhancement of intrinsic stochastic operation under pump-probe procedure in Pt-nanoparticle-embedded VO<sub>2</sub> (Pt-VO<sub>2</sub>) two-terminal devices. In particular, metallic Pt nanoparticles enable an extension of memorization time from pump pulse, which enhances probability of certain selection to show random firing of on/off (1 or 0) states under probe pulse; the extended recovery time to the insulating state presents a wide range of options in terms of probe voltage amplitude and delay time, thereby enhancing the randomness of the switching behavior upon application of the second probe pulse. Moreover, this device has the advantage of high speed (667 kbits/s), low power consumption (12 nJ/bit), high endurance (>105200 bits), and mass production, which is key requirement to realize true random number generator (TRNG). Therefore, our result provides a new strategy to improve stochastic switching characteristics in Mott threshold switches for high performance TRNG.

**Aubergine to Blackberry: Nature Derived Chromophores to Mimic Photosensitive Neurons in Human Eye** Maxim Shkunov<sup>1</sup>, Aimee Sweeney<sup>1,1</sup>, Annelot Nijkoops<sup>1,2</sup>, Leslie Askew<sup>1</sup>, Manuela Ciocca<sup>2</sup> and Luisa Petti<sup>2</sup>; <sup>1</sup>University of Surrey, United Kingdom; <sup>2</sup>Free University of Bozen-Bolzano, Italy

Visual information processing in vertebrates begins with light detection by the eye's retina cone and rod cells. Tri-colour cones, typical for primates, respond to blue, green and red/yellow spectral bands, whereas rods cell are extremely sensitive to low light intensities, providing grey-scale vision. Mimicking behaviour of these cells with optoelectronic devices opens up opportunities for neural stimulation, artificial retina, superhuman vision devices, and self-powered optical sensors. Nature is also rich in conjugated, organic semiconductor molecules, with various bandgaps, thus offering colour-specific responses in the visible spectral range.

In this work we explore fruit- and vegetable-derived conjugated chromophores from various berries, including raspberry, blackberry, elderberry, blueberry, as well as aubergine, beetroot, red cabbage and spinach, targeting photo-induced response in three spectral bands, red, green and blue. Self-assembly binding properties of these molecules allow to build chromophores-decorated TiO<sub>2</sub> nano-porous structures inspired by dye-sensitised solar cell technologies. We demonstrate photo-capacitor devices employing the chromophores, interfaced with biological electrolyte (phosphate buffered saline), showing spiking photocurrent (photovoltage) response under low-intensity pulsed light excitation.

Absorption spectra of chromophores were found to be in the visible part of the spectrum, with chlorophyll derived from spinach peaking at 440 nm, and with anthocyanins and betalains chromophores' peaks at around 520 nm. The photocurrent spectral response of the samples was correlated with that of absorption; however, some spectral shifts were observed. Photo-current response signals were clearly present for all samples, with magnitude from few tens to hundreds of nA when exposed to pulsed-light flash cycles with a pulse length of few tens of milliseconds. This is comparable to typical biological response times. The results suggest that nature- derived conjugated chromophores present feasible environmentally-friendly semiconductors for opto-stimulated devices with colour-selectivity. They also produce photo-current and -voltage responses corresponding to hyperpolarisation and depolarisation of cell membranes associated with neurons' spiking behaviour.

**Tuning the Relaxation Time of Diffusive Memristors for Neuromorphic Applications** Qiangfei Xia; University of Massachusetts, United States

A diffusive memristor is a volatile resistance switch with a metal/oxide/metal structure. It goes to a low resistance state when an electrical stimulus is applied and automatically relaxes back to its original high resistance state if the stimulus is removed. The switching behavior is attributed to the formation and rupture of a localized conducting channel within the oxide layer. Because of their structural similarity with biological ion channels, diffusive memristors have been successfully used to emulate typical synaptic and neuronal behavior such as spike-timing-dependent plasticity, leaky integrate and fire, etc. However, a remaining issue of the diffusive memristor is the non-uniform and non-controllable relaxation time (the time it takes to go from low to high resistance states), which limits the wide-range adoption of such devices in large arrays for real-world problems. In this work, we designed and fabricated diffusive memristors with uniform and tunable relaxation times. We adopted a double oxide switch layer that led to an over ten-fold improvement in the cycle-to-cycle uniformity. By connecting the device to different resistors, we tuned the relaxation time up to three orders of magnitude. This controllable and uniform relaxation process was utilized to generate the time surfaces in the hierarchy of time surface (HOTS) algorithm for pattern recognition.

**Characterization of Crystallization Kinetics in Phase-Change Materials using Indirectly Heated Phase-Change Memory and its Application to One-Shot Weight Transfer** Inhyuk Choi, Minseung Kang, Wonseok Choi and Sangbum Kim; Seoul National University, Korea (the Republic of)

Phase-change memory (PCM) exhibits notable advantages such as non-volatility, fast operating speed, scalability, and high reliability, making it a promising candidate for analog synaptic devices in neuromorphic computing. However, challenges related to nonlinearity and asymmetry in weight modulation need to be addressed [1]. Consequently, weight modulation predominantly relies on the gradual crystallization process, as amorphization through a melt-quench process induces abrupt changes in weight values [2]. In the context of off-chip training, concerns regarding nonlinearity and asymmetry can be alleviated since the weights pre-trained by the software can be accurately transferred to the PCM synaptic array using an iterative program and verify scheme [3]. However, it is noteworthy that this iterative scheme is not energy-efficient and can potentially accelerate the endurance failure of PCM devices.

In contrast to conventional PCM structures that employ self-heating of phase-change materials, indirectly heated PCM structures utilizing externally generated heat have been suggested for high-reliability memory devices [4] and RF switches [5]. Here, for the first time, we propose the application of indirectly heated PCM as an energy-efficient and highly reliable one-shot weight transfer device through a single programming pulse with a simultaneous verify process. To ensure precise weight transfer, a comprehensive understanding of the crystallization process occurring within the device is crucial. Indirectly heated PCM itself can be used to characterize the crystallization kinetics [6], enabling faster heating rates close to device operation and broader temperature ranges encompassing melting points compared to previous characterization studies using differential scanning calorimetry (DSC), a laser with transmission electron microscope (TEM) analysis, and other device-based approaches [7-9]. After optimization through finite element method (FEM) simulation, we fabricated an indirectly heated PCM device designed to achieve a uniform temperature distribution in the phase-change material. Crystallization properties, including crystallization temperature, time, and activation energy, were measured over a wide temperature range for various phase-change materials exhibiting either nucleation-dominated or growth-dominated crystallization. For growth-dominant materials, growth rates spanning several orders of magnitude were estimated in conjunction with calibrated FEM simulations. Additionally, we will discuss the crystallization characteristics and device structures that need to be considered to enhance the energy efficiency and accuracy of one-shot weight transfer in indirectly heated PCM devices.

**Mechanisms in Gadolinium-Doped Gallium Nitride for Future Computing and Quantum Applications** Vishal Saravade<sup>1,2</sup>, Chuan Zhou<sup>3</sup>, Zhe Chuan Feng<sup>2</sup>, Benjamin Klein<sup>2</sup> and [Ian T. Ferguson](#)<sup>2</sup>; <sup>1</sup>Pennsylvania State University, United States; <sup>2</sup>Kennesaw State University, United States; <sup>3</sup>Missouri University of Science and Technology, United States

Characterizations and mechanisms in gadolinium-doped gallium nitride (GaGdN) that can enable its applications for future neuromorphic and quantum computing will be presented. Gallium nitride (GaN) has been a well-investigated compound semiconductor for power devices, LEDs, photodetectors, and neutron detection applications. However, spintronic properties of GaN have either not been found to be suitable for future quantum computing applications or have not been well explored. In this work, the results obtained and mechanisms observed and identified in GaGdN indicate the potential suitability of GaGdN for spintronic applications. Monocrystalline GaGdN thin films were deposited on sapphire substrates by metal-organic chemical vapor deposition (MOCVD). Two Gd precursors were used to observe the variations in the properties with different metal-organic sources. GaGdN grown using a (TMHD)<sub>3</sub>Gd precursor showed Anomalous Hall Effect (AHE) based on a carrier-mediated mechanism due to carrier-hopping and metallic conduction. GaGdN grown using a Cp<sub>3</sub>Gd precursor exhibited Ordinary Hall Effect (OHE) indicating no signs of spin polarizations. A key difference between the (TMHD)<sub>3</sub>Gd and Cp<sub>3</sub>Gd precursors is that (TMHD)<sub>3</sub>Gd precursor contains oxygen in its organic ligand. In order to clearly understand the mechanisms for spin properties in GaGdN, GaGdN grown using Cp<sub>3</sub>Gd source were implanted and doped with oxygen and carbon. As-grown Cp<sub>3</sub>Gd that showed OHE, after O or C implantation showed AHE, which is a sign of spin polarization. Resistivity of GaGdN from Cp<sub>3</sub>Gd source increased after O or C-implantation increasing which indicates the introduction of O- and C-induced deep interstitial states. The n-type carrier concentration reduced upon implantation, which indicates that these energy states are acceptor-type. Annealing was done to stabilize the O- and C-dopants in GaGdN from Cp<sub>3</sub>Gd. After annealing, AHE signal in GaGdN:O reduced in smoothness but the resistivity decreased and the carrier concentration increased. On the other hand, annealed GaGdN:C showed a smoother AHE signal, an increased resistivity, and a reduced carrier concentration. X-ray diffraction (XRD) measurement showed that O and C stabilize in GaGdN:O and GaGdN:C at interstitial sites and render the AHE. The nature of crystallographic incorporation and effects of annealing on the spin-related properties of GaGdN:O and GaGdN:C were different even though both showed room temperature AHE. The mechanism in GaGdN for room temperature spintronics is carrier-mediated and is activated by O or C-induced deep interstitial acceptor energy states. Insights into these mechanisms can aid the further developments in III-Nitrides for future heterogeneous computing, machine-learning devices, neuromorphic computing, and quantum applications.

#### 4:30 PM \*EL20.07.04

**Integration of Ag-CBRAM Crossbars and Mott ReLU Neurons for Efficient Implementation of Deep Neural Networks in Hardware** Duygu Kuzum, [Jaeseoung Park](#), Yuhan Shi and Sangheon Oh; University of California, San Diego, United States

In-memory computing with emerging non-volatile memory devices (eNVMs) has shown promising results in accelerating matrix-vector multiplications (MVMs). However, activation function calculations are still being implemented with general processors or large and complex neuron peripheral circuits. Here, we present the integration of Ag-based conductive bridge random access memory (Ag-CBRAM) crossbar arrays with Mott ReLU activation neurons for scalable, energy and area-efficient hardware implementation of deep neural networks (DNNs). We develop Ag-CBRAM devices that can achieve a high ON/OFF ratio and multi-level programmability. Compact and energy-efficient Mott ReLU neuron devices implementing rectified linear unit (ReLU) activation function are directly connected to the columns of Ag-CBRAM crossbars to compute the output from the weighted sum current. We implement convolution filters and activations for VGG-16 using our integrated hardware and demonstrate the successful generation of feature maps for CIFAR-10 images in hardware. Our approach paves a new way toward building a highly compact and energy-efficient eNVMs-based in-memory computing system.

**Describing the Analog Resistance Change of HfO<sub>x</sub> Neuromorphic Synapses** [Fabia Farlin Athena](#) and Eric M. Vogel; Georgia Institute of Technology, United States

At the forefront of memristive device research, significant attention is paid to the understanding of resistance variations in Titanium/Hafnium Oxide (Ti/HfO<sub>x</sub>) synapses. These changes are typically dictated by a thin-oxide barrier, a result of oxidation and reduction within a Hafnium-rich conducting filament [1, 2, 3, 4]. Yet, despite a broad understanding of these principles, direct experimental investigation of the conducting filament proves notably complex. Consequently, crucial physical attributes and processes, such as the exact location of the barrier, the temporal fluctuations in thickness during analog pulsing, and the influence of temperature on the current, remain elusive and demand a more thorough elucidation.

We aim to take a step forward to unravel these intricacies by utilizing a compact model rooted in Trap-Assisted-Tunneling and Ohmic transport principles. This model has demonstrated significant value in shedding light on the mechanisms of analog switching in HfO<sub>x</sub> synapses. It not only accurately mirrors the experimentally observed current-voltage relationship, but also faithfully reproduces its sensitivity to temperature changes.

In deploying this model, we have been successful in extracting the barrier heights during analog pulsing. These data align with a barrier situated adjacent to the reset anode [5, 6]. Our findings are supported by an independent Finite Element Analysis simulation using COMSOL Multiphysics® that incorporates the migration of oxygen vacancies.

The proposed model's utility has been further amplified by its capacity to estimate the barrier's thickness in response to the analog pulses. It is able to simulate the evolution of the current-voltage relationship from the low resistance state to the high resistance state by simply modulating the thickness of the barrier.

In summary, this work enables us to delve deeper into the relationship between the physical characteristics of the HfO<sub>x</sub> synapses and the analog switching dynamics.

**Atomic Layer Deposition of WO<sub>x</sub>-Doped In<sub>2</sub>O<sub>3</sub> for High-Performance BEOL-Compatible Transistors** [Chanyoung Yoo](#)<sup>1,2</sup>, Balreen Saini<sup>2</sup>, Jonathan Hartanto<sup>2</sup>, Fei Huang<sup>2</sup>, Cristian R. Arens<sup>2</sup>, John D. Baniecki<sup>1</sup>, Wilman Tsai<sup>2</sup>, Baylor B. Triplett<sup>2</sup> and Paul McIntyre<sup>1,2</sup>; <sup>1</sup>SLAC National Accelerator Laboratory, United States; <sup>2</sup>Stanford University, United States

The semiconductor industry has undergone a revolution over the last five decades, driven by Moore's statement on dimensional scaling. However, the challenges for continued area scaling via lithographic patterning and the memory bottleneck limit the efficiency of computing. A new paradigm of improved energy efficiency, high bandwidth, and low latency on-chip memory access can be achieved by using 3D computing architectures with monolithic integration of logic and memory devices at high density (M3D, Monolithic three-dimensional). To realize M3D integration in future computing, fabricating high-performance thin film transistors and memories under back-end-of-line (BEOL) compatible conditions having a limited thermal budget (<400°C maximum temperature) must be addressed.

Metal oxide semiconductors incorporating In<sub>2</sub>O<sub>3</sub>, have received significant attention as they possess high mobility, high I<sub>ON</sub>/I<sub>OFF</sub> ratio, ultra-scaled gate length, and sufficient drive currents. Doping In<sub>2</sub>O<sub>3</sub> with several mole % tungsten oxide to form "IWO" has been reported to improve the threshold voltage stability of these semiconductor channel materials. However, currently reported film deposition for IWO is limited to sputtering, which cannot grow conformal films on topographically complex surfaces. This limitation becomes critical when utilizing these films as channel materials in gate-all-around or FinFET structures, which inherently possess 3D geometries. To address the increasing demand for high on-current, the shift towards 3D structures is necessary.

Consequently, we use the 3D-compatible atomic layer deposition (ALD) method to deposit IWO by adjusting the cycle ratios for In and W precursors and the oxidant co-reactant, enabling precise control over the doped film composition. We demonstrate deposition of IWO (1~4 mol% WO<sub>x</sub>) films using ALD and fabricate both bottom- and top-gated thin film transistors with a 3-nm thick IWO channel in a BEOL-compatible process with a maximum temperature of less than 250°C. The 1 mol% WO<sub>x</sub>-doped IWO transistor exhibits exceptional performance characteristics, including a subthreshold slope of 65 mV/decade, a high I<sub>D,sat</sub> of 70 (W=12, L=1.5) at V<sub>DS</sub>=1.0 V and V<sub>GS</sub>=2.0 V, and remarkable stability under bias stress. The transistor showed negligible hysteresis and maintained excellent threshold voltage (V<sub>th</sub>) stability under negative and positive bias stress conditions (ΔV<sub>th</sub> = -0.06, and +0.1 V, respectively, at an electric field of 4.2 MV/cm for 1000 seconds). This V<sub>th</sub> stability under bias stress highlights the reliability of ALD-grown IWO for ferroelectric field-effect transistors and its potential to enable high-performance monolithic 3D integrated devices.

**Investigation of Connection Strength Modulation Between the Artificial Neuron Devices Based on 2D hBN Threshold Switching RRAM** Yooyeon Jo<sup>1</sup>, Gichang Noh<sup>1</sup>, Eunpyo Park<sup>1</sup>, Min Jee Kim<sup>1</sup>, Yong Woo Sung<sup>1</sup>, Dong Yeon Woo<sup>1</sup>, Dae Kyu Lee<sup>1</sup> and Joon Young Kwak<sup>1,2</sup>; <sup>1</sup>Korea Institute of Science and Technology, Korea (the Republic of); <sup>2</sup>Korea University of Science and Technology, Korea (the Republic of)

The brain-inspired neuromorphic computing has attracted many researchers to solve the von Neumann bottleneck problems of conventional computing systems [1-2]. Various emerging materials and structures have been proposed to emulate the performance of biological neurons and synapses successfully. In particular, 2D materials-based memristors have been investigated by many researchers because of their excellent electrical performance, simple structure, and small device scale as promising building blocks of neuromorphic computing [3-5]. Although many artificial synaptic devices based on 2D materials-based memristors have been reported, there are very few reports in artificial neuron research, which is one of the key components in neuromorphic computing systems. Also, the integration of developed artificial neuromorphic devices based on emerging materials is an essential field of research to verify the performance of an artificial neural network (ANN) on the system level and successfully demonstrate large-scale ANN hardware [6-7].

In this study, we fabricated the threshold switching resistive random-access memory (RRAM) based on 2D multi-layer hBN film to mimic the behavior of the biological neuron for neuromorphic computing. The fabricated device was composed of Au/Ti bottom and Au/Ag top electrodes, respectively. The fabricated volatile memristor showed the highly-reliable resistance switching characteristics with 0.22 V of the average set voltage even at 110 fA of compliance current. Additionally, it showed a huge ON/OFF ratio over  $3 \times 10^6$  at 0.1 V of reading voltage. The threshold switching characteristics were well maintained with the different series resistors from 100 k $\Omega$  to 10 M $\Omega$ . We evaluated the switching speed of the fabricated device via an AC response experiment. The 100 k $\Omega$  series resistor was connected to protect the device from a breakdown. As a result, it showed 22.7 and 30.9  $\mu$ s of ON and OFF time, respectively.

The leaky-integrate-and-fire (LIF) neuron behaviors were demonstrated with the fabricated device and passive components. According to the RC time delay and the input pulse amplitude, the number of output spikes of the artificial neuron could be modulated, resulting in tailoring the artificial neuron properties to the desired performance for various applications. Lastly, we integrated the two artificial neurons to demonstrate the biological neural networks. The two LIF neurons were connected via a synaptic resistor as a biological synapse. Depending on the resistance (connection strength between the neurons), the number of output spikes of the post-synaptic neuron was modulated. We believe that our experimental results pave the way for the development of large-scale neural network hardware in the future.

**Low-Temperature Liquid Metal Printing for Sustainable Fabrication of 2D Oxide Electronics** William J. Scheideler, Andrew B. Hamlin and Simon A. Agnew; Dartmouth College, United States

Low-thermal budget fabrication of metal oxide semiconductors could unlock these materials' potential for emerging applications in sensing, computing, and memory devices via 3D heterogeneous integration with CMOS electronics. Towards that goal, we present a low-temperature, energy-efficient approach to deposit high performance two-dimensional (2D) metal oxides and heterostructures. Our approach consists of continuous liquid metal printing (CLMP) driven by Cabrera-Mott oxidation of liquid metal alloys, for depositing of 2D oxide layers as thin as 1 nm and multilayers 10's of nm. The simplicity of this vacuum-free CLMP process mitigates the need for high capital expenditure equipment and eliminates use of toxic gases. Metal oxidation is thermodynamically favorable, allowing rapid growth kinetics at the millisecond time-scale for wafer scale deposition in less than 2 seconds at temperatures from 200 °C down to 120 °C for back-end-of line (BEOL) applications as well as flexible electronics.

We present a study of the physics of liquid metal printing of 2D binary and ternary oxides based on alloys of In, Ga, Zn, and Sn by utilizing rapid film thickness measurements based on spectroscopic reflectometry. We investigate the limits of printing speed and model the influence of speed and print temperature on 2D oxide growth kinetics and crystallinity as determined from XRD. Finally, we apply CLMP to assemble heterostructures with 1 nm-level precision for enhancing modulation doping at 2D oxide interfaces, resulting in exceptionally conductive (> 500 S/cm) printed conductive oxide layers.

Self-assembled computing nanoarchitectures based on interacting nanoobjects have been recently proposed as biologically plausible substrates for neuromorphic computing [1,2]. In these nanonetworks, functionalities arise from the emergent behavior of the system that rely on collective phenomena.

Here, we report on NW networks as versatile substrate for physical (*in materia*) computing. We show that the emergent behavior in these complex networks arise from resistive switching phenomena in single network elements, as revealed by investigating switching properties of single NW and single NW junctions. The emergent spatio-temporal dynamics of these nanoarchitectures in multiterminal characterization is shown that can be exploited for neuromorphic-type of data processing and represent versatile substrates for the implementation of unconventional computing. In the framework of physical reservoir computing (RC), we report on the computing capabilities of these networks by considering different computing tasks such as pattern recognition, time-series prediction and speech recognition. A combined experimental and modeling approach will be discussed, and a theoretical framework based on graph theory to describe complex nanonetworks will be discussed. Going beyond the concept of two terminal measurements, we report on experimental evidence of memory engrams (or memory traces) in NW networks, i.e., physicochemical changes in biological neural networks supposed to endow the representation of experience stored in our brain. Results show that these networks represent a versatile substrate for computing, allowing both encoding and consolidation of information in the same physical substrate, paving the way for a development of new *in materia* computing paradigms.

**Robust and Reliable Computation using Heterogeneous Devices and Circuits** [Giacomo Indiveri](#); ETH Zürich, Switzerland

For many practical tasks, that involve real-time processing of sensory data and closed-loop interactions with the environment, conventional artificial intelligence neural network accelerators cannot match the performance of biological ones.

Neuromorphic intelligence aims to emulate the principles of computation of animal brains, exploiting the physics of computation of electronic and memristive devices.

Similar to their biological counterparts, neuromorphic devices and circuits are affected by variability and inhomogeneities.

In this talk I will present brain-inspired methods and strategies to achieve reliable and robust computation using an unreliable and inhomogeneous computing substrate, and present examples of neuromorphic systems that use these methods to solve edge-computing and sensory processing applications.

**Sustainable Fabrication of Nanoscale Memories Based on Molecular Materials and Nanogap Electrodes** [Dimitra G. Georgiadou](#); University of Southampton, United Kingdom

Nanotechnology is widely used in electronics to further miniaturise electronic components. Nanomaterials have played a major role in this, as they possess many attractive inherent properties derived from their low dimensionality. However, nanoparticles and self-assembled monolayers are usually processed from solution and they are difficult to be implemented with high yield in large area electronics. On the other hand, two-terminal electronic devices commonly comprise a generic metal/semiconductor/metal structure in a vertical (sandwich) configuration. This poses restrictions in the device fabrication when nanomaterials are involved, as the quality of the film is often compromised due to the small scale of the nanomaterials that do not guarantee uniform, continuous and pinhole-free film formation. A solution to this is offered by lateral devices, where the two metals are placed on the same plane and separated by a gap, which is filled by the semiconductor. If this gap is small enough, comparable to the dimensions of the materials used, the nanomaterials can effectively bridge this gap and connect the two electrodes electrically without causing a short-circuit.

Adhesion lithography (a-lith) is a nanopatterning technique with reduced manufacturing energy as compared, for example, with e-beam lithography, that allows the fabrication of asymmetric nanogap metal electrodes at a low cost and with high throughput on a variety of rigid and flexible substrates of arbitrary size. We have so far demonstrated ultra-high speed (GHz) Schottky diodes (1) and fast photodetectors (2) as well as multi-bit and ferroelectric memories (3) based on different solution-processed semiconductors and a-lith patterned electrodes separated by a <10 nm gap.

Herein we present different classes of molecular materials, based on the polyoxometalate and Pb-free perovskite families, which are successfully implemented in nanoscale memory applications. Our results indicate that multi-state memory behaviour is within reach with polyoxometalate materials, while we also present molecular self-assembly approaches to better control the resistive switching at the nanoscale. Since only a few electrons are required to function, these devices hold promise for low power consumption and high-speed operation. Furthermore, we show that the combination of coplanar nanogap electrodes with Bi-based perovskites holds great promise for achieving low power consumption and fast switching speeds, while their planar geometry facilitates a light-controlled operation, enabling both analogue tuning of resistance states and elimination of sneak currents in the array configuration.

This work paves the way to the development of a new form of greener devices and systems that merge photonic, electronic and ionic effects, bringing new prospects for in-memory computing and artificial visual memory applications.

**Hexagonal Si and Ge Polytypes as Optoelectronic Materials** Martin Keller<sup>1</sup>, Abderrezak Belabbes<sup>1,2</sup>, Jürgen Furthmüller<sup>1</sup>, Friedhelm Bechstedt<sup>1</sup> and Silvana Botti<sup>3,1</sup>; <sup>1</sup>Friedrich Schiller University Jena, Germany; <sup>2</sup>Sultan Qaboos University, Oman; <sup>3</sup>Ruhr University Bochum, Germany

The group IV elements silicon and germanium crystallize in cubic diamond structure under ambient conditions and feature indirect bandgaps. Therefore they cannot emit light efficiently and are not applicable in active optoelectronic devices. Under high pressure, however, as well as using different growth techniques, several Si and Ge polymorphs, have been observed. Lonsdaleite Ge as well as Ge-rich hexagonal alloys have even been found to have a direct bandgap and strongly emit light with varying frequency. Thus hexagonal systems have become of great interest for potential optical emitters that may be integratable with CMOS technology. We have performed extensive ab initio studies of the energetic, structural and electronic properties as well as oscillator strengths of the hexagonal Si and Ge polytypes 2H, 4H and 6H using Density Functional Theory and approximate quasiparticle treatments, and trends between the different geometries are analysed. The results for cubic and hexagonal Si and Ge agree excellently with existing experimental findings. The electronic structures point to promising optical properties.

### 2:45 PM \*EL20.07.01

**Impact of Phase-Change Memory Nonidealities on Analog In-Memory Computing Deep Learning Accuracy** Ning Li<sup>1,2</sup> and Qiangfei Xia<sup>1</sup>; <sup>1</sup>Lehigh University, United States; <sup>2</sup>IBM Research, United States

Among the emerging approaches for deep neural network (DNN) acceleration, compute-in-memory (CIM) in crossbar arrays using non-volatile memories (NVMs) is very promising for achieving high execution speeds and high energy efficiency. Phase change memory (PCM) is one of the most promising candidates for analog CIM – particularly for inference using previously-trained DNN weights. However, when NVMs are used in analog mode, devices will exhibit nonidealities compared to a perfect analog resistor, limiting the computing accuracy. These nonidealities for PCM devices mainly include resistance drift, read noise, limited memory window, and various device failures due to fabrication yield and limited device endurance and retention. In this presentation, I will talk about our study on the impact of these nonidealities on the analog CIM deep learning accuracy.

We systematically varied PCM memory window, resistance drift, and read noise, and studied their impact on the accuracy of large neural networks of various types and with tens of millions of weights.[1] We show that the DNN accuracy can be improved by the PCM with reduced read noise, even if the memory window is also reduced. However, there is a limit on the memory window, below which the accuracy drops significantly. DNN inference accuracy decreases over time due to the PCM resistance drift. However, the long-term accuracy loss can be minimized using an optimized mapping of weights to unit cells with multiple PCMs representing weights of varying significance. The energy efficiency dependence on the resistance drift was also studied [2]. There are tradeoffs and correlations between PCM device characteristics, which we used to identify the device optimization space to achieve better short term and long-term accuracy.

In addition, there are typically some failed devices of various types in NVM CIM chips, due to nonperfect fabrication yield and device failure over time. We studied the impact of these different types of failed devices on the analog CIM accuracy for various DNNs.[3] We find that larger networks with fewer reused layers are more tolerable to failed devices. Devices stuck at high resistance states are more tolerable than devices stuck at low resistance states. To improve the robustness of DNNs to defective devices, we developed training methods that add noise and corrupt devices in the weight matrices during network training and show that this can increase the network accuracy in the presence of the failed devices. Our approach is based on a single generic training and a subsequent mapping of the weight to any chip with unknown failed device locations.

In summary, we systematically studied the impact of nonidealities of PCMs on the DNN accuracy, using the PCM devices fabricated at IBM [1] and the hardware-aware simulation tool [4] developed at IBM Research. We proposed a few methods, including optimization of device specification, optimized weight mapping, special hardware aware training, to enhance the DNN performance.

**Recent Progress in Developing Next Generation Neuromorphic Devices Based on Ferroelectric Hafnia by the U.S. Army Research Laboratory** Andreu Glasmann<sup>1,2</sup>, Sina Najmaei<sup>1</sup>, Wendy Sarney<sup>1</sup>, Alex Mazzoni<sup>1</sup>, Justin Pearson<sup>1</sup> and Matthew Chin<sup>1</sup>; <sup>1</sup>U.S. Army Research Laboratory, United States; <sup>2</sup>Boston University, United States

In this presentation, I will present on the research progress by the U.S. Army Research Laboratory (ARL) in creating a framework for maturing emerging non-volatile memory devices based on ferroelectric hafnia for integration into front- and back-end CMOS neuromorphic integrated circuits. Next generation edge applications require a dramatic shift in computing paradigms, which utilize new electronic devices and circuit architectures to address the increasing power demands of enabling cognitive sensing and autonomy in extreme environments. Ferroelectric hafnia exhibits promising attributes, such as scalability, sub-nanosecond switching, back-end-of-the-line (BEOL) and front-end-of-the-line (FEOL) CMOS-compatibility, and good endurance that make it a promising candidate to address these needs.

In this presentation, I will discuss our material and device efforts in developing BEOL 2D ferroelectric field effect transistors. Our research demonstrates that within the CMOS compatible thermal processing envelope the ferroelectric landscape of HZO shows unique characteristic that have significant

implications on the neuromorphic device properties of FeFETs. We examine these properties by integrating HZO into BEOL 2D WSe<sub>2</sub> based-FeFET device architectures, a prototypical van der Waals system, and verify their robust synaptic plasticity within a 3.5 order of magnitude conductive range. These discoveries highlight a roadmap for material processing, dimensional scaling, and integration of HZO-based FeFETs.

I will further discuss our complementing activities that focus on creating the design and simulation tools required for integration of FeFETs into CMOS. In this effort we seek to develop a framework for multiscale modeling of ferroelectric-based devices. To that end we will focus on our efforts in developing a physics-based compact device model for three-terminal ferroelectric field effect transistors. The model has been designed with explicit support for transient analysis to capture time-dependent polarization switching dynamics down to nanosecond scale with multiple types of ferroelectric domains. In the presentation, we will discuss the model's calibration against experimental data and use in optimizing the design of a ferroelectric-metal field effect transistor (FeMFET). Finally, we conclude with future direction of the work, including how we intend to couple this model to a Monte Carlo analysis framework to feed into neural network-level hardware simulations of neural accelerator crossbar architectures.

#### 4:15 PM EL20.11.02

**Wake-Up of Ferroelectric HZO Films -- Towards a BEoL Compatible Wake-Up Free Material** David Lehninger, Ayse Sünbül, Anant Rastogi, Pratik Bagul, Shouzhuo Yang, Konrad Seidel and Maximilian Lederer; Fraunhofer IPMS, Germany

The discovery of ferroelectricity in thin doped hafnium oxide films has revived interest in the concept of ferroelectric (FE) memory. Zirconium-doped hafnium oxide (HZO) crystallizes at low temperatures (400°C and below), making this material interesting for back-end-of-line (BEoL) implementation. Metal-FE-Metal (MFM) capacitors are critical building blocks for the realization of BEoL-compatible FE memory concepts. Located in the BEoL, they can be connected to either the gate or drain of a standard logic device to realize a one transistor-one capacitor (1T1C) FE field effect transistor (FeFET) or a 1T1C FE random access memory (FeRAM), respectively. [1]

Since its discovery, researchers have made great efforts to improve important properties of hafnium oxide-based ferroelectrics, such as remanent polarization, endurance, retention, imprint, and wake-up. Typical approaches include, but are not limited to, the investigation of different dopant elements, dopant concentrations, film thicknesses, and stacking options such as interface/electrode materials and superlattice structures.

While much progress has been made, certain issues, such as wake-up, remain challenging. Wake-up is the opening of the initially pinched polarization versus electric field hysteresis loop, which leads to a gradually increasing remanent polarization during field cycling until saturation. Since memory applications require stable polarization, an initial field cycling ("wake-up") is necessary. However, the need for this wake-up makes the realization of hafnium oxide based FE memories more complex and reduces the maximum number of endurance cycles. Therefore, a wake-up-free material would be highly desirable.

Several theories have been proposed to explain the wake-up effect. These theories can essentially be summarized as follows [2]: (i) defect redistribution, which reduces internal bias fields and promotes the depinning of domain walls, (ii) defect redistribution and subsequent stabilization of the orthorhombic phase ("field-induced phase transformation"), and (iii) 90° domain wall motion ("ferroelastic switching").

The wake-up effect of FE-HZO films could be mitigated by: (i) using mesa-etched test structures [3]; (ii) reducing the number of defects and carbon contamination by applying longer ozone pulses durations during the atomic layer deposition process [4]; (iii) interface engineering by plasma treatment [5] or epitaxial growth [6].

Herein, we investigate the effect of post-deposition annealing temperature, film stoichiometry, film thickness, and co-doping on the wake-up characteristics of FE HZO films embedded in MFM capacitors. Several structural and electrical characterization techniques, such as X-ray diffraction and polarization versus electric field measurements, are applied to obtain a comprehensive overview. The goal is to present a BEoL-compatible material stack with significantly reduced wake-up without compromising other important parameters such as remnant polarization and reliability.

**Cryogenic Characterization of Polarization Switching in Ultra-Thin Ferroelectric Hf<sub>0.5</sub>Zr<sub>0.5</sub>O<sub>2</sub> Capacitors** Balreen Saini<sup>1</sup>, Chanyoung Yoo<sup>2</sup>, Fei Huang<sup>1</sup>, John D. Baniecki<sup>2</sup>, Wilman Tsai<sup>1</sup> and Paul McIntyre<sup>1,2</sup>; <sup>1</sup>Stanford University, United States; <sup>2</sup>SLAC National Accelerator Laboratory, United States

The demand for smaller, faster, and more energy-efficient logic and memory devices is continuously increasing, leading to a heightened requirement for new materials that can be scaled down dimensionally and that are compatible with CMOS fabrication processes. A material system that shows promise for nonvolatile memory applications is HfO<sub>2</sub>-based ferroelectrics. Since the discovery of ferroelectricity in HfO<sub>2</sub> thin films, research in this area has surged due to their potential as nonvolatile memory elements in 1 transistor-1 capacitor ferroelectric random-access memory (FeRAM) and in ferroelectric field-effect transistors (FeFET). Many of these research efforts have focused on reducing the programming voltage, improving reliability at lower operating voltages, and, in some cases, achieving compatibility with back-end-of-line (BEOL) process temperatures. However, compared to traditional perovskite-based ferroelectrics, there is a less comprehensive understanding of the domain-switching mechanisms involved in programming the polarization of these fluorite-type ferroelectric materials.

The metastable assembly of phases typically present in as-fabricated HfO<sub>2</sub>-based thin films exhibit a field-induced phase evolution at room temperature that can result in the increase (wake-up) or decrease (fatigue) of the remnant polarization with switching cycles. Other mechanisms such as domain depinning and charged defect redistribution with field cycling are also reported to cause the observed polarization evolution with field cycling (endurance). The extent to which various proposed mechanisms for polarization evolution can contribute to experimental observations will depend on their activation energies. In the present work, we explore the effect of measurement temperature on the functional properties of ferroelectric Hf<sub>0.5</sub>Zr<sub>0.5</sub>O<sub>2</sub> (HZO) capacitors to further our understanding of the atomistic mechanisms responsible for the observed endurance characteristics. To carry out this investigation, we utilize a cryogenic probe station, which has the capability for measurements over a range of temperatures, as low as 10 K.

We examine HZO capacitors with different thicknesses (ranging from 4 nm to 10 nm) with Mo and TiN electrodes. A decrease in remnant polarization is observed for all samples as the measurement temperature is decreased to 10 K. This polarization reduction is recovered by increasing the temperature back to room temperature, suggesting reduction in the thermally activated domain wall motion at low temperatures. Polarization hysteresis (P-V) measurements for capacitors with pristine state pinched loops at room temperature show a negligible pinching effect at cryogenic temperatures. A positive-up-negative-down (PUND) pulse scheme is utilized to separate the polarization switching current from the displacement current. Frequency-dependent and electric field-dependent endurance measurements are performed to further elucidate the possible contributions of different switching mechanisms to the observed temperature dependence of polarization switching.

**4:45 PM EL20.11.04**

**Hf<sub>0.5</sub>Zr<sub>0.5</sub>O<sub>2</sub> Based Ferroelectric Memories for Applications Down to Deep Cryogenic Temperatures** Heorhii Bohuslavskyi<sup>1</sup>, Kestutis Gregorius<sup>1</sup>, Mika Prunnila<sup>1</sup> and Sayani Majumdar<sup>2</sup>; <sup>1</sup>VTT Technical Research Centre of Finland, Finland; <sup>2</sup>Tampere University, Finland

Since the last decade, extensive studies on HfO<sub>2</sub>-based ferroelectric devices have been carried out to unlock their applications in high-density, low-power, and high-speed electronics, and most importantly in non-volatile memories and logic circuits. Emergence of HfO<sub>2</sub>-based ferroelectric memories has its origin in the CMOS compatibility and scalability potential, therefore bringing the prospect of easy integration with the existing foundry processes [1]. Among ferroelectric hafnia, Zr-doped HfO<sub>2</sub> (HZO) has received most attention due to its low crystallization temperature, making it a suitable candidate for CMOS back-end-of-line (BEOL) integration. More recently, memories operating at cryogenic temperatures became a topic of high interest due to their potential applications in high-performance computing, quantum computing and space technologies [2]. To realize the memory devices functional down to deep cryogenic temperatures with reasonably low power dissipation, understanding of fundamental device physics and proper material engineering are of vital importance. Previously, perovskite oxide based ferroelectric tunnel junctions, when cooled down to low temperatures, were demonstrated to have several key parameters improved as compared to room temperature operation, featuring higher on/off ratio, faster switching and improved endurance [3]. In terms of HZO-based capacitors or junctions, a few recent papers reported operation down to low temperatures [4-6]. However, a comprehensive understanding of the cryogenic physics and properties of HZO devices within the wide temperature window from 300 K down to 4 K temperatures as well as the optimization of interfaces and material stack for cryogenic operation are currently missing. In the present work, we report high remnant polarization from quasi wake-up free Hf<sub>0.5</sub>Zr<sub>0.5</sub>O<sub>2</sub> thin film devices together with state-of-the-art endurance down to deep cryogenic temperatures [7]. The HZO films, grown and annealed under CMOS BEOL-compatible conditions, were characterized within the 300 – 4 K temperature range with a particular focus on the analog switching properties of the films. Finally, we evaluate the overall performance of our HZO devices as cryogenic memories aiming at optimizing the domain dynamics control for achieving high classification accuracy of in-memory computing circuits [7,8].

The authors gratefully acknowledge the financial support from the Academy of Finland projects (Grant no. 350325, 345068, and 350667). This work was realized using experimental facilities of Micronova National Research Infrastructure for Micro- and Nanotechnology.

**10:30 AM \*EL20.12.01**

**Vector Matrix Multiplication with 2D Materials** Mario Lanza; King Abdullah University of Science and Technology, Saudi Arabia

Most artificial intelligence systems are based on artificial neural networks (ANNs), which are normally implemented in traditional silicon microchips. These microchips contain complementary metal-oxide-semiconductor (CMOS) circuits that realize different operations, including mathematical operations, digital-to-analogue and analogue-to-digital conversion, and transimpedance amplifiers. One of the most critical operations in ANNs is the vector matrix multiplication (VMM), but realizing it with traditional CMOS circuits consumes too much time and energy. Using crossbar arrays of memristors is much more efficient because the VMM is done in parallel via Ohm's law and Kirchhoff's law. In the past few years, multiple studies presented VMM based on memristive devices made of metal-oxides and phase-change materials. Here we present the first VMM operation using two-dimensional (2D) layered materials, and discuss its advantages and challenges compared to traditional memristive materials.

**Improved Microcontact Printing of Choline Oxidase using a Polycation-Functionalized Zwitterionic Polymer as Enzyme Immobilization Matrix** Ming Zhao<sup>1,2</sup>, Brenda Huang<sup>1</sup>, Yan Cao<sup>1</sup> and Harold Monbouquette<sup>1</sup>; <sup>1</sup>University of California, Los Angeles, United States; <sup>2</sup>Massachusetts Institute of Technology, United States

Electroenzymatic sensors typically rely on specific oxidase enzymes to catalyze oxidations of the target analyte to produce hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) that is oxidized or reduced at an underlying electrode at moderate potential to give a current signal. Development of microelectrode array (MEA) microprobes for multiple detection through selectively deposit multiple different enzymes onto specific microelectrode sites is in great demands.

Enzyme deposition and immobilization on microelectrode surfaces is most commonly achieved by manually loading a mixture of enzyme, bovine serum albumin (BSA), and glutaraldehyde (GAH) as crosslinker on the electrode surface. However, the manual approach becomes problematic when the MEA feature size is in the micrometer range. In previous work, we demonstrated the use of microcontact printing (μCP) for creation of multianalyte sensing microprobes by patterning two different enzyme/BSA mixtures onto selected, distinct sites on a MEA and subsequent crosslinking with GAH vapor. Although this accomplishment demonstrates the potential of MEAs for recordings of multiple neurochemicals simultaneously *in vivo* with high spatiotemporal resolution, the use of enzyme/BSA mixtures in aqueous solution as the “ink” has important disadvantages. Since the BSA protein behaves as a globular particle in solution that contributes little to the viscosity of the “ink”, imprinted enzyme patterns tend to be so thin that low sensitivity results or problematic surface spreading and low spatial-resolution deposits occur when higher enzyme loading is attempted. For the application described in this work, excessive spreading of “ink” deposits is highly undesirable as it can lead to contamination of adjacent microelectrodes less than 100 μm away resulting in sensor crosstalk. As these problems are inherently related to ink properties, there has been a need for a new formulation that provides high adhesion to substrate, stronger intermolecular forces for higher viscosity and yet similar functionality as BSA to enable enzyme immobilization through covalent crosslinking.

While great strides have been made in modifying “ink” properties to achieve high resolution patterns, the focus has been on creating very thin layers of chemicals or proteins on substrates via covalent attachment. In this report, we designed a novel graft polymer, poly(2-methacryloyloxyethyl phosphorylcholine)-*g*-poly(allylamine hydrochloride) (PMPC-*g*-PAH), which serves as an alternative enzyme immobilization matrix to BSA that enhances the capability and efficiency of enzyme transfer to microelectrode surfaces via  $\mu$ CP. The zwitterionic polyphosphorylcholine moieties of the graft polymer serve to enhance surface hydrophilicity, the free amine groups provide functional groups for crosslinking with GAH vapor, and the polymer itself increases solution viscosity so as to curtail undesirable “ink” spreading. The minimization of ink surface spreading enables longer stamp alignment times, enhanced control of enzyme loading for better sensor performance, as well as potentially minimizing immune response that would improve long-term stability *in vivo*.

**Architectures and Circuits for Analog-Memory-Based Hardware Accelerators for Deep Neural Networks (Invited) Hsinyu Tsai; IBM Almaden Research Ctr, United States**

Analog non-volatile memory (NVM)-based accelerators for Deep Neural Networks (DNNs) can achieve high-throughput and energy-efficiency by computing multiply-accumulate (MAC) operations using Ohm’s law and Kirchhoff’s current law on arrays of resistive memory devices [1]. In recent years, energy-efficient, weight-stationary MAC operations in analog NVM memory-array “Tiles” were demonstrated in hardware with Phase Change Memory (PCM) devices integrated in the backend of 14-nm CMOS [2, 3]. Competitive end-to-end DNN accuracies can be obtained with the help of hardware aware training, accurate weight programming, and sufficiently linear MAC operations in the analog domain [4].

In this paper, I describe architectural and circuit advances for such Analog NVM-based accelerators and specialized digital compute units, designed to accelerate Transformer, Long- Short-Term-Memory (LSTM), and Convolution Neural Networks (CNNs). A highly heterogeneous and programmable accelerator architecture that takes advantage of a dense and efficient circuit-switched 2D mesh to exchange vectors of neuron-activation over short distances in a massively parallel fashion [5] is presented. Based on a 14-nm inference chip consisting of multiple arrays of PCM devices, the impact of memory materials on the accuracy and performance of these systems will be discussed.

The author would like to thank colleagues at IBM Research Almaden, Yorktown, Albany, Zurich and Tokyo for their contributions to this work and the IBM Research AI HW Center.

**Atomic Layer Deposition on 1D Nanomaterials for Electrochemical Applications** Jan M. Macak<sup>1,2</sup>; <sup>1</sup>University of Pardubice, Czechia; <sup>2</sup>Brno University of Technology, Czechia

One-dimensional nanomaterials – materials with one dimension outside the nanoscale, further noted as 1D NMs – represent a class of very important nanomaterials with continuously increasing importance. Due to their intrinsic features, unique properties and diversity of functionalities, they count among the most widely studied materials nowadays. While considerable research efforts have been spent to synthesize various 1D NMs (e.g. nanopores, nanotubes or nanofibers), limited efforts have been devoted to surface modification and property tailoring of these materials.

However, it is their surface that comes into direct contact with various media (air, gases, liquids, solids) and influences the reactivity, stability and biocompatibility of these materials. The surface and aspect ratio (defined as their diameter to length ratio) influence the performance of these materials in various applications. Considering these facts, it is more relevant to tailor the surface of these materials and to be able to influence their properties and reactivity at the nanoscale, rather than to deal with tailoring their own bulk material composition.

The focus of this presentation is on the modification of two types of 1D nanomaterials – nanotubes and nanofibers. Numerous techniques can be utilized for this purpose, such as for example wet chemical or physical deposition techniques. However, it is only the Atomic Layer Deposition (ALD) that is capable of really uniform and homogenous coating of these 1D nanomaterials, in particular those of very high-aspect ratio.

The presentation will be mainly focused on modification of TiO<sub>2</sub> nanotube layers and various nanofibers of different aspect ratios via ALD for electrochemical applications.

Experimental details and some very recent application examples in photocatalysis, catalysis, sensors, batteries, etc. [1-10] and structural characterizations of these modified materials will be discussed.

 Monday Afternoon, November 27, 2023  
 Hynes, Level 2, Room 200

**1:30 PM \*EN01.02.01**

**How Building Batteries for Robots Enabled Pressure Free Lithium Anodes and Instantly Rechargeable 850 Wh kg<sup>-1</sup> Catholytes for Electric Aircraft** James H. Pikul; University of Wisconsin–Madison, United States

This talk will cover new approaches for powering robotic systems across scales. Starting with microbatteries made for tiny robots, we will show how molten salt manufacturing and 3D printing enable 3-4X improvements in battery energy density and pressure-free lithium anodes. We will then move to larger systems where new chemistries and bioinspired design led to 10X improvements in macroscale robot operation time and long-range, instantly-rechargeable electric aircraft.

Current lithium (Li) metal pouch cells require high external pressures of 69 to 1,000 kPa and have huge volume increases of 39 to 220% after cycling, which makes them incompatible with small and flexible robotic applications because the clamping systems required to apply the pressure eliminate any energy or flexibility benefits. This talk will demonstrate swelling-free and pressure-free Li metal anodes with 1580 mAh cm<sup>-3</sup> capacity enabled by polymer gyroid microlattices that allow 3D control of the molecular interaction between Li, polymer, and electrolyte. The geometry augments the chemical functionality to realize dense Li growth through complex 3D printed geometries by maximizing the Li volume fraction, polymer-Li-electrolyte contact, and manufacturability. Stable Li deposition was realized at a practical areal capacity of 5 mAh cm<sup>-2</sup> in 10 minutes. A 308 Wh kg<sup>-1</sup> anode-free pouch cell (2.1 Ah) incorporating a polymer gyroid had 80.2% capacity retention after 226 cycles, and the cell swelling was below 7%. Over 860 cycles were achieved when the pouch cell was prepared with 2.6 times excessive Li.

As robots and electric machines get bigger, they present increasing energy storage challenges. For example, the energy densities required to electrify aviation, heavy machinery, and robots (~1,000 Wh kg<sup>-1</sup>) seem insurmountable with current battery architectures based on solid intercalation materials (250 Wh kg<sup>-1</sup>), but animals can store ~2,000 Wh kg<sup>-1</sup> and operate continuously. The clear gaps in energy density and operational capability between machines and animals motivate new ways to extract electrochemical energy via bioinspired designs. The last part of this talk will report an electrochemical stomach that near-continuously powers electric aircraft and robots by ingesting small molecules as beverages and converting that chemical energy to electricity by pairing them with metals. We demonstrate a 10.4 Ah stomach that delivers an energy density of up to 850 Wh kg<sub>stomach</sub><sup>-1</sup> at 192 A kg<sub>stomach</sub><sup>-1</sup> and restores the chemical energy in 1 minute. The stomach powered a commercial quadcopter and doubled the flight time of the manufacturer's state-of-the-art batteries. Owing to the diversity of small molecules, we tailor beverages to enable 1,447 Wh kg<sup>-1</sup> discharge energy density or fire-safe energy storage.

**2:00 PM EN01.02.02**

**MOF-Derived Fe, N Co-Doped Porous Carbon Polyhedrons (Fe-N-C) for High-Performance Lithium-Ion Battery Anode Materials** Kaiyi Qin;

Northeastern University, China

The lithium storage performance and structural stability of anode materials have a significant influence on the capacity performance and cycling stability of lithium-ion batteries. Despite the cost, conductivity, non-toxicity, and non-polluting advantages of graphitic carbon materials, their cycle stability is compromised by volume changes during lithium storage. Additionally, the theoretical capacity of 372 mAh/g is no longer sufficient to meet the growing demand for high-capacity LIBs. Metal-organic frameworks (MOFs) and their derivatives have emerged as promising anode materials for LIBs due to their tunable structure, high surface area, and high porosity. In this study, we successfully synthesized Fe, N co-doped carbon materials (Fe-N-C) with exceptional properties by calcination and co-doping Fe and N elements into a ZIF-8 precursor. Scanning electron microscopy (SEM) results revealed that the morphology of the synthesized samples was identical to that of ZIF-8. X-ray diffraction (XRD) and X-ray photoelectron spectroscopy (XPS) analyses confirmed the successful co-doping of Fe and N into the carbon material. The porous structure provided a buffer for volume changes and improved cycling performance. After 300 cycles at a current density of 500 mA/g, the Fe-N-C anode exhibited charge and discharge specific capacities of 538 mAh/g and 543 mAh/g, respectively. The co-doping of Fe and N enhanced the conductivity and rate performance of Fe-N-C, resulting in excellent cycling stability. This study demonstrates the exceptional electrochemical activity and potential of Fe, N co-doped carbon polyhedrons for high-performance lithium-ion batteries. Carbonization of metal-organic frameworks and co-doping with Fe and N elements represents a promising strategy to enhance the electrochemical performance of graphitic carbon anode materials.

### 2:15 PM EN01.02.03

**Enhancement of Cycling Performance by use of Li Anode with Additive Leaching-Type Polymer Layer for Lithium Metal Batteries** OH Myung-keun and Dong-Won Kim; Hanyang University, Korea (the Republic of)

Rechargeable lithium batteries using lithium metal as an anode are attractive candidates for high energy density power sources in portable electronic devices and electric vehicles, because lithium metal offers a high specific capacity ( $\sim 3,862 \text{ mAh g}^{-1}$ ) and possesses a low reduction potential. However, the development of rechargeable lithium metal batteries has been hindered by the high reactivity of lithium metal with liquid electrolytes and the occurrence of dendrite growth during charge and discharge cycles. Therefore, it is essential to form the stable solid electrolyte interphase (SEI) on lithium metal to prevent lithium dendrite growth and minimize side reactions of liquid electrolyte. Recently, various additives have been investigated to form a stable SEI layer on Li metal. However, during repetitive charge and discharge process, the additives in the electrolyte can be gradually depleted, resulting in capacity fading. In this work, we developed additive leaching-type polymer layer containing excessive amounts of additives that form the stable SEI layer. The additives can be stored in the polymeric layer, continuously released to the electrolyte during the repeated cycling. Electrochemical analyses such as linear sweep voltammetry and cyclic voltammetry were investigated, and the Li/Li symmetric cells showed the regulation of lithium deposition with small overpotential. The cycling performance of lithium metal batteries employing additive leaching-type polymer layer was evaluated with high nickel NCM cathode. Furthermore, characterization techniques such as cyclic voltammetry, X-ray photoelectron spectroscopy,  $^7\text{Li}$  nuclear magnetic resonance, and electrochemical impedance spectroscopy were employed to analyze the release behavior of additives and investigate the mechanisms associated with released additives for improvement of cycling performance.

### 2:30 PM EN01.02.04

**Structure Tailoring and Material Modification of the Thick Cathode for Fast Charging and Long Lifespan Li-S Batteries** Yuxuan Zhang<sup>1</sup>, Han Wook Song<sup>2</sup> and Sunghwan Lee<sup>1</sup>; <sup>1</sup>Purdue University, United States; <sup>2</sup>Korea Research Institute of Standard and Science, Korea (the Republic of)

It is urgent to develop both affordable and sustainable batteries with high energy density and fast charging speed to alleviate the range anxiety of electric vehicles.<sup>1,2</sup> The lithium-sulfur (Li-S) system is especially attractive because of its high theoretical specific energy (around  $2600 \text{ Wh kg}^{-1}$ ), low cost, and low toxicity. However, the application of sulfur cathodes to date has been hindered by several obstacles, including low active material loading, low electronic conductivity, shuttle effects, and sluggish sulfur conversion kinetics. Herein, we combine a material-agnostic approach based on the asymmetric cathode structure design with a controllable vapor-deposited polymer to realize fast charging Li-S batteries with high sulfur loading.<sup>3</sup> Specifically, the active materials and the tortuosity of the cathode were tailored by the 3D printing (stereolithography technique), which distributed in an inhomogeneous way to compensate for the gradient distribution of Li ions originated in the cathode depth direction, leading to less polarization in the electrode scale. The as-printed cathode is then sintered at  $900 \text{ }^\circ\text{C}$  in an  $\text{N}_2$  atmosphere to generate a carbon skeleton (i.e.: carbonization of resin) with intrinsic carbon defects. The structure design and defects engineering are expected to synergistically create favorable sulfur conversion conditions and mitigate the polarization in thick electrodes. The oCVD technique is leveraged to produce a conformal coating layer to eliminate shuttle effects for the elongated battery life. In-situ XRD diffractograms show a distinguishable difference between the printed cathode and the 2D planer cathode with similar mass loading, confirming an eminent sulfur conversion kinetic condition. Overall, the customized cathode delivered  $820 \text{ mAh g}^{-1}$  at  $4 \text{ C}$  with a mass loading of  $8.3 \text{ mg cm}^{-2}$ , and the cathode with oCVD polymer showcased high-capacity retention (85% after 300 cycles), which indicates high mass loading with elevated sulfur utilization ratio, accelerated reaction kinetics, and stabilized electrochemical process have been achieved on the sulfur cathode by implementing this innovative cathode design strategy. The results of this study suggest a promising way of employing structural optimization and material modification for the higher energy and power density battery.

SESSION EN01.03: Energy Management Strategies for Real World Devices

Session Chairs: Trisha Andrew and Markus Niederberger

Tuesday Morning, November 28, 2023

Hynes, Level 2, Room 200

### 8:00 AM \*EN01.03.01

**Flexible and Durable Batteries for Wearable Sensors** Ana Claudia Arias; University of California, Berkeley, United States

On skin detection of vital signs and biomarkers, a non-invasive approach, holds tremendous significance for evaluating the body's response to physical activity and clinical diagnostics. When integrated into wearable devices, flexible sensors offer several advantages, including continuous data acquisition, high performance, and cost-effectiveness. Powering such devices while maintaining their mechanical properties has driven active innovation in the field of wearable compliant batteries. Incorporating additional functionalities often compromises the energy storage capacity of these devices, resulting in lower gravimetric or volumetric capacity compared to commercially available batteries. Maximizing the energy density of wearable batteries remains a crucial goal. Most demonstrations in this field rely on lithium-ion battery chemistry, which often includes toxic and/or flammable components. Thus, designing non-toxic systems utilizing abundant and disposable materials is of utmost importance. We have developed an electrode composite with an interpenetrated binder network, enabling a flexible battery with energy density comparable to commercial AA alkaline batteries. Wire-shaped batteries based on helical band springs will be presented, demonstrating resilience to fatigue and the ability to maintain electrochemical performance over 17,000 flexure cycles. Intrinsically safe and non-toxic silver-zinc (Ag/Zn) and zinc-manganese dioxide (Zn/MnO<sub>2</sub>) battery chemistries are employed in our work.

### 8:30 AM EN01.03.02

**A Solar-Powered Optogenetic System for Long-Term, Wirelessly-Controlled Neuromodulations** [Jaemin Park](#), Kyubeen Kim, Tae Soo Kim and Ki Jun Yu; Yonsei University, Korea (the Republic of)

Optogenetics has revolutionized neuroscience by enabling the manipulation of neural activity using light-sensitive proteins to modulate brain function. To facilitate advanced neuromodulation in freely moving animals, various optical stimulation devices have been developed. Presently, wireless optogenetic devices predominantly utilize either coil-powered or battery-powered systems. Battery-powered systems necessitate frequent battery replacements, which can cause stress for the animals. Furthermore, recharging the batteries requires the charger to be located within a specific area. Coil-powered systems, on the other hand, require a structure that wraps around the animal's cage to provide power, limiting their operation to confined spaces where such a setup is established. In addition to these constraints, specialized techniques like impedance matching with expensive, bulky equipment such as radiofrequency (RF) generators are essential for operating these systems.

On the contrary, an innovative wireless solar-powered optogenetic device (WSOD) takes advantage of light energy to autonomously charge and operate. This remarkable feature eliminates the need for spatial restrictions, enabling the experimental subject to move freely without confinement. Additionally, the WSOD functions independently without relying on external components such as an RF generator or amplifier. To harness sufficient power from diverse light sources, including sunlight and lamps, we have implemented highly efficient flexible InGaP/GaAs tandem solar cells, which are incredibly thin (< 5 μm). The solar cell has an impressive power conversion efficiency of 18 % and a wide spectral range from 300 nm to 900 nm. This outstanding efficiency allows the WSOD to operate continuously for more than 80 minutes with just a 10-minute charging period during daylight hours. The fully assembled WSOD incorporates these photovoltaic cells with a power management system and Bluetooth technology on a flexible substrate, enabling control via a smartphone application. Furthermore, the WSOD allows multiple connections to numerous devices from a single mobile device, facilitating in vivo experiments in diverse environments and with various subjects.

To demonstrate these capabilities, we performed optical stimulation in the secondary motor cortex (M2) region of a transgenic mouse brain, observing subsequent locomotion behavior. Through quantitative analysis, we identified compulsive circling behaviors and increased velocity during the stimulation period. Furthermore, we demonstrated the long-term stability of the WSOD by observing no significant differences in locomotion behavior over a month-long duration. This study introduces a wirelessly rechargeable optogenetic device powered by solar energy, facilitating wireless charging without any spatial constraints. The pivotal advantage of this system lies in its ability to naturally recharge during the course of regular activities, eliminating the need for bulky and expensive equipment like RF generators or amplifiers. With this feature, we are moving closer to the ultimate objective of developing wireless optogenetic devices that enable the completely unrestricted behavior of the subjects.

### 8:45 AM EN01.03.03

**Enhancing Single Electrode Triboelectric Generators via Charge Trapping Layer Integration** [Wei-Lin Wu](#), Cheng-Yu Shih, Yen Shuo Chen and Fu-Hsiang Ko; National Yang Ming Chiao Tung University, Taiwan

With the rapid development of internet of things (IoT), the increasing need of self-power sensor is expected. Triboelectric generator (TEG) has become a promised candidate in mechanical stimuli sensing(1, 2), which is distinguished from several conventional sensors in that it doesn't need any extra power source.

The triboelectric effect can be explained by Maxwell's equations and involves both contact electrification and electrostatic induction. In contact electrification, two dissimilar materials come into contact and exchange charges, resulting in a potential difference between them. In electrostatic induction, an external electric field polarizes the charges in a material, creating a potential difference between two regions of the material. However, the insufficient output performance of triboelectric generators hinders their widespread application. To enhance the energy-harvesting capabilities of these generators, we are focusing on device structures(3), surface topography(4), and material selection(5).

In this paper, we introduce the charge storage layer to optimize device structure. For the purpose to increase the surface charge by raising the bulk charge, the low mobility polymer is inserted between friction layer and metal plate as charge storage layer. Then, polydimethylsiloxane (PDMS) as friction layer with micro-pyramid structure to increase the surface area and pressure sensitivity. We choose polydimethylsiloxane (PDMS) and polytetrafluoroethylene (PTFE) to be the friction double layer for the reason of low cost, high flexibility, and great output performance. The output voltage of dual layer triboelectric generator can achieve 150 V, which is eight times higher than the triboelectric generator without charge storage layer.

Keywords: triboelectric effect; charge storage layer; energy harvesting; pyramid structure

**Understanding Interplay of Cycling Conditions on Li-Ion Battery Performance for EVTOL Applications** [Anuj Bisht](#), Ruhul Amin and Ilias Belharouak; Oak Ridge National Laboratory, United States

The advancement of improved energy storage systems has garnered significant attention in Electric Vertical Takeoff and Landing (EVTOL) applications. To ensure optimal performance and safety of onboard batteries, comprehending their behavior under varying charging/discharging protocols and environmental conditions is crucial. This work provides a comprehensive evaluation of commercial Li-Ion batteries for EVTOL applications, with a

specific focus on their response to different charging/discharging strategies and mechanical vibrations encountered during flight. Controlled experiments are conducted to explore the effects of rapid cycling on battery performance, encompassing lifespan, capacity, and internal resistance. Additionally, the impact of mechanical vibrations on battery behavior is assessed to identify potential challenges for onboard batteries. The study's results reveal intriguing insights into the interplay between temperature, vibration, and battery performance, bridging the gap between battery performance and EVTOL applications. This work contributes to the wider adoption of electric aerial transportation, promising a greener and safer future for urban mobility.

**Conductive Polymers at The Nexus of Innovation: Empowering Nanogenerators and Smart Interactive Wearables** [Rodrigo F. Martins<sup>1</sup>](#), Guilherme Ferreira<sup>1</sup>, Sumita Goswami<sup>2</sup>, Elvira Fortunato<sup>1</sup> and Suman A. Nandy<sup>1</sup>; <sup>1</sup>Universidade Nova de Lisboa, Portugal; <sup>2</sup>Almascience, Portugal

Conducting polymers have emerged as versatile materials with transformative potential in two key domains: nanogenerators and smart interactive sensor applications for wearable substrates. This abstract explores the exciting advancements and synergistic possibilities created by integrating conducting polymers into these cutting-edge technologies.

In the realm of nanogenerators, conducting polymers are being investigated as a functional element because of their remarkable electro-mechanical properties. Good electrical conductivity, coupled with mechanical flexibility, makes them ideal for smart wearable applications. This abstract delves into the principles of energy conversion, highlighting the ability of conducting polymers to convert mechanical energy, such as vibrations or pressure, into electrical energy. This breakthrough has far-reaching implications, powering wearable electronics, Internet of Things (IoT) devices, and remote sensors, ultimately reducing our reliance on traditional energy sources.

Shifting focus to wearable substrates, conducting polymers unveil a new era of smart, interactive sensor applications. These polymers are seamlessly integrated into textiles, cellulose substrate, foam, enabling the development of large area of wearable markets such as garments, healthcare, defense, sports, transportation that can sense a wide array of stimuli. From monitoring physiological parameters to tracking environmental conditions and enabling user interactions, conducting polymer-based sensors provide real-time data acquisition and actionable insights.

Furthermore, the synergies between nanogenerators and interactive sensors powered by conducting polymers are being explored. Wearable devices can harness energy from user movements and ambient vibrations to sustain continuous sensor operation. This integration not only enhances the autonomy of wearable devices but also enables novel functionalities such as self-powered biosensors and adaptive clothing. As this abstract demonstrates, conducting polymers represent a bridge between the worlds of energy harvesting and wearable technology. Their remarkable properties and adaptability promise a future where self-sustaining, sensor-rich wearables seamlessly integrate into our daily lives, revolutionizing how we interact with technology and our environment. This abstract serves as an invitation to explore the dynamic landscape of conducting polymer applications, fostering innovation and advancements in nanogenerators and smart interactive wearables.

#### 9:30 AM EN01.03.06

**A Low-Cost Self-Powered Sensor-Network System for Renewable Gas Transportation Infrastructure System Powered using Energy Harvesting** [Yaaqoub Malallah<sup>1</sup>](#), Tiffany Nguyen<sup>2</sup>, Saud Al-Qabandi<sup>2</sup>, Callan Hall<sup>2</sup>, Rajinder S. Deol<sup>2</sup>, Henam S. Devi<sup>3</sup>, Madhusudan Singh<sup>3</sup> and Ioannis Kymissis<sup>2</sup>; <sup>1</sup>Kuwait Institute for Scientific Research, Kuwait; <sup>2</sup>Columbia University, United States; <sup>3</sup>Indian Institute of Technology Delhi, India

Hydrogen is one of the most important fuels for a sustainable and renewable energy economy. One of the challenges with working with hydrogen, however, is that it requires the use of well-sealed pipelines due to its very fast diffusivity, flammability, and chemical reactivity leading to complication during incorporation of sensors in the delivery and distribution network. There is also a huge interest in examining the blending of hydrogen with natural gas, in which the hydrogen concentration is controlled to stay below 20 % to prevent embrittlement of the metal components commonly used in natural gas containment and transportation networks. Incorporation of sensors is especially important for these hydrogen supply infrastructures. It has been shown that a number of contaminants in the hydrogen supply can be especially harmful for fuel cell applications. In particular, epoxies commonly used in building components such as assembling fuel systems, sensors, and pipelines can foul fuel cell membranes and lead to a dramatic loss in energy delivery and irreversible damage to the fuel cell systems. Our proposed design will use a mechanical energy harvesting approach which will stimulate a high-quality factor (Q) resonator on the inside of the pipe without the need to penetrate the walls of the pipe system. Such sensors could also report on the pressure in hydrogen fuel pipelines, measure flow, and monitor the blending ratio in natural gas/hydrogen mixed delivery systems. Acoustic communication is also used to transmit information between the sensing and communication base unit, eliminating the need for pipe penetrations and risk of leaks, embrittlement, etc. Meanwhile, the sensor package will be powered with piezoelectric, solar, and flow of gas as wind energy harvesting systems. Piezoelectric energy harvesting using materials like PVDF and KNN (Potassium Sodium Niobate) was performed on a stainless-steel sheet through mechanical vibrations of a speaker. The resonance frequency that the PVDF sheet vibrates most readily and efficiently was successfully analyzed and recorded through multiple isolation techniques. In order to observe the resonance frequency, five different methods were implemented into the experiment to reduce noise. Visually, the resonance frequency can be seen from 180 Hz to 220 Hz. The experimental results confirm the visual resonance frequency and reveals external factors that can affect the resonance of the piezoelectric material. We were able to transmit and receive signals through the metallic pipeline at 200 kHz to 500 kHz using PVDF sensors for communication purposes. The power received through 4 mm thick solid iron pipe was 5 %, which is enough to transmit bytes of sensor data from inside the metallic pipe that acts as a Faraday cage. Meanwhile, our lab scale prototype for the energy harvesting systems generated about: 0.02 W for piezoelectric, 2 W for solar, and 0.8 W for wind. A large industrial scale version will be more economically viable.

**Ultraflexible and Stretchable Monocrystalline Silicon Solar Cells for Wide Ranging Deployment** [Nazeek El-Atab](#); King Abdullah University of Science and Technology, Saudi Arabia

Flexible and stretchable solar cells are of importance for state-of-the-art applications such as solar powered vehicles, wearables, buildings and robots, among others. While organic materials show good flexibility and stretchability, however, they generally show low efficiencies and stabilities. In terms of inorganic materials, silicon has been the material of choice in the photovoltaic industry due to its low cost, availability, low toxicity and maturity of the manufacturing process. Nevertheless, silicon is rigid and when thinned down to achieve flexibility, the material becomes brittle and the mechanical

resilience of the cell is degraded. Moreover, the efficiency of the cells gets degraded too as the active material that absorbs light is thinned down. In this talk, I will discuss a corrugation technique that allows the transformation of rigid silicon solar cells into their ultra-flexible and stretchable version without thinning down the original thickness of the silicon and without degrading the normalized efficiency of the cells. The corrugation technique is based on creating alternating grooves with different shapes, resulting in interconnected islands of silicon using interdigitated back contacts. The different corrugation patterns enable different flexing and stretching capabilities, specific weight and output power which allows customization based on the application requirements. The technique allowed for the world-record flexible and stretchable inorganic solar cells which can be bent down to 140  $\mu\text{m}$  radius and stretched up to twice their original size without degradation in the original normalized efficiency.

