electronics and optics. Ga$_2$O$_3$, being supported by its bandgap as wide as ~5 eV, is gaining increasing interests as a material for power electronics devices. Progress of monoclinic-structured Ga$_2$O$_3$ ($\beta$-Ga$_2$O$_3$) bulks and substrates, which is the thermodynamically most stable phase in a variety of polymorphs of Ga$_2$O$_3$, grown by solution-methods has accelerated the evolutionary research on high-performance power devices. On the other hand, our research has directed on semistable corundum-structured Ga$_2$O$_3$ ($\alpha$-Ga$_2$O$_3$) grown on sapphire ($\alpha$-Al$_2$O$_3$). One of the reasons for paying attention to $\alpha$-Ga$_2$O$_3$ is that there are a variety of corundum-structured oxide materials, which can be combined with $\alpha$-Ga$_2$O$_3$ to establish novel devices. Alloys and heterostructures of Al$_2$O$_3$, Ga$_2$O$_3$, and In$_2$O$_3$ can achieve heterostructure devices by arbitral tuning of the bandgaps. We have succeeded in the bandgap tuning from 3.7 to 8.8 eV, and the n-type conductivity control of $\alpha$-Ga$_2$O$_3$ with doping Sn and Si, leading to the device-oriented research. A start-up company, FLOSFIA, Inc., has demonstrated Schottky barrier diodes with on-resistance as low as 0.1 m$\Omega$cm$^2$, their reasonable heat resistivity, and the low-loss power conversion. Heterojunctions of $\alpha$-(Al,Ga)$_2$O$_3$ alloys show the type-I band lineup, and this allows fabrication of a variety of heterojunctions and quantum wells for novel devices. $\alpha$-In$_2$O$_3$ showed the higher electron mobility compared to that of $\alpha$-Ga$_2$O$_3$, and we demonstrated the operation of an MOSFET with the field-effect mobility of 187 cm$^2$/Vs. The bandgap of $\alpha$-In$_2$O$_3$ (3.7 eV) is still wider than that of GaN and SiC, suggesting that $\alpha$-In$_2$O$_3$ can also be a candidate material for power devices.

A various combination of corundum structured oxides allows unique materials properties. One of the examples is above-room temperature ferromagnetic properties of $\alpha$-(Ga,Fe)$_2$O$_3$ and $\alpha$-(In,Fe)$_2$O$_3$. $\alpha$-Rh$_2$O$_3$ and $\alpha$-Ir$_2$O$_3$ are native p-type materials. Especially, $\alpha$-Ir$_2$O$_3$ is closely lattice-matched to $\alpha$-Ga$_2$O$_3$. We demonstrated p-type conductivity of $\alpha$-Ir$_2$O$_3$, followed by fabrication of $\alpha$-Ir$_2$O$_3$/Ga$_2$O$_3$ pn junction. Efforts are continuing to control the bandgap and the hole concentration of p-type $\alpha$-(Ir,Ga)$_2$O$_3$.

For optical applications of UWBG oxide semiconductors, we have focused on UWBG Mg-rich ($x\approx0.7$) rocksalt-structured Mg$_x$Zn$_{1-x}$O, whose maximum band gap can be ~7.8 eV (at $x=1$). This attracts its potential as deep UV light emitters in the wavelength region which cannot be reached by III-nitrides, whose maximum band gap is ~6.0 eV of AlN. We used mist CVD method for the growth of MgZnO with the carbon-free source precursors. The x-ray and electron-beam diffraction evidenced rocksalt structure without noticeable incorporation of other phases. In the TEM images, it was revealed that dislocation defects were formed in the MgZnO layer originating from the defects on the MgO substrate surface, that is, the dislocation defects density in the MgZnO layer at present is dominated by the quality of the MgO substrate. Mg$_x$Zn$_{1-x}$O films with $x=0.95$ and 0.92 showed the CL peaking at 199 and 212 nm at 6 K and at 205 and 217 nm at 300 K, respectively, without noticeable luminescence at the longer wavelengths. However, the luminescence peak energies were lower by 0.5-0.7 eV than the band gap energies. This large Stokes-like shift is attributed to the local band gap fluctuation. Efforts were continued for Mg$_x$Zn$_{1-x}$O/MgO quantum wells. For the sample with $x=0.92$, the CL peak blue-shifted by 1-8 nm (0.08-0.21 eV) at 6 K compared to the single MgZnO layer with decreasing the thickness of the MgZnO layer. The spectrally integrated CL intensity at 300 K over that at 6 K ($I_{300}/I_6$), which is supposed to be the internal quantum efficiency at 300 K, reached ~13%, which was apparently higher than that of the single layer. The overall results suggest that MgZnO can pave the way for deep UV photonics.

**Halide Vapor Phase Epitaxy of Group-III Sesquioxides**
Yoshinao Kumagai$^1$, Ken Goto$^1$, Rie Togashi$^2$, Hisashi Murakami$^1$, Akito Kuramata$^3$, Shigenobu Yamakoshi$^4$ and Masataka Higashiwaki$^5$; $^1$Tokyo University of Agriculture and Technology, Japan; $^2$Sophia University, Japan; $^3$Novel Crystal Technology, Inc., Japan; $^4$Tamura Corporation, Japan; $^5$National Institute of Information and Communications Technology, Japan

Group-III sesquioxides such as Ga$_2$O$_3$ and In$_2$O$_3$ are ultra-wide bandgap semiconductor materials. It is well known that bulk single crystals of thermally stable phases $\beta$-Ga$_2$O$_3$ ($E_g = 4.5$ eV) and c-In$_2$O$_3$ ($E_g = 3.7$ eV) can be grown by melt growth methods [1,2]. At present, high-speed growth of conductivity controlled homoepitaxial layers of $\beta$-Ga$_2$O$_3$ and c-In$_2$O$_3$ has attracted much attention to apply both materials for fabrication of vertical high-power electronic devices. In this presentation, the authors introduce high-temperature and high-speed growth of $\beta$-Ga$_2$O$_3$ and c-In$_2$O$_3$ by halide vapor phase epitaxy (HVPE) [3-7].

First, source gases and their carrier gases for HVPE growth of Ga$_2$O$_3$ and In$_2$O$_3$ were examined by thermodynamic analyses. The results clarified that by removing hydrogen atoms (H) from the system and using an inert carrier gas such as N$_2$, He and Ar, HVPE growth of high-quality Ga$_2$O$_3$ and In$_2$O$_3$ films becomes possible at high temperatures exceeding 1000 °C using GaCl$_2$O$_2$ and InCl$_2$O$_2$ systems, respectively.

Then, based on the results of thermodynamic analyses, HVPE systems for growing Ga$_2$O$_3$ and In$_2$O$_3$ were constructed. GaCl and InCl were generated in the upstream region of the reactor maintained at 800-850 °C by introducing Cl$_2$ gas over Ga and In metal, respectively. It was clarified that homoepitaxial growth at 1000 °C on bulk $\beta$-Ga$_2$O$_3$(001) substrates is possible at a...
growth rate above 10 μm/h without deterioration of crystalline quality. The unintentionally doped layer showed a low effective donor concentration ($N_d - N_a$) of less than $10^{15}$ cm$^{-3}$, and it was found that n-type carrier density can be controlled in the range of $10^{15}$ to $10^{19}$ cm$^{-3}$ by intentional Si-doping using SiCl$_4$. These results indicate that the HVPE method is a suitable method for producing homoepitaxial wafers for Ga$_2$O$_3$-based vertical power devices. Also in the In$_2$O$_3$ growth, heteroepitaxy at 1000 °C on (0001) sapphire substrates showed c-In$_2$O$_3$ growth at a rate of several μm/h. These results suggest that high-temperature and high-speed growth of (In$_x$Ga$_{1-x}$)$_2$O$_3$ alloy by HVPE is also possible.

Advanced Diamond FET and MEMS Devices Yasuo Koide; National Institute for Materials Science, Japan

Diamond is a candidate material for next-generation power electronics and integrated circuit (IC) and micro-electro mechanical systems (MEMS) devices which operate under extreme environment. In order to use an advantage of high-density hole channel of hydrogenated diamond (H-diamond) surface, we have developed the high-k stack gate dielectrics and AlN heterojunction gate for H-diamond MOSFETs, such as HfO$_2$/HfO$_2$, LaAlO$_3$/Al$_2$O$_3$, Ta$_2$O$_5$/Al$_2$O$_3$, and ZrO$_2$/Al$_2$O$_3$, AlN/Al$_2$O$_3$ prepared by a combination of sputter-deposition (SD) and atomic layer deposition (ALD) techniques. In addition, we developed the routine ion-implantation process for preparing the diamond cantilever with a resonant frequency quality factor as high as one-million. Recently, we demonstrated the artificial diamond Fin-FETs with high-current level and the nanolaminate insulator gate MOSFET with $k$ value as high as 100, and the new transistor concept named by metal-insulator-metal-semiconductor field-effect transistor (MIMS-FET) to achieve normally-off operation by combining the advantages of MOSFET and metal-semiconductor FET. In this presentation, we will show the comprehensive work on the diamond FET and MEMS devices.