#### 11:00 AM EN01.04.02

**Intrinsically Stretchable Organic Solar Cells on Crack-Free Substrate/Electrode Platform under 40% Strain** Yeonjee Jeon, Seungbok Lee and Jung-Yong Lee; Korea Advanced Institute of Science & Technology, Korea (the Republic of)

The increasing demand for off-grid power sources in soft robotics and wearable electronics has sparked considerable interest in stretchable organic solar cells (SOSCs). However, the brittleness of materials used in traditional solar cells makes them susceptible to cracks even under mild strain, limiting their application in wearable devices. To overcome this limitation, intrinsically stretchable organic solar cells (IS-OSCs) have emerged as a promising solution. They offer advantages, including omnidirectional stretchability, seamless integrability, and compatibility with conventional manufacturing processes. In our study, we revealed that the mechanical failure of IS-OSCs under strain can be traced back to the PH1000 layer. Cracks originating from the PH1000 layer subsequently propagate to the photoactive layer, resulting in a decrease in power conversion efficiency (PCE) in the IS-OSCs under strain. To achieve crack-free IS-OSCs under human body elongations as high as  $\sim 40\%$ , we propose a double-locked substrate/transparent electrode platform. To enhance the adhesion of the most fragile layer, the PH1000 layer, we developed techniques to enhance both physical and chemical adsorption, including surface treatment of the substrate and cross-linking between the substrate and modified PH1000. Remarkably, our double-locked system sustained strains exceeding 40% without developing cracks, while the untreated PH1000 film exhibited cracks at a strain level of 20%. Our double-locked IS-OSCs achieved an initial PCE of 10.2%, demonstrating significantly enhanced mechanical robustness, with nearly double the  $\epsilon_{\text{PCE}70}$  (44%) compared to the control device (24%), where  $\epsilon_{\text{PCE}70}$  represents the strain at which 70% of the initial PCE is retained<sup>1</sup>. Additionally, our IS-OSCs maintained 90% of the initial PCE even after undergoing 1,000 stretch-release cycles under a 10% strain.

#### 11:15 AM EN01.04.03

**A Wearable Sweat Sensor Powered by a Flexible Perovskite Solar Cell** Jihong Min<sup>1</sup>, Stepan Demchysyn<sup>2</sup>, Martin Kaltenbrunner<sup>2</sup> and Wei Gao<sup>1</sup>; <sup>1</sup>California Institute of Technology, United States; <sup>2</sup>Johannes Kepler Universität Linz, Austria

Continuous monitoring of physiochemical biomarkers using wearable sensors has the potential to revolutionize personalized healthcare. While sweat sensing has emerged as a promising method for continuous biochemical screening, ensuring a sustainable power supply remains a challenge. Previous energy harvesting modules, such as biofuel cells and triboelectric nanogenerators, have relied on exercise-induced power and sweat generation, limiting their applicability to fitness monitoring. In this study, we propose a flexible perovskite solar cell (FPSC) powered autonomous sweat sensor that efficiently harvests energy from ambient light, enabling continuous and sustainable sweat monitoring throughout the day, even during sedentary activities. The wearable device integrates a long-term reusable FPSC and electronic system, alongside a cost-effective and replaceable microfluidic biosensor array produced through inkjet printing technology. The FPSC features a record-breaking power conversion efficiency (PCE) of 31% under indoor illumination conditions. Its exceptional performance is attributed to the incorporation of  $\alpha$ -methylbenzylamine (MBA) as an organic spacer in the quasi-2D perovskite absorber layer, enhancing defect passivation and overall device functionality. Furthermore, the FPSC exhibits high durability, withstanding thousands of rigorous bending cycles, making it suitable for wearable applications. It maintains a high power output under a wide range of illumination conditions, including dim indoor lighting, ensuring uninterrupted operation during various activities throughout the day. Our battery-free device was validated for on-body use by continuously extracting sweat and capturing real-time cross-calibrated sweat biomarker levels (glucose, sodium, pH, skin temperature, and sweat rate) throughout the day over 12 hours under various lighting conditions and daily activities ranging from outdoor resting to indoor exercise.

#### 11:30 AM EN01.04.04

**Are Luminescent Solar Concentrators Worth the Effort?** Tomi Baikie<sup>1</sup>, Benjamin Daiber<sup>2</sup>, Neil Greenham<sup>1</sup>, Akshay Rao<sup>1</sup> and Bruno Ehrler<sup>2</sup>; <sup>1</sup>University of Cambridge, United Kingdom; <sup>2</sup>AMOLF, Netherlands

Luminescent Solar Concentrators (LSCs) are devices that capture and concentrate light using a transparent matrix doped with chromophores. LSCs have the potential to outperform other light concentration technologies due to their ability to concentrate diffuse light and reshape the solar spectrum to match the optimum spectral characteristics for photovoltaic (PV) technology. This study compares different LSC technologies, including solar windows, within a simulated real-world environment and outlines the potential impact of upcoming LSC technologies to determine their commercialization potential.

We utilised a calendar year of real-world solar spectrum data from Boulder and Amsterdam and combined it with a machine learning model, a ray-tracing algorithm and recombination current diode model to determine the potential power efficiencies from different luminescent solar concentrators (LSC) configurations.

**Enhancing Solar Energy Conversion Efficiency in Interfacial Evaporation Technology using Graphite Nanoflakes/Polydimethylsiloxane Composite** Anh Tuan Nguyen, Suman Chhetri and Woonchul Lee; University of Hawaii at Manoa, United States

Carbon-based materials such as graphite, graphene, and carbon nanotubes have been shown as a promising high-performance photothermal materials for the application in interfacial evaporation technology. In this study, we prepared a flexible graphite nanoflake (GnF)/polydimethylsiloxane (PDMS) composite with varying amounts of GnF from 1 to 10 wt%. It was found that the GnF/PDMS composite's photothermal property was optimized at 3 wt% of GnF, resulting in excellent total solar absorption of 94.8%. As proof of concept, GnF/PDMS composite was coated on polyurethane (PU) foam to create a floatable interfacial water evaporator. Under 1 sun illumination, the coated PU with 1 wt% of GnF/PDMS composite yields an evaporate rate of 1.14 Kg/m<sup>2</sup>h with solar-vapor conversion efficiency of  $\sim 68\%$ . With the promising photothermal effect, the GnF/PDMS composite can also be used in various solar-powered applications, including desalination and purification.

**Recent Progress on V2O5 Based Electroactive Materials: Synthesis, Properties and Supercapacitor Application** Adil Alshoaibi; King Faisal University, Saudi Arabia

The concerns of sustainable energy rely on highly efficient renewable energy sources and effective storage devices. Supercapacitor is practically reliable energy storage devices with rapid charging rate, high power density, simple setup, and good stability. Electrode materials have significant impacts on the performance of supercapacitors. Therefore, finding highperforming electroactive material is a critical concern of the area. Herein, the recent progress of vanadium pentoxidebased electroactive materials for supercapacitor application has been reviewed. Vanadium pentoxide is a potential electroactive material for supercapacitor due to its mixed oxidation states, eco-friendliness, low cost, high capacitance, and high energy density. But, poor conductivity and low cyclic stability are major drawbacks of the oxide which affect its electrochemical properties. This review points out different strategies of mitigating such limitations. Finally, future perspectives on V2O5-based electroactive materials for supercapacitor application have been highlighted.

#### 2:15 PM EN01.05.03

**Okra-Derived Hierarchical Porous Structured Activated Carbon Tuning with Metal-Oxide for Advanced Supercapacitors** Ekta Majhi and Atul S. Deshpande; Indian Institute of Technology Hyderabad, India

A hybrid supercapacitor is designed to fulfill the need for power and energy density by utilizing the composite of activated carbon and metal oxide. Naturally abundant bio-waste (Okra) has been explored to develop porous activated carbon for supercapacitors due to their easy availability, excellent specific surface area, a wide range of micro and mesopore structures giving extremely high performance, and a cost-effective synthesis approach. The bio-waste precursors have excellent microstructural properties, heteroatoms, and mineral content, which outline their subsequent effect on electrochemical performances. Moreover, the surface modification of carbon materials depending upon the pre-processing, carbonization, and etching by chemical activation method is explored, showing the impact on the capacitance. The electrode material is synthesized by freeze-drying biomass precursor followed by carbonization, acid treatment, and one-step activation. Its physicochemical properties are studied by characterization techniques like FESEM, EDS, XRD, Raman, TEM, BET, FTIR, XPS, and TGA analysis. Here, hierarchical honeycomb-structured porous activated carbons giving high surface area were synthesized from okra biowaste by the combination of chemical treatment and heat treatment at different temperatures, facilitating ion penetration and ion diffusion on the electrode-electrolyte interface, and the abundant macropores can serve as ion-buffering reservoirs. Transition metal oxide is synthesized by co-precipitation technique, having a unique characteristic. The electrochemical measurements CV, GCD, EIS, and cyclic stability tests are performed in an electrolyte solution using a carbon-metal oxide composite electrode, giving ultra-high specific capacitance and cyclic stability with high energy and power density. Here in this work carbon matrix is enriched with co-doped heteroatom facilitating the pseudo behavior with the enhancement of electrical conductivity and its hierarchical porous structure, providing easy accessibility to the electrolyte ions. The charge storage mechanism is explored in detail better to understand the dependence between physicochemical and electrochemical properties. Accordingly, we can tune the properties for individual applications. This work provides a facile, scalable synthesis route to get okra-derived activated carbon and transition metal oxide to achieve outstanding super-capacitive performance without compromising energy density.

#### 2:30 PM EN01.05.04

**Green Fabrication of Flexible Supercapacitors by using Silk Biomaterials** Xuelian Liu, Nicholas Ostrovsky-Snider, Marco Lo Presti, Taehoon Kim, Jeff Roshko and Fiorenzo Omenetto; Tufts University, United States

Energy storage devices that are eco-friendly, high-performance, and flexible are needed for integration into wearables, smart sensors, and implantable medical devices. The raw materials used in such devices determine both their performance and ecological impact. Here, we describe the process of assembling supercapacitors using three distinct silk fibroin (SF)-based composite biomaterials and carbon electrode materials. Photo-crosslinkable SF (Sil-MA) hydrogel, SF-polydopamine (SF-PDA), and SF bioplastic have been used to create a gel electrolyte, electrode binder, and encapsulation respectively. Together, these elements form a mechanically and electrochemically robust skeleton for bio-friendly energy storage devices. Combined with carbon materials, symmetric supercapacitors were built with methods that minimize energy consumption and the device's carbon footprint. The devices can achieve capacitance over 200 mF cm<sup>-2</sup> at a charge-discharge current of 10 mA cm<sup>-2</sup> with 94% capacitance retention after 20000 cycles. Moreover, the devices can be stretched, bent, twisted and compressed with minimal influence on the electrochemical performance.[1]

The SF biomaterials and green fabrication methods developed can also be applied to other aqueous electrochemical energy storage systems such as zinc-ion hybrid supercapacitors. The tough SF hydrogel can provide additional benefits to zinc anode by protecting it from the formation of dendrites and corrosion by-products.[2] This strategy for the use of SF biomaterials may open a route for the development of eco-friendly energy storage devices that can be integrated into future wearable and biomedical systems.

[1] Xuelian Liu, Nicholas Ostrovsky-Snider, Marco Lo Presti, Taehoon Kim, and Fiorenzo G. Omenetto, Silk biomaterials enable green fabrication of flexible supercapacitors, In preparation.

[2] Xuelian Liu, Nicholas Ostrovsky-Snider, Taehoon Kim, Marco Lo Presti, Jeffery Roshko, and Fiorenzo G. Omenetto, Silk hydrogel electrolyte for dendrite free Zn anode, In preparation.

**Strong and Highly Ionic Conductive Ionogel for Wearable Solid State Supercapacitor** Hongli Zhu, Ruobing Bai, Ying Wang and Zhengxuan Wei; Northeastern University, United States

To follow the pace of the high-speed development of wearable electronic devices, the mechanical and electrochemical performances of the corresponding flexible and stretchable solid state energy storage devices need to be further improved. As a kind of solid polymer electrolyte for wearable energy storage devices, ionogel is a promising candidate exhibiting a broad stability window, exceptional mechanical performance, exceptional thermal stability, and low vapor pressure. Nevertheless, it is difficult to simultaneously enhance the mechanical and electrochemical performances of ionogel. In this work, we constructed an ionogel using polymerized poly (acrylic acid) and polyvinyl alcohol interpenetrating polymer networks as the host material and injecting 1-Ethyl-3-methylimidazolium dicyanamide ionic liquid as a filling solvent. Adequate contorted polymer chains and abundant reversible hydrogen bonds within the network aided in energy dissipation during tensile and compression, contributing to the exceptional mechanical properties. The improved electrochemical performances of ionogel result from the development of ion transfer kinetics. In particular, the subsequent ions impregnation and solvent exchange procedures modified the network structure and elevated the ion concentration in the ionogel. Concurrently, ionic liquid occupied in the networks rendered this ionogel with an outstanding stability of volume, mass, and ionic conductivity under conditions of low relative humidity. After a series of treatments, this ionogel performed a remarkable strain of 2500 %, an exceptional ionic conductivity of 3.18 S/m at room temperature, and a virtually

constant weight, volume, and ionic conductivity over about forty hours at a relative humidity of 20%. Sandwiching this ionogel electrolyte using electrospun polyacrylonitrile-based carbon fibers electrodes, a solid-state supercapacitor exhibited remarkable areal capacity, outstanding power density, and exceptional energy density. As a result, we synthesized a novel ionogel that breaks long-standing confinement while simultaneously exhibiting expected mechanical and electrochemical properties, thereby promoting the development of ubiquitous solid-state energy storage devices.

**Flexible/Stretchable Supercapacitors for Powering Integrated Sensors of Wearable Patch Devices** Jeong Sook Ha; Korea University, Korea (the Republic of)

In accordance with the miniaturization of personal wearable electronics, there has been extensive effort to develop high performance flexible/stretchable energy storage devices for powering integrated active devices. Supercapacitors are expected to achieve this purpose owing to their simple structures, high power density, and cyclic stability. As integrated wearable powering devices, supercapacitors are required to have stability over mechanical deformation such as bending and stretching due to body movements in addition to high electrochemical performance. The application of flexible/stretchable supercapacitors can be expanded further through the introduction of additional novel functionalities.

In this talk, we will introduce our recent works on the fabrication of high performance flexible/stretchable supercapacitors and their application as integrated energy storage devices to power various sensors in stretchable patch devices. In particular, our design strategy to fabricate the stretchable array of supercapacitors using serpentine and liquid metal interconnections as well as the intrinsically stretchable supercapacitors will be discussed. Finally, we will demonstrate our currently developed flexible/stretchable supercapacitors with novel functionality of self-healing, temperature tolerance, biodegradability, shape memory, and electrochromic display for advanced wearable patch devices with high durability, environmental friendliness, and color-changing display.

#### 4:00 PM EN01.05.07

**Sustainable Approaches for 1D Supercapacitors and Triboelectric Devices based on Functionalized Carbon Fiber Yarns** Luis Pereira<sup>1,2</sup>; <sup>1</sup>FCT NOVA, Portugal; <sup>2</sup>AlmaScience, Portugal

Carbon fibers (CFs) are versatile materials for energy harvesting and storage applications, particularly when focusing on wearable device applications. They present a combination of some unique properties, such as suitable electrical conductivity and mechanical strength, being also lightweight. Stretch-broken carbon fiber yarns (SBCFYs) can be used as current collectors to fabricate 1D fiber-shaped supercapacitors (FSCs) using regenerated cellulose-based electrolyte. The areal-specific capacitance reaches  $433.02 \mu\text{F cm}^{-2}$  at  $5 \mu\text{A cm}^{-2}$ . The maximum achieved specific power density is  $0.5 \text{ mW cm}^{-2}$ , at  $1 \text{ mA cm}^{-2}$ . The 1D FSCs possess a long-life cycle, 92% capacitance retention after 10000 charge/discharge cycles. The specific capacitance can be improved through functionalization of CFs with  $\text{MoS}_2$  nanosheets, reaching  $58.6 \text{ F g}^{-1}$  at  $1 \text{ mV s}^{-1}$  with a power density of  $15.17 \text{ W g}^{-1}$  and energy density of  $0.5 \text{ mWh g}^{-1}$ .

Functionalization of CF by introducing functional groups or nanoparticles onto the fiber surface is also crucial in optimizing power conversion efficiency in energy harvesting devices, such as triboelectric ones. We propose triboelectric generator yarns (TEG yarns) with axially grown ZnO nanorods using a new method for depositing PDMS directly onto conductive carbon yarns. The in-situ PDMS curing method allows the fast formation of a uniformly thick coating over functionalized CFs. Single-electrode configuration TEG yarns were developed, and their electrical output was optimized by precisely adjusting the PDMS layer thickness and by changing the chemical and physical nature of the SBCFYs surface, reaching a power density of  $74.1 \mu\text{W cm}^{-2}$ . We demonstrate that electrodeposited cellulose nanocrystals layers can replace ZnO nanorods in improving local polarization, which results in an increase of 100% of the TEGs electrical output to around  $142.7 \mu\text{W cm}^{-2}$ .

Both SBCFYs supercapacitors and triboelectric devices can be hand-stitched onto fabrics showcasing the practicality and versatility of the prepared 1D CFs energy harvesting and storage devices to power the future generation of wearables electronics.

#### 4:15 PM EN01.05.09

**Metal-Organic Framework Based Ultrafine-Fe1-xS-Nanoparticle-Confined Het-Erodimensional Anode and Hierarchical 3D Porous Carbon Cathode for Perfor-Mance Maximization of Sodium-Ion Hybrid Capacitors** Jong Hui Choi and Dong Won Kim; KAIST, Korea (the Republic of)

While being the most popular, lithium-based energy storage devices have issues of geological distribution and rarity in the earth's crust. Due to their abundance, sodium ion-based hybrid capacitors (SIHCs) are drawing significant attention as an alternative. However, the sluggish kinetics and low capacities of their anode and cathode need to be overcome. Here, we report a strategy to realize ultrahigh-performance SIHCs anode and cathode electrode materials derived from metal-organic frameworks (MOFs). Facile carbonization of MIL-100(Fe) precursor and subsequent sulfidation process generated ultrafine pyrrhotite nanoparticles in the carbon matrix. The embedded fine particles exhibited outstanding rate performance due to the reduced size effect. Moreover, heteroatom-rich cathode materials were synthesized via the pyrolysis of ZIF-8. The subsequent KOH activation maximized the surface area and constructed a porous structure to the cathode material. High capacity was achieved due to pseudocapacitance that was induced by abundant surface heteroatoms. As a result, the SIHC device that was composed of the as-synthesized anode and cathode materials exhibited ultrahigh energy density ( $>200 \text{ Wh/kg}$ ) and power density ( $>19,000 \text{ W/kg}$ ). This study suggests a novel design strategy for realizing high-performance SIHCs.

**Flexible and Fast Chargeable Lithium-Ion Battery Based on Percolative Network-Based Electrospun Nickel Microfibers and Electrospayed Nanotextured Anode Materials** Daekyu Choi and Hong Seok Jo; Sungkyunkwan University, Korea (the Republic of)

High-performance flexible energy-storage devices have great potential as power sources for portable and wearable electronics. The major obstacle for developing such next-generation flexible batteries is the absence of flexible electrodes that can simultaneously meet high stability, high energy-density, and fast charging features. In this study, we present a novel approach employing an electrospun nickel microfiber (NiMF)-based flexible current collector. Not

only does the current collector developed here show high mechanical properties, high electrical conductivity, and lightweight design, but the percolative network thereof also enables high flexibility and fast-charging speed with high stability. For the anode coating material, the mixture of lithium titanium oxide (LTO), carbon nanotubes (CNTs), polyvinylpyrrolidone (PVP), and polyvinylidene fluoride (PVDF) with a mixing ratio of 85:5:1:9 was used. In particular, the use of the electrostatic spraying method herein enabled the manipulation of the coating-thickness, -uniformity, and -texturing of the anode material being deposited on the randomly-entangled individual NiMFs. In case of the NiMF-based LTO electrode, despite being coated with the same loading mass of active materials, its total weight was only 25 mg because of an extremely low weight of the NiMF current collector relative to its volume. On the other hand, the Ni foil-based LTO electrode had a total weight of 475 mg. This difference in weight enabled the NiMF-LTO electrode to achieve a significant energy-density increase of more than 20 times compared to the Ni foil-LTO electrode. The resistance of the NiMF-LTO electrode was measured to be 6.3  $\Omega$ , which was significantly lower than that of the Ni foil-LTO electrode, which was 261  $\Omega$ . In addition, the NiMF-LTO electrode showed a 1.5% change in resistance after 100 cycles of bending test, while the Ni foil-LTO electrode yielded a large change of 10% with the formation of cracks. In the half-cell test, as increasing the current rate (C-rate) from 0.1 to 2 C and subsequently reducing to 1 C, the corresponding discharge capacity ( $C_{dis}$ ) of the NiMF-LTO case decreased from 166 to 75 mAh/g, followed by a recovery to 145 mAh/g, showing a high retention rate of 99.5%. In contrast, the  $C_{dis}$  of the Ni foil-LTO case exhibited a significant decrease from 165 to 4.5 mAh/g and then recovered to 10.5 mAh/g, showing a lower retention rate of 37%. Moreover, the NiMF-LTO case demonstrated a high stability with a capacity decay rate of only 0.05% over 100 cycles at 1 C. This advancement was attributed to the low impedance possibly identified by the charge transfer and ion transfer resistances ( $R_{ct}$  and  $R_{it}$ ). At 0.1 C, the  $R_{ct}$  of the NiMF-LTO electrode-based half-cell was measured to be 142  $\Omega$ , lower than that of the Ni foil-LTO case (297  $\Omega$ ). This difference indicates that the percolative structure of the NiMF-LTO electrode facilitated the efficient transportation of lithium ions from the electrolyte to electrode. Furthermore, the  $R_{it}$ , corresponding to the concentration gradient of lithium ions within the electrode, was measured to be 100 m $\Omega$  for the NiMF-LTO case, while that measured from the Ni foil-LTO case was higher as 704  $\Omega$ . This also indicates that the high uniformity and texturing (or surface area) of the LTO layer electrosprayed on the NiMFs enhanced the ion diffusion rate within the electrode. The approach and materials employed here are expected to show great promise for developing next-generation flexible batteries with offering high and stable electrochemical and mechanical features.

**The Power of Stress—A DFT Approach to Mitigate Fuel Cells Poisoning** Mohamed Mahrous; The American University in Cairo, Egypt

Fuel cells are a promising alternative to traditional power sources due to their high efficiency and low environmental impact. However, the problem of carbon monoxide (CO) poisoning remains a significant challenge for fuel cell technology. In this study, we propose to use density functional theory (DFT) calculations to investigate the effects of stress on the electrodes to mitigate the adsorption of CO on its surface. We will employ DFT simulations to study the changes in the metal's electronic and structural properties under different stress and CO concentration levels. By analyzing the combined effects of stress and CO on the metal, we will identify optimal stress levels for mitigating CO poisoning and provide insights into the underlying mechanisms.

**Surface Facet Controlled Zinc Metal Anode for High Performance Aqueous Zinc Ion Energy Storage System** HeeBin Jeong<sup>1</sup>, John Hong<sup>1</sup>, Dong Il Kim<sup>1</sup>, Hyeong Seop Jeong<sup>1</sup> and SeungNam Cha<sup>2</sup>; <sup>1</sup>Kookmin University, Korea (the Republic of); <sup>2</sup>Sungkyunkwan University, Korea (the Republic of)

Several issues exist with the current organic electrolyte based electrochemical energy storage system, including the lack of metal resources, thermal expansion problems, and toxicity. In contrast, aqueous Zinc (Zn) ion batteries (AZIBs) have garnered substantial attention due to their abundance in resources and the cost-effectiveness and environmental friendliness of their electrode materials. Additionally, a water-based electrolyte solution can act as a successful block layer, thereby improving thermal stability. However, the use of a water medium can result in the formation of Zn dendrites on the Zn metal anode. The protruding structure of these dendrites can damage the separator and short-circuit the cell. Moreover, the generation of hydrogen and corrosion caused by parasitic surface reactions on the native passivation layers of Zn metal anodes pose significant problems, leading to decreased cycling stability of AZIBs. Therefore, the properties of the Zn metal surface should be well-tailored to address these issues. In this work, we proposed the use of a highly active acidic etching process on the Zn metal anode to increase the effective surface area and control the surface facet for favorable and smooth Zn deposition and stripping. Without any heat treatment, a mere 2-minute etching time can effectively create a closely spaced array within the etched grooves, resulting in a preferential (002) crystal plane orientation on the Zn metal anode. The high surface area can provide more active sites on the Zn metal anode. Moreover, the tailored (002) surface orientation can ensure the continuous deposition of planar zinc metal during the charge-discharge process, which can minimize the growth of protruding Zn dendrites. According to the suggested highly active acidic etching process, the electrochemical performance was greatly improved in terms of stability, specific capacity, and symmetric cell cyclability. Our results demonstrate that using acid-etched planar zinc foils as the anode can effectively increase the electroactive surface area, suppress hydrogen evolution reactions, and inhibit dendrite formation on the Zn metal anodes. As a result, the Zn anode symmetry cell showed long and stable cyclability for 250 hours at both current densities of 3 mA cm<sup>-2</sup> and 1 mA h cm<sup>-2</sup>. Moreover, in the full cell configuration with the  $\alpha$ -MnO<sub>2</sub> cathode, the full cell displayed a long cycle life with a capacity retention of 73 % for up to 150 cycle at current density 0.5A/g. This acid etching process has a significant advantage of being short and simple in the experimental process compared to previously reported studies, thus providing new opportunities for stable and high-performance AZIBs.

#### 8:00 PM EN01.06.06

**High Performance Lithium-Sulfur Batteries by Ultrathin Mixed Ionically-Electrically Conductive Interlayer via Solution Shearing** Hyunmin Park, Donghyeok Son and Steve Park; Korea Advanced Institute of Science & Technology, Korea (the Republic of)

In an endeavor to mitigate the low energy density associated with lithium-ion batteries, lithium-sulfur batteries (Li-S batteries) have emerged as a prominent area of research due to their considerably high theoretical capacity of 1675 mA h g<sup>-1</sup>. The utilization of sulfur as a cathode material confers several advantages to Li-S batteries, including the non-toxicity and abundant availability of sulfur, which can be obtained as a byproduct of crude oil refining. Despite the considerable potential of Li-S batteries, their commercialization has been hindered by the shuttle phenomenon, primarily caused by soluble lithium polysulfide (LiPS) intermediates (Li<sub>2</sub>S<sub>x</sub>, 4 ≤ x ≤ 8). Numerous efforts have been made to address this issue, including the utilization of sulfur host materials with diverse functions such as electrocatalysis, adsorption, and facile electron transfer. Nevertheless, these approaches do not provide a fundamental solution as they fail to prevent the dissolution of sulfur into the electrolyte in the form of polysulfides during repeated charging and discharging. Therefore, it is recommended to develop a functional separator or interlayer that can reactivate inactive sulfur and suppress the shuttle phenomenon. Particularly, the introduction of an interlayer that acts as an additional barrier to the diffusion of soluble LiPSs has been regarded as a more direct, efficient, and scalable strategy to alleviate the shuttle phenomenon compared to modifying the cathode. Nonetheless, unresolved concerns regarding existing interlayers necessitate additional scholarly exploration. Firstly, the utilization of transition metal compounds (e.g., metal oxides, sulfides) as interlayers, capable of chemically adsorbing soluble LiPSs without a conductive carbon-based material, results in low initial discharge capacity and inadequate utilization of sulfur due to low electrical conductivity. Secondly, the overall energy density is diminished due to insufficient thickness and weight of the interlayers. Lastly, Blade casting and vacuum filtration methods for interlayer production have limitations hindering uniformity and large-area thinness. Consequently, scalable approaches for fabricating ultrathin and homogeneous interlayers on a large scale are imperative for the practical application of interlayers in Li-S batteries. In this study, we have successfully developed a large-area (10 cm × 10 cm), ultrathin (750 nm), and lightweight (0.182 mg cm<sup>-2</sup>) mixed ionic-electronic conducting CNP interlayer comprising carbon nanotubes (CNTs), Nafion, and poly(3,4-

ethylenedioxythiophene):polystyrenesulfonate (PEDOT:PSS) with 1-ethyl-3-methylimidazolium tetracyanoborate ionic liquid counter-ion exchange via a scalable solution shearing technique. The CNP interlayer effectively suppresses the shuttle phenomenon through the synergistic segregation effect, facilitated by the ion-conductive Nafion that induces electrostatic repulsion towards negatively charged soluble polysulfides, as well as the supplementary adsorption effect towards soluble polysulfides exhibited by CNTs and PEDOT. Additionally, the CNP interlayer demonstrates high electrical conductivity through counter-ion exchange with an ionic liquid, thereby enabling facile reactivation of inactive sulfur as a secondary current collector. Impressively, the lithium-sulfur pouch cell with the CNP interlayer achieves a high discharge capacity of 1029 mA h g<sup>-1</sup> and exhibits stable cyclability over 20 cycles, even under lean electrolyte conditions (5 μl mg<sup>-1</sup>) and high areal sulfur loading (5.3 mg cm<sup>-2</sup>). The scalable strategy to fabricate a shuttle-suppressing interlayer using solution shearing and counter-ion exchange guides future advancements in lithium-sulfur battery interlayers.

**A Promising Approach Towards the Commercialization of Lithium Sulfur Batteries: Prelithiated Graphene** [Mahmud Tokur](#)<sup>1,2</sup>; <sup>1</sup>Sakarya University, Turkey; <sup>2</sup>NESSTEC Energy & Surface Technologies A.S., Turkey

Lithium-sulfur (Li-S) batteries are a promising candidate technology for high-energy rechargeable batteries due to their advantages of abundant materials and inherently high energy [9]. However, the practical applications of Li-S batteries are challenged by several obstacles, including the low sulfur utilization and poor lifespan, which are partly attributed to the shuttle of lithium polysulfides and lithium dendrite growth during cycling [12]. The shuttling of polysulfide ions between the electrodes in a Li-S battery is a major technical issue triggering the self-discharge and limiting the cycle life. [11]. A stable lithium anode is essential for maintaining the good cycle stability of Li-S batteries in practical applications [13]. To address these lithium-related issues, various carbon materials, including graphite and graphene, have been investigated as suitable lithium hosts to use as anode materials for Li-S batteries [9]. Prelithiation is a crucial strategy to compensate for the lithium needs of the system when using lithium-free active materials, but most of the prelithiation reagents developed so far are highly reactive and sensitive to oxygen and moisture, making them difficult for practical battery application. In this study, prelithiated graphite and graphene-based anode materials are obtained by the galvanostatic charging method to improve the performance of Li-S batteries and compare the electrochemical properties, especially in terms of capacity retention and rate capability. According to the results, graphene showed better performance due to its high lithium storage capacity and fast lithium-ion diffusion rate. A pouch cell was assembled with prelithiated graphene anode showing an energy density of about 360 Wh kg<sup>-1</sup> in the first cycle and protected its specific capacity of 60% after 100 cycles in a liquid-based Li-S battery. **Keywords:** Lithium Sulfur Battery, Prelithiation, Graphene Anode

**A New Strategy for Hexagonal Boron Nitride Coating on Zinc Metal Anode for High-Performance Zinc Ion Batteries** [Dong Il Kim](#), HeeBin Jeong and John Hong; Kookmin University, Korea (the Republic of)

The high demand for new electrochemical storage systems with high energy densities and operational stability has driven recent studies on aqueous zinc-ion batteries (AZIBs). AZIBs, which consist of aqueous electrolytes and electrode materials, are promising alternatives to flammable organic batteries. However, further research efforts on Zn metal anodes are still required due to issues such as the formation of protruding Zn deposition morphology (Zn dendrites) and parasitic reactions, including hydrogen evolution reactions between the Zn metal anode and the water electrolyte. These issues can reduce the high-efficiency electrochemical cycling of AZIBs. Therefore, finding a proper protective layer for the Zn metal is crucial to reduce the direct nucleation sites of Zn dendrites, provide high mechanical strength to the Zn anode, and improve selectivity and uniformity at the electrode surface during the charge-discharge process.

Here, we present the first report on utilizing bulk hexagonal boron nitride (h-BN) layers as a promising coating for the Zn metal anode. The thin and uniform bulk h-BN coating reduces the nucleation radius of Zn dendrites, resulting in uniform Zn stripping and deposition. Furthermore, h-BN is a two-dimensional (2D) material with superior insulating properties, making it highly desirable. In particular, the h-BN layers can serve as effective energy barriers, preventing electron tunneling from the Zn metal to the electrolytes. This can minimize the parasitic surface reactions on the surface of the Zn metal anode.

In this study, we propose a practical coating method using commercial h-BN powders, which allows for uniform deposition on the Zn metal anode over a large area. Through the optimization of the coating process and h-BN layer thickness, the Zn/h-BN symmetry cells exhibited a reduced overpotential (29 mV) and extended lifespan (over 250 hours) at a current density of 1 mA cm<sup>-2</sup> during the deposition and stripping processes. Additionally, a full cell configuration of Zn/h-BN//α-MnO<sub>2</sub> was fabricated to demonstrate its electrochemical performance. The Zn/h-BN//α-MnO<sub>2</sub> full cell displayed a high electrochemical performance of 345 mAh g<sup>-1</sup> at a current density of 0.1 A g<sup>-1</sup>, with long-term cyclability of 75.4% after over 500 cycles at a current density of 0.5 A g<sup>-1</sup>. This simple and effective coating method utilizing h-BN materials represents a promising approach towards the commercialization of Zn-ion batteries.

#### 8:00 PM EN01.06.09

**High Performance Metal Halide Batteries Enabled by Electrolyte Optimization** [Liliang Huang](#), Wenjun Zhu and Ivan Situ; Sidus Energy Limited, United States

As one of the most promising energy storage devices, the Li-ion battery has witnessed tremendous success and growth over recent decades.<sup>1</sup> As society transitions into a carbon-neutral era,<sup>2</sup> there becomes an urgent need for the development of novel cathode materials, whose cost and performance significantly impact the future widespread application of Li-ion batteries. The recent development of metal halide cathodes enables deviation from conventional intercalation chemistry and thus greatly expands the chemical space for high-performance cathodes.<sup>3-4</sup> To date, lithium halide-based batteries with excellent energy density and rate performance have been developed, but cycling lifetime and self-discharge are still a challenge in their commercialization.<sup>3-6</sup> Herein, we demonstrate that electrolyte optimization can serve as a promising strategy to address these issues. Specifically, we show that increasing the lithium salt concentration in ether-based electrolytes is beneficial for cycling and stationary stability through alleviating the detrimental side reactions introduced by the metallic lithium as well as the shuttling of lithium halides. Further incorporating fluorinated solvents into the electrolyte can increase not only the electrolyte ionic conductivity but also the columbic efficiency. Moreover, in contrast to the conventional notion that carbonate solvents are incompatible with Li metal anodes, we discover a unique synergy between certain carbonate and ether-based solvents, resulting in significantly improved battery performance. Finally, enabled by this improved electrolyte design, we have successfully prepared pouch cells with good cycling lifetime and higher energy density than commercial cells.

##### **An Asymmetric Moisturizing 3D Foam with High Deformability for Complementary Energy Harvesting via Moisture-Induced Electric and Triboelectric Generator** Gwanho Kim and Cheolmin Park; Yonsei University, Korea (the Republic of)

Moisture-induced electric generators (MEGs) have emerged as promising candidates for next-generation energy conversion. However, existing MEG devices face limitations such as low current and voltage outputs, high moisture dependence, and lack of mechanical robustness. In this study, we introduce a novel 3D asymmetric moisturizing deformable MEG device that exhibits exceptional mechanical performance and simultaneously harnesses power from both MEG and triboelectric nanogenerator (TENG) effects. Our device combines an organo-ionic hydrogel infusion within the lower section of a 3D melamine foam substrate, coated with 2D conductive MXene ( $\text{Ti}_3\text{C}_2\text{T}_x$ ) and hydrophilic poly(vinyl alcohol), resulting in superior water capturing and rapid ion transport capabilities. Notably, this device operates efficiently across a wide range of temperatures (-20 to 60 °C) and relative humidities (20 to 90% RH). Leveraging the negative surface charge of MXene, positive ions from salts and water in the organo-ionic hydrogel are preferentially selected, enabling continuous power generation with a maximum open-circuit voltage and short-circuit current density of 0.32 V and 877  $\mu\text{A cm}^{-2}$ , respectively. Additionally, the upper layer of our device generates a high voltage (~80 V) through contact electrification with a perfluoroalkoxy alkane film over ~30,000 cycles. The integration of MEG and TENG components yields a high-power output (~83  $\mu\text{W cm}^{-2}$ ), showcasing the device's practical potential for emergency exit sign applications by leveraging the distinctive characteristics of MEG's direct current and TENG's alternating current.

##### **High Voltage Generated by Moving Drops** Pravash Bista<sup>1</sup>, Aaron Ratschow<sup>2</sup>, Hans-Jürgen Butt<sup>1</sup> and Stefan A. Weber<sup>1,3</sup>; <sup>1</sup>Max Planck Institute for Polymer Research, Germany; <sup>2</sup>Technische Universität Darmstadt, Germany; <sup>3</sup>Universität Stuttgart, Germany

Water drops sliding on insulating, hydrophobic substrates can become electrically charged [1–3]. Despite many decades of research, this spontaneous electrification of moving drops is still far from being understood. By precisely measuring charge and voltage, we found that moving water drops accumulate a voltage of several kilovolts after sliding for just a few centimeters. To enable an efficient utilization of this simple electric energy generation mechanism, a detailed and quantitative understanding of the underlying physical process would be required. Using a simple electrostatic model, we show that the drop voltage is fundamentally connected to the properties of the electrostatic double layer at solid-liquid interfaces. The observation of high drop voltages will have important implications for energy harvesting applications, as well as droplet microfluidics and electrostatic discharge protection.

##### **Ultra-Flexible Li-Ion Batteries using High Mass-Loading Polymer-Rich Thick Electrodes** Niguss h. Hatsey<sup>1,2</sup>, Hye-Mi So<sup>1</sup>, Areum Kim<sup>1</sup>, Minsub Oh<sup>1</sup> and Seungmin Hyun<sup>1,2</sup>; <sup>1</sup>Korea Institute of Machinery and Materials (KIMM), Korea (the Republic of); <sup>2</sup>University of Science and Technology (UST), Korea (the Republic of)

Flexible batteries have been the research of interest due to various applications of Internet of things (IoT), soft robots and wearable electronics. For the development of advanced electronics, flexible batteries with high energy density and mechanical stability are essential. However, conventional electrodes are limited to achieve both flexibility and high energy density of batteries.

In this work, we developed novel electrode structure to fabricate ultra-flexible Li-ion battery with high energy density. This novel electrode structure was fabricated through reinforcing thermally induced polymer-rich electrode by stainless-steel (SS) fiber current collector. The polymer-rich electrode made through thermally induced phase separation (TIPS) process was suggested for flexible thick electrode. The SS fiber current collector was prepared by a facile method from a bundle. The combination of the polymer-rich electrode and SS fiber current collector enabled structural flexibility and mechanical stability. The electrochemical property and mechanical properties of the battery with the novel electrode were analyzed by comparing with battery of polymer-rich electrode coated on conventional metal foil current collector. The battery with LiNiMnCoO<sub>2</sub> thick-film electrodes with SS fiber electrodes showed high rate capability. At 2C rate, the specific capacity of foil electrode is 60 mAh g<sup>-1</sup> and that of the SS fiber electrode is 135 mAhg<sup>-1</sup>, which is two times higher. Moreover, up to 12 mA hcm<sup>-2</sup> high areal capacity is attained using about 1 mm thick electrode with SS current collector. Electrochemical performance of high mass-loading pouch-type battery after 2000 bending cycles also showed very high retention of specific capacity. The structural flexibility and mechanical reliability of the novel electrode structure enables to make flexible batteries with high energy density.

##### **Sulfur Cathode Integrating Nanoscale Carbon-Layered Mesoporous Silica Particles for Prolonged Cycle Life of Lithium-Sulfur Batteries** Sun Hyu Kim, Ji Yang Lim, Si Won Choi, Sandeul Ryoo, Hye Ran Kim and Yongju Jung; Korea University of Technology and Education, Korea (the Republic of)

Lithium-sulfur (Li-S) batteries have garnered significant attention as a promising energy storage system owing to the high energy density and high natural abundance of sulfur. Nonetheless, their practical application has been slowed down by limited cycle life attributed to soluble polysulfide species generated on discharge. The migration of these dissolved polysulfide ions towards the lithium anode gives rise to the formation of inert materials on its surface. The solubility of polysulfides is necessary for the discharge-charge process of the sulfur cathode, so it is inevitable to effectively confine them within the cathode to protect the diffusion phenomena of polysulfide out of cathode. Several approaches have been proposed, such as the utilization of sulfur-infiltrated carbon nanotube (CNT) films. However, the macro-porous structure of CNTs limits their ability to effectively accumulate polysulfides. Another strategy involves incorporating ordered mesoporous silica (OMS) as an additive to mitigate the diffusion of polysulfides, yet OMS lacks long-term stability

as a polysulfide reservoir. To address these limitations, this study introduces a novel solution for effectively immobilizing polysulfides. It entails the synthesis of carbon-layered OMS (c-OMS) through surface-selective polymerization inside silica mesopores, followed by carbonization. Comparing the performance of the sulfur-CNT cathode with c-OMS to that of the sulfur-CNT cathode alone, the former demonstrates a significantly enhanced capacity (942 mAh/g) and superior cycle stability (91% retention after 100 cycles). These outcomes underscore the advantageous surface properties of c-OMS, which exhibit a high chemical affinity for electrolyte solvents. This research presents a promising approach for enhancing the performance of Li-S batteries by effectively addressing issues related to polysulfide dissolution and confinement.

**Zeolitic Imidazolate Framework -8-Based Passive Daytime Radiative Cooling Paint for Energy-Efficient Cooling** [Hangyu Lim](#), Jaemin Park, Dongwoo Chae, Jisung Ha and Heon Lee; Korea University, Korea (the Republic of)

Owing to increasing energy consumption, especially for cooling, as well as climate change and the emergence of new industries, there is a growing demand for new cooling technologies to replace the existing systems that consume a large amount of energy and contribute to environmental pollution. To overcome these problems, radiative cooling can be utilized, which uses the optical properties of materials to achieve cooling without emitting pollutants or consuming energy. Paint is the most practical form for the application of a radiative cooling material. Therefore, we fabricated a passive daytime radiative cooling (PDRC) paint using a polyurethane binder and zeolitic imidazolate framework (ZIF)-8 powder. The ZIF-8 powder was synthesized in an environmentally friendly manner using deionized water as the solvent, and the resulting paint had a reflectance of 94.9%, an emissivity of 94%, and a cooling power of 113 W/m<sup>2</sup>. Actual temperature measurement results showed that the paint cooled the surroundings by an average of 5.7 °C and up to 8.1 °C during the daytime. As a result, ZIF-8-based PDRC paint is capable of cooling below room temperature and is expected to reduce the energy used for cooling and alleviate environmental pollution in various fields, such as building exteriors.

**Photocatalytic Reductive C-C Coupling Driven by Light-Induced Electron Transfer/Phase Migration of a Redox Mediator in a Biphasic Solution** [Ren Itagaki](#)<sup>1,2</sup>, [Akinobu Nakada](#)<sup>1,3</sup>, [Hajime Suzuki](#)<sup>1</sup>, [Osamu Tomita](#)<sup>1</sup>, [Ho-Chol Chang](#)<sup>4</sup> and [Ryu Abe](#)<sup>1</sup>; <sup>1</sup>Kyoto University, Japan; <sup>2</sup>JSPS Reserch Fellow DC1, Japan; <sup>3</sup>PRESTO/JST, Japan; <sup>4</sup>Chuo University, Japan

Natural photosynthesis establishes highly efficient molecular-conversion reactions driven by solar light energy, based on the combination of ingenious parts, such as light capturing, charge separation and migration, and catalysis in the reaction center. In addition to extensive studies on artificial photosynthetic systems mimicking the natural system, photoredox catalysis has recently had great impact on the field of photochemical organic synthesis. In any case, photoinduced electron transfer from/to electron donor(s)/acceptor(s) is a key initial step. One of the most important issues in the construction of highly efficient artificial photocatalytic systems is to suppress undesired backward electron transfer that decreases total efficiency. Herein, we developed a new photocatalytic system using biphasic solution media to mitigate such backward charge recombination. Two-immiscible solution composed of water and 1,2-dichloroethane (DCE) was employed with ferrocenium/ferrocene (Fc<sup>+</sup>/Fc) electron mediator. The change in dissolubility of Fc<sup>+</sup>/Fc (hydrophilic/hydrophobic) by photocatalytic electron transfer is expected to play an important role for the spatial charge separation to suppress the backward electron transfer. We demonstrated photocatalytic reductive coupling of benzyl bromide by utilizing the photoinduced inter-liquid phase migration of Fc<sup>+</sup>/Fc; suppressing the undesired backward charge recombination significantly.

Visible-light irradiation to a biphasic solution that composed of water and DCE solution containing an Ir(III)-photosensitizer, Fc, and benzyl bromide (Bn-Br) facilitated the reductive coupling of Bn-Br to dibenzyl (Bn<sub>2</sub>). Given the energy diagrams of the photosensitizer and Fc, the Fc should act as an electron donor for the photoexcited Ir(III)-photosensitizer. The reduced Ir(III) complex has an enough potential for one-electron reduction of benzyl bromide forming Bn<sub>2</sub>. Importantly, Fc<sup>+</sup>, generated by photooxidation, migrates to the aqueous phase due to the drastic change in its partition coefficient compared to that of Fc. On the other hand, visible-light irradiation to the same solution without water phase did not give any product. This finding indicates that the phase migration of Fc<sup>+</sup> across a biphasic solution suppresses the unfavorable backward charge recombination, which enables the photoreduction of Bn-Br. The results on the coupled phase migration/photoinduced electron transfer prompted us to further investigate design principles in order to improve the efficiency of this photocatalytic reaction. The co-existence of anions can further modify the driving force of phase migration of Fc<sup>+</sup> depending on their hydrophilicity; the best photocatalytic activity was obtained with 99% yield after continuous photocatalysis for 90 min in the presence of NBu<sub>4</sub><sup>+</sup>Br<sup>-</sup> compared to 25% one without additive. Thus, the liquid-liquid phase migration of the mediator results in effective charge separation, which leads to facilitate the reduction of Bn-Br in the DCE phase.

**Boosting Energy-Harvesting Performance of PVDF Nanofiber-Based Piezocomposite using Metal-Free Organohalide Crystals** [Kiyong Kim](#), Hoimin Kim and Joo-Hong Lee; Sungkyunkwan University, Korea (the Republic of)

Polyvinylidene fluoride (PVDF) has been widely studied in the field of self-powered active implantable medical devices (AIMDs). Because it has decent piezoelectricity, which is required for sensing various body signals, biocompatibility, and mechanical flexibility. To enhance the polar  $\beta$ -phase of PVDF, which is associated with its piezoelectric behavior, the incorporation of inorganic piezoceramics into PVDF has been a commonly considered approach. The physicochemical interfacial interaction between PVDF and these piezoceramics enables the non-polar  $\alpha$ -phase of PVDF to be transitioned to the polar  $\beta$ -phase, resulting in the improved piezoelectric response with a high piezoelectric coefficient ( $d_{33}$ ). In recent studies, although metal-based piezoceramics, such as lead zirconate titanate (PZT), barium titanate (BTO), and lead magnesium niobate (PMN), have been effective in enhancing the piezoelectric properties of the resulting PVDF-based piezocomposite, they showed limits in terms of mechanical flexibility, biocompatibility, and cytotoxicity, which are important for developing industrially viable AIMDs. In this study, we develop an ultra-thin and flexible piezocomposite by incorporating the metal-free organohalide crystals into the PVDF matrix using the electrospinning process. The electrohydrodynamic spinning process facilitates the interfacial attraction between the polymer chain and the organohalide crystals, which promotes the alignment of the  $\beta$ -phase of PVDF. Herein, 1,4-diazabicyclo[2.2.2]octane (DABCO)-NH<sub>4</sub>I<sub>3</sub>, which is the metal-free organohalide crystals having ABX<sub>3</sub> molecular structure with hexagonal crystal system and consists of one-dimensional chains of face-sharing (NH<sub>4</sub>)<sub>2</sub>X<sub>6</sub> octahedra separated by organic cations, was used. Compared to the bare PVDF electrospun nanofibers, DABCO-NH<sub>4</sub>I<sub>3</sub>-incorporated PVDF electrospun nanofiber exhibits a significantly improved piezoelectric response with showing a high  $d_{33}$  value of 202 pC/N. The enhanced  $\beta$ -phase of the PVDF nanofibers was examined using the grazing-incidence wide-angle X-ray scattering (GIWAXS) technique. Its high biocompatibility was also demonstrated by the cell viability test using fibroblast cells. The piezoelectric nanogenerator (PENG) fabricated using the piezoelectricity-enhanced nanofibers yields an outstanding energy-harvesting performance with a maximum output voltage of ~ 80 V, which is 10-fold higher than that observed from the bare PVDF nanofiber-based PENG. Since the DABCO-NH<sub>4</sub>I<sub>3</sub>-incorporated PVDF nanofibers developed here not only have high biocompatibility and flexibility but also show enhanced piezoelectric behaviors, it is expected to show great potential in the field of self-powered AIMDs.

#### 8:00 PM EN01.06.19

**Highly Efficient, Flexible and Self-Healable Moisture-Driven Energy Harvester based on 2D Vanadium Pentoxide Nanosheets** [Kundan Saha](#) and Sameer Sonkusale; Tufts University, United States

The ubiquitous source of atmospheric moisture brought about a fascinating research avenue of extracting atmospheric water to generate sustainable electricity. Energy may be extracted from ambient moisture with obvious and substantial advantages. This point-of-use technology provides a decentralized alternative to meet the energy needs in isolated off-grid places. Unlike traditional energy generators which predominantly rely upon fossil fuel, moisture-induced energy generators can extract energy from moisture in a sustainable and eco-friendly way. Herein, we demonstrated a self-healable moist electric generator (MEG) based on vanadium pentoxide ( $V_2O_5$ ) 2D nanosheet membranes. Lamellar membranes of  $V_2O_5$  nanosheets have been shown to be excellent cation conductors and excellent materials for harvesting energy from ambient moisture. Ultra-thin 2D nanosheets of  $V_2O_5$  was obtained by treatment of bulk  $V_2O_5$  crystals with hydrogen peroxide.  $V_2O_5$  nanosheet membrane was fabricated by vacuum-assisted filtration of 2D  $V_2O_5$  nanosheets dispersion over a PTFE support membrane. The  $V_2O_5$  membrane was easily peeled off from the support membrane on drying to obtain a flexible and freestanding  $V_2O_5$  membrane. The  $V_2O_5$  membrane consisting of percolated nanofluidic channels was sandwiched between a bottom solid copper foil and a perforated copper foil as the bottom electrode. The top electrode is perforated for exposure to atmospheric humidity. As the atmospheric water molecules come in contact with the  $V_2O_5$  surface, an open-circuit voltage of 0.5 Volts and a short-circuit current of 0.3 microamperes is generated. The generated voltage and current is attributed to the preferential flow of cations through the  $V_2O_5$  nanochannels. The exposed surface and edges of  $V_2O_5$  nanosheets have a high negative surface charge which results in the splitting of water molecules into  $H_3O^+$  and  $OH^-$  ions. An electrical double layer (EDL) is established at the  $V_2O_5$ /water interface which selectively permits  $H_3O^+$  ions through the channels. The mobile ions of the EDL transport through the nanofluidic channels creating a gradient between the two electrodes, resulting in a constant potential difference between the top and bottom electrodes which is harvested as electric current. The MEGs can be easily connected in parallel or series to enhance the current and voltage respectively. We demonstrate ten MEGs connected in series to power small electronic devices such as calculators and humidity meters. One of the key features of the  $V_2O_5$  MEG is its ability to repair any physical damage to the active material owing to the water-assisted healing characteristics  $V_2O_5$  membrane.

**Flexible Energy-Dense Li-Ion Batteries based on Super-Lightweight and Highly Flexible Metal-Coated Fabrics** [Wancheng Yu](#), Jian Shang, Lei Wang and Zijian Zheng; The Hong Kong Polytechnic University, China

Flexible Li-ion batteries (FLIBs) are in urgent demand but the balance of flexibility and energy density of the battery is a great challenge. Hundreds of works reported flexible Li batteries fabricated by special structure design or soft materials. However, getting flexibility always leads to lower energy density because of the introduction of inactive weight or volume. Hence, we proposed a new type of flexible, super-lightweight, and three-dimensional current collector, metal-coated fabrics (MCFs). They can be employed in large-scale fabrication and roll-to-roll production. By replacing the Cu foil with Cu-coated fabrics (CuCF), the energy density is increased by 10%. MCFs also show advantages on the flexible applications. For the MCF-based pouch cell, after 1,000 bending cycles at the bending radii of 5 mm and 2 mm, the capacity retention is higher than 90%. The  $f_{FOM}$  of the LIB made with MGFs reaches over 50, outperforming industrial flexible LIB and most reported flexible LIB made with soft current collectors. Since MCFs are prepared with cost-effective materials and a highly scalable process, they are promising, from a commercial viability point of view, to replace metal foils as current collectors in a wide variety of energy storage industries.

**Energy Harvesting with Fiber based Triboelectric Laminates for Wearable Devices** [Artis Linarts](#), Linards Lapčinskis, Kaspars Malnieks and Andris Sutka; Riga Technical University, Latvia

Triboelectric nanogenerators (TENG) are intriguing energy harvesting devices that convert mechanical energy into electricity and could power small portable devices or charge batteries [1]. Herein, we develop a broad and scalable approach to introduce volumetric dipoles into TENGs and break the surface charge paradigm by generating layer-by-layer triboelectric laminate structures from sequential electrospinning of large and small polymer fibers. When large fibers are electrospun onto smaller fibers, the interface between the laminate layers will slip, leading to internal contact electrification. In contrast, when small fibers are electrospun onto large fibers, they form an interpenetrated network with tight binding, creating a nonslip interface. This combination of ordered interfaces leads to parallel dipole moments being formed within the bulk volume of the laminate leading to an effective macroscopic dipole being formed. Increasing the total number of layers within a laminate, of the same total volume, leads to a linear relationship between charge and layer number. Most importantly we demonstrate that this concept not only works for laminates made of 2 different polymers but from identical polymer as well. We also show that exploiting triboelectric laminates in TENG devices can enhance their current output by 40 times. We believe that this concept will be widely used in the future for designing wearable devices with low power demand.

**Engineering Polymer Interfaces Toward Controlling Triboelectric Surface Charge for Wearable Systems** [Kaspars Malnieks](#), Andris Sutka, Artis Linarts and Linards Lapčinskis; Riga Technical University, Latvia

Developing pathways and materials that efficiently convert ambient energy from the environment into electricity is critical to powering distributed sensing networks, wearable and implantable electronics, and other Internet of Things (IoT) devices.[1] Mechanical and kinetic motions exist everywhere in our society, from human movement, blood flow, railway vibrations, car vibrations, rain fall bicycle motion, geological activity, or even simply water flowing through pipes. This abundance of motion has led to an explosion of research in small-scale mechanical energy harvesters. The goal of these mechanical energy harvesting technologies is to extract electrical energy from an otherwise stable material and convert it into useable electricity. Adding functionality where a certain material can also harvest heat and/or light can also boost energy generation and reduce energy loss.[2] Generally, such harvesting is practical to autonomously power low-energy devices ( $\mu W$ – $mW$ ).

Triboelectric energy harvesting devices, or so called triboelectric nanogenerators (TENG), have recently gained momentum for mechanical energy harvesting to power autonomous microdevices and portable electronics. Polymer-based TENGs can be easily fabricated from cheap, lightweight, flexible, and abundantly available materials. In comparison to piezoelectric, ferroelectric, and piezoelectrochemical principles, TENGs do not require costly materials or processes to enable energy harvesting, although significant developments are overcoming some difficulties in some piezoelectric polymer systems.

In our research within the field of TENG, we have explored the intricate nature of triboelectric charging in polymers and elucidated various strategies for enhancing the performance of TENGs. Our investigations into triboelectric surface charge engineering have encompassed a range of material factors operating at the nanoscale. Key factors we have examined include: Triboelectrification Mechanisms: We have delved into the mechanisms underlying triboelectrification, which encompass mass transfer, ion transfer, and electron transfer processes.

Effect of Surface Roughness: Our studies have investigated how surface roughness influences charge generation, shedding light on its crucial role in TENG performance. Temperature Influence: We have explored the impact of temperature on charge generation, providing valuable insights into optimizing TENG operation under varying environmental conditions. Influence of Fillers: Our research has examined how the presence of fillers within polymers affects

charge generation, uncovering strategies to enhance TENG efficiency.

Adhesion and Surface Properties: We have analyzed the interplay of adhesion and surface properties in charge generation, emphasizing their significance in TENG design. Polymer Chemistry and Bond Energy: Our investigations have considered the role of polymer chemistry and bond energy in triboelectric charging processes, offering a comprehensive view of material design. Collectively, these multifaceted aspects have culminated in the development of a flexible wearable triboelectric nanogenerator capable of achieving remarkable results, including a peak power output of 24 mW m<sup>-2</sup> and energy generation of 4.5 mJ. This underscores the potential for harnessing TENG technology in wearable applications and beyond.

**Redox-Targeting Approach with Hard Carbon and Biphenyl Semi-Liquid Electrode for Enhancing Energy Density in Seawater Batteries** Downan Kim and Youngsik Kim; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Renewable energy sources such as solar, wind, and wave power are growing in importance due to concerns about fossil fuels and climate change. To make these sources reliable, energy storage systems (ESSs) are essential. Among ESS designs, Seawater Batteries (SWB) stand out as the next generation of large-scale ESSs, utilizing the abundant Na<sup>+</sup> ions in seawater and an open cathode design for high theoretical energy density. SWB requires specific anode materials and liquid electrolytes due to the presence of a solid electrolyte (NASICON) that separates the anode and cathode. Unlike traditional batteries, SWB's liquid electrolyte requires a narrow electrochemical stability window only for the anode, allowing electronic conductivity without the risk of short circuits. Previous studies have used Na metal, solid anodes, and liquid anode materials in SWB. While sodium metal can provide high volumetric energy density, it suffers from limited cycle life. Solid-state anodes face electrode stacking challenges that limit energy density improvements. Liquid anodes such as sodium-biphenyl fill the cell efficiently, but offer lower volumetric energy density. Nevertheless, the use of a liquid anode with high cyclability made it possible to realize the most reliable seawater battery and it became the most widely used. To address the energy density challenge, a concept called "Redox-targeting" from redox flow battery systems has been applied to SWB. This approach incorporates semi-liquid active materials in a powder state and redox-mediated electrolytes in a liquid state, forming a semi-liquid electrode (SLE) configuration. Sodium-biphenyl (Na-BP), with ionic and electronic conductivity, and hard carbon (HC) were used as active materials for the HCBP SLE electrode. For Na-BP and HC, the overlapping response voltage bands were confirmed by the dQ/dV plot to confirm the amount of available capacity. After confirming the reaction mechanism of the HC used by the galvanostatic intermittent titration (GITT) method, it was found that the intercalation reaction could be involved, which could be confirmed by ex-situ TEM images. The electrochemical properties were then evaluated in a seawater half-cell system using sodium ferrocyanide as the cathode material and were confirmed to be 11.1 mAh cm<sup>-2</sup> for over 500 cycles (5000 hours). Using this approach, successful mass production of HCBP SLE and its application in seawater batteries has achieved, indicating the potential for industrial utilization.

#### 8:00 PM EN01.06.24

**Additive Manufacturing of Bearing Inspired TENGs for Integrated Energy Storage** Murathan Cugunlular, Onur Demircioglu, Melih O. Cicek, Doga Doganay, Mete Batuhan Durukan and Husnu E. Unalan; Middle East Technical University, Turkey

With the recent advancement in soft, flexible, and wearable devices, the need for innovative energy sources increases rapidly to overcome the energy needs for such devices. The capabilities of conventional energy storage devices may be insufficient to meet the energy needs of these devices. The solution to this problem may be to improve the performance of storage devices or their integration with energy harvesters. These harvesters include photovoltaics, piezoelectric, electromagnetic, and triboelectric nanogenerators (TENGs). Among these devices TENGs stand out with their unique features such as adaptability, simple-structure, high power density and integrability to modern devices. However, there are some problems that hinder the widespread applicability of TENGs. One of these problems is the breakdown voltage of the air, which acts as a barrier to obtain high power density. Recent studies suggests that the use of lubricants can increase this breakdown voltage while providing polarization between electrodes to improve their performance. In this work, an innovative, bearing inspired TENG (Bi-TENG) design was explored using polylactic acid (PLA) fused deposition modeling. The effect of lubricant and rotation speed on the performance of Bi-TENG was investigated. A peak power of 20 μW was obtained from the fabricated Bi-TENGs and the addition of lubricant was found to increase power by 110% compared to non-lubricated Bi-TENG. The fabricated TENG was also used to charge energy storage devices to demonstrate its use in wearable applications.

### SESSION EN01.07: Stretchable Batteries—Fabrication and Mechanical Challenges

Session Chairs: Mihai Duduta and Carmel Majidi

Wednesday Morning, November 29, 2023

Hynes, Level 2, Room 200

#### 8:15 AM \*EN01.07.01

**Design and Fabrication of Stretchable and Transparent Rechargeable Batteries** Markus Niederberger; ETH Zurich, Switzerland

The main task of a battery is to store energy and supply power to electronic devices. Although the areas of application for batteries have expanded massively in recent years - from portable devices to e-mobility and stationary storage options - the basic structure of the battery has hardly changed: It consists of two electrodes with electrolyte and separator, which are housed in a more or less rigid casing. Compared to batteries, portable electronic devices are constantly changing their design, depending on fashion and consumer tastes, but also with the intention of implementing new mechanical properties that make the devices flexible, rollable, stretchable or perhaps even transparent. For fully integrated systems that contain the battery and thus do not require wiring to an external power source, the batteries must have similar physical properties, which requires a complete rethink of battery design, but also allows for certain trade-offs in electrochemical performance [1].

In this talk, examples of the design and fabrication of a stretchable lithium-ion battery [2] and a transparent and stretchable zinc-ion battery [3] will be presented and discussed. In the Li-ion battery, all components (current collector, anode and cathode, electrolyte and packaging) were stretchable, making the battery flexible and twistable. The current collector was fabricated by depositing Ag microflakes as a conductive layer on a stretchable carbon-polymer composite. Anode (pre-lithiated V<sub>2</sub>O<sub>5</sub>) and cathode (LiMn<sub>2</sub>O<sub>4</sub>) powders were sprayed onto the silver flakes. A polyacrylamide 'water-in-salt' hydrogel was used as the electrolyte, which exhibited high ionic conductivity and excellent stretchability. The full cell battery worked even at a high strain of 50%. The second example concerns a transparent and stretchable Zn-ion battery with two electrodes featuring a hexagonal grid structure deposited on a polydimethylsiloxane (PDMS) substrate with a polyacrylamide (PAM) hydrogel electrolyte. In both electrodes, Au nanowires (NWs) were used as current collectors together with Zn for the anode and α-MnO<sub>2</sub> for the cathode. For the full cell battery, the PAM hydrogel was sandwiched between aligned films

of PDMS+Au NWs/Zn and PDMS+Au NWs/ $\alpha$ -MnO<sub>2</sub>, showing a high transmittance of 73% and 65% at 550 nm without and with 50% strain, respectively. The battery provided a capacity of 176.5 mA h g<sup>-1</sup> after 120 cycles under varying strain conditions up to 50%.

##### **Mechanical Failure Modes and Effect on Electrochemical Performance for Conventional LiCoO<sub>2</sub> Electrodes for Flexible Li-Ion Batteries**

Kyungbae Kim, Roberto Martinez and Candace K. Chan; Arizona State University, United States

As the demand for flexible electronic devices like wearables and foldable gadgets increases, it becomes necessary to develop appropriate components such as flexible batteries. While there has been progress in flexing entire battery cells during electrochemical cycling, further research is needed to understand how mechanical failure affects individual battery components, especially the electrodes, after flexing. In this study, we intend to highlight how characteristics of various lithium cobalt oxide (LCO) electrodes, such as particle size and mass loading differences, impact mechanical failure during flexing. This will entail an analysis of bending diameters corresponding to curvature angles and flexing duration, as well as studying the electrochemical performance of the electrodes after repeated bending (up to 3000 times) at diameters of 100, 50, and 25 mm. The mechanical strength (cohesion and adhesion properties) of the bent electrodes was evaluated through peel and scratch tests after undergoing flexing under different bending conditions. Optical and scanning electron microscopy were used to observe the mechanical failures on the surface and cross-section of the peeled and scratched electrodes after bending. The findings reveal that using a smaller LCO particle size can improve the durability of flexible electrodes, while high mass loadings cause formation of distinctive pore distribution with microcracks that propagate across the cross-sectional microstructure. Additionally, certain electrode microstructures can allow for mitigation of the deleterious effect of bending on the discharge capacity obtained at different C-rates.

#### 9:15 AM \*EN01.07.04

##### **Integration of Stretchable Batteries and Printed Circuit Board** Soojin Park; Pohang University of Science and Technology, Korea (the Republic of)

Stretchable electronics have been considered as a key technology in wearable and implantable medical devices. Although substantial advances have been made in key stretchable components, a stretchable electronic platform that integrates a stretchable power source and a stretchable printed circuit board (SPCB) has been a great challenge. Here, we propose an intrinsically stretchable electronic device platform powered by a stretchable film battery so that the platform can be used stand-alone. The stretchable battery is used as a substrate for manufacturing device platforms where SPCB is printed and directly connected through via holes, thereby enabling an increase in integrated devices density. To achieve intrinsically stretchable battery and high-performance circuit board, we designed a novel design concept of stretchable, self-healable, and pressure sensitive polymer composite. The platform is water-proof and maintains its stable electrical performance under extreme physical deformations. As a proof of concept, we demonstrate the integration of LEDs on the platform that can operate at large biaxial strain (125%) underwater.

### SESSION EN01.08: Energy Transducers—From Harvesting to Actuation

Session Chair: Mihai Duduta

Wednesday Morning, November 29, 2023

Hynes, Level 2, Room 200

#### 10:15 AM \*EN01.08.01

##### **Soft Matter Transducers for Energy Harvesting and Electrochemical Actuation with Liquid Metal** Carmel Majidi; Carnegie Mellon University, United States

Liquid metal alloys like eutectic gallium-indium (EGaIn) have attracted tremendous attention over the past decade for their use as microfluidic circuits encapsulated in soft elastomers. Applications include strain gauges, pressure sensors, mechanically tunable antennae, and highly stretchable electronics. However, in recent years, there's been increasing interest in extending liquid metals to applications in energy harvesting, energy storage, and electrochemical actuation. In this talk, I will review recent contributions from my research group in exploring the development of soft matter transducers that utilize EGaIn as electrodes for these emerging applications. This will include new classes of soft material architectures for stretchable batteries, triboelectric energy harvesting, and thermoelectrics. In addition, I will present efforts to use these EGaIn-based material systems to create wearable devices that can power body mounted electronic devices using energy harvested from body heat or motion. Lastly, I will discuss our latest work on exploiting the influence of electrochemical reactions on the surface tension of EGaIn droplets to create soft actuators. Inspired by the architecture of sarcomeres in natural muscle tissue, these actuators contract in response to low voltage stimulation. Where possible, I will relate experimental analysis of these soft actuators to underlying principles in fluid mechanics and elasto-capillary interaction.

#### 10:45 AM DISCUSSION TIME

#### 11:00 AM EN01.08.03

##### **Silicone Oil Emulsions as Oxygen-Enriched Flow Battery Catholytes for Multifunctional Energy Storage** Alissa Johnson, Alice S. Fontaine, Emily Beeman and James H. Pikul; University of Pennsylvania, United States

In biology, multifunctional interconnected systems provide increased system-level efficiency. Animal circulatory systems, for example, transport oxygen and nutrients while simultaneously regulating temperature and maintaining homeostasis. Inspired by biology, recent work has shown how multifunctional fluids can increase the total energy density of a robotic fish by both storing electrochemical energy and transmitting mechanical work to hydraulic actuators<sup>1</sup>. Despite the low energy density of the zinc-iodide electrolytes, this multifunctional approach increased the robot energy density by 4 times compared to the same robot with just a lithium-ion battery.

Gas transport in aqueous environments is important for many biological and chemical processes; however, the low solubility of gases in water is often

performance limiting. When animals require more energy in the form of oxygen, they can breathe in air to extract oxygen from their surroundings. Animal blood contains hemoglobin which allows for high concentrations of oxygen to be dissolved into the bloodstream and then distributed throughout the body to provide power locally to various cells. Combining multifunctional fluidic energy storage with the high energy density of air-rechargeable oxygen reduction chemistry will unlock the potential for ultra-high energy density soft robotic systems.

We present a fluid capable of storing twice as much oxygen as water and demonstrate its use as a catholyte for oxygen reduction in a metal air flow battery. Our catholyte is an emulsion with silicone oil droplets suspended in 0.5M potassium hydroxide (KOH) (1:4 v/v), stabilized by a surfactant (Span-60, 1.0 % w/v). The silicone oil acts like hemoglobin to increase the oxygen solubility of the entire emulsion. The silicone oil droplets have an average diameter of 280 nm and are uniformly dispersed within the aqueous phase. While droplet agglomeration is observed over time, this can be reversed with a simple re-homogenization process. Emulsions can maintain a uniformly dispersed oil phase and remain saturated with oxygen (15 mg/L) for several months.

We can extract energy directly from the oxygen in this fluid with a fully submerged electrode that is not exposed to surrounding air. Our emulsion-based electrolyte shows fast oxygen reduction reaction (ORR) kinetics, demonstrating twice as much diffusion limiting current as a control 0.5M KOH electrolyte in a rotation disk electrode study. Kinetics studies with stationary electrodes showed well-defined oxygen-reduction peaks with five times as much ORR peak current density for an emulsion electrolyte compared to KOH. Once the oxygen in the emulsion has been depleted, emulsions can be re-saturated and thus recharged with an influx of surrounding air.