Toward Fundamental Limits of Ga2O3 Power Devices Huili G. Xing, Wenshen Li and Debdeep Jena; Cornell University, United States

Ga2O3, as a very wide bandgap semiconductor, promises a very high critical breakdown field. The theoretically estimated breakdown field is about 8 MV/cm, and the experimentally observed values are as high as 5.4 to 5.9 MV/cm to date. To take full advantage of the bandgap of Ga2O3, it is necessary to manage the electric field distribution in a Ga2O3 device to be as slow-changing as possible. In this talk, I will review various strategies and their underlying physical principles to manage the field distribution. With these strategies, record high figure-of-merits BV^2/Ron have been demonstrated in Ga2O3 Schottky barrier diodes and fin-transistors [1,2].

Gallium oxide has many compelling material properties that have generated a large and growing interest for applications in opto-electronics, power devices, and RF devices. The wide bandgap of ~4.6-4.8 eV leads to a large breakdown field, which increases the Baliga and Johnson figures of merit, indicating potentially superior performance in high-power and high-frequency devices. Additionally, wide bandgap materials have a propensity for better radiation hardness due to higher required displacement energies. As such, there are many applications for β-Ga2O3 based devices within space technology, where harsh radiation environments may be present. There has been significant work to understand the impact of radiation on the GaN based devices, which degrades device performance due to the introduction of crystal defects. Ga2O3 has been shown to have higher displacement energies compared to GaN, so it may have improved radiation tolerance. The device studied here is a Si δ-doped β-Ga2O3 MESFET, which has already been demonstrated in separate work to be highly scalable and has the potential for RF performance with an experimentally measured cutoff frequency of 27 GHz [1]. The impact of neutron radiation on this device design is explored and monitored by changes in the device characteristics, such as maximum drain current (IMAX), on-resistance (RON), threshold voltage (VT), transconductance (g_m), and effective mobility (μ_eff). The devices are simulated using Silvaco Atlas, informed through bulk radiation studies on Ga2O3, to model how the radiation damage is influencing the device performance.

The MESFETs were grown by plasma-assisted molecular beam epitaxy (PAMBE) on an (010) EFG Fe-doped substrate. The growth was done at a substrate temperature of 630°C (pyrometer calibrated to Si emissivity), with Si being used as the channel dopant. The device has a 550 nm thick buffer to reduce any trapping effects due to the Fe doped substrate, with a 30 nm top layer above the channel. This led to a charge density of 1.19×10¹³ cm⁻² with a μ_eff of 73 cm²/V-s. The process was dropped from 1.19×10¹³ cm⁻² to 7.78×10¹² cm⁻². The effective mobility vs. n_s curve is measured through a gated transfer length method structure, which shows a reduction in mobility over the range of n_s. The zero bias condition n_s showed a 24% drop in μ_eff from 74 cm²/V-s to 56 cm²/V-s. The mobility is currently being modeled to understand the driving scattering mechanism that caused the reduction. The charge is expected to be compensated through the introduction of new defect states in Ga2O3, which trap the free electrons in the channel. These defects cause dispersion in both the V_T and R_ON as shown in prior work [2-3], and the change in the defect spectrum from radiation is being investigated in these devices. Our previous investigations on the radiation-induced trap introduction in bulk Ga2O3 materials studies [4] is currently being used to inform Silvaco simulations to match the pre- and post-radiation device characteristics. The Silvaco modeling will provide an understanding of how the generated defects caused the reduction in charge, as well as how the device design can be modified to be more tolerant to such defects.

β-Ga2O3 with a bandgap of 4.8 eV is expected to be a high-power semiconductor surpassing the capabilities of SiC and GaN. Recently we demonstrated 20 ampere-class β-Ga2O3 Schottky barrier diodes (SBDs). However, the reliability of these SBDs is quite important for their commercialization in power system circuits. In this study, we used an emission microscopy to observe SBDs with various bias conditions in operation. The emission...
microscopy comprised a photon-sensitive electron-multiplying CCD camera and a probe station enabling the observation of light emission patterns of an SBD in real time. The sample was HVPE-grown ~10 μm-thick epitaxial layer grown on EFG-grown β-Ga2O3 (001) substrate. The Pt/Ti/Au Schottky electrodes with diameters of 50, 100, 200, 500, 800, and 1000 μm were formed on the surface, and Ti/Au ohmic contacts were formed on the back surface.

In the reverse bias conditions, we observed light emission patterns from SBD from the back surface. As reverse bias increased, leakage current increased, and the number of emission spots increased. We confirmed clearly a relation between the number of emission spots and the leakage current. When additional high reverse voltage was applied, new emission spots appeared, and at a certain voltage catastrophic breakdown occurred at the new emission spot. Thus, emission spots could be classified into leakage-current related emission spots and catastrophic-breakdown related emission spots. Finally, we studied the crystal structure of the observed emission spots using the etch pit, AFM, and cross-sectional TEM methods.

Ultrafast Thermal Imaging for Analysis of Transport Characteristics of Ga2O3 Based Field Effect Transistors Nitish Kumar1, Diego Vacca1, Amitav Tikadar1, Chandan Joishi2, Zhanbo Xia3, Siddharth Rajan1 and Satish Kumar1; 1Georgia Institute of Technology, United States; 2Indian Institute of Technology Bombay, India; 3The Ohio State University, United States

β-Ga2O3 has an ultrawide bandgap (~ 4.8 eV), high critical electric field strength (~8 MV/cm), and significantly higher Baliga’s and Johnson’s figure of merit compared to GaN and SiC, which makes it promising for deep UV solar blind detectors, radio frequency applications, power rectifiers. β-Ga2O3 power MOSFETs emerged as promising candidates for the future high power/high voltage market. However, Ga2O3 has a much lower thermal conductivity (~10 - 30 W/mK) than GaN or Si. The heat dissipation at high voltages can significantly affect the performance and reliability of these devices. It is necessary to understand the thermal characteristics of β-Ga2O3 based electronics for design of packaging and thermal solutions. In this work, we are using Transient Thermoreflectance Imaging (TTI) to perform ultrafast thermal measurements of β-Ga2O3 FETs. TTI is a promising technique to do temporal and spatial measurements with submicron-scale resolution. A thermoreflectance coefficient was first calculated at the top surface of electrode pads of FETs. The selection of LED of appropriate wavelength is important for high signal-to-noise ratio and accurate measurements. Then, this coefficient is used to calculate the temperature over the electrode pads with a spatial and temporal resolutions of nanoscales (approximately up to 50 nm/pixel and 400 ns). We have calculated the Joule heat generation profiles and temperature distribution at different gate voltages using TCAD Sentaurus. The simulations are compared against the experiments and highlighted that peak temperatures are different at different gate voltages even though the power dissipation is same. We have performed thermal measurements at different gate voltages and calculated thermal time constants of a device to better understand the device’s thermal dynamics.

MacEtch of β-Ga2O3, SiC and GaN—Plasma-Damage-Free and High-Aspect-Ratio Hsein-Chih Huang1, Julian Arthur Michaels1, Charence Yat-Yin Chan1, A F M Anhar Uddin Bhuiyan2, Zixuan Feng2, Hongping Zhao2 and Xiuling Li1; 1University of Illinois at Urbana-Champaign, United States; 2The Ohio State University, United States

Metal-assisted Chemical Etching (MacEtch), discovered in 2000 for porous Si generation originally, is a local (open-circuit) electrochemical etching method capable of producing anisotropic high aspect ratio semiconductor structures with a simple wet etching process catalyzed by a patterned metal film. MacEtch eliminates plasma and high-energy ion induced damage typically occur in conventional reactive ion etching. Nanowires, vias, trenches, and numerous other patterns have been demonstrated using MacEtch for silicon (Si), germanium (Ge), and compound semiconductors (including GaAs, InGaAs, InP, GaP, SiC, GaN, β-Ga2O3), with unprecedented aspect ratio and sidewall quality. In this talk, we present the MacEtch process and characterization of wide bandgap semiconductors including β-Ga2O3, GaN, and SiC.

MOCVD Epitaxy of β-Ga2O3 Thin Films with Record Mobilities Zixuan Feng, A F M Anhar Uddin Bhuiyan, Md Rezaul Karim, Yuxuan Zhang and Hongping Zhao; The Ohio State University, United States

β-Ga2O3 with an ultra-wide bandgap of 4.5-4.9 eV and capability of n-doping promises its applications for high power electronics. β-Ga2O3 is predicted to have high breakdown field (6-8 MV/cm) with room temperature mobility of ~200 cm²/Vs. The Baliga figure of merit (BFOM) of β-Ga2O3 for power electronics is predicted to be 2 to 3 times higher than that of GaN and SiC. More advantageously, the availability of high-quality native Ga2O3 substrates produced from melt growth
techniques is critical for large scale production. High voltage (>1 kV) devices, as well as RF devices with 27 GHz cut-off frequency, have been demonstrated recently [1, 2]. Nevertheless, development of high-quality β-Ga2O3 thin film growth technology is the cornerstone for high-performance device applications. Epitaxy of β-Ga2O3 has been investigated via different methods, including MBE, MOCVD, LPCVD, PLD, ALD and etc. Recently, MOCVD grown β-Ga2O3 has exhibited record high electron mobilities in both unintentionally doped (UID) [3] and Si-doped films [4].