We demonstrate the electrochemical performance of emulsion air-catholytes in two electrochemical cell configurations, a stationary flow cell and a multifunctional actuator flow cell (MAFC). Both configurations use a zinc anode and an emulsion electrolyte with a platinum carbon cloth catalyst for oxygen reduction. In the flow cell configuration, we achieve 4.6 mW/cm<sup>2</sup> peak instantaneous power density at 5.6 mA/cm<sup>2</sup> discharge current density. The MAFC demonstrates the ability for emulsion catholytes to enable multifunctional, flexible power sources for soft robotic systems. This cell uses the emulsion catholyte as a hydraulic working fluid for a McKibben actuator. The MAFC expands and contracts (~20% maximum strain) while energy is being extracted as the cell discharges. Our emulsion catholyte is a fundamental first step toward integrating soft robotic systems with multifunctional, high-energy, air-rechargeable energy storage.

#### 11:15 AM EN01.08.04

**Mechanically Rupturing Liquid Metal Oxide Induces Electrochemical Energy** Xing Ye and John W. Boley; Boston University, United States

Liquid metals, such as alloys of gallium, have unique mechanical and electrical properties because they behave like liquid at room temperature. These properties make liquid metals an ideal candidate for soft electronics and stretchable conductors. In addition, these metals spontaneously form a thin oxide layer on its surface. Applications that are made possible by this delicate oxide skin include shape reconfigurable electronics, microfluidic devices, and unconventional actuators. This presentation introduces another class of applications of liquid metals as an electrochemical energy source. By mechanically rupturing their surface oxide, liquid metals can form a galvanic cell and convert its chemical energy to electrical energy. When dispersing liquid metals into an ionically-conductive liquid to form emulsions, this hybrid material can provide ~500 mV of open-circuit voltage and ~10 μA of short-circuit current. This approach is further used to make a strain-activated stretchable electrochemical device that can supply up to ~4 μW of power. Protected by the oxide skin naturally, this passivating layer of the liquid metal shields it from self-discharge over time or changes in operating environment. Future applications of this device are demonstrated by supplying energy to a LED or a capacitor during repeated stretches. Strategies to further improve the output power of these devices are also discussed. These findings may unlock new soft battery designs due to the special surface oxide of liquid metals and offer new pathways to harness their inherent energy for self-powered devices.

#### 11:30 AM EN01.08.05

**Energy Storage in Stiff Hydrostatic Skeletons** Duhan Zhang; Massachusetts Institute of Technology, United States

The multifunctionality of energy components allows versatility and compactness in biology. For example, fat, as energy storage in many animals, doubles as insulation and as a structural element. Multifunctional energy storage can also improve the operating time of robots. In this work, we demonstrate that a liquid energy source can be used to create a controllably stiff “hydroskeleton” type structure for use in robots. This hydroskeleton type structure can be combined with tendon actuation for fast, efficient motion. We characterize this method of stiffening for a generalizable structure, and use it in a demonstration soft marine creature inspired robot’s motion. We adopt a flow battery with this scheme, where the battery electrolyte is used as the fluid in the hydroskeleton, optimizing materials and methods for incorporating a flow battery into a soft robot, and improving lifetime and performance. The power system and actuation would interact symbiotically: the motors would be powered by the flow battery to make the electrolyte flow inside the robot, which provides controllable stiffness to help the robot swim. Simultaneously, the electrolytic hydraulic fluid increases energy density and reduces system resistance. We show why flow battery soft robots are most competitive in swimming applications and discuss more possibilities for multifunctional fluid energy storage in soft robots.

#### 11:45 AM EN01.08.06

**Synchronous Generations of Electrical and Cellular Energies without Battery, Wiring even Generators: Inevitable Electrical Stimulation via Body-Mediated Energy Transfer** Hyungseok Yong<sup>1</sup>, Sangmin Lee<sup>2</sup> and Jinkee Hong<sup>1</sup>; <sup>1</sup>Department of Chemical & Biomolecular Engineering, Korea (the Republic of); <sup>2</sup>School of Mechanical Engineering, Korea (the Republic of)

Wearable technologies have become increasingly prevalent in various fields, ranging from smart devices and IoT to health monitoring and bioelectronics. However, finding a sustainable power source remains a challenge. Despite advancements in battery energy density, the need for frequent charging, heavy weight, and inconvenience continue to hinder the adoption of wearable technologies. Recent proposals for energy generation methods aim to harvest energy from the human body, but they often face limitations, such as being restricted to specific body parts or requiring large area devices like light exposure or physical motion. To address these constraints and eliminate the need for additional devices, researchers have explored utilizing the human body itself as a medium for transmitting energy and signals (nanogenerator-based ultrasound receivers, human body communication). However, the effectiveness of these methods is affected by the location of the energy source on the body, and the energy magnitude diminishes significantly with distance. On the other hand, low-frequency electric fields generated by electronic devices or physical activities can be converted into usable energy through the human body. Given the body's high relative permittivity at low frequencies, the transfer of low-frequency electric fields can be highly efficient regardless of the transmission distance. Nevertheless, existing body-mediated energy harvesting methods often neglect the physiological effects on biological tissue, such as cellular vitalization or necrosis. Although these electromagnetic waves inevitably affect biological tissues, conventional body-mediated technologies have not considered such physiological effects at all. In the end, ignorance of the correlation between physiological effects and body-mediated energy transfer undermines the latent ripple effect of this technology.

In this study, we aim to validate through various pre-clinical and clinical trials that body-mediated energy harvesting leads to local electric field concentration in the body, resulting in positive physiological effects. By focusing on the design factors and employing a trade-off approach between usability and energy strength, we propose a method for designing electrode grounds that can be implemented in practical applications. The waveform (AC

and DC) and intensity (10 - 3000 mV/mm) of these electric fields can be adjusted by controlling several variables (grounding method, external resistance, charging capacitor) depending on the purpose (usefulness, energy strength) without using any additional battery or wiring. Practical body-mediated wearable devices were implemented using conductive threads and fabrics, and body-mediated bioelectronics for zero-powered ion release and electrical stimulation was also implemented through stimuli-responsive ion-diffusive hydrogel. Complex mechanisms for the body-mediated energy transfer and electric field concentration have been demonstrated in various environments through in human body, ex-vivo setup and simulations. In in-vivo setup we confirmed the positive effects of 1) wound healing and 2) hair regeneration of mice. Eventually, through clinical protocols, we have observed a 3) reduction in muscle fatigue of up to 6.4% using such electrical stimulation designs. Particularly outstanding is that when cellular energy is generated by electrical stimulation under the skin, electrical energy is generated outside the skin, allowing 4) small electronics (1.5 mW) to be operated synchronously. These findings underscore the potential of the human body to harvest low-frequency electrical energy from physical activities or electronic devices while offering positive physiological effects. Overall, this research will contribute to the advancement of wearable technologies by providing insights into the relationship between body-mediated energy generation and physiological effects, paving the way for comfortable and sustainable power sources.

#### SESSION EN01.09: Zinc Batteries—Material Advances Towards New Applications

Session Chair: Mihai Duduta

Wednesday Afternoon, November 29, 2023

Hynes, Level 2, Room 200

##### 1:30 PM \*EN01.09.01

**Zn Batteries—Stable Anode and High Energy Cathodes** Chunyi Zhi; City University of Hong Kong, Hong Kong

Our research focuses on a stable aqueous Zn-based battery with long cycling stability, decent energy density, and ultimate safety performance for large-scale energy storage. To achieve this purpose, we did systematic studies on the Zn metal anode, electrolytes, and new cathode development.

For the anode side, we developed a few strategies, including pH value manipulation, ion redistribution coating, gradient coating, etc to induce stable stripping and plating of Zn. Moreover, we also found that a Zn initially plated can be much more stable than the one initially stripped during the subsequent deposition. We further utilize this observation to develop a pre-deposited Zn for Zn batteries with improved stability.

For the electrolyte, we develop a reverse micelle electrolyte, with it, the Zn anode exhibits balanced merits including strong H<sub>2</sub> coevolution suppression, prevention of dendritic and dead Zn, inhibition of corrosion, as well as relatively fast reaction kinetics. In a more extensive context, the new reverse micelle structure of electrolytes is expected to benefit other emerging battery chemistries, where a balance between fast ion transport and sufficient stabilization against side reactions is required.

For the cathode with high energy density, we studied the critical research concerns and further potential developments of chalcogen/halogen-based batteries, primarily focusing on the electrochemically active chalcogen/halogen sources, reaction modes, soluble products, and electrolyte adaptability.

For the cathode, we use iodine as the fixing agents working in highly concentrated electrolytes to successfully enable reversible Cl-based redox electrode. The interhalogen coordinating chemistry fixes Cl in a configuration of ICl<sub>3</sub><sup>-</sup>. Furthermore, we simultaneously exploit two redox centers of Cl and I to realize a novel three-electrons transfer electrode, in which the Cl-I electrode can deliver remarkably high capacity up to 612.5 mAh g<sup>-1</sup> and energy density as 905 Wh kg<sup>-1</sup>. The as-obtained energy density is 387% higher compared to the traditional one-electrons transfer of Zn||I<sub>2</sub> battery system and superior cycling stability with capacity retention as 95.7% after 2,000 cycles.

##### 2:00 PM EN01.09.02

**Reversible Zn Powder Electrodes for Aqueous Batteries and Supercapacitors** Zhixiao Xu and Xiaolei Wang; University of Alberta, Canada

Aqueous energy storage devices require highly reversible Zn electrodes, but this has been impeded by challenges including dendrite growth, low efficiency, hydrogen evolution, and metal corrosion. Here, we report reversible Zn powder electrodes for aqueous batteries and supercapacitors. In the first part, through thermal reduction of spent anode in alkaline batteries, Zn powder anode was regenerated, which shows super-zincophilicity and low overpotentials even under fast rates (8 mA cm<sup>-2</sup>) and high depth-of-discharge (50 %), resulting from coating of hydroxyl-rich organic layer with abundant nucleation sites as well as high orientation of favorable (002) plane and induced horizontal plating behavior. On the other hand, through thermal oxidation, spent MnO<sub>2</sub>-based cathode was also regenerated to pair with the regenerated Zn powder anode. Under a low negative-to-positive (N/P) ratio of 3.8 and high loading of ~10 mg cm<sup>-2</sup>, the regenerated full cell demonstrates high energy and power densities (94 Wh kg<sup>-1</sup>, 1349 W kg<sup>-1</sup>), holding potential for practical applications. In the second part, guided by theoretical calculation, we further fabricated Zn powder anodes *via* engineering the growth of zinc crystals in different solvents. Theoretical calculations demonstrate that the adsorption energy gap of different solvents on the (002) or (100) facet of Zn metal varies and that a larger energy gap favors a higher orientation of Zn (002) plane. Highly oriented Zn (002) powder exhibits horizontal deposition, corrosion resistance, faster kinetics and longer life under deep discharge (60%) in symmetric cells compared with less oriented Zn. Under practical conditions including low N/P ratios (1-3), high-loading cathodes (10-18 mg cm<sup>-2</sup>), and lean electrolyte (5-9 μL mg<sup>-1</sup>), highly (002)-oriented Zn powder-based batteries and supercapacitors demonstrate large capacity (~3 mAh cm<sup>-2</sup>) and energy/power density (108 Wh kg<sup>-1</sup>/2317 W kg<sup>-1</sup>), showing promise for practical use.

**High-Performance Aqueous Zinc-Ion Batteries with Synergistic Stabilized Zinc Anodes Through Molybdenum Dioxide Coating and Tween 80 Electrolyte Additive** Nhat Anh T. Thieu<sup>1</sup>, Wei Li<sup>1</sup>, Xiujuan Chen<sup>1</sup>, Qingyuan Li<sup>1</sup>, Qingsong Wang<sup>2</sup>, Murugesan Velayutham<sup>1</sup>, Khramtsov V. Valery<sup>1</sup>, David Reed<sup>3</sup>, Xiaolin Li<sup>3</sup> and Xingbo Liu<sup>1</sup>; <sup>1</sup>West Virginia University, United States; <sup>2</sup>University of Bayreuth, Germany; <sup>3</sup>Pacific Northwest National Laboratory, United States

Owing to their low cost, safety, environmental friendliness, and high energy density, aqueous zinc-ion batteries (AZIBs) have recently been considered a promising candidate for the new-generation energy storage systems. However, AZIBs usually suffer from poor cyclability due to various factors, including severe dendrite growth, self-corrosion, hydrogen evolution, and irreversible side reactions occurring at the Zn anodes. This work proposes a novel approach to develop a highly stable Zn anode by combining a surface coating layer with electrolyte additives. Molybdenum dioxide (MoO<sub>2</sub>) is introduced as a coating layer, and Tween 80 acts as an electrolyte additive. As MoO<sub>2</sub> is structured in nanoplates, the coating layer facilitates the rapid diffusion of Zn<sup>2+</sup> ions, which assists in inhibiting dendrite growth and by-products. Also, the MoO<sub>2</sub> coating layer shows a large redox capability due to the multivalent of Mo atoms in the nanostructure, which may be capable of homogenizing the concentration field of Zn<sup>2+</sup> in the vicinity of the Zn anode. In addition, Tween 80, a

surfactant additive, functions as an inhibitor of Zn metal corrosion as it is preferentially absorbed to the surface of the Zn anode to induce the deposition of  $Zn^{2+}$  ions. The  $MoO_2$ -coated Zn anode ( $MoO_2@Zn$ ) then exhibits excellent electrochemical stability in a mildly acidic electrolyte due to the dual synergistic effects of the  $MoO_2$  coating layer and Tw80 additive. With an optimal 1 mM Tw80, the symmetric cells of  $MoO_2@Zn$  achieve exceptional cyclability for 6000 h at 1 mA  $cm^{-2}$ . Even at a high current density of 5 mA  $cm^{-2}$ , the cells remained stable over 700 h. When assembled with the  $VO_2$  cathode, the full cells exhibit a high capacity of 105.6 mAh  $g^{-1}$  after 1000 cycles with outstanding rate performance (171.4 mAh  $g^{-1}$  at 10 A  $g^{-1}$ ). Hence, this study suggests an innovative strategy for stabilizing Zn anodes to develop long-life, cost-effective, and scalable AZIBs.

## 2:30 PM BREAK

### 3:30 PM EN01.09.04

**Simple Fabrication of Single Crystal Zinc Metal via Dislocation Motion for Zinc Ion Batteries** [Chihyun Hwang](#)<sup>1</sup>, Myung-Jun Kwak<sup>1</sup>, Ji-Hyun Jang<sup>2</sup> and Hyun-Kon Song<sup>2</sup>; <sup>1</sup>Korea Electronics Technology Institute, Korea (the Republic of); <sup>2</sup>UNIST, Korea (the Republic of)

Despite being one of the most promising candidates for grid-level energy storage, practical aqueous zinc batteries encounter limitations that compromise their safety and cycling performance, primarily due to dendrite formation. However, this study introduces a novel approach by fabricating a single-crystal zinc metal, effectively preventing dendrite formation. The manufacturing method employed in this study is remarkably straightforward. By subjecting a zinc ingot to a pressing process at a high temperature for few hour pressing, single crystal zinc metal is successfully produced. Remarkably, the dendrite-free electrode retains its integrity even after prolonged cycling, surpassing 2000 cycles at 4 mA  $cm^{-2}$ . This exceptional electrochemical performance is attributed to the use of single-crystal zinc metal, which effectively suppresses the primary sources of defect generation during electroplating and promotes planar deposition morphologies. By minimizing defect sites, including those typically found along grain boundaries or arising from lattice mismatch, the opportunity for dendritic structures to form is significantly reduced, even under extreme plating rates. Overall, this study demonstrates the potential of single-crystal zinc metal in achieving high-performance aqueous zinc batteries. By addressing the dendrite formation issue, we can enhance the safety and cycling stability of these batteries, making them even more suitable for large-scale energy storage applications.

### 3:45 PM \*EN01.09.06

**Wear and Wash: Stretchable Zn-MnO<sub>2</sub> Rechargeable Cells** [John D. Madden](#)<sup>1</sup>, Tan N. Nguyen<sup>1</sup>, Bahar Iranpour<sup>1</sup>, Evan Cheng<sup>1</sup>, Cliff L. Ng<sup>2</sup> and Ziqiang Chen<sup>1</sup>; <sup>1</sup>University of British Columbia, Canada; <sup>2</sup>Simon Fraser University, Canada

Wearable devices require power. There are opportunities to store energy in watch straps, belts, waistbands, suspenders, bra straps, shoes, hats, jackets and in custom fabrics. Typically, however, batteries have a hard metal shell, and are not suited for washing. Here we present a cell that is entirely stretchable and washable. It need not be removed from a garment prior to washing, and it conforms to its surroundings. The approach makes use of one of the lowest permeability elastomers— poly(styrene – isobutylene – styrene) block co-polymer or SIBS – as the encapsulation layer. This allows it to operate over the course of more than a year and a half without drying out. The active materials are zinc and manganese dioxide, both in powder form, combined with a near neutral aqueous electrolyte, making for safe operation, low cost, and possible recycling. The current collectors, active layers, and separator all contain SIBS, which helps to bind the device together, and allows the device to stretch to more than double its length. Carbon black provides electrical conduction, combined with carbon nanofibers to reduce resistance (27 ohms per square) and keep resistance stable over time. The cell has a reversible capacity of 160 mAh/g based on cathode active mass, shows 75% capacity retention after 500 cycles, and underwent 39 washing cycles before it began to leak. The cell is shown to operate effectively after mechanical cycling, runs a low power digital watch from a custom strap, and can briefly drive low energy Bluetooth. In the process of applying the cell we have found that it is relatively stiff. The stiffness can be reduced by making the cell thinner or combining SIBS with a softer polymer. The separator is created using evaporation induced phase separation to create pores in SIBS. The hydrophobicity of the bare SIBS separator could be improved by incorporating surfactant into the electrolyte or embedding hydrophilic groups onto the separator surface. The cell would also benefit from lower resistance current collectors, as these appear to be limiting power output. Applications such as wireless communications are difficult to run continuously as a result of the relatively high resistance. Finally, the chemistry can be improved – and in particular cycle life and stability in the discharged state. Some approaches to further improving the cell are discussed, along with prospects for application.

SESSION EN01.10: Electrolyte and Binder Materials for Improved Li-ion Battery Performance

**End-Group Assisted Electrodeposition of Ultrathin Solid Polymer Electrolyte Films on 3D-Micro Architected Electrodes** [Zhaoyi Zheng](#), Joerg G. Werner, Anton Resing and Wenlu Wang; Boston University, United States

Solid state batteries with three-dimensional micro-architected cell geometry are promising candidates for next-generation batteries with high power density, high energy density, and low safety risks because they take advantage of short ion diffusion distance and high active material loading in 3D interdigitated thin-film structures.

A major challenge in producing 3D micro-architected batteries is the fabrication of a thin and uniform solid electrolyte layer that separates the two interdigitated electrodes. Electrodeposition as a non-line-of-sight fabrication method is readily adapted to modify conductive 3D substrates such as architected electrodes with a polymer film as a thin electrolyte layer. While previous studies reported the electrodeposition of polymer electrolytes on micro structured materials, the resulting thin films exhibited limited functionality, heterogeneous topography, or were only applicable to a single substrate material. To address those issues, we developed the electrodeposition of a polymer electrolyte utilizing a two-component electrocoupling reaction to form a step-growth polymer network instead of the conventional electrochemically initiated chain-growth polymerization that causes uncontrolled polymer formation and precipitation in solution.

Specifically, poly(ethylene oxide) (PEO), known for high dielectric constant and Li-ion conductivity, is selected as the backbone of the polymer electrolyte network. The PEO chain ends are functionalized with electrochemically labile groups that undergo direct coupling reactions with a small molecule crosslinker. This electrochemically mediated coupling reaction of polymeric extender and polyfunctional crosslinker generates a polymer network close to the 3D electrode surface that leads to film deposition. This method is applied to coat a layer of solid polymer electrolyte on a low-tortuosity 3D Carbon electrode. As a result, the entire surface of the 3D Carbon electrode is effectively enveloped by a sub-micron polymer film. The deposited polymer film exhibits high electronic resistance and is able to serve as solid electrolytes. Our approach decouples the polymer functionality from its electrodeposition chemistry with electrochemically active end groups that make up only a small fraction of the resulting polymer thin film and can be combined with

arbitrary functional polymer chains. Therefore, this method can be a universal method to coat various conductive micro-architected 3D substrates with tailorable functional polymers.

#### 8:45 AM EN01.10.02

**Demixing the Miscible Liquids: Toward Biphasic Battery Electrolytes Based on the Kosmotropic Effect** Won-Yeong Kim<sup>1</sup>, Hong-I Kim<sup>1</sup>, Kyung Min Lee<sup>2</sup>, Eunhye Shin<sup>2</sup>, Xu Liu<sup>3</sup>, Hyunseok Moon<sup>1</sup>, Henry Adenusi<sup>4</sup>, Stefano Passerini<sup>3</sup>, Sang Kyu Kwak<sup>2</sup> and Sang-Young Lee<sup>1</sup>; <sup>1</sup>Yonsei University, Korea (the Republic of); <sup>2</sup>Ulsan National Institute of Science and Technology, Korea (the Republic of); <sup>3</sup>Karlsruhe Institute of Technology, Germany; <sup>4</sup>Hong Kong Quantum AI Lab, China

Exploring new electrolyte chemistry beyond conventional single-phase battery electrolytes is needed to fulfill the heterogeneous requirements of anodes and cathodes. Here, we report a biphasic liquid electrolyte (BLE) based on the kosmotropic effect. The key underlying technology for the BLE is phase separation of its electrolyte couples using a principle of "demixing the miscible liquids". Kosmotropic/chaotropic anions affect the ion coordination structures and the intermolecular interactions of electrolyte couples, enabling on-demand control of their immiscibility/miscibility. Despite the intrinsic miscibility of water (in aqueous electrolytes) and acetonitrile (in nonaqueous electrolytes), the structural change of the aqueous electrolyte induced by kosmotropic anions allows demixing with the nonaqueous electrolyte. The resultant BLE facilitates redox kinetics at cathodes and Zn plating/stripping cyclability at anodes. Consequently, the BLE enables Zn-metal full cells to exhibit a long cyclability (86.6% retention after 3500 cycles). Moreover, Zn anode-free full cells with the BLE exhibit a higher energy density (183 Wh kg<sup>-1</sup>) than previously reported Zn batteries.

#### 9:00 AM EN01.10.03

**Regulating Electrostatic Phenomena by Cationic Polymer Binder: Toward Scalable High-Areal-Capacity Li Battery Electrodes** Jung Hui Kim<sup>1,2</sup>, Kyung Min Lee<sup>1,3</sup>, Sang Kyu Kwak<sup>3</sup> and Sang-Young Lee<sup>2</sup>; <sup>1</sup>Ulsan National Institute of Science and Technology, Korea (the Republic of); <sup>2</sup>Yonsei University, Korea (the Republic of); <sup>3</sup>Korea University, Korea (the Republic of)

The promising potential of forthcoming smart electronics, electric vehicles, and grid-scale energy storage systems has spurred the unremitting pursuit of high-energy-density Li batteries. Accordingly, in addition to the ever-continuing search for advanced electrode active materials, designing high-areal-capacity (C/A) electrodes has garnered attention as a facile and scalable approach to achieve this goal. High-C/A electrodes increase the energy density of a cell without requiring the synthesis of new electrode active materials.

To achieve high-C/A electrodes (= areal-mass-loading (M/A) × specific capacity of electrode active materials (C<sub>sp</sub>)), the M/A should be maximized while stably maintaining the C<sub>sp</sub>. However, owing to the use of thick electrodes (physical issue) and non-uniform charge transfer throughout the electrodes (electrochemical issue), conventional electrodes cannot achieve this requirement. Particularly, the drying of processing solvents, such as N-methyl pyrrolidone (NMP) and water, during the fabrication of thick electrodes often induces crack formation and delamination from metallic current collectors, thus limiting the increase in the M/A values. Additionally, with an increase in the electrode thickness, charge transfer in electrode active materials tends to demonstrate uneven and sluggish reaction kinetics in the through-thickness direction of the electrodes, resulting in the loss of the C<sub>sp</sub> values.

Herein, we present a cationic semi-interpenetrating polymer network (c-IPN) binder strategy, with a focus on the regulation of electrostatic phenomena in electrodes. Compared to conventional neutral linear binders, the c-IPN suppresses solvent-drying-induced crack evolution of electrodes and improves dispersion state of electrode components owing to its surface charge-driven electrostatic repulsion and mechanical toughness. The c-IPN immobilizes anions of electrolytes inside the electrodes via electrostatic attraction, thereby facilitating Li<sup>+</sup> conduction and forming stable cathode-electrolyte interphases. Consequently, the c-IPN enables high-C/A (20 mAh cm<sup>-2</sup>) cathodes with decent cyclability using commercial slurry-cast electrode fabrication, while fully utilizing the theoretical C<sub>sp</sub> of LiNi<sub>0.8</sub>Co<sub>0.1</sub>Mn<sub>0.1</sub>O<sub>2</sub>. Further, coupling of the c-IPN cathodes with Li-metal anodes yields double-stacked pouch-type cells with high-energy-density (376 Wh kg<sub>cell</sub><sup>-1</sup>/1043 Wh L<sub>cell</sub><sup>-1</sup>), demonstrating practical viability of the c-IPN binder for scalable high-C/A electrodes.

#### 9:15 AM EN01.10.04

**Tuning the Electronic and Ionic Thermoelectric Transport Properties in Lithium- and Sodium-Based Polymer Electrolytes by Carbon Based Additive** Maximilian Frank, Julian-Steven Schilling, Philipp Kessler, Theresa Zorn, Ann-Christin Pöppler and Jens Pflaum; Julius-Maximilians-Universität Würzburg, Germany

Hybrid-organic energy storage media utilize the electrochemical transport of ionic species, at present, preferentially originating from lithium compounds. As such, much work on the device performance is devoted to cyclability, energy density and conductivity. Vice versa, the ionic transport characteristics offer also intriguing possibilities for the implementation of this material class in thermoelectrics (TE), the latter considered essential for recovering waste heat into electrical power. At the same time, the electrolytes' sustainability and alternatives to lithium are becoming increasingly important.

In this work, we present a comparative study on the electrical and thermoelectrical properties of a methacrylate-based solution processable solid polymer electrolyte containing lithium bis(trifluoromethanesulfonyl)imide salt (LiTFSI) [1] and sodium bis(trifluoromethanesulfonyl)imide salt (NaTFSI), respectively. By means of impedance spectroscopy over a frequency range from 10<sup>-1</sup> Hz up to 5 × 10<sup>5</sup> Hz and in a technologically relevant temperature range between 263 K and 363 K, we investigate the transport and dynamics of charge carriers in the solidified electrolytes. The observed high ionic conductivity of about 10<sup>-3</sup> S m<sup>-1</sup> at room temperature distinguishes this material for polymer battery applications [2]. In combination with highly sensitive thermovoltage measurements, we demonstrate that the electronic and ionic transport properties can be efficiently tuned by the content of lithium- and sodium-salt, respectively. Complementary multinuclear solid-state NMR studies further indicate interactions between ions and the polymer backbone. Additionally, a significant influence of the cations on the crosslinking of the resulting polymer network can be observed. These results showcase the potential for sustainable sodium-based ionic thermoelectric applications.

By further varying the concentration of suspended carbon-based additives, we investigate the influence of the respective dimensionality on the charge carrier transport. Different transport regimes merge and can be related to a Vogel-Fulcher-Tammann and Arrhenius activated conductivity. For these composite materials, we were able to increase the power factor by several orders of magnitude. Even more, we can reversibly switch the sign of the occurring thermovoltage and thus the respective operational mode by tuning the ambient temperature, which promises new applications in autonomous TE units.

Together with the high electrical conductivity achieved on macroscopic length scales, thermovoltages of about 2 mV K<sup>-1</sup> allow for high output powers while the polymeric matrix maintains the temperature gradient which in turn is a prerequisite for application in thermoelectric generators (TEG). As a proof-of-concept, an all organic TEG verifies the functionality of our approach and, thereby, substantiates the potential of mixed ionic and electronic materials for future TE applications.

**High-Performance Polymeric Electrode Materials for Organic Lithium-Ion Batteries** Febri Baskoro, Hui Qi Wong and Hung-Ju Yen; Academia Sinica, Taiwan

This talk covers our recent works on high performance aromatic polymers as electrode materials for Li-ion batteries. Polymers with high thermal stability and thermo-oxidative stability complemented by excellent solvent resistance, good electrical and mechanical properties and chemical resistance make them as great candidate as electrode materials. Electrochemical performance tests reveal that these electrode materials delivered a reversible specific capacity and stability over thousand cycles. The long cycle lifetime and excellent battery performance further suggest that the reported polymers are promising electrode materials for next generation Li-ion batteries.

### 9:45 AM EN01.10.06

**A Highly Reversible Electroconductive Liquid–Solid Electrolyte System for Na Metal Plating/Stripping with High Areal Capacity** Youngjae Jung, Youngsik Kim and Wang-Geun Lee; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Anode-free sodium metal batteries (AFSMB) are promising candidates for maximizing energy density and minimizing cost and safety hazards in the absence of metallic sodium during cell assembly. The practical implementation of AFSMBs is hindered by the low cycling stability of Na metal plating and stripping, particularly under high areal capacities. Despite the high energy density of AFSMBs, most of their reported areal capacities are less than 5 mAh/cm<sup>2</sup>, which is a similar level to those of conventional lithium-ion batteries, owing to the irreversibility of Na metal plating and stripping. The main causes of irreversible metal plating/stripping can be classified into two categories: 1) electrolyte decomposition and the formation of a solid electrolyte interphase (SEI) layer, and 2) the formation of an electronically inactive dead metal.

Here, we proposed an electroconductive liquid/solid dual electrolyte system that simultaneously suppresses the side reactions of electrolytes and confers electronic conductivity to connect the inactive dead Na. The electroconductive liquid electrolyte accepts electrons at a certain energy level and forms electronic conductivity, and the solid electrolyte can prevent internal short-circuit through a low electronic conductivity. Each function is verified using sodium biphenyl (NaBP) liquid electrolyte and NASICON (Na Super Ionic CONductor, Na<sub>1-x</sub>Zr<sub>2</sub>Si<sub>4</sub>P<sub>3-x</sub>O<sub>12</sub>) solid electrolyte through a seawater battery (SWB) system, which consists of an infinite seawater sodium source at the cathode. Compared with conventional 1 M NaPF<sub>6</sub> in dimethoxyethane (DME) electrolyte, the NaBP electrolyte suppresses side reactions such as gas evolution according to the redox-active properties. In addition, the electronic conductivity of NaBP enables the full stripping of dead Na in the absence of direct contact with the current collector, and the stripping efficiency is quantitatively confirmed through the designed experiments. Finally, the anode-free SWB cells have achieved a high coulombic efficiency of >99.9% for over 60 cycles at a high areal capacity of ~24 mAh/cm<sup>2</sup>. This study provides insight into the Na plating/stripping properties in anode-free systems and proposes a significant strategy for improving the reversibility of metal anodes for various battery systems with solid electrolytes.

**Deicing with Bubbles** Saurabh Nath, Henri-Louis Girard, Ha Eun David Kang, Srinivas B. Subramanyam, Yang Shao-Horn and Kripa Varanasi; MIT, United States

Ice accretion is ubiquitous and destructive: from car windshields to powerlines, wind turbines to airplanes, ice-induced damages comprise a multibillion-dollar problem in the United States alone. Traditional deicing methods rely on mechanical scrubbing, heating, or chemical melting that are crude, inefficient, and even environmentally toxic. Here we propose a fundamentally different approach to the classical problem of deicing using bubbles generated via in situ electrolysis of the liquid water – before it freezes. We show with experiments how a progressing ice front can trap the electrolytically generated bubbles at the interface that subsequently act as stress concentrators to diminish the energy required to fracture ice. Our proposed mechanism constitutes a self-starting, self-limiting means to reduce ice adhesion – a feature hitherto non-existent.

### 10:45 AM EN01.11.02

**Photoresponsive Electrospun PVDF-TiO<sub>2</sub> Meshes with Switchable Wettability for Fog Water Harvesting and Energy Harvesting** Gregory Parisi<sup>1,2</sup>, Piotr Szweczyk<sup>2</sup>, Shankar Narayan<sup>1</sup> and Urszula Stachewicz<sup>2</sup>; <sup>1</sup>Rensselaer Polytechnic Institute, United States; <sup>2</sup>AGH University of Krakow, Poland

Water scarcity is a global issue that affects the lives of billions of people. Fog water harvesters can catch water droplets out of humid air and provide water to arid areas. An efficient fog harvester catches majority of liquid from a fog stream and quickly evacuates it to storage. A fiber mesh is an efficient way to collect water due to its larger surface area, permeability, and tunable material properties. This study will take advantage of electrospinning to produce water harvesting polymer fibrous mats with specific surface characteristics. The efficiency and particular usages of fog harvesters depends heavily on surface wettability, which is the liquids' ability to form interfaces with solid surfaces. Hydrophilic surfaces can easily catch water and hydrophobic surfaces minimize the pinning effect of water on the mat surface improving the water collection rate.

To create meshes for water harvesting, polyvinylidene fluoride-titanium dioxide (PVDF-TiO<sub>2</sub>) core-shell fibers were produced by electrospinning and additional TiO<sub>2</sub> nanoparticles were electrospayed on the electrospun membrane. Due to the presence of TiO<sub>2</sub> particles, the wettability of the PVDF-TiO<sub>2</sub> mats can reversibly switch between hydrophilic and hydrophobic with the exposure of UV light and heat, respectively. Since the surface properties of meshes are tunable, the dynamic switch of their wettability increases the potential application of PVDF water collectors. Additionally, PVDF exhibits piezoelectric behavior, meaning it generates electric charges when subjected to mechanical stress, such as the wind from foggy conditions. This provides multifunctional technology that is more efficient and sustainable, as it doubles as an energy harvesting device. Energy generation offers the potential of operating necessary devices without external power sources, such as fog and wind sensors. This switchable fog water collector can be utilized in arid or humid environments and adds additional advantages of energy harvesting and sensing.

### 11:00 AM EN01.11.03

**Modeling and Optimizing Temperature-Dependent Elastocaloric Effects in Elastic Olefin Block Copolymer Fibers** You Lyu<sup>1,2</sup>, Buxuan Li<sup>1</sup>, Volodymyr Korolovych<sup>1</sup>, Duo Xu<sup>1</sup>, Yuan Zhu<sup>2</sup> and Svetlana V. Boriskina<sup>1</sup>; <sup>1</sup>Massachusetts Institute of Technology, United States; <sup>2</sup>Southern University of Science and Technology, China

Solid-state cooling technology based on elastocaloric effects [1–3] provides a competitive alternative to vapor-compression refrigeration technology by demonstrating higher energy efficiency, compactness, noise-free operation, and environmental friendliness. Well-studied metal alloy-based elastocaloric materials such as Ni-Ti and Cu-Al-Ni fail to reach industrial adoption due to their high cost of fabrication and operation, despite exhibiting high temperature spans (Tspan) of 12–30 K and coefficients of performance (COP) of 6–18 [4]. Polymers, on the other hand, are the largest product synthesized by volume nowadays, and have low tensile stress, chemical inertness, light weight, and low cost. Recent progress in elastocaloric polymer experiments shows performances comparable with those of metal alloys. E.g., Tspan around 15 K and COP over 10 in natural rubber [5] and other elastomers [6] have been demonstrated, opening new opportunities for polymer-based elastocaloric materials.

Different from the well-known cross-linked elastomers like natural rubber, we present an experimental study on an entanglement-enabled-elastic olefin block copolymer(OBC) fibers, whose elastocaloric performances feature a high cooling COP exceeding 10 and stable performance for at least 1000 cyclic loadings. We observed a Tspan over 22 K for the first loading, exceeding all existing polymer-based materials. After over 100 cyclic loadings, the stabilized Tspan at room temperature is 5 K. For stabilized Tspan, we noticed a non-linear temperature dependence on cooling Tspan with peaks at 6 K at -20 °C and 60 °C, while 2 K at room temperature. We explained such a nonlinear trend quantitatively by modeling the configurational entropy change upon deformations and predicted different temperature dependences for different deformation trajectories. Such temperature and deformation dependencies suggest a new direction for optimizing and designing polymer-based elastocaloric cooling devices. Finally, a conceptual device for heating and cooling is designed and analyzed with practical working cycles.

The entanglement-enabled reversible deformation of flexible polymer segments in the melt-spun OBC fibers makes them elastic at room temperature without cross-linking. We built a twisting-stretching coupled stage with an IR camera and force/torque sensors to measure in-situ temperature responses and force/torque during the fiber adiabatic deformation process. Experiments revealed that our fibers achieve greater than 10 cooling COP under stretching at room temperature and twisting at higher (60 °C) and lower (-20 °C) temperatures. We also characterized fiber structural changes by X-ray and Raman spectroscopy to understand the mechanisms underlying the elastocaloric fiber performance. Significant drops in both orthorhombic crystalline (6%) and amorphous domains by (13%) were observed upon stretching, while the interfacial oriented amorphous domains grew by 19%, accompanied by Herman's orientation factor increase from 0.02 to 0.17. These observations suggest the entropic change due to chain alignment, rather than strain-induced crystallinity, is revealed to be a dominant factor that explains the elastocaloric effects and its temperature dependence. Finally, the new elastomer fibers are extremely inert and suitable for operation in harsh corrosive environments, as well as fully mechanically recyclable at the end of their lifespan.

**Thermoelectric Materials in Membrane Distillation: Improving Performance Metric** Olawale Makanjuola<sup>1,2</sup> and Raed Hashaikeh<sup>2</sup>; <sup>1</sup>New York University, United States; <sup>2</sup>New York University Abu Dhabi, United Arab Emirates

The commercial deployment of membrane distillation (MD) as an alternative to reverse osmosis (RO) and multistage flash (MSF) or multi-effect distillation (MED) for desalination has been largely hindered by the high specific energy consumption (SEC) in MD systems. Many studies have succeeded in reducing the SEC in MD to a threshold value of around 1,000 kWh/m<sup>3</sup> by using energy recovery devices (ERD) and other techniques. While this is a significant improvement for MD, RO and thermal desalination present much lower SEC values (7 – 150 kWh/m<sup>3</sup>), and the ERD incorporated in MD systems will increase the complexity, equipment cost, and required real estate for MD operations.

Our previous works have indicated that using thermoelectric devices as a direct thermal source inside the MD module can reduce the SEC by more than 35% below the 1,000 kWh/m<sup>3</sup> threshold (i.e. < 650 kWh/m<sup>3</sup>) whilst greatly simplifying the MD system by eliminating the support subsystems generally required for heating and cooling in MD. The thermoelectric device doubles as both a direct thermal source to drive the process and as an ERD reducing heat exchange losses to near zero. By combining high-fidelity computational fluid dynamics simulation and mathematical modeling of the thermoelectric device with experimental validation, we developed a fairly good model for predicting the performance of a thermoelectric MD system.

We are currently investigating the possibility of embedding column-type p and n thermoelectric pellets inside the MD membrane itself. This thermoelectric membrane is expected to provide a more localized thermal source and sink for driving the MD process. This in turn is likely to lower the SEC when used in an MD system. A theoretical model developed from the constitutive relations under isotropic conditions while assuming steady-state conditions, one-dimensional heat flow, and constant properties for both the membrane and thermoelectric material allows us to predict the SEC (in kWh/m<sup>3</sup>) in an MD process driven by a thermoelectric membrane. The result indicates that while a thermoelectric membrane can potentially reduce the SEC by over 90% below the 1000 kWh/m<sup>3</sup> threshold for conventional MD equipped with ERD, the SEC cannot go below around 15 kWh/m<sup>3</sup> even for the best permeable thermoelectric membrane.

Our current efforts are geared towards realizing a physical thermoelectric membrane. Several avenues are being explored to successfully embed thermoelectric bismuth telluride pellets inside electrospun membrane. Concurrently, we are also working to improve the current theoretical model by accounting for all pertinent thermal and electrical resistances. Contact resistance and small-scale effects are some of the phenomena that the improved model will account for.

**Enhancing Thermoelectric Performance with Electrically Aligned Single-Walled Carbon Nanotubes in Polymer Matrix** Hyunjin Joh<sup>1</sup>, Gopinathan Anoop<sup>1</sup>, Seunghyun Jo<sup>1</sup>, KwangSup Eom<sup>1</sup>, Hyeon Jun Lee<sup>2</sup> and Ji Young Jo<sup>1</sup>; <sup>1</sup>GIST, Korea (the Republic of); <sup>2</sup>Kangwon National University, Korea (the Republic of)

Polymer-based thermoelectrics are a promising material to generate energy for wearable devices due to their flexibility and ability to directly convert thermal energy into electrical energy in low temperature. However, the fundamental limit of thermoelectric performance arising from interdependent parameters (electrical/thermal conductivity, Seebeck coefficient) is the main obstacles in preexisting homogeneous thermoelectric materials based on conducting polymers [1]. In the pursuit of enhancing the thermoelectric ZT of flexible thermoelectric generators, a composite consisting of an insulating polymer and conducting nanoparticles is proposed. This study explores the use of single-walled carbon nanotubes (SWCNTs) in a poly(vinylidene fluoride-trifluoroethylene) P(VDF-TrFE) polymer matrix. In polymer-CNT composites, the CNTs form networks within the polymer matrix that are electrically conductive but less thermally conductive due to phonon scattering at the polymer-nanotube interfaces, thereby enhancing the ZT of the composite [2]. The unique approach of electrical alignment of SWCNTs in the polymer matrix is employed to optimize their orientation and distribution. This method involves applying an external electric field during the drying process of the composites, causing the SWCNTs to align along the field lines through in-plane direction. The alignment of SWCNTs facilitates direct paths for charge carriers, thereby reducing scattering events and increasing carrier mobility. This enhancement in carrier mobility, coupled with a reduction in thermal conductivity, leads to a significant improvement in thermoelectric properties. Here, we have successfully fabricated freestanding composite films that exhibit excellent flexibility. Dispersion-drying method is used for the fabrication of the composite film, and electrical field is induced before the drying process to align the SWCNTs in the matrix. The alignment of CNTs are observed in the cross-sectional SEM image, and the resistance change according to the in-plane measurement direction. By incorporating 11.3 wt% of CNTs into the composite, the initial thermoelectric power factor (PF) was measured to be  $1.25 \mu\text{W}/\text{mK}^2$ . To further enhance the PF, an alternating electric field (150 V, 1 kHz) was applied during the solution process to align the SWCNTs within the P(VDF-TrFE) matrix. CNT alignment resulted in a significant increase in electrical conductivity and a slight decrease in Seebeck coefficient, leading to an overall increase in PF up to  $1.79 \mu\text{W}/\text{mK}^2$ . Even when highly bent (with a bending radius of less than 5 mm), the PF remained over 95%, and it also remained stable after undergoing  $10^3$  cycles of bending tests. The results demonstrate a substantial increase in the thermoelectric ZT from  $1.54 \times 10^{-3}$  to  $5.67 \times 10^{-3}$ , paving the way for the development of highly efficient, flexible thermoelectric generators. This research provides a promising direction for future advancements in flexible electronics and energy harvesting technologies.

**Chemical Additive-Regulated Thermocells with High Thermopower for Low-Grade Heat Harvesting** Yijie Mu<sup>1</sup>, Wendi Li<sup>1</sup> and Shien-Ping Feng<sup>2</sup>;

<sup>1</sup>The University of Hong Kong, Hong Kong; <sup>2</sup>City University of Hong Kong, Hong Kong

Low-grade heat (below 373 K) is ubiquitous in the human body, environment, and industry, but is usually wasted without proper recovery. Thermogalvanic cells (TGCs) are one of the most investigated technologies that can directly convert such waste heat into electricity, which present satisfactory thermopower in the magnitude of mV K<sup>-1</sup>. A typical method to improve the thermopower of aqueous TGCs is to introduce additives to change the solvation entropy or establish a concentration ratio difference between two electrodes at different temperatures. However, the introduction of additives may lead to the lower ionic conductivity of electrolyte, thus the current density of TGCs is not promising for powering electronics. From this point of view, further modification towards electrodes is required, making it complicated to optimize the performance of TGCs as a whole. Here, we first introduced a small amount of guanidine hydrochloride (GdnHCl) into 0.4 M potassium ferri/ferrocyanide (K<sub>3</sub>Fe(CN)<sub>6</sub>/K<sub>4</sub>Fe(CN)<sub>6</sub>) aqueous electrolyte. With the thermosensitive crystallization and redissolution effect between GdnHCl and Fe(CN)<sub>6</sub><sup>4-</sup>, a low local concentration of Fe(CN)<sub>6</sub><sup>4-</sup> due to the crystallization induced by GdnHCl at the cold electrode and a high local concentration of Fe(CN)<sub>6</sub><sup>4-</sup> via the redissolution process at the hot electrode were established, corresponding to a low concentration ratio of Fe(CN)<sub>6</sub><sup>4-</sup>/Fe(CN)<sub>6</sub><sup>3-</sup> at the cold side ([Fe(CN)<sub>6</sub><sup>4-</sup>/Fe(CN)<sub>6</sub><sup>3-</sup>]<sub>cold</sub>) and a high concentration ratio of Fe(CN)<sub>6</sub><sup>4-</sup>/Fe(CN)<sub>6</sub><sup>3-</sup> at the hot side ([Fe(CN)<sub>6</sub><sup>4-</sup>/Fe(CN)<sub>6</sub><sup>3-</sup>]<sub>hot</sub>), respectively. A thermopower of 1.91 mV K<sup>-1</sup> was achieved by solely adding 0.75 M GdnHCl to the electrolyte. On the basis of thermopower being enhanced by regulating the concentration profile of Fe(CN)<sub>6</sub><sup>4-</sup> via GdnHCl, in this work, we proposed to further improve the thermopower from the perspective of Fe(CN)<sub>6</sub><sup>3-</sup>. We added the second chemical, cysteamine hydrochloride (CysHCl), into the K<sub>3</sub>Fe(CN)<sub>6</sub>/K<sub>4</sub>Fe(CN)<sub>6</sub> aqueous electrolyte with 0.75 M GdnHCl to trigger a high temperature-favored chemical reaction with Fe(CN)<sub>6</sub><sup>3-</sup>. CysHCl was featured with temperature selectivity, the kinetic reaction rate of which was relatively slow at lower temperatures, making little contribution to the thermopower enhancement. But at temperatures above 323 K, which were within our designed temperature range for low-grade heat recovery application, the chemical interaction between CysHCl and Fe(CN)<sub>6</sub><sup>3-</sup> played a prominent part in the thermopower improvement, leading to a high ([Fe(CN)<sub>6</sub><sup>4-</sup>/Fe(CN)<sub>6</sub><sup>3-</sup>]<sub>hot</sub>) ratio. As a result, a large concentration ratio difference between the cold and hot electrodes was established by GdnHCl via inducing the crystallization and redissolution of Fe(CN)<sub>6</sub><sup>4-</sup>, and was further enlarged by CysHCl via chemically regulating the concentration of Fe(CN)<sub>6</sub><sup>3-</sup>. A high thermopower of 4.32 mV K<sup>-1</sup> and a short-circuit current density of 133.33 A m<sup>-2</sup> were generated using planar graphite sheets as electrodes, compared with the performance of 1.0 mV K<sup>-1</sup> and 56.44 A m<sup>-2</sup> of pristine electrolyte in the same cell configuration. Furthermore, a maximum thermopower of 9.06 mV K<sup>-1</sup> and a short-circuit current density of 129.24 A m<sup>-2</sup> were achieved by optimizing the concentrations of both GdnHCl and CysHCl simultaneously. The results elucidate that the introduction of GdnHCl enables a high thermopower and current density via the thermosensitive crystallization effect, and more importantly, by interacting with Fe(CN)<sub>6</sub><sup>4-</sup>, it allows more free Fe(CN)<sub>6</sub><sup>3-</sup> to react with CysHCl, which enables the thermopower and current density being boosted to a higher level via chemical regulation effect. This work develops a new design route for TGCs to achieve high thermopower and current density, while no complex modification towards both electrolyte and electrodes is needed, which is highly important for extending the possible application fields of TGCs.

**Electro-Spun Polymer Fibres Derived Carbon-Supported 1D Hierarchical WO<sub>3</sub>/SnO<sub>2</sub> Nanocomposites with Enriched Surface Defects for High-Performance Supercapacitor Devices** Vaishali Tanwar, Saurabh Kumar Pathak and Pravin P. Ingole; Indian Institute of Technology Delhi, India

Pseudocapacitive metal oxides are considered promising energy storage systems; however, their overall performance suffers from low intrinsic conductivity. [1] Herein, we report the design of 1D hierarchical architecture, carbon-supported WO<sub>3</sub>/SnO<sub>2</sub> nanocomposite-based fibers, via efficient and scalable strategies of single-spinneret electrospinning followed by controlled annealing for high-performance supercapacitor devices. As evident from the XPS and Raman analyses, the composite surface is enriched with surface defects such as oxygen vacancies (O<sub>vac</sub>), which improves surface chemical

structure, aids in efficient diffusion of the charge carriers, and enhances the conductivity.[2] The significant contribution of the two distinctive charge storage mechanisms accounts for the synergistic contribution of  $\text{WO}_3$  and  $\text{SnO}_2$  to the overall electrochemical behavior of the electrode.[3] Moreover, an interfacial charge build-up between  $\text{WO}_3$  and  $\text{SnO}_2$  due to nanoscale integration eradicates the charging and discharging processes, leading to better performance. Overall the unique combination of 1D hierarchical nanostructures, abundant electrochemically active sites ( $\text{O}_{\text{vac}}$ ), and unique heterointerfacial properties have boosted the performance.[4] The half-cell measurements demonstrated a specific capacitance of  $589 \text{ F g}^{-1}$  at  $6 \text{ A g}^{-1}$  and enhanced columbic efficiency with a capacity retention of  $\sim 80\%$  after 5000 charging-discharging cycles, indicating longer durability. Importantly, a flexible all-solid-state symmetric device (full-cell configuration) was assembled having energy density ( $E_d$ ) of  $2000 \text{ mW h kg}^{-1}$ , power density ( $P_d$ ) of  $1200 \text{ W kg}^{-1}$ , 100% durability (1,000 cycles), and the gravimetric capacitance of  $10 \text{ F g}^{-1}$  at  $0.5 \text{ A g}^{-1}$  for an extended working voltage window of 1.2 V. This work provides insight into the synthesis of hierarchical 1D nanocomposites of bimetallic metal oxides for high-performance, portable, and flexible supercapacitor device applications.

**LaMnO<sub>3</sub>-Mn<sub>3</sub>O<sub>4</sub> Nanocomposite Supercapacitor: Synergetic Effect Towards High Electrochemical Performance** Alisha Dhakal and Sanjay Mishra; University of Memphis, United States

Metal oxide materials have been a focus of research for energy storage devices. The perovskite oxide  $\text{LaMnO}_3$  and  $\text{Mn}_3\text{O}_4$  have drawn much attention as a sustainable energy storage system. In  $\text{LaMnO}_{3\pm\delta}$ , perovskite oxygen-ion intercalation leads to rapid energy storage, and electrodes are good supercapacitor material [1]. At the same time, multiple oxidation states of manganese in  $\text{Mn}_3\text{O}_4$  facilitate the faradic process to get enhanced pseudocapacitance [2]. However, the poor electrical conductivity and structural stability of the  $\text{Mn}_3\text{O}_4$  material limit their practical use as an electrode material for energy storage devices. To overcome the above stated limitation  $\text{LaMnO}_3$ - $\text{Mn}_3\text{O}_4$  composite samples (9:1,7:3,1:1) were prepared via a one-pot synthesis method followed by annealing in air at  $80^\circ\text{C}$ . The x-ray diffraction analysis confirms the presence of individual compounds in the desired ratio. The maximum surface area of  $7.68841 \text{ m}^2/\text{g}$  was recorded for the  $\text{LaMnO}_3$ . The chemical composition of composites was determined by x-ray photoelectron spectroscopy (XPS). The presence of  $\text{Mn}^{2+}$  and  $\text{Mn}^{3+}$  oxidation states conform to the presence of both  $\text{LaMnO}_3$  and  $\text{Mn}_3\text{O}_4$  in the composite. The electrochemical performance of composite electrodes prepared using nickel foam was assessed in 1M KOH solution. The cyclic voltammetry shows high specific capacitance for the 7:3 composite with a value  $\sim 584 \text{ F/g}$  at a scan rate  $1 \text{ mV/s}$ , which decreased with further addition of  $\text{Mn}_3\text{O}_4$  in the composite. At the same time, charge-discharge curves revealed a maximum specific capacitance of around  $405 \text{ F/g}$  for a 7:3 sample at a current density of  $0.5 \text{ A/g}$ . The energy density of  $\text{LaMnO}_3$  -  $\text{Mn}_3\text{O}_4$  composites (9:1,7:3, 1:1, and pure) are 5.33, 19.76, 3.71, and  $7.66 \text{ Wh/Kg}$  with power density 354.19, 308.67, 294.60, and  $304.94 \text{ W/Kg}$ , respectively at  $1 \text{ A/g}$  current density. The composites of  $\text{LaMnO}_3$  and  $\text{Mn}_3\text{O}_4$  help to reduce internal resistance due to the interconnected structure as well as reversible faradic process at the interface and create high degree of columbic efficiency [3]. The improvement in energy density, power density, and specific capacitance may result from enhanced charge transfer kinetics through the electrode-electrolyte interface between  $\text{LaMnO}_3$  and  $\text{Mn}_3\text{O}_4$ . Also, easy electron hopping pathways are expected between  $\text{LaMnO}_3$  (electron donor) and  $\text{Mn}_3\text{O}_4$  (electron acceptor) in the composite. These findings are more significant to develop high energy supercapacitor devices using this new composition as an electrode material.

**Novel Multifunctional Additives for Enhancing the Efficiency and Stability of Perovskite Solar Cells** Alex K. Jen; City University of Hong Kong, Hong Kong

Minimizing energy loss and increasing the quality of crystalline perovskite films are keys to improve the performance and long-term stability of perovskite solar cells. To address these challenges, we have developed several multifunctional, nonvolatile additives that can be used to modulate the kinetics of perovskite film growth to enable large-sized grains and coherent growth of perovskites from bottom to surface to be achieved. The improved film morphology resulted in significantly reduced non-radiative recombination, helping enhance the power conversion efficiency (PCE) of inverted (p-i-n) device to  $\sim 25\%$  with low energy loss and good stability. In addition, these multifunctional additives can also be applied to address one of the most challenging problems involved in large bandgap perovskites and their derived devices for single junction and tandem solar cells. The commonly observed halide segregation critically limits the stability of mixed-halide perovskites under device operational conditions. There is a strong indication that halide movement/oxidation is the primary driving force behind halide de-mixing. To alleviate this problem, we have developed a series of multifunctional mediators that can suppress these factors while simultaneously passivate defects through tailored substitution. These effects enable wide-bandgap (1.81 eV) perovskite solar cells to achieve an outstanding PCE of 19.58%, with 95% of its initial PCE retained after tracking at maximum power point for 500 h. Integrating this layer into a monolithic perovskite-organic tandem solar cell as a wide-bandgap subcell afforded a record-high PCE of 25.22% and impressive long-term stability ( $T_{90} > 500 \text{ h}$  under continuous operation).

#### 9:00 AM EN01/EN02/EN04.05

**Unveiling the Fatigue Behavior of 2D Hybrid Organic-Inorganic Perovskites: Insights for Long-Term Durability** Doyun Kim<sup>1</sup>, Eugenia S. Vasileiadou<sup>2</sup>, Ioannis Spanopoulos<sup>3</sup>, Xuguang Wang<sup>4</sup>, Jinhui Yan<sup>4</sup>, Mercouri G. Kanatzidis<sup>2</sup> and Qing Tu<sup>1</sup>; <sup>1</sup>Texas A&M University, United States; <sup>2</sup>Northwestern University, United States; <sup>3</sup>University of South Florida, United States; <sup>4</sup>University of Illinois at Urbana-Champaign, United States

2D hybrid organic-inorganic perovskites (HOIPs) are commonly found under subcritical cyclic stress states and suffer from fatigue issues during device operation, significantly limiting their service lifetime. However, the fatigue properties of these materials remain unknown, which is crucial for mitigating fatigue failure and predicting the lifetime for scheduled maintenance. Here, we systematically investigate the fatigue behavior of  $(\text{C}_6\text{H}_9\text{NH}_3)_2(\text{CH}_3\text{NH}_3)_2\text{Pb}_3\text{I}_{10}$ , the archetype 2D HOIP, by atomic force microscopy (AFM) dynamic stretching suspended 2D membranes. We find that 2D HOIPs are much more fatigue resilient than polymers and can survive over 1 billion cycles. The failure morphology indicates that the 2D HOIPs tend to exhibit brittle failure at high mean stress levels but behave as ductile materials at low mean stress levels. Our results suggest the presence of a plastic

deformation mechanism in these ionic hybrid organic-inorganic materials at low mean stress levels, which may contribute to the long fatigue lifetime but is inhibited at higher mean stresses. The stiffness and strength of 2D HOIPs are gradually weakened under subcritical loading, potentially as a result of stress-induced defects accumulating and nucleating. The cyclic loading component can further accelerate this process. The fatigue lifetime of 2D HOIPs can be extended by reducing the mean stress, stress amplitude, or increasing the thickness. Our results can provide indispensable insights into designing and engineering 2D HOIPs and other hybrid organic-inorganic materials for long-term mechanical durability.

**Conductivity Studies of Mechanochemically Processed LAGP/PEG Hybrid Solid Electrolytes** Abdul Latif Bamba<sup>1</sup>, James Buckley<sup>1</sup>, Megan Noga<sup>1</sup>, Kerry Sun<sup>1</sup>, Christine McGinn<sup>1</sup>, Dan Steingart<sup>1</sup>, Nicholas W. Gothard<sup>2</sup>, Ioannis Kymissis<sup>1</sup> and L. Jay Deiner<sup>3</sup>; <sup>1</sup>Columbia University, United States; <sup>2</sup>Bob Jones University, United States; <sup>3</sup>The City University of New York, NYC College of Technology, United States

Solid state lithium ion batteries promise to provide safe, high power energy storage to support increasing electrification of the transportation sector. Realizing the promise of solid state lithium ion batteries requires development of solid electrolytes whose conductivity and processability allow for the high rate capability and manufacturability of conventional liquid electrolyte lithium ion batteries. While ionically conducting ceramics may approximate the conductivity of conventional liquid electrolytes, operate safely over a range of temperatures, and resist dendrite formation, their manufacture and integration with battery electrodes is a challenge. In specific, ceramic electrolytes tend to form poor interfaces with electrodes, and require high temperature sintering. Polymer electrolytes are easier to process and join to electrodes, but they suffer from low room temperature conductivity. The ideal solid electrolyte would be a hybrid material that combines the high conductivity of ceramics with the processability of polymers. In such a hybrid material, the polymer concentration would be low enough and the distribution uniform enough so that lithium ions would follow a conduction pathway primarily through the ceramic whose grains were “glued” together by the polymer. Further, in contrast to a simple organic/inorganic composite, specific attachment of the polymer to the ceramic may facilitate charge transport through the hybrid.

As a step towards a readily processable solid state electrolyte, we have recently shown a mechanochemical synthesis of a true hybrid solid electrolyte in which the organic phase, polyethylene oxide (PEO), and the inorganic phase, lithium aluminum germanium phosphate (LAGP), are chemically associated through a surface condensation reaction that takes place under the high energy milling conditions. Solid state nuclear magnetic resonance (NMR) spectroscopy confirmed that after milling, protons from the polymer and/or water condensate are in bonding proximity of the Q<sup>2</sup> metaphosphate sites of the glassy phase of the LAGP. In the present work, we investigate the room temperature conductivity of a range of these mechanochemically synthesized PEO/LAGP hybrids. Conductivity is tracked as a function of organic to inorganic component ratio and as a function of milling condition. The correlation of the conductivity with hybrid material structure provides insight into mechanisms of lithium ion conduction in ceramic/polymer hybrids.

**Synthesis of High-Quality and Low-Cost Li<sub>6</sub>PS<sub>5</sub>Cl via Naphthalene Assisted Li<sub>2</sub>S-Free One-For-All Method for Commercial Synthesis** Mukarram Ali<sup>1,2</sup>, Chil H. Doh<sup>1,2</sup> and Yoon C. Ha<sup>1,2</sup>; <sup>1</sup>Korea Electrotechnology Research Institute, Korea (the Republic of); <sup>2</sup>University of Science and Technology, Korea (the Republic of)

The commercialization of sulfide-based all-solid-state batteries (ASSBs) has been hindered by the lack of sustainable synthesis techniques for sulfide-based solid electrolytes (SSEs) [1]. While mechano-chemical and solid-state sintering methods are energy-intensive and commercially non-viable, solvent/wet chemistry-based routes involving organic solvents have become the focus of extensive research [2]. Thus, it is crucial to develop a viable process that eliminates the need for Li<sub>2</sub>S as a starting reagent.

In this study, we present a Li<sub>2</sub>S-free one-for-all (OFA) method capable of producing high-quality Li<sub>6</sub>PS<sub>5</sub>Cl, a key SSE material, at the world's lowest cost of \$47/kg. The OFA method offers a universal approach for the synthesis of Li<sub>x</sub>MS<sub>4</sub> (x = 3 or 4, M = P, Sb, or Si) and Li<sub>6</sub>PS<sub>5</sub>X (X = Cl, Br, or I) in a single-step technique, eliminating the need for pre-synthesized Li<sub>2</sub>S. This process uses lithium metal (Li) and sulfur powder (S) as a precursor for Li<sub>2</sub>S along with LiCl and P<sub>2</sub>S<sub>5</sub> in tetrahydrofuran (THF), Li<sub>6</sub>PS<sub>5</sub>Cl can be synthesized within 9 hrs. The synthesis of Li<sub>6</sub>PS<sub>5</sub>Cl was carried out using the OFA method, and the resulting material exhibited exceptional ionic conductivity of 2.5 mScm<sup>-1</sup> and electronic conductivity below 10<sup>-7</sup> Scm<sup>-1</sup>. The low-cost production of Li<sub>6</sub>PS<sub>5</sub>Cl was achieved by utilizing readily available precursors, and the process cost was reduced to \$47/kg, making it highly attractive for large-scale manufacturing.

The synthesis mechanism of Li<sub>6</sub>PS<sub>5</sub>Cl was investigated using electrospray ion mass spectrometry (ESI-MS) and nuclear magnetic resonance (NMR) spectroscopy, revealing the formation pathway of the desired Li<sub>6</sub>PS<sub>5</sub>Cl structure. The wet synthesis started from spontaneous Li oxidation and naphthalene reduction, and the resulting naphthalene radical anion initiated the reduction reaction of elemental S to form polysulfide anions (S<sub>n</sub><sup>2-</sup>). Subsequently, P<sub>2</sub>S<sub>5</sub> reacted with polysulfide anions and co-precipitated in the form of Li<sub>3</sub>PS<sub>4</sub>, Li<sub>2</sub>S, and LiCl at the end. Electrospray ion mass spectrometry (ESI-MS) and nuclear magnetic resonance (NMR) spectroscopy are employed to elucidate the underlying chemistry between Li-NAP solution with S and P<sub>2</sub>S<sub>5</sub> with LiCl during Li<sub>6</sub>PS<sub>5</sub>Cl synthesis. We found that S<sub>7</sub><sup>2-</sup> and S<sub>9</sub><sup>2-</sup> are predominantly formed in the polysulfide solution, and the additional LiCl, P<sub>2</sub>S<sub>5</sub>, and Li made PS<sup>7-</sup> and PS<sup>9-</sup> at the initial stage. With increasing Li-ion concentration in the solution (as the lithium dissolved further in the reaction mixture), PS<sup>3-</sup> and PS<sup>4-</sup> coordinated with THF remained in the supernatants while Li<sub>3</sub>PS<sub>4</sub>, Li<sub>2</sub>S, and LiCl were co-precipitated at the end in a Li<sub>3</sub>PS<sub>4</sub>·x(Li<sub>2</sub>S-LiCl) complex. To further explain the argyrodite growth X-ray photoelectron spectroscopy (XPS) and X-ray diffraction (XRD) are used to investigate the phase growth of complex as-prepared product Li<sub>3</sub>PS<sub>4</sub>·x(Li<sub>2</sub>S-LiCl) to final argyrodite Li<sub>6</sub>PS<sub>5</sub>Cl from the OFA method.

To evaluate the electrochemical performance of the OFA Li<sub>6</sub>PS<sub>5</sub>Cl, it was paired with a high nickel cathode Li(Ni<sub>0.8</sub>Mn<sub>0.2</sub>Co<sub>0.2</sub>)O<sub>2</sub> (NMC-811) cathode. Galvanostatic cycling tests showed excellent cycling stability, with a capacity retention of over 90% after 1000 cycles at 2C (100 mAh g<sup>-1</sup>) with a high 1<sup>st</sup> discharge capacity of 180 mAhg<sup>-1</sup> at 30 °C. The OFA Li<sub>6</sub>PS<sub>5</sub>Cl-NMC811 system demonstrated superior performance, highlighting the effectiveness of the Li<sub>2</sub>S-free synthesis method in achieving high-performance solid-state batteries.

We believe that the results of this study have the potential to revolutionize SSE and ASSLB production, significantly contributing to the scientific community's understanding of cost-effective synthesis methods and paving the way for future advancements in one-pot co-precipitation techniques.

**Advancing Solid Polymer Electrolytes: Enhancing Ionic Conductivity, Transference Number and Li<sub>0</sub>-SSB Cycle Life Through Conduction Mechanism Design and Integration of Zero-Strain Cathodes** Huolin Xin, Yubin He and Lei Wang; University of California, Irvine, United States

Solid polymer electrolytes (SPEs) are promising alternatives to liquid electrolytes, offering advantages in flexibility, safety, and processability. However,

their widespread adoption is hindered by their limited room-temperature ionic conductivity ( $\sigma_{RT}$ ) resulting from insufficient ion conduction pathways. Additionally, both liquid and solid electrolytes commonly suffer from non-selective ion transport, causing a low transference number that adversely affects energy output and can lead to failures. In this presentation, I will discuss the methodology for overcoming these challenges. We will explore how to finely tune the composition of SPEs to change their ion conduction behavior from Vogel-Fulcher-Tammann to Arrhenius, thereby achieving a remarkable room-temperature conductivity exceeding 1 mS/cm. Additionally, we will discuss innovative strategies to enable single-ion conduction, effectively improving the transference number to unity. These advancements will significantly enhance the overall performance of SPE-based systems. Furthermore, we will shed light on the advantages of integrating zero-strain cathodes in LiO-SSB full cells. By mitigating strain-related issues, these cathodes can dramatically improve the cycle life of LiO-SSB batteries, extending their durability and reliability.

The work is in part supported by the Assistant Secretary for Energy Efficiency and Renewable Energy, Vehicle Technology Office of the U.S. Department of Energy (DOE) through the Advanced Battery Materials Research Program under contract no. DE-SC0012704 and the startup funding of HLX.

**Novel Custom-Shaped Batteries with Ionogel Polymer Electrolytes** Olga Gucho<sup>1</sup>, Gilat Ardel<sup>1</sup>, Hadar Nakar<sup>1</sup>, Heftsi Ragonos<sup>2</sup>, Allen Zheng<sup>3</sup>, Steven Greenbaum<sup>3</sup> and Diana Golodnitsky<sup>1</sup>; <sup>1</sup>Tel Aviv University, Israel; <sup>2</sup>Holon Institute of Technology, Israel; <sup>3</sup>Hunter College of City University of New York, United States

The rapid rise of flexible and stretchable electronics for healthcare, sensing, sport and textiles caused a growing demand for more efficient, reliable, environmentally friendly materials and continuous advancements of battery technologies. Our research pioneers a simple approach to the fabrication of novel flexible lithium-ion batteries. It is based on a single-shot extrusion - 3D printing method of a multi-shell-architecture battery comprising biodegradable polymer-based components. We used the thermoplastic polymers PLA and TPU to improve the mechanical properties of the well-known LiTFSI-PEO-based polymer electrolytes. The extruded electrolytes of different PEO-to-TPU/PLA ratios and salt content were characterized by means of ESEM imaging, mass spectroscopy, differential-scanning calorimetry (DSC), electrochemical-impedance spectroscopy (EIS) and solid-state nuclear magnetic resonance (NMR) diffusion measurements. All the polymers were found to form complexes with lithium salt. Flexible extruded *in-situ* plasticized ionogel polymer electrolyte (IGPE) exhibited bulk conductivity of 0.2mS/cm at room temperature and addressed the issues of inferior interface contacts. All-extruded cells with TPU-MWCNT-based current collector, LFP cathode, LTO anode and IGPE demonstrated good reversibility with close to 96% coulombic efficiency.

**Bringing the Performance of Conventional Thermoelectric Energy Harvesters to Unconventional Form Factors: Direct Laser Printing of Large-Area Inorganic Thermoelectric Materials on Flexible Plastic Foil** Yuan Tian, Isidro Florenciano Cano, Heyi Xia, Francisco Molina-Lopez and Chongchan Kim; KU Leuven, Belgium

Thermoelectric generators (TEGs) are gaining increasing attention as a renewable power source that can generate electricity from abundant waste heat in the environment. As such, TEGs can easily complement batteries and expand their lifespan by facilitating recharging instead of periodic replacement. However, some of the emerging fields that demand urgently new energy solutions, such as wearables and soft robotics, also imposes challenging mechanical properties and form factors like tolerance to repeated bending, conformability to curved surfaces and large area. Despite their high performance, traditional inorganic thermoelectric (TE) materials are brittle and expensive to integrate in a large-area device. On the other hand, the reported efforts to fabricate flexible and low-cost printed TEGs based on polymers yielded lackluster outcomes due to low performance. In this presentation, we will combine the best of both worlds by showing how high-performance inorganic TE materials can be directly printed on flexible substrates and over large areas. Printing techniques are known for their scalability, minimal material waste, and capabilities to achieve intricate designs. While printing (from melts or solutions) belongs mostly to the realm of organic materials, laser-based additive manufacturing is becoming common for the manufacturing of inorganic bulk parts. However, the extreme high temperatures potentially occurring during laser scanning discourage the use of laser printing for patterning materials directly on flexible substrates, e.g. plastic foil. In this presentation, we will show the selective-laser sintering of a film of Bi<sub>2</sub>Te<sub>3</sub> that is blade-coated from a slurry onto a polyimide substrate. The laser scanning parameters are carefully selected to achieve a high thermoelectric performance, while ensuring excellent adhesion between the inorganic film and the flexible substrate, which is enabled by a mechanical "interlock" design. The enhanced adhesion along with the highly-textured morphology of the laser-printed films, result in flexible films of pure Bi<sub>2</sub>Te<sub>3</sub> (i.e. without organic binders) that could bent to radii of curvature as low as 9 mm, without compromising their TE performance. This innovative fabrication method is further evolving towards multi-layer printing, which will enable 3D-printed TEGs as well.

#### 10:40 AM EN02.03.34

**Unexpected Lowering of Charge Transfer Resistance in Ultra-Long Cycled (>30,000 cycles) Solution-Processed Lamellar-Crystalline Li<sub>3</sub>VO<sub>4</sub> Anodes** Tejveer S. Anand, Aashish Joshi, Amit Gupta and Madhusudan Singh; Indian Institute of Technology Delhi, India

Transition metal oxide-based anodes such as Li<sub>3</sub>VO<sub>4</sub> (LVO) offer alternatives to commercial graphite based device architectures in lithium-ion batteries. Traditional methods of synthesis of LVO - solid state synthesis and hydrothermal, have typically resulted in moderate half-cell (LVO||Li) lifetime, thereby limiting its practical applicability [1]. In this work, we explore the impact of an alternative synthesis - a surfactant-free sol gel process on long cycling stability and an unexpected high charge (C)-rate performance. Ammonium metavanadate (Sigma-Aldrich) precursor was mixed in 2-methoxyethanol to form a solution (A), while lithium acetate dihydrate was mixed in the same solvent to form another solution (B). Solution B was added dropwise to A while being vigorously stirred (48 hr, 60°C). The product LVO was annealed (800 °C, 4 hr) prior to materials analysis. Powder X-ray diffraction (PXRD, Rigaku Ultima) reveals an orthorhombic phase with the Pmn21 space group [2], with Rietveld refinement yielding lattice constants: a=5.448 Å, b=6.327 Å, and c=4.949 Å. Solid-state UV-Vis spectra (Perkin-Elmer) reveals a wide band gap (3.95 eV). High-resolution transmission electron microscopy (HRTEM, JEOL with a selected area electron diffraction (SAED) attachment) data shows non-ring like diffraction spots, suggesting a high degree of crystallinity, with formation of lamellar flakes. The active material (LVO) was mixed with super-P carbon black: carbon multiwall nanotubes with n-methyl pyrrolidone with polyvinylidene fluoride (PVDF) binder to form a slurry, subsequently coated on a copper foil and dried at 80°C. Electrodes were punched out from the coated copper foil, and assembled using a standard process to form a CR2016 cell. The LVO||Li half-cell was found to deliver a capacity (Biologic BC810 battery cycler/Neware) of 764 mAh/g at a current density of 0.7 A/g when deeply discharged to 0.02 V. During the rate performance test; there is a 10.26% decrease in the intercalation potential of the cell, with a change in current density from 0.7 A/g to 3.5 A/g. Further testing of the cell at a current density of ~13.5 A/g for over 30,000 cycles has shown that it can still deliver a specific discharge capacity of ~155 mAh/g at the 15000<sup>th</sup> cycle (asymptotic point), with a coulombic efficiency (CE) of >95 %. After 30000 cycles of persistent deep charging (3 -> 0.02V), the cell can still deliver a capacity between 100-160 mAh/g. The estimated fading in the discharge capacity in the cycle range [15000, 30000] is ~0.002 mAh/g. We observe a rise in the initial capacity of the LVO||Li cell till it reaches the asymptotic point. Electrochemical impedance spectroscopy (EIS) measurements for aged cells indicate a lower charge-transfer resistance compared to the fresh cell at the discharge state, suggesting that the solid electrolyte interface (SEI) layer holds no barriers for lithium ions diffusion inside the material. The pre-lithiated LVO||Li cell is combined with the commercially available LiFePO<sub>4</sub> (LFP) cathode to form a full cell using a similar assembly procedure. The full cell is cycled (>1000 cycles) with an initial capacity of 165 mAh/g

at 0.15 A/g between 1-3.5 V. Interestingly, post-cycling TEM results indicate that the laminar morphology remains intact even after 30,000 cycles of continuous charging and discharging under high-rate conditions. We are carrying out additional ex-situ analysis, including techniques such as time-of-flight secondary ion mass spectrometry (ToF-SIMS) to elucidate the distribution of Li and operation byproducts such as the SEI layer in the cycled cell for better understanding of the mechanism.

**Poly(vinylidene fluoride)- and Poly(urethane acrylate)-Based Electrolytes for Solid State Batteries** [Enyuan Hu](#), Dean Yen, Nan Wang and Sha Tan; Brookhaven National Laboratory, United States

Solid-state batteries (SSB) have better safety characteristics than conventional lithium-ion batteries which are based on flammable liquid electrolyte. A key enabler for SSB is the solid state electrolyte. Among possible candidates, polymer electrolytes have attracted a lot of attention as they offer a wide range of tunable structure, have good physical contact with electrodes and are easy to fabricate. This talk will include our recent work on two kinds of polymer electrolytes: Poly(vinylidene fluoride), or PVDF-based electrolyte and poly(urethane acrylate), or PUA-based electrolyte. PVDF polymer electrolyte is prepared by the solvent-casting method. We will discuss its performance in full cells using various kinds of cathodes. We will also discuss the effect of residual solvent on the eventual cell performance. PUA polymer electrolyte is prepared by a solvent-free method. Through controlling the degree of cross-linking, we were able to introduce PUA with gradient structure in the polymer electrolyte. This provides both good physical contact with electrode and good mechanical strength against lithium dendriate penetration. The  $\text{LiNi}_{0.8}\text{Mn}_{0.1}\text{Co}_{0.1}\text{O}_2|\text{PUA}|\text{Li}$  cell is evaluated and shows good performance.

### 11:00 AM \*EN02.01.02

**Scalable Solid-State Electrochemical Devices** [Ju Li](#); Massachusetts Institute of Technology, United States

Low-cost, earth-abundant, and easy-to-recycle battery chemistries are key for the impending global energy transition. We provide some examples of proton solid-state battery ["Acid-in-Clay Electrolyte for Wide-Temperature-Range and Long-Cycle Proton Batteries," *Advanced Materials* (2022) 2202063 ], fast-acting neuromorphic computing ionic transistor ["Nanosecond protonic programmable resistors for analog deep learning," *Science* 377 (2022) 539], and lithium silicide guided lithium-metal batteries ["Ultra-Thin Lithium Silicide Interlayer for Solid-State Lithium-Metal Batteries," *Advanced Materials* (2023) 2210835] that may compete successfully with liquid electrolyte based devices. Full-cell performance evaluation and techno-economic assessment are essential for judging different device architectures.

### 11:30 AM \*EN02.01.03

**Toward Solid-State  $\text{Li}_{\text{metal}}$ -Air Batteries; An SOFC Perspective of Solid 3D Architectures, Heterogeneous Interfaces and Oxygen Exchange Kinetics** [Eric D. Wachsman](#), George Alexander, Roxanna Moores, Gibson Scisco, Christopher Tang and Michael Danner; University of Maryland, United States

The full electrification of transportation will require batteries with both 3-5X higher energy densities and a lower cost than what is available in the market

today. Energy densities of  $> 1000$  Wh/kg will enable electrification of air transport and are among the very few technologies capable of achieving this energy density.  $\text{Li}_{\text{metal}}$ -air is theoretically able to achieve this energy density and also capable of reducing the cost of batteries by replacing expensive supply chain constrained cathode materials with “free” air. However, the utilization of liquid electrolytes in  $\text{Li}_{\text{metal}}$ -air batteries has presented many obstacles to the optimum performance of this battery including oxidation of the liquid electrolyte and the  $\text{Li}_{\text{metal}}$  anode. In this paper a path towards the development of a  $\text{Li}_{\text{metal}}$ -air battery using a cubic garnet  $\text{Li}_7\text{La}_3\text{Zr}_2\text{O}_{12}$  (LLZ) solid-state ceramic electrolyte in a 3D architecture is described including initial cycling results of a  $\text{Li}_{\text{metal}}$ - $\text{O}_2$  battery using a recently developed mixed ionic and electronic (MIEC) LLZ in that 3D architecture. This 3D architecture with porous MIEC structures for the air cathode is essentially the same as a solid oxide fuel cell (SOFC) indicating the importance of leveraging SOFC technology in the development of solid-state  $\text{Li}_{\text{metal}}$ -air batteries.

**Statistical and Machine Learning-Based Durability-Testing Strategies for Energy Storage** [Stephen J. Harris](#) and Marcus M. Noack; Lawrence Berkeley National Laboratory, United States

There is considerable interest in developing new energy storage technologies for the electric grid, but economic viability will require that manufacturers provide warranties guaranteeing 15+ years of life. Although there are extensive efforts to make early predictions for the expected life of new storage technologies, we argue here that for the purposes of pricing warranties and valuing second-life potential—considerations that are crucial to whether the technologies can be commercialized—the full failure probability distribution, not just the expected life, is required. We use published battery cycle-life data to suggest efficient statistical and machine learning-based testing and analysis strategies that can rapidly estimate and also take advantage of the failure probability distribution. One approach is a Weibull analysis, which can (1) reduce the number of testing machine hours required for setting a warranty, (2) quickly determine whether a new technology is better than a baseline technology, and (3) estimate the maximum intensity of testing acceleration that does not change the failure mode. A second approach is driven by the idea that all measured data—such as capacity or energy as a function of time or cycle number—are valuable and generated by an underlying latent function. This analysis employs a Gaussian process to find the underlying latent function, together with its uncertainties, which can be used to calculate the failure distribution.

### 2:00 PM \*EN02.02.02

**Mechano-Electrochemical Phenomena in Solid-State Batteries** [Jeff Sakamoto](#); University of Michigan, United States

There is tremendous interest in making the next super battery, however Li ion technology continues to improve and has inertia in several commercial markets. Recent material breakthroughs in solid-electrolytes (SE) could enable a new class of non-combustible solid-state batteries delivering twice the energy density ( $>1,300$  Wh/L) compared to Li-ion. However, technological and manufacturing challenges remain, creating the impetus for fundamental and applied research.

This discussion will consist of fundamental aspects such as the mechano-electrochemical phenomena at solid interfaces as well as manufacturing challenges related to the integration of Li metal electrodes. The underlying physics that control the stability and kinetics of Li/SE interfaces are fundamentally different from interfaces in Li ion technology. Moreover, the mechano-electrochemical phenomena that occur during discharge and charge at the Li/SE interface are considerably different. For example, during charging at higher rates Li metal filaments can initiate at defects and propagate through relatively hard ceramics. During discharge, if the Li stripping rate is sufficiently high and the temperature is sufficiently low, voids form at the interface causing delamination at of the interface.

In another example, novel mechano-electrochemical phenomena are emerging when analyzing the formation of Li anodes in using the  $\text{Li}^0$ -free manufacturing approach. Using this approach for solid-state batteries, Li metal is interposed between a current collector and the SE. The mechanics at this interface will determine the feasibility of this approach by controlling the homogeneity of the *in situ* formed Li anode. While significant progress is advance the technological maturity of solid-state batteries, there remain fundamental questions regarding the physics at interfaces and whether or not they exhibit sufficient stability and kinetics that are relevant to EVs.

### 2:30 PM \*EN02.02.03

**All Solid State Batteries Based on Sodium Electrochemistry** [Y. Shirley Meng](#)<sup>1,2,3</sup>; <sup>1</sup>The University of Chicago, United States; <sup>2</sup>University of California, San Diego, United States; <sup>3</sup>Argonne National Laboratory, United States

Solid-state batteries have gained significant attention in recent years as they have the potential to be the leading next-generation energy storage devices, offering improved safety, higher energy densities, and longer cycle life. For grid-level energy storage, where having an accessible supply of battery materials and low cost per kilowatt-hour is important, sodium solid-state batteries are a promising technology. Within the past five years, halide-based solid electrolyte materials have become increasingly popular due to their superior oxidation stability, excellent deformability, and moderate ionic conductivities. As such, they are ideal catholytes for enabling high-voltage-coating-free cathode materials. However, to improve sluggish solid-state battery kinetics, it is

still necessary to enhance their ionic conductivity, especially for sodium systems, which calls for new approaches to materials design. I will talk about a novel approach towards synthesizing nanocrystalline and amorphous chlorides for use as *superionic* conductors in sodium all-solid-state batteries. Our concept is based on the tendency of chlorides to form these phases by adjusting the composition of the system, as demonstrated using the NaCl–YCl<sub>3</sub>–ZrCl<sub>4</sub> phase composition diagram as an example. We show that by controlling the molar amount of NaCl, electrolytes with low sodium concentrations and nanocrystalline or amorphous nature can be obtained. The structural amorphization, along with an increase in free volume, and preferential population of prismatic Na<sup>+</sup> local environments, leads to an exceptional ionic conductivity at room temperature. Our approach has the potential to be applied universally to other halide-based systems, leading to a shift in the design of future solid electrolytes for high-performance all-solid-state batteries operating at ambient temperatures.

### 3:00 PM BREAK

#### 3:30 PM \*EN02.02.04

**Solid State Electrolyte: Li-B-S System and Inorganic-Polymer Composite** [Yi Cui](#); Stanford University, United States

This presentation include two topic areas related to solid state electrolyte. First, I will present a new family of Li-B-S solid electrolyte, which was predicted using machine learning approach and recently experimentally validated to have a good ionic conductivity and expanded voltage stability window compared to other sulfide electrolytes. Second, I will our decade long study on inorganic-polymer composite electrolyte, which utilize the mechanical flexibility and processibility of polymer and the ionic conductivity enhancement and mechanical enhancement by inorganic materials.

#### 4:00 PM \*EN02.02.05

**Li-Metal Alloys and Their Unique Thermodynamic and Kinetic Properties** [Anton Van der Ven](#); University of California, Santa Barbara, United States

All-solid-state batteries will enable significant increases in energy density as they will allow the use of metallic Li anodes instead of graphite intercalation compounds. However, before metallic Li can be used as an anode, major metallurgical challenges must be overcome. Alloying of Li is a promising path with which to modify the intrinsic thermodynamic, mechanical and kinetic properties of metallic Li to enable the uniform deposition and stripping of Li at the anode/solid-electrolyte interface. Li forms a rich variety of intermetallic compounds when alloyed with different elements. Li diffusion within these intermetallic compounds can be complex due to the nature of anti-site defects and the relative mobilities between Li and the alloying elements. The unique thermodynamic and kinetic properties of different Li-metal alloys have important consequences for morphological evolution during Li deposition and stripping. In this talk, we will describe our first-principles statistical mechanics studies of non-dilute diffusion in Li-metal alloys such as Li-Sb, Li-Al, Li-Mg and Li-In and elucidate how strain and varying degrees of long and short-range order affect the kinetics of Li anodes.

#### 4:30 PM \*EN02.02.06

**Towards Automated Discovery of Inorganic Solids for Next-Generation Batteries** [Yan Eric Wang](#); Samsung Advanced Institute of Technology, United States

In this talk I will present our scientific discovery in identifying the descriptors of solid-state electrolytes especially the oxides, and our recent efforts in solid-state battery materials discovery with an automated lab with high-throughput computation and robotic synthesis.

**Database Driven Solid-State Electrolyte Material Search for Li and Na-Metal** [Gunyoung Heo](#)<sup>1</sup>, [Taehun Lee](#)<sup>2</sup> and [Aloysius Soon](#)<sup>1</sup>; <sup>1</sup>Yonsei University, Korea (the Republic of); <sup>2</sup>Princeton University, United States

Li and Na metal anode-based batteries are currently some of the most desirable technologies for high-energy density storage systems. However, internal dendrite formation is considered one of the biggest challenges in battery manufacturing. Suppressing the dendrite formation of Li or Na metal might be achievable with solid-state electrolytes as they have demonstrated a higher chemical stability in the presence of the anode. The development of a solid-state electrolyte for Li and Na metal anode involves several challenges, including the need for the material to have high ionic conductivity, good mechanical properties, and good compatibility with the anode material. To address these challenges, there is a need for a systematic approach to discover new solid-state electrolytes that are specifically tailored for Li or Na metal anodes. The objective of this work is to screen out optimal and compatible solid-state electrolytes for both Li and Na metal batteries from the Materials Project (MP) database [1]. In total, five criteria were considered in the screening process [2] – the formation energy, energy above hull, band gap, reaction energy with anode material and mechanical property – which are all available within the MP database. After screening out the potential candidates, we assessed their dynamic/transport properties. By performing molecular dynamics simulations using the universal graph deep learning interatomic potential M3Gnet [3], the ionic diffusivity for all solid-state electrolyte candidates was analyzed. Through this work, we provide the Pareto front for the most optimal solid-state electrolytes for both Li and Na metal anode batteries.

#### 8:00 PM EN02.03.02

**Elucidating Differences in Surface and Bulk Properties of Solid-State Electrolytes** [Zeeshan Ahmad](#); Texas Tech University, United States

Solid-state batteries with metal anodes are now widely recognized as the next frontier of battery research to satisfy the stringent requirements of safety, energy and power density for transportation and aviation applications. There is still a plethora of interfacial and chemomechanical challenges to be solved before these batteries achieve mass market adoption. These challenges include interface stability and dendrite growth, limits on stripping and plating current densities, and device integration [1]. These challenges warrant an investigation of the buried surfaces and interfaces present in solid-state batteries

in the presence of electric fields encountered during battery operation. In this talk, I will discuss how the properties of surfaces and interfaces of solid-state batteries differ from the bulk using large scale simulations of defects based on first-principles and machine learning force fields. Our results confirm a high degree of atomic disorder at the interface, which effectively modulates the defect thermodynamics. Further, I will show how the mechanical stress at the interface affects these defects. These results have broad implications on ionic transport, charge transfer and rate capability, and dendrite growth in solid-state batteries through control of the properties of grain boundaries and interfaces. This work demonstrates the need for continuum models to be refined to account for the drastically different properties at the surfaces and interfaces.

#### 8:00 PM EN02.03.03

**Investigating Different Solvents for Liquid Phase Synthesis Routes of Lithium Indium Chloride Solid Electrolyte for Solid-State Batteries** Jacob Otabil Bonsu and Dipan Kundu; The University of New South Wales Sydney, Australia

Solid-state batteries (SSBs) have emerged as a promising technology that has the potential to revolutionise the area of energy storage by providing more safety, better energy density, and longer cycle life when compared to current lithium-ion batteries. Polymer, oxide, and sulfide-based solid-state electrolytes (SSEs) have been widely researched to aid in the development of solid-state batteries. However, these SSEs' drawbacks, such as high-temperature sintering of oxides, air instability of sulphides, and small electrochemical windows of polymer electrolytes, severely limit their practical implementation. As a result, it is necessary to design SSEs with strong ionic conductivity, good air stability, a wide electrochemical window, great electrode interface stability, and low-cost mass manufacturing. Because of their strong ionic conductivity and compatibility with high-voltage electrodes, halide electrolytes are emerging stars among inorganic solid-state electrolytes. However, as compared to liquid-mediated approaches, their traditional synthesis processes, such as ball-milling and annealing, are often more energy-intensive and time-consuming. Furthermore, the only approach in an aqueous solution is not ideal due to the negative effect of water traces on battery performance. We provide three comparison alternatives (Tetrahydrofuran, Acetonitrile, Ethanol, and Water) for the halide  $\text{Li}^+$  superionic conductor,  $\text{Li}_3\text{InCl}_6$ , with good ionic conductivities of 4.02, 3.67, 3.07, and 2.72 MilliSiemens per centimetre at ambient temperature respectively. In addition, their ionic conductivities can be recovered after dissolution in their respective solvents. Combined with an NMC 622 cathode, the solid-state Li batteries show good cycling stability.

#### 8:00 PM EN02.03.04

**Effect of Lithium Precursor on the Crystal Structure and Ionic Conductivity of  $\text{Li}_7\text{La}_3\text{Zr}_2\text{O}_{12}$  Oxide Electrolyte** Lee Hyeju<sup>1</sup>, So Hyun Park<sup>1</sup>, Mingyu Lee<sup>1</sup>, Sojeong Roh<sup>1</sup>, Dongjoo Kim<sup>2</sup> and Young Soo Yoon<sup>1</sup>; <sup>1</sup>Gachon University, Korea (the Republic of); <sup>2</sup>Auburn University, United States

The garnet-structured solid electrolyte  $\text{Li}_7\text{La}_3\text{Zr}_2\text{O}_{12}$  (LLZO) has attracted attention as a solid electrolyte for all-solid-state batteries due to its wide electrochemical window and high ionic conductivity. However, the formation of impurity phases and tetragonal LLZO during synthesis can rapidly reduce lithium-ion conductivity, and the low stability in air and water can lead to lithium loss. The effect of lithium sources including  $\text{Li}_2\text{CO}_3$ ,  $\text{LiOH}$  and  $\text{LiNO}_3$  on the crystal structure, microstructure, and ionic conductivity of LLZO was investigated. X-ray diffraction (XRD) analysis was performed to confirm the crystallization and phase formation of the synthesized LLZO and scanning electron microscopy-energy dispersive X-ray spectroscopy (SEM-EDS) was used to analyze the microstructure and chemical composition. Electrochemical impedance spectroscopy (EIS) was also used to confirm the ionic conductivity. As a result, LLZO prepared with  $\text{LiOH}$  as the source was confirmed to be cubic without impurities or intermediate phases, compared to solid electrolytes prepared with  $\text{Li}_2\text{CO}_3$  and  $\text{LiNO}_3$ . In addition, a uniform particle size and distribution of less than  $2 \mu\text{m}$  and an ionic conductivity of  $1.311 \times 10^{-4} \text{ S cm}^{-1}$  at room temperature were confirmed. These results suggest that the choice of lithium source can significantly affect the properties of LLZO, and that  $\text{LiOH}$  is a promising lithium source for the preparation of high-performance LLZO solid electrolytes. In future studies, the effect of lithium sources on the properties of LLZO should be investigated in more detail and new methods should be developed to fabricate high-performance LLZO solid electrolytes.

#### 8:00 PM EN02.03.05

**A Highly Conductive and Stable Ionic Liquid Gel Electrolyte for Calcium Metal Batteries** Xinlu Wang; Syracuse University, United States

Calcium batteries are promising alternatives to lithium batteries due to their high energy density, comparable reduction potential, and mineral abundance. Calcium is the fifth most abundant metal in the Earth's crust (4.1%), surpassing Na, K, Mg, and Li, and ranks third after aluminum and iron. Calcium batteries can achieve volumetric capacities comparable to incumbent Li-ion and emerging Li metal systems. Additionally, calcium-ion batteries generally exhibit improved safety characteristics compared to lithium-ion batteries, being less susceptible to thermal runaway and reducing the risk of overheating, combustion, or explosion.

However, to meet practical demands in high-performance applications, suitable electrolytes must be developed. Polymer gel electrolytes are emerging as a promising system for calcium metal batteries. Polymer gel electrolytes consist of polymer hosts swollen in liquid electrolyte and offer a combination of mechanical and electrochemical robustness from the polymer host, high ion conductivity and electrochemical reactivity from the liquid electrolytes, excellent wetting contact with the electrodes, more uniform electrode reactions (specifically, metal deposition), and have proven attractive for Li, Na, K, Zn, and Mg metal systems. Moreover, they provide a decent level of mitigation against potential leakage, electrolyte volatility, and flammability, thus offering the desired safety benefits similar to quasi-solid-state batteries.

In this study, polymer gel electrolytes (GPEs) for calcium-ion conduction were synthesized and characterized by photo-cross-linking poly(ethylene glycol) diacrylate (PEGDA) in the presence of calcium salt  $\text{Ca}(\text{BF}_4)_2$  and an ionic liquid EMIM triflate. The ionic conductivity of the GPEs was observed to increase with salt concentration and temperature, reaching a maximum conductivity of 2.16 S/cm. The Ca stripping/plating behavior was analyzed on a Ca substrate with a current density of  $0.2 \text{ mA cm}^{-2}$  and a total discharge areal capacity of  $0.4 \text{ mA h cm}^{-2}$ . The overpotential at the first cycle was 0.4 mV and increased with subsequent cycles. Furthermore, the PEGDA-based GPEs exhibited an electrochemical stability window of 4 volts and a thermal stability window exceeding 200 degrees Celsius.

Overall, these results demonstrate the potential of PEGDA-based GPEs as high-performance electrolytes for calcium batteries and provide valuable insights into the development of advanced GPEs for next-generation energy storage devices.

#### 8:00 PM EN02.03.06

**Improving Lithium-Ion Conductivity by Co-Doping Al/Ta to  $\text{Li}_7\text{La}_3\text{Zr}_2\text{O}_{12}$  using Molten Salt Synthesis Method** So Hyun Park<sup>1</sup>, Lee Hyeju<sup>1</sup>, Sojeong Roh<sup>1</sup>, Ji-Hyeok Choi<sup>1</sup>, Dongjoo Kim<sup>2</sup> and Young Soo Yoon<sup>1</sup>; <sup>1</sup>Gachon University, Korea (the Republic of); <sup>2</sup>Auburn University, United States

Solid state batteries are attracting attention as promising materials for next-generation energy storage systems due to their high energy density and safety. The sulfide solid electrolyte has excellent lithium-ion conductivity, but sulfur electrolyte easily reacts with moisture in the air to release sulfide. On the

other hand, the oxide solid electrolyte does not exhibit the above toxic gas when decomposed. This research selected  $\text{Li}_7\text{La}_3\text{Zr}_2\text{O}_{12}$  (LLZO), a garnet-type cubic phase, in light of chemical stability and introduced the molten salt synthesis (MSS) method and doped Al/Ta co-doped to improve lithium-ion conductivity. In particular, this method can overcome the disadvantage of MSS that forms an impurity phase during multi-component synthesis. In addition, using molten salt-based LiCl-KCl can form the cubic phase at a lower temperature in a shorter time than the traditional solid phase synthesis method. Al/Ta co-doping may induce more vacancies occupied by Li ions than single doping. In particular, Al single doping can inhibit 96h site substitution that interferes with lithium ion conductivity, and Al/Ta co-doping induces displacement of Li vacancy to 24d site, extending the path of  $\text{Li}^+$ . Such a mechanism increases ion conductivity because the atoms of 24d having a small Li vacancy are located close to each other, thereby shortening the movement path of  $\text{Li}^+$ . Preparation of pure cubic LLZO phase was performed in the range of 900°C to 1000°C with a calcination process of less than 4 hours. The synthesized powder was pelletized and subjected to a heat treatment process to increase the density at 900°C for 6 hours. For the measurement of  $\text{Li}^+$  conductivity, electrochemical impedance spectroscopy (EIS) was used in the frequency range of 10 Hz~1 MHz. As a result, small particles of 0.8~1.3  $\mu\text{m}$  were obtained compared to the single-doped LLZO by a similar method, and the ion conductivity was  $2.398 \times 10^{-4} \text{ S cm}^{-1}$ , and a small amount of Al/Ta doping was sufficient to impart stability to the garnet structure of LLZO. In conclusion, the Al/Ta co-doped MSS method suggested that the LiCl-KCl molten salt serves to remove impurities, which is advantageous in synthesizing high-purity materials.

#### 8:00 PM EN02.03.07

**LIPON Layer Effect for Reduction of Interfacial Resistance of LLZO/Li for All-Solid-State Battery** Mingyu Lee, Sojeong Roh, So Hyun Park, Ha Eun Kang, Lee Hyeju and Young Soo Yoon; Gachon University, Korea (the Republic of)

Cubic garnet-type solid electrolytes for all-solid-state batteries (ASSBs) have attracted attention due to their stability over a wide electrochemical window and high ionic conductivity. However, current challenges for garnet-type solid electrolytes include overcoming poor wettability and high interfacial resistance with lithium metal anodes. When a lithium metal anode contacts an oxide solid electrolyte, a passivation layer of  $\text{Li}_2\text{CO}_3$  forms on the surface of the solid electrolyte, which can lead to increased resistance. Additionally, non-uniform  $\text{Li}^+$  intercalation/extraction can lead to increased resistance and electrochemical instability at the solid electrolyte/anode interface. To improve contact resistance, interfacial modification methods have been introduced. One such method is to coat the surface of the solid electrolyte with a ceramic material that is highly reactive with lithium. This can stabilize the interfacial chemistry and improve lithium wettability and charge transport. In this study, LIPON coating was deposited on the surface of LLZO pellets using an RF sputtering process. The interface between the coating layer and the LLZO pellet was analyzed using transmission electron microscopy-energy dispersive spectroscopy (TEM-EDS) to confirm the X-ray photoelectron spectroscopy (XPS) depth profile spectrum. Molten Li contact angle measurements were also performed to confirm wettability with metallic lithium. The results showed that the LIPON coating forms a Li-LiPON layer when in contact with molten Li and exhibits a low contact angle of less than 90°. This indicates that the LIPON coating can improve lithium wettability and reduce interfacial resistance. These results suggest that the chemical properties of the lithium electrode and the properties of the interface play an important role in the interfacial resistance and lithium wettability, compared to the microstructure of the LLZO solid electrolyte. This discovery will have implications for the design of LLZO/Li interfaces for ASSBs containing LLZO as the electrolyte.

**Ultrathin Sulfide-Based Composite Electrolyte Membrane for Solid-State Sodium Metal Batteries** Xiaolin Guo, Yang Li and Hui Wang; University of Louisville, United States

Rechargeable solid-state sodium batteries that utilize solid electrolytes (SEs) have garnered considerable attentions due to their features of intrinsic non-flammability and abundant sodium resources. Among different types of sulfide-type SEs,  $\text{Na}_3\text{SbS}_4$ -family conductors show advantages of high ionic conductivity at room temperature and densification through cold-pressing. However, one of their most significant challenges is related to the electrochemical stability towards Na metal. Solid composite electrolytes (SCEs) with ceramic particles dispersing in a polymer matrix, provide a viable approach to address this challenge. In this work, we report an ultra-thin, flexible and stable SCE through embedding micro-sized  $\text{Na}_3\text{SbS}_3\text{Se}$  (NSSE) particles in polymer electrolyte (PVDF-HFP). The prepared SCE membranes exhibit an adjustable thickness, and impressive ionic conductivity at room temperature as well as enhanced interfacial stability in Na symmetric cells. Moreover, the assembled Na|SCE|TiS<sub>2</sub> solid-state batteries demonstrate stable cycling and great rate performance. This work promotes new composite SEs, and their application in solid-state Na metal batteries.

For the past decade, lithium-ion batteries (LIBs) have dominated the electric vehicle sector due to their high energy density and cycle life. Currently, the purpose of LIBs for electric vehicles is to provide and store energy. A structural battery is defined as being multifunctional; it is a load bearing system as well as an electrochemical cell [1]. The electrolyte system is the key enabler for a multifunctional structural battery as it must possess sufficient ionic conductivity ( $\sim 10^{-4} \text{ S/cm}$ ) and mechanical strength (Young's modulus  $\sim 2\text{-}3 \text{ GPa}$ ) simultaneously.

In the present work, we study the development of a dual-phase structural battery electrolyte to optimize ionic conductivity and mechanical performance simultaneously. An epoxy resin-based system is chosen due to its high mechanical strength and ability for in situ polymerization. [3] Diglycidyl ether of Bisphenol A (DGEBA) accounts for the epoxy to provide hard segments in the matrix and is cured by an amine compound (Jeffamine T-403). A liquid electrolyte is added to the system for improving the conductivity enhancement without compromising its mechanical strength substantially. Three liquid components consisting of lithium salt and solvents are considered here -lithium bis(trifluoromethanesulfonyl)imide (LiTFSI) dissolved in a solution of ethylene carbonate (EC) and dimethyl methyl phosphonate (DMMP), LiTFSI dissolved in Tetraethylene glycol dimethyl ether (Tetra glyme) and LiTFSI dissolved in 1-Ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide (EMIM-TFSI). Ionic conductivity of the electrolyte systems as a function of temperature is measured utilizing electrochemical impedance spectroscopy. Uniaxial load tests are performed to evaluate the mechanical properties (e.g., Young's modulus, Yield strength) of the epoxy-based electrolyte systems with and without the addition of the ion conducting liquids. Comparative data on the three epoxy-based systems containing varying amounts of liquid components will be presented.

**Li<sup>+</sup> Conduction Mechanism in Anion-Substituted Halide Solid Electrolytes for All-Solid-State Batteries** Yeji Choi<sup>1</sup>, Hiram Kwak<sup>1</sup>, Daseul Han<sup>2</sup>, Jae-Seung Kim<sup>3</sup>, Kyung-wan Nam<sup>2</sup>, Dong-Hwa Seo<sup>3</sup> and Yoon Seok Jung<sup>1</sup>; <sup>1</sup>Yonsei University, Korea (the Republic of); <sup>2</sup>Dongguk University, Korea (the Republic of); <sup>3</sup>Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The recent emergence of halide superionic conductors, such as Li<sub>3</sub>YCl<sub>6</sub>, as solid electrolyte (SE) materials for all-solid-state batteries (ASSBs) is considered a game changer. These halide SEs offer a combination of advantageous properties that include excellent (electro)chemical oxidative stability, high Li<sup>+</sup> conductivity, and mechanical deformability. This unique combination of properties position halide SEs as promising candidates for the development of next-generation ASSBs, surpassing the limitations of sulfide or oxide SEs.

However, despite these benefits, the practical deployment of these materials has been hindered by the high cost associated with the use of expensive or rare transition metals. To overcome this, a cost-effective and abundant Zr-based compound Li<sub>2</sub>ZrCl<sub>6</sub> has emerged. Yet, there remains a need to improve Li<sup>+</sup> conductivity further and develop a more comprehensive understanding of the underlying ion conduction mechanisms.

This presentation delves into the impact of anion substitution on changes in the local structure and ion conductivity of halide SE, offering an in-depth explanation of the ion conductivity mechanism. Particularly, we present noteworthy findings that demonstrate nearly twofold enhancements in ion conductivity upon anion-substitution of halide superionic conductors. Furthermore, we also investigate the feasibility of these materials in ASSB cells.

**Surficial Degradation of Jet-Milled Li<sub>6</sub>PS<sub>5</sub>Cl under Mild Temperature Heat-Treatment** Kern-Ho Park, Yo-Seob Kim, KyungSu Kim, Woosuk Cho and Goojin Jeong; Korea Electronics Technology Institute, Korea (the Republic of)

All-solid-state batteries using sulfide solid electrolytes are considered a promising next-generation energy storage system. Especially, argyrodite-type Li<sub>6</sub>PS<sub>5</sub>Cl (LPSCI) is in spotlight for their good ionic conductivity and malleability. In electrode level, achieving efficient Li<sup>+</sup> pathway with the maximized active material proportion and electrode mass loading is crucial for the high energy density. Thus, solid electrolytes with a small particle size is highly sought for. Here, we demonstrated a spiral jet mill process for refining LPSCI particle size, reducing the mean particle size ( $D_{50}$ ) of LPSCI 39.9  $\mu\text{m}$  to 1.9  $\mu\text{m}$  where the ionic conductivity was decreased from 2.0  $\text{mS cm}^{-1}$  to 0.23  $\text{mS cm}^{-1}$ . The post-annealing in a mild temperature ( $T < 250$  °C) led to the even more decreased ionic conductivity. Although the ionic conductivity was recovered when  $T > 300$  °C, these high temperature heat-treatment resulted in severe particle agglomeration. Spectroscopic study suggested that the particle surfaces were damaged during the jet-mill process and the irreversible sulfur losses occurred during the mild temperature annealing.

**8:00 PM EN02.03.14**

**New Amorphous Quaternary Sulfide Compounds as Solid Electrolyte for All-Solid-State Li-Ion Batteries** Yuna Kim and Sung-Jin Kim; Ewha Womans University, Korea (the Republic of)

In recent years, interest in all-solid-state lithium secondary batteries with high energy density and output performance has increased due to the possibility of mitigating safety issues related to liquid electrolytes. However, the development of a suitable solid electrolyte (SE) remains a major challenge in advancing all-solid-state battery technology. Sulfide-based compounds are advantageous as solid-state electrolytes due to their high ionic conductivity and efficient transport of lithium ions, which can be attributed to their high polarizability and low electronegativity. In this work, an amorphous new sulfide compound, LiSbGeS<sub>4</sub>, was synthesized as a Li-ion conductor. The amorphous characteristics of LiSbGeS<sub>4</sub> were investigated using PXRD, XAS, XRS, Raman spectroscopy, and thermal analysis. XPS and Raman spectroscopy provided information about into the local structure and chemical bonding of LiSbGeS<sub>4</sub>, indicating the presence of metal-metal bonds and metal-S polyhedral units. LiSbGeS<sub>4</sub> was modified to have a high ionic conductivity through anion aliovalent substitution of the Cl<sup>-</sup> on S<sup>2-</sup> sites while maintaining amorphous phase. LiSbGe<sub>0.8625</sub>S<sub>3.45</sub>Cl<sub>0.55</sub> exhibited a significantly higher lithium-ion conductivity, reaching 7.26  $\text{mS/cm}$ , which is approximately 2400 times higher than that of pristine LiSbGeS<sub>4</sub>. This study presents new amorphous sulfide compounds with enhanced Li-ion conductivity as a promising solid electrolyte for Li-ion batteries.

**Lithium Containing Fluorides and Oxyfluorides as Solid Electrolytes** Michael J. Brady, Jessica Andrews and Brent C. Melot; University of Southern California, United States

Research on all solid-state batteries has increased as lithium-ion based chemistries approach theoretical capacities with conventional graphite anodes. Aside from the safety-related improvements that come with the removal of traditional liquid electrolytes, all solid-state batteries offer advantages related to cost, operating conditions, and energy density. Most of the materials that show high lithium-ion conductivity are oxide- or sulfide-based and have vastly different diffusion conditions, operating windows, and stabilities against lithium metal. As a result, exploring other chemistries—as has been done recently with halides in the argyrodite structure—is paramount to the understanding and improving the properties of solid electrolytes.

We chose to explore fluoride and oxyfluoride based compositions with the motivation that fluoride substitution should widen the stability window as well as provide a passivating layer of LiF in the SEI when used against lithium metal. This will work to combat the deposition of lithium metal that can occur along the grain boundaries in oxide based solid electrolytes leading to dendrite formation and cell failure. Exploring compounds in this phase space is

accompanied by many challenges associated with synthetic methods as well as sample preparation and instrumental setup for various characterization methods. Conventional solid-state synthetic methods for oxides and sulfides are not applicable to fluorides due to their volatility and reactivity with several common vessels. Additionally, fluoride materials tend to be less stable at elevated temperatures which makes sintering of samples to raise the density challenging.

We will present our work on the examination of new lithium containing fluoride and oxyfluoride materials for use as solid electrolytes beginning with a gallium-based fluoride garnet. We have developed new synthetic methods for fluoride-based phases using custom high-temperature and high-pressure autoclaves. Cold-isostatic pressing was used to produce pellets of near theoretical density without the need for high-temperature sintering. We examine the effects of substitution of different redox-inactive metal centers through X-ray diffraction and electrochemical impedance spectroscopy. Additionally, through computational methods we investigate the activation energy of lithium ion hopping in these phases and compare these values to those extracted from Arrhenius plots derived from conductivity measurements.

**High-Voltage Anode-Free Sodium Metal Batteries with Polymer Electrolyte Membranes** Yu-Hsien Wu, Haocheng Yuan, Shundong Guan and Liangliang Li; Tsinghua University, China

With the growing demands of electronic vehicles, portable electronics and large-scale energy storage, lithium metal batteries have been intensively studied due to the superior energy density provided by the lithium anode. However, the scarcity of lithium reserve significantly increases the cost of lithium metal batteries. Among alternatives, high-voltage anode-free sodium (Na) metal batteries (AFSMBs) are attracting enormous interest since they can attain high energy density in a low-cost way. One challenge that hinders the development of AFSMBs is that the highly reactive Na metal deposited on the current collector reacts with liquid electrolyte easily, especially when carbonate electrolytes are employed. As a result, the growth of Na dendrites and the formation of "dead Na" are exacerbated and thus shorten the lifespan of AFSMBs. Herein, we proposed some poly(vinylidene fluoride)-based polymer electrolyte membranes (PEMs) for stable and dendrite-free AFSMBs in carbonate electrolytes. The electrochemical properties of the PEMs are optimized by tuning the solvent, Na salt, and polymer matrix. The optimal PEMs have the merits of high ionic conductivity ( $>5 \times 10^{-4} \text{ S cm}^{-1}$ ), great electrochemical stability with Na (the Na|PEM|Na cell runs steadily for over 4,000 hours at a capacity of  $0.1 \text{ mAh cm}^{-2}$  with a low voltage hysteresis), good electrolyte resistance and decent mechanical strength; therefore, when they are applied on the current collectors in AFSMBs, Na metal can be uniformly deposited on the current collectors and the deposited Na metal is effectively separated from carbonate-based electrolyte, leading to the reduction of parasitic reactions and the elongation of the cycle life of the batteries. With the PEMs, high-voltage AFSMBs with a 4.0V-class layered oxide cathode and carbonate electrolyte are assembled and tested. These batteries can run for  $\sim 60$  cycles due to the stabilized interface between deposited Na and the corrosive carbonate electrolyte. In contrast, batteries without a PEM fail quickly in just a few cycles due to the poor Na deposition and much side reactions. In short, with the support from the chemically/thermally stable and mechanically strong PEMs, it is promising to fabricate long-cycle-life, high-energy-density, and low-cost AFSMBs.

**Electrochemical Properties of Porous Nickel-Based Alloy Foam as Anodes in Lithium Metal Batteries** Jae-Seong Yeo, Hye-Ryeon Yu, Sang-Hyeon Ha, Tae-Young Ahn, Eunji Yoo and Yusong Choi; Agency for Defense Development, Korea (the Republic of)

Traditional graphite-anode-based lithium (Li)-ion batteries are challenged by the ever-increasing demand of today's energy storage and power applications, especially for smart grid and electric vehicles because they have almost reached their theoretical specific energy limits. Among varieties of alternative anode materials, Li metal has been widely recognized as an ultimate anode material for high-energy rechargeable batteries due to its ultrahigh theoretical specific capacity ( $3860 \text{ mAh g}^{-1}$ ) and very low redox potential ( $-3.04 \text{ V}$  vs. standard hydrogen electrode). To date, considerable efforts have been made to developing ultra-high energy density Li metal-anode-based batteries, such as Li-S and Li-air batteries. However, uncontrollable dendritic growth and high reactivity of Li metal anodes result in poor cycle performance and severe safety concerns, hindering the practical application of Li metal anodes in rechargeable Li metal batteries. To solve these issues, various approaches have been developed to suppress Li dendrite formation, including artificial SEI layer construction, additives of electrolyte to improve the uniformity of Li-ion deposition, utilization of high-modulus polymer or ceramic solid-state electrolytes, separator modification, current collector modification, and so on. Particularly, current collectors play a critical role in facilitating uniform Li nucleation and deposition. Fabricating three-dimensional current collectors is emerging as an effective strategy for designing dendrite-free Li anodes. Recently, Y. Choi et al. have reported an oxidation method for achieving an ultra-lithiophilic NiO layer on the surface of a three-dimensional nickel (Ni)-foam, resulting in stable Li plating and stripping in an anode prepared using Li-infused oxidized Ni-foam. In this study, Ni-based alloy, NiCrAl, with porous three-dimensional or two-dimensional structures was used as an anode in Li metal batteries. NiCrAl showed higher mechanical properties than pure Ni in the molten Li, anticipating in facile electrode stacking and cell assembly of NiCrAl-foam anode compared to Ni-foam anode. Oxidized NiCrAl-foam was prepared by heat treatment at  $600^\circ\text{C}$  for 10 min in ambient air. Li was introduced into the oxidized NiCrAl-foam by dipping into molten Li or electroplating. We present the electrochemical properties of oxidized NiCrAl-foam anodes with different foam thickness (0.2–1.0 mm) in the Li metal batteries.

#### 8:00 PM EN02.03.20

**Electrochemical Characteristics of Various Lithium-Based Anodes for Thermal Batteries** Hye-Ryeon Yu, Jae-Seong Yeo, Chae-Nam Im, Sang-Hyeon Ha, Jaemin Lee and Yusong Choi; Agency for Defense Development, Korea (the Republic of)

The thermal battery is primary battery used for special fields such as defense due to its high power and high reliability characteristics. As the demand for thermal battery increases, development of various thermal battery electrodes having high energy density and power density is required. Therefore, as interest in high performance anodes increases, attempts are being made on various anodes for thermal batteries. In the case of a conventional thermal battery anode (Li-Si alloy), it has difficulty in large-area because it is manufactured through a powder pressing method. For this reason, many studies on development of liquid lithium-based anodes have recently been conducted. In particular, the Li-Fe (LiFe) anodes manufactured by mixing molten lithium and iron powder, a research has been carried out significantly and some commercialized. In addition, research on lithium impregnated metal foam anode (LIMFA) that are used by impregnating molten lithium in metal foam has been actively conducted recently. The research on the manufacture and performance of lithium boron (LiB) anodes for lightening the weight of thermal battery is also being studied. In this paper, various lithium-based thermal battery anodes were fabricated and applied to improve thermal battery performance. The prepared anodes were fabricated single cells applying  $\text{FeS}_2$  cathode, and electrolyte. The single cell was discharged at  $500^\circ\text{C}$  to evaluate electrochemical properties, and performance as an anode of a thermal battery compared.

#### 8:00 PM EN02.03.21

**Studying *In-Situ* Passivating Interphase Between Halide Solid-Electrolyte and Li-Based Anode in All-Solid-State Batteries** SeYoung Kim<sup>1,2</sup>, Seong-Min Bak<sup>3,4</sup>, KyuJung Jun<sup>5,2</sup> and Guoying Chen<sup>2</sup>; <sup>1</sup>Korea Institute of Science and Technology, Korea (the Republic of); <sup>2</sup>Lawrence Berkeley National Laboratory, United States; <sup>3</sup>Brookhaven National Laboratory, United States; <sup>4</sup>Yonsei University, Korea (the Republic of); <sup>5</sup>University of California,

Berkeley, United States

All-solid-state batteries (ASSBs) have been highlighted as a promising alternative for future energy storage systems due to their high thermal stability and high energy density compared to lithium-ion batteries using liquid electrolytes. Among many types of solid electrolytes, halide solid electrolytes (SE) with high oxidative stability have been intensively proven as a feasible SE that enables cycling 4 V class cathode materials. However, undesirable thermodynamic instability of halide SEs to Li metal anode hinders achieving high energy density ASSBs for practical use. To this end, lithium-indium (Li-In) alloy has been extensively employed due to their (electro)chemical stability to halide SEs that enables stable cycling of ASSB using halide SEs. Although the decomposition of halide SEs and its reactants in direct contact with Li metal has been experimentally and theoretically studied, no in-depth investigations on interphase evolution and charge transfer mechanism at the LYC SE and Li-In anode interphase have been conducted. In this work, we report the evolution of the interphase layer between In metal anode and halide solid electrolyte,  $\text{Li}_3\text{YCl}_6$  (LYC), that enables stable long-term cycling of ASSB coupled with crack-free single-crystal (SC)  $\text{LiNi}_{0.8}\text{Co}_{0.1}\text{Mn}_{0.1}\text{O}_2$  (NMC811) cathode active material. Through the combination of high-resolution microscale x-ray based analysis on a cross-section of the ASSBs, we demonstrate the crosstalk between LYC and In anode that results in the evolution of interphase layer consists of  $\text{InCl}_x$ ,  $\text{YCl}_3$ ,  $\text{LiCl}$ , and In diffused LYC which suppressed dendritic growth of Li-In alloy over the ASSB cycling.

#### 8:00 PM EN02.03.23

**Rare-Earth Fluoridesulfide Compounds with Fluoride Ion Conducting Layers** Shintaro Tachibana<sup>1</sup>, Chengchao Zhong<sup>1</sup>, Kazuto Ide<sup>2</sup>, Hisatsugu Yamasaki<sup>2</sup>, Takeshi Tojigamori<sup>2</sup>, Hidenori Miki<sup>2</sup>, Takashi Saito<sup>3</sup>, Takashi Kamiyama<sup>3</sup>, Keiji Shimoda<sup>1</sup> and Yuki Orikasa<sup>1</sup>; <sup>1</sup>Ritsumeikan University, Japan; <sup>2</sup>Toyota Motor Corporation, Japan; <sup>3</sup>High Energy Accelerator Research Organization(KEK), Japan

All-solid-state fluoride-ion batteries (FIBs) are highly attracted attention due to high theoretical energy density and high safety compared with those of conventional lithium-ion batteries(LIBs)[1]. However, it is far from practical use because there is no solid electrolyte which exhibits high ionic conductivity and wide electrochemical potential window at room temperature like lithium-ion conductor. Most of the previously reported fluoride-ion conductors have been limited to the single-anion fluorides with fluorite-type, tysonite-type, and perovskite-type structures [2]. In the field of material sciences, mixed-anion compounds with more than more anions have recently attracted attention. Compared with single-anion compounds such as oxides and fluorides, mixed-anion compounds have the possibility to exhibit innovative functions due to their specific crystal and coordination structure[3]. In mixed anion compounds, combinations of anion species with different ionic radius result in anion-order structures[4]. Fluorosulfides, which contains  $\text{S}^{2-}$  and  $\text{F}^-$  with largely different ionic radii, are ideal for creating anion-ordered structures suitable for fluoride-ion conduction. To our best knowledge, there is few reports on the fluoride-ion conductor materials containing mixed-anion compounds. In this study, we synthesized rare-earth fluorosulfides compounds by solid-state reaction under vacuum[5]. In the crystal structure of these fluorosulfides, the fluoride- and sulfide-ion layers are present across cation layers. The separation of fluoride and sulfide ions is attributed to the difference anionic size. The presence of multiple anions results in the formation of an anion-ordering two-dimensional crystal structure with fluoride ion conducting layers, which cannot be realized for single-anion compounds. The material development of fluoride ion conductors using fluorosulfide compounds is expected to increase crystal structure variations with fluoride-ion conduction pathways.

**Pumice Additives in Iron Oxide for Solid-State Lithium-Ion Batteries** Ping-Huan Tsai, Tri-Rung Yew and Kuo-Tzu Hao; Tsinghua University, Taiwan

Solid-state lithium-ion batteries are indispensable for the next-generation energy storage device because of their safety and lightweight. High-capacity, low-cost, earth-abundance, and low flammability make iron oxides a promising active material for solid-state batteries. However, one of the shortages of both iron oxide actives and solid-state batteries is poor ionic conductivity, causing the short cycle life of batteries.

Pumice, a natural silicon oxide-based porous material formed through volcanic activities, is selected as an additive candidate in iron oxides for solid-state battery applications. Pumice is expected to act as an ion transport path that can effectively reduce the diffusion path length between actives, resulting in lower impedance and overpotential. Therefore, it will lead to a higher rate-capability, shorter reaction time, and enhanced retention. Besides, pumice is earth-abundant and environmentally sustainable. Utilizing pumice as an additive offers a simple method to recycle flooding volcanic pyroclastic flow.

The composition of iron oxide actives with pumice additives will be optimized. The actives will be mixed with carbon black (super P), carboxymethyl cellulose (CMC), and styrene-butadiene rubber (SBR) to form a water-based slurry. The slurry will be further coated on a copper foil through the doctor-blade coating process. The fabricated electrode will be dried in a vacuum oven and then assembled into batteries. The pumice morphology and structure will be characterized by field-emission scanning electron microscopy (FE-SEM) and energy-dispersive X-ray spectrometry (EDX), respectively. Galvanostatic charge-discharge (GCD) and electrochemical impedance spectroscopy (EIS) analyses will be applied to analyze the charge/discharge cycle life, Coulombic efficiency, and impedance resulting from the addition of pumices. These analyses will be used to investigate the mechanism of pumice additives in iron oxides.

This work will offer insights into using pumice additives to enhance the retention of solid-state batteries for future applications.

#### 8:00 PM EN02.03.25

**Titanium Oxide-Based Additives in Iron Oxides as Electrode Materials for Solid-State Batteries I** Han Lee, Jia-Chien Ma and Tri-Rung Yew; National Tsing Hua University, Taiwan

Clean energy technologies, such as electric vehicles (EVs) and stationary energy storage systems (ESSs), have become flourishing along with the increasing awareness of environmental protection in recent years. Rechargeable solid-state batteries (SSBs) exhibit the advantages of light weight, high energy density, good rate-capability, and safety, making them a vital choice for the applications of consumer electronics, EVs, and ESSs. However, poor structural stability and high cost impede the development of SSB's applications.

Iron oxides exhibit the merits of high theoretical capacity, earth-abundance, lower carbon emission, and non-toxicity, suitable for being active materials in SSBs. However, iron oxides show the drawbacks of low electrical and Li-ionic conductivities, high volume expansion and easy to crack, and excess solid-electrolyte interphase (SEI) layers, during charge/discharge reactions. In this work, titanium oxide-based additives will be applied to iron oxides to improve structural stability and ion conductivity. It is expected that the additives can function as stabilizers to improve the structural stability of iron oxides, which can improve cycle stability and rate capability.

The composition of titanium oxide-based additives in iron oxides will be optimized. The additives powders will be mixed with carbon black (super P), carboxymethyl cellulose (CMC), and styrene-butadiene rubber (SBR) to form an aqueous-based slurry. Following that, the slurry will be coated on a copper foil by doctor-blade casting as an electrode and baked in a vacuum oven. After battery assembling, galvanostatic charge-discharge (GCD) and electrochemical impedance spectroscopy (EIS) analyses will be applied to analyze the improvement of cycle-life retention, Coulombic efficiency, and impedance reduction attributed to titanium oxide-based additives. Besides, after charge/discharge cycling, the active materials will be characterized by field-emission scanning electron microscopy (FE-SEM), energy-dispersive X-ray spectroscopy (EDX), and X-ray diffraction (XRD). The results of this work will provide an innovative approach to improving the retention of SSBs by adding additives in iron oxides.

#### 8:00 PM EN02.03.26

**Innovative Gel Polymer Electrolyte for Safe and Long-Lasting Active Implantable Medical Devices** Mike Molinski<sup>1</sup>, Hailey Simon<sup>1</sup>, Brian Chiou<sup>2</sup> and Arijit Bose<sup>2</sup>; <sup>1</sup>Audiance, Inc., United States; <sup>2</sup>University of Rhode Island, United States

Active implantable medical devices (AIMDs) play a pivotal role in modern healthcare, offering advanced therapeutic solutions for a variety of medical conditions. The power sources within them play a critical role and have demanding performance attributes, namely high energy density, long-term reliability, and exceptional safety. Primary lithium-ion batteries have emerged as a popular choice due to their high energy density, predictable performance, and long cycle life. However, their implementation in AIMDs faces certain limitations, primarily concerning safety considerations as novel more capable devices demand higher battery capacities. AUDIANCE has developed an innovative safe, stable, and non-flammable gel polymer electrolyte (GPE) that address the limitations of current lithium-ion battery technologies and unlocks the potential for use of rechargeable or secondary lithium-ion batteries in AIMDs.

Consisting of a carrier, a high molecular weight polymer, and a conductive lithium salt, the GPE exhibits excellent lithium-ion conductivity of  $2.58 \times 10^{-3}$  S/cm at 37°C and demonstrates a wide electrochemical stability window with a polymer decomposition voltage of about 4.2V. Notably, the mechanical properties of the high viscosity electrolyte are highly composition-dependent, which enables precise control over its rheology, facilitating processability and preventing electrolyte leakage while infiltrating electrode pores. Extensive safety testing has validated the reliability of AUDIANCE's technology. In flammability tests, the electrolyte self-extinguishes, ensuring enhanced safety even during catastrophic failure events. Moreover, nail penetration, overcharge, and external short circuit tests conducted on cells fabricated with the GPE resulted in minimal temperature change and no gas emissions. Long-life cycle testing of LTO/LFP cells demonstrated negligible capacity loss over 4,750 cycles at 37°C, underscoring the stable electrochemical performance and prolonged lifespan of AUDIANCE's batteries.

The outcomes of this research present a promising pathway towards safer and more efficient power sources for AIMDs. The utilization of the novel GPE holds the potential to enhance the reliability and longevity of implantable medical devices, paving the way for novel therapeutic interventions and improving the quality of life for countless patients worldwide.

**Thin Single-Ion Solid-State-Electrolyte Film using Covalent Organic Frameworks for Lithium-Ion Cells** Rak Hyeon Choi and Hye Ryung Byon; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Organic solid-state electrolytes have emerged as a solution for developing less flammable and flexible batteries. While polymeric electrolytes have been developed for decades, their practical applications have been hindered by low ionic conductivity and high activation energy at room temperature. Alternatively, a new class of porous and crystalline organic materials called covalent organic frameworks (COFs) shows promise. COFs are highly crystalline materials where desired molecules are periodically bonded to form a two-dimensional layer. The well-ordered stacking of these organic layers extends the three-dimensional structure while creating porous channels. COFs are also mechanically robust and chemically stable, unlike soft and non-crystalline polymer films. By introducing anionic pendants and Li<sup>+</sup> ions, COFs have been demonstrated as single-ion conductors in previous studies [1,2]. However, the ionic conductivity was still moderated ( $>10^{-5}$  S cm<sup>-1</sup>) at room temperature. This limitation can be attributed to the powder-like form of COFs and their typical fabrication into pellet-type electrolytes, which results in high thickness ( $>100$  μm) and significant interfacial resistances ( $>1$  kΩ), even when mechanical pressure is applied. These factors contribute to challenges such as nonuniform interfacial contact with electrodes and long Li<sup>+</sup> transport paths.

Here, we developed thin-film COF electrolytes and demonstrated improved Li-ion cell performances. We fabricated COF films with a thickness of approximately 35 μm using a one-pot synthetic method at room temperature. The interfacial resistance of the COF film with metallic Li was approximately 224 Ω, which was 8 times lower than that of the pellet-type ones. For molecular designs, Li<sup>+</sup> ions and sulfonate functional groups were included in a hexagonal unit of COF. The Li<sup>+</sup> conductivity of the COF film was highly dependent on the concentration of sulfonic groups and the crystallinity of the film. Higher Li<sup>+</sup> contents, corresponding to a higher number of sulfonic groups, and better crystallinity resulted in higher ionic conductivity and lower activation energy. Consequently, we achieved an optimum Li<sup>+</sup> conductivity and transference number of  $1.01 \times 10^{-4}$  S cm<sup>-1</sup> and 0.91, respectively, at room temperature. The COF film also exhibited excellent performance in Li|Li symmetric cells at room temperature, with over 1000 hours at 0.1 mAcm<sup>-2</sup> and 0.1 mAhcm<sup>-2</sup>. Additionally, Li|LiFePO<sub>4</sub> cells using the COF electrolyte delivered a capacity of 150 mAhg<sup>-1</sup> at 0.1 C for 150 cycles with negligible capacity fading. In this presentation, I will discuss details of COF film synthesis, several COF designs and their characteristics, and COF-based Li-ion cell performances.

**Enhancing Low-Pressure Operability of Si Anodes in All-Solid-State Batteries Through Interlayer Engineering and Prelithiation** Seunggoo Jun, Yong Bae Song, Haechannara Lim, Ki Heon Baek, Eun Suh Lee and Yoon Seok Jung; Yonsei University, Korea (the Republic of)

The growing demand for vehicle electrification and energy storage systems has spurred research on high-energy-density lithium-ion batteries (LIBs). Solidifying electrolytes using inorganic materials has gained interest due to its potential to enhance energy density and safety. However, challenges, such as dendritic growth and limited Li<sup>+</sup> diffusion, have impeded the integration of Li metal anodes (LMAs) in all-solid-state batteries (ASSBs). Si anodes, not constrained by the same issues, could present an advantageous alternative. However, in LIBs, Si anodes undergo severe volume changes ( $>300\%$ ) during charge-discharge cycles, leading to fractures and a loss of electrical connectivity. To overcome this, Si is often electrically wired with nanostructured carbonaceous materials like carbon nanotubes (CNTs) and graphene. While this strategy can also be applied to ASSBs, it raises concerns about adverse

reactions between carbon materials and SEs. Recent studies reported that the performance of Si ASSBs could be enhanced by eliminating solid electrolytes and carbon additives in Si electrodes, demonstrating 80% capacity retention after 500 cycles at 50 MPa. This performance is attributed to the mechanically sintering ability of lithiated Si and the lack of destructive side reactions. However, the high operating pressures used need to be addressed for practical applications.

In our study, we present a comprehensive Si ASSB design incorporating a thin metallic interlayer at the Si electrode-SEs interface and integrating the Si electrodes with CNTs. This interlayer allows  $\text{Li}^+$  transport maintenance across the interface despite the dimensional changes of Si anode, demonstrating improved performance of ASSBs under low-pressure conditions.

**Stabilizing Li Metal/Argyrodite Interface for Sulfide-Based All-Solid-State Lithium Batteries** Hui-Tae Sim, OH Myung-keun, Ye-Eun Park, Hyo-Jin Kim and Dong-Won Kim; Hanyang University, Korea (the Republic of)

The achievement of carbon neutrality is the first step in addressing the issue of global climate change. Rechargeable batteries with high energy density are one of the promising techniques to reduce carbon emission. After the commercialization of lithium-ion batteries (LIBs) in 1991, rechargeable LIBs have been universally applied in portable electronic to electric vehicles. However, the conventional LIBs using liquid electrolytes have serious safety problems such as flammability, solvent leakage, and explosion under unusual conditions. In addition, the use of Li metal anode ( $3860 \text{ mAh g}^{-1}$ ) with high specific capacity tends to exacerbate risks due to the interfacial side reactions and dendrite growth of lithium. In this respect, all-solid-state lithium metal batteries (ASSLMBs) have attracted attention as the most promising high energy density storage system. Among various solid electrolyte systems, sulfide electrolytes are being widely studied due to their high ion conductivity and ductile property. However, the lithium dendrite growth can be also occurred in sulfide based-ASSLMBs because of voids, cracks, grain boundaries in solid electrolyte, and side reactions between Li and solid electrolyte.

In this work, the surface modification of Li was performed using  $\text{LiNO}_3$  with nitrogen-based solvent. The protective layer formed on Li metal was composite of organic and inorganic materials based on  $\text{Li}_3\text{N}$ . The symmetric Li/solid electrolyte/Li cell with protective layer exhibited good cycling stability without short circuit, indicating the uniform plating/stripping of lithium and good interfacial properties. Consequently, an all-solid-state lithium battery assembled with  $\text{LiNi}_x\text{Co}_y\text{Mn}_{1-x-y}\text{O}_2$  cathode delivered a high initial discharge capacity and exhibited good cycling stability.

#### 8:00 PM EN02.03.30

**Unlocking High-Performance Quasi-Solid-State Multivalent Metal Ion Batteries** Sarah K.W. Leong, Wending Pan and Dennis Leung; University of Hong Kong, Hong Kong

In the pursuit of advancing post-Li-ion battery technology, the development of rechargeable Mg batteries has shown tremendous promise due to their high theoretical capacity, material abundance, and low cost. However, the passivating nature of Mg, particularly in aqueous solutions, presents a significant obstacle. The practicality of Mg anodes within aqueous electrolytes has been largely dismissed due to the perceived lack of reversibility and narrow electrochemical window, leading researchers to focus on non-aqueous systems. Nonetheless, non-aqueous electrolytes also suffer from poor ionic conductivity, high cost, and safety hazards such as flammability and toxicity.

This work addresses these challenges by introducing a pioneering quasi-solid-state magnesium-ion battery (QSMB), designed to harness the advantages of both aqueous and non-aqueous systems. By immobilizing the electrolyte's water network, the polyethylene polymer polymer suppresses the hydrogen evolution reaction at the magnesium metal anode, and achieves a fully reversible Mg dissolution and deposition chemistry through a Cl-induced transformation of the impermeable passivation film into a conductive metallic oxide complex.

The quasi-solid-state electrolyte also plays a major role in attaining high voltage and capacity by facilitating true multivalent Mg ion storage. Through confining the hydrogen bond network, the electrolyte effectively impedes proton insertion which competes with multivalent metal-ion insertion in aqueous batteries. In this study, in-situ characterizations reveal that the electrolyte promotes the high-voltage (de-)intercalation of both  $\text{Mg}^{2+}$  and  $\text{MgCl}_2^+$  ions instead, delivering unparalleled battery performance.

The QSMB showcases a remarkable energy density of  $264 \text{ Wh kg}^{-1}$ —nearly five times higher than its aqueous Mg-ion counterparts, and a voltage plateau (2.6-2.2 V) that surpasses other Mg-ion batteries. Moreover, it retains an impressive 90% capacity after 900 cycles, even at subzero temperatures ( $-22^\circ\text{C}$ ). By leveraging the high ionic conductivity from aqueous systems and a broad electrochemical window from non-aqueous systems, the quasi-solid-state battery represents an innovative avenue for the design of high-performing Mg-ion batteries.

More importantly, this study provides invaluable insights into interphase passivation, metal stripping and plating mechanisms at the anode, and ion storage regulation at the cathode to produce high-energy, rechargeable, solid-state battery technologies. This quasi-solid-state approach could be extended to the design of other multivalent metal-ion batteries, including Zn-ion and Al-ion batteries, demonstrating the potential for broader applications.

#### 8:00 PM EN02.03.31

**Mechanical Design Strategies in Facilitating Durable Ni-Rich Layered Cathodes for Lithium-Ion Batteries** Sangho Yoon, Jaewoon Lee and Duho Kim; Kyunghee University, Korea (the Republic of)

Along with the growth of the electric vehicle market, the Ni-rich layered oxides ( $x \geq 0.8$ ) for cathode active materials have attracted great attention because their high Ni content provides high-energy-density to meet the needs of high-energy-density applications. However, the large amount of Ni often results in severe micro-crack propagation that causes capacity degradation due to structural instability such as heterogeneous phase transformations and anisotropic structural changes under high charging voltage conditions. Until recently, many previous studies have focused on inhibiting micro-crack formation due to structural instability, specifically the anisotropic lattice variation that leads to mismatch of primary particles in Ni-rich layered oxides upon repeated (de)intercalation. While the degradation mechanisms by which anisotropic lattice variation act between primary particles have been identified, the mechanism inside the particles is not yet fully understood. In this regard, a more systematic and comprehensive study could be required to explore the mechanisms of anisotropic behavior inside particles in Ni-rich layered oxides. Additionally, through advanced experimental analysis and computational calculations, a comparison of the thermodynamic features of Ni-rich layered oxides ( $\text{Li}[\text{Ni}_x\text{Co}_y\text{M}_z]\text{O}_2$ , where M represents the transition metal) reveals similar phase transitions ( $\text{H1}$  (hexagonal 1)  $\rightarrow$   $\text{M}$  (monoclinic)  $\rightarrow$   $\text{H2}$   $\rightarrow$   $\text{H3}$ ) regardless of the transition metal M. However, the cycle retention varies significantly depending on the composition of the transition metal.

In this work, to understand these undesired phenomena, we systematically apply thermodynamic, chemo-mechanic, and physicochemical perspectives to analyze the correlation between (in)coherent phase separation and volume conservation behavior to propose an opposite view of the traditional aspect of

anisotropic lattice variation and a new design strategy for single-crystal Ni-rich layered cathodes that reduces the internal stress between separated phases to zero grain internal stress. First, we analyzed the (in)coherent phase separation of  $\text{Li}_{1-x}[\text{Ni}_{10}/\text{Co}_{12}/\text{Mn}_{12}]\text{O}_2$  (NCM) and  $\text{Li}_{1-x}[\text{Ni}_{10}/\text{Co}_{12}/\text{Ti}_{12}]\text{O}_2$  (NCT) by comparing the thermodynamic phase stability during the whole delithiation process along the formation energy of mixing enthalpy and found that NCT was thermodynamically more stable and relatively coherent phase separation occurred than commercial NCM. Furthermore, for a direct understanding of the cycle degradation mechanism by (in)coherent phase separations, we calculate the directional lattice strain and volumetric variation for NCM and NCT combined with phase transition. Interestingly, upon volume change, both oxide models exhibited volume-conserving regions due to anisotropic lattice changes, which resulted in a relative decrease in internal stress. Moreover, the NCT exhibits near zero volumetric lattice variation. Based on the correlation between thermodynamics and the volumetric lattice misfit, the oxygen bond populations for both oxide models are identified, and a severe reduction is observed across the entire oxygen framework in the incoherent phase separation model NCM, whereas a preserved feature is observed in the coherent phase model NCT. These systemically novel concepts underpin the Ti-induced “zero volumetric misfit” concept makes coherent phase separation. These concepts are expected to play a global role in the layered oxide cathodes, and it provides a crucial design strategy leading to the enhancement of cycle retention for durable high-energy-density LiBs.

#### 8:00 PM EN02.03.32

**Effect of Various Carbon Nanomaterials as Conductive Additives in EDLC** Vladimir Pavlenko<sup>1</sup>, Zhanibek Ayaganov<sup>2</sup> and Annie Ng<sup>1</sup>; <sup>1</sup>Nazarbayev University, Kazakhstan; <sup>2</sup>Al-Farabi Kazakh National University, Kazakhstan

A comprehensive study was performed to investigate the effect of different carbon nanomaterials including single-walled carbon nanotubes, graphene nanoplatelets, activated carbon nanofibers and fullerene C60 on the performance of aqueous-based electric double layer capacitors (EDLC) based on a neutral aqueous electrolyte ( $\text{Li}_2\text{SO}_4$ ). The performance of commercially available and laboratory synthesized carbon nanomaterials having different morphologies were investigated and compared with carbon black C45 which is widely used as conductive additive. Electrochemical studies were performed by cyclic voltammetry, galvanostatic charge-discharge and impedance spectroscopy. It is found that conductive additives exhibit limited effectiveness in EDLC capacitance at low current densities, while at high current loads the discrepancies of EDLC's performance become pronounced. The use of activated carbon nanofibers having large surface area synthesized from polyacrylonitrile by electroforming increases the specific capacitance by 16%, energy efficiency by 7% and energy densities by 22% at current densities equal to 20 A/g. The addition of conductive additives with a small specific surface area leads to a decrease in the characteristics of the EDLCs. The results provide important information for the community to develop new energy conversion and storage devices.