In this work, we continue optimizing the MOCVD β-Ga2O3 homoeopitaxial process on (010) Ga2O3 crystal orientation, and expand our investigation of β-Ga2O3 MOCVD growth along different orientations including (-201), (001) and (100). Key growth parameters, including growth temperature, growth pressure, Ga/O molar ratio, and substrate preparation, were investigated. Films grown on semi-insulating Fe doped (010) Ga2O3, the epi-film exhibit low background doping. From secondary ions mass spectroscopy (SIMS) depth profile, impurities such as hydrogen (H), carbon (C), chlorine (Cl), iron (Fe) were all below the detection limit. With low intentional Si doping, we demonstrated (010) β-Ga2O3 films with controllable doping between 10^{16} to 10^{19} cm^{-3}. From temperature dependent Hall measurements and analysis taking into account various carrier scattering mechanisms, we extracted a very low compensation level of N_i < 1 \times 10^{15} cm^{-3}. Peak electron mobility reaches ~9500 cm^2/Vs at T~45 K for an unintentionally doping (010) β-Ga2O3 film. We demonstrated record high room temperature mobility of ~194 cm^2/Vs with n = 8 \times 10^{15} cm^{-3}. The superior transport properties of the MOCVD grown (010) β-Ga2O3 films demonstrated high purity MOCVD epitaxy process with low defects densities.

For films grown along different crystal orientations, we use scanning electron microscopy (SEM) and atomic force microscopy (AFM) to characterize the surface morphologies, which have shown significant dependence on substrate orientation. Film growth rate, doping incorporation and transport properties are investigated. In summary, we demonstrated superb electrical transport properties from MOCVD grown (010) β-Ga2O3 thin films with high purity and low defect densities. Growth mechanisms will be investigated for films grown along other orientations. The results from this study will provide fundamental understanding of the material properties of β-Ga2O3, which determines its potential for power device applications.

The Effect of Silicon Ion-Implant on Charge Transport Mechanisms of Ti/Au Ohmic Contacts to β-Ga2O3 Ming-Hsun Lee and Rebecca L. Peterson; University of Michigan, United States

To achieve the full potential of high-power, high-frequency Ga2O3 power devices, a low-resistance ohmic contact with good stability is needed to minimize conduction loss. The location of the β-Ga2O3 charge neutrality level within the ultra-wide bandgap (~4.8 eV) causes upward band bending and a surface depletion layer. This facilitates the formation of rectifying Schottky contacts, but the lack of Schottky-Mott metal-semiconductor band alignment makes ohmic contact formation difficult. One well-known way to improve ohmic contacts is to degenerately dope the semiconductor to enable tunneling across the junction. For the emerging β-Ga2O3 system, this often has been done by performing silicon donor ion implantation, post-implant anneal, and reactive ion etch (RIE) before Ti/Au metallization. Here, we quantitatively analyze the effect of silicon ion implantation, activation, and RIE on the charge transport mechanisms across ohmic Ti/Au - Ga2O3 junctions. Silicon-doped n-+ conduction layers (~1.8 \times 10^{18} cm\(^{-3}\)) were grown by molecular beam epitaxy on bulk semi-insulating Fe-doped (010) Ga2O3. The substrates were solvent cleaned before Ti/Au deposition followed by a 470°C 1-min N\(_2\) post metallization anneal. Temperature dependent current-voltage measurements were performed on Circular Transmission Line Model (CTLM) structures, and the results were analyzed to determine the specific contact resistivity versus temperature. We found that Ti/Au metallization on this heavily n-type doped (010) Ga2O3 epi-layer has a specific contact resistivity of 3.29 \times 10^7 \ \Omega \ cm^2 at room temperature. At an elevated temperature of 175°C, the specific contact resistivity decreases significantly to 6.35 \times 10^5 \ \Omega \ cm^2. The temperature-dependent data fit the thermionic emission (TE) model, in which the barrier height of the pseudo-ohmic junction is ~0.27 eV. Surprisingly, this value agrees with the barrier height predicted from the difference between metal work function and semiconductor electron affinity. To analyze the impact of n++ doping on contact properties, a second sample was made using the same epitaxial substrate, this time with a box-shaped n++ profile of ~3 \times
10^{19} \text{cm}^{-3}$ by Si ion implantation, a post-implant anneal to remove implant damage, and a RIE process prior to metallization. CTLM measurements show that the ion implant significantly reduces the contact resistance to $1.51 \times 10^{-4} \Omega \text{cm}^2$ at room temperature. The contact resistance of the ion-implanted structures is only slightly temperature dependent, with a contact resistance at 175°C of $6.16 \times 10^{-3} \Omega \text{cm}^2$. The thermionic-field emission (TFE) model can be used to describe this Ti/Au – implanted-Ga$_2$O$_3$ junction. We will furthermore report our latest results on optimizing the ohmic contacts to gallium oxide and assessing their microstructure and stability.

7:15 AM S.EL15.01.10
Process and Characterization of Ohmic Contacts for Beta-Phase Gallium Oxide Rebecca L. Peterson and Ming-Hsun Lee; University of Michigan, United States

Power electronic devices require ohmic contacts with low specific contact resistance to ensure low conduction loss and high-frequency operation. Gallium oxide, unlike other oxide semiconductors, has a charge neutrality level that falls within its ultra-wide bandgap of ~4.8 eV, causing upward band bending at the semiconductor surface. This upward band bending has enabled easy formation of Schottky rectifiers using a variety of metals and metal oxides. Such Schottky diodes are remarkably stable, with operation recently demonstrated at high temperatures up to 500°C. However the surface electron depletion layer of gallium oxide makes formation of ohmic contacts more challenging. Most of the existing work on ohmic contacts uses titanium as the metal layer directly in contact with gallium oxide. However our thermodynamic calculations predict that titanium will react with gallium oxide even at room temperature, causing formation of various titanium oxides. In this talk, we describe our observation of reactions at the interface between beta-phase (010) surface bulk gallium oxide and titanium/gold contact layers as a function of gallium oxide doping, metallization layer thickness, and post-metallization anneal time. Using transmission electron microscopies such as TEM, HR-TEM, and STEM with EDX and EELS, we observe the formation of a complex multi-layer interfacial structure that includes a defective gallium oxide layer, an approximately 5-nm thick Ti/TiO$_x$ interfacial layer that - under certain processing conditions - is lattice-matched to gallium oxide, and a mixed-metal Ti/Au contact layer containing titanium-rich nanocrystals. The same layers form on both unintentionally doped (UID) and heavily tin-doped gallium oxide. In addition, Sn-doping appears to play a minor role in reducing the amount of gallium out-diffusion from the gallium oxide bulk into the mixed metal layer. We will also outline some of the future challenges for ohmic contacts to gallium oxide. For the future success of gallium oxide power devices, further work is needed to understand the mechanisms of charge transport across the contact and to assess the stability of the Ti/Au ohmic contact to subsequent anneals and operation at elevated temperatures under bias or current stress. In addition, new methods may be needed to form reliable and stable ohmic contacts to lightly-doped beta-gallium oxide and gallium oxide with different orientations or crystal phases.

MOCDV Growth and Characterizations of $\beta$-(Al$_{1-x}$Ga$_x$)$_2$O$_3$ Thin Films and n-Type Doping A.F.M. Anhar Uddin Bhuiyan, Zixuan Feng, Jared Johnson, Zhaoying Chen, Hsien-Lien Huang, Jinwoo Hwang and Hongping Zhao; The Ohio State University, United States

$\beta$-Ga$_2$O$_3$ has attracted significant attention due to its promising advantages such as large energy bandgap (~4.8 eV), controllable n-type doping and high predicted breakdown field strength (6-8 MV/cm). Energy bandgap engineering by alloying Ga$_2$O$_3$ with Al$_2$O$_3$ can expand the accessible bandgap up to 8.8 eV. Lateral device structures based on AlGaO/GaO heterostructures forming two dimensional electron gas (2DEG) has been demonstrated recently [1]. In order to maximize the advantages provided by the AlGaO/GaO heterostructures, the development of high quality AlGaO with controllable Al composition and n-type doping is critical. In this work, $\beta$-(Al$_{1-x}$Ga$_x$)$_2$O$_3$ thin film growth on (010) Ga$_2$O$_3$ substrates via metalorganic chemical vapor deposition (MOCDV) were investigated [2]. Triethylgallium (TEGa), Trimethylaluminum (TMAI) and pure O$_2$ were used as Ga, Al and O precursors, respectively. Argon (Ar) was used as the carrier gas. The growth temperature was varied between 825°C and 920°C [3].