#### 8:00 PM EN02.03.33

**Charge Separation Nanoclay in Gel Polymer Electrolytes: Empowering Sustainable Anion Storage** Sungho Kim and Soojin Park; Pohang University of Science and Technology, Korea (the Republic of)

The dual-ion battery (DIB) represents a significant advancement in sustainable energy storage. It employs intercalation-type graphite as a cathode, enabling anion penetration into interlayers during high-potential charges, resulting in an elevated operational voltage exceeding 5V. DIBs distinguish themselves from conventional lithium-ion batteries by moving away from transition metal oxide cathodes, like Lithium cobalt oxide (LCO), offering a more eco-friendly and cost-effective alternative. However, DIBs face challenges due to high operating voltages causing electrolyte decomposition, which leads to a passivation layer on the electrodes, increased resistance, and potential performance degradation.

To tackle the issue of electrolyte decomposition, researchers are exploring high-concentration electrolytes (HCE) enriched with lithium salts. These electrolytes predominantly contain contact ion pairs (CIP) and aggregates (AGG), enhancing electrochemical stability. Notable efforts have been made using a 4.0 M LiFSI in TMS, but increased salt concentrations lead to higher viscosity, reducing ionic conductivity.

Another approach is incorporating gel polymer electrolyte (GPE), known for its high voltage stability, moderate ionic conductivity, and safety attributes. However, as ionic conductivity increases, mechanical integrity decreases. To address this, functional groups are added to the polymer matrix, reducing anion-solvent interactions and promoting a stable anode interface. Nevertheless, a trade-off remains between physical rigidity and ionic conductivity.

Additives are essential to enhance GPE mechanical stability and modify ion solvation. These additives include carbon-based conductive fillers, ceramics, polymers, and nanoparticles, improving ion conduction and cell performance. Facilitating anion mobility and integration is crucial for optimizing dual-ion battery performance, necessitating additives that dynamically interact with anions, promote a stable surface interface, and align with sustainability standards.

This study explores GPEs infused with surface-charged nano clay as an innovative additive for DIBs. Nanoclay, due to its abundant availability and non-toxic nature, enhances GPE's mechanical resilience and influences cation and anion solvation structures. The investigation involves a comparative analysis of three nano clay variants with distinct characteristics. Zeta potential, nuclear magnetic resonance (NMR), molecular dynamics (MD) simulations, and density functional theory (DFT) calculations confirm the findings.

Halloysite (HS), with its tubular morphology, stands out as a superior candidate. It fosters a slender, homogeneous cathode electrolyte interface (CEI) with reduced anion-solvent interactions and fewer salt decomposition products. The tubular structure of HS improves anion transport pathways, optimizing DIB operation. Consequently, a DIB full-cell incorporating HS-GPE exhibits impressive rate capability, exceeding 60 mAh/g at 50 C-rate, and remarkable stability, sustaining over 5000 cycles at 20 C-rate.

#### 8:00 PM EN02.03.36

**Synthesis and Characterization of Transition Metal Doped Lithium Composites for Application in Lithium Ion Based Batteries** Neeraj Chauhan<sup>1,2</sup>, Amrit Pal Toor<sup>1</sup>, Stefan Krause<sup>2</sup> and Alok Srivastava<sup>1</sup>; <sup>1</sup>Panjab University, India; <sup>2</sup>University of Birmingham, United Kingdom

The research aims to enhance the physicochemical and electrochemical properties of cathode materials for application in lithium-ion batteries, specifically  $\text{Li}_2\text{TMSiO}_4$  (TM=Transitions metals) silicates. These materials have high theoretical capacity, but most often suffer from poor conductivity. To improve their performance, methods like particle size reduction, coating, and ion doping were being employed. Among different transition metals-based silicates,

$\text{Li}_2\text{MnSiO}_4$  is of particular interest, but often faces issues with cycling performance due to low conductivity and stability. Further, the structural characterization of the different lithium composites had shown that  $\text{Li}_2\text{CoSiO}_4$  exhibited high crystallinity with an orthorhombic crystal structure. Therefore, trivalent ions doping and anionic doping were carried out to enhance conductivity and electrochemical properties of  $\text{Li}_2\text{MnSiO}_4$  and  $\text{Li}_2\text{CoSiO}_4$  silicates. The resulting silicates i.e.  $\text{LiMnAlSiO}_4$  and  $\text{LiMnCoAlSiO}_4$  displayed patterns similar to  $\text{Li}_2\text{MnSiO}_4$ , indicating a mixture of polymorphs. The addition of dopants did not only alter the structure but significantly improves the properties of the silicates. In terms of electrical characterization, cyclic voltammetry measurements showed different potential values for the composites, where  $\text{Li}_2\text{CoSiO}_4$  displayed cathodic and anodic potentials with slight variations and a decrease in cathodic current after 10 cycles.  $\text{LiMnAlSiO}_4$  showed stable potentials but a 28% drop in current, while  $\text{LiMnCoAlSiO}_4$  had minimal changes in potentials and currents. Moreover, the electrochemical impedance spectroscopy demonstrated that  $\text{LiMnAlSiO}_4$  and  $\text{LiMnCoAlSiO}_4$  had undergone least charge transfer resistance compared to  $\text{Li}_2\text{CoSiO}_4$ , indicating improved  $\text{Li}^+$  ion diffusion. Based on these results,  $\text{LiMnCoAlSiO}_4$  showed better stability, resistance and conductivity compared to  $\text{LiMnAlSiO}_4$  and  $\text{Li}_2\text{CoSiO}_4$ . Further investigations will be carried out to explore the thermal stability of the composites beyond  $400^\circ\text{C}$  and to evaluate the potential of  $\text{LiMnCoAlSiO}_4$  as an electrode material. Overall, the study demonstrated the ortho-rhombic structures of transition metal-doped  $\text{Li}_2\text{SiO}_4$  composites and highlighted the superior performance of the quaternary composite  $\text{LiMnCoAlSiO}_4$  in terms of electrical conductivity, capacitance, and structural stability.

#### 8:00 PM EN02.03.37

**High Conductivity in  $\text{Na}^+$ -Ion Conducting Solid Electrolytes for Na-Ion Batteries Through a Co-Doping Strategy** Xuankai X. Huang and Isaac Abrahams; Queen Mary University of London, United Kingdom

Rechargeable batteries are regarded as the most promising energy storage technology because of their reliability and high energy conversion efficiency. Although Li-ion batteries (LIBs) have been widely used in portable electronic devices, Na-ion batteries (NIBs) are considered as a potential candidate to replace LIBs because of their non-toxicity, low cost, and elemental abundance. Solid state sodium-ion batteries are seen as potentially cheaper and safer alternatives to current lithium-ion battery systems. The replacement of the presently used liquid electrolytes by non-flammable solid electrolytes is an important avenue to create safer batteries, while the high natural abundance of sodium compared to lithium would allow for significant cost reduction. The sodium superionic conductor, NASICON, first reported by Hong, is one of the best-known sodium-ion conducting solid electrolytes, displaying high bulk ionic conductivity and good stability toward NASICON-based electrodes. However, the practical use of NASICON has been impeded by low ion mobility at room temperature and poor interfacial connectivity. Here, the improvement of total conductivity has been achieved via La and Zn co-doping of NASICON. Total conductivity values of  $4.68 \times 10^{-3} \text{ S cm}^{-1}$  at room temperature and  $2.89 \times 10^{-2} \text{ S cm}^{-1}$  at  $100^\circ\text{C}$  were obtained for NZSP-LZ-0.2, which are amongst the highest values recorded for a NASICON based system. Furthermore, the system shows good air stability and could represent a suitable material for application in the field of Na-ion batteries. Symmetric cells with sodium metal as electrodes (Na|NZSP-LZ-0.2|Na) are assembled and cycled stably for over 3000 cycles at a current density of  $0.2 \text{ mA/cm}^2$ .

#### 8:00 PM EN02.03.38

**Thermodynamics of Multi-Sublattice Battery Active Materials: From an Extended Regular Solution Theory to a Phase-Field Model of  $\text{LiMn}_x\text{Fe}_{1-x}\text{PO}_4$**  Pierfrancesco Ombrini; Delft University of Technology, Netherlands

Phase separation during the lithiation of redox-active materials is a critical factor affecting battery performance, including energy density, charging rates, and cycle life. Accurate physical descriptions of these materials are necessary for understanding underlying lithiation mechanisms, performance limitations, and optimizing energy storage devices. This work presents an extended regular solution model that captures mutual interactions between sublattices of multi-sublattice battery materials, typically synthesized by metal substitution. We apply the model to phospho-olivine materials and demonstrate its quantitative accuracy in predicting the composition-dependent redox shift of the plateaus of  $\text{LiMn}_x\text{Fe}_{1-x}\text{PO}_4$  (LFMP),  $\text{LiCo}_y\text{Fe}_{1-y}\text{PO}_4$  (LFCP),  $\text{LiCo}_x\text{Mn}_y\text{Fe}_{1-x-y}\text{PO}_4$  (LFMCP), as well as their phase separation behavior. Furthermore, we develop a phase-field model of LFMP that consistently matches experimental data and identifies  $\text{LiMn}_{0.4}\text{Fe}_{0.6}\text{PO}_4$  as a superior composition that favors a solid solution phase transition, making it ideal for high-power applications.

**Formulating Electron Beam-Induced Covalent Linkages for Stable and High-Energy-Density Silicon Microparticle Anode** Minjun Je and Soojin Park; Pohang University of Science and Technology, Korea (the Republic of)

High-capacity silicon (Si) materials hold a position at the forefront of advanced lithium-ion batteries. The inherent potential offers considerable advantages for substantially increasing the energy density in batteries, capable of maximizing the benefit by changing the paradigm from nano- to micron-sized Si particles. Nevertheless, intrinsic structural instability remains a significant barrier to its practical application, especially for larger Si particles. Here, we first report a covalently interconnected system employing silicon microparticles ( $5 \mu\text{m}$ ) and a highly elastic gel polymer electrolyte (GPE) through electron beam irradiation. The integrated system mitigates the substantial volumetric expansion of pure Si, enhancing overall stability, while accelerating charge carrier kinetics due to the high ionic conductivity. Through the cost-effective but practical approach of electron beam technology, the resulting 500 mAh-pouch cell showed exceptional stability and a high volumetric energy density of  $1022 \text{ Wh L}^{-1}$ , highlighting the feasibility even in current battery production lines.

#### 8:00 PM EN02.03.40

**Hierarchical 3D Electrode Design with High Mass Loading Enabling High-Energy-Density Flexible Lithium-Ion Batteries** Jaeho Jung, Dong-Yeob Han and Soojin Park; POSTECH, Korea (the Republic of)

Flexible lithium-ion batteries (LIBs) have garnered considerable attention due to their increasing utilization in flexible and wearable electronic devices. However, the practical implementation of flexible LIBs in these devices has been hindered by the dual challenge of attaining both high energy density and exceptional flexibility. In this study, we introduce a hierarchical 3D electrode (H3DE) with a substantial mass loading capacity, which enables the creation of highly flexible LIBs boasting an exceptionally high energy density. The H3DE boasts a bicontinuous architecture, ensuring that active materials and conductive agents are uniformly dispersed throughout the 3D framework, irrespective of the specific type of active material employed. This seamless integration of the electrode and electrolyte facilitates rapid ion and electron transportation, thereby enhancing redox kinetics and reducing internal cell resistance. Furthermore, the H3DE displays remarkable structural resilience and flexibility even under repeated mechanical deformations. Capitalizing on these remarkable physicochemical attributes, pouch-type flexible LIBs employing the H3DE exhibit consistent cycling performance under various bending conditions. They achieve a groundbreaking energy density of  $438.6 \text{ Wh kg}^{-1}$  and  $20.4 \text{ mWh cm}^{-2}$ , as well as an areal capacity of  $5.6 \text{ mAh cm}^{-2}$ , surpassing the performance of all previously documented flexible LIBs. This research offers a practical solution for the development of high-energy-density flexible LIBs suitable for a wide array of energy storage devices.

#### 8:00 PM EN02.03.43

**Study of Amorphous Vanadium Oxide Cathodes for Li-Ion Batteries Prepared by Reactive Magnetron Sputtering** Mackarena Briceño, Juan Fernandez, Marcos Flores and Rodrigo Espinoza; Universidad de Chile, Chile

Within the technological development focused on lithium-ion batteries, vanadium pentoxide ( $V_2O_5$ ) thin films have been a good candidate to be used as cathodic material due to their high-capacity charge, allowing to increase in the efficiency of lithium-ion batteries [1]. The technique of reactive magnetron sputtering allows the manufacture of homogenous thin films with low thicknesses and specific microstructure. In addition, with this technique we can generate different stoichiometries of vanadium oxides and specifically of  $V_2O_5$  [2-3]. The formation of different vanadium oxides mainly depends on the oxygen content of the system [4]. The aim of this work is based on the preparation of thin films of vanadium oxides on steel substrate by reactive sputtering at different oxygen flows followed by reduction with hydrogen *in situ*, and their electrochemical evaluation as a potential cathode material. The target was metallic vanadium, while the plasma was argon (15 sccm) combined with oxygen at 1.25, 1.75, 2.25, 2.5, 3.0 and 3.25 sccm. The samples were characterized by XRD, EDS, Raman confocal spectroscopy, XPS and AFM. Cyclic voltammograms, the charge/discharge processes and cyclability of batteries were studied. XRD results demonstrated that the samples were amorphous for all the different oxygen flows. Raman analysis indicated the presence of the V-O-V bonding corresponding to a crystalline structure of the rhombohedral type of  $V_2O_5$ , by the vibrational stretching modes ( $143\text{ cm}^{-1}$ ), and of the V=O bonding by the second flexion vibrational band ( $995\text{ cm}^{-1}$ ) for the sample deposited at 3.0 sccm of oxygen. XPS established a correlation between the oxygen flow and the main V oxidation state:  $V^{+4}$  at 1.25 O-flow,  $V^{+4}/V^{+3}$  at 1.75 O-flow, and  $V^{+5}$  over 2.5 O-flow. The sample of 3.0 sccm of oxygen at 1 hour of deposition has a capacity of 295 mAh/g with a charge retention percentage of 96.5% at 50 charge/discharge cycles at 1C. The electrochemical behavior of the samples in reduction with hydrogen, shows a better retention percentage of 99.9% at 50 charge/discharge cycles at 1C, but not an improvement in the charge and discharge capacity, which is 213 mAh/g for the sample of 3.0 sccm of oxygen at 8%  $\text{pf H}_2$ .

We acknowledge the financial support of the national fellowship sponsored by ANID.

**Single-Ion Conducting Borate Network Polymer Electrolytes for Lithium Metal Batteries with Excellent Rate Capability** Jingyi Gao and Dong-Myeong Shin; University of Hong Kong, Hong Kong

Although it is possible to readily estimate the theoretical energy densities of battery chemistries, the molecular processes that hinder practical performance are still unknown. Especially, the charging and discharging rates have become a major limiting factor in energy storage applications. Several solid electrolytes with exceptional ionic conductivity have been discovered, but all-solid-state batteries with high energy density have been only realized at limited rates (close to equilibrium), indicating that the minimization of overpotential requires to be considered to improve the rate performance other than the ionic transport. As single-ion polymer electrolytes, in which only selective cations are mobile across polymer electrolytes, facilitate minimizing not only the concentration gradient but also the overpotentials in the cells, such electrolytes pose great potential for overcoming these problems. However, single-ion polymer electrolytes have suffered from low ionic conductivity ( $<10^{-5}\text{ S cm}^{-1}$  at ambient temperature) which is at least two orders of magnitude smaller than that of liquid electrolytes. In this talk, I will present our ongoing efforts to develop a new class of single-ion conducting polymer electrolytes using an interpenetrated network polymer with weakly coordinating anion nodes, with a wide electrochemical stability window, a high room temperature conductivity of up to  $1.5 \times 10^{-4}\text{ S cm}^{-1}$ , and exceptional selectivity for Li-ion conduction ( $t_{\text{Li}^+} = 0.95$ ). Significantly, lithium metal battery prototypes containing these electrolytes are shown to outperform a conventional battery featuring a polymer electrolyte.<sup>1-3</sup>

**Enabling Low  $T_g$  Ester-Functionalized Polysiloxane Electrolytes for Lithium-Metal Batteries Utilizing Semi-Interpenetrating Networks** Jannik Petry, Markus Dietel and Mukundan Thelakkat; University of Bayreuth, Germany

Lithium-ion battery technology is dominating the electrochemical energy storage industry. To access higher energy densities, all solid-state lithium-metal batteries (LMB) utilizing elemental lithium as anode material are of high research interest. Commonly used liquid electrolyte systems are not compatible towards lithium-metal anodes, due to lithium dendrite formation and safety issues during cycling; requiring new classes of solid-state ion-conductors. In this regard, polyether-based electrolytes have been studied extensively because of their low glass transition temperature ( $T_g$ ) and high solubility of lithium salts. However, the strong Li-ion/ether-oxygen interactions result in low effective lithium-ion conductivities. In addition, the inherent crystallinity of poly(ethylene oxide) (PEO) allows its application only to temperatures above its melting point ( $65\text{ }^\circ\text{C}$ ).<sup>[1,2]</sup> Oligo-/polyester-based materials show comparable compatibility with lithium salts with a reduced  $\text{Li}^+$ -carbonyl interaction strength, resulting in improved lithium transference numbers and in turn higher effective lithium-ion conductivities. However, the commonly used poly( $\epsilon$ -caprolactone) (PCL) is semicrystalline still requiring elevated temperatures for optimum ionic conductivity.

In recent studies we demonstrated the application of diester-functionalized poly(meth)acrylates and poly(glycidyl propargyl ethers) as alternative to linear polyesters. The amorphous polymers show high room-temperature ionic conductivity and good applicability in LMBs.<sup>[3,4]</sup> The  $T_g$  of the polymers significantly influences the ion conduction properties, with lower glass transition temperatures resulting in improved ionic conductivities.

Here we propose poly(siloxane)-based diester functionalized polymer electrolytes to further decrease the  $T_g$  and improve the low temperature performance. Poly(methylhydro)siloxane was functionalized with an adipate-based (diester) side chain in a hydrosilylation reaction. The diester functionalized polysiloxane (PSi-adipate) exhibits an amorphous character and a very low  $T_g$  of  $-76$  °C. Electrolytes consisting of 20 wt% LiTFSI and the PSi-adipate showed the highest ionic conductivities with  $2.7 \times 10^{-5}$  and  $1.8 \times 10^{-4}$  S  $\text{cm}^{-1}$  at 40 and 70 °C, respectively. Furthermore, the lithium transference number was determined as 0.7, compared to 0.5 for linear PCL, indicating a very efficient lithium-ion conduction mechanism. Unfortunately, the improvements in electrolyte characteristics and the low glass transition temperature are countered by the lacking mechanical integrity of PSi-adipate. An investigation of the depletion/plating reversibility of lithium ions at lithium electrodes revealed the necessity to mechanically reinforce the electrolyte. The strategy here is to design a semi-interpenetrating network (sIPN) electrolyte.

We therefore synthesized a PCL-based diacrylate as a network former to form a structure giving network. The network is formed in situ in the presence of the polysiloxane electrolyte to yield a semi-interpenetrating network (sIPN) electrolyte (PSi-adipate-sIPN). The network results in significant increase of the mechanical properties as observed in rheology measurements and effectively stabilizes the lithium interface during cycling. Further, the network incorporation in PSi-adipate-sIPN has no negative effect on the ionic conductivity. Finally, the PSi-adipate-sIPN electrolytes are evaluated in lithium-metal batteries with lithium iron phosphate (LFP)- and nickel manganese cobalt oxide (NMC)-based cathodes at different C-rates and temperatures.

**Solid-State Batteries Based on Ionogel Electrolytes** Bruce S. Dunn, Yunkai Luo, Bintao Hu and Patricia McNeil; University of California, Los Angeles, United States

Ionogels are pseudo-solid state electrolytes in which an ionic liquid electrolyte is confined in an organic or inorganic matrix. One well established ionogel synthesis route is based on sol-gel chemistry where silica precursors dissolved in an ionic liquid electrolyte undergo hydrolysis and condensation polymerization. By using an ionic liquid as the solvent, no evaporation occurs and the resulting material is a macroscopically rigid, nonporous material in which the ionic liquid is trapped by capillary forces in the nanometer sized pores in the silica network. Because of their unique architecture, ionogels maintain a nanoscale fluidic state and thus mitigate the interfacial resistances which commonly arise at solid-solid interfaces. Using this approach, we have been able to develop pseudo-solid state materials that possess the electrochemical, thermal and chemical properties of the ionic liquid. Moreover, sol-gel synthesis enables the precursor sol to penetrate porous electrodes before solidifying, a feature which is especially attractive for solid-state batteries. Our recent work has been directed at developing ionogels for anode free solid-state batteries. In this work we take advantage of the ability to solvent exchange the ionic liquid phase with a liquid electrolyte which is more conducive to lithium plating and stripping. We start by synthesizing an ionogel based on dissolving the silane precursors (tetramethyl orthosilicate and methyltrimethoxy silane) in a 1-butyl-1-methylpyrrolidinium bis(fluorosulfonyl)imide (PYR14 FSI) ionic liquid, using acetic acid as a catalyst. After gelation, the ionic liquid is solvent exchanged with an electrolyte consisting of 1 M lithium bis-(tri-fluoromethylsulfonyl)imide (LiTFSI) in 1 : 1 of 1,3-dioxolane (DOL) and 1,2-dimethoxyethane (DME) with 1 wt% of  $\text{LiNO}_3$ . We have cycled Li/ionogel/Cu cells for over 500 cycles with minimal interfacial resistance and nearly 100% coulombic efficiency. We have also investigated the use of 3D printed copper electrodes and are able to plate and strip lithium at current densities up to  $10 \text{ mA cm}^{-2}$ . Anode-free solid-state batteries based on these solvent exchanged ionogels show that the ability to substitute the desired electrolyte for the ionic liquid offers an important new direction which, when coupled with their thermal and electrochemical stability, makes ionogel electrolyte materials a very promising approach for solid-state batteries.

**Liquid Electrolytes and Solid Electrolytes for High Energy Lithium Batteries** Jun Liu<sup>1,2</sup>; <sup>1</sup>Pacific Northwest National Laboratory, United States; <sup>2</sup>University of Washington, United States

Batteries play a critical role in modern society. The electrification of transportation and deep decarbonization require the development and deployment of high energy, low-cost battery materials and technologies. Among the many different battery chemistries investigated, rechargeable batteries using lithium metal anode remain as one of the most feasible approaches for next generation high-performance and low-cost batteries. There are different approaches to design high energy cells: using liquid electrolytes or solid electrolytes. In the last several years, great progresses have been made in developing lithium metal compatible electrolytes for high energy rechargeable lithium batteries. The new electrolytes significantly reduced the reactions between the solvent molecules and the lithium metal. Combining these electrolytes with high capacity cathodes and proper cell design, practical pouch cells have been fabricated to achieve 350 to 450 Wh  $\text{kg}^{-1}$  specific energy and stable long cycle life. Solid electrolytes offer new opportunities to better control the lithium deposition and stripping processes during charge and discharge. However, solid electrolytes and all solid state cells are difficult to fabricate and scale up. New approaches are needed to enable the solid electrolytes to have good conductivity, good mechanical property and flexibility to accommodate the electrochemical and mechanical changes at the interfaces.

**Functionalized Single-Ion Charge-Transfer Complexes as Solid-Sate Electrolytes for Lithium Batteries** Romain Kunert, Noëline Tessier, Laurent Bernard and Lionel Picard; CEA Grenoble, France

The global climate context has made us reconsider the way to generate and store energy in a more responsible way. The use of alternative renewable energy sources is tightly correlated to the development of electrochemical storage systems. A great example of this idea is with the transition away from vehicles using thermic combustion. While other technologies are slowly maturing, like hydrogen fuel cells, the golden standard in the industry remains lithium-ion batteries.<sup>[1]</sup> The rising demand for the mass production of portable electronic devices and electric vehicles now leads to new expectations.<sup>[2]</sup> To fulfill them, research is now focusing on the development of All-Solid-Sate Batteries. The replacement of the conventional liquid electrolytes by solid-state materials is expected to improve safety<sup>[3]</sup> while ensuring higher energy density with the use of lithium metal as negative electrode.<sup>[4]</sup>

Polymer-based electrolytes have gathered great attention since the first report of lithium ion conductivity in poly(ethylene oxide) in the 1970s.<sup>[5]</sup> Despite different upsides, these types of materials still show some limitations, especially considering ion conductivity at ambient temperatures. More recently, organic charge-transfer complexes (CTCs) have shown promising super-ionic conductivity in the solid-state at room temperature by associating a donor-acceptor organic couple with a lithium salt.<sup>[6]</sup> This specific chemical structure holds great potential to tune their electrochemical properties by changing the different partners (acceptor, donor and Li salt) and their molar ratios in the CTC.

In this work, we proposed to functionalize charge-transfer complexes to develop single-ion materials, expected to enhance mechanical and electrochemical properties for solid-state batteries.<sup>[7]</sup> We studied the covalent graphing of polyphenylene polymers with different anions derived from lithium salts

conventionally used to develop solid-state electrolytes. We also used these types of single-ion polymers to develop charge-transfer complexes and analyzed their electrochemical properties. The ionic conductivity and lithium transport number of our functionalized CTC electrolytes was compared to the state-of-the-art CTC conducting materials. We finally offer to rationalize plausible conduction mechanisms in our materials and in the conventional CTC systems that is still in debate today.

**Measuring Free Volume and Li-Salt Dissolution of the Polymer in Composite Electrolytes** Sara C. Sand<sup>1</sup>, Jennifer L. Rupp<sup>2,1</sup> and Bilge Yildiz<sup>1</sup>;

<sup>1</sup>Massachusetts Institute of Technology, United States; <sup>2</sup>Technische Universität München, Germany

Ceramic and Polymer electrolytes are the two categories of materials that have emerged to replace flammable electrolytes in Li-ion batteries. Composite electrolytes, typically in the form of dispersed ceramic particles or nanowires in polymer matrix, combine these two materials to have good ionic conductivity while maintaining the mechanical properties of the polymer. Despite achieving relatively high levels of conductivity (typically 10-4 S/cm), the underlying mechanism governing ion conduction in these composite electrolytes remains inadequately elucidated.

The polymer likely plays a crucial role as the ceramic volume fractions are typically under 20 vol. %.<sup>2,3</sup> Three possible ways that polymers could increase in conductivity in the composite have been identified: decreased crystallinity, increased free volume, and increased lithium ion dissolution due to acidic surface groups on the ceramic.<sup>2,4,5</sup> To explore the interface between the polymer and ceramic, we developed a thin film model system through spincoating. We observed that the conductivity of the thin film was significantly higher than that of the bulk. We utilized differential scanning calorimetry to identify probe the crystallinity and found that the small crystallinity variation could not account for the variation in conductivity. Subsequently, we utilized conductivity measurements on various ceramic surfaces to understand the effects of charge surface groups on the ceramic on polymer conductivity. X-ray Absorption measurements were similarly utilized to probe the variation in lithium ion environments within these materials to understand any variation in the lithium salt dissolution. It was found that the variation in conductivity based on this effect is small.

In order to probe the possible variation in free volume, Small Angle Neutron Scattering was utilized to quantify the free volume within thin films, bulk polymer, and composite electrolytes. This can quantify the volume associated with each monomer and therefore how much space is between polymer chains for lithium ion movement. It was found that the free volume in the thin film was significantly increased as compared to the bulk polymer. Lastly, additionally, positron annihilation is used as an additional measure small voids or measure of the distribution of free volume in these systems.

**Solid Organic Charge-Transfer Composites as Lithium-Ion Battery Electrolytes** Lingyu Yang and Jennifer L. Schaefer; University of Notre Dame, United States

Solid-state polymer electrolytes, where ion transport is facilitated by polymer chain segmental motion, for lithium-ion batteries have attracted considerable research interest because of the potential for high safety and electrochemical stability, but applications are limited by their low ionic conductivities. However, recent reports found that certain organic charge-transfer crystals could present high ionic conductivity via ion transport pathways on the crystal surfaces.[1] In our work, we reported charge-transfer complex electrolytes composed of a pair of tetrathiafulvalene-tetracyanoquinodimethane (TTF-TCNQ) complex matrix with different molar ratios of lithium bis(trifluoromethylsulfonilymide) (LiTFSI).[2] It was found that thermal annealing and water vapor treatment can impact charge transport properties of charge-transfer complex electrolytes. Trace water promoted the dissociation of LiTFSI, resulting in the electrolyte with 1-1-2-0.45 molar ratio of TTF-TCNQ-LiTFSI-H<sub>2</sub>O showing an ionic conductivity of  $2 \times 10^{-3}$  S/cm at 25 °C with electronic conductivity as low as  $1 \times 10^{-7}$  S/cm at the same temperature. By further fabrication of similar charge-transfer composite electrolytes lacking water, the performance of full cells will be investigated.

**Strategies to Improve the Electrochemical Properties of Single-Ion Conductive Polymer Electrolytes** Liangliang Li, Kaihua Wen and Ce-Wen Nan; Tsinghua University, China

Solid electrolytes are the key materials used in solid-state batteries with a high energy density and good safety. Among various solid electrolytes, polymer-based electrolytes are attracting a lot of research interest due to the advantages of flexibility, low cost and easiness for mass production. Traditional polymer-based electrolytes use dual-ion Li salts such as LiPF<sub>6</sub>, LiClO<sub>4</sub>, LiTFSI, et al., and they have a low Li-ion transference number, leading to unwanted polarization and side reactions in solid-state batteries. Recently, single-ion conductive polymer electrolytes (SICPEs) with a Li-ion transference number close to one have been widely studied. One of the challenges for SICPEs is to achieve both high ionic conductivity and wide electrochemical stability window. In this talk, we are going to present two strategies to enhance the electrochemical properties of SICPEs. First, we precisely regulate the ion-dipole interactions in an SICPE containing carbonyl and cyano groups. The resulting SICPE shows a Li-ion transference number of more than 0.9, a large ionic conductivity of 10<sup>-4</sup> S cm<sup>-1</sup>, a wide electrochemical stability window of more than 4.5 V, and an excellent electrochemical compatibility with Li metal. Second, we prepare a composite electrolyte by adding garnet ceramic nanoparticles into the SICPE. Due to the interactions between the garnet active fillers and the SICPE, the key electrochemical properties such as the Li-ion transference number, electrochemical stability window, and ionic conductivity are all further improved. Based on the high-performance SICPEs above, both LiFePO<sub>4</sub> and LiCoO<sub>2</sub>-based solid-state batteries demonstrate good rate performance and a long cycle life at room temperature. In summary, regulating the ion-dipole interactions in single-ion conductive polymers and synthesizing ceramic/polymer composite electrolytes are effective strategies to improve the electrochemical properties of SICPEs.

#### 11:15 AM DISCUSSION TIME

##### 11:30 AM EN02.04.10

**Mechanistic Investigation of Superionic Conduction in Halide Solid Electrolytes** Zhantao Liu<sup>1</sup>, Alex Chien<sup>2</sup>, Shuo Wang<sup>3</sup>, Yifei Mo<sup>3</sup>, Jue Liu<sup>2</sup> and Hailong Chen<sup>1</sup>; <sup>1</sup>Georgia Institute of Technology, United States; <sup>2</sup>Oak Ridge National Laboratory, United States; <sup>3</sup>University of Maryland, United States

Halide-based solid electrolytes, such as Li<sub>3</sub>MX<sub>6</sub> (M=Y, Sc, etc., X=halogen), are attracting great attention in the field of solid state Li-ion batteries owing to their good compatibility with high-voltage cathodes and high room temperature conductivities. In our recent research, we found that many halides, such as Li<sub>3</sub>YCl<sub>6</sub>, show a type-II superionic transition, where their diffusion energy barrier is significantly lowered once the temperature is raised above the transition point T<sub>c</sub>. It is therefore interesting to explore the mechanism of this transition to further understand this class of materials and design better solid electrolytes. We systematically characterized the detailed crystal structures of a series of halides using variable temperature high-resolution synchrotron X-ray and neutron diffractions and refinements, and AIMD computations. A novel mechanism that explains this superionic transition in halides is proposed and supported by the experimental results. The new finding will help us to design better halide electrolytes with higher conductivity and lower activation energy, and thus facilitate the development of solid state Li-ion batteries.

**Experimental Mechanical Investigation of Composite Cathode for Enhanced Performance in All-Solid State Batteries** Howard Qingsong Tu; Rochester Institute of Technology, United States

All-solid-state-batteries (ASSBs) are leading the way in safer and more efficient energy storage. This study investigates the macro-scale mechanical properties of cathode active material (CAM) and solid electrolyte (SE) components in ASSBs. Through compression testing, we analyze CAM and SE materials—LiNi<sub>0.8</sub>Mn<sub>0.1</sub>Co<sub>0.1</sub>O<sub>2</sub>, Li<sub>6</sub>PS<sub>5</sub>Cl, Li<sub>3</sub>YCl<sub>6</sub>, Li<sub>3</sub>YBr<sub>3</sub>Cl<sub>3</sub>, and Li<sub>7</sub>La<sub>3</sub>Zr<sub>2</sub>O<sub>12</sub>. We examine the effects of fabrication pressure and CAM-to-SE weight ratio on elastic modulus, bulk modulus, yield strength, and deformation. Our study bridges the gap in understanding the macro scale mechanical properties, contributing to advancements in ASSB technology. Understanding the mechanical properties of composite cathodes will enable us to develop strategies to mitigate issues such as solid-electrolyte debonding and capacity loss, leading to improved battery performance, stability, and lifespan. The findings of this study have the potential to drive the design and development of more efficient and reliable ASSBs. **Experimental Mechanical Investigation of Composite Cathode for Enhanced Performance in All-Solid State Batteries**

**High-Performance Solid-State Electrolytes: Ultra-Fast High Temperature Sintering (UHS) Oxides and Expanded Cellulose** Liangbing Hu; University of Maryland, United States

We recently reported an ultrafast high temperature sintering (UHS) for solid state electrolytes (Science, 2020, May Cover). The long sintering time of conventional syntheses can lead to Li loss in garnet SSEs caused by the evaporation of Li and the formation of secondary phases that lead to lower ionic conductivity. In contrast, the UHS technique enables us to tune the sintering time in units of seconds, which provides excellent control in terms of the Li content and grain growth. I will discuss our progress on applying UHS method to sintering various solid-state electrolyte, from compositions to microstructures. By programming the temperature and time (T-t), we can establish process diagrams to sinter porous vs. dense structures. The rapid sintering also allows us to sintering multilayer solid-state electrolytes with significantly reduced interlayer diffusion.

In a separated topic, I will discuss a general design strategy for achieving one-dimensional (1D), high-performance polymer solid-state ion conductors through molecular channel engineering, which we demonstrate via Cu<sup>2+</sup>-coordination of cellulose nanofibrils. The cellulose nanofibrils by themselves are not ionic conductive; however, by opening the molecular channels between the cellulose chains through Cu<sup>2+</sup> coordination we are able to achieve a Li-ion conductivity. This improved conductivity is enabled by a unique Li<sup>+</sup> hopping mechanism that is decoupled from the polymer segmental motion. Also benefitted from such decoupling, the cellulose-based ion conductor demonstrates multiple advantages, including a high transference number (0.78 vs. 0.2–0.5 in other polymers<sup>2</sup>), low activation energy (0.19 eV), and a wide electrochemical stability window (4.5 V) that accommodate both Li metal anode and high-voltage cathodes. Furthermore, we demonstrate this 1D ion conductor not only as a thin, high-conductivity solid-state electrolyte but also as an effective ion-conducting additive for the solid cathode, providing continuous ion transport pathways with a low percolation threshold, which allowed us to utilize the thickest LiFePO<sub>4</sub> solid-state cathode ever reported for high energy density (Nature, Oct 22).

##### 2:00 PM \*EN02.05.02

**Liquid-Phase Synthesis of Sulfide Solid Electrolyte: Achieving Extended Composition Ranges and Minimized Carbon Impurities for All-Solid-**

**State Batteries** Yoon Seok Jung; Yonsei University, Korea (the Republic of)

Advancements in all-solid-state battery (ASSB) technology, featuring non-flammable inorganic solid electrolytes, are gaining significant traction, mainly due to their promise of increased safety and energy density compared to traditional lithium-ion batteries, which rely on flammable organic liquid electrolytes. A key focus of this evolution towards practical ASSBs is the development of sulfide SEs (SSEs), recognized for their exceptional ionic conductivities (reaching up to  $\sim 10^{-2}$  S  $\text{cm}^{-1}$ ) and their ability to be mechanically sintered. Additionally, the employment of wet-chemical synthesis or processing methods for SSEs unlocks intriguing opportunities for the future advancement of ASSB technologies. However, thus far, the number of viable precursor-solvent combinations for the liquid-phase synthesis of SSEs remains limited, primarily due to the solubility constraints of metal chalcogenide precursors such as  $\text{MS}_2$  ( $\text{M} = \text{Ge}, \text{Sn}$ ). This limitation hinders the wet-chemical route for synthesizing metal-inclusive compositions like  $\text{Li}_{10}\text{GeP}_2\text{S}_{12}$ . Furthermore, the liquid-phase synthesis of SSEs often leaves significant amounts of organic residues derived from organic solvents, leading to the carbonization issue, which could instigate harmful side reactions or self-discharge when used in ASSB cells.

In this presentation, we report on our recent results in developing liquid-phase synthesis strategies for SSEs that extend the compositional availability while minimizing carbon impurities. By leveraging amine-thiol chemistry, metal sulfide precursors can participate in the liquid-phase synthesis alongside conventional precursors of  $\text{Li}_2\text{S}$ ,  $\text{P}_2\text{S}_5$ , and  $\text{LiX}$  ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ). Moreover, we introduce a novel heat treatment method that results in near carbon-free SSE products derived from liquid-phase synthesis. These developments hold promising potential for significantly enhancing the electrochemical performance of ASSBs.

**Ion-Exchange in Solid Electrolytes to Induce Compressive Stress and Improve Electrochemical Performance** Sydney Morris<sup>1</sup>, Harsh D. Jagad<sup>1</sup>, Stephen J. Harris<sup>2</sup>, Changmin Shi<sup>1</sup>, Matthew Fang<sup>1</sup>, Yue Qi<sup>1</sup> and Brian W. Sheldon<sup>1</sup>; <sup>1</sup>Brown University, United States; <sup>2</sup>Lawrence Berkeley National Laboratory, United States

There is continued interest in improving the electrochemical performance of the solid electrolyte (SE) lithium lanthanum zirconium oxide (LLZO) by preventing lithium (Li) filaments from penetrating the SE. This study builds upon a model that analyzed the impact ion-exchange (IX) has on Li transport through LLZO [1]. While IX is a common practice to strengthen glass, and has even been used with glass solid electrolytes, this work presents the first attempt to apply the IX process to LLZO in order to induce compressive stress at the surface and delay the penetration of Li filaments [2]. A wide variety of ion-exchange conditions were investigated, and the resulting materials were characterized with a scanning electron microscope (SEM), electron-dispersive X-ray spectroscopy (EDS), X-ray diffraction (XRD), electrochemical impedance spectroscopy (EIS), and critical current density (CCD) experiments using symmetric Li cells. Comparisons with control samples were used to elucidate the impact of processing conditions on critical current density, stress at the surface of the SE pellet, and the LLZO surface structure. The results demonstrate that improved CCDs are possible, but that a variety of phenomena can complicate the ion-exchange process and lead to reduced ionic conductivity and chemical degradation of the LLZO.

**The Impact of Interface layer on Li Plating and Stripping Morphology** Yue Qi; Brown University, United States

Li metal is the preferred anode material for high energy Li batteries. However, stable plating and stripping of Li metal in both liquid and solid electrolytes remain a significant challenge, particularly at practically feasible current densities. This Li/electrolyte interface is further complicated by a complex solid electrolyte interface (SEI). The electronic, ionic, and mechanical properties of the Li/SEI interface can significantly change the Li plating and stripping morphology.

A Density Functional Theory (DFT) informed phase-field method was developed to integrate electrochemistry with mesoscale plating morphology. It revealed that the Li intergranular growth in  $\text{Li}_7\text{La}_3\text{Zr}_2\text{O}_{12}$  solid electrolytes originated from the trapped electrons at grain boundaries and internal surfaces. This phenomenon is material specific, as several other key solid electrolytes do not trap electrons at grain boundaries or internal defects. [1]

The lithium stripping process generates vacancies, which may accumulate as voids and lead to uneven current distribution and dendrite growth in the following plating cycles. A stack pressure is typically required during stripping, causing large scale lithium metal creep. Here, we captured the multiple length and time scales by combining interface interactions with DFT simulations, vacancy hopping with kinetic Monte Carlo (KMC), and plastic deformation with continuum simulations. Generally lithiophilic interface requires less stack pressure to maintain a flat surface while a higher stack pressure is needed at lithiophobic interfaces to accelerate Li vacancy diffusion into the bulk and maintain a flat surface. This critical stack pressure needs to be high enough to alter the Li forward-and-backward hopping barriers at the interface. This multiscale simulation scheme illustrates the importance of including the chemical-mechanical effects during Li stripping morphology evolution. [2,3]

**Chemo-Mechanical Regulation of Li Intrusion in Garnet Solid Electrolytes via Ultra-Thin Metallic Coating** Xin Xu<sup>1,2</sup> and William C. Chueh<sup>1,2</sup>; <sup>1</sup>Stanford University, United States; <sup>2</sup>SLAC National Accelerator Laboratory, United States

Solid electrolytes in rechargeable lithium-metal batteries are prone to lithium-metal short-circuiting during plating, and the underlying cause is not well understood. The growth of lithium-metal, termed as "Li intrusions," within the solid electrolyte can lead to surface cracks and short-circuiting during battery charging process. In our previous research<sup>1</sup>, we have determined that the root cause of lithium intrusion into the electrolyte is a combination of current focusing and the presence of nanoscale cracks, rather than electronic leakage or electrochemical reduction.<sup>2</sup> These insights highlight the mechanical tunability of electrochemical plating reactions in brittle solid electrolytes.<sup>3</sup>

In this study, we propose a chemo-mechanical approach to control Li intrusions in a leading solid electrolyte,  $\text{Li}_{6.6}\text{La}_3\text{Zr}_{1.6}\text{Ta}_{0.4}\text{O}_{12}$  (LLZO), through the use of ultra-thin nanoscale metallic coatings. Specifically, we apply a nanoscale metallic Ag coating on the LLZO surface and anneal it at various elevated temperatures without air exposure. The coated and annealed surface demonstrates enhanced tolerance to Li intrusion, particularly under high local stress, as confirmed by operando SEM plating. Compared to the pristine LLZO surface, the coated surface exhibits a local current density that is three times higher, a charge density that is 25 times higher, and a total charge of Li plating that is 1400 times higher. Depth profiling using nanoscale secondary ion mass spectrometry (NanoSIMS) indicates that Ag may diffuse into the subsurface of LLZO, showing no discernible differences in the location of grain interior or grain boundaries. Furthermore, in-situ XPS experiments reveal that the oxidation state of the Ag coating on LLZO transitions from metallic Ag to oxidized Ag. These observations suggest that Ag likely induces chemical antisite defects on the surface of LLZO. In-situ nanoindentation experiments demonstrate that the mechanical strength of the coated surface surpasses that of the pristine surface. Finite element method (FEM) simulations indicate that the generated antisite defects introduce additional surface compressive strain due to the larger ionic radius of Ag compared to Li, thereby suppressing the probability of Li intrusion. Our research indicates the potential of chemo-mechanical regulation of Li intrusion in solid electrolytes through the use of chemical defects. These new findings suggest that nanoscale coatings may be sufficient to tune electrochemical Li plating reactions, making it feasible for cost-effective, large-scale engineering and manufacturing of interfaces in solid-state batteries.

**Direct Observations of Dendrite-Induced “Subcritical” Cracking in Oxide Solid Electrolytes** Cole D. Fincher<sup>1</sup>, W. Craig Carter<sup>1</sup>, Brian W. Sheldon<sup>2</sup> and Yet-Ming Chiang<sup>1</sup>; <sup>1</sup>Massachusetts Institute of Technology, United States; <sup>2</sup>Brown University, United States

Dendrite-induced short circuits threaten the deployment of solid-state batteries with metal anodes. Dendrites grow from the anode due to plating-induced pressure and subsequent fracture of the electrolyte. Whether electrochemical activity within the electrolyte aids that fracture process has remained a topic of debate. For oxide solid-electrolytes, we address this issue by conducting operando photoelastic microscopy to directly observe the stress fields around dendrites under dynamic electrochemical loading. From this data, we measure the thermodynamic driving force for fracture (i.e., the stress intensity factor, a measure of apparent surface energy) as a function of applied potential. These experiments reveal dendrite growth under “subcritical” conditions, meaning that the stress intensity factor during propagation is less than should be expected based on linear elastic fracture theory. We discuss these results in the context of historical subcritical cracking due to corrosive action. Finally, we develop a mechanistic framework to connect the observations here with expected behavior in sandwich-style cell formats.

**Dendrite Growth in Lithium Metal Solid-State Batteries** Dominic Melvin<sup>1</sup>, Ziyang Ning<sup>1</sup>, Guanchen Li<sup>2</sup>, T. J. Marrow<sup>1</sup>, Charles W. Monroe<sup>1</sup> and Peter Bruce<sup>1</sup>; <sup>1</sup>University of Oxford, United Kingdom; <sup>2</sup>University of Glasgow, United Kingdom

Solid-state batteries which combine both a lithium anode and ceramic solid electrolytes promise a step change in cell energy density. However, there are significant challenges to charging and discharging these cells at high current densities in the range of several  $\text{mA cm}^{-2}$ . At high rates of charge, dendrites (filaments of lithium metal) are observed to crack through ceramic electrolytes, leading to critical failure of the cell. The realisation of solid-state batteries with lithium metal anodes therefore depends on understanding how a soft metal such as Li can induce fracture of a stiff ceramic electrolyte.

Using a combination of X-ray computed tomography and FIB-SEM we have made observations which reveal both how Li dendrites crack  $\text{Li}_6\text{PS}_5\text{Cl}$  electrolytes and how these dendrite-cracks propagate across the solid electrolyte. We have made the finding that dendrite-cracks propagate whilst partially filled, driven by Li at the back of the crack not the tip. This has enabled advances in understanding dendrites in ceramics and the factors that influence then and their progression to a short-circuit.

**Dilatometric Measurement of Pore Volume During Stripping of Metal Electrodes in Solid-State Batteries** Thomas Schall, Till Fuchs, Jill Kessler, Klaus Peppeler, Joachim Sann, Boris Mogwitz and Jürgen Janek; Justus Liebig University Gießen / Institute for Physical Chemistry, Germany

Solid-state batteries may allow the use of a lithium metal anode (LMA), enabling a significant increase in energy density. However, morphological challenges such as dendrite growth and contact loss of the LMA during cycling limit the available capacity. The formation of resistive pores occurs when the local current density exceeds the effective diffusion of vacancies within the LMA, leading to a vacancy accumulation (1,2). Therefore, external pressure can mitigate pore formation by inducing plastic deformation of the lithium metal (1). To address the limitations imposed by pore formation, a deeper understanding is required.

This work employs a novel dilatometric measurement setup providing a precision of  $< 1$  nm for measuring height changes, maintaining precise constant pressure, and facilitating the metrological separation of one electrode. As pore formation leads to non-uniform removal of lithium, resulting in the formation of indentations (pores) due to adatom diffusion (1), the overall height reduction during operation is decreasing. Despite a continuous amount of lithium being stripped, our setup can therefore detect the onset of pore formation.

The dilatometer is employed to measure the changes in height during both pore-free uniform stripping and stripping with pore formation in a  $\text{Li}|\text{LLZO}|\text{Li}$  model system. From the difference between the height change of uniform stripping and stripping with pore formation, the pore volume can be determined

and related to GEIS and PEIS measurements. Using this approach, the pore volume is determined for different current densities and pressures, providing a comprehensive understanding of the pore formation under varying conditions. To complement the results, the pores at the stripping electrode are analyzed post-mortem using scanning electron microscopy (SEM). The measured data allow new insights into the morphology of pore formation.

**Solvent-Free Single-Ion Conducting Polymer Electrolytes for Lithium Metal Batteries under Harsh Environments** Jingyi Gao and Dong-Myeong Shin; The University of Hong Kong, Hong Kong

Rechargeable lithium-ion batteries are widely used in consumer applications. However, these batteries are limited in their ability to function under extreme thermal environments, such as high temperatures, which are required for medical devices requiring sterilization and various industries like subsurface exploration and thermal reactors. However, the conventional lithium-ion batteries have limited high-temperature performance due to material properties that lead to safety concerns or low power usage. Many efforts have focused on developing solvent-free single-ion conducting (SIC) polymer electrolytes to solve these issues by covalently immobilizing anionic groups onto a polymer backbone, which only allows  $\text{Li}^+$  cations to be mobile through the polymer matrix, leading to minimal dendrite growth during charging/discharging process. While the SIC polymer electrolytes hold much promise for next-generation batteries possessing high safety and high energy density, this approach typically yields a significant drop of ionic conductivity ( $<10^{-5} \text{ S cm}^{-1}$  at ambient temperature), compared to liquid electrolytes. Quasi-solid or gel polymer electrolytes incorporating organic plasticizers have been employed to enhance the ionic conductivities, but their practical implementation is still constrained by their vulnerability to thermal runaway under high-temperature circumstances. Herein, we present a novel approach for the one-step synthesis of a solvent-free single-ion perfluorinated-tetraphenylborate-anions membrane via click reaction. The resulting flexible membrane displays exceptional cyclability performance at high temperatures, high lithium selectivity ( $\sim 0.932$ ), and a wide working window (up to 5 V). The one-step synthesis of the membrane exhibits a high ionic conductivity ( $\sim 3 \times 10^{-5} \text{ S cm}^{-1}$ ) at  $88^\circ\text{C}$  due to its consistent structure. Notably, the membrane demonstrates superior non-flammability properties. Furthermore, the membrane can operate under large temperature ranges from  $60$  to  $120^\circ\text{C}$ , even under negative pressure, making it suitable for a variety of applications. Remarkably, stable long-term cycling of  $\text{LiFePO}_4$  cathodes can be achieved at  $100^\circ\text{C}$  with a coulombic efficiency of approximately 100% over 300 cycles at 0.5C.

#### 8:00 PM EN02.07.03

**Long Cycling Performance of the All-Solid-State Lithium-Ion Batteries using Modified Silicon Anodes** Minjae Kim<sup>1</sup>, JunHyeok Seo<sup>2</sup>, Dahee Song<sup>2</sup> and Kuk Young Cho<sup>1</sup>; <sup>1</sup>Hanyang University(ERICA), Korea (the Republic of); <sup>2</sup>Hanyang University, Korea (the Republic of)

The continuous growth of electric vehicles and energy storage systems has increased demand for lithium-ion batteries (LIBs) that offer both safety and high energy density. Consequently, research on next-generation LIBs with high energy density has expanded, focusing on new electrode materials such as lithium metal, high-nickel ternary cathodes, sulfur cathodes, and silicon anodes. Particularly, silicon anodes offer superior capacity compared to the conventional graphite anodes used in commercial LIBs, along with the advantages of low electrode potential and abundant resources. However, challenges remain due to the volume expansion of silicon anodes and the unstable form of the solid electrolyte interphase (SEI), which affects their cycling performance.

All-solid-state lithium-ion batteries (ASSLBs) are an up-and-coming solution for achieving safety and high energy density by eliminating issues related to liquid electrolyte leakage and fire hazards. Furthermore, applying silicon anodes in ASSLBs can serve as a viable means to overcome the limitations of conventional LIBs while suppressing silicon's volume expansion through solid electrolytes, thereby addressing the drawbacks associated with silicon anodes. Therefore, ASSLBs and silicon anodes offer highly promising alternatives to overcome the limitations of conventional LIBs and silicon anodes. However, further research is required to address potential issues that may arise from applying silicon anodes and ASSLBs.

In this study, we fabricated ASSLBs using silicon anodes and sulfide-based solid electrolytes. We investigated the degradation characteristics of silicon anodes in ASSLBs with silicon thin-film electrodes and confirmed the performance enhancement of modified silicon anodes.

**Stable 4 V-Class All-Solid-State Lithium Battery with Hydroborate Electrolyte and NMC811 Cathode** Hugo Braun, Ryo Asakura, Edouard Querel, Corsin Battaglia and Arndt Remhof; Empa - Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Solid-state batteries are expected to extend the energy and power density beyond the limits of lithium-ion batteries, and to replace their flammable liquid electrolytes with safer alternatives. Each of the most studied solid electrolyte materials has disadvantages such as limited electrochemical stability (sulfides), low ionic conductivity (polymers), mechanical stiffness (oxides) or incompatibility with metallic anodes (halides). Complex hydride electrolytes, especially hydroborates, combine many attractive characteristics such as high ionic conductivity, compatibility with alkali metal anodes and soft mechanical properties. Some of us recently reported stable 3 V and 4 V all-solid-state sodium hydroborate batteries. Lithium hydroborate solid-state batteries offer the potential to use cathodes with much higher specific discharge capacity, but have so far been limited to low-voltage cathodes such as sulfur or  $\text{TiS}_2$  due to the limited oxidative stability of the electrolyte. Herein, we demonstrate all-solid-state lithium metal batteries employing a hydrocarborate solid electrolyte with a 4 V-class  $\text{LiNi}_{0.8}\text{Mn}_{0.1}\text{Co}_{0.1}\text{O}_2$  (NMC811) cathode. This is achieved by tailoring the  $\text{LiCB}_{11}\text{H}_{12}$ - $\text{LiCB}_9\text{H}_{10}$  electrolyte mixing ratio towards high oxidative stability ( $\sim 3.9 \text{ V}$ ), while maintaining high conductivity ( $>1.5 \text{ mS cm}^{-1}$  at room temperature). Unlike many other stable solid-state cells, we use one single electrolyte material in contact with the lithium metal, as the separator layer and in the cathode composite. Corresponding cells with lithium metal anodes display a high discharge capacity of  $175 \text{ mAh g}^{-1}$  and stable cycling, demonstrating the potential of hydroborate electrolytes for 4 V-class solid-state lithium metal batteries.

**Functional Design and Investigation of Mg-Ion Conductors for Solid-State Mg Batteries** Zhixuan Wei and Jürgen Janek; Institute of Physical Chemistry & Center for Materials Research, Justus Liebig University Giessen, Germany

Secondary batteries using multivalent cations as charge carrier have attracted increasing attention in recent years due to the high theoretical energy density given by multi-electron redox reactions. Nevertheless, the large charge density of these cations inevitably causes sluggish kinetics of the ion migration under room temperature, which is challenging for the development of multivalent-ion solid-state batteries.<sup>[1]</sup> Taking  $Mg^{2+}$  as a case study, we investigated a series of functional materials to figure out the design principle for Mg-ion solid-state conductors. First of all, an ionogel electrolyte using a MOF (metal-organic framework) as skeleton was prepared.<sup>[2]</sup> An ionic liquid was incorporated into UiO-66, which has a large inner surface area as well as a rich porous structure. Comparably high ionic conductivities of  $5.7 \times 10^{-5} \text{ S cm}^{-1}$  and  $2.4 \times 10^{-4} \text{ S cm}^{-1}$  could be achieved at room temperature and at mildly elevated temperature (60 °C), respectively. Apart from the good ionic conductivity, the prepared electrolyte also exhibits good chemical and electrochemical stability against magnesium metal. By pairing the magnesium metal anode with an aromatic organic material as cathode material, a proof-of-concept quasi-solid-state Mg battery can work reversibly at 60 °C. Secondly, we replaced the ion-insulating MOF framework by a new Mg-ion conducting NASICON-structured material,  $Mg_{0.5}Sn_2(PO_4)_3$ . By combining it with a small amount of Mg ionic liquid to improve the  $Mg^{2+}$  migration at grain boundary, the prepared Mg-ion conducting hybrid solid electrolyte shows superior room-temperature ionic conductivity of  $1.1 \times 10^{-4} \text{ S cm}^{-1}$  and an activation energy of 0.36 eV. Through in situ scanning electron microscopy, for the first time we observed the room temperature Mg growth inside a solid-state cell by the evidence of clear-cut metal particle formation and electrolyte particle cracking. The results shown here can act as a good starting point for the understanding of Mg transport behavior in solid-state batteries.

**Mechanism of High Li-Ion Conductivity in Li-Excess Garnet  $Li_{7-x}La_xSr_zZr_2O_{12}$**  Masahide Kaneko<sup>1,2</sup>, Kakeru Ninomiya<sup>1</sup>, Tomoko Hishida<sup>2</sup>, Yuki Takeuchi<sup>2</sup>, Kazushi Otani<sup>2</sup> and Maiko Nishibori<sup>1</sup>; <sup>1</sup>Tohoku University, Japan; <sup>2</sup>Niterra Co., Ltd., Japan

$Li_7La_3Zr_2O_{12}$  (LLZO) is a promising solid electrolyte for all-solid-state batteries, and various dopants have been investigated to improve its conductivity. However, the dopants have mainly been studied to increase the conductivity by reducing the amount of  $Li^+$ , and dopants that increase the amount of  $Li^+$  have yet to be studied. Therefore, the structure of LLZO with excess  $Li^+$  and its function as an electrolyte need to be clarified. Here, we report on the correlation between the conductivity and the structure of LLZO with excess  $Li^+$  by partial substitution of Sr at the La sites. Sr-doped LLZO sintered pellets were prepared by solid-state reaction method. The sintered pellets exhibit high conductivity of up to  $5.7 \times 10^{-4} \text{ S/cm}$  at room temperature, indicating a promising material as a solid electrolyte. Sr *K*-edge XANES spectra confirmed that Sr was located at the La sites of the LLZO. The crystal structure of Sr-substituted LLZO was measured by X-ray diffraction and neutron diffraction, and the results showed that the crystal structure of LLZO continuously changes from tetragonal to cubic with increasing the amount of Sr substitutions. At the same time, the  $Li^+$  arrangement was also changed, with  $Li^+$  occupying some tetrahedral sites that are vacant in the unsubstituted LLZO. The local structure of Sr-substituted LLZO was discussed from Zr *K*-edge and La *K*-edge XANES. La *K*-edge XANES spectra did not change with Sr substitution, while Zr *K*-edge XANES spectra showed a spectral change corresponding to the amount of Sr substitution. This result suggests that the crystal structure change of Sr-substituted LLZO is not the result of the homogeneous deformation of the entire structure but is mainly due to the deformation of the Zr sites, which are unsubstituted. The above results suggest that the high conductivity of Sr-substituted LLZO is due to multiple factors: the change in the  $Li^+$  arrangement and the change in the  $Li^+$  conduction pathway due to the local structure deformation. Our results contribute to a better understanding of the correlation between the structure and properties of LLZOs in Li excess compositions and the development of higher-performance electrolytes.

**Understanding the Role of Powder Protective Layers on the Chemical Reactivity of Sulfide-Based Solid Electrolytes in All-Solid-State Batteries** Taewoo Kim, Udochukwu D. Eze, Zachary D. Hood, Anil U. Mane, Jeffrey W. Elam and Justin Connell; Argonne National Lab, United States

Sulfide-based solid-state electrolytes (SSE) are a promising class of materials to enable high-performance, all-solid-state Li-ion batteries due to 1) their favorable mechanical properties for processability at scale and 2) comparable Li-ion conductivities to conventional liquid electrolytes. However, their poor atmospheric stability remains a challenge toward commercial manufacturing processes as environmental moisture and oxygen content, even in dry room environments, are sufficient to degrade sulfide-based SSEs. To circumvent these limitations, we previously developed thin (~1 nm)  $Al_2O_3$  coatings grown directly on  $Li_6PS_5Cl$  (LPSCl) powders via atomic layer deposition (ALD). Through this approach, we successfully demonstrated substantial suppression of the chemical reactivities of the coated LPSCl under aggressively oxidizing conditions as compared to the uncoated LPSCl. In this work, we provide a comprehensive investigation to understand the role of ALD alumina protective layers on the environmental reactivity of LPSCl utilizing pellets pressed from coated and uncoated powders. Thermogravimetric analysis indicates significantly suppressed weight gain from powders and pellets made from coated versus uncoated materials after exposure to humidified  $O_2$ , demonstrating the effectiveness of the ALD coating strategy in suppressing environmental reactivity regardless of material form factor. Surprisingly, X-ray photoelectron spectroscopy shows little to no changes in the surface chemistry on the uncoated LPSCl surface while the coated LPSCl exhibits a trace of the surface oxidation upon exposure to oxidizing conditions, suggesting that the surface oxidation products of LPSCl are volatile and evaporate under ultra-high vacuum conditions. Correlative X-ray and vibrational spectroscopic and diffraction analysis will be utilized to expand upon the mechanisms by which powder coatings stabilize LPSCl to environmental reactivity and the specific changes in the surface chemistry and the corresponding chemical reactivities. These results provide a clear pathway to enabling stable precursor powder materials with favorable properties for processing at scale in realistic manufacturing environments.

**8:00 PM EN02.07.10**

**Porous Silicon-Based Anodes for Extreme Temperatures** Morteza Sabet<sup>1</sup>, Mihir Parekh<sup>1</sup>, Yi Ding<sup>2</sup>, Srikanth Pilla<sup>1</sup> and Apparao M. Rao<sup>1</sup>; <sup>1</sup>Clemson University, United States; <sup>2</sup>U.S. Army DEVCOM GVSC, United States

Primary lithium thionyl chloride batteries are common power sources for applications requiring extreme temperature windows. However, the peak performance of these non-rechargeable batteries is between 20 °C and 55 °C. Advancing lithium-ion batteries (LIBs) with robust electrodes and proper electrolyte formulation for high temperatures (>50 °C) would offer rechargeability, higher power capability, and reduced toxicity. Common LIB anode materials, such as silicon (Si), rely on forming solid-electrolyte interphase (SEI) as an effective passivation layer to operate properly. Damages to these

surface structures would render the interfaces vulnerable at elevated temperatures. The chemical composition and morphological evolution of the SEI strongly depend on the electrolyte used. In the presence of organic electrolytes, the exposure of Si to elevated temperatures leads to a fast SEI thickening and capacity loss. Ionic liquids exhibit a wide electrochemical potential stability up to 5.0 V, high thermal stability (>300 °C), and moderate Li ion conductivity at room temperature. The use of ionic liquids in combination with appropriate additives could be an ideal solution to stabilize the SEI at high temperatures. In the current study, we demonstrated the potential of Si nano-quills (SiNQs), a porous Si-based material with elemental Si pockets distributed in a matrix of Si suboxides, as the active material for high-temperature LIB anodes. Electrodes were prepared by casting the aqueous slurry of SiNQ on copper foil, followed by hot rolling to a desired density. Half cells were prepared using SiNQ electrodes and a piperidinium-based ionic liquid electrolyte and cycled at 50, 60, and 70 °C. At 50 °C, the SiNQ anodes exhibited a reversible capacity of 225 mAh g<sub>Si</sub><sup>-1</sup> at the current rate of 0.1C (420 mA g<sub>Si</sub><sup>-1</sup>). Testing at higher temperatures of 60 and 70 °C resulted in a higher capacity of 1040 and 1240 mAh g<sub>Si</sub><sup>-1</sup>. This indicates the reduced electrolyte viscosity at higher temperatures, which can enhance the kinetics of lithiation and delithiation in the SiNQ active material.

**Utilizing High Tensile Alloys of Copper to Eliminate Mechanical Degradation in High Loading Silicon Anodes** Devashish Salpekar, Daniel Abraham, Wenquan Lu, Marco-Tulio F. Rodrigues and Stephen E. Trask; Argonne National Laboratory, United States

Silicon is a promising candidate to replace the conventionally used graphite anodes due to its high theoretical capacity (3579 mAh/g; Li<sub>3.75</sub>Si), low cost, and abundance. However, silicon undergoes huge volumetric expansion (~300%) upon lithiation, which leads to particle isolation and thus, poor cycle life. Polymeric binders such as polyacrylic acid and carboxy methyl cellulose, have been used to overcome this problem by binding with silicon particles. However, these binders do not provide a strong adhesion between the coating and the current collector, which can lead to delamination upon prolonged cycling. Recently, stronger polymeric binders (such as polyimide, polyamide, etc.) have received attention due to their improved interfacial interactions and mechanical strength, creating a cohesive silicon anode with excellent coating adhesion to the current collector. However, at higher loadings the huge volumetric changes in the silicon combined with the strong adhesive properties of binders leads to plastic deformations in the current collector, which on extended cycling can significantly wrinkle or in the worst case shred the metal foil. We are investigating high tensile alloy (HTA) copper current collector foils, which have tensile strengths that are more than double that of conventional copper foils. Due to their improved mechanical properties, these foils do not undergo plastic deformation upon silicon lithiation and prevent shredding upon continuous cycling. Electrochemical testing data suggest that at moderate silicon loadings (2.5-3 mAh/cm<sup>2</sup>), electrodeposited or rolled copper show significant wrinkling after only 5 cycles in a half-cell, whereas the HTA foils show no wrinkling. This effect increases significantly at higher loadings (>5 mAh/cm<sup>2</sup>), where the conventional copper foils show significant wrinkling after just one lithiation-delithiation cycle, while the HTA copper shows no wrinkling. By utilizing this HTA copper foils, it is possible to eliminate mechanical issues in the anode current collector, especially in high loading silicon cells with strong polymeric binders.

**Alkali-Independent Anion Redox in LiNaFeS<sub>2</sub>** Michelle Qian, Eshaan Patheria, Colin Morrell and Kimberly A. See; Caltech, United States

Batteries based on sodium ions are a promising, more sustainable alternative to the currently dominant lithium-ion battery, but have comparatively lower energy densities. One method of increasing energy density is to develop cathode materials that can undergo multielectron cation and anion redox, which we have previously observed using the layered material LiNaFeS<sub>2</sub> in a lithium cell. In LiNaFeS<sub>2</sub>, anion redox occurs through the formation of persulfide bonds that is correlated to a plateau in the galvanostatic charge curve at ~2.5 V vs Li/Li<sup>+</sup>. We now demonstrate that LiNaFeS<sub>2</sub> can also be used as a multielectron sodium cathode, although the anion-redox plateau region of the second charge curve resembles the sloping profile of a solid-solution process rather than the two-phase process reflected in a lithium cell. Inductively-coupled mass spectrometry studies verify sodium as the dominant mobile ion after first charge, correlating the difference in electrochemical behavior with the active alkali ion. Fe and S K-edge X-ray absorbance spectroscopy shows that the charge compensation mechanisms for the material in the two cell configurations are fundamentally the same. The disparate electrochemical behavior is entirely due to physical rather than electronic structural effects. Our work provides a fundamental study on the differences between Li- and Na-based anion redox in the same material.

#### 8:00 PM EN02.07.15

**A Solid-State Zinc-Iodide Battery with Zinc Dendrite Free and Long Cycle Life** Yongxin Huang, Bin Luo and Lianzhou Wang; The University of Queensland, Australia

Rechargeable zinc-iodide (ZnI<sub>2</sub>) batteries have become a popular choice for applications in aqueous batteries due to their natural abundance, intrinsic safety, and high theoretical capacity. However, in the alkaline or weakly acidic water environment of aqueous electrolytes, the hydrogen evolution reaction and the subsequent battery swelling and failure have hindered the practical application of such batteries so far. In addition, the environment of electrolyte will also promote the growth of zinc dendrites, which will not only reduce the utilization of zinc foil, but also cause the dendrites to penetrate the separator and cause a short circuit in the battery. Based on traditional zinc salts and a Perfluoropolyether (PFPE)-based polymer, an all-solid-state zinc iodide battery with solid polymer electrolyte was designed and synthesized by ion exchange. According to the results of XPS and XRD, it can be proved that this polymer solid electrolyte forms a SEI layer containing rich Fluorine on the surface of zinc to induce the horizontal growth of zinc dendrites and increase the utilization of zinc. More importantly, this induction method inhibits the possibility of continuously generated dendrites penetrating the separator and greatly extends the cycle life of the battery. In addition, it can also be proved that this solid electrolyte can also hinder the iodine ion shuttle effect, thereby reducing the corrosion of the zinc sheet and further prolonging the life of the battery. Symmetric batteries based on this electrolyte exhibit excellent cycle performance of more than 4000 hours at room temperature, and all-solid-state ZnI<sub>2</sub> batteries can be stably cycled for more than 3000 times. This work proposes a potential route to achieve stable energy storage in solid-state ZnI<sub>2</sub> batteries, and also provides new ideas for flexible and wearable Zn-based batteries.

#### 8:00 PM EN02.07.19

**Strain Effect on Li-Ion Conduction in β-Li<sub>3</sub>PS<sub>4</sub> and Garnet Al-Li/La<sub>3</sub>Zr<sub>2</sub>O<sub>12</sub> Solid Electrolytes** Pjotr Zguns, Shikha Saini and Bilge Yildiz; Massachusetts Institute of Technology, United States

Solid-state batteries offer better safety and higher energy density, yet the Li-ion conductivity of the solid electrolytes remains lower than that of liquid organic electrolytes, limiting battery charging rate and power density. The ionic conductivity of solid electrolytes can be significantly affected by strong electrochemo-mechanical coupling, especially near the electrode/electrolyte interfaces. Mechanical stresses due to volumetric electrode changes and interfacial reactions can reach as high as 1..10 GPa [1,2] and can substantially affect solid electrolyte's conductivity. However, experimental quantification of the sole strain effect is difficult as other factors such as space charge effects and interfacial reactions also contribute to conductivity. In this work [3], we have quantified the effect of strain on conductivity in bulk β-Li<sub>3</sub>PS<sub>4</sub> by means of ab initio molecular dynamics. Strain tensors that compress the c-axis increase the Li-ion diffusivity, while the strains which stretch the c-axis reduce the diffusivity. The relative change in diffusivity with 2% biaxial strain is 2-fold at 500 K and is up to 10-fold when extrapolated to room temperature. Compression of the c-axis facilitates diffusion through the increased disorder of the Li-sites in β-Li<sub>3</sub>PS<sub>4</sub>. Strain decreases the Li-Li distance and thus increases Coulomb repulsion between the bottleneck 8d and 4b sites, pushing Li to the

4c site and promoting disorder. This boosts the concentration of active Li-ion carriers, which quantitatively correlates with the changes in conductivity. The magnitude of the strain effect on Li-ion diffusion is comparable to that of chemical doping, and it is therefore important to consider strain for accurate understanding and prediction of solid-state Li-ion battery interface properties. Our findings not only provide a quantitative understanding and accurate estimates of Li-ion conductivity relevant to strained interfaces, but also a design strategy for how to increase disorder and promote superionic conduction in solid electrolytes by strain engineering. We are also extending these findings to materials that possess intrinsic Li-ion disorder such as garnet Al-doped LLZO ( $\text{Li}_7\text{La}_3\text{Zr}_2\text{O}_{12}$ ). By applying molecular dynamics simulations, we will investigate how Al-LLZO conductivity is affected by strain and whether decreasing/increasing Li–Li distances contribute to ionic disorder and conductivity in a similar fashion to  $\beta\text{-Li}_3\text{PS}_4$ .

**A Synthesis of Block Copolymers Based on Dynamic Covalent Bonds and its Application to All-Solid-State Battery Electrolyte** Sojeong Roh, Trong Danh Nguyen, Lee Hyeju, Mingyu Lee, So Hyun Park, Jun Seop Lee and Young Soo Yoon; Gachon University, Korea (the Republic of)

Recently, all-solid-state batteries (ASSB) have been in the spotlight as an alternative to potentially overcome the limitations of the existing liquid electrolyte lithium-ion batteries (LIB). Compared to liquid electrolyte LIB, ASSB has a lower risk of explosion, a higher energy density, and a relatively large electrochemical window. Solid electrolytes are largely classified into three categories: sulfide-based solid electrolytes, oxide-based solid electrolytes, and polymer-based solid electrolytes as key elements of ASSB. The most representative case among them is the lithium lanthanum zirconium oxide (LLZO), which has been extensively studied because it may easily compensate for the shortcomings of the sulfide-based solid electrolyte. Nevertheless, due to the brittleness of the ceramic-based material, it is still difficult to solve a serious interface contact problem between the electrolyte and the electrode. Therefore, many previous studies have attempted to introduce flexible polymer materials as binders to provide better wettability between solid interfaces. Specifically, ceramic-polymer composite solid electrolytes with soft interlayer in LLZO are feasible solutions that improve interfacial contact and inhibit dendrite generation in LIB. However, it is difficult to obtain sufficient ion conductivity and required mechanical properties in the polymer layer at the same time. Therefore, it is necessary to manufacture a flexible polymer membrane that can effectively promote efficient ion transport and control adhesion. This presentation proposes to synthesize a block copolymer based on a dynamic polymer chain structure and apply the material to an ASSB electrolyte. First, the disulfide (S-S) dynamic bond between the dithiol contained oligomer and PEG chain is synthesized using a disulfide generating agent (pentaerythritol tetrakis (3-mercaptopropionic acid)). The polymer solution for interlayer film is generated by adding bis (trifluoromethanesulfonyl)imide (LiTFSI). Then, a hybrid ceramic-polymer complex is manufactured using a drop casting method that introduces a block copolymer layer on the surface of garnet LLZO. As a result, the dynamic disulfide bond in co-polymer chain improves the adhesion between the solid electrolyte and the cathode as well as the anode, leading to a better contact interface and good dendrite suppression ability. That is, the lithium-ion conductive dynamic network not only lowers the overall impedance and interfacial resistance, but also increases the adhesion of the electrolyte to the electrode material. These modified polymer networks provide adequate ion conductivity and improved wettability to the interface. Through this work, it is possible to effectively develop LLZO-based solid electrolyte that improves surface properties and regulates the ion conduction mechanism.

#### 8:00 PM EN02.07.21

**Development of Von-Alpen-Type NASICON Electrolytes with High Ionic Conductivities and Relative Densities** Il-Seop Jang<sup>1,2</sup> and Jinyoung Chun<sup>1</sup>; <sup>1</sup>Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of); <sup>2</sup>Korea University, Korea (the Republic of)

The NASICON compound, represented by the chemical formula  $\text{Na}_{1+x}\text{Zr}_2\text{Si}_x\text{P}_{3-x}\text{O}_{12}$  ( $0 \leq x \leq 3$ ), exhibits a  $\text{Na}^+$  ion conductivity of approximately  $10^{-4}$  S  $\text{cm}^{-1}$  and a wide electrochemical window. It is chemically stable not only in air but also in seawater. However, the ion conductivity of NASICON compounds is relatively lower compared to typical liquid electrolytes ( $10^{-2}$  S  $\text{cm}^{-1}$ ), leading to decreased performance. In this study, a method is proposed to enhance the ion conductivity and density of vA-NASICON (von-Alpen-type NASICON) ceramic electrolytes by doping them with heterogeneous element  $\text{Mg}^{2+}$  ions. Additionally, a synthesis method utilizing a sintering aid for vA-NASICON is suggested to achieve higher ion conductivity and density at lower temperatures and shorter times.

Considering factors such as raw material cost, ion radius, and oxidation state,  $\text{Mg}^{2+}$  ions were chosen as heterogeneous element dopants compared to the  $\text{Zr}^{4+}$  ions present in NASICON compounds. The effects of Mg dopant incorporation on the modified crystal structure, surface changes, and formation of secondary phases were analyzed, and their influence on the ion conductivity of vA-NASICON was studied. The dopant precursor,  $\text{MgO}$ , can enhance the surface diffusion coefficient, increase the densification rate, and promote crystal growth. However, excessive introduction of  $\text{Mg}^{2+}$  leads to the formation of undesirable secondary phases, such as  $\text{Na}_x\text{Mg}_y\text{PO}_4$ , which results in a decrease in the ion conductivity of Mg-doped vA-NASICON. By analyzing the ion conductivity, the optimal Mg doping level was determined. The vA-NASICON synthesized with the optimal Mg doping exhibited a higher ion conductivity of  $3.64 \times 10^{-3}$  S  $\text{cm}^{-1}$  compared to undoped vA-NASICON ( $2.03 \times 10^{-3}$  S  $\text{cm}^{-1}$ ).

The introduction of Glass-frit in vA-NASICON can increase the sinterability of the ceramic matrix and lower the densification sintering temperature. vA-NASICON was prepared by solid-state reaction, and systematic investigations were conducted on crystal structure, microstructure, and electrochemical properties. Glass-frit added vA-NASICON sintered at 1200 degree for 1 hour showed a high ionic conductivity of  $2.1 \times 10^{-3}$  S  $\text{cm}^{-1}$  and a relative density of 97.2%, surpassing vA-NASICON ( $2.54 \times 10^{-3}$  S  $\text{cm}^{-1}$ , relative density 65.7%) without addition. Glass-frit is that by forming an amorphous phase at the grain boundary, it can promote grain boundary contact and promote densification of ceramic electrolyte. The results of this study are expected to be effectively utilized in the development of oxide-based solid electrolytes with high ionic conductivity and density.

**Understanding Cold Sintering Processes in Densification of Halide-Based Solid Electrolytes** Qianqian Yan, Cole D. Fincher and Yet-Ming Chiang; Massachusetts Institute of Technology, United States

Halide-based ceramics have emerged as promising candidates for solid-state Li battery applications due to their high ionic conductivity and air stability. However, their manufacture and processing pose a challenge for solid-state batteries, as conventional ceramic processing often requires elevated temperatures and pressures. In this study, we develop cold sintering processes (CSPs) for halide-based solid-state electrolytes. We enable densification of these materials below  $300^\circ\text{C}$  by studying the impact of liquid-phase additives on dissolution / reprecipitation during pressure-densification. We further explore the influence of pressure, dwell time, temperature, and precursor compositions on the electrolyte's mechanical and electrochemical properties. The systematic investigation of these parameters provides crucial insights into the underlying mechanisms governing the densification process and contributes to designing and manufacturing of ceramic solid electrolyte architectures.

**Multicomponent Protective Layers for All-Solid-State Li Metal Batteries** [Haechannara Lim](#), Seungwoo Jun, Ki Heon Baeck and Yoon Seok Jung; Yonsei University, Korea (the Republic of)

The advancement of electric vehicles has stimulated extensive research into lithium-ion batteries (LIBs) with higher energy densities and improved safety. Consequently, all-solid-state Li metal batteries (ASLMBs) have emerged as a promising alternative due to the exceptional theoretical capacity (3,860 mA h g<sup>-1</sup>) and low electrochemical potential (-3.04 V vs SHE) of Li metal anode, as well as their improved safety resulting from the utilization of nonflammable inorganic solid electrolytes (SEs) compared to conventional lithium-ion batteries employing liquid electrolytes. Especially, sulfide solid electrolytes (SEs) have been one of the most promising candidates thanks to their high ionic conductivities (maximum  $\sim 2.0 \times 10^{-2}$  S cm<sup>-1</sup>) and mechanically ductile property. Nevertheless, the implementation of ASLMBs has been hindered by the unstable interfaces between Li metal and SEs, leading to severe decomposition of sulfide SEs and the formation of dendrites. To address the challenges related to interfacial instability, researchers have proposed various materials, such as lithiophilic metals and inorganics, as protective layers for Li metal. Nevertheless, no single protective coating has achieved acceptable interfacial stability between Li metal and SEs. Recently, the concept of multi-component protective layers comprising lithiophilic metals and robust inorganic materials has been introduced. However, there remains a lack of comprehensive analysis regarding the configuration or structure of the protective layer and its influence on the performance of ASLMBs.

In this study, we present our recent investigation into the configuration of protective layers for Li metal and their impact on the performance of ASLMBs. Additionally, we discuss different mechanisms of Li metal plating and stripping based on variations in the protective layer's structure.

**8:00 PM EN02.07.24**

**Liquid-Phase Synthesis of Metal-Containing (M = Ge, Sn) Sulfide Solid Electrolytes for All-Solid-State Batteries** [Boyeong Jang](#), Jehoon Woo, Yong Bae Song, Hiram Kwak and Yoon Seok Jung; Yonsei University, Korea (the Republic of)

All-solid-state batteries (ASSBs) have been spotlighted for their potential to enhance both energy density and safety compared to conventional lithium-ion batteries that rely on organic liquid electrolytes. Sulfide solid electrolytes (SEs) are viewed as crucial components for ASSBs due to their high ionic conductivity, deformability, composition flexibility, and processability. Sulfide SEs can be prepared through either solid-state or liquid-phase synthesis. Particularly, the liquid-phase synthesis of sulfide SEs offers potential advantages for large-scale production, including product homogeneity, particle size control, and lower energy consumption. However, the compatibility and solubility challenges between precursors and solvents limit the liquid-phase synthesis of various compositions of sulfide SEs. Specifically, the poor solubility of metal chalcogenides (e.g., GeS<sub>2</sub> and SnS<sub>2</sub>) has hindered the synthesis of sulfide SEs with MS<sub>2</sub> (M = Ge, and Sn) units. Furthermore, liquid-phase synthesized SEs are often contaminated by impurities such as carbon, derived from solvent residues, which are detrimental to the performance of ASSB cells.

In this presentation, the liquid-phase syntheses of sulfide SEs with various compositions, including metals (e.g., Ge and Sn). Importantly, we report a novel heat treatment technique to address the chronic carbon impurity issue in liquid-phase synthesized SEs. Compared to SEs prepared through conventional furnace heating, SEs obtained through a new heating protocol exhibit outstanding electrochemical performance in terms of capacity and cycling stability.

**Transforming Commercial Paper into Flexible Solid Electrolyte with High-Ionic Conductivity for Durable Lithium-Sulfur Batteries** Morteza Sabet<sup>1</sup>, [Nawraj Sapkota](#)<sup>1</sup>, Mihir Parekh<sup>1</sup>, Nancy Chen<sup>1</sup>, Yi Ding<sup>2</sup>, Srikanth Pilla<sup>1</sup> and Apparao M. Rao<sup>1</sup>; <sup>1</sup>Clemson University, United States; <sup>2</sup>U.S. Army DEVCOM GVSC, United States

Solid-state lithium-sulfur (Li-S) battery technologies could power future electric mobility due to their potential high energy density. However, the current solid-state Li-S batteries face several challenges, such as high internal impedance at the electrode/electrolyte interfaces, shuttling of lithium polysulfides, and Li dendrite formation. Herein, we introduced a Li-rich cellulose-based solid-state electrolyte in combination with sulfurized polyacrylonitrile (SPAN, 36.5 wt.% S) cathode, leading to high-capacity and durable Li-S batteries. We utilized SPAN due to its reasonable conductivity, high reversible capacity, and stable cycling performance. Adopting the procedure described in **Ref. 1**, the solid-state electrolyte in this study was prepared by infusing Li ions (Li<sup>+</sup>) into a copper-coordinated commercial cellulosic paper. The infusion of Li<sup>+</sup> was carried out by soaking the copper-treated paper in a 1 M LiTFSI in EC<sub>0.5</sub>DME<sub>0.25</sub>DOL<sub>0.25</sub> solution (where subscripts indicate the volume fraction), followed by complete evaporation of the solvents. The prepared solid-state electrolyte ( $\sim 300$   $\mu$ m in thickness) exhibited high room-temperature ionic conductivity of  $1.5 \times 10^{-4}$  S cm<sup>-1</sup>, superior to the reported values for solid-state electrolytes with similar thicknesses. The Li-SPAN cell with paper-based electrolyte delivered a room-temperature reversible capacity of 1350 mAh g<sup>-1</sup> in the first cycle and 990 mAh g<sup>-1</sup> after 100 cycles at 0.1C (1C: 1675 mAh g<sup>-1</sup>), with a capacity retention of 73.33%. The conformability of the paper-based electrolyte ensures good interfacial contact with the SPAN and Li electrodes. As a result, when this solid-state Li-S battery was tested at 0.5C and 1C, it delivered a reversible capacity of 800 and 400 mAh g<sup>-1</sup>, respectively. In this talk, we will outline the results from our electron microscopy, electrochemical impedance spectroscopy, and cyclic voltammetry studies to unravel the superior performance of paper-based Li-S batteries. We will also present the cycling performance of our cells for high-temperature applications.

**Evolution of Interfacial Cathode Kinetics in Sulfide All-Solid-State Li Batteries Measured with Electrochemical Impedance Spectroscopy (EIS)** [Alyssa Stavola](#), Dominick Guida, Xiao Sun, Hongli Zhu and Joshua W. Gallaway; Northeastern University, United States

Sulfide all-solid-state Li batteries (ASLBs) suffer from a large capacity loss on the first cycle jeopardizing their commercialization and energy density. This

large initial coulombic mismatch is theorized to be due to formation of the cathode electrolyte interface (CEI) and volume changes in the cathode material resulting in increased internal resistance and a loss of electrochemically active surface area respectively.<sup>1</sup> We have previously reported an operando analysis of  $\text{Li}^+$  and  $e^-$  conduction across a composite cathode based on  $\text{Li-Ni}_{1/3}\text{Mn}_{1/3}\text{Co}_{1/3}\text{O}_2$  (NMC111) and  $\text{Li}_4\text{PS}_4\text{Cl}$  (LPSC) during initial cycling.<sup>2</sup> This analysis indicated that conduction during initial cycling was subject to high tortuosity factors ( $t^2$ ) for both the LPSC and NMC phases. Additionally, the  $t^2$  values evolved during the initial battery charge step. Because cathode performance was limited by conduction, we were unable to infer information about kinetic phenomena, e.g. the charge transfer rate between LPSC and NMC, from the experimental results. In particular, the first cycle capacity loss may be caused by a drop in interfacial kinetics.

To study this capacity loss as a function of state-of-charge, in situ EIS was performed during initial cycling of a full cell with a composite cathode based on NMC111 and LPSC ( $\text{Li/In}|\text{Li}_4\text{PS}_4\text{Cl}|\text{NMC111/Li}_4\text{PS}_4\text{Cl}$ ). This piecewise EIS allows us to analyze both time dependent and state-of-charge dependent interfacial processes while the battery cycles with no modifications to cell design. A transmission line model allowed for quantification of the electrochemically active surface area and its effect on resulting capacity during the first charge of this ASLB system.

**Decoupling Irreversible and Reversible Inefficiencies at Dynamic Interfaces in Sulfide Solid State Battery Positive Electrodes** Emma Kaeli<sup>1</sup>, Xiaomian Yang<sup>1</sup>, Zhelong Jiang<sup>1</sup>, Sunny Wang<sup>1</sup>, Edward Barks<sup>1</sup>, Yan-Kai Tzeng<sup>2</sup>, Stephen Kang<sup>1</sup> and William C. Chueh<sup>1</sup>; <sup>1</sup>Stanford University, United States; <sup>2</sup>SLAC National Accelerator Laboratory, United States

Battery systems present a uniquely difficult environment for disentangling sources of inefficiency. As an example, positive electrode-electrolyte interfaces incur simultaneous charging-induced side reactions, surface area change, and lithiation-state dependent intercalation rates. For sulfur-based composite electrodes in solid state batteries (SSBs) these parallel processes present a formidable challenge to addressing first cycle Coulombic inefficiency.<sup>1</sup> Without fully decoupling inefficiencies, it is unclear which degradation mechanism is most critical to address and, further, how applied solutions impact each mechanism in turn. For example, to mitigate unwanted side reactions between sulfide solid electrolytes (SEs) and positive electrode materials like  $\text{LiNi}_x\text{Mn}_y\text{Co}_{1-x-y}\text{O}_2$  (NMC), the field has implemented interfacial coatings to increase Coulombic efficiency.<sup>2-4</sup> While coating design focuses on thermodynamic stability at the interface, the coatings could be improving battery performance by addressing other inefficiencies in parallel, such as increasing the rate of the intercalation reaction or reducing ionic constriction at the NMC/SE interface.

This work systematically decouples the impacts of ionic constriction, electrolyte redox and NMC/SE interphase formation in sulfide-SE SSB first cycle electrochemistry to better inform design of solutions for the NMC/SE interface. Using uncoated  $\text{LiNi}_{0.5}\text{Mn}_{0.3}\text{Co}_{0.2}\text{O}_2$  we demonstrate a method to delineate contributions to Coulombic inefficiency between slow kinetics and irreversible reactions. To determine the reversibility of interphase products and the impact of cycling history we track lithiation state and generation of interphase products during cycling. We determine the ability of generated interphase products to contribute to self-discharge of NMC and the resultant impact on Coulombic inefficiency. Using two different electrolytes,  $\text{Li}_3\text{PS}_4$  and  $\text{Li}_4\text{PS}_4\text{Cl}$ , which have well-defined but unique thermodynamically-predicted redox reactions and reaction potentials, we separate contributions to Coulombic inefficiency between electrolyte redox reactions and reactions involving transition metals and oxygen from NMC. Finally, by comparing borate-coated and uncoated NMCs, we investigate the coating's impact on interphase formation, ionic constriction and intercalation reaction rate.

**Studying Li Evolution in Mixed Ionic-Electronic Conducting Interlayer of Sulfide Based All-Solid-State Batteries Through Operando Raman and Neutron Images** Daxian Cao and Hongli Zhu; Northeastern University, United States

Lithium-metal ( $\text{Li}^0$ ) anode potentially enables all-solid-state batteries with high energy density. However it shows incompatibility with sulfide solid-state electrolytes (SEs). One strategy is introducing an interlayer, generally made of a mixed ionic-electronic conductor (MIEC). Yet, how Li behaves within MIEC remains unknown. Herein, we investigated the Li dynamics in a graphite interlayer, a typical MIEC, using operando neutron imaging and Raman spectroscopy. This study revealed intercalation-extrusion-dominated mechano-chemical reactions during cell assembly transform the graphite into a Li-graphite interlayer consisting of SE,  $\text{Li}^0$ , and graphite-intercalation compounds. During charging,  $\text{Li}^0$  preferentially plated at the Li-graphite|SE interface and then transferred into the Li-graphite interlayer without intercalation. Upon further plating,  $\text{Li}^0$ -dendrites formed, inducing short circuits and reverse immigration of  $\text{Li}^0$ . Continuum modeling was conducted to explain the Li dynamics. We concluded that the lowest nucleation barrier at the  $\text{Li}^0$  side is necessary to drive the  $\text{Li}^+$  across the MIEC and preferentially deposit onto the  $\text{Li}^0$ .

#### 9:00 AM EN02.08.04

**Electronic Conductivity of Lithium Solid Electrolytes** Fudong Han; Rensselaer Polytechnic Institute, United States

While significant efforts have been devoted to improving the ionic conductivity of lithium solid electrolytes (SEs), electronic transport, which has an important role in the calendar life, energy density, and cycling stability of solid-state batteries (SSBs), is rarely studied. In this talk, we will present our recent results on the electronic conductivities of three representative SEs, including  $\text{Li}_3\text{PS}_4$ ,  $\text{Li}_7\text{La}_3\text{Zr}_2\text{O}_{12}$ , and  $\text{Li}_3\text{YCl}_6$  for sulfide-, oxide-, and halide-based SEs, respectively. By revisiting direct current polarizations using two-blocking-electrode cells and the Hebb-Wagner approach, we propose that the

electronic conductivities of SEs are overestimated from the conventional measurements. We will discuss the limitations and sources of inaccuracy for these measurements and highlight the anodic decomposition of SE as the key source for the overestimated result. Modifications in the electrode selection and data interpretation are also proposed to approach the intrinsic electronic conductivity of SEs. To estimate the electronic conductivity of sulfides that decompose during measurement, a two-step polarization method will also be introduced. The electronic conductivities of all SEs measured by the modified approach are one or two orders of magnitude lower than the reported value. Despite that, the electronic conductivity of sulfides seems to be still quite high to enable SSBs with a long calendar life of >10 years, highlighting the critical need for a more careful study of electronic transport in lithium SEs.

#### 9:15 AM EN02.08.05

**Computational Investigation of Dynamic Voltage Stability in Solid State Batteries** Yichao Wang, William Fitzhugh, Xi Chen, Luhan Ye and Xin Li; Harvard University, United States

Intrinsic or interface thermodynamic voltage windows of solid electrolytes are often narrower than the operational voltage range needed by a full battery, thus various decomposition reactions can happen in a practical solid-state battery. These decompositions can undergo local volume expansions, which will compress the reaction front in a solid environment under a mechanical constriction and modify the reaction thermodynamics and kinetics. Experimentally, it was found that a proper battery design utilizing the effect can lead to dynamic voltage stability for advanced battery performance. Here we articulate first our state-of-the-art understanding about how computationally the dynamic voltage stability should be interpreted and treated. We further apply our constrained ensemble computational approach across these solid-state electrolytes to systematically evaluate and compare their dynamic stability voltage windows in response to the mechanical constriction effect. High throughput calculations are used to search for coating materials for different interfaces between sulfide, halide, and oxide electrolytes and typical cathode materials with enhanced dynamic voltage stability.

**Atomic Insights into the Oxidative Degradation Mechanisms of Sulfide Solid Electrolytes** Chuntian Cao<sup>1</sup>, Matthew Carbone<sup>1</sup>, Jagriti Shekhawat<sup>2</sup>, Cem Komurcuoglu<sup>2</sup>, Kerry Sun<sup>2</sup>, Haoyue Guo<sup>2</sup>, Sizhan Liu<sup>1</sup>, Ke Chen<sup>1</sup>, Seong-Min Bak<sup>1</sup>, Yonghua Du<sup>1</sup>, Conan Weiland<sup>3</sup>, Xiao Tong<sup>1</sup>, Dan Steingart<sup>2,2,2</sup>, Shinjae Yoo<sup>1</sup>, Nongnuch Artrith<sup>2,4</sup>, Deyu Lu<sup>1</sup> and Feng Wang<sup>1</sup>; <sup>1</sup>Brookhaven National Laboratory, United States; <sup>2</sup>Columbia University, United States; <sup>3</sup>National Institute of Standards and Technology, United States; <sup>4</sup>Utrecht University, Netherlands

Electrochemical degradation of solid electrolytes is a major roadblock in the development of solid-state batteries, and the formed solid-solid interphase (SSI) plays a key role in the performance of solid state batteries. In this study, by combining experimental X-ray absorption spectroscopy (XAS) measurements, first-principles simulations, and unsupervised machine learning, we have unraveled the atomic-scale oxidative degradation mechanisms of sulfide electrolytes at the SSI using the baseline Li<sub>3</sub>PS<sub>4</sub> (LPS) electrolyte as a model system. The degradation begins with a decrease of Li neighbor affinity to S atoms upon initial delithiation, followed by the formation of S-S bonds upon the deformation of the PS<sub>4</sub> tetrahedra. In the second and following delithiation cycles, the PS<sub>4</sub> motifs are strongly distorted and PS<sub>3</sub> motifs start to form. Spectral fingerprints of the local structural evolution are identified, which correspond to the main peak broadening and shifted to higher energy by about 2.5 eV in P K-edge XAS and a new peak emerging at 2473 eV in S K-edge XAS during the delithiation. The spectral fingerprints serve as a proxy of the electrochemical stability of phosphorus sulfide solid electrolytes, as demonstrated in argyrodite Li<sub>6</sub>PS<sub>5</sub>Cl. We have observed that the strong distortion and destruction of PS<sub>4</sub> tetrahedra and the formation of S-S bonds are correlated with the increased interfacial impedance. To our knowledge, this study provides the first atomic-scale insights into the oxidative degradation mechanism of the LPS electrolyte, which can provide guidance for controlling macroscopic reactions through microstructural engineering and, more generally, can advance the rational design of sulfide electrolytes.

#### 9:45 AM EN02.08.07

**Viscoplasticity Driven Approach to Increase Critical Current Density in Sulfide Electrolytes** Changmin Shi<sup>1</sup>, Cristina Lopez Pernia<sup>1</sup>, Xing Liu<sup>2</sup>, Pradeep Guduru<sup>1</sup> and Brian W. Sheldon<sup>1</sup>; <sup>1</sup>Brown University, United States; <sup>2</sup>Georgia Institute of Technology, United States

All-solid-state batteries (ASSBs) show a high practical potential to achieve safe battery design with high energy densities when using Li metal as an anode. Sulfide electrolytes due to their high ionic conductivity (0.1 mS/cm to >10 mS/cm) are among the most promising candidates. However, Li dendrite growth results in shorting at critical current densities (CCD) that are well below values that are needed for practical applications. This currently limits the development of sulfide-based ASSBs, and therefore, it is very important to stabilize sulfide-electrolyte/Li-metal interfaces to enable high current densities without shorting.

Extensive efforts have been devoted to increasing the interfacial stability with methods that emphasize chemical and electrochemical modifications. However, methodologies that increase the CCD in sulfide electrolytes based on mechanics have not been reported. Herein we report a viscoplasticity based approach to increase the CCD of sulfide electrolytes. Previous studies have demonstrated that some sulfide SEs deform in a viscous manner<sup>1,2</sup>. Considerations of this effect offer a new perspective on how to suppress Li dendrite growth. To investigate the viscoplastic properties of sulfide electrolytes, Li<sub>6</sub>PS<sub>5</sub>Cl (LPSC) was selected as an important candidate due to its high ionic conductivity and high stability against Li metal compared with other sulfide electrolytes. Viscoplasticity in this material was investigated and characterized by integrating nanoindentation experiments and finite element simulations, and improved CCD was observed by employing cycling conditions that take advantage of this inelastic deformation. Such improvement is attributed to the interaction between the specially designed charging-discharging cycles and the viscous deformation of the electrolyte. We have also performed finite element simulations to further validate our argument. This type of approach can provide major improvements in the performance of ASSBs and can also be combined with chemical/electrochemical methods to further enhance cell performance using sulfide electrolytes.

**Interfacial Engineering of Solid-State Batteries: From Metal Anodes to Composite Cathodes** [Neil P. Dasgupta](#); University of Michigan, United States

Solid-state batteries have the potential to be a disruptive technology because of their ability to improve safety and increase energy density by incorporating Li metal anodes. However, all solid-state interfaces present unique challenges, including high interfacial impedances, accommodation of mechanical stresses due to solid-solid interfacial contact, and (electro)chemical instabilities that can evolve during dynamic cycling conditions. Furthermore, a significant challenge facing the scale-up of SSBs is to improve our understanding of processing science needed to enable manufacturing.

To address these challenges, our group focuses on gaining new fundamental insights into the coupled phenomena occurring at interfaces, and applied this knowledge to rationally design interfacial composition and structure to address the root cause of performance limitations. In this talk, I will describe our journey to deepen our understanding of interfacial phenomena at both the Li metal anode side, as well as in composite solid-state cathode materials. On the anode side, there is a critical need to understand and control the coupling between electrochemistry, morphology, and mechanics, to improve the uniformity and reversibility of plating and stripping during charge and discharge, respectively. On the cathode side, we focus on overcoming energy/power tradeoffs, which exhibit unique phenomena owing to the single-ion conducting nature of ceramic electrolytes, as well as improving stability at high voltages.

Equipped with this fundamental understanding, I will describe our efforts to engineer modified interfaces through control of the surface chemistry, incorporation of interlayers, and fabricating 3-D architectures. Through this interdisciplinary approach of fundamental materials chemistry and applied engineering, strategies to address future interfacial challenges will be addressed, pointing towards rational design and manufacturing of optimized interfaces.

**10:45 AM \*EN02.09.02**

**Cross-Talk Between Anode and Cathode Degradation Mechanisms in all Solid State Batteries** [Kelsey B. Hatzell](#); Princeton University, United States

All solid-state batteries (ASSB) can potentially achieve high gravimetric and volumetric energy densities (900 Wh/L) if paired with a lithium metal anode and solid electrolyte. However, there is a lack in critical understanding about how to operate lithium metal cells at high capacities with composite solid state cathodes. The interconnection and cross-talk between anode and cathode degradation mechanisms is largely not well understood. Herein, we investigate how pressure and temperature influence the formation and annihilation of unrecoverable voids in lithium metal upon stripping and subsequent contact evolution challenges at cathode. Here we use both x-ray and electron imaging techniques to characterize degradation mechanisms across multiple scales.

**11:15 AM \*EN02.09.03**

**Understanding the Evolution of High-Capacity Anodes in Solid-State Batteries** [Matthew T. McDowell](#); Georgia Institute of Technology, United States

Solid-state batteries offer the promise of improved energy density and safety compared to lithium-ion batteries, but electro-chemo-mechanical evolution and degradation of materials and interfaces can play an outsized role in limiting their performance. Here, I will present my group's recent work on understanding structural evolution, interfacial dynamics, and chemo-mechanics in solid-state batteries with two different types of anodes: zero-lithium excess anodes ("anode-free") and alloy anodes. Anode-free solid-state batteries, in which there is no initial lithium metal at the anode interface, offer extremely high energy density, but there is a lack of understanding of the mechanisms that govern their behavior in solid-state batteries. Using X-ray tomography, cryo-FIB, and finite-element modeling, we show that anode-free solid-state batteries are intrinsically limited by current concentrations at the end of stripping due to localized lithium depletion. This causes accelerated short circuiting compared to lithium-excess cells. Based on these results, the beneficial influence of metal alloy interfacial layers on controlling lithium evolution and mitigating contact loss from localized lithium depletion will be introduced and discussed. In the second part of the talk, a new design for dense aluminum foil alloy anodes is introduced, in which microstructural control over the foil is shown to play a key role in significantly improving reversibility in solid-state batteries. This anode design mitigates chemo-mechanical degradation and offers a paradigm that does away with slurry coating, potentially reducing manufacturing costs. Taken together, these findings show the importance of controlling chemo-mechanics and interfaces in solid-state batteries for improved energy storage capabilities.

**11:45 AM EN02.09.04**

**Understanding The Li Dendrite "Soft Short" in Solid-State Li Metal Batteries by Phase-field Method** Kena Zhang<sup>1</sup>, Daxian Cao<sup>2</sup>, Tongtai Ji<sup>2</sup>, Hongli Zhu<sup>2</sup> and [Ye Cao](#)<sup>1</sup>; <sup>1</sup>The University of Texas at Arlington, United States; <sup>2</sup>Boston University, United States

Lithium (Li) dendrite growth in Li metal batteries is a long-standing problem, which causes critical safety concerns and severely limits the advancement of rechargeable Li batteries. Replacing conventional liquid electrolyte with solid electrolyte (SE) of high mechanical strength and rigidity was once thought as an effective strategy to suppress the Li dendrite growth. However, defects in SEs (such as cracks, voids, grain boundaries etc.) and the imperfect contact between the electrode and the SE can even facilitate the Li dendrite growth. Recently, it was postulated that the Li dendrite growth in SEs could be the reason for "soft short" of the cell. Compared to "hard short" in which the voltage of the battery decreases suddenly during the charging process, in "soft short" the voltage is dynamically stable but cannot increase during the charging process. However, the underlying mechanism of "soft short" is still not well understood. In this work, we developed a phase-field model coupled with electrochemistry and solid mechanics to unravel the dynamics of Li dendrite growth in a porous SE under the applied external pressure during charging, and its correlation with the "soft short". It is revealed that Li dendrite growth causes a hydrostatic pressure inside the Li metal, which increases with the external pressure and is responsible for the suppression of Li dendrite growth. Without external pressure, Li dendrite growth is less restricted by the SE and can fill the small pores inside the SE to form a tree-like morphology. The growth of multiple Li dendrites eventually penetrates through the entire SE, causing "hard" short circuit of the cell. This is evidenced by the sudden increase of leakage current during charging process in the simulation. When the external pressure increases to 10MPa, the hydrostatic pressure is maximized at the pore-SE interface which blocks the Li dendrite to fill into the pores, and eventually breaks parts of the Li dendrites to form dead Li. Our simulation results agree with the X-ray computed tomography of the deposited Li metal and cracks inside the SE by our collaborators. More importantly, the simulated fracture of Li dendrite (disconnection to the anode) and the subsequent reconnection to the Li anode can well explain the "soft short" in experiments, as they prevent the Li dendrite from completely penetrating the SE. This is further evidenced by the leakage current fluctuations in our simulation, indicating a typical "soft short" behavior. Our work thus provides a deeper understanding of the Li dendrite growth dynamics in porous solid electrolyte and the "soft short" phenomenon in solid state batteries.

**Engineering Sulfur Cathodes for Solid State Batteries** [Ping Liu](#); University of California, San Deigo, United States

Solid state batteries with sulfur-based cathodes are highly appealing due to their intrinsic cost and energy density advantages. If fully realized, they also promise a departure from our reliance on transition metals and even facile recycling. Extensive effort has been dedicated to improve the electrical conductivity and manage the volume change during cycling. In this regard, sulfur-containing polymers have shown stable cycling stability but with limited capacity. Recently we have shown poly thiocyanogen can deliver material-level energy density of > 1400 Wh/kg. However, the material is found only to have enough electron and ionic conductivities at elevated temperatures. The result illustrates the limitation of using conductive polymer or carbon backbones to provide electronic conductivity. We have recently explored the possibility of heteroatom doping into sulfur composite materials. Selected dopants have shown promise in facilitating the charge transfer in the solid electrode as well as increasing the ductility of the composite structure. Both of these features help improve the rate capability and cycle life of the sulfur based cathode. We will discuss how these findings can offer design rules for new sulfur based cathodes, including further improvement to enable cycling at reduced pressure.

**2:00 PM \*EN02.10.02**

**Materials Challenges for High-Energy and Long-cycle-Life All-Solid-State Lithium-Sulfur Battery** [Dongping Lu](#), Michael Kindle, Daniel Marty, Jing Wu, Dahee Jin and Un Hyuck Kim; Pacific Northwest National Laboratory, United States

All Solid-state Lithium-Sulfur battery (ASSLSB) is regarded as a promising next-generation battery technology for vehicle electrification due to its merits of high energy, low cost, and high safety. However, performance improvement and deployment of the technology are still largely hindered by the challenges associated with both sulfur (S) cathode and lithium anode. Although issues of polysulfide dissolution, Li corrosion, and electrolyte consumption existing in liquid Li-S cells are fully eliminated, achieving both high energy and stable cycling in S cathode is still very challenging. Those include (1) low S content and mass loading, 2) low operation current densities, and 3) large electrode volume change upon cycling. This is due to extremely low ionic and electronic conductivities of S and  $\text{Li}_2\text{S}$ , which relies on the effectiveness and completeness of  $\text{Li}^+/\text{e}^-$  conduction networks built on both solid-state electrolyte (SSE) and carbon (C) conductors. The clear understanding or a design principle of an optimal S/SSE/C triple phases is still lacking. The other grand challenge of ASSLSB is how to achieve long-term and dendrite-free Li cycling at both high current densities and high areal capacities. Properties of Li/SSE interface impacts early-stage Li nucleation, which dictates subsequent Li growth. For this aspect, uniformity of Li/SSE interface both in chemistry and morphology could even reduce local current density, promoting uniform Li growth. The interfacial stability of Li/SSE could be achieved by forming a stable SEI. However, it is challenged by Li dynamics during repeated cycling, particularly at practically high current density and areal capacity conditions, which may boost the potentials of inhomogeneous Li deposition and even dendrite formation. To overcome those issues, rational designs of materials, electrode, and interface are essentially needed to both boost S reaction kinetics and stabilize Li/SSE interface. At the conference, we will discuss our understandings of those key challenges and new progresses we achieved in addressing them.

**Lithiation Gradients and Tortuosity Factors in Thick NMC111-Argyrodite Solid-State Cathodes** [Joshua W. Gallaway](#), Alyssa Stavola, Dominick Guida, Andrea M. Bruck, Xiao Sun and Hongli Zhu; Northeastern University, United States

Achieving the high energy density targets for all-solid-state batteries (ASSBs) will require thick cathodes optimized for full utilization of active material. In composite cathodes with sulfide solid-state electrolytes (SSEs), the exclusion of carbon additives makes cathode design to balance ionic and electronic conductivities all the more important.  $\text{Li-Ni}_{1/3}\text{Mn}_{1/3}\text{Co}_{1/3}\text{O}_2$  (NMC111) is a widely studied cathode material for its high energy density and high working voltage. The lattice parameters of this well-studied structure directly correlate to the amount of Li in the material, allowing for very accurate measurements of lithium-ion concentration gradients (lithiation gradients) throughout the cathode depth.

In this work, we report an operando analysis of  $\text{Li}^+$  and  $\text{e}^-$  conduction across 120  $\mu\text{m}$  thick composite cathodes based on NMC111 and  $\text{Li}_6\text{PS}_5\text{Cl}$  (LPSC) during initial cycling.<sup>1</sup> This analysis indicates that conduction during initial cycling is subject to high tortuosity factors ( $\tau^2$ ) for both the LPSC and NMC phases. Additionally, the  $\tau^2$  values evolve during the initial battery charge step, increasing steeply. By analyzing composite cathodes with a range of cathode active material (CAM) loadings, we observe the effect of CAM loading on the non-uniformity of the electrochemical reaction. For 80% CAM we observe that the initial reaction heavily favors regions of the cathode that are nearest the anode. For 70% and 40% CAM, the opposite is true, with initial reaction favoring the regions farthest from the anode. These non-uniformities are very large, often amounting to a gradient of over 50% of the total cycleable capacity across the cathode thickness.

Spatially resolved lithiation gradients in thick NMC111/ $\text{Li}_6\text{PS}_5\text{Cl}$  composite cathodes were measured using operando energy dispersive X-ray diffraction (EDXRD) on sealed and pressurized ASSBs with varying relative amounts of CAM and SSE. Electrochemical impedance spectroscopy (EIS) and transmission line modeling were employed to test the ionic and electronic conductivities of composite cathodes with similar varied CAM and SSE ratios. The balance of ionic and electronic conductivities was found to determine the lithiation gradients and utilization of active material in the cell.

**3D Printed Porous LLZO Multi-Layer Scaffolds for Li-Garnet Solid-State Batteries** Bor-Rong Chen, Asa G. Monson, Pete Barnes, Jorgen F. Rufner, Arin S. Preston, Donna P. Guillen and Eric J. Dufek; Idaho National Laboratory, United States

Garnet-based oxides ( $\text{Li}_7\text{La}_3\text{Zr}_2\text{O}_{12}$ , LLZO) are promising solid-state electrolyte materials to achieve higher energy density and improved safety for the next-generation solid-state batteries (SSBs) due to their high ion conductivity and chemical stability. To enhance the performance of garnet-based SSBs, a dense-porous design of microstructure has been introduced in recent years. The design consists of a dense layer as the separator and one or two porous layers as the host of anode or cathode active materials [1-3]. The porous structure mitigates volume changes in the anode by accommodating Li in the pores during Li deposition, while the dense layer prevents short circuiting and provides additional mechanical support. Such bi- or tri-layer scaffolds are usually fabricated using tape-casting, in which the porous and dense layers are prepared separately, followed by trimming and stacking into the desired architectures. As a result, this process is challenged by workflow inefficiency due to the multiple separated casting and stacking steps.

To improve the efficiency in fabricating the porous-dense scaffold, we introduce an alternative approach using digital light processing (DLP), a unique 3D printing technology capable of layer-by-layer printing of multiple components and complex architectures in a single print [4]. Using DLP, the entire multilayer structure in the desired dimension is created *all-at-once* on the same printing platform by alternating printing slurries that respectively form the dense and porous layers. We produce free-standing, sub-millimeter-thick Ta-doped (LLZTO) porous-dense layers and demonstrate that the porosity is tunable by adjusting the particle size and solid loading in the printing slurry. This strategy for controlling the porosity is distinct from current approaches such as adding pore formers or controlling heat treatment conditions. By tuning the porosity in each of the printed layers, we show that a graded porosity can be created across the scaffold. In the future, this DLP printing approach will provide more opportunities to produce various microstructures and chemistries of SSBs with more efficiency and sustainability.

**Self-Healing Laminated LLZO/Reduced Graphene Oxide/LLZO Composite Solid-State Electrolytes for Arresting Dendrite Penetration in Solid-State Batteries** Zikang (Austin) Yu, Changmin Shi, Cristina Lopez Pernia, Chenjie Gan and Aleksandar Mijailovic; Brown University, United States

Solid state lithium metal batteries using inorganic solid electrolytes are widely regarded as next-generation devices that can enable substantial improvements in energy density. However, the performance of these electrolytes is currently limited as they are largely unable to hinder the propagation and penetration of lithium metal dendrites that lead to the shorting of cells at practical current densities. In this work, we propose a novel architecture for solid state electrolytes, using a laminated composite structure consisting of reduced Graphene Oxide (rGO) interlayers that are embedded inside of Tantalum-doped LLZO ( $\text{Li}_{6.4}\text{La}_3\text{Zr}_{1.7}\text{Ta}_{0.3}\text{O}_{12}$ ) to create a stable layered solid-state battery that effectively arrests dendrite penetration. Testing of these interlayer-engineered LLZO electrolyte with symmetric lithium metal electrodes, leads to critical current density increases of more than 7 times at room temperature. FEM simulations of these multi-layered structures were also conducted to provide insight into designing a broader range of laminated solid electrolyte architectures. Our results indicate that solid state electrolytes can be engineered with interlayers to deflect dendrites and improve critical current densities.

**Low-Temperature Design of Solid Oxide Electrolyte Through Amorphization** Giyun Kwon, Hyeokjo Gwon, Youngjoon Bae, Jusik Kim and Taeyoung Kim; SAIT, Korea (the Republic of)

In recent years, there have been a significant increase in solid Li-ion conducting electrolytes that have the potential to enable such batteries. Among them, garnet-type oxide electrolytes have demonstrated great promise due to their robust stability and high ionic conductivity. However, due to the rigid nature of solid oxide electrolytes, the high ionic conductivity is only achievable along with high temperature sintering process (> 1000 °C) to form dense structure, which introduces cost challenges and undesired chemical reactions. Although there have been many efforts to lower the sintering temperature through the use of sintering aids, they require additional additives and their effect remains unsatisfactory. In this study, a low-temperature design for garnet solid electrolyte is suggested without the need for sintering aids. The approach involves amorphization, which imparts deformability to the material. Consequently, the material becomes way softer compared to crystalline electrolyte, allowing for the easy formation of a dense amorphous matrix by applying pressure. Subsequently, the high ionic conductivity can be obtained through a low-temperature crystallization process. We believe that this strategy paves the way for showcasing rigid solid electrolytes processed at lower temperature.

**Understanding Lithium-Ion Transport in Selenophosphate-Based Lithium Argyrodites and Their Limitations in Solid-State Batteries** Johannes

Hartel<sup>1</sup> and Wolfgang Zeier<sup>1,2</sup>; <sup>1</sup>Department of Inorganic and Analytical Chemistry, Germany; <sup>2</sup>Helmholtz-Institut, Germany

Solid electrolytes providing high ionic conductivities are required for the realization of solid-state batteries with competitive power and energy densities. Among all reported fast lithium-ion conductors, superionic lithium argyrodites provide a promising, highly tunable compositional space, in which superior lithium-ion conductivities can be realized by elemental substitutions.

In this work, selenophosphate-based lithium argyrodites  $\text{Li}_{6-x}\text{PSe}_{5-x}\text{Br}_{1+x}$  ( $0 \leq x \leq 0.2$ ) with exceptional ionic conductivities up to  $8.5 \text{ mScm}^{-1}$  are reported and underlying reasons for their fast lithium-ion transport are unveiled based on structural characterization using a combination of neutron powder diffraction, <sup>7</sup>Li and <sup>31</sup>P NMR and Raman spectroscopy. Rietveld refinement of the neutron powder diffraction data uncovers a significantly improved interconnection of the lithium-ion cages when compared to the thiophosphate analogue  $\text{Li}_6\text{PS}_5\text{Br}$  as a result of the occupation of two additional lithium-ion sites, leading to enhanced lithium-ion transport. A larger unit cell volume, lattice softening and higher structural disorder between halide and chalcogenide provide further structural reasons for improved lithium-ion conduction. Interestingly, when testing  $\text{Li}_{5.85}\text{PSe}_{4.85}\text{Br}_{1.15}$  as catholyte in In/LiIn| $\text{Li}_6\text{PS}_5\text{Br}$ | $\text{LiNi}_{0.83}\text{Co}_{0.11}\text{Mn}_{0.06}\text{O}_2$ : $\text{Li}_{5.85}\text{PSe}_{4.85}\text{Br}_{1.15}$  solid-state batteries, severe degradation is observed by electrochemical impedance spectroscopy upon charging of the cells, revealing that selenophosphate-based lithium argyrodites are not suitable for application in lithium nickel cobalt manganese oxide (NCM) based solid-state batteries from a performance perspective.

Besides providing further insights into the structure-transport relationship of lithium argyrodites with high lithium-ion conductivities, this work reemphasizes the necessity to consider chemical and electrochemical stability of solid electrolytes against the active materials when developing fast lithium-ion conductors.

**Design Principles for Fast Ionic Conductors** Yifei Mo; University of Maryland, United States

Super-ionic conductors, characterized by exceptionally high ionic conductivities, are highly sought after as solid electrolytes or electrodes for energy applications like batteries and fuel cells. Despite numerous mechanisms proposed for super-ionic conductor materials and the emergence of various design principles, the capability to rationally design these materials has yet to be fully actualized. Conventionally, the analyses largely concentrated on experimental data from a single class of materials with varying compositions. In our computational study, analyzing and studying a vast array of materials across a broad spectrum of materials chemistry and structure allow us to understand the mechanisms and trends across materials, enabling us to devise generally applicable design principles. In this talk, I will present our latest progress toward understanding the mechanisms of ion diffusion and formulating these design principles for fast ion conductors.

**Understanding the Correlation Between Anion Group Rotations and Lithium Ion Diffusion in Superionic Conductors** KyuJung Jun<sup>1</sup>, Byungju Lee<sup>2</sup>, Ronald Kam<sup>1</sup> and Gerbrand Ceder<sup>1</sup>; <sup>1</sup>University of California, Berkeley, United States; <sup>2</sup>Korea Institute of Science and Technology, Korea (the Republic of)

Since the 1980s, the paddlewheel effect has been proposed as a mechanism to boost lithium-ion conductivity in inorganic materials by using rotating anion groups to assist lithium-ion migrations (*I–5*). However, to this date, the physical mechanism behind how anion-group dynamics affect lithium-ion diffusion has not been clearly quantified. In this work, we define three types of rotational motions of anion-groups. To detect and differentiate various types of rotational motions, we track rotational motion of anion groups using quaternion-based representations. By applying a quaternion-based algorithms throughout a total of 10<sup>7</sup>s of ns ab-initio molecular dynamics trajectories of various types of superionic conductors and performing rigorous statistical analysis of various rotational events as well as lithium-ion diffusion events, we reveal how each type of anion rotational motion is related to lithium-ion diffusion. Our work resolves the ongoing debate about the existence of a paddlewheel effect and provides a clear mechanistic understanding of how anion-group rotations are correlated to fast ionic diffusion in inorganic materials.

**Unlocking Li Superionic Conductivity in Fcc-Type Oxides via Face-Sharing Configurations** Yu Chen<sup>1,2</sup>, Bin Ouyang<sup>3</sup> and Gerbrand Ceder<sup>1,2</sup>; <sup>1</sup>University of California, Berkeley, United States; <sup>2</sup>Lawrence Berkeley National Laboratory, United States; <sup>3</sup>Florida State University, United States

Li metal oxides with a face-centered cubic (*fcc*) anion sublattice have been generally excluded from the search for solid-state Li superionic conductors, as the structural framework is thought to be unfavorable for Li superionic conduction. Herein, we demonstrate a face-sharing design strategy that turns *fcc*-type oxides into superionic conductors, with a Li ionic conductivity of  $3.38 \times 10^{-4} \text{ S cm}^{-1}$  at room temperature and a low migration barrier of 255 meV. The combination of experimental and theoretical investigations reveals that the high Li-ion conductivity is attributed to the facile Li-ion diffusion pathways comprising the face-sharing polyhedra. Our work unlocks the great potential of designing Li superionic conductors in a prototypical structural framework with vast chemical flexibility, providing a fertile ground for discovering new solid-state electrolytes for all-solid-state batteries.

#### 9:30 AM EN02.12.05

**Investigating Aliovalent Sn(+IV) and Isovalent P(+V) Substitution Series in  $\text{Li}_3\text{SbS}_4$**  Bianca Helm<sup>1</sup> and Wolfgang Zeier<sup>1,2</sup>; <sup>1</sup>University of Muenster, Germany; <sup>2</sup>Forschungszentrum Jülich GmbH, Germany

An in-depth understanding of  $\text{Li}^+$  migration within solid electrolytes is fundamentally needed to develop new material classes and to enhance the existing ones. The thio-LISICON family exhibits three distinct ordering types of the non-lithium polyhedra leading to three different polymorphs, namely  $\alpha$ -,  $\beta$ - and  $\gamma$ - $\text{Li}_3\text{PS}_4$ .<sup>1,2</sup> These show completely different  $\text{Li}^+$  substructures and migration pathways. Depending on the non-lithium cation either the  $\beta$ - or  $\gamma$ -polymorph

is preferred synthetically.  $\text{Li}_3\text{SbS}_4$  crystallizes in the  $\gamma$ -polymorph, which has the most unpropitious  $\text{Li}^+$  substructure for fast  $\text{Li}^+$  motion in comparison to the  $\alpha$ -,  $\beta$ - and  $\gamma$ -polymorph. Nevertheless, the aliovalent  $\text{Li}_{3+x}\text{Sb}_{1-x}\text{Sn}_x\text{S}_4$  ( $0 \leq x \leq 0.2$ ) and isovalent  $\text{Li}_3\text{Sb}_{1-x}\text{P}_x\text{S}_4$  ( $0 \leq x \leq 0.5$ ) substitution series were prepared, and the ionic conductivity increased from  $9.2 \times 10^{-11} \text{ S} \times \text{cm}^{-1}$  to  $2.9 \times 10^{-6} \text{ S} \times \text{cm}^{-1}$  and  $4.9 \times 10^{-7} \text{ S} \times \text{cm}^{-1}$  for the highest substitution degree, respectively. Remarkably, the conductivity is three times faster improved for the Sn(+IV) compared to the P(+V) substitution implying that more  $\text{Li}^+$  are beneficial for faster ionic transport within this system. However, as these materials are bad ionic conductors at low substitution degree, the defect formation energy might be the dominating factor for easier ionic transport.

**Overcoming Low Initial Coulombic Efficiency of Si Anode by Effective Prelithiation in All-Solid-State Batteries** So-Yeon Ham<sup>1</sup>, Elias Sebt<sup>2</sup>, Ashley Cronk<sup>1</sup>, Tyler Pennebaker<sup>2</sup>, Grayson Deysher<sup>1</sup>, Yu-Ting Chen<sup>1</sup>, Jin An Sam Oh<sup>1</sup>, Jeong Beom Lee<sup>3</sup>, Marta Vicencio<sup>1</sup>, Phillip Ridley<sup>1</sup>, Baharak Sayahpour<sup>1</sup>, Darren Tan<sup>1</sup>, Raphaële Clement<sup>2</sup>, Jihyun Jang<sup>1</sup> and Y. Shirley Meng<sup>4</sup>; <sup>1</sup>University of California, San Diego, United States; <sup>2</sup>University of California, Santa Barbara, United States; <sup>3</sup>LG Energy Solution, Korea (the Republic of); <sup>4</sup>The University of Chicago, United States

All-solid-state batteries using the Si anode has shown promising high-capacity performance without continual SEI growth. However, the low initial Coulombic efficiency (CE) of Si remains a challenge. In this work, a prelithiation strategy was adopted to improve the CE and conductivity of Si anodes. The lithiated Si was examined in a symmetric-, half- and full-cell configuration to understand the cell level improvement of each component. With  $\text{Li}_1\text{Si}$  lithiation, the full cell achieved over 95% ICE when paired with the lithium cobalt oxide (LCO) cathode. Additionally, improvement using the prelithiation method was found to only influence anode-limited cases when comparing two active materials; NCM and LCO when paired with Si and  $\text{Li}_x\text{Si}$ . Ramping tests and prolonged cycling performance was evaluated using both Si and  $\text{Li}_1\text{Si}$  cells. With  $\text{Li}_1\text{Si}$ , 73.8% after 1000 cycles was achieved, a 15% improvement in retention versus the bare Si anode. Utilizing the  $\text{Li}_1\text{Si}$  composition, high areal capacity up to 10 mAh/cm<sup>2</sup> was attained using a dry-process LCO film, validating the prelithiation method which may be a suitable candidate used in high loading next generation batteries.

**Fast Cycling of Lithium Metal Solid State Batteries by Constriction-Susceptible 3D Anode** Luhan Ye and Xin Li; Harvard University, United States

Lithium (Li) metal anode, due to its ten times larger capacity than commercial graphite anode, is a desired component for solid-state batteries. Fast cycling of commercial level of thick cathode, however, requires the fast cycling of a thick layer of Li metal at anode stably. The goal is challenging as the cycling condition naturally promotes inhomogeneity in lithium plating and stripping, and hence Li dendrite penetration. This talk provides a solid-state battery with 3D anode design that enables fast cycling of lithium in solid state batteries. It is shown that the constriction-susceptible materials in a solid-state battery structure can be modulated as a 3D scaffold, in which the plating and stripping of Li metal is uniform. Furthermore, the advantage of multi-electrolyte-layer solid electrolyte layer will also be discussed. We showed that the rate capability of lithium metal battery can be significantly improved after applying a multi solid electrolyte structure, with less stable solid electrolyte sandwiched by more stable solid electrolytes. The electrolyte layer can capture lithium dendrite by local decomposition, which together with the 3D matrix anode, enables a fast rate with long cycling life.

**10:45 AM EN02.13.03**

**Silver-Carbon Composite Interlayers for "Anodeless" Solid-State Batteries** Dominic Spencer-Jolly<sup>1,2</sup>, Varnika Agarwal<sup>1</sup> and Peter G. Bruce<sup>1,2</sup>; <sup>1</sup>University of Oxford, United Kingdom; <sup>2</sup>The Faraday Institution, United Kingdom

Lithium-free so-called "anodeless" solid-state batteries promise to deliver high cell energy densities. However, at charge rates on the order of 1 mA cm<sup>-2</sup>, plating of Li at the current collector/solid electrolyte interface is highly inhomogeneous, and dendrites (filaments of Li metal) are observed to penetrate through the solid electrolyte resulting in cell failure. Recent work has suggested that introduction of a silver-carbon composite interlayer between the solid electrolyte and current collector can protect the solid electrolyte against dendrite growth whilst promoting more homogeneous deposition of Li metal.<sup>1</sup> In this work, we investigate silver-carbon composite interlayers, revealing the structural changes within the interlayer during charge and discharge, and the rate dependency of these changes. We go on to investigate the homogeneity of Li-Ag alloy and Li metal formation at the current collector with and without silver nanoparticles present in the interlayer, and how this affects the processes of charge and discharge. We demonstrate dendrite-free charge at 2 mA cm<sup>-2</sup> and reveal the origin of the failure of the interlayer at higher rates.<sup>2</sup>

**Probing 3D Evolution and Electrochemical Behavior of Nano Silicon Anodes in Sulfide All-Solid-State Batteries via Nano X-Ray Tomography and in Operando XAS** Tongtai Ji<sup>1</sup>, Daxiao Cao<sup>1</sup>, Yonghua Du<sup>2</sup>, Xianghui Xiao<sup>2</sup> and Hongli Zhu<sup>1</sup>; <sup>1</sup>Northeastern University, United States; <sup>2</sup>Brookhaven National Laboratory, United States

Silicon (Si) is one of the most promising anode materials for the next generation Li-ion batteries on account of its ultrahigh specific capacity (3590 mAh g<sup>-1</sup>) and relatively low working potential of 0.4 V (vs. Li+/Li). The utilization of silicon anode in all-solid-state lithium batteries (ASLBs) can further boost

the energy density compared with the conventional graphite anode. Among various ASLBs with different solid electrolytes (SEs), the ASLBs with sulfide SEs delivered remarkable performances because of the excellent ionic conductivity ( $>1 \text{ mS cm}^{-1}$ ) and relative “soft” mechanical properties (compared with oxides SEs) for intimate contact with electrode materials of sulfide SEs. However, the compatibility of Si and sulfide SEs is questioned because of the potential electrochemical decomposition. In addition, the extreme volume change (400%) of Si during cycling also brings great challenges to the structural stability of the ASLBs. Nano-Si ( $<100 \text{ nm}$  in diameter) have a higher structural stability because the smaller geometry size can relieve stress. Therefore, in this study, we systematically analyzed the electrochemical and structural evolution of different nano-Si-based anodes in ASLBs with sulfide SE via *in-operando* synchrotron X-ray absorption near-edge structure (XANES) spectroscopy and scanning electron microscopy (SEM) combined with X-ray nanotomography (XnT). Three kinds of nano Si-based anodes (pure nano-Si (Si), nano-Si compositing with SE (Si-SE), nano-Si compositing with SE and carbon (Si-SE-C)) were analyzed. The Operando XANES revealed that the sulfide SE experiences an electrochemical decomposition in the nano-Si anode and the addition of carbon accelerates this process. However, this electrochemical decomposition only occurs at the first lithiation process and the products are stable in the following cycles and has comparable ionic conductivity. The ex-situ SEM and ex-situ XnT exhibit that the addition of SE and carbon in the nano-Si anode benefits the structural stability, which is further explained by a chemo-elasto-plastic modeling framework. Owing to the enhanced reaction kinetics and mechanical structural stability, the Si-SE-C achieved the highest Si utilization, with a lithiation/delithiation capacity of 3288/2917  $\text{mAh g}^{-1}$  and an initial coulombic efficiency of 88.7%, which are significantly higher than the capacities of 2653/2291  $\text{mAh g}^{-1}$  and ICE of 86.4% in Si-SE, and the capacities of 2353/1935  $\text{mAh g}^{-1}$  and ICE of 82.2% in Si. This work indicated that the addition of SE and carbon into nano-Si anode can enhance the reaction kinetics, improve the utilization of Si, and benefit the mechanical structure stability, though the SE shows slight decomposition but the generated chemistry is ionically conductive and stable in the following cycles. Through the comprehensive evaluation between the pros and cons of adding SE and carbon, in terms of improvements in reaction kinetics and structural stability compared with the limited electrochemical decomposition of SE, nano-Si-SE-C composite anode demonstrates the best Si utilization with the highest specific capacities.

11:15 AM EN02.13.05

**Highly Reversible Solid-State Silicon Anodes Enabled by Hydride Based Electrolytes** [Yonglin Huang](#)<sup>1</sup>, Bowen Shao<sup>1</sup>, Yan Eric Wang<sup>2</sup> and Fudong Han<sup>1</sup>; <sup>1</sup>Rensselaer Polytechnic Institute, United States; <sup>2</sup>Advanced Materials Lab, Samsung Advanced Institute of Technology-America, Samsung Semiconductor Inc., United States

Silicon is considered a promising candidate for anodes in solid-state batteries due to its high energy density and unique properties in addressing problems associated with Li metal anodes such as dendrite formation and morphological instability. Despite many exciting results from previous works on solid-state Si anodes, the initial Coulombic efficiency, a critical parameter that characterizes the electrochemical reversibility for the first cycle and directly influences the battery's energy density, has not been well considered. In this presentation, we report our study on the (electro)chemical stability between Si and three representative solid electrolytes, including a typical sulfide ( $75\text{Li}_2\text{S}-25\text{P}_2\text{S}_3$ ), an iodide-substituted sulfide ( $70(0.75\text{Li}_2\text{S}-0.25\text{P}_2\text{S}_3)-60\text{LiI}$ ) and a hydride-based solid electrolyte ( $3\text{LiBH}_4\text{-LiI}$ , LBHI). Our results indicate that LBHI demonstrates superior electrochemical and chemical stability with Si anodes compared with sulfide-based electrolytes, enabling a high-performance solid-state Si anode with a record high initial Coulombic efficiency of 96.2% among all Si anodes reported to date. The excellent (electro)chemical reversibility of Si anodes was also demonstrated in solid-state full cells with nickel-rich layered oxide cathodes. The results highlight the importance of solidifying Si anode to improve its performance, and the excellent stability of hydride-based solid electrolytes also offers potential opportunities to be used as an interlayer or 3D ionic framework for other low voltage anodes, including Li metal.

**Using Holey Graphene for Improved Interfacial Contact in Solid Electrolyte Ionic Conductivity Measurements** [Lopamudra Das](#)<sup>1</sup> and Yi Lin<sup>2</sup>; <sup>1</sup>Analytical Mechanics Associates, United States; <sup>2</sup>NASA Langley Research Center, United States

Solid-state batteries (SSBs) are poised to become the batteries of the future with advantages such as higher energy density, lighter weight, versatile geometry, and greater safety due to low flammability risk. An important parameter of the solid electrolyte (SE) used is its ionic conductivity. The ionic conductivity is generally calculated from the bulk resistance of a SE pellet, measured from the electrochemical impedance spectroscopy data. The SE pellet is typically prepared from the electrolyte powder by dry compression and is sandwiched between two blocking current collectors to obtain the impedance spectroscopy data. One of the challenges in conducting this measurement is poor interfacial contacts between the SE pellet and the current collector surfaces. Therefore, measurements reported in the literature may underestimate the true ionic conductivity of a given electrolyte. Holey graphene is a carbon nanomaterial with high electrical conductivity and unique dry compressibility, which is unusual for carbon materials but similar to many oxide and sulfide SEs. In this work, it is demonstrated that adding a thin layer of holey graphene between the electrolyte and the stainless steel current collectors significantly improves the interfacial contact. The ionic conductivity values obtained in the effort were sometimes several times higher than the data measured for SEs without the holey graphene layers. This work calls for more standardized measurement procedures to reduce the discrepancies in reported ionic conductivity values.

1:45 PM EN02.14.02

**Ni-Rich Layered Cathodes in Sulfide-Based All-Solid-State Batteries: Improving Interface Stability by Oxide Nanoparticle Coating** [Ruizhuo Zhang](#)<sup>1</sup>, Yuan Ma<sup>1</sup>, Aleksandr Kondrakov<sup>1,2</sup>, Jürgen Janek<sup>1,3</sup> and Torsten Brezesinski<sup>1</sup>; <sup>1</sup>Battery and Electrochemistry Laboratory, Institute of Nanotechnology, Karlsruhe Institute of Technology (KIT), Hermann-von-Helmholtz-Platz 1, Germany; <sup>2</sup>BASF SE, Carl-Bosch-Str, Germany; <sup>3</sup>Institute of Physical Chemistry, Justus-Liebig-University Giessen, Heinrich-Buff-Ring, Germany

Owing to the superior ionic conductivity and mechanical ductility, sulfide-based solid electrolytes (SEs) such as  $\text{Li}_6\text{PS}_5\text{Cl}$  (LPSCI) have been extensively investigated for use in all-solid-state batteries (ASSBs). However, the practical implementation of ASSBs requires making significant improvements to various aspects of their components. When utilizing a high areal capacity electrode composite with a Ni-rich layered oxide cathode material,  $\text{LiNi}_{0.85}\text{Co}_{0.10}\text{Mn}_{0.05}\text{O}_2$  (NCM85), the poor interfacial stability arising from the narrow electrochemical window of LPSCI poses a significant challenge. Hence, effective coating strategies are needed to mitigate or decelerate adverse side reactions occurring during battery operation. Here, we present a facile coating approach based on preformed oxide nanoparticles (NPs) such as  $\text{ZrO}_2$  and  $\text{HfO}_2$ , enabling uniform surface coverage of the

NCM85 cathode material via wet-chemistry processing. From pellet-stack cell testing, the NP coatings are found to result in substantial improvements in reversibility, kinetics, capacity and longevity (compared to the uncoated counterpart). Detailed characterization revealed the effectiveness of the coating method in reducing electro-chemo-mechanical degradation at the cathode interface. Furthermore, the adaptability to processing slurry-cast electrodes has been explored, potentially allowing for scalable preparation of ASSBs.

#### 2:00 PM EN02.14.03

**Linking Microstructure and Ionic/Electronic Conductivity of Sulfide-Based Composite Cathodes with the Cell Performance** Nikolaos Papadopoulos, Elias Reisacher, [Pinar Kaya](#) and Volker Knoblauch; Materials Research Institute (IMFAA)/Aalen University, Germany

Compared to conventional lithium-ion batteries (LIBs) bearing liquid electrolytes, ASSBs (all-solid-state batteries) have the potential to improve safety and achieve higher performance and energy density [1]. However, there are still many challenges to tackle in order to achieve Li-ASSBs with sufficient cell performance. One of those challenges is overcoming the complexity within the composite cathode. Liquid electrolytes can penetrate composite cathodes easily, while solid electrolytes cannot, leading to residual porosity in the cathode, which then blocks the ionic and electronic charge transport pathways. On the other hand, the degradation of the solid electrolyte (SE), cathode active material (CAM), and conductive additive (CA) caused by parasitic side reactions have to be tackled with protective coatings that hinder the degradation but at the same time keep the charge transport pathways open [2,3]. Therefore, the composite cathode microstructure (e.g., optimal composition ratios<sub>CAM:SE:CA</sub>, particle characteristics, distribution of the phases) must be designed for different materials systems to ensure a perfect percolation and provide sufficient ions and electrons, thus tortuosity [4-7]. In this study, we aim to deepen the understanding of the correlation between microstructure and ionic/electronic conductivity of composite cathode with the cell performance. For this purpose, a conductive matrix (CM) comprising  $\text{Li}_6\text{PS}_5\text{Cl}$  and C65 was developed and used within the composite cathode. Effective ionic and electronic conductivities of different cathode mixtures of the conductive matrix and NMC622, as well as microstructural evolution, were analyzed. Subsequently, these findings were correlated with the rate capability and cycling performance of the cells. We determined the electronic percolation threshold of the conducting matrix (CM) to keep the amount of C65 as low as possible and detected the ionic/electronic limitations for the composite cathode mixtures by varying the active material content. The results of this study will shed light on how to optimize the microstructure to achieve the best cell performance

**Overcoming the Interfacial Challenges of  $\text{LiFePO}_4$  in Inorganic All-Solid-State Batteries** [Ashley Cronk](#)<sup>1</sup>, Yu-Ting Chen<sup>1</sup>, Grayson Deysher<sup>1</sup>, So-Yeon Ham<sup>1</sup>, Hedi Yang<sup>2</sup>, Phillip Ridley<sup>1</sup>, Baharak Sayahpour<sup>1</sup>, Long Hoang Bao Nguyen<sup>1</sup>, Jin An Sam Oh<sup>1</sup>, Jihyun Jang<sup>1</sup>, Darren Tan<sup>1</sup> and Y. Shirley Meng<sup>2</sup>; <sup>1</sup>University of California, San Diego, United States; <sup>2</sup>The University of Chicago, United States

All-solid-state batteries (ASSBs) are one of the most promising systems to enable long-lasting and thermally resilient next-generation energy storage. Ideally, these systems should utilize low-cost resources with reduced reliance on critical materials. Pursuing cobalt- and nickel-free chemistries, like  $\text{LiFePO}_4$  (LFP), is a promising strategy. Morphological features of LFP essential for improved electrochemical performance are highlighted to elucidate the interfacial challenges when implemented in ASSBs, since adoption in inorganic ASSBs has yet to be reported. In this work, the compatibility of LFP with two types of solid-state electrolytes,  $\text{Li}_6\text{PS}_5\text{Cl}$  (LPSCI) and  $\text{Li}_7\text{ZrCl}_6$  (LZC), are investigated. The potential existence of oxidative decomposition products is probed using a combination of structural, electrochemical, and spectroscopic analyses. Bulk and interfacial characterization reveal that the sulfide-based electrolyte LPSCI decomposes into insulative products, and electrochemical impedance spectroscopy is used to quantify the resulting impedance growth. However, through utilization of the chloride-based electrolyte LZC, high-rate and stable electrochemical performance is achieved at room temperature.