$\beta$-(Al$_{1-x}$Ga$_x$)$_2$O$_3$ thin films with Al composition x ≤ 40% were achieved by the systematical tuning of TEGa/TMAI molar flow ratio. For x<27%, high quality $\beta$-(Al$_{1-x}$Ga$_x$)$_2$O$_3$ films were achieved, while the XRD spectra showed phase segregation when Al composition x > 27%. SEM and AFM characterization show smooth and featureless surface morphology with RMS roughness of 0.51 nm for a $\beta$-(Al$_{0.1}$Ga$_{0.9}$)$_2$O$_3$ film with thickness of ~800 nm. As Al composition increases, the films show increased roughness which can be related to the phase separation observed in high-Al AlGaO films. The high resolution scanning transmission electron microscopy (STEM) imaging of $\beta$-(Al$_{0.1}$Ga$_{0.9}$)$_2$O$_3$ thin film demonstrated high crystalline quality without extended defects or dislocations. Atomic resolution STEM images showed coherent growth of 8-periods of...
Device efficiency was reported at Al content, x>0.25 [2]. It is crucial to understand the structural and chemical evolution of structural transformation of this material. Atom probe tomography (APT) is a nanoscale characterization tool capable of (AlxGa1-x)2O3 as the Al content changes from low (x=0.10) to high (x>0.25) that will provide researchers an insight about the chemistry. Here PCA was conducted on time-of-flight (TOF) of atoms collected by APT to study the structural and chemical based on principal component analysis (PCA), can decipher patterns in APT data to understand material’s structural providing atomic level information of material’s structure and chemistry in sub-nanometer resolution [3]. However, due to massive data points collected in APT, some material’s features are lost as noise along with uncertainty of data arising from multi-hit events. This hinders the exact quantification of chemical heterogeneity within the material. A data mining approach, 

(AlxGa1-x)2O3 increases monotonically with Al content that could be beneficial for device applications. Surprisingly degraded pulse energy of 30 pJ, employing CAMECA LEAP 5000X HR atom probe system. The location of each atom was traced vapor deposition (MOCVD) [4]. The controlled removal of atoms via field evaporation was achieved using a UV laser with β-(AlxGa1-x)2O3 samples with Al content of x=0.10-1.0 was grown on (010) β-Ga2O3 substrate by metal organic chemical phase lattice structure was maintained in the first few layers. The XRD spectrum also showed sharp and distinguishable high order satellite peaks along with strong 0th order peak for SL structure with 23% Al, indicating sharp interfaces and uniform alloy composition in the AlGaO layers. The decrease of the XRD satellite peak intensities and periodicities for SL structure with 40% Al content indicated inhomogeneous alloy compositions especially in the upper layers. N-type doping of β-(AlxGa1-x)2O3 from 6.3% to 33.4% of Al content was demonstrated using Si as n-type dopant. By tuning the Silane flow rate, controllable n-type doping concentrations from low-1017 cm-3 to low-1018 cm-3 were achieved at room temperature (RT). For x = 23.3%, the RT mobility of 108 cm2/V.s was measured with carrier concentration of 1.36x1017 cm-3. A low temperature peak mobility of ~575 cm2/V.s at T = 65K with carrier concentration of 1.2x1017 cm-3 were measured for x = 17%. As the Al content reaches 33.4%, the RT mobility of 82 cm2/V.s was measured with carrier concentration of 2.42x1017 cm-3, while the corresponding low temperature peak mobility of ~200 cm2/V.s was recorded at T = 90K with carrier concentration of 1.0x1017 cm-3. In summary, we focus on the MOCVD development of AlGaO with high-Al composition, and understanding the phase segregation and n-type doping in AlGaO with varied Al compositions. Comprehensive physical/structural/chemical characterization of the MOCVD grown AlGaO films will provide in-depth understanding of this emerging UWBG material.

8:00 AM S.E.L15.01.13 Data Mining for Structural and Chemical Evolution of (AlxGa1−x)2O3 Using Atom Probe Tomography Jith Sarker1, A F M Anhar Uddin Bhuiyan2, Zixuan Feng2, Hongping Zhao2,2 and Baishakhi Mazumder1; 1University at Buffalo, The State University of New York, United States; 2The Ohio State University, United States

(AlxGa1-x)2O3 is an ultra-wide bandgap semiconductor with a bandgap tunability ranging from 4.8 eV (β-Ga2O3) to 8.7 eV (α-Al2O3), highly promising for future high power transistors and deep ultraviolet (DUV) photodetectors [1]. The bandgap of (AlxGa1-x)2O3 increases monotonically with Al content that could be beneficial for device applications. Surprisingly degraded device efficiency was reported at Al content, x>0.25 [2]. It is crucial to understand the structural and chemical evolution of (AlxGa1-x)2O3 as the Al content changes from low (x=0.10) to high (x>0.25) that will provide researchers an insight about the structural transformation of this material. Atom probe tomography (APT) is a nanoscale characterization tool capable of providing atomic level information of material’s structure and chemistry in sub-nanometer resolution [3]. However, due to massive data points collected in APT, some material’s features are lost as noise along with uncertainty of data arising from multi-hit events. This hinders the exact quantification of chemical heterogeneity within the material. A data mining approach, based on principal component analysis (PCA), can decipher patterns in APT data to understand material’s structural chemistry. Here PCA was conducted on time-of-flight (TOF) of atoms collected by APT to study the structural and chemical evolution of (AlxGa1-x)2O3 with varying Al compositions.

β-(AlxGa1-x)2O3 samples with Al content of x=0.10-1.0 was grown on (010) β-Ga2O3 substrate by metal organic chemical vapor deposition (MOCVD) [4]. The controlled removal of atoms via field evaporation was achieved using a UV laser with pulse energy of 30 pJ, employing CAMECA LEAP 5000X HR atom probe system. The location of each atom was traced back using its TOF and position on the detector. PCA was performed on the TOF of ions to determine the pattern in structural chemistry of (AlxGa1-x)2O3 layers with x=0.1-1.0. Typical APT output is a single TOF spectrum. Our approach converts this spectrum into ten TOF spectra with 4 million ions in each. The count of ions vs. TOF in these spectra were used as input variables for PCA. Principal component 1 (PC1) captures the change in TOF values of the ions while principal component 2 (PC2) provides the randomness of elemental distribution in lateral planes, perpendicular to the growth direction. When PC2=0, the layer is homogeneous due to random Al distribution, while PC2>0, the (AlxGa1-x)2O3 layers are inhomogeneous. For Al composition of x=0.10-0.20, PC2<0, indicating the layers are homogeneous. As the Al content increases, the increasing trend of PC2 suggests inhomogeneity starts to appear. For x=0.30, PC2>0, elemental segregation is present in the layer resulting in degraded crystallinity. For x=0.40-0.60, PC2 remains greater than zero, implying chemically inhomogeneous layers. As the Al content continues to increase towards x=0.80, a decreasing trend of PC2 suggests a gradual reduction of chemical heterogeneity. At high Al content (x=0.80-1.0), PC2<0, an indication of (AlxGa1-x)2O3 layers regains

homogeneity.

Here we investigated the structural and chemical transformation of \((\text{Al}_{x}\text{Ga}_{1-x})_2\text{O}_3\) as the Al content varies from low (10\%) to high (100\%) by employing data mining incorporating PCA in APT data analysis. This approach provides information about structural and compositional alteration of alloy directly by quantifying the degree of layer inhomogeneity correlated to ion’s TOFs. The information thus obtained will be significant for designing of \(\beta-(\text{Al}_{x}\text{Ga}_{1-x})_2\text{O}_3\) devices.

Advanced Diamond FET and MEMS Devices Yasuo Koide; National Institute for Materials Science, Japan

Diamond is a candidate material for next-generation power electronics and integrated circuit (IC) and micro-electro mechanical systems (MEMS) devices which operate under extreme environment. In order to use an advantage of high-density hole channel of hydrogenated diamond (H-diamond) surface, we have developed the high-k stack gate dielectrics and AlN heterojunction gate for H-diamond MOSFETs, such as HfO2/HfO2, LaAlO3/Al2O3 Ta2O5/Al2O3, and ZrO2/Al2O3, AlN/Al2O3 prepared by a combination of sputter-deposition (SD) and atomic layer deposition (ALD) techniques. In addition, we developed the routine ion-implantation process for preparing the diamond cantilever with a resonant frequency quality factor as high as one-million. Recently, we demonstrated the artificial diamond Fin-FETs with high-current level and the nanolaminate insulator gate MOSFET with k value as high as 100, and the new transistor concept named by metal-insulator-metal-semiconductor field-effect transistor (MIMS-FET) to achieve normally-off operation by combining the advantages of MOSFET and metal-semiconductor FET. In this presentation, we will show the comprehensive work on the diamond FET and MEMS devices.

Toward Efficient Electron Sources Based on Diamond p-i-n Emission Diodes Franz A. Koeck1, Manpuneet Benipal2 and Robert J. Nemanich1; 1Arizona State University, United States; 2Advent Diamond Inc., United States

Electron sources are widely deployed in communications through travelling wavetubes, industrial applications through magnetrons, and analytical instruments like electron microscopes, x-rays in industrial/medical/security settings and scientific fields, foremost free electron lasers (FELs). These apparatus, in general, utilize electrons from a thermionic cathode where the emission current is determined by the operating temperature as described by the Richardson-Dushman formalism. A figure of merit can be defined by the emission current (A) in terms of the power (W) dissipated in the device, i.e. \([A/W] \). A novel approach for electron sources exploits the negative electron affinity (NEA) of a diamond p-i-n diode in a mesa etched design. Operating the device under forward bias allows a fraction of the diode current to be released from the NEA sidewall of the diode. We utilized plasma-enhanced CVD to prepare modified diamond p-i-n diodes using boron-doped (111) oriented substrates and a nitrogen-incorporated nano-structured (nanoC) contact layer. Dedicated plasma deposition systems were used for the intrinsic, phosphorus-doped n-layer, and nitrogen-doped nano-structured carbon layer. Photo-lithography was employed to etch mesa structures with varying geometries and Ti/Pt/Au contacts. We present results from diamond p-i-n-nanoC diodes with an intrinsic layer thicknesses of 10\(\mu\)m. To control ohmic losses in the device the reduced thicknesses of
the n-layer and nanoC layer, were 300nm and 150nm, respectively. At an applied bias of 2.2V a diode forward current of 1.15x10^-5A was established and an emission current of 2.14x10^-7A presented an electronic emission efficiency of 1.8% which is significant for electron emitters. With an increase in the bias to 2.7V the electronic emission efficiency was somewhat reduced to 1.5%. Operating the device at 2.7V shifted the power efficiency to 0.015 [A/W] which exceeds efficiencies for cathodes used in commercially available travelling wavetubes (TWTs) and magnetrons. We will discuss the p-i-n-nanoC diode operation and emission efficiency in terms of doping concentrations and layer structure and elaborate on the contribution of excitons to the electron emission.

Space Charge Limited Current in Diamond Diodes Harshad Surdi, Mohammad Faizan Ahmad, Franz A. Koeck, Trevor J. Thornton, Stephen M. Goodnick and Robert J. Nemanich; Arizona State University, United States

Diamond based Schottky barrier and PIN diodes are currently of great interest for high power high temperature applications. To improve performance in terms of device metrics such as the on resistance and breakdown voltage, it is critically important to understand the current conduction mechanisms in the different voltage regions of operation of such diodes. Current in diamond diodes has been shown to exhibit space charge limited Mott-Gurney behavior some research groups. However, there has never been a systematic study of the various voltage and current regimes in forward biased diamond diodes. We perform Silvaco Atlas drift-diffusion simulations of Schottky PIN (SPIN) and PIN diamond diodes in comparison to experimentally measured J-V characteristics on the same structures. Incomplete ionization of dopants and nearest-neighbor/variable range hopping mobility models are included in the Silvaco simulations. Space charge limited current (SCLC) with single carrier injection is dominant in Schottky PIN (SPIN) diamond diodes with a relatively low doped and thin n-layer whereas SCLC with double carrier high injection limits current in PIN diamond diodes with a high doped and thicker n-layers. Measurements of SPIN and PIN diamond diode with i-layer >~1.5 μm show evidence of a Mott-Gurney region where J ∝ V^2 within a wide operating voltage range. For SPIN and PIN diamond diodes with thinner i-layers (<~1 μm) the Mott-Gurney region is short lived only for a small voltage range and the current transitions back into a linear region limited by the resistivity of the quasi-neutral region. Furthermore, temperature dependent simulations and measurements were also performed to observe a “cross-over voltage” beyond which the increasing trend of diode forward current as a function of temperature is reversed, which is additional evidence of space charge limited current as corroborated by temperature dependent analytical curves of the Mott-Gurney law.

This research is supported by the NASA HOTTech program.

6:00 AM S.EL15.02.06
Low On-Resistance Diamond PIN Diodes Franz A. Koeck, Harshad Surdi and Robert J. Nemanich; Arizona State University, United States

Diamond is a wide band gap semiconductor with outstanding semiconductor properties and the highest known thermal conductivity. The high electron and hole mobilities of diamond are unusual compared to all other wide band gap semiconductors, and support both high power and high frequency applications. PIN diodes have been used for microwave switching where the high power capability of diamond diodes may have a distinct advantage over other semiconductors. In this project, PIN diamond diodes were fabricated on (111) diamond substrates. High performance diodes show light emission during forward bias operation confirming bipolar operation. These diodes show a reduction in on-resistance as the forward voltage is increased beyond 10V. The reduction of the on-resistance is achieved with a phosphorus doped n-type layer and a
nanocarbon interfacial layer between the metal contact and n-type diamond. This presentation discusses the role of the n-type contact resistance in achieving bipolar device characteristics and an exceedingly low differential on-resistance for high power microwave switching applications.

6:15 AM S.EL15.02.08
Nanostructured Boron Doped Nanocrystalline Diamond for Superconducting Devices Georgina M. Klemencic, Majdi Salman, Scott Manifold, Evan Thomas, Soumen Mandal, Sean R. Giblin and Oliver A. Williams; Cardiff University, United Kingdom

Diamond, when boron doped above the metal-insulator transition, is known to enter the superconducting state below a transition temperature of approximately 4 K for nanocrystalline films. The high normal state resistance of boron doped nanocrystalline diamond is particularly attractive for application to Josephson junction-based devices, while the high Young’s modulus is well suited to nanoelectromechanical devices. A severely limiting factor – with some similarity to many high temperature superconductors – is the short coherence length $\xi \sim 10$ nm, coupled with the naturally top-down nature of the device fabrication.

Here we describe the fabrication and measurement of nanoscale superconducting diamond devices, highlighting the technical challenges involved. We discuss the impact of the morphology on the results, and present some surprising results given the length scales involved.

6:30 AM S.EL15.02.09
High Current (0.7 A/mm) for Diamond MOSFETs with 1.4-µm Gate and NO2 P-Type Doping on High Quality Heteroepitaxial Diamond Substrates Niloy Chandra1, Toshiyuki Oishi1, SeongWoo Kim2, Yuki Kuwamata2, Koji Koyama2 and Makoto Kasu1; 1Saga University, Japan; 2Adamant Namiki Precision Jewel Co., Ltd., Japan

Diamond semiconductor with a bandgap of 5.47 eV can be used in high-power devices beyond SiC and GaN. Kubovic and Kasu [1] demonstrated that NO2 p-type doping on H-diamond produced a high hole sheet concentration of $1.4 \times 10^{14}$ cm$^{-2}$. Moreover, Hirama and Kasu et al. [2] fabricated a diamond p-type MOSFET with NO2 p-type doping and obtained a high drain current of 1.3 A/mm for a gate length of 0.4-µm length by using EB lithography. In this paper, we demonstrate a drain current of 0.7 A/mm with a gate length of 1.4-µm length using all photolithography, except EB lithography. Diamond MOSFETs were fabricated on a 1-inch heteroepitaxial diamond. In heteroepitaxy, epitaxial overgrowth (ELO) technology is used to drastically decrease the dislocation density. Furthermore, microneedle technology has been proposed and used to delaminate heteroepitaxial diamond from the substrate without cracking[Editor4] it. In the final process of heteroepitaxy, chemical mechanical planarization process is important to obtain a damage-free and smooth heteroepitaxial diamond surface. The FWHM of (004) was as low as 0.03°, indicating the world’s highest quality level of heteroepitaxial diamond. NO2 p-type doping was performed on H-diamond. Al2O3 as gate insulator and passivation layers were deposited by ALD. All pattern processes including gate formation were made by photolithography, not EB lithography. The gate electrode was deposited overhang to reduce the source resistance. In the DC drain-voltage characteristics, the drain current of 0.7 A/mm was obtained for FET with a gate length of 1.4-µm.

6:45 AM S.EL15.02.10
Machine Learning (ML) Based Study of Chemical and Electronic Properties of Doped Molybednum Trioxide (MoO3) Surface Mahesh R. Neupane1, Michael Groves2, Anthony G. Birdwell2, Dmitry Ruzmetov2, Kevin Crawford2, Pankaj Shah1, James Weil1 and Tony Ivanov1; 1U.S. Army Research Laboratory, United States; 2California State University, Fullerton, United States

Molybednum trioxide (MoO3) is a widely used transition metal oxide with high electron affinity (EA) and work function (WF) and frequently employed as electron acceptor layers in surface-doped diamond field effect transistors (SDFET). The process of electron transfer from the hydrogen-terminated diamond surface to the acceptor layer i.e. MoO3, while creating a hole channel in the surface, is a central mechanism that governs the operating principle of these devices. In addition, the electron extraction strength of the MoO3 layer is defined by its molecular chemical properties such as acidic strength and band gap. In order to understand the role of chemical composition and local structural configuration in modulating the acidic properties of the MoO3 layer, we have performed a density functional theory study and probed the acidic properties of the MoO3 (010) surface doped with other transition metals (Zr, Nb, V, Re, and W). A suitable doping site for each of the dopant
is accelerated using a machine learning (ML) approach. Most of the dopants tend to prefer the first few layers of the surface as their preferred sites. Using the optimized doped configuration, the acidic properties of the surface was evaluated by calculating the adsorption potential energy (APE) of ammonia on the surface because the Lewis acidity of a surface is related to its ability to act as an electron acceptor. A correlation between the electronegativity of the dopant and the Lewis acidity of the surface was observed. Specifically, metals with an electronegativity lower than Mo increased the acidity of the surface while metal dopants with an electronegativity higher than Mo tended to decrease the acidity of the surface. In addition, the size and the electronegativity of the dopants significantly influences the overall electronic properties of the host oxide. This result will help guide the development of SDFETs with properties tuned to desired specifications for high-power RF applications.