**Development of Materials for All-Solid-State Metal-Sulfur Batteries** [Donghai Wang](#); The Pennsylvania State University, United States

With advances in electrification in transportation, extensive use of power electronics, and utilization of renewable energy and their assimilation into the electrical grid, there is a clear need to develop high-performance, safer, and more sustainable energy storage technologies for future emerging applications. All-solid-state metal-sulfur battery technology is the most promising candidate for next-generation batteries due to its high energy density, long cycle life,

and superior safety. However, it faces many challenges from both metal anodes and sulfur cathodes, such as metal dendrite penetration and poor sulfur utilization of the cathode. In this talk, first, I will present a novel approach based on the use of organic-inorganic nanocomposite interphase to construct a stable lithium/solid-state electrolyte interface for stable Li plating/stripping. Second, I will present approaches to developing high-performance solid-state metal-sulfur batteries, including synthesizing highly conductive solid-state electrolytes and fabricating low-cost cathode materials, potentially for electric vehicle and stationary energy storage applications. Together, I would like to demonstrate the research effort aiming to build our knowledge, expertise, and understanding of critical electrochemical processes and mechanisms to employ desired features in electrochemical energy storage systems to meet the requirement of new energy applications.

**Composite Cathode Engineering for Advanced All-Solid-State Lithium-Sulfur Batteries** Guiliang Xu, Jieun Lee, Khalil Amine and Chen Zhao; Argonne National Laboratory, United States

In this talk, we will overview the challenges of all-solid-state lithium-sulfur batteries. We will then introduce our strategies by composite cathode engineering to significantly improve the sulfur utilization (~100%) and reversibility towards high S loading under room temperature. We will also talk about advanced characterization techniques to reveal the underlying mechanism for the improved cell performance. The findings will provide new insights into the failure mechanism and offer new strategies to advance all-solid-state lithium-sulfur batteries.

### 4:00 PM \*EN02.15.03

**Electrolyte Design for Intermediate-Temperature Na-S Batteries with High Energy Density** Yuan Yang; Columbia University, United States

The conventional high-temperature sodium sulfur battery is an attractive technology for grid-level energy storage due to its low cost, high energy density and long cycle life. However, this system operates at 300-350 °C, which not only increases cost, but also accelerates degradation and causes potential safety issues. On the other side, Na-S batteries working at intermediate temperatures (e.g., 100-150 °C) are attractive, but the formation of solid Na<sub>2</sub>S<sub>2</sub> and Na<sub>2</sub>S with low ionic diffusivity and electronic conductivity limits its specific capacity to ~500 mAh/g and thus energy density. In this study, we have developed a new electrolyte solvent that can dissolve all sulfides and polysulfides, which avoids the poor kinetics in Na<sub>2</sub>S<sub>2</sub> and Na<sub>2</sub>S, and allows Na-S batteries to operate at ~75 °C. Based on the 1 mol L<sup>-1</sup> sulfur catholyte, a high specific capacity of 1640 mAhg<sup>-1</sup> is achieved at 0.13 mA cm<sup>-2</sup>. When increased to the 4 mol L<sup>-1</sup>, the capacity is achieved 830 mAhg<sup>-1</sup> and shows capacity retention of 70% over 1000 cycles. Such a system has potential applications for long-duration energy storage.

### 4:30 PM EN02.15.04

**Understanding Electrochemical Reaction Mechanisms of Sulfur in All-Solid-State Batteries Through *Operando* and Theoretical Studies** Hongli Zhu; Northeastern University, United States

Sulfur, with its high theoretical specific capacity of 1675 mAh g<sup>-1</sup>, affordability, and earth abundance, stands as a promising candidate for cathodes. Lithium-sulfur (Li-S) batteries, boasting an ultrahigh theoretical energy density (2600 Wh kg<sup>-1</sup>)— a value ten times higher than that of contemporary commercial Lithium-ion batteries, hold immense potential. Yet, Li-S batteries employing ether-based liquid electrolytes face challenges such as the formation of long-chain polysulfides and the shuttle effect, leading to rapid capacity decay, low coulombic efficiency, and poor cycling life. All-solid-state lithium-sulfur batteries (ASLSBs), which substitute traditional organic liquid electrolyte with solid-state electrolytes (SEs), are considered to be a fundamental solution to these issues. SEs provide enhanced safety compared to their flammable and volatile organic counterparts and are assumed to eliminate the formation of polysulfides, thereby inherently addressing the shuttle effects.

Nevertheless, the absence of clear experimental evidence to understand the chemistries and mechanisms of sulfur's electrochemical reaction in ASLSBs prompts further investigation. Existing literature suggests the chemistries in ASLSBs transition directly from S<sub>8</sub> to Li<sub>2</sub>S. However, the overlooked formation of Li<sub>2</sub>S<sub>2</sub>, insoluble in liquid electrolytes, could potentially impact ASLSB performance. Considering Li<sub>2</sub>S<sub>2</sub> is a thermodynamically unstable phase, the implementation of advanced in-operando characterization becomes crucial for a deeper understanding of the reaction mechanisms in ASLSBs. In this talk, we present four key findings that would be of interest to the readership of MRS audiences:

1. We study the chemical transformation of sulfur in ASLSBs and elucidate the reaction mechanism via a combination of operando Raman spectroscopy and ex-situ X-ray absorption spectroscopy (XAS). This gives us the first empirical proof of electrochemical pathways in ASLSBs.
2. We designed a unique cell for the operando Raman study, facilitating the characterization of the battery in an inert argon atmosphere within a cleanroom-in-a-glovebox system. This custom cell with a side window and a pressure-controlling stainless-steel framework allows internal battery material exposure post-assembly without further sealing. Moreover, its square design ensures a focused laser beam on a flat sample surface, eliminating background distractions.
3. We have, for the first time, unveiled a two-step transformation in the Li-S redox reaction in ASLSBs. Our findings prove that the process does not generate any long-chain polysulfides, thereby inhibiting the shuttle effect in SE, a significant departure from the scenario with liquid electrolyte.
4. We found that the transition among S<sub>8</sub>, Li<sub>2</sub>S<sub>2</sub>, and Li<sub>2</sub>S exhibits sluggish reaction kinetics, caused by the slow "point-to-point" ion diffusion at the interface in ASLSBs and high "solid to solid" reaction barrier, resulting in incomplete reactions during both discharging and charging processes. These insights will contribute to the continued research and development in the field of ASLSBs.

### 4:45 PM EN02.15.05

**Influence of Carbon Blends for Cathode Active Material Pre-Treatment on Battery Performance** Martin A. Lange and Wolfgang Zeier; WWU Münster, Germany

Solid state batteries show significant potential. Specifically, the lithium-sulfur system shows significant potential thanks to its large gravimetric capacity and the lack of the problematic sulfur-shuttle effect as encountered in liquid cells. To achieve sufficient utilization of the active material, appropriate solid conductors for both ionic and electronic conduction have to be added to the cathode material mixture. While solid electrolytes are studied intensively in regards to optimizing their ionic conductivity, influences of electron conductors are studied more sparsely. Somewhat structured carbons such as carbon fibers are often used with the idea to provide prefabricated conductive pathways, but without in-depth investigation of the interactions between the individual components of the solid cathode composites during mixing.

In this study, we show how already simple mixing of two basic carbons in solid sulfur cathode composites alters significantly the cycling behavior in half-cells. For this purpose, we analyzed two mixtures of two different carbon species in different ratios. For both systems, cathode composites prepared with pure carbons results in vastly different performance than achieved by simple blending of the two carbons. It can be shown, that rather than utilizing purely one sort of carbon, improvements in performance can be achieved by application of specific carbon mixtures, although the exact ratio depends strongly on the type of the added carbons. This means that it is already possible to make significant improvements to the solid lithium-sulfur battery system by mixing simple, inexpensive carbons rather than using complex-structured, expensive carbons, which is particularly interesting in terms of advances in industrial applications and commercialization.

**Fast Sintering and Polymorphism of NASICON-Type  $\text{LiZr}_2(\text{PO}_4)_3$  Solid Electrolyte Materials** Lin Lin and Kelsey B. Hatzell; Princeton University, United States

Conventional solid electrolyte manufacturing and materials processing methods are too complex and expensive for scalability. Specifically for oxide solid electrolytes, the high-temperature and long synthesis and sintering procedures introduce significant time and energy cost. Various fast sintering methods have been developed in the past decade to address this manufacturing challenge [1]. Manufacturing dense, highly conducting solid electrolytes in air and in minutes (or seconds) are desirable for solid state battery manufacturing. (NASICON)-type  $\text{LiZr}_2(\text{PO}_4)_3$  (LZP) in one type of solid electrolyte which demonstrates excellent air and water stability, as well as good resistance to Li reduction at interfaces [2]. However, LZP exhibits rich polymorphism, with different phases showing distinct crystal structures and ion transport mechanisms [2]. Previous studies have shown that polymorphism observed in garnet-type  $\text{Li}_7\text{La}_3\text{Zr}_2\text{O}_{12}$  solid electrolyte significantly affects the transport and chemo-mechanical properties [3]. Yet the polymorphism in solid electrolytes has seldom been exclusively studied and controlled. In this work, we developed a modified air-compatible ultrafast high-temperature sintering (UHS) approach and successfully sintered LZP within a few minutes. X-ray diffraction analysis reveals how processing impacts polymorphism in this class of materials. The green body contains almost fully  $\alpha'$ -triclinic, low ionic conductivity phase. The highly conducting  $\alpha$ -rhombohedral polymorph can be achieved in only minutes with ultrafast sintering. The ratio of two phases are strongly affected by the processing temperatures and times. The percentages of rhombohedral phase increase from 53% to 68% as the sintering temperature increases from 900 to 1200 °C when keeping a 5 min sintering time. On the other hand, with the sintering temperature kept at 1200 °C, the percentages of rhombohedral phase increase from 54% to 83% when increasing the sintering time from 1 min to 8 min. These results present pathways to ultrafast manufacturing process that enable control over structure and transport.

**Not Just an Unwanted Impurity Phase: Pyrochlores as Convenient Precursors to Li Conducting Garnets** Jinzhao Guo and Candace K. Chan; Arizona State University, United States

Garnet-type solid-state electrolytes such as Ta-doped  $\text{Li}_7\text{La}_3\text{Zr}_2\text{O}_{12}$  (LLZTO) are promising ceramic electrolytes for all-solid-state batteries because of their high (electro)chemical stability and ionic conductivity. LLZTO is typically synthesized from oxide precursors via solid-state reaction, but use of other precursors can lead to improved phase purity and more homogenous dopant distribution. We recently demonstrated that pyrochlores, usually seen as an unwanted impurity phase in the synthesis of garnets, can actually serve as the starting precursor for LLZTO, a process we call “pyrochlore-to-garnet” (P2G). Nanocrystalline pyrochlore prepared using molten salt synthesis and a scalable sol-gel method are demonstrated to enable formation of dense LLZTO ceramic directly via reactive sintering of the pyrochlore and a lithium source. The LLZTO prepared via P2G displays high relative density and ionic conductivity comparable to LLZTO prepared by solid-state reaction, but with much shorter sintering times. Investigation of the synthesis parameters shows that liquid phase sintering is important for achieving high pellet densities and phase-purity. Additionally, while the LLZTO grain sizes obtained using this P2G method are smaller than those from conventional sintering of LLZTO particles, the P2G pellets can sustain higher critical current densities before shorting in lithium stripping/plating experiments compared to conventional LLZTO prepared by solid-state reaction. This work shows P2G is promising as an alternate method for the synthesis and processing of LLZTO materials.

#### 8:30 AM EN02.16.03

**Multifunctional Coatings on Sulfide-Based Solid Electrolyte Powders with Enhanced Processability, Stability and Performance for Solid-State Batteries** Zachary D. Hood, Anil U. Mane, Aditya Sundar, Sanja Tepavcevic, Peter Zapol, Udochukwu D. Eze, Shiba P. Adhikari, Eungje Lee, George Sterbinsky, Jeffrey W. Elam and Justin Connell; Argonne National Laboratory, United States

Sulfide-based solid-state electrolytes (SSEs) represent one of the most promising classes of materials for next-generation all-solid-state Li-ion batteries due to their many beneficial properties, including high ionic conductivity and favorable mechanical properties that make them more readily amenable to processing at scale. However, widespread adoption of these materials is hindered by their intrinsic instability under ambient conditions, as well as by (electro)chemical instability at the Li||SSE and cathode||SSE interfaces, which limits cell performance and lifetime. We have developed a method that utilizes atomic layer deposition (ALD) to grow thin, oxide-based coatings on argyrodite  $\text{Li}_6\text{PS}_5\text{Cl}$  (LPSCl) powders to address both issues simultaneously. We demonstrate that thin films of aluminum oxide ( $\text{Al}_2\text{O}_3$ ) can be directly grown onto argyrodite particles using trimethyl aluminum and  $\text{H}_2\text{O}$  with minimal chemical modification of the underlying material. These coatings enable exposure of LPSCl powders to pure and  $\text{H}_2\text{O}$ -saturated oxygen environments for  $\geq 4$  hours with little to no reactivity, compared with significant degradation of the uncoated powder. Furthermore, pellets fabricated from coated LPSCl powders exhibit bulk ionic conductivities up to  $2\times$  higher than those made from uncoated material, with a simultaneous decrease in electronic conductivity. These favorable transport properties are coupled with significant suppression of  $\text{Li}_2\text{S}$  and  $\text{Li}_3\text{P}$  formation observed at the Li-SSE interface, confirming improved chemical stability with Li metal anodes. These benefits result in significantly improved room temperature cycle life at high capacity and current density ( $\geq 150$  cycles at  $1 \text{ mAh/cm}^2$  per cycle and  $0.5 \text{ mA/cm}^2$ ). We hypothesize that these enhanced properties derive from improved electronic and chemical properties at intergranular boundaries, as well as improved Li metal adhesion at the interface. Similar improvements in materials properties are achieved using ALD coating chemistries beyond  $\text{Al}_2\text{O}_3$ . This work points to a completely new framework for designing active, stable, and scalable materials for next-generation solid-state batteries.

**Spray-Flame Synthesis of NASICON-Type  $\text{Li}_{1.3}\text{Al}_{0.3}\text{Y}_{0.3-x}\text{Ti}_{1.7}(\text{PO}_4)_3$  ( $x=0-1.5$ ) Solid Electrolytes** Md Yusuf Ali<sup>1</sup>, Hans Orthner<sup>1</sup> and Hartmut Wiggers<sup>1,2</sup>; <sup>1</sup>Institute for Energy and Materials Processes – Reactive Fluids; University of Duisburg-Essen, Germany; <sup>2</sup>Center for Nanointegration Duisburg-Essen, Germany

Due to its safety, low cost, and high energy density characteristics, solid-state lithium-ion batteries have been recognized as one of the most promising candidates for future green energy storage technologies. Electrolytes made of polymers and ceramics are prime candidates to expand the use of lithium metal batteries. Single-ion conducting polymers can lessen polarization and the formation of lithium dendrites, but they eventually become extremely inflexible mechanically, necessitating mobilizers such as organic solvents to move Li ions. Inhomogeneous solvent dispersion and the accompanying preferred Li transport paths may result in favored locations for Li plating, adding mechanical stress and maybe even causing early cell short-circuits. However, ceramic-based electrolytes, such as  $\text{Li}_{1.3}\text{Al}_{0.3}\text{Ti}_{1.7}(\text{PO}_4)_3$  (LATP) NASICON, are renowned for their superior dendritic growth inhibitor and high-temperature adaptability. In contrast to other wet synthesis methods, spray-flame synthesis is affordable and incredibly simple to scale up with excellent purity, thus we looked into the best conditions to synthesize LATP solid electrolyte. We found that nitrates are better than acetates as metal precursors, and excess Li is indeed necessary in precursor solution to synthesize pure phase LATP. We characterized the resulting nanoparticles by state-of-the-art techniques such as XRD, XPS, TEM, Raman Spectroscopy etc. The as-prepared spray flame synthesized nanoparticles are found to be  $\text{TiO}_2$  and with Li carbonate on the surface as confirmed by XPS, and it requires a high-temperature calcination ( $\sim 750^\circ\text{C}$ ) to finally form LATP phase. However, the ionic conductivity of LATP phase samples (0.049 mS/cm) were not up to the industrial standard. To further increase the ionic conductivity of LATP electrolytes the  $\text{Al}^{3+}$  (0.535 Å) substitution with similar charge  $\text{Y}^{3+}$  (0.93 Å) was carried out  $\text{Li}_{1.3}\text{Al}_{0.3}\text{Y}_{0.3-x}\text{Ti}_{1.7}(\text{PO}_4)_3$  ( $x=0$  to 1.5). Moreover, the large size of  $\text{Y}^{3+}$  distorts the NASICON structure and provides broad passage for the  $\text{Li}^+$  ion to pass through. The enhanced electrochemical characteristics of LATP samples make it possible to see how Y doping affects the samples. The synthesized sample ( $x=0.1$  doped) has a conductivity of around 0.000092 mS/cm. Because of as synthesized  $\text{TiO}_2$  phase. However, after calcining at  $700^\circ\text{C}$ , a rise in conductivity (0.006042 mS/cm) can be seen for the sample due to phase transformation to LATP. Further increment in ionic conductivity was done while simultaneously increasing the grain boundary of the pellet. And the final conductivity was reached as high as 0.87 mS/cm which almost reaches the milestone for NASICON solid state electrolytes.

**Unveiling Low-Temperature Sintering of Solid-State Ceramic Composite Electrolytes via *In-Situ* Electrochemical Impedance Spectroscopy** Bo Nie and Hongtao Sun; Penn State University, United States

The increasing safety concerns surrounding high-energy density rechargeable batteries have spurred interest in the development of solid-state electrolytes, aiming for nonflammable and tolerance to extreme conditions. However, conventional fabrication methods of ceramic-based composites face two primary challenges: limited ability to simultaneously tune the intergranular phase and achieve high material density, as well as a lack of efficient methodology to address interfacial issues under mild processing conditions. Consequently, producing stable solid-state electrolytes with low interface resistance, particularly solid-state oxide electrolytes, without resorting to high-temperature sintering for extended periods remains a challenge. To overcome these challenges, we introduce a cold sintering process (CSP), a multistage nonequilibrium approach combining dissolution-precipitation under external stress, viscous flow of saturated solutions, and species diffusion for the fabrication of highly ionic conductive solid-state electrolytes at low processing temperatures. Additionally, CSP bridges the temperature gap between high melting point constituents (e.g., ceramics) and low melting point constituents (e.g., nano-sized additives, or polymers), enabling the co-sintering of ceramic-based composites for a wide range of solid-state electrolytes. In this study, CSP was utilized to prepare a solid-state NASICON-Halide (nanosized  $\text{Li}_3\text{InCl}_6$  in LATP matrix) composite electrolyte. To gain further insight into the sintering dynamics and the process-structure-property correlation, we employed electrochemical impedance spectroscopy (EIS) as an in-line monitoring tool to study the real-time impedance during the CSP. We considered the mixed ceramic powders with a small volume of transient solvent as an effective dielectric medium. Through simulations using an equivalent circuit comprising a constant phase element and a resistive element, we captured the dielectric properties and resistance sensitive to CSP, which vary as evaporation and densification occur. Decoding the resulting resistance data provided a profound understanding of the temperature and pressure effects. Furthermore, we investigated the associated microstructures and ionic conductivities to understand the process-structure-property correlation. The highly dense composite electrolyte, with a small fraction of  $\text{Li}_3\text{InCl}_6$ , exhibited an impressive ionic conductivity of  $10^{-4} \text{ S cm}^{-1}$  at room temperature, along with excellent reversibility in transporting Li ions for thousands of hours at a cycling capacity of  $1 \text{ mAh cm}^{-2}$ .

**High-Entropy Lithium Argyrodite Superionic Conductors** Jing Lin<sup>1</sup>, Mareen Schaller<sup>2</sup>, Sylvio Indris<sup>2</sup>, Jürgen Janek<sup>1,3</sup>, Aleksandr Kondrakov<sup>4</sup>, Torsten Brezesinski<sup>1</sup> and Florian Strauss<sup>1</sup>; <sup>1</sup>Battery and Electrochemistry Laboratory, Institute of Nanotechnology, Karlsruhe Institute of Technology (KIT), Germany; <sup>2</sup>Institute for Applied Materials–Energy Storage Systems, Karlsruhe Institute of Technology (KIT), Germany; <sup>3</sup>Institute of Physical Chemistry, Justus-Liebig-University Giessen, Germany; <sup>4</sup>BASF SE, Germany

Solid-state batteries (SSBs) are a potentially safe, next-generation energy storage technology. For SSBs to be commercially viable, the development of solid electrolytes with high ionic conductivity, high (electro)chemical stability, and good processability is imperative. A new strategy for modifying materials, potentially leading to improved properties, is the high-entropy (HEMs) concept, referring to compounds having five or more elements occupying a single crystallographic site (resulting in a configurational entropy  $\Delta S_{\text{conf}} \geq 1.5R$ ). Our recent research has shown that high-entropy argyrodites (HEAs) can be synthesized both by multianionic and/or -cationic substitution. Especially, multication substituted HEA shows a low activation energy ( $E_A \approx 0.20 \text{ eV}$ ) for lithium transport and a high r.t. ionic conductivity ( $\approx 10 \text{ mS/cm}$ ) as shown by  $^7\text{Li}$  pulsed field gradient (PFG) nuclear magnetic resonance (NMR) spectroscopy and electrochemical impedance spectroscopy (EIS). These findings were rationalized from a structural point of view via neutron powder diffraction in combination with magic angle spinning (MAS) NMR spectroscopy. For the multication substituted HEA, high  $\text{S}^{2-}/\text{T}$  anion site disorder (up to  $\sim 11\%$ ) and  $\text{Li}^+$  redistribution led to shortened jump distances and therefore facilitated long-range ion diffusion. Conversely, multianionic substitution resulted in increased intercege jump distances. Overall, our results emphasize the potential of high-entropy lithium argyrodites (large compositional space) for developing novel superionic conductors with enhanced properties.

**Materials Design for Solid State Sodium-Ion Batteries** Xianguang Miao, Yichao Wang, Yifan Wu, Junyeob Moon and Xin Li; Harvard University, United States

Solid state sodium-ion batteries with nonflammable inorganic electrolytes are promising for large-scale energy storage applications. The current battery performance is hindered by problems related to the electrolyte materials, e.g., severe dendrite propagation and interface reaction of conventional Na<sub>3</sub>PS<sub>4</sub> anolyte, and low Na<sup>+</sup> conductivity of halide catholyte. Here we propose a newly designed electrolyte with high conductivity, superior formability under cold-press process and improved electrochemical stability toward the anode. The battery with NaCrO<sub>2</sub> cathode demonstrates a long cycling life at high rate. We demonstrate that this material platform is also applicable to many other cathodes with higher charge voltage.

**The Influence of Synthesis Procedure on the Structure and Ionic Transport Property of Substituted Sodium Metal Halide** Tong Zhao and Wolfgang Zeier; University of Münster, Germany

Sodium all-solid-state batteries have attracted growing interest in recent years because of their potentially high energy densities and superior safety as well as the abundance of sodium. Sodium metal halides are viewed as promising candidates for catholytes in sodium all-solid-state batteries since they have wide electrochemical windows and excellent electrochemical compatibility toward oxide cathode materials, as well as good mechanical deformability and scale-up capability. However, the low ionic conductivity hinders their practical application. Substitution is an effective way to improve the ionic transport properties of ionic conductors.

Herein, we introduced aliovalent cation In<sup>3+</sup> in Na<sub>2</sub>ZrCl<sub>6</sub> and the X-ray diffraction analyses show a full indium solubility in the 200°C annealed Na<sub>2+x</sub>Zr<sub>1-x</sub>In<sub>x</sub>Cl<sub>6</sub> crystallized in a P2<sub>1</sub>/n phase while that exsolves at higher heat treatment temperatures because the indium-rich Na<sub>2+x</sub>Zr<sub>1-x</sub>In<sub>x</sub>Cl<sub>6</sub> compound tends to partially transform to a P1c phase. By assessing the ionic conductivity of the differently synthesized Na<sub>2+x</sub>Zr<sub>1-x</sub>In<sub>x</sub>Cl<sub>6</sub> series, we can show the synergistic effect of the Na<sup>+</sup>/vacancy ratio and crystallinity on sodium ion transport in this class of materials which can enhance the ionic conductivity by three orders of magnitude.<sup>1</sup> Besides the cation doping, anion-mixed sodium halide (Na<sub>3</sub>InCl<sub>6-x</sub>Br<sub>x</sub>) is also explored. By milling, the Na<sub>3</sub>InCl<sub>6-x</sub>Br<sub>x</sub> (0 ≤ x ≤ 1.5) solid solution series crystallizes in a monoclinic P2<sub>1</sub>/n phase, while the subsequently annealed Na<sub>3</sub>InCl<sub>6-x</sub>Br<sub>x</sub> (0 ≤ x ≤ 2) series transforms into a trigonal P1c phase. A greater anion solubility can be achieved by annealing and changing the structure type. Unlike the cation substituted Na<sub>2+x</sub>Zr<sub>1-x</sub>In<sub>x</sub>Cl<sub>6</sub> series, in Na<sub>3</sub>InCl<sub>6-x</sub>Br<sub>x</sub> only slight improvements to the ionic conductivity are observed possibly due to an unfavorable trade-off between high pre-factor and low activation energy resulting from an enthalpy-entropy compensation behavior fulfilling the Meyer-Neldel rule.<sup>2</sup>

These works further highlight the strong dependence of the structure and solubility of sodium metal halides on the synthesis protocol and shed light on the design principle and synthesis strategy of this class of materials as solid electrolytes.

**A New Halide Solid Electrolyte for Sodium Solid-State Batteries** Erik Wu and Darren Tan; Unigrid Inc., United States

UNIGRID Battery aims to develop a sodium solid-state battery (Na SSBs) for stationary storage applications such as residential and grid storage. Na SSBs have been touted to offer improved safety (from the use of nonflammable solid-state electrolytes, or SSEs), lowered costs due to the use of abundant sodium-based materials, and higher performance, potentially culminating in a device with long life and high volumetric energy density. In recent years, the development of new SSEs for Na SSBs, such as halides and closo-borates, have advanced high-performance Na SSB chemistries closer to feasibility. However, each of these materials have their own drawbacks; the halides typically have lower sodium ion conductivity and are unstable with the anode, and the closo-borates are primarily cost-prohibitive and are less stable with cathodes. Thus, a single electrolyte with high Na ion conductivity, low costs, and stability with both electrodes remains elusive. Here, we report a new, thermally robust halide with a conductivity of 1 x 10<sup>-3</sup> S/cm at room temperature, at least an order of magnitude increase compared to previously reported Na-conducting halides. The halide is employed as a catholyte and cycling is demonstrated in a bilayer Na SSB configuration with superior rate performance.

#### 11:00 AM EN02.17.04

**On the Discrepancy Between Local and Average Structure in Solid Electrolytes** Oliver Maus<sup>1,2</sup> and Wolfgang Zeier<sup>1,2,3</sup>; <sup>1</sup>University of Muenster, Germany; <sup>2</sup>Baccara Graduate School, Germany; <sup>3</sup>Helmholtz-Institut Muenster, Germany

All-solid state batteries are promising candidates to achieve high energy densities and enable the use of high capacity anodes such as lithium metal or silicon alloys but for highly performing solid-state batteries it is crucial to have solid electrolytes with high ionic conductivities above 10 mS/cm. Aliovalent substitution is a common strategy to improve the ionic conductivity of solid electrolytes. The substitution of SbS<sub>4</sub><sup>3-</sup> by WS<sub>4</sub><sup>2-</sup> in the Na<sup>+</sup> ionic conductor Na<sub>2.9</sub>Sb<sub>0.9</sub>W<sub>0.1</sub>S<sub>4</sub> leads to a very high ionic conductivity of 41 mS/cm at room temperature. While pristine Na<sub>3</sub>SbS<sub>4</sub> crystallizes in a tetragonal structure, the substituted Na<sub>2.9</sub>Sb<sub>0.9</sub>W<sub>0.1</sub>S<sub>4</sub> seems to crystallize in a cubic structure based on its X-ray diffractogram. By allowing 3D diffusion pathways, the cubic structure was assumed to be one of the driving forces for the conductivity enhancement in Na<sub>2.9</sub>Sb<sub>0.9</sub>W<sub>0.1</sub>S<sub>4</sub>. Here, we show by performing pair distribution function analyses and static single-pulse <sup>121</sup>Sb NMR experiments that the short-range order of Na<sub>2.9</sub>Sb<sub>0.9</sub>W<sub>0.1</sub>S<sub>4</sub> remains tetragonal despite the change in the Bragg diffraction pattern. Temperature-dependent Raman spectroscopy revealed that changed lattice dynamics due to the increased disorder in the Na<sup>+</sup> substructure leads to dynamic sampling causing the discrepancy in local and average structure. While showing no differences in the local structure, when compared to pristine Na<sub>3</sub>SbS<sub>4</sub>, quasi-elastic neutron scattering and solid-state <sup>23</sup>Na nuclear magnetic resonance measurements revealed drastically improved Na<sup>+</sup> diffusivity and decreased activation energies for Na<sub>2.9</sub>Sb<sub>0.9</sub>W<sub>0.1</sub>S<sub>4</sub>. The obtained diffusion coefficients are in very good agreement with theoretical values and long-range transport measured by impedance spectroscopy. This work shows how aliovalent substitution can lead to discrepancies of local and average structure and systematically studies the causes and effects of the

phenomenon. It demonstrates the importance of studying the local structure of ionic conductors in order to fully understand their transport mechanisms, a prerequisite for the development of faster ionic conductors.

**Exploring the Effect of Phosphorous Deficiency on Ionic Conductivity in NaSICON-Type Solid-Electrolytes derived from Flame-Made Nanoparticles** Mohammed-Ali Sheikh<sup>1</sup> and Hartmut Wiggers<sup>1,2</sup>; <sup>1</sup>University of Duisburg-Essen, Germany; <sup>2</sup>Center for Nanointegration Duisburg-Essen (CENIDE), Germany

The battery market has recently shown that Na-ion batteries (SiB) have become a serious alternative to Li-ion batteries (LiB) [1, 2]. However, SiBs exhibit inferior energy density compared to their lithium-ion-based counterparts [3]. For further improving the energy density and safety of SiBs, solid-state SiBs (SSiBs) have gained a lot of interest and NaSICON-type solid-electrolytes are promising materials for such an application owing to their high ionic conductivity of  $10^{-4}$ – $10^{-3}$  Scm<sup>-1</sup> at room temperature and chemical as well as mechanical stability [4]. Recent studies revealed that the conductivity of Na<sub>3</sub>Zr<sub>2</sub>Si<sub>2</sub>PO<sub>12</sub> (NZSP) can be enhanced by increasing the silicon to phosphorous ratio [5] or doping NZSP with divalent cations [6].

In this work, we present the spray-flame synthesis (SFS) of NaSICON nanoparticles as a facile method to produce powders of different compositions and stoichiometries. For morphological characterization, transmission electron microscopy is employed. Structural information is obtained by X-ray diffraction (XRD) and Raman-spectroscopy. Thermogravimetry (TG) and differential scanning calorimetry (DSC) are utilized for thermal analysis of powders. Pressed pellets are sintered at 1100°C for 3h and their ionic conductivities are measured with impedance spectroscopy.

From SFS, nanoparticles with a mean diameter of 5 nm are obtained. They consist of fine ZrO<sub>2</sub> crystallites embedded in an amorphous phase of Na, Si and P. After a short annealing step of 1h at 1000°C, this mixture can be converted almost quantitatively into the desired rhombohedral NaSICON phase. Especially the composition Na<sub>3+x</sub>Zr<sub>2</sub>Si<sub>2+y</sub>P<sub>1-x</sub>O<sub>12</sub> and Mg-doped Na<sub>3+2y</sub>Mg<sub>y</sub>Zr<sub>2-y</sub>Si<sub>2</sub>PO<sub>12</sub> show - with respect to the short sintering time of 3h - remarkably high ionic conductivities of  $4 \times 10^{-4}$  Scm<sup>-1</sup> (for x=0.1) and  $9.3 \times 10^{-4}$  Scm<sup>-1</sup> (for y=0.2), respectively. XRD reveals that the addition of Mg beyond the solubility limit in NZSP leads to the formation of Mg-phosphates, creating a P-deficiency in the lattice of NZSP and thus improving the ionic conductivity significantly.

In conclusion, SFS enables the scalable production of NaSICON nanoparticles with tailored compositions allowing fast sintering. The improved ionic conductivities observed in the Mg-doped and phosphorous-deficient compositions hold promise for the development of high-performance solid-electrolytes.

**Critical Interphase Overpotential as a Lithium Dendrite Suppression Criterion for All-Solid-State Lithium Battery Design** Hongli Wan and Chunsheng Wang; University of Maryland, College Park, United States

Suppressing Li dendrite growth is a crucial challenge in the development of all-solid-state Li-metal batteries (ASSLBs). Penetration of Li dendrites through the solid-state electrolyte (SSE) can lead to short-circuiting of the cells, presenting a safety concern. The current density at which Li dendrites penetrate through the SSE and cause short-circuiting is termed the critical current density (CCD). The CCD not only depends on the intrinsic properties of the SSE but also on the thickness of the SSE. Furthermore, as the Li plating or stripping capacity, stack pressure, and interfacial resistance change the overpotential, which is the driving force for Li plating and stripping, these factors also change the CCD. Thus, because the CCD is not an intrinsic property of an SSE, it is difficult to use CCDs to design SSEs. Herein, we evaluate the lithium dendrite suppression capability of SSE using critical interphase overpotential (CIOP). The CIOP is the intrinsic property of the interphase, which depends on electronic/ionic conductivity, lithiophobicity, and mechanical strength. When the applied interphase overpotential (AIOP) is larger than CIOP, Li will grow into interphase as dendrites. To reduce AIOP but increase CIOP, we design a mix-conductive Li<sub>2</sub>NH-Mg interlayer between Li<sub>6</sub>PS<sub>5</sub>Cl SSE and Li-1.0wt%La anode, which transfers into Li<sub>6</sub>PS<sub>5</sub>Cl/LiMgS<sub>x</sub>/LiH-Li<sub>3</sub>N/LiMgLa after Mg migration during annealing and activation cycles. The LiMgS<sub>x</sub> interphase increases the CIOP from 9~12mV (of Li<sub>6</sub>PS<sub>5</sub>Cl) to ~220mV. The Li plates on LiMgLa surface and reversible penetration into the formed porous LiH-Li<sub>3</sub>N reducing AIOP. The CIOP provides design guidelines for high-energy and room-temperature all-solid-state lithium-metal batteries.

**Composites of Alkali Carbonphosphonitride Thermosets with LLZO and other Ion Conducting Ceramics** Andrew Purdy<sup>1</sup>, Ryan J. Buchwalder<sup>1,2</sup>, Daniel M. Fragiadakis<sup>1</sup>, Hunter O. Ford<sup>1,3</sup>, Christopher A. Klug<sup>1</sup>, Mark O. Bovee<sup>1,3</sup>, Megan B. Sassin<sup>1</sup> and Brian L. Chaloux<sup>1</sup>; <sup>1</sup>Naval Research Laboratory, United States; <sup>2</sup>NREIP Intern, United States; <sup>3</sup>NRC Postdoctoral Associate, United States

Lithium dicyanamide (LiN(CN)<sub>2</sub>) reacts with phosphorus cyanides (P(CN)<sub>3</sub> or RP(CN)<sub>2</sub>) in a 2:1 or greater mole ratio in an anhydrous aprotic mutual solvent to form a resin, which then cures at temperatures of 200-300 °C to a non-flammable ion conductor. When fully cured, these films have a low ionic conductivity, probably due to rigid crosslinking of the thermoset. We found previously that adding compounds to the resin, such as LiCN that contain a higher concentration of Li than LiN(CN)<sub>2</sub>, and some non-volatile organic plasticizers, increase the room temperature ionic conductivity from 10<sup>-12</sup> S/cm to around 10<sup>-8</sup> S/cm, and the Na versions can also be more conductive than those with Li. Post-cure treatment with diglyme also causes a dramatic

conductivity increase, presumably by complexing the mobile Li ions and plasticizing the material. While it seems unlikely that practical conductivities can be obtained in the pure resins, they might be attractive as binders for more highly conducting ceramic powders such as lithium lanthanum zirconium oxide (LLZO), in order to produce a composite material that can be cured to a solid electrolyte at temperatures compatible with other components. We will report our systematic efforts to use these dicyanamides and A-P-C-N (A = Li, Na) thermosets as binders for commercially available ion conducting ceramics. The ratios of resin to ceramic and the conditions of preparation are varied to produce solid composite films for measurement, and the ionic conductivity and chain motions of these films are characterized by impedance and dielectric relaxation spectroscopy. Test cells with Li foil are constructed and measured to evaluate electrochemical stability and lithium transference numbers. Additionally, solid state NMR is used to examine the compositional stability of the composite and the ion mobility between different ionic conductors.

#### 2:15 PM EN02.18.04

**Material Design of Quaternary Halide Electrolytes** [Anthony Onwuli](#)<sup>1</sup>, Alex M. Ganose<sup>1</sup>, Aron Walsh<sup>1,2</sup> and Ieuan D. Seymour<sup>3,1</sup>; <sup>1</sup>Imperial College London, United Kingdom; <sup>2</sup>Ewha Womans University, Korea (the Republic of); <sup>3</sup>University of Aberdeen, United Kingdom

The future of electrochemical energy storage can be considered to be within the development of all-solid-state batteries (ASSBs). The key to enabling this future resides in the result of solid-state electrolytes (SSEs). For lithium-ion battery systems, halide electrolytes have been reported with room temperature ionic conductivities  $>10^{-3}$  S cm<sup>-1</sup>, good stability against oxidation, and good stability against cathode materials<sup>1</sup>. We find that the space explored for sodium halide electrolytes has been somewhat limited within the literature and primarily focused on ternary sodium chloride SSEs with the limited investigation of sodium bromide and iodide SSEs<sup>2,3,4</sup>. Previous studies have demonstrated that Li-halide systems such as Li<sub>3</sub>YCl<sub>6</sub> (P-3m1) and Li<sub>3</sub>InCl<sub>6</sub> (C2/m) form layered structures with high ionic conductivity. In contrast, ternary halides such as Na<sub>3</sub>YCl<sub>6</sub> often form double perovskite structures (P21/n) with intrinsically low ionic conductivity. Discovering new layered Na-halide systems is crucial to improving the ionic conductivity of this class of materials. This study provides a high-throughput materials design workflow to provide insight into the development of quaternary sodium metal halide SSEs through theoretical calculations of thermodynamic stability, electrochemical stability, stability against common sodium cathodes, transport properties as well as the synthesis of Na<sub>6</sub>M<sup>+</sup>M<sup>+</sup>X<sub>12</sub> SSEs. 3710 compositions are considered in four different space groups, P21/n, P-3m1, P31c, C2/m. Our candidate pool is screened to 25 candidates by filtering for a ground state phase in the C2/m structure, on the convex hull (E<sub>hull</sub>=0), no radioactive elements and an insulator (PBEsol bandgap  $>2$  eV). High oxidation potentials are often observed for the candidates indicating stability against cathodes. Further interface thermodynamics stability analysis revealed that there is a driving force for reactions at the interface between the SSEs and cathodes. On-the-fly machine-learning molecular dynamics (MLMD) was used to probe the ionic conductivity of the candidates. Synthesis of promising candidate material Na<sub>6</sub>CaZrBr<sub>12</sub> revealed the existence of a sodium halo spinel phase not initially considered in the initial high-throughput screening. The high-throughput screening and synthesis performed in this study can provide design principles for the development of new SSEs and can be extrapolated to other conducting-ion systems as well as providing a method to expand the search space of known SSE chemistries.

**Deep Learning of Experimental Electrochemistry for Battery Cathodes Across Diverse Compositions** [Peichen Zhong](#)<sup>1</sup>, Bowen Deng<sup>1</sup>, Tanjin He<sup>1</sup>, Zhengyan Lun<sup>2,1</sup> and Gerbrand Ceder<sup>1</sup>; <sup>1</sup>University of California Berkeley, United States; <sup>2</sup>University of Chinese Academy of Sciences, China

Artificial intelligence (AI) has emerged as a powerful tool in the discovery and optimization of novel battery materials. However, the adoption of AI in battery cathode representation and discovery is still limited due to the complexity of optimizing multiple performance properties and the scarcity of high-fidelity data. In this study, we present a comprehensive machine-learning model (DRXNet) for battery informatics and demonstrate the application in the discovery and optimization of disordered rocksalt (DRX) cathode materials. We have compiled the electrochemistry data of DRX cathodes over the past five years, resulting in a dataset of more than 30,000 discharge voltage profiles with 14 different metal species. Learning from this extensive dataset, our DRXNet model can automatically capture critical features in the cycling curves of DRX cathodes under various conditions. The model gives rational predictions of the discharge capacity for diverse compositions in the Li-Mn-O-F chemical space and high-entropy systems. As a universal model trained on diverse chemistries, our approach offers a data-driven solution to facilitate the rapid identification of novel cathode materials, accelerating the development of next-generation batteries for carbon neutralization.

**The Mechanical Behavior of Li Metal Anodes During Electrochemical Cycling** [Jungho Shin](#) and Matt Pharr; Texas A&M University, United States

Pure lithium metal anodes are highly promising due to their superior capacities yet remain challenging to implement commercially. Key remaining challenges include non-uniform deposition of the Li metal which can lead to dendrite formation and capacity loss, as well as mechanical stresses and strains induced by the “infinite volume change” associated with its host-less nature during electrodeposition. These issues are intimately connected to the mechanical properties of lithium itself, as well as details of its behavior during electrochemical cycling. With these issues in mind, we investigated the mechanical response of pure Li metal during electrodeposition at room temperature. The tests revealed rate-dependent mechanical behavior during electrodeposition, which we largely attribute to the strain-rate dependent mechanical properties of lithium itself by drawing an analogy between the deposition rate and the strain-rate. This talk will further discuss the practical implications of these experimental observations, particularly concerning dendrite growth in batteries. Specifically, this talk will provide general insight into lithium penetration into solid-state electrolytes, which must be prevented to fully harness the potential of lithium metal anodes in future battery technologies.

#### 3:00 PM BREAK

**3:30 PM EN02.19.01**

**Compatibility Study of LiCoO<sub>2</sub> and LiCoPO<sub>4</sub> Cathode Materials with NASICON-Type Solid Electrolyte LAMP** Fumihiko Ichihara<sup>1</sup>, Kodai Niitsu<sup>1</sup>, Machiko Ode<sup>1</sup>, Kazutaka Mitsuishi<sup>1</sup>, Yoshinori Niwa<sup>2</sup>, Shogo Miyoshi<sup>1</sup>, Takahisa Ohno<sup>1</sup> and Takuya Masuda<sup>1,3</sup>; <sup>1</sup>National Institute for Materials Science, Japan; <sup>2</sup>High Energy Accelerator Research Organization, Japan; <sup>3</sup>Hokkaido University, Japan

All-solid-state lithium-ion batteries (ASSLIBs), particularly those employing oxide-based solid electrolytes, are expected to be the next generation of rechargeable batteries because they guarantee safety and dependability by replacing highly combustible organic electrolyte solutions with solid electrolytes. In contrast to conventional liquid LIBs, in which electrolyte/electrode interfaces can be formed spontaneously by injecting liquid electrolyte into cells, the formation of a well-defined solid electrolyte/electrode interfaces with a high ionic conductivity is a key challenge for the development of ASSLIBs.

The conventional method for obtaining the oxide-based solid electrolyte/electrode material interfaces is high-temperature sintering, as these materials have a high melting point and exhibits poor plasticity. However, co-sintering of solid electrolytes and electrode materials often leads to undesired side reactions. Thus, understanding the reaction between solid electrolyte and electrode materials is especially important not only for fundamental science but also for a possible synthetic route to form a well-defined interface with a high ionic conductivity.

In this study, we performed the compatibility assessment of a highly ion-conducting solid electrolyte, Li<sub>1.3</sub>Al<sub>0.3</sub>Ti<sub>1.7</sub>(PO<sub>4</sub>)<sub>3</sub> (LAMP) with a high-capacity cathode material, LiCoO<sub>2</sub> (LCO) and a high-voltage cathode material, LiCoPO<sub>4</sub> (LCP) based on thermodynamic calculations. The calculation results showed that co-sintering LAMP and LCO react with each other to form completely different chemical species instead of forming a well-defined interface. On the other hand, co-sintering LAMP and LCP does not cause severe reaction. Thus, we experimentally co-sintered the composite of LAMP/LCO and LAMP/LCP as combination that reacts intensely and a combination that maintains their crystalline structure and characterized their property.

In the intensely reactive combination LAMP/LCO, various mixing ratios of LAMP and LCO were sintered at various temperatures, and the crystalline phases formed by the reaction were identified and quantified by Rietveld analysis of X-ray diffraction (XRD) and phases including amorphous phase by linear combination fitting of X-ray absorption fine structure (XAFS). The results showed that regardless of the mixing ratio, LAMP and LCO react at 300°C, which is relatively low for sintering temperatures, to form Co<sub>3</sub>O<sub>4</sub>, Li<sub>3</sub>PO<sub>4</sub> and amorphous-TiO<sub>2</sub>. Further increasing the sintering temperature, it was found that the chemical species formed by the reaction depended on the mixing ratio of LAMP and LCO. In addition, we used thermodynamic calculations to calculate the chemical species produced at each temperature and mixing ratio and compared these with the experimentally observed chemical species. For sintering temperatures between 900°C and 700°C, the chemical species observed experimentally and those predicted to be formed by thermodynamic calculations were in reasonable agreement. On the other hand, for sintering temperatures below 600°C, there was a significant disagreement between the calculation and experimental results.

In the maintaining their crystalline structure combination LAMP/LCP, we co-sintered the mixture of LCP and LAMP at 800°C and characterized the structure of their bulk and interfaces by XRD, XAFS and microscopic techniques. XRD showed that LAMP and LCP maintained their crystalline structures after sintering. XAFS results for Ti and Co K-edges showed no change in chemical state around Ti before and after sintering, whereas a slight change was observed for Co, suggesting the small amount of LCP was decomposed to form Co-containing reaction products due to sintering. The microscopic measurements clearly imaged the formation of Co-containing amorphous layers at the grain boundaries within LAMP/LCP composites. XAFS and electron energy loss spectroscopy analyses identified the major species of Co-containing amorphous layers to be CoO and Li<sub>3</sub>PO<sub>4</sub>.

**3:45 PM EN02.19.02**

**Ionic Conductivity Transitions in Sodium Antiperovskite Ionic Conductors** Duhan Zhang and Yiliang Li; Massachusetts Institute of Technology, United States

Na<sub>3</sub>OCl is a well-studied prototypical fast ion conducting compound representative of the antiperovskite (AP) family, which is of interest for solid-state electrolytes. Here, we observe a two-order-of-magnitude increase in its ionic conductivity (from 10<sup>-1</sup> to 10 mS/cm) with increasing temperature at 305°C. Temperature-dependent synchrotron X-ray diffraction (SXRD), differential scanning calorimetry (DSC), quasi-elastic neutron scattering (QENS), and impedance spectroscopy, are used to show that the increase in conductivity is correlated with a transition from tetragonal to cubic symmetry associated with a change in octahedral tilt disorder. While previous work has shown that octahedral tilting in APs can create ion migration pathways with lower migration energies than in the regular cubic structure, this is the first instance where such a large increase (100 times) in ionic conductivity due to a change in octahedral tilt disorder has been observed. The octahedral tilt disorder may be exploited as a pathway to increasing the ionic conductivity of antiperovskites and structurally related compounds.

**4:00 PM EN02.19.03**

**Electrochemical Lithiation and Delithiation Reactions Observed by Multimodal *In Situ* Techniques** Takuya Masuda; NIMS, Japan

We developed in-situ X-ray photoelectron spectroscopy (XPS) and bimodal atomic force microscopy (AFM) systems and applied them to electrochemical lithiation and delithiation reactions of a silicon electrode deposited on a solid electrolyte sheet in an all-solid-state lithium-ion battery configuration. XPS showed that not only lithium silicide but also lithium oxide, lithium silicate and lithium carbonate were formed due to the lithiation of silicon and native oxide, followed by undesired side reactions with residual gasses such as oxygen and carbon dioxide in the inert condition. The spectral features of lithium silicide reversibly responded to the successive lithiation and delithiation cycles, while lithium oxide, lithium silicate and lithium carbonate formed at the surface remained unchanged as irreversible species. As long as the lithiation and delithiation cycles were repeated in the range of Li content x= 0 – 2.4 in Li<sub>x</sub>Si, the position of lithium silicide peak in the Si 2p region shifted monotonically. However, a drastic shift was observed in the successive delithiation after inserting lithium in silicon electrode up to Li<sub>3.5</sub>Si. This drastic shift was assignable to the phase transformation of crystalline Li<sub>15</sub>Si<sub>4</sub> to amorphous Li<sub>x</sub>Si. AFM showed that the Young's modulus of silicon/lithium silicide changes consistently with change in lithium content x in Li<sub>x</sub>Si. Such spectroscopic chemical information and nanoscale mechanical information will be discussed in detail in the context of mechanical degradation.

**Impact of Transport Properties at The Grain-Scale Engineering of Solid Electrolytes: Case Studies on Anti-Perovskite** Ruhul Amin, Marm Dixit and Ilias Belharouak; Oak Ridge National Laboratory, United States

Antiperovskites of composition  $M_3AB$  ( $M = \text{Li, Na, K}$ ;  $A = \text{O}$ ;  $B = \text{Cl, Br, I, NO}_2$ , etc.) have recently been investigated as solid-state electrolytes for all-solid-state batteries. Inspired by the impressive ionic conductivities of  $\text{Li}_3\text{OC}_{10.5}\text{Br}_{0.5}$  and  $\text{Na}_3\text{OBH}_4$  as high as  $10^{-3}$  S/cm at room temperature, many variants of antiperovskite-based Li-ion and Na-ion conductors have been reported, and K-ion antiperovskites are emerging. These materials exhibit low melting points and thus have the advantage of easy processing into thin body and intimate contacts with electrodes. However, there are also issues in interpreting the stellar materials and reproducing their high ionic conductivities. We synthesized the antiperovskite materials by melt casting method and processed them through isostatic pressing (ISP) and conventional approaches. In this presentation, we discuss the critical role of isostatic pressing (ISP) on the crystal- and micro-structural features that originate the higher ionic conductivities of antiperovskites compared to conventional processing. We then discuss its impact on the electrochemical performance of the systems and scalable processing of solid-state battery (SSB) components, and their integration is a key bottleneck toward practical deployment. Finally, we also provide some key perspectives, challenges, and future directions for large-scale production of SSB components and integration.

#### 4:30 PM EN02.19.05

**Copper Sulfides as Cathode Active Materials in All Solid-State Batteries** Katherine A. Mazzi<sup>1,2</sup>, Zhenggang Zhang<sup>3,1</sup>, Kang Dong<sup>4</sup>, Ingo Manke<sup>2</sup> and Philipp Adelhelm<sup>1,2</sup>; <sup>1</sup>Humboldt-Universität zu Berlin, Germany; <sup>2</sup>Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; <sup>3</sup>Southern University of Science and Technology, China; <sup>4</sup>Institute of High Energy Physics, China

One bottleneck in the development of solid-state battery (SSB) technologies is the cathode active material (CAM). Layered oxide materials commonly utilized in other lithium-ion battery technologies are quickly approaching their limits in terms of capacity. It is also clear that realizing the benefits of lithium metal anodes in SSBs necessitates the use of high-capacity conversion-type cathodes. Sulfides offer an intriguing direction for further research because they can reversibly contribute to charge storage through stable anion redox ( $2\text{S}^{2-} \rightarrow (\text{S}_2)^{2-} + 2\text{e}^-$ ). In this talk I will discuss our recent work on metal sulfide-based conversion reactions as CAMs for SSBs, including the dynamic microstructural evolution of CuS using *in-situ* synchrotron X-ray tomography and the use of ternary  $\text{Cu}_3\text{PS}_4$  with  $\beta\text{-Li}_3\text{PS}_4$  solid electrolyte.[1,2] Copper sulfide (CuS) is a naturally occurring mineral that reacts with lithium via a conversion reaction to form  $\text{Li}_2\text{S}$  and Cu with a theoretical energy density of 961 Wh/kg. CuS demonstrates a peculiar feature of Cu displacement into large ( $\mu\text{m}$ -sized) domains during cycling that are highly reversible during electrochemical cycling. We were able to follow this dynamic microstructural evolution *in-situ* by synchrotron X-Ray tomography.[1] In addition to these phase transformations, we also observe significant crack formation in the cathode that we found to be dependent on the stacking pressure of the cell. When replacing the binary compound CuS with the ternary compound  $\text{Cu}_3\text{PS}_4$ , the theoretical energy density increases to 1301.5 Wh/kg and at the same time we anticipate greater compatibility with the  $\beta\text{-Li}_3\text{PS}_4$  solid electrolyte due to similarities in chemical composition and structure.[2] We studied the reaction mechanism of  $\text{Cu}_3\text{PS}_4$  in SSBs and found that it undergoes an irreversible conversion reaction in the 1st cycle. The subsequent redox is largely dominated by  $\text{Cu}_2\text{S}$  and  $\text{S}_8$  which form finely dispersed redox centers that promote stable cycling behavior.

**Materials and Methods for Sustainable Soft Electronic and Robotic System - From Biodegradable Gels to Mycelium Based Elektronik Skins**  
Martin Kaltenbrunner; Johannes Kepler University, Austria

Modern societies rely on a multitude of electronic and robotic systems, with emerging stretchable and soft devices enabling ever closer human machine interactions. These advances however take their toll on our ecosystem.

Mitigating some of these adverse effects, this talk introduces materials and methods for soft systems that biodegrade. Based on highly stretchable biogels and degradable elastomers, our forms of soft electronics and robots are designed for prolonged operation in ambient conditions without fatigue, but fully degrade after use through biological triggers. Enabling autonomous operation, stretchable and biodegradable batteries power wearable sensors. 3D printing of biodegradable hydrogels enables omnidirectional soft robots with multifaceted optical sensing abilities. Going beyond, we introduce a systematically-determined compatible materials systems for the creation of fully biodegradable, high-performance electrohydraulic soft actuators. They reliably operate up to high electric fields, show performance comparable to non-biodegradable counterparts, and survive over 100,000 actuation cycles. Pushing the boundaries of sustainable electronics, we demonstrate a concept for growth and processing of fungal mycelium skins as biodegradable substrate material. Mycelium-based batteries allow to power autonomous sensing devices including a Bluetooth module and humidity and proximity sensors, all integrated onto mycelium circuit boards.

**11:00 AM EN03.01.02**

**Ultrasound-Driven Bioresorbable Triboelectric Nanogenerator with Controllable Lifetime** Inah Hyun<sup>1</sup>, Dong-Min Lee<sup>2</sup> and Sang-Woo Kim<sup>1</sup>;  
<sup>1</sup>Yonsei University, Korea (the Republic of); <sup>2</sup>Sungkyunkwan University, Korea (the Republic of)

On-demand bioresorbable electronics have gained significant attention due to their dissolution capabilities and the elimination of secondary surgical procedures for device removal, thereby minimizing the side effects associated with implantation. However, the reliance of these electronics on non-transient commercial energy supplies limits their practicality. In this study, we propose a fully biodegradable and implantable triboelectric nanogenerator (FBI-TENG) that harnesses ultrasound as both a non-invasive power source and a means of device removal. Under low-intensity ultrasound ( $\leq 0.5 \text{ W cm}^{-2}$ ), the FBI-TENG efficiently generates energy to power other electronic devices. To enhance its electrical performance, we optimize the triboelectric layer by incorporating polyethylene glycol, resulting in a remarkable 58.5% increase in voltage output underwater, from 2.625 to 4.160 V. In contrast, high-intensity ultrasound ( $\geq 3.0 \text{ W cm}^{-2}$ ) can trigger the degradation process of our FBI-TENG, leading to the complete loss of its energy-generating function within a few minutes. Through finite element method simulation, we investigated that the triggering event occurs due to the porous structures of the poly(3-hydroxybutyrate-co-3-hydroxy valerate) with locally intensified pressure under the high intensity of ultrasound. This research provides valuable insights into the practical application of implantable triboelectric nanogenerators based on ultrasound-triggered transient material design. This research offers valuable insight into the practical application of implantable triboelectric nanogenerators on the basis of ultrasound-triggered transient material design.

**11:15 AM \*EN03.01.03**

**Scalable Synthesis and Manufacturing of Piezoelectric Biomaterials and Architectures** Xudong Wang; University of Wisconsin--Madison, United States

Piezoelectric materials are a group of important functional building blocks that interfacing the human body by coupling biomechanical energy and electricity. So far, many technology innovations have advanced piezoelectric materials and composites toward a broad range of biomedical applications, which possess unique biocompatibility and flexibility. Fundamentally, materials design and engineering draw the boundary where this technology may advance. In this talk, I introduce our most recent development of piezoelectric materials and composites that are particularly designed for implantable nanogenerator applications. First, I present our wafer-scale approach to creating piezoelectric biomaterial thin films based on  $\gamma$  glycine crystals. The self-assembled sandwich film structure enabled both strong piezoelectricity and largely improved flexibility. We will further discuss strategies of controlling the orientation and morphology of amino acid crystals to improve the piezoelectricity. Then, new ferroelectric composites are presented as a new composite used in 3D printing for directly manufacturing of piezoelectric architectures with tunable piezoelectric and mechanical properties. This group of materials enable new capability of in vivo charging and electrostimulations, which revolutionaries the design and implementation of many biomedical therapeutics.

SESSION EN03.02: Biodegradable Electronics  
 Session Chairs: Shweta Agarwala and Amay Bhandodkar  
 Monday Afternoon, November 27, 2023  
 Hynes, Level 2, Room 206

**1:30 PM EN03.02.01**

**Biodegradable, Self-healing, Recyclable, Conductive Coatings for Wearable Electronics and Soft Robotics** Pietro Cataldi; Italian Institute of Technology, Italy

Electrically conductive coatings are essential for transitioning electronic components and circuitry from stiff and rigid substrates to more flexible and stretchable platforms, such as thin plastics, textiles, and foams.[1] In parallel, the push for more sustainable, biodegradable, and cost-efficient conductive inks to coat these substrates has led to the development of innovative formulations involving biopolymers and nanomaterials that results in soft composites layer with unique functionalities.

The proposed talk unveils diverse electrically conductive coating (resistivity  $\approx 10^{-4} \Omega \text{ m}$ ) that entails salient properties such as broad substrate types paintability, tunable piezoresistivity, self-healing, tunable degradability, and recyclability. Such a broad collection of properties is obtained simply by changing the substrates employed, the binders, and the conductive nanofillers.

Particularly, one new class of coating based on biobased and biodegradable vitrimer binders is proposed. Using the vitrimer ensures satisfying adhesion to diverse substrates, flexibility, and recyclability of the conductive coating. This coating enables human-mimicking soft robotics skin since it is self-healing and biodegradable. Tests for the live monitoring of SoftHand3, the grasping system of many worldwide diffused robots, have yielded promising results. The use of biodegradable ingredients and the possibility of recycling makes it an appealing material to face the sustainability issue of today's electronics and robotics.

Another class of coating proposed is applied to textiles. Such coatings have controllable electrical resistance change with deformation and transiency (i.e., dissolution in water).[2] The modulation of the piezoresistivity and transiency is obtained by controlling the nanofiller geometry, binder composition, and textile twill orientation. The electrical resistance shows an anisotropic response to bending depending on the composition of the coating and the stress direction, functioning either as a deformable compliant electrode or a tunable piezoresistor. Indeed, it can withstand thousands of bending cycles with a

change in resistance of less than 5% or change its resistance by many orders of magnitude with the same deformation thanks to the combination of cotton twill and different nanofillers. A simple modification in the binder composition adding waterborne polyurethane, allows the coating to go from entirely transient in water within minutes to withstanding simulated washing cycles for hours without losing its electrical conductivity. This versatile green conductor may serve opposing needs by altering the material composition and the deformation direction.

**Biodegradable Resistive Random Access Memory Based on Natural Organic Carbohydrate Materials for Sustainable Neuromorphic Computing Systems** Feng Zhao and Yuan Xing; Washington State University, United States

Current computing systems are facing two essential challenges: (1) tremendous energy consumption due to the conventional Von Neumann architecture with low energy efficiency; and (2) environmental sustainability by depletion of nonrenewable materials, production of electronic waste, etc. One potential solution to simultaneously address these two issues is by “brain-like” and “green” neuromorphic computing with energy-efficient operation, sustainable material resources, and environmentally friendly disposals. Such neuromorphic computing systems require hardware components not only capable of mimicking human neuron and synapse - the basic building block of biological neural networks, but also made from natural organic materials such as polypeptides (proteins) and polysaccharides (carbohydrates) which are renewable, abundant in nature, and biodegradable. In this paper, we report resistive random access memory (ReRAM) made from encouraging natural organic carbohydrate materials, honey and fructose, for emerging neuromorphic computing systems and neural networks. Honey or fructose resistive films were formed by a low cost solution-based process and sandwiched between bottom and top electrode, a simple metal-insulator-metal structure analogous to a biological synapse with presynaptic neuron (top electrode), postsynaptic neuron (bottom electrode), and synaptic cleft (fructose film). The nonvolatile memory behaviors were demonstrated by modulating the conductance by voltage stimuli applied on the memory device, with excitatory current flow in the device being monitored. Characteristics including bipolar resistive switching, retention, endurance cycles, long-term potentiation and depression, desolution in water, etc. were reported. All these results testify that carbohydrate-ReRAM devices are promising for energy-efficient and sustainable neuromorphic systems.

**2:00 PM \*EN03.02.03**

**Edible Electronics: Recent Results and Perspectives** Mario Caironi; Istituto Italiano di Tecnologia, Italy

Edible electronics envisions a technology that is safe for ingestion, environmentally friendly, and cost-effective. Differently from “ingestible” electronics, it aims at realizing electronic devices that are degraded within the body after performing their function, either digested or even metabolized, thus removing any retention hazard. Edible electronics could potentially target a significant number of biomedical applications, such as remote healthcare monitoring, and of applications for food quality monitoring as well, such as edible electronic tags directly in contact with food. Here I will first give an introduction to this emerging field and propose long-term opportunities in terms of environmentally friendly smart technologies, remote healthcare monitoring, along with the challenges ahead. Then, I will report on our recent progress in the development of edible circuitry and components, towards future integrated edible electronic systems. Perspectives for adoption of edible electronic systems for sensors and control in future edible robots will also be shared.

**2:30 PM BREAK**

SESSION EN03.03: Bioresorbable Adhesives and Tissue Mimics

Session Chairs: Shweta Agarwala and Jahyun Koo

Monday Afternoon, November 27, 2023

Hynes, Level 2, Room 206

**3:00 PM \*EN03.03.01**

**Biodegradable Bioadhesive Technology Platform** Xuanhe Zhao; Massachusetts Institute of Technology, United States

This presentation focuses on an innovative biodegradable bioadhesive technology platform. Firstly, I will outline a general approach to designing and manufacturing biodegradable bioadhesives that possess rapid and tough adhesion capabilities with a wide range of wet dynamic organs. Subsequently, I will explore the numerous contemporary technologies and applications made possible by this biodegradable bioadhesive platform, such as sutureless wound sealing, coagulation-independent homeostasis, bioadhesive bioelectronics and implants. To wrap up, I will provide insights into the future prospects and potential advancements in the field of biodegradable bioadhesive technology.

**3:30 PM EN03.03.02**

**Hyperbranched *In Situ* Polymerized Cyanoacrylate Tissue Adhesives and Their Degradation** Alexander P. Roxas and Zhengtang Luo; The Hong Kong University of Science and Technology, China

Cyanoacrylates are bioresorbable tissue adhesive materials whose ability to rapidly polymerize in situ into a strongly adhering film is suitable for closing wounds during emergencies. This polymerization method, which generates high-molecular-weight linear chains, has been applied and barely changed since the early clinical use of the adhesive because the requirement of rapid, straightforward in-situ polymerization for practicality restricted innovations involving the method and the material composition. Tissue adhesives, however, have been increasingly demanded to exhibit enhanced properties to cater to the needs of emerging trends in biomedical engineering. Our group has recently formulated a procedure to in situ polymerize cyanoacrylates into a branched adhesive film without sacrificing their practical features. Branching in the adhesive film, despite potentially introducing softness and enhancing mechanical properties, among others, can, however, influence the degradation of the adhesive film. The effects of branching on the rate of degradation and the composition of the degradation products were analysed by studying the degradation of branched polycyanoacrylates with varying degrees of branching and comparing them with conventionally polymerized linear equivalents. The degradation behavior of the adhesive is essential to avoid complications resulting not only from toxicity but also from the premature sloughing of the adhesive film from the wound surface.

**3:45 PM EN03.03.03**

**Large-Scale Fabrication of Silk Fibroin-Based Artificial Skin for Cosmetic Research** Hangming Fan and Xiaodong Chen; Nanyang Technological University, Singapore

Silk fibroin, a widely utilized material in skin-related applications, possesses a comparable structure and amino acid composition to the cornified cell envelope found in the stratum corneum. This similarity suggests its potential as an alternative to animal experimentation in cosmetic research, particularly as artificial skin. However, improvements are required in silk fibroin-based films to achieve sufficient similarity for practical usage and enable large-scale industrial production. In this study, various methods were employed to synthesize different types of artificial skin for key application scenarios in cosmetic research, including deposition tests, sensation tests, and absorption tests. For mass production of silk fibroin-based films, the conventional solvent casting method, though slow and resulting in poor thickness uniformity, has been commonly used. In this work, we adopted a coating method that allows for easy modification of the artificial skin's surface properties, enabling representation of different skin types (e.g., oily, dry, and combination skin). Furthermore, the proposed method offers significant advantages such as faster production and improved thickness uniformity, making it feasible for industrial-scale manufacturing.

## SESSION EN03.04: Poster Session I: Biomedical Devices

Session Chairs: Amay Bandodkar and Lan Yin

Monday Afternoon, November 27, 2023

Hynes, Level 1, Hall A

**8:00 PM EN03.04.01**

**Highly Stretchable Thermally-Grown Silicon Dioxide with Wavy Structures Encapsulation for Biomedical Applications** Hyeonji Yoo, Hangeul Kim, Gyeong-Seok Hwang and Ju-Young Kim; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Flexible and stretchable bioelectronic devices that can be applied to targets such as heart and liver where repetitive deformation occurs are currently being actively investigated as next-generation devices. These organic material-based electronic devices require an encapsulation layer for long-term stability. Therefore, the development of mechanically stretchable and highly impermeable encapsulating materials is required to develop stretchable bioelectronic devices.

In this research, we developed the highly stretchable and impermeable encapsulations by applying a wavy-structure to the thermally-grown SiO<sub>2</sub>. A thermally-grown SiO<sub>2</sub>, oxidized from single-crystalline silicon wafer at high temperature, has an extremely low water vapor transmission rate (WVTR) due to amorphous structure and high density with low defects. In addition, we effectively implemented high stretchability through wavy-structure design, overcoming the intrinsically low elastic deformation limit of SiO<sub>2</sub>. The stretchability and barrier properties were carried out by uniaxial tensile test and electrical Ca test. By theoretically analyzing the mechanical behavior of wavy-structured SiO<sub>2</sub>, the universal deformation model and correlation between stretchability and characteristic of wavy structure were carried out. This stretchable encapsulation shows 20.1% of uniaxial stretchability and 1.11 x 10<sup>-6</sup> g m<sup>-2</sup> day<sup>-1</sup> of WVTR, simultaneously. Moreover, it demonstrates highly reliable barrier properties even after 1,000 stretching cycles at 90% of their stretchability. Therefore, the developed wavy-structured thermally grown SiO<sub>2</sub> is suitable to protect stretchable organic-based bioelectronic devices.

**8:00 PM EN03.04.02**

**Minimally Invasive and Biodegradable Electronics for Transient Brain Interfaces** Jae-Young Bae<sup>1</sup>, Gyeong-Seok Hwang<sup>2</sup>, Young-Seo Kim<sup>1</sup>, Jooik Jeon<sup>3</sup>, Jung Keun Hyun<sup>3</sup>, Ju-Young Kim<sup>2</sup> and Seung-Kyun Kang<sup>1</sup>; <sup>1</sup>Seoul National University, Korea (the Republic of); <sup>2</sup>Ulsan National Institute of Science and Technology, Korea (the Republic of); <sup>3</sup>Dankook University, Korea (the Republic of)

Monitoring brain activities is crucial for diagnosing and providing post-care for brain disorders like epilepsy or traumatic brain injury. However, after the monitoring period, the implanted device needs to be removed to avoid complications such as inflammation. The removal surgery is even riskier and more time-consuming than the initial implantation procedure, causing distress to the patient. Biodegradable electronics is an emerging technology that can dissolve completely into biocompatible molecules once their function is complete, eliminating the risk of biofilm formation or secondary injuries during the removal process. Some biodegradable implantable devices, which combine organic and inorganic materials, have been used to monitor increasing pressure inside the skull caused by traumatic brain injuries and to stimulate the regrowth of peripheral nerves using wireless electrical stimulators. However, current biodegradable electronic devices still require surgical implantation, which adds to the patient's burden. Here, we propose a platform for biodegradable electronics in the brain, including bio-potential electrodes, temperature and strain/pressure sensors, and a wireless communication system capable of monitoring various physiological signals. This platform is designed to dissolve all inserted materials without leaving a potential biofilm formation or causing secondary injuries during the removal process. Furthermore, we introduce the concept of a minimally invasive strategy to reduce the invasiveness of the implantation procedure. This platform holds promise as a transient and minimally invasive brain-interface platform for future clinical applications.