Development of High-Voltage Vertical GaN PiN Diodes Robert J. Kaplan1, Andrew A. Allerman1, Brendan P. Gunning1, Mary H. Crawford1, Gregory Pickrell1, Andrew Armstrong1, Jeramy Dickerson1, Andrew Binder1, Jack Flicker1, Jason Neely1, Ozgur Aktas2, James Cooper1, Karl Hobart1, Travis Anderson1, Andrew Koehler4, Marko Tadjer4, James Gallagher4, Mona Ebrish4, Matthew Porter6, Srabanti Chowdhury6, Ke Zeng6 and Rafael Martinez6; 1Sandia National Laboratories, United States; 2EDYNX, United States; 3Sonrisa Research, United States; 4U.S. Naval Research Laboratory, United States; 5U.S. Naval Postgraduate School, United States; 6Stanford University, United States

With its high avalanche breakdown electric field and resulting high figure-of-merit, Gallium Nitride (GaN) represents today’s state-of-the-art semiconductor for high-performance power electronics. However, the most prevalent GaN-based power device, the High Electron Mobility Transistor (HEMT), has not realized the full potential of GaN. This is partly due to the epitaxial growth of GaN on Silicon substrates for such devices, which results in a high density of defects in the material. Further, the HEMT typically shows breakdown at a voltage lower than ideal, due to a complex electric field distribution resulting from its lateral structure, as well as the related problem of the proximity of the high electric field to the surface of the device. Thus, HEMTs not only need to be over-designed for their rated voltage, but typically show catastrophic destructive breakdown (often dominated by surface effects) and do not have avalanche ruggedness. While this is acceptable for many lower-voltage applications (typically 650 V or less), it is not suitable for higher-voltage applications. In contrast, vertical GaN power devices grown on native GaN substrates do not possess these limitations. Breakdown voltages of nearly 5 kV have been reported, and several groups have shown evidence for avalanche breakdown in such structures. However, vertical GaN power devices are immature relative to GaN HEMTs as well as other wide-bandgap power semiconductor devices such as those based on Silicon Carbide. Fundamental materials challenges for vertical GaN in areas such as substrate quality and the epitaxial growth of thick (of order 100 um), low-doped (less than 10^{16} cm^{-3} n-type) drift layers are topics of current research. Additionally, challenges exist in the processing of epitaxial layers into vertical device structures. One notable challenge is the realization of selective-area doping, which is needed not only for the functionality of many devices, but also for the edge-termination structures needed to prevent premature breakdown. Finally, minimal manufacturing infrastructure currently exists that can produce devices in quantity with good yield and good long-term reliability. In this talk, we will describe our team’s progress on the design, fabrication, and characterization of vertical GaN PiN diodes ultimately targeted at voltage ratings as high as 20 kV. We will discuss the growth of thick, low-doped drift layers by Metal-Organic Chemical Vapor Deposition as well as the design and processing of these layers into high-voltage devices. The processing effort includes the establishment of a foundry capability to demonstrate pilot production of these vertical GaN diodes, which encompasses evaluation of yield as well as extensive reliability testing and failure analysis. We will also describe methods to test the avalanche ruggedness of the devices, including the time response of the avalanche breakdown process. Finally, we will discuss some potential applications of the devices, including protection of the electric grid. This work was supported by the ARPA-E OPEN+ kilovolt devices cohort managed by Dr. Isik Kizilyalli. Sandia National Laboratories is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

5:30 AM *S.EL15.03.04
GaN-on-Si Power Devices Takeya Okuno, Kenichiro Tanaka, Yasuhiro Uemoto, Tsuguyasu Hatsuva and Tetsuzo Ueda; Panasonic Corporation, Japan
GaN transistors are very promising for power switching applications taking advantages of the material’s superior properties. Successful demonstration of the epitaxial growth of GaN on large diameter Si substrates has made the GaN devices emerged as a viable alternative with expectation of the low cost fabrication. Use of AlGaN/GaN hetero-junction as the current channel is one of the most notable features of the GaN transistor. Two dimensional electron gas (2DEG) with extremely high carrier concentration originated from the polarization-induced electric fields and the high electron mobility greatly help to reduce the on-state resistances. Lateral GaN transistors with the hetero-junction formed on the insulating buffer layers exhibit extremely low parasitic capacitances as well. These features of the GaN transistor enable high frequency switching with low operating losses. Thus, the GaN transistors can make power switching systems highly efficient and very compact by increasing the switching frequencies. Although achieving normally-off operation overcoming the high carrier concentration of the 2DEG had been the most critical issue for the practical use of GaN transistors, a newly proposed Gate Injection Transistor (GIT) with p-type gate has successfully demonstrated the normally-off operation with low on-state resistance.

In this presentation, current status of the GaN power devices on Si is reviewed. Here, the updated structure of the GIT called as Hybrid Drain-embedded GIT (HD-GIT) is described. Holes are injected from the p-type region formed as a part of the drain. The holes fill the trapping states in the GaN, which suppresses the current collapse even at higher drain voltages. Switching lifetime tests using an inductive load that can be called as dynamic high-temperature operating life (D-HTOL) test are proposed as the severe reliability test considering the practical application of GaN transistors. The HD-GITs ensure sufficient long lifetime under the D-HTOL test. Based on acceleration factors extracted from the Weibull plots of the D-HTOL test results, the D-HTOL lifetime of the 3kW totem-pole PFC (Power Factor Correction) is estimated to be 23.8 years. At present, the above-mentioned GITs are commercially available and the wide-spread use is expected as a game-changing power device enabling compact and energy-saving switching systems.

6:00 AM S.E.L.15.03.05
BaTiO3/AlGaN Heterojunction Diodes with Breakdown Fields >8 MV/cm Towhidur Razzak1, Hareesh Chandrasekar1, Kamal Hussain2, Choong Hee Lee1, Abdullah Mamun2, Hao Xue1, Zhanbo Xia1, Shahadat H. Sohel1, Mohammad Wahidur Rahman1, Sanyam Bajaj1, Caiyu Wang1, Wu Lu1, Asif Khan1 and Siddharth Rajan1; 1The Ohio State University, United States; 2University of South Carolina, United States

High Al-composition AlxGa1-xN are estimated to have high critical breakdown field, F_BB, (~9 MV/cm for x=0.5) and high electron saturated velocity, v_sat, which are attractive material properties for high voltage and high frequency power applications. [1] The extremely high F_BB is especially attractive, since this can potentially enable ultra-scaled devices with power density scaling which incumbent technologies cannot match. However, demonstration of electric fields approaching the material breakdown limit in an actual device remains a standing challenge. While PN junctions have achieved material breakdown limits for wide-band gap semiconductors, such demonstration for lateral diodes and FETs is challenging due to non-uniform electric field distribution in the depletion region (which causes electric field peaking), and is further limited by tunneling breakdown at the Schottky gate/anode electrode. A potential solution to this problem can be achieved by using extreme permittivity oxides inserted between the gate/anode metal and semiconductor and in the gate-drain region. [2, 3] Such extreme permittivity dielectrics enable improved breakdown by: a) reducing the electric field peaking in lateral electric field and b) reducing gate/anode leakage currents which suppresses gate/anode leakage related breakdowns. In this work, we demonstrate a BaTiO3/Al0.58Ga0.42N lateral heterojunction diodes (HJDs) with significantly enhanced breakdown characteristics.

The epilayers were grown by LP-MOCVD and consisted of a 500 nm thick undoped i-Al0.58Ga0.42N buffer layer followed by 60 nm thick [Si+] doped n-type Al0.58Ga0.42N layer ([Si+] =4×10^{18} cm^{-3}). Ohmic contact was achieved by employing selective area regrowth by MBE of reverse Al-composition graded contact layers on these MOCVD grown epilayers. A Ti-based metal stack was then deposited on the MBE-regrown contact regions via an e-beam evaporator followed by device isolation by ICP-RIE plasma etching. BaTiO3 was then deposited via RF sputtering in an oxygen ambient. BaTiO3 was then etched away using SF6 plasma ICP-RIE etching under the anode regions, access regions and the region between the anode and access regions for control Schottky barrier diodes (SBDs) while BaTiO3 was etched away only from the access regions for the HJDs. Finally, a Pt-based metal stack was used as anodes.