**8:00 PM EN03.04.03**

**Recycled UHT Milk Carton Cellulose Surface as a Novel Substrate for Dual-Lactate Sensor for Milk Spoilage Indication** Wisarttra Phamnonpon<sup>1,2</sup>, Nadtinan Promphet<sup>1</sup>, Sarute Ummartyotin<sup>2</sup> and Nadnudda Rodthongkum<sup>1</sup>; <sup>1</sup>Chulalongkorn University, Thailand; <sup>2</sup>Thammasat University, Thailand

Recycled cellulose substrate from UHT milk carton waste was firstly applied as a novel substrate for the colorimetric and electrochemical lactate sensor for milk quality indication. The cellulose and aluminum foil were extracted from the packaging. For preparing the recycled cellulose substrate, chemical treatment (alkali and bleach treatment) was used for the extraction. Then, the recycled cellulose substrate has done enzymatic immobilization for the colorimetric sensor to enhance the specific reaction with the lactate on its surface. For the electrochemical sensor, the recycled cellulose substrate was immersed into the extracted aluminum solution to fabricate the conductive working electrode to improve the surface roughness compared with the recycled cellulose substrate, confirmed by atomic force microscopy. Scanning electron micrograph presented a 3D fibrous network including with air space in between, and X-ray photoelectron spectroscopy showed the binding energy of Al-O at 73.256 eV, confirming the appearance of the aluminum on the recycled cellulose substrate after the surface modification with aluminum solution. For the analytical performance, the colorimetric sensor showed the increasing purpleness of color upon increasing lactate concentration. Furthermore, the aluminum-coated recycled cellulose substrate provided an increasing current response toward the increment of lactate concentration. This dual-lactate sensor can offer linearity of 0.125-2 M, covering a cut-off lactate value in cow's milk (1.0 M) for milk spoilage indication, which can be used for lactate determination in actual milk samples. Eventually, this platform can represent a new utilization of UHT milk carton waste for the colorimetric and electrochemical sensor that can be applied in food quality control applications.

**8:00 PM EN03.04.05****Fragmentation Behavior and Surface Characteristics of Different Plastics: Influence on the Potential Toxicity to Macrophages and Angiogenesis** Kyungtae Park and Jinkee Hong; Yonsei University, Korea (the Republic of)

The production and waste of plastics are increasing rapidly, and there is a growing interest in investigating the impact of microplastics (MPs) smaller than 5mm on human beings as pollutants. Previous research has primarily focused on the toxicity of engineered plastic particles with a spherical shape, overlooking the fact that microplastics tend to fragment under environmental conditions, resulting in various morphological characteristics and sizes. This fragmentation behavior has not been adequately considered in toxicity analysis. Therefore, it is crucial to comprehend the fragmentation behavior of different plastics and analyze the surface characteristics of each microplastic to gain a better understanding of their potential toxicity.

In this study, we conducted a comprehensive investigation into the fragmentation patterns of plastics, specifically focusing on polypropylene (PP), acrylonitrile butadiene styrene copolymer (ABS), and polyethylene terephthalate (PET) as representative plastics. To simulate the fragmentation of each plastic, we employed a ball-milling process, which resembles the physical fragmentation process that occurs during plastic weathering.

After the fragmentation process, we characterized the surface of the microplastics using scanning electron microscopy (SEM), FT-IR, Raman spectroscopy, and x-ray photoelectron spectroscopy. We also examined the change in crystalline structure using a differential scanning calorimeter (DSC). Considering that the micronization behavior of plastics is highly dependent on the amorphous structure, we confirmed the crystalline and amorphous parts and their respective crystallinity. Additionally, we conducted size and shape analysis of the microplastics to investigate cellular uptake and toxicity.

Macrophages were selected as representative immune cells due to their ability to recognize infectious agents and remove toxicants through phagocytosis. We studied the cellular uptake of each microplastic and observed cellular reactions such as ROS generation in the macrophage cytosol, polarization, and immune-cytokine secretion. Furthermore, we investigated the complex cellular reactions by co-culturing macrophages with human umbilical vein endothelial cells (HUVECs). As HUVECs possess angiogenic abilities, we analyzed *in vitro* tube formation under co-culture conditions and quantified the amount of angiogenic growth factors after exposing macrophages to microplastics.

Our findings revealed three significant points in understanding the potential toxicity of microplastics:  
 The characteristics of fragmented microplastics differ significantly from engineered microplastics.  
 The fragmentation behavior and properties of each microplastic should be considered to understand their potential toxicity.  
 Depending on the composition of the microplastics, the reaction of macrophages and subsequent effects on angiogenesis vary.

**8:00 PM EN03.04.06****Directed Evolution of Microorganisms for Engineered Living Materials** Julie M. Laurent, Anton Kan, Ankit Jain, Mathias Steinacher, Nadia Enriquez Casimiro, Stavros Stavrakis, Andrew J. deMello and André R. Studart; ETH Zürich, Switzerland

With the environmental challenges we face, a shift is needed in the materials we produce and use. Materials found in Nature are made at atmospheric temperature and pressure, and they are robust, long-lasting, and renewable. Incorporating life into human-made materials would bring us closer to mimicking them, adding functionalities not accessible by current synthetic material production methods. The rich biochemical diversity in bacteria provides an immense design space for the engineering of adaptable living materials.

However, bacteria have evolved to perform specific biological functions in their particular environment. Their phenotypes thus might not fulfill the demands of engineering and industrial applications. In particular, we lack control over the shaping of bacterial communities and living materials. Biofilms are an example of naturally occurring self-assembled living materials produced by bacteria. Although three-dimensional, they are conformal to surfaces and relatively limited in terms of shape complexity and control.

Here, we show that 3D printing of engineered bacteria embedded in a matrix can help us shape complex living materials with programmable functionalities. Using genetic engineering tools and readily available 3D printing techniques, engineered bacteria-laden living materials were shaped into complex structures. The metabolism of microorganisms was harvested to add a function (luminescence, melanin secretion) or produce a material (cellulose, calcium carbonate) in three-dimensional objects.

The freedom in shape design provided by 3D printing techniques enabled additional functionalities that were not present in the natural world. Bacterial luminescence was increased with a gyroid structure, and dampened when printing a surrounding layer populated with melanin-producing engineered microorganisms. In the future, printing material-producing microorganisms and exploiting their evolved cellular machinery will provide new ways of making sustainable materials.

**8:00 PM EN03.04.07****Programming Hierarchical Architectures in Biodegradable Microcapsules for Advanced Functions** Muchun Liu and Benedetto Marelli; Massachusetts Institute of Technology, United States

Programming biomaterials at multiscale is critical in developing advanced technologies in addressing environmental issues. For instance, several industries have a compelling need to substitute open-used, non-degradable, intentionally added microplastics with biodegradable alternatives. Biopolymers extracted from natural products or food waste, such as regenerated silk fibroin, offer many merits. However, assembling biopolymers at multiscale remains challenging due to their complex compositions.

To address this challenge, we present a biodegradable silk-based microencapsulation technique achieved by modulating the structural protein protonation and chain relaxation at the point of material assembly. It can sustain the release of soluble and insoluble payloads typically used in cosmetic and agriculture applications. Manufacturing through well-established fabrication techniques, such as spray drying, yields microcapsules with tunable morphology and degradation kinetics. As a proof-of-concept for agrochemicals delivery, a greenhouse trial demonstrated that a commonly used herbicide (i.e., Saflufenacil) delivered via silk microcapsules on corn plants reduced crop injury compared to the non-encapsulated version.

Additionally, we introduce a synergistic assembly of biopolymer microparticles into hierarchical structures, such as spiny microcapsules and interconnected micro-network. We can tune the biopolymer type, geometry, structure, crystallinity, payload, and mechanical properties for different functions. For example, engineered multi-spines effectively improved the retention percentage of microcapsules on smooth spinach leaves after wash-off. Furthermore, the echinate micro-network can transfer and co-localize different fluorescent payloads in the micro-bridges. Our findings provide a platform for the advanced biopolymers assembly into functional structures, which is of great potential in agriculture, environmental remediation, and other applications that interact directly with the environment.

**8:00 PM EN03.04.08****Biodegradable Polymers for Tuning Properties of Long-Acting HIV Pre-Exposure Prophylaxis (PrEP) Implants** Archana Krovi<sup>1</sup>, Guadalupe Arce Jimenez<sup>1</sup>, Leanna Levin<sup>1</sup>, Daniela Cruz<sup>1</sup>, Pafio Johnson<sup>1</sup>, Ellen Luecke<sup>2</sup>, Chasity Norton<sup>1</sup> and Leah Johnson<sup>1</sup>; <sup>1</sup>RTI International, United States; <sup>2</sup>Women's Global Health Imperative, United States

**Introduction:** The development of new biodegradable implants for long-acting (LA) drug for HIV pre-exposure prophylaxis (PrEP) can advantageously eliminate the requirement of a second medical procedure to remove the devices at the end of use when drugs are depleted. We have previously demonstrated tunable antiretroviral (ARV) release through tailoring the implant surface area, wall thickness, molecular weight of polymer, and ratios of homopolymer blends. Here, we further advance our implant platform by exploring biocompatible and biodegradable polymers with differing compositions, degradation profiles, and physicochemical properties that ensure drug transport through the polymer membrane under physiological conditions.

**Methods:** Biodegradable polymers poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV), polycaprolactone (PC-17, PCL-C18E), PEGylated polycaprolactone (PCL-C18-PEG), and polybutylene succinate (FZ71PM, FD92PM) were extruded into cylindrical tubes with an outer diameter of 2.5 mm and a wall thickness 300  $\mu\text{m}$ . Implants were prepared by loading antiretroviral formulations into an extruded tube and then enclosing the tube via heat sealing. Implants were sterilized via gamma irradiation at 18-24 kGy and submerged in phosphate buffered saline (pH 7.4) at 37 °C to mimic physiological conditions. Antiretroviral concentrations released in the buffer over time were measured by high performance liquid chromatography or UV-Vis. Crystallinity, molecular weight, and mechanical properties of the tubes were characterized using differential scanning calorimetry, inherent viscosity, and tensile testing, respectively.

**Results:** PHBV had the highest crystallinity ( $60.6 \pm 1.2\%$ ) among all the polymers evaluated and showed the lowest drug release rate. Interestingly, while PCL materials with slightly different molecular weights PC-17 (IV 1.82) and PC-C18E (IV 1.93) had similar crystallinities of  $51.3 \pm 1.1\%$  and  $50.3 \pm 6.4\%$ , respectively, the introduction of a PEG end group on the PCL polymer (PCL-C18-PEG) led to significantly lower crystallinity ( $36.4 \pm 1.5\%$ ) and the highest release rate. We hypothesize that the biocompatible PEG modifier potentially disrupts the packing of the polymer chains and can affect the drug release rates. Crystallinity of PBS (FD92PM) was the lowest ( $25.2 \pm 0.2\%$ ) but exhibited similar drug release rates comparable to that of PC-17. This is a significant finding as FD92PM polymer may offer an approach to deliver an antiretroviral at the target doses with a potentially faster biodegradation timeframe in contrast to the approximately 2-year degradation timeframe for PCL. Lastly, FZ71PM had a similar crystallinity to that of PC-17 ( $46.4 \pm 9.4\%$ ) but exhibited lower drug release from the implant form factor. Despite the insignificant drug release, this polymer could be utilized for indications with lower drug release targets and with a potentially faster biodegradation profile.

**Conclusions:** We explored biodegradable implants designed for HIV PrEP that comprise extruded tubes from polymers of varying physicochemical properties. These differing polymers offer an effective approach for tuning the drug release rates, implant duration and integrity, and ultimately the biodegradation profiles of the implants. Next steps include evaluation of the polymer degradation kinetics, in real time (in vitro and in vivo) and under accelerated conditions. An in-depth understanding of the degradation characteristics of this platform will enable new implant designs for varied medical indications that might require tailored degradation timeframes.

**Preconditioning of Long-Acting Subcutaneous Implants to Support Evaluation of *In Vivo* Pharmacokinetic Depletion Profiles** [Daniela Cruz](#), Christine Strickland, Leanna Levin, Guadalupe Arce Jimenez, Archana Krovi, Pafio Johnson, Chasity Norton, Ellen Luecke and Leah Johnson; RTI International, United States

The pharmacokinetic depletion period (i.e., tail) of long-acting (LA) drug delivery systems can result in a gradual decrease of drug concentration over time. Comprehensive characterization of the depletion tail can provide insight about effectiveness of the drug delivery system and the possibility for subtherapeutic drug levels, which can lower efficacy or enable the emergence of drug-resistant strains. The thorough evaluation of the depletion tail also provides details about the optimal dosing period to maintain therapeutic drug levels throughout the course of treatment. In this study, we explore the preconditioning of a biodegradable subcutaneous implant for LA HIV pre-exposure prophylaxis (HIV PrEP) that sustainably releases antiretroviral (ARV) drug. By preconditioning the implant via accelerated conditions during the zero-order release phase, we can achieve an efficient way of testing long-acting drug formulations.

Poly- $\epsilon$ -caprolactone (PCL) extruded tubes were filled with bictagvir (BIC) formulated with castor oil. The ends of the tubes were heat-sealed and implants were sterilized by gamma irradiation (18-24 KGy). For in vitro release studies, implants were submerged in phosphate-buffered saline (pH 7.4) and drug release was monitored using UV-vis while maintaining sink conditions. Implants were divided into six groups that explored various experimental conditions, including drying, sterilization, and different temperature profiles. Groups 1-4 were used to test in-vitro preconditioning and second round of sterilization and were placed at 37°C for 46 days. After 46 days, Group 1 was placed in an oven at 40°C for two weeks to ensure drying followed by sterilization by gamma irradiation. Group 2 also underwent a drying process but was not sterilized a second time. Group 3 did not undergo a drying process but was sterilized a second time. Group 4 served as the control, which remained in-vitro at 37 °C throughout the duration of the study. To study accelerated conditions, Group 5 was placed at 45°C throughout the study's duration, and Group 6 was placed at 45°C for 66 days before taken to 37°C for the rest of the study.

The in vitro pre-conditioning of implants resulted in similar release rates of BIC before and after exposure to a second round of sterilization. Also, no notable differences were observed in the release rates of BIC between implants under different experimental conditions for drying or sterilization. For implants exposed to accelerated conditions at 45°C, the release rate increased by 3.2-fold when compared to the control maintained at 37°C. In addition, devices switched from 45°C to 37°C demonstrated release rates similar to the control group, showing that release rates can be tuned through temperature change.

In this work, we demonstrate an advantageous method to precondition long-acting subcutaneous implants to support subsequent in vivo studies. Our results show that implants are unaffected after removal from in-vitro conditions and after a drying process and a second round of sterilization. In addition, we demonstrate a successful acceleration of in vitro drug release using a higher temperature (45°C). This approach can potentially shorten the timeframe of preclinical studies by preconditioning implantable drug delivery systems during the phase of zero-order release kinetics. Overall, this approach supports approaches to characterize LA drug delivery systems without sole reliance on long-term animal studies.

#### 8:00 PM EN03.04.10

**Rapid Synthesis of Multifunctional Hydroxyapatite Using Laser-Induced Hydrothermal Process** [Sangmin Song](#)<sup>1,2</sup>, Seung-Hoon Um<sup>3,1</sup>, Seung Hwan Ko<sup>2</sup>, Yu-Chan Kim<sup>1</sup> and Hojeong Jeon<sup>1</sup>; <sup>1</sup>Korea Institute of Science and Technology, Korea (the Republic of); <sup>2</sup>Seoul National University, Korea (the Republic of); <sup>3</sup>Université Laval, Canada

Synthetic biomaterials are used to overcome the limited quantity of human-derived biomaterials and to impart additional biofunctionality. Although numerous synthetic processes have been developed using various phases and methods, Existing synthetic processes suffer from issues such as lengthy processing time, challenges in size control, and difficulties in achieving high-concentration metal ion substitution for additional functionality. In this presentation, we will present a rapid synthesis method using a laser-induced hydrothermal process. Based on the thermal interaction between the pulsed laser beam and titanium plate, which was used as a thermal reservoir, hydroxyapatite particles ranging from nanometer to micrometer scale could be synthesized in seconds. Moreover, this laser-induced hydrothermal synthesis can enable metal ion substitution into the matrix of hydroxyapatite with a controllable concentration. We calculated the theoretical maximum temperature achieved by thermal interaction at the surface of the thermal reservoir based on the validation of three simplification assumptions. Subsequent linear regression analysis showed that laser-induced hydrothermal synthesis

follows an Arrhenius chemical reaction. Synthesized hydroxyapatite and  $Mg^{2+}$ -,  $Sr^{2+}$ -,  $Zn^{2+}$ -substituted apatite powders exhibited promotion of bone cell attachment and proliferation ability due to ion release from the synthesized powders, which had a low crystallinity and relatively high solubility. This laser-induced hydrothermal synthesis is expected to be used in biomaterials, catalyst, 3D printing, and solar cell technology.

#### 8:00 PM EN03.04.11

**Paper-Based Green Laser-Induced Graphene for Disposable and Wearable Sensing Applications** [Rodrigo F. Martins](#), Tomas Pinheiro and Elvira Fortunato; FCT UNL, Portugal

Laser-induced graphene (LIG) has established itself as a very attractive material for electrode fabrication, within several applications in bioelectronics. The straightforward, high throughput graphitization of several precursor materials using this laser conversion process allows for the simultaneous synthesis and patterning of this 3D graphitic material with diverse electrode architectures, to target several biosensing applications, from biophysical to biochemical monitoring.

Recently, paper has appeared as a viable alternative to conventional petroleum-based plastic polymer precursors, such as polyimide. This is due to the possibility of photothermally converting aliphatic cellulose monomers into graphene lattices, using several cellulose substrate treatment strategies.

Application of fire-retardant chemical modifications and external aromatic moieties improves the graphitization potential of cellulose, to reach LIG film with 5  $\text{ohm}\cdot\text{sq}^{-1}$  sheet resistance and conductivities as high as 67  $\text{S}\cdot\text{cm}^{-1}$ .

With these improved conductive properties of paper-derived LIG, this precursor material can be easily employed for the fabrication of disposable biosensing units, where paper acts as both the support substrate and precursor material for conductive electrode fabrication, without the need for more intricate printing techniques. Alternatively, strategies can be employed to separate converted and unconverted phases, through transfer methods, to make this material compatible with wearable applications.

In this presentation, we report the use of cellulose as a material in the toolbox of LIG precursors, aimed at the development of both disposable and wearable biosensing applications. Paper-based electrochemical sensors using this material are presented, aiming at disposable sensor development for different analytes. Glucose and pH electrochemical sensors were fabricated, showing the compatibility of the material with several sensing strategies, such as enzymatic and non-enzymatic sensing. To translate patterned electrodes for wearable applications, a straightforward transfer method is presented, using a water-induced peel-off method. This method is capable of efficiently separating unconverted cellulose and converted LIG phases, allowing for the transfer of LIG patterns onto flexible, conformable, and elastomeric substrates with adhesive properties, for example, medical grade adhesives. Using this method, electrochemical biosensors, strain sensors for biophysical monitoring and electrodes for electrophysiological signal monitoring are presented.

In conclusion, the concepts explored herein show the applicability of LIG towards the fabrication of robust point-of-care, disposable analytical devices, but also its potential for integration in wearable sensing systems, aiming at more sustainable, accessible bioelectronic applications.

#### 8:00 PM EN03.04.13

**Buoys and Bacteria for Microplastic-Free Oceans** [Douglas X. Shattuck](#)<sup>1,2</sup>, Charlotte McConville<sup>3</sup>, Victoria Sekenski<sup>4,2</sup> and Saman Abbas<sup>4,2</sup>; <sup>1</sup>St Joseph School Wakefield, United States; <sup>2</sup>National STEM Honor Society, United States; <sup>3</sup>Quincy High School, United States; <sup>4</sup>Malden Catholic High School, United States

Microplastics are abundant and polluting our oceans. In recent years, a solution to this problem has presented itself: bacteria. Specifically, *Ideonella sakaiensis* and azotobacter work together to break down plastics over time. Some challenges in the research include keeping the bacteria to the proper 86 degrees and how to gauge when to close off the machine. It has been determined that it takes six weeks for the bacteria to break down plastics, thus our machine will run on six-week intervals. Ideonella and Azotobacter have proven to have no adverse effect on marine or human life.

Our goal is to create a buoy that will float in the ocean, collect the water, and break down the plastics. In order to keep the bacteria to the correct temperature, we plan to test the use of insulation and heating pads. We will need to periodically change them out, as well as checking the bacteria frequently to ensure its quality. That provides another challenge: keeping the insulation from getting wet. To combat this problem, we plan to install PVC or smurf piping to lead the water directly to the filter. This filter will catch the plastics and separate them from the outgoing water. We hope to develop a system of locks and sensors that will slide into place once we determine the buoy is full. After the six-week degradation period, we will have to manually open the machine and re-release it, replacing bacteria or heating pads as necessary.

Presented here will be the conceptual design and schematics for our scale prototype.

**A Self-Powered Microbial Inactivation and Nanoparticle Removal Ultrathin Gelatin Multilayer Triboelectric Nanogenerators** [Habtamu G. Menge](#) and Yong Tae Park; Myongji University, Korea (the Republic of)

Internet of Things technologies significantly improve the quality of life by utilizing wearable electronics. Among mechanical energy harvesting technologies, triboelectric nanogenerators (TENGs), which utilize the coupling effects of triboelectrification and electrostatic induction between two contact surfaces, have been considered a novel miniaturized mechanical energy scavenger that generates electricity. However, in most TENGs, synthetic polymers dominated triboelectric materials (TMs) fabrication. Therefore, this study fabricated ultrathin, biodegradable, and biocompatible gelatin (GE) multilayer-based TENG via an eco-friendly layer-by-layer self-assembly method. The electrostatic self-assembly of one species was realized using its dependence on the solution pH. GE is suitable owing to its film-forming abilities, abundance, pyrrolidine electron donor-rich groups, and tunable properties, significantly enhancing the TENG outputs and enabling extended layered growth. The electrical properties and device performance of self-assembled GE multilayer (ML)-TENG were identified by manipulating the pH of the GE medium from 4 to 7. At pH 5, 110 nm-thick of the 3 adsorbed cycles of GE ML-TENG exhibited the highest output power density of 15.9  $\text{W m}^{-2}$ , owing to its highest surface potential of 208 mV. We successfully exhibited the self-powered GE ML-TENG-driven electrophoretic device for removing  $\text{SiO}_2$  and ZnO nanoparticles in water. Furthermore, integrating GE multilayer-TENG as electric stimulation of antibacterial devices is a promising approach and exhibited a significant inhibitory effect on gram-negative *Escherichia coli* (*E. coli*) and gram-positive *Staphylococcus aureus* strains. We also demonstrated the harmony of the vertical axis wind turbine GE free-standing film TENG electricity. The graphene-based filtration system worked simultaneously to attain approximately 100% *E. coli* inhibition efficiency without an external power supply for the water disinfection system. Therefore, this eco-friendly multifunctional GE-based material can be a promising candidate for high-performance self-driven Electrical stimulation nanogenerators.

**8:15 AM EN03.05.02**

**Exploring the Chemical Space of Bioinspired Materials for Sustainable Electronics** Micaela Matta; King's College London, United Kingdom

The field of organic semiconductors and mixed ionic-electronic conducting materials is currently dominated by polymers and small molecules that, despite their good conductivity and processability, have limited biocompatibility. The demand for implantable, edible or degradable devices for nanomedicine or low-cost consumer electronics is growing, and will require a new generation of sustainable materials.[1]

This research combines cheminformatics, quantum chemistry and molecular simulation to design novel bioinspired materials for sustainable electronics and bioelectronics. High throughput calculations are used to screen the electronic and conformational properties of a large dataset of conjugated fragments with different linkers and functional groups. Within a range of bioderived fragments, we focus on the potential of melanin-inspired conjugated fragments as components of bioinspired mixed conducting materials.[2] The oligomers resulting from the best combinations of conjugated units, linkers and side chains are presented. Molecular dynamics simulations are then used to provide information about the charge/ion percolation pathways, aggregation and order. The results of this study can help focus experimental effort towards more sustainable organic materials.

**Exploring Form and Functionalization in Crystalline Nanocellulose Inks for Environmentally Sustainable Printed Electronics** Brittany N. Smith, Nicolas Chen, James L. Doherty and Aaron D. Franklin; Duke University, United States

Printed flexible electronics show promise for providing a sustainable solution to the increasingly negative impact of electronics manufacturing and waste. However, current print processes and inks tend to rely on hazardous solvents, extensive post-processing at high temperatures, and/or materials that are not recyclable or biodegradable. Recent work on water-based inks from nanomaterials shows that these challenges can be overcome (i.e., no hazardous chemicals, relatively low temperature processing, and all recyclable or biodegradable materials), but the resultant devices still require improvement in performance and reproducibility. In this work, we investigated two new water-based inks for use in carbon nanotube (CNT) thin-film transistors (TFTs): nanocellulose, a biodegradable ionic dielectric, and nanoparticle gold, a recyclable conductor. We developed inks and aerosol jet printing processes for crystalline nanocellulose (CNC) and cellulose nanofibrils (CNF) with various surface groups to gain insights into the working mechanisms of nanocellulose as an ionic dielectric. Our results reveal that the general ionic nature of the printed films is invariant with the nanostructure form or surface group. However, the capacitance and sweep rate characteristics of the dielectrics, as well as the electrical and mechanical resilience, do show dependencies on nanocellulose form and functionalization. Further, we investigated the influence of the sulfonic surface group content on transistor performance, revealing that the foremost impact of increasing the sulfonation is a positive shift in the device threshold voltage. Since nanocellulose breaks down under high temperatures, the top-gate contact must be readily conductive when printed to form fully printed CNT-TFTs. Therefore, as an alternative to using graphene, a novel gold ink formulation was used as the contacts for CNT-TFTs. This new ink exhibited a resistance of  $\sim 5 \Omega$  in its as-printed state, without any post-print sintering at high temperatures. The impressive device performance of these printed CNT-TFTs shows promise for the use of water-based inks in environmentally sustainable printing of electronics.

**Laser Induced Graphene from Bio-Derived Sources for Biodegradable and Sustainable Electronics** Anna Chiara Bressi<sup>1</sup>, Iuliia Steksova<sup>1</sup>, Sreenadh T. Sankaran<sup>1</sup>, Alexander Dallinger<sup>2</sup>, Felix Steinwender<sup>2</sup>, Hana Hampel<sup>2</sup>, Hilda Gomez Bernal<sup>1</sup> and Francesco Greco<sup>1,1,2</sup>; <sup>1</sup>Sant'Anna School of Advanced Studies, Italy; <sup>2</sup>Graz University of Technology, Austria

Laser Induced Graphene (LIG) is a porous conductive carbon material produced by laser-induced pyrolysis of polymer precursors, with technological applications in flexible/stretchable/wearable electronics, electrochemical sensors, energy harvesting and storage, among others.<sup>1-4</sup> Several bioderived polymers and raw natural materials are good LIG precursors.<sup>5</sup> For this reason our group is investigating LIG for sustainable approaches to green electronics and soft electronics/robotics. Here, we present some results of our studies on LIG obtained from both raw natural materials and processed bio-derived polymers. These include starch-based bioplastic, composites of polysaccharides (starch, chitosan) + hazelnut or almond shells (i.e., waste from agricultural and food industry), lignin (waste from paper pulp process). For each class of precursors specific laser scribing strategies have been tailored and the resulting LIG materials are characterized in terms of their structure, composition, morphology, and of their functional properties (e.g., conductivity, piezoresistivity, wettability), useful for the development of LIG sensors. Also, the degradation behavior of these materials in different conditions is assessed, in view of applications in biodegradable/transient electronics.

**Large Area Elastomer-Based Printed Electronics** Peter Zalar; Holst Centre / TNO, Netherlands

Holst Centre is a leading applied research institute focusing on the development of flexible and thin electronic systems using industrially relevant fabrication methods. For nearly two decades, our primary objective has been to make technological advancements that facilitate the industrialization of printed electronics systems, thereby turning future visions into reality. With the increasing demand for integrating electronics into a wide range of form factors, it is essential to develop systems that possess key qualities such as accuracy, conformability, ruggedness, lightweight design, and sustainability. These qualities are crucial in applications spanning healthcare, automotive, and robotics, where traditional rigid printed circuit board (PCB) technology falls short. To address this challenge, we have explored the use of elastomeric carriers as a viable solution. In this presentation, I will delve into Holst Centre's contributions towards the development of sensor systems on elastomeric carriers, highlighting our efforts on an all-printed, large area, multimodal sensing surface.

**Soft, Resorbable Bioelectronics** Suk-Won Hwang; Korea University, Korea (the Republic of)

An ultimate goal of a conventional silicon-based integrated system is its capability to last forever without any malfunction and physical deformation, in almost any practical uses. Recent works demonstrate a new class of electronics that has the opposite behavior -- it physically dissolves or disappears in water, environment or biofluids, in a controlled fashion, at predefined times or on demand and with programmed rates. This type of 'transient' technology opens up completely new application opportunities for electronic devices in areas, such as implantable medical devices that exist for medically useful timeframes but then dissolve and disappear completely by resorption into the body. This talk summarizes recent works on bioresorbable electronic systems with mechanically soft, deformable platforms, ranging from fundamental chemistry of the key materials, to development of various components and systems for biosensors, to in vivo evaluations for biocompatibility and potential applications

**Chitosan Nanocomposite Thin Films as Sustainable Biopolymer Based Colorimetric Humidity Sensors** Wafa Tonny<sup>1</sup>, Samuel J. Wallaert<sup>1</sup>, Justin D. Smith<sup>1</sup>, Venkatesh Balan<sup>2</sup>, Megan L. Robertson<sup>1</sup> and Alamgir Karim<sup>1</sup>; <sup>1</sup>University of Houston, United States; <sup>2</sup>University of Houston Sugarland, United States

Humidity sensors play an essential role in monitoring product quality and lifetime in the manufacturing and pharmaceutical industries for vaccine and drug viability. Recently thermoplastic polymers and inorganic semiconductors-based humidity sensors are raising environmental concerns owing to non-degradability despite their performances. Biodegradable and renewably sourced chitosan-based nanocomposite films could provide a more sustainable alternative. Chitosan has randomly distributed  $\beta$ -linked D-glucosamine and N-acetyl-D-glucosamine and the protonation of  $\text{NH}_2$  groups of chitosan increases the affinity of these films towards moisture. Here, thin chitosan films of 120-350nm thickness were coated on Si substrate. Rapid swelling of the thin films in humid environment was spontaneously identified with visible changes in color explained by *thin-film interference* phenomenon. Over the full relative humidity range of 95%, film thicknesses increase 50% compared to dry state, confirmed by *in-situ* ellipsometry and interferometric techniques. The response to humidity change was ultrafast ( $\sim 5$ s) and the absorption-desorption of moisture exceeded 50 cycles with confidence. The moisture absorption kinetics followed non-Fickian type diffusion pathway. By blending polar nanofillers like graphene oxide (GO) in a small amount (0.5-2wt%), the swelling behavior of these blend films followed similar trend of rapid moisture absorption while maintaining film stability because of the interaction of oxygen-rich groups of GO and  $\text{NH}_2$  groups of chitosan. The nanocomposite thin films had reliable thermal properties and stable tensile strength. This highly sensitive humidity dependent colorimetric property of chitosan nanocomposite films enables its potential as a biodegradable sensor for monitoring quality assurance systems benefiting several industries.

**Bio-Inspired Proline Sensors for Diagnosis and Surveillance of Plant Stress** Cassandra L. Martin<sup>1</sup>, Josephine Cicero<sup>1</sup>, Audrey Moos<sup>1</sup> and Daniel Wilson<sup>1,2</sup>; <sup>1</sup>Kostas Research Institute, United States; <sup>2</sup>Northeastern University, United States

In response to environmental stresses such as drought, excessive salt, high temperatures, heavy metals, and pathogens, plants accumulate amino acids and other metabolites resulting from protective homeostatic processes. Specifically, the amino acid proline can counteract the effects of osmotic stress, chelate metals, and act as an antioxidant, resulting in increased concentrations of proline within plant tissue in response to environmental stimuli. While proline can serve as a general diagnostic indicator of plant or crop health, there are limited field-deployable options for measuring the proline content of plant tissue on-location without requirements for secondary equipment. We have developed bio-inspired proline sensors based on the coloration mechanism of *Nesocodon mauritianus*. The color of the nectar in this flowering plant, ranging from pale yellow to blood red, is directly dependent on both internal pH and proline concentration. By leveraging the chemistry of this natural system, we have developed colorimetric, paper-based proline sensors that provide quantifiable visible signals in response to increasing proline concentrations. We are integrating these sensors into biodegradable, user-friendly form factors that enable a plant-based, eco-friendly approach to monitoring plant health.

**Wireless Continuous Glucose Monitoring for Smart Home Diagnosis via Biodegradable Fluorescent Microneedle Sensor** Mingyu Sang, Myeongki Cho, Selin Lim, In Sik Min and Ki Jun Yu; Yonsei University, Korea (the Republic of)

According to the International Diabetes Federation, the number of patients with diabetes worldwide is 536.6 million, i.e., 10.5% of the total population. In particular, hypoglycemia is a serious condition that can cause behavioral and cognitive impairment, seizures, loss of consciousness, coma, brain damage, or death. In addition to the severity of diabetes itself, this condition can also cause serious medical complications in other organs, such as the kidneys, liver, and heart. Diabetes requires constant management to avoid unfortunate consequences, such as death. Therefore, precise monitoring of the blood-glucose level in the body, which is an important indicator for managing type 1 and type 2 diabetes, is necessary. Continuous glucose monitoring (CGM) is crucial for tracking blood-glucose levels in real-time, providing critical information to effectively prevent diabetic complications arising from hypo- or hyperglycemic episodes. While invasive lancet measurement is not compatible with CGM, commercial and research efforts have been directed toward developing biosensors for CGM. However, the current CGM sensors has discomfort from the attached transmitter on skin and require implantation and removal surgery, which increases the possibility of wounding and bacterial infection, presenting critical barriers for use. Despite the considerable progress made by commercial CGMs, there remains a pressing need to develop user-friendly, minimally invasive CGMs. Therefore, a new class of CGM biosensors is needed for monitoring skin interstitial fluid glucose, like commercial CGMs, in a user-friendly, minimally invasive way that overcomes the limitations of existing systems. Here, we introduce the CGM system consisting of biodegradable microneedle sensor array with high fluorescence sensitivity to glucose and portable smart device with image processing applications. This system produced straightforward yet robust outcomes by measuring the fluorescence intensity of microneedles, which was reversibly modulated based on glucose concentration, without the need for enzymes or reagents. Through this sophisticated integration, our system could continuously measure glucose levels without blood collecting, wound or pain over up to 3 days, clearly tracing the results of commercially available blood glucose meters like lancet diagnostic method. Users such as diabetics can easily and wirelessly check the glucose concentration with this on-demand tether free glucose monitoring system by simply taking the picture with the smartphone, thus allowing measurement at any desired time while the patient moved freely. The fluorescence intensity of the microneedle sensor, which changes according to the glucose concentration, can be successfully obtained through the mobile device equipped with software for analyzing pixel data of the fluorescence image. Compared to previous CGM studies, our system has the advantage that the sensors are ultra-thin and light, minimally invasive, very simple to use, and

completely biodegraded and discharged from the body without the insertion and removal surgery. Unlike other sensors, the biodegradable microneedle eliminates the risk of the sensor breaking or remaining in the body, enhancing human safety. This feature notably reduces the risk of infection and further enhances patient comfort and compliance, making our system a more prospective solution for CGM. Furthermore, the microneedle sensor-based home glucose diagnostic platform not only serves as another promising candidate for patients to help prescription and treatment, but also provides potential possibilities to improve health and quality of life. This new platform offers opportunities to autonomous and accurate CGM, a powerful and promising tool in the management of diabetes, using the glucose-responsive fluorescent microneedle sensor and user-friendly home diagnosis mobile service technology.

**Materials for Environmentally Resorbable Batteries, Microelectromechanical Systems and Chemical Sensors** John A. Rogers; Northwestern University, United States

Recently developed classes of functional materials serve as the basis for microsystems technologies that dissolve, disintegrate, degrade or otherwise physically disappear at triggered times or with controlled rates. Water-soluble technologies of this type are of interest for zero-impact environmental monitors, 'green' consumer electronic gadgetry and resorbable medical implants. This talk describes the foundational concepts in materials science, electrical engineering and assembly processes for various applications. The emphasis is on environmentally resorbable batteries, microelectromechanical systems and chemical sensors, the latter of which adopt 3D designs inspired wind-dispersed seeds to facilitate deployment.

**Everyday Materials for Transient Supercapacitors** Mete Batuhan Durukan, Deniz Keskin, Melih O. Cicek, Yigitan Tufan, Orcun Dincer, Simge Cinar Aygun, Batur Ercan and Husnu E. Unalan; Middle East Technical University, Turkey

Due to the substantial advancements achieved in wearable technology, including consumer electronics and medical monitoring devices, there has been a sharp rise in electronic waste during the past ten years. As electronic devices contain hazardous materials and have limited recyclability, the environmental threat is steadily increasing and the volume of e-waste grows exponentially each year. A significant portion of electronic waste comprises energy storage devices that consist of materials that are toxic or non-recyclable. Therefore, research and development in green energy storage systems that are made of non-hazardous materials is highly needed. Transient electronics, which are intended to disintegrate at the end of their use or when required, have emerged as a solution to this need, producing nearly little waste.

Green and transient electronics require transient energy storage units. Being biodegradable, biocompatible, and non-toxic are essential properties that energy units must possess in line with the requirements of transient electronics. This is especially important for on-demand electronics, which are mostly used for health monitoring devices such as ingestible or implantable devices.

Herein, we propose transient and even edible supercapacitors with everyday materials – such as supplements and foods [1,2]. We successfully fabricated transient supercapacitors based on all-PVA layers and successfully achieved a perfectly working EDLC type supercapacitors with an excellent rate capability up to  $1 \text{ V}\cdot\text{s}^{-1}$ . The entire structure is based on biodegradable and biocompatible products and showed excellent physical transiency in simple aqueous solutions. To further this quest, we also successfully fabricated cellulose-based edible supercapacitors utilizing soy-sauce based, zwitterionic gel as an electrolyte. Fabricated food-based gel has shown to enhance the L929 proliferation – which is an excellent indication of biocompatibility – and allowed a textbook-like capacitive behavior due to its excellent ionic conductivity. Simulated gastric fluid tests shown a complete dissolving of the edible supercapacitors, indicating its digestibility. These studies indicate excellent developments in the production of transient and edible supercapacitors, being fresh prospects to be the energy units for environmentally friendly and biocompatible transient electronics.

#### 2:00 PM \*EN03.07.03

**Design of Degradable Rechargeable Batteries** Markus Niederberger; ETH Zurich, Switzerland

Transient or degradable electronics based on materials, devices and systems that disappear after a stable operating period with minimal or undetectable residues can help reduce the enormous amounts of electronic waste [1]. Ideally, the battery is integrated into these devices and degrades along with them. However, conventional batteries are optimized for long-term operation and contain a whole range of hazardous and/or expensive components. Therefore, transient batteries must be designed so that they can be disposed of without negatively impacting the environment. For efficient degradation, it is also important that the components and materials can decompose in an aqueous environment. However, some of the most important electrically conductive materials, e.g., copper and aluminum, which play a major role in batteries, do not fall into this category. For such materials, special concepts have to be developed on how they can be decomposed.

In this presentation, a wide range of materials, fabrication methods, and assembly techniques will be presented to develop transient lithium-ion, sodium-ion, and zinc-ion batteries. Special emphasis will be placed on the development and characterization of separator-electrolyte systems based on biodegradable polymers. These separator-electrolyte systems were combined with a Li metal anode and a vanadium oxide cathode and packaged in a biodegradable case, resulting in a transient rechargeable lithium-ion battery (LIB) that can operate for over 400 cycles, but quickly dissolved in water within 15 minutes [2]. In order to be able to degrade copper and aluminum as well, a packaging concept was developed based on a water-soluble polymer composite film containing an oxidizing agent. When triggered with water, the film released the oxidant into the solution, which reacted with the copper and aluminum current collectors and led to their degradation [3]. For sodium-ion batteries biodegradable separators composed of agarose and nanocellulose were applied and tested in half-cell configurations with  $\text{Na}_3\text{V}_2(\text{PO}_4)_3$  and  $\text{Na}_2\text{Fe}_2(\text{SO}_4)_3$  as cathode materials [4]. Both separators showed promising electrochemical performances with high specific capacities and good cyclability, opening new avenues for the use of these renewable resources for

sustainable energy storage devices beyond lithium-ion batteries. Finally, a carefully tailored bottom-up design of a transient zinc ion battery will be introduced that combined both excellent transience properties with outstanding electrochemical performance [5]. The battery consisted of a biopolymeric hydrogel electrolyte based on environmentally friendly polysaccharides, a Zn anode, and a biocompatible polydopamine-based cathode. A polysaccharide-based packaging made it possible to control the degradation of the battery, which is essential to maintain its functionality for as long as desired. This carefully tuned battery design displayed an open circuit voltage of 1.12 V and a specific capacity of 157 mAh g<sup>-1</sup> (current density of 50 mA g<sup>-1</sup>) for over 200 cycles. The battery exhibited a pronounced transiency under composting conditions, evidenced by a weight loss of 50 wt.% after 63 days.

**Implantable Bioelectronics for Probing Brain Chemistry** Yi Zhang; University of Connecticut, United States

The human central nervous system contains billions of neurons that communicate through the propagation of action potentials along the cell membrane and the release, transport, and metabolism of neurochemicals at the synapses. Technologies for *in vivo* electrophysiology have been intensively studied, with recent examples of Neuropixels 2.0 and Neural Matrix for recording over several thousand channels. Compared with these tools for electrophysiological recordings, the technologies for real-time neurochemical monitoring are very limited. In this presentation, I will present our recent developments on implantable bioelectronics for probing brain chemistry, including 1) a soft implantable aptamer-graphene microtransistor probe for real-time monitoring of neurochemical release with nearly cellular-scale spatial resolution, high selectivity (dopamine sensor >19-fold over norepinephrine), and picomolar sensitivity, simultaneously (*Nano Lett.* 2022, 22, 9, 3668–3677), 2) a soft neural probe for multiplexed neurochemical monitoring via the electrografting-assisted site-selective functionalization of aptamers on graphene field-effect transistors (*Analytical Chemistry* 2022, 94 (24), 8605-8617), and 3) a wireless, programmable push-pull microsystem for membrane-free neurochemical sampling with cellular spatial resolution in freely moving animals (*Science Advances* 2022 8 (8), eabn2277). These new sets of implantable bioelectronics create opportunities for neuroscientists to understand where, when, and how the release of neurochemicals modulates diverse behavioral outputs of the brain.

### 3:30 PM \*EN03.08.03

**The Next Biodegradable Electronics for Minimally Invasive Implantation for Brain Cortex** Seung-Kyun Kang; Seoul National University, Korea (the Republic of)

Biodegradable electronic devices are gaining prominence as minimally invasive tools that mitigate issues such as biofilm formation due to residual foreign-body materials and infections and hemorrhage arising from secondary removal surgeries. Over the past few years, various implantable medical devices using biodegradable organic and inorganic hybrid materials have demonstrated the feasibility of biodegradable electronics. Notably, these include sensors for monitoring raised intracranial pressure due to traumatic brain injuries with a latency period, and wireless electrical stimulators to promote peripheral nerve regeneration. Systems that use electrical stimulation to control drug delivery can also serve as short-term post-operative drug treatment technologies. However, a limitation of existing biodegradable electronic devices is the need for an implantation process, which unavoidably involves surgical burden. In this presentation, we introduce representative examples of implantable biodegradable electronic devices noted in above. Furthermore, we explore the concept of injectable electronic devices as a means to minimize invasiveness during the implantation process, examining this through the application of large-area signal measurement in the cerebral cortex.

### 4:00 PM EN03.08.02

**Bio-implantation Strategy for the Bio-Interfaces with Minimally Invasive Surgery Based on the Mechanical Analysis** Gyeong-Seok Hwang<sup>1</sup>, Jae-Young Bae<sup>2</sup>, Seung-Kyun Kang<sup>2</sup> and Ju-Young Kim<sup>1</sup>; <sup>1</sup>UNIST (Ulsan National Institute of Science and Technology), Korea (the Republic of); <sup>2</sup>Seoul National University, Korea (the Republic of)

Among the deformable electronic devices, there are bio-implantable electronics that consist of biocompatible materials and withstand biological motions with deformability. It can operate in the body with biocompatible materials for all components, and it is considered to be a key technology for the future. The general bio-implantable electronics use biocompatible materials, but it needs extra removal surgery after the functional period. If all components of bio-implantable electronics are substituted with biocompatible and bioresorbable materials, it does not have to conduct extra removal surgery and it can be naturally resolved with the body fluid after the functional period. It means that the patient becomes free from the anesthesia and secondary infection through the extra surgery. The minimally invasive surgery concept is also actively researched in the bio-medical field. It pursues the minimization of a wound during surgery or the implantation process. It is possible to incise the minimum area to minimize the recovery time of the wound and greatly reduce the probability of infection and scarring even if surgery is performed when it uses this concept.

In this research, we intend to fabricate a biocompatible and bioresorbable electronic device that can resolve after the functional period, and it can highly expand into a large area when injected into the body. The bioresorbable shape memory polymers are a strong candidate for the shape expansion behavior near the body temperature. In addition, the electronic device must be spread through the narrow gap between the tissue and the skull to place the electronic device on the tissue. Therefore, during the process of suction and injection into the tube, the analysis of the mechanical properties of the entire electronic device and the optimization of the deformation mode and mechanism depending on the device structure are intended to be achieved at the same time. The deformation behavior was analyzed based on the accurately measured mechanical properties of all constituent materials to realize this concept. The suction & injection process was simulated through 3D finite element simulation based on the measured mechanical properties, and a general design rule for the structural design of mechanically reliable, bioresorbable, shape expandable, minimally invasive implantable electronics can be presented. As a result, it is expected that this concept can open a novel paradigm of bio-implantable electronics.

## SESSION EN03.09: Poster Session II: Sustainable Materials I

Session Chairs: Shweta Agarwala and Jahyun Koo

Tuesday Afternoon, November 28, 2023

Hynes, Level 1, Hall A

**8:00 PM EN03.09.01**

**Reinforcement of Physical Properties of Biodegradable Cellulose Composites for Landfill using Cellulose-Based Resins** Mikyung Kim<sup>1</sup>, Jiyoung Woo<sup>1</sup>, Jeonghyun Yeum<sup>2</sup>, Jungeon Lee<sup>2</sup>, Sejin Lee<sup>3</sup>, Changhoon Han<sup>3</sup>, Jinsoo Kim<sup>4</sup>, Seokhyeon Song<sup>4</sup> and Hyaemi Son<sup>4</sup>; <sup>1</sup>DYETEC Institute, Korea (the Republic of); <sup>2</sup>Kyungpook National University, Korea (the Republic of); <sup>3</sup>Korea Conformity Laboratories, Korea (the Republic of); <sup>4</sup>Green Package Solution, Korea (the Republic of)

The general garbage bags are made of polyethylene(PE) or polypropylene(PP), and most of the garbage bags are landfilled in the ground and incinerated. Landfill garbage bags manufactured using petroleum-based resins such as PE and PP take more than 500 years to decompose naturally in the ground. In addition, when PP, PE bags are incinerated, dioxins and volatile organic compounds, which are first-class carcinogens, are generated, which poses a threat to human health.

Garbage bags using resins such as PLA(Poly lactic acid), PBS(Polybutylene succinate) and PBAT(Polybutylene adipate terephthalate), which are biodegradable polymers, are decomposed only under composting conditions(58°C, within 6months), and are difficult to decompose when buried in the ground at room temperature, so they are incinerated like general garbage bags made of PP or PE. Therefore, even if biodegradable plastic materials such as PLA and PBS are selected, it will not be the ultimate eco-friendly product.

In order to replace garbage bags made of PP or PE, which cause environmental pollution, cellulose material, which is abundant on earth and can be biodegraded in soil, was used as a biodegradable garbage bag material for landfill. However, the film materials using cellulose resin have problems such as lack of elasticity and low tear strength.

As a study to improve the physical properties of these cellulose films, the physical properties of cellulose-CNF composites, which were compounded by adding CNF(Cellulose nanofibers), were investigated. In addition, the physical properties such as elasticity, flexibility, and biodegradability were investigated for cellulose composite films compounded with bio-organic compound additives such as eco-friendly plasticizers and starches, and the possibility of using these cellulose composite films as materials for resource circulation garbage bags was examined.

**8:00 PM EN03.09.02**

**Enhanced Mechanical Properties of Biodegradable Polybutylene Adipate-Co-Terephthalate Blended with Cellulose Nanofiber Modified with Silica Nanoparticles** Joheun Yoon and Youngsoo Seo; University of Sejong, Korea (the Republic of)

Polyethylene (PE) mulching films are widely used in crop fields. However, residual PE films have been accumulated in the soil reducing crop yield. It has been tried that PE films are replaced by biodegradable polymers such as Polybutylene adipate-co-terephthalate (PBAT). In order to increase the use of PBAT mulching films, problems such as its low mechanical properties, short degradation period and low UV resistance still need to be addressed. In this study, through a sol-gel reaction, silica nanoparticles were synthesized on the surface of the cellulose nanofiber (CNF) to have a bumpy surface. The surface-modified CNF (s-CNF) could be obtained in powder form after drying because aggregation due to capillary force between the fibers is suppressed. s-CNF was well-dispersed in PBAT or PBAT/PLA blends using a melt-mixer. The mechanical properties of the composite films were improved, for example, tensile strength at break was enhanced by 35% with 3wt% s-CNF addition. The mechanical property was systematically studied in terms of s-CNF and PLA contents. Controlling silica particle content and morphology will be presented. The degradation rate and UV resistance of the composite films may also be presented.

**8:00 PM EN03.09.03**

**Mechanical, Thermal and Rheological Characteristics of Ternary Blended System, Poly(lactic acid)/Poly(hydroxyalkanoates)/Poly(butylene adipate-co-terephthalate) (PLA/PHA/PBAT) via the Morphological Influence** Min Yeong Jeong<sup>1</sup>, Jin Hee Noh<sup>2</sup>, Kibeom Nam<sup>1</sup>, Hyojin Kim<sup>2</sup> and Dong Yun Lee<sup>1</sup>; <sup>1</sup>Kyungpook National University, Korea (the Republic of); <sup>2</sup>Advanced Materials & Components Center, Korea (the Republic of)

This study explores the potential of biodegradable polymer blends as environmentally friendly alternatives to conventional plastics. Single biodegradable polymers have limitations in fully replacing traditional polymer materials. To overcome these limitations, blending different polymers or using compatibilizers has been investigated. However, compatibility issues arise due to the high molecular weight and surface energy differences between materials. In this study, we aim to enhance compatibility by controlling the composites and investigating the effects of polymer surface energy in ternary blends of Poly(lactic acid) (PLA)/Poly(hydroxyalkanoates) (PHA)/Poly(butylene adipate-co-terephthalate) (PBAT). Our analysis includes the examination of morphology, mechanical properties, rheological characteristics, and a particular focus on the effects of PHA at the blend's interface. The results reveal that PHA acts as a compatibilizer, transforming the blend structure from a sea-island morphology to a co-continuous structure, with PHA encapsulating PBAT. This not only enhances impact strength but also achieves the highest tensile strength and elongation at break by optimizing the PHA content. The aggregation and reinforcement effects of PHA in the PLA/PBAT blend contribute to these improvements. The morphological prediction of the blend is conducted using diffusion coefficients, and the influence of PHA on interfacial properties is confirmed through scanning electron microscopy (SEM). The co-continuous interface achieved by encapsulating PBAT with PHA contributes to a consistent and stable structure. Rheological properties are evaluated using a rheometer, revealing a decrease and subsequent increase in complex viscosity with increasing PHA content. This behavior can be attributed to the formation of complex fluidity during the heating process, followed by the formation of a new structure. Moreover, for immiscible blends, the influence of the interface becomes more significant, resulting in a larger increase in storage modulus. However, as PHA content increases, the rate of increase in storage modulus decreases. Overall, these findings highlight the role of PHA as a compatibilizer in PLA/PBAT blends. Furthermore, by increasing the content of biomass-based PHA instead of petroleum-based PBAT, this study suggests the possibility of sustainable plastics for eco-friendly packaging materials.

**8:00 PM EN03.09.04**

**Identification and Characterization of Digestive Enzymes and Intestinal Microorganisms that Degrade Polystyrene in *Tenebrio Molitor* Larvae** Hwicheol Shin<sup>1</sup> and Dong-Ku Kang<sup>1,2,3</sup>; <sup>1</sup>Incheon National University, Korea (the Republic of); <sup>2</sup>Research Institute of Basic Sciences, Korea (the Republic of); <sup>3</sup>Bioplastic Research Center, Korea (the Republic of)

Plastic has been produced since 1950s and it has been also widely used successfully as a fundamental material. However, it is now considered as a major reason of environmental hazard because its non-biodegradable property. More specifically, non-biodegradable plastic (NBP) mean a high-molecular-

carbon-polymers that does not break down in a natural condition by biological processes. In recent decades, various research groups have been conducted to develop a solution for the biodegradation of non-biodegradable plastics such PE, PP, PS, PET and PVC. Recent research indicated that mixed-microbial can be used for digestion of NBPs. Bacterial strains have been isolated from environment or living-organisms and their ability of biodegradation was confirmed that convert into low-molecular-weight organics or mineralize to CO<sub>2</sub>. In this study, up-regulated enzymes were identified when insects were feed with NBPs instead bran. Microorganisms were also isolated from various insects and characterized that could biodegrade NBPs. To isolate NBP-digesting microorganisms, the larvae of *Galleria mellonella*, *Tenebrio molitor Linnaeus*, *Plodia interpunctella* and *Sitotroga cerealella* were collected from environment and NBPs (polyethylene (PE), polystyrene (PS), and polypropylene (PP)) were produced instead bran. It is identified that *T. molitor* larvae had a potential for consuming PS comparing other insects. In order to identify the intestinal digestive enzymes and intestinal microorganisms of *T. molitor* involved in PS biodegradation, we divided them into 5 groups according to the diet. The survival rate was higher in the group of 'PS fed only' comparing with 'starvation'. This indicated that larvae have an ability that can convert energy source from digestion of PS. Intestinal microorganisms were excluded by feeding antibiotics to confirm the PS digestion ability only by digestive enzyme. Frass were characterized with various analytical approaches (such as GPC, FTIR, NMR and TGA) and result indicated that there were no significant differences in PS degradation ability between the presence or absence of intestinal microorganisms. To identify the digestion enzymes of PS with or without treatment of antibiotics, total mRNA was isolated from intestine and sequenced. Lipase3, Phospholipase A11, and Peroxiredoxin-6 were up-regulated that is known as relating fatty acid-digestion. In addition, Calcium uniporter protein mitochondrial, Sulfate permease chloroplast and Sialin were also up-regulated that regulate cell bioenergetics. These results indicate that intestinal enzymes are related in the process of PS digestion process and cellular-energetics. Furthermore, metagenome analysis of the intestinal microflora was performed at 5-day intervals to confirm the change in the microbials community of *T. molitor* according to PS feeding. It is confirmed that increasing and decreasing-bacterial strains over time and intestine was isolated to identify digesting-microorganisms. Isolated intestine was crushed and cultured in various medium condition including LB, NB, BHI, TSB and GPY. Isolated microorganisms were cultured in an inorganic medium with PS (as an only carbon source). As a result, 6 types of bacterial strains were successfully identified: *Bacillus* sp., *Bacillus mycoides*, *Bacillus cereus*, *Enterobacter xiangfangensis*, *Enterobacter cancerogenus* and *Enterococcus gallinarum*. Our result indicates intestinal bacteria and enzymes are relating in the process of digestion of PS and cellular-energetics.

#### 8:00 PM EN03.09.07

**Improving the Weatherability and Intumescent Effects of Naturally Sourced Wood Flame Retardant Coatings.** Mary K. Ruxsarash<sup>1</sup>, Douglas Fox<sup>1</sup> and Whirang Cho<sup>2</sup>; <sup>1</sup>American University, United States; <sup>2</sup>National Institute of Standards and Technology, United States

Approximately 1 billion acres or half of all the United States is considered wildland. As wildland-urban-interface (WUI) development expands, millions of homes are at risk of ignition and destruction. As a result, these communities must adapt by acquiring fire-resistant materials and protectants for their homes. However, commercially available wood flame retardant coatings (WFRC) are perceived to present harm to both human health and the environment. In addition, commercial fire-resistant paints often leach into the environment, losing their efficacy shortly after application in external applications. To properly address this, it is imperative to explore WFRC which use natural products as feedstocks. Chitosan is an abundant, biodegradable, and nontoxic binding agent that can be easily incorporated as a primary component in water-based WFRC. Prior studies in our laboratory have shown that using reduced valence phosphorus-containing acids in chitosan WFRC can significantly delay or prevent ignition of wood under a 50 kW/m<sup>2</sup> heat flux. However, Chitosan's solubility in water threatens the overall weatherability of the coating. Photo crosslinking agents were utilized to allow for on-site application in vulnerable WUI areas. After exposure to sunlight, no chitosan dissolved in artificial acidic rainwater, and coated wood substrates self-extinguished immediately after flame impingement was removed. These findings offer a valuable glimpse into which methods and additives may contribute to an overall optimized, weatherable, and flame-retardant Wood Flame Retardant Coating.

#### 8:00 PM EN03.09.08

**Higher Strength and Carbon Sequestration in Cement and Cementitious Material using Biomimetic Zinc Complex** Rebecca J. Gilchrist, Allison L. Morin, Sara Heidarneshad, Shuai Wang, Nima Rahbar, Suzanne F. Scarlata and Ronald L. Grimm; Worcester Polytechnic Institute, United States

The cement industry is a prominent contributor to anthropogenic greenhouse gases and is responsible for about 8% of global emissions, which drives research into cement alternatives. We have previously incorporated carbonic anhydrase into concrete to create an enzymatic, self-healing, cementitious material (ECM) for carbon sequestration. While this material demonstrates high strength and self-healing properties, it is limited by the short lifespan (i.e. ~2 weeks) of carbonic anhydrase and nonspecific limestone incorporation. It motivates our exploration of non-biological alternatives such as zinc cyclen (cyclen = 1,4,7,10-tetraazacyclododecane). With a ~3300 M<sup>-1</sup> s<sup>-1</sup> rate constant, zinc cyclen is among the most efficient molecular carbonic anhydrase mimics and demonstrates extreme stability at cement-relevant temperatures and alkaline pH values.

Recently, we utilized zinc cyclen to produce calcium carbonate as an aqueous solute and covalently tethered to sand surfaces. In recent results, we found when tethered to the sand aggregate, the covalent attachment affords high strength and healing properties by catalytically producing calcium carbonate at the sand-cement interface while providing a flexible organic connector to accommodate interfacial atomic mismatches. This catalytic sand should enable future inexpensive, robust, green construction materials with long lifetimes and self-healing properties that can withstand extreme environments.

**Self-Organized Hydroxyapatite Construct for Biomedical Applications: From Pack Cementation to Structure and Mechanical Characterization.** Obinna A. Osuchukwu<sup>1,2</sup>, Abdu Salihi<sup>1</sup>, Ibrahim Abdullahi<sup>1</sup>, Precious O. Etinosa<sup>3</sup> and David O. Olubiyi<sup>2</sup>; <sup>1</sup>Bayero University, Nigeria; <sup>2</sup>Ahmadu Bello University, Nigeria; <sup>3</sup>Worcester Polytechnic Institute, United States

This work presents the bioprocessing and robust characterization of the physical and mechanical properties of hydroxyapatite (HA) synthesized from two bio-precursors: bovine and catfish bones. The precursors are deproteinized by carbonization and calcination, then sintered using conventional heat treatment to form HA microparticles. Pulverization and the sol-gel process are performed to achieve homogeneity of well-packed cementitious powder constructs of controlled percentage weight compositions of HA from each precursor. The structural and compositional qualities, fracture mechanics, and mechanical properties of the synthesized powder and cementitious construct are assessed via X-ray diffraction, Fourier transform infrared spectroscopy, scanning electron microscopy, and mechanical testing. The specimen composed of an equal percentage weight of HA from bovine and catfish (B50/C50) exhibited the highest fracture toughness and highest compressive strength. The highest hardness and brittleness index values are measured in the B25/C75 specimen. Under dynamic loading, the B100/C0 specimen exhibited the highest resistance to wear. The X-ray diffraction patterns revealed that the B75/C25 specimen has the highest fraction of crystallinity. The implications of these findings are discussed for the potential biomedical applications of HA in dentistry and orthopedic medicine.

**Functional Paper for Self-Powered Sustainable Digitalization** Rodrigo F. Martins<sup>1</sup>, Guilherme Ferreira<sup>1</sup>, Sumita Goswami<sup>2</sup>, Elvira Fortunato<sup>1</sup> and Suman A. Nandy<sup>1</sup>; <sup>1</sup>FCNT UNL, Portugal; <sup>2</sup>AlmaScience Colab, Portugal

2020, world is taken aback by a pandemic. It is turning into an unprecedented crisis in people's lives and economy. But it warns us too, to be careful and prepare for the future. We can live better now, but we must think best for tomorrow. Today, another threatening part is increasing global emissions significantly, the majority caused by energy production that is consumed in industry, services, households, and transport. The worldwide concern over energy security and environmental issues due to fossil fuel consumption has generated the urgent need of sustainable and renewable energy sources. Therefore, alternative energy actions can support the goals of green world with economic stimulus programs. The majority of renewable energy sources are based on solar, wind, hydroelectric, geothermal or biomass. But most of them needs a huge plant. Though, in this faster digitalization era, most of the technologies are portable that connected with IoTs which requires a flexible energy resource that will provide power uninterrupted. Still today, the battery is a prime option. But super flexibility and biocompatibility is still a limitation for it. Moreover, the native drawbacks of conventional systems are recharging, periodical maintenance and replacement that causes environmental pollution. Therefore, self-powered technology which can work independently without any other external energy supplier, will be a great choice.

Therefore, the biggest challenge in smart technology is sustainable power sources, that can back up the electronics unconditionally. This situation considers a new platform of self-powered technology, operating without any external power sources! In this context, the principal vision of us is to speed up the concept of self-powered technology based on different wearable and low-cost platform, by constructing in such a way, that will buckle wearables platform with electronics to bring a new smart technology which will have inbuilt self-powered system.

**Commercial Organic Dyes and Pigments as Semiconductor Photocatalysts** Eric D. Glowacki; Brno University of Technology, Czechia

Semiconductor-based catalysts can convert solar energy into chemical fuels such as hydrogen, hydrogen peroxide, or hydrocarbons produced via carbon dioxide reduction. Long overlooked due to stability concerns, some organic semiconductors have recently emerged as promising electrocatalysts and photocatalysts for operation in aqueous environments. Our attention has focused on dyes and pigments of commercial origin, everyday materials used on a large scale with an established safety profile. Many of these light-absorbing molecules have indeed been selected due to their outstanding stability, which is a feature that translates to useful applications in the field of aqueous photocatalysis. We have found a high selectivity of organic semiconductors for oxygen reduction reactions, by both one-electron and two-electron pathways. The products of these reactions are superoxide or hydrogen peroxide. We find this occurs on numerous organic semiconductors and conducting polymers in a pH range from 1 to 12. We have found that while photogenerated electrons reduce oxygen, the fate of the holes represents a complex picture. When the semiconductor is used as a photocathode and efficient p-type transport is available, photogenerated holes can easily be extracted and stability is very high. This talk will discuss the promises, potential applications, as well as obstacles facing the use of low-cost commercial photocatalytic organic dyes and pigments.

**Sustainable and Controlled Synthesis of Carbon Nanoparticles from Lignin using Single-Step Aerosol Methods for Application in Energy Storage** Sujit Modi<sup>1</sup>, Onochie C. Okonkwo<sup>1</sup>, Sulay Saha<sup>1</sup>, Hao Zhou<sup>1</sup>, Shalinee Kavadiya<sup>2</sup>, Marcus Foston<sup>1</sup> and Pratim Biswas<sup>2</sup>; <sup>1</sup>Washington University in Saint Louis, United States; <sup>2</sup>University of Miami, United States

With the rapidly growing demand for renewable energy and portable devices, developing high-performance energy storage materials and meeting sustainability requirements is significant. Lignin, a biomass constituent and byproduct waste of biorefineries, is one of the few renewable sources of carbon that have the abundance and desirable properties to displace or replace fossil derived carbon sources. A renewable resource, low cost, and high aromatic content make lignin an ideal precursor to obtaining carbon materials for energy storage. However, present efforts on the large-scale synthesis of carbon materials from lignin are limited either by multistep and batch processes or the use of activating agents/templates [1].

The present work aims to engineer a process that valorizes waste and by-product lignin. In particular, we develop an original and innovative method, based

on a one-step continuous aerosol technique, to manufacture high-performance carbon nanoparticles for energy storage without the use of activating agent/template. This one-step approach requires a significantly lower time for synthesis: an order of seconds in comparison to hours for existing methods. Temperature and residence time are expected to have a key impact on the properties of carbon materials synthesized from lignin, hence, an aerosol technique utilizing a furnace aerosol reactor is used; furnace aerosol reactor is known for enabling precise control over a wide range of temperatures and residence times [2]. Subsequently, the effect of temperature and residence time inside the reactor on carbon nanoparticle size, functional groups, surface area, and morphology is systematically investigated. Furthermore, the as-obtained carbon nanoparticles are tested for specific capacitance and the best-performing material (surface area 925 m<sup>2</sup>/g) exhibited a specific capacitance of 247 F/g at 0.5 A/g with excellent capacity retention of over 98 % after 10,000 cycles. This is a clear demonstration of their superior performance compared to supercapacitors synthesized earlier from lignin.

Moreover, the size and morphology of carbon particles, which are impacted by interparticle collision and sintering, are known to play a crucial role in their stability as well as energy storage performance. However, experimental as well as modeling efforts on size and morphology-controlled synthesis of carbon nanoparticles from lignin are limited, partly due to the complexity of studying collision and sintering under simultaneous lignin reactions (pyrolysis). We systematically investigate the kinetics of reaction, sintering, and collisions using a novel and generalizable numerical model based on a geometric modeling approach [3]. Knowledge of kinetics will provide better control over the size and morphology for efficient utilization of carbon nanoparticles in energy storage.

Overall, the simple (one-step, continuous, and rapid) operation, avoiding the use of activating/templating chemicals, and precise control over size and morphology make the aerosol technique a promising candidate for the scalable and sustainable synthesis of energy storage materials.

#### 11:00 AM EN03.11.05

**Cellulose Nanocrystals Based Flexible Substrates as Electrodes for Zn Batteries and Tribolayer in Triboelectric Nanogenerators (TENG) Devices**  
 Amit K. Sonker<sup>1,2,2</sup>, Shizhao Xiong<sup>2</sup>, Aleksandar Matic<sup>2</sup> and Gunnar Westman<sup>2</sup>; <sup>1</sup>VTT, Technical Research Center of Finland, Finland; <sup>2</sup>Chalmers University of Technology, Sweden

Nanocellulose is a promising polymer for applications in energy and electronic devices due to its biodegradable nature and properties. Among nanocelluloses, cellulose nanocrystals (CNC) are the most crystalline than bacterial cellulose and cellulose nanofibrils. Sulfate groups on CNC surfaces make them suitable for use as dispersants. In the presented work, a novel method of exfoliating MoS<sub>2</sub> in water using CNC and the use of exfoliated MoS<sub>2</sub> as an electrode in battery application is presented. In detail, electrodes are prepared from exfoliated MoS<sub>2</sub> (active material)-Cellulose Nano Crystals-(binder) with carbon nanotubes (electron-conducting support) and used in a Zinc battery half-cell that demonstrated a coulombic efficiency of 90%. Successful exfoliation of layered MoS<sub>2</sub> into nanosheets is performed by sonicating Bulk MoS<sub>2</sub> with sulfated cellulose nanocrystals (CNC) for 4 hours. In addition to Raman and TEM confirmation, the Raman signals for exfoliated MoS<sub>2</sub> show a blue shift of both A<sub>1g</sub><sup>1</sup> and E<sub>2g</sub><sup>1</sup> bands, suggesting CNC-induced lattice strain on nanosheets. The resulting stable water suspension shows no tendency for precipitation after two months of standing. The zeta potential, ζ, for sodium sulfated CNC (CNC-OSO<sub>3</sub>Na)-MoS<sub>2</sub> in water suspension is observed as -45 mV, whereas sulfated CNC (CNC-OSO<sub>3</sub>H)-MoS<sub>2</sub> in water suspension had a zeta potential of -35 mV. CNC in the sodium form showed micelle characteristics like sodium dodecyl sulfate (SDS), with a critical aggregation concentration (CAC) of 1.1 wt%. Using CNCs at CAC efficiently exfoliated MoS<sub>2</sub> at a much lower concentration than has been reported for synthetic surfactants like SDS and CTAB (Cetyl trimethyl ammonium bromide). In addition to application in energy storage devices, flexible CNC films were also utilized to fabricate triboelectric nanogenerators (TENG). As CNCs are highly crystalline and to make them flexible, a plasticizer is optimized with a concentration of less than 13.5 wt% to maintain its recyclability. Flexible CNC films as a tribo-positive layer shows an output voltage of 120-200 V.

**Bio-Based Energy Technology and Low-Power Electronics for Internet of Things** Magnus Berggren; Linköping University, Sweden

Cellulose and lignin are the two most abundant biopolymers on earth. These materials offer structural integrity and electrochemical functionality for efficient energy technologies, especially for energy scavenging and electrical energy storage. Here, piezo-electric energy generators and printed batteries are reported, targeting sustainable manufacturing, circularity, and energy efficiency. In addition, a printable organic electronic complementary circuit technology has been developed enabling low-power operation at voltages that are compatible with bio-based organic batteries. Together, these devices and circuits provide a platform for future internet of things solutions, specifically targeting sustainable production and materials, and an easy end-of-life handling.