Breakdown characteristics measured with an Agilent B1500 parameter analyzer on randomly selected devices showed significant average breakdown fields improvement for BaTiO3/AlGaN HJDs. In general, for the HJDs, for an anode to cathode spacing in the range of 0.2-0.3 μm, the minimum breakdown fields observed were in the range of 6-8 MV/cm. In contrast, the control SBDs displayed an average breakdown field ~4 MV/cm for devices with similar dimensions. The highest average breakdown field observed in this study, 8.5 MV/cm, is the highest observed experimental breakdown field for any semiconductor material to date. This demonstration provides a framework to realize ultra-scaled lateral devices with improved breakdown characteristics.
High crystal quality AlGaN epitaxial films are highly desirable for near to deep UV optoelectronics applications due to a tunable wide bandgap ranging from 3.4 to 6.0 eV. For many years, the use of foreign substrates for AlGaN epitaxy resulted in highly-mismatched heterostructures with high dislocation densities. The use of recently available AlN single crystals allowed for close matching to AlGaN lattice parameters and thermal expansion coefficients. This lead to high crystalline quality AlGaN epitaxial films exhibiting a significantly reduced dislocation density resultant in improved device performance. However, the lattice mismatch between AlGaN and AlN results in compressively strained alloy films, varying in strain magnitude with composition. This compressive misfit strain can consequentially affect the properties of AlGaN-based devices leading to undesirable compositional non-uniformities to wavelength shifts or unreliable performance. This would require novel strain management schemes to minimize the influence of this strain. Nevertheless, there are no current models to describe AlGaN relaxation mechanisms on c-plane AlN as it is expected that these films are pseudomorphic on these substrates. This is expected as there is no resolved shear stress to activate the primary slip systems in hexagonal wurtzite structure under biaxial strain. As such, in this work, the strain relaxation of AlGaN on AlN single crystal substrate with relatively large lattice misfit is investigated. Mismatch strain relaxation could happened by dislocation nucleation, dislocation bending, crystallographic tilting or surface roughening. In the case of preexisting dislocations in the substrate, their propagation through the film would play an important role in strain relaxation through dislocation bending. Al,Ga,N layers were grown by MOCVD either on a c-plane AlN single crystal substrate or an AlN template on sapphire substrate to elucidate the role of these preexisting dislocations. The dislocation density in an AlN substrate is below 10³ cm⁻², whereas it’s around 2×10¹⁰ cm⁻² in an AlN layer grown on sapphire. Al mole fraction was varied from 30% to 90% by varying metalorganic precursor flow rates. High resolution X-ray diffraction (HRXRD) was employed to determine the composition and strain relaxation. Atomic force microscopy (AFM) and transmission electron microscopy (TEM) were carried out to characterize the surface morphology and defect structures. HRXRD symmetric (002) and asymmetric (105) reciprocal space mappings (RSMs) revealed that Al,Ga,N layers grown on AlN substrate were pseudomorphic, regardless of alloy composition (0.5<x<0.9). Instead of plastic relaxation, the AlGaN films exhibited so-called “epilayer tilt”. The crystallographic tilt increased linearly with substrate miscut, as expected from the Nagai tilt model. In contrast, full relaxation of the in-plane lattice parameter was observed in Ga-rich 1 μm thick Al,Ga,N epilayers grown on AlN substrates. The relaxed Al,Ga,N epilayer did not show a strain gradient. This is in contrast to the strain gradient that was observed in AlGaN on AlN/sapphire, which is believed to result from dislocation inclination. The comparison between Al,Ga,N/AlN and Al,Ga,N/AlN/sapphire indicates that Al,Ga,N layer was abruptly relaxed due to a lack of the preexisting dislocations in AlN substrate. In addition, AFM revealed high density of growth spirals on the relaxed Al,Ga,N epilayer. X-ray rocking curve measurement also showed much broader AlGaN peaks compared the AlN bulk crystal. Therefore, Ga-rich AlGaN is plastically relaxed on AlN by generating dislocations seemingly contradicting the hypothesis that there is no resolved shear stress activating the primary slip system due to the expected biaxial strain. The dislocation structure in the relaxed AlGaN layer will be presented as well as possible relaxation mechanism including the resulting critical layer thickness.

Point Defect Management in Ultra-Wide Bandgap AlGaN by Chemical Potential Control Pegah Bagheri, Shun Washiyama, Ji Hyun Kim, Ronny Kirste, Pramod Reddy, Yan Guan, Andrew Klump, Seiji Mita, Ramón Collazo and Zlatko Sitar; North Carolina State University, United States

Significant challenges in point defect control in AlGaN epitaxy has precluded commercialization of AlGaN based devices. Si and recently Ge are typically employed as n-type dopant in AlGaN and exhibit a low activation energy (<50 meV) in Al,GaN with x<0.8 and x<0.5 respectively. However, Si doped AlGaN exhibits a “knee behavior” resulting in a conductivity and carrier concentration maxima at a specific Si concentration. Hence a high doping limit exists for Si in AlGaN that lowers the maximum achievable carrier concentrations that are necessary for AlGaN based optoelectronics. Similarly, a low doping limit (a minimum achievable carrier concentration with a corresponding maximum mobility) exists in AlGaN similar to that in

This work is sponsored by AFOSR (Kenneth Goretta)

GaN which precludes implementation of AlGaN power electronics that require low doped drift regions. Hence a major “point defect problem” exists in AlGaN that needs to be solved for implementation of AlGaN technology.

In this work, we demonstrate a systematic chemical potential control (CPC) based point defect control (PDC) where we relate the growth environment variables to the defect formation energy by determining and controlling the impurity chemical potentials and optimize the growth environment accordingly for minimal point defect incorporation or generation. Here, we employed this framework to provides a quantitative relationship between point defect formation energies and growth process parameters for the case of Si and Ge doping over the whole Al composition range of AlGaN. This allowed for classifying the difference between these two dopants in terms of incorporation and major compensating defect formation.

Accordingly, the V_{III}nSi_{III} and V_{III}nGe_{III} complexes and C_{V} were identified as the primary defects responsible for the doping limits in AlGaN with different compositions grown by metalorganic chemical vapor deposition (MOCVD) on c-plane sapphire substrate and AlN single crystal substrates. We demonstrate control over the knee behavior (improving the peak carrier concentration by impeding the formation of complexes) and low doping limit (achieving lower carrier concentrations by reducing the compensating impurity (C_{V}) density) by controlling the chemical potentials of III/N and growth temperature for both types of dopants. Si was more effective for doping Al-rich (>40%) AlGaN while Ge was more effective for Al-poor (<40%) AlGaN. For the case of Ge doped AlGaN with Al composition of 40%, a plateau with constant carrier concentration (1.2×10^{19} \text{ cm}^{-3}) followed by a sharp drop (one order of magnitude to 10^{18} \text{ cm}^{-3}) in carrier concentration is observed which differs from the Si “sharp knee” doping behavior. This behavior is explained by formation of different types of complexes in Ge doping than Si. Moreover, two orders of magnitude increase in conductivity is observed by decreasing NH_{3} flow rate from 3 slm to 0.3 slm, which results in III-richer growth environment and the resulting high formation energy of cation vacancy-related point defects. We also demonstrate the strong increase in vacancy formation with increase in growth temperature and consequently higher peak conductivity at lower growth temperatures.

Identification of Point Defects for the Full Compositional Range of Al_{x}Ga_{1-x}N (0\leq x \leq 1) via Photoluminescence Ji Hyun Kim1, Isaac Bryan1, Ronny Kirste2, Zach Bryan1, Pramod Reddy2, Doug Irving1, Ramón Collazo1 and Zlatko Sitar1; 1North Carolina State University, United States; 2Adroit Materials Inc, United States

GaN, AlN, and its ternary alloy have had significant development and implementation in commercial devices due to its wide range of applications in UV optoelectronics and power devices. However, it is subject to various point defects that limit their electrical and optical properties. Correct identification of point defects can aid in developing methods to reduce or eliminate undesirable defects that will lead to the properties needed for the devices exploiting the intrinsic material properties. The defects discussed here include self-compensating native defects, unintentional impurities, and various defect complexes. These are mainly point defects that are commonly present in undoped and doped Al_{x}Ga_{1-x}N of different compositions with various doping levels of n and p-type dopants such as Si, Ge, and Mg.

Photoluminescence (PL) is a widely used characterization technique for the identification of point defects in GaN, AlN, and its ternary alloy. While PL is a commonly used technique that provides significant insight into various materials, analyses of the spectra are a major topic of debate in the community. Point defect identification has been a contentious issue especially due to previous DFT analyses underestimating the bandgap. Therefore, with the development of photoluminescence techniques along with updated hybrid functional studies, there have been many corrections and updates to previous statements regarding identification of point defects. However, hybrid functional studies still have a limitation when it comes to ternary alloys. This study utilizes defect energy values of GaN and AlN identified via hybrid functional studies and confirmed with PL as end points to identify the energy values of the defects in AlGaN experimentally via PL. The samples were grown via metal organic chemical vapor deposition at distinct growth conditions to ensure the presence of the point defect of interest. The measured PL spectra of the samples grown with precise growth parameters elucidate the energy of the defect over the entire Al composition of AlGaN. As expected, the defect energies increase with the increase of Al content. The energy values of the point defects follow a similar trend seen by the bandgap of AlGaN as a function of Al content as described by Vegard’s law with a bowing parameter. With this defined relationship, this work aims to provide up-to-date identifications of common point defects and their energies for the entire Al composition range of Al_{x}Ga_{1-x}N for future development of AlGaN based technologies.
Ultra-Wide Bandgap 2D Materials—Challenges and New Approaches Joan M. Redwing¹, Anushka Bansal¹ and Zakaria Al Balushi²; ¹The Pennsylvania State University, United States; ²University of California, Berkeley, United States

There is growing interest in wide and ultra-wide bandgap 2D materials such as hexagonal boron nitride (hBN) to serve as dielectric encapsulation layers for 2D heterostructures, as a host matrix for single photon emitters and as an integral part of III-nitride heterostructure devices. In the case of hBN, flakes and films have been formed by exfoliation of bulk crystals and CVD growth on metal substrates, respectively, but further advances are needed to realize wafer-scale single crystal films and expand the available range of wide bandgap 2D materials.

Our studies have focused on epitaxial growth of hBN and other 2D nitride layers by metalorganic chemical vapor deposition (MOCVD). High temperature epitaxial growth of hBN on c-plane sapphire was investigated using B₂H₆ and NH₃ precursors to achieve high purity films. Gas phase pre-reactions between B₂H₆ and NH₃ result in a significantly reduced growth rate for hBN at 1350°C and 50 Torr in a H₂ carrier gas. Sequential precursor pulsing was used to minimize gas phase mixing and enable the growth of films with controlled thicknesses ranging from 5-100 nm. The hBN films on sapphire were subsequently used as templates for epitaxial growth of 2D transitional metal dichalcogenides such as MoS₂ and WSe₂. We have also investigated novel methods to stabilize 2D forms of conventional III-nitride materials such as GaN. This process uses controlled intercalation and reaction of group III and V precursors within the interfacial region of quasi-free standing epitaxial graphene formed on SiC to form stable ultrathin GaNx films. The graphene capping layer provides thermodynamic stabilization of a unique R3m structure as identified by aberration-corrected scanning transmission electron microscopy.

Density functional theory predicts a bandgap energy in the range of 4.79-4.89 eV for this structure which correlates well with experimental results from UV-visible reflectance and absorption measurements. The realization of few layer films of group III-nitrides would broaden the range of accessible bandgap energies of 2D materials providing new avenues for scientific exploration and electronic/optoelectronic device development.

Defects and Band Positions in the P-Type Transparent Conductor CuI Andrea Crovetto, Sergiu Levcenko, Hannes Hempel, Marin Rusu and Thomas Unold; Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

While high-performance n-type transparent conductive materials (TCMs) have existed for decades, heavy p-type doping of wide band-gap materials has proven much more challenging. The simple cubic compound CuI (band gap 3.1 eV) was recently rediscovered for this application and is currently the p-type TCM with the highest figure of merit. However, the native defects responsible for p-type conductivity in CuI, as well as compensating defects limiting the maximum achievable doping levels, have not yet been identified experimentally. Furthermore, there is disagreement in the literature on the work function and absolute band positions of CuI relative to vacuum. In this experimental study, we employ temperature- and intensity-dependent photoluminescence to draw new conclusions on the defect landscape of CuI. We then employ a combined photoemission spectroscopy-Kelvin probe system to show that the measured band positions depend critically on surface phenomena related to air exposure, with variations in work function up to 900 meV. Finally, we demonstrate that terahertz spectroscopy is an ideal tool for characterizing the electrical properties of CuI reliably and non-destructively.

Ohmic Contacts to MBE-Grown n-Type SrSnO₃ Thin Films V.R. Saran Kumar Chaganti, Tristan Truttmann, Bharat Jalan and Steven Koester; University of Minnesota Twin Cities, United States

Ultra-wide gap (UWG) semiconductors with band gap, E_g, in the range of 4-6 eV can offer significant device performance improvements over their narrow-gap counterparts in high-power RF electronics, and provide unique research opportunities including deep-UV optoelectronics, extreme-environment electronics, and exploration of ultra-high-field transport [1]. SrSnO₃ (SSO), a perovskite oxide, is an emerging UWG semiconductor with E_g in the range of 4-5 eV [2] that offers particular advantages over other UWG materials including potential p-type doping, and a greater range of device engineering achievable via integration with other functional perovskites including ferroelectrics. High-quality epitaxial SSO films have been grown using hybrid molecular beam epitaxy (MBE) [2], and long-channel field effect transistors (FETs) with promising performance have recently been demonstrated [3]. However, RF-compatible FETs that validate the potential of this material system have not yet been reported. This is due in part to the high contact resistance, R_c, of ~38 Ω-mm for Sc contacts used in previous studies [3]. Therefore, identifying Ohmic contacts with low R_c to doped SSO is essential before high-performance SSO FETs can be realized. In this study, we report the results of contact work-function engineering on Nd-doped n-type SSO thin films. Specific contact resistance, R_c, of the range of 0.1-0.5 mΩ·cm² were achieved.
A controlled experiment was performed on heavily Nd-doped n-type SSO thin films and contact passivation was explored. The details of the MBE growth technique can be found elsewhere [4]. A 10-nm-thick unintentionally-doped SSO buffer layer was first grown on a 5 mm × 5 mm GdScO3 insulating substrate followed by a 25-nm-thick n-SSO active layer. The concentration of Nd was controlled in the active layer by setting the Nd effusion cell temperature to 940 °C during growth. A sheet resistance, \(R_s\) of 1874 Ω/■, carrier concentration of \(3.5 \times 10^{19} \text{ cm}^{-3}\), and a mobility of 37 cm²/Vs was obtained using Van der Pauw Hall measurements. A combination of electron-beam lithography, Ar plasma etch, evaporation and lift-off were used to pattern transfer length measurement (TLM) structures. A pre-treatment using O₂ plasma clean and a 45 s Ar plasma etch was performed prior to the contact formation. Sc, Mn, Ti, Al, and Cr metals whose work functions are in the range of 3.5 to 4.6 eV were explored, and all contact metals were capped with additional Ti/Au to form the metal lines in the TLM structures. Al and Cr contacts were found to be highly resistive when measured immediately after lift-off and were not considered for further studies. Sc, Mn, and Ti were less resistive, with Mn having the lowest \(R_c\) of 11 ± 3 Ω-mm, immediately after lift-off. To test the effect of annealing, contact passivation was performed by depositing 55 nm of Al₂O₃ via atomic layer deposition at 200 °C. After this process, all three metals showed strong Ohmic behavior. The Ti contacts had the lowest \(R_c\) of 2.3 ± 0.3 Ω-mm after passivation, with a resultant \(R_s\) of 1687 ± 71 Ω/■ obtained from the TLM measurements. Annealing at 300 °C did not result in any significant change in the \(R_c\). \(R_{c-sp}\) values of 0.1, 0.26 and 0.5 mΩ-cm² were determined for Ti, Sc, and Mn respectively. In conclusion, we have performed a thorough study of metal contacts to n-doped SSO and the results show that Ti provides the lowest \(R_c\) among the metals analyzed. This work is an important step for evaluating SSO in electronic applications and can pave the way for demonstration of high-performance RF FETs using this emerging high-mobility UWG perovskite oxide.

The work was supported by the AFOSR through award number FA9550-19-1-0245.

Metallic Line Defect in Perovskite BaSnO₃ Thin Films Hwanhui Yun and K. Andre Mkhoyan; University of Minnesota, United States

In perovskite oxides, defects are present in various dimensions and structures, where each defect forms unique and localized atomic bondings different from the host material. Crystalline defects not only modify physical and chemical properties of the host materials locally, but also create specific local electronic and magnetic structures. Defects often exhibit distinct properties such as enhanced chemical activity [1], different bandgaps [2], etc, which provides an opportunity to exploit defects as functional nanostructures. In recent years, new types of line defects have been discovered in oxides thanks to atomic-resolution imaging with scanning transmission electron microscopy (STEM) [2,3]. These defects are reported to alter the local electronic structures showing potential for defect-based nano-devices. Here, we present a new metallic-like line defect in La-doped BaSnO₃ thin films. The line defect is aligned along the film growth direction and exhibits a unique atomic arrangement. Structural and compositional analyses are performed using STEM-energy dispersive X-ray (EDX) spectroscopy. \textit{Ab-initio} calculations including structure optimization and ground-state electronic structure calculations are also carried out. STEM-electron energy-loss spectroscopy (EELS) is employed to test the calculated electronic structures of the line defect.

La-doped BaSnO₃ films studied here were grown on various substrates by DC sputter deposition [4] and hybrid molecular beam epitaxy [5]. Plan-view STEM samples were prepared by mechanical polishing. STEM experiments were carried out using an FEI Titan G2 60-300 (S)TEM equipped with EDX and EELS. \textit{Ab-initio} calculations were performed using the \textit{Quantum Espresso} package [6] for structural relaxation and \textit{WIEN2K} code [7] for ground-state calculations and EELS cord-edge simulations.

Halide Vapor Phase Epitaxy of Group-III Sesquioxides Yoshinao Kumagai¹, Ken Goto¹, Rie Togashi², Hisashi Murakami¹, Akiro Kuramata³, Shigenobu Yamakoshi⁴ and Masataka Higashiwaki⁵; ¹Tokyo University of Agriculture and
Group-III sesquioxides such as Ga$_2$O$_3$ and In$_2$O$_3$ are ultra-wide bandgap semiconductor materials. It is well known that bulk single crystals of thermally stable phases β-Ga$_2$O$_3$ ($E_g = 4.5$ eV) and c-In$_2$O$_3$ ($E_g = 3.7$ eV) can be grown by melt growth methods [1,2]. At present, high-speed growth of conductivity controlled homoepitaxial layers of β-Ga$_2$O$_3$ and c-In$_2$O$_3$ has attracted much attention to apply both materials for fabrication of vertical high-power electronic devices. In this presentation, the authors introduce high-temperature and high-speed growth of β-Ga$_2$O$_3$ and c-In$_2$O$_3$ by halide vapor phase epitaxy (HVPE) [3-7].

First, source gases and their carrier gases for HVPE growth of Ga$_2$O$_3$ and In$_2$O$_3$ were examined by thermodynamic analyses. The results clarified that by removing hydrogen atoms (H) from the system and using an inert carrier gas such as N$_2$, He and Ar, HVPE growth of high-quality Ga$_2$O$_3$ and In$_2$O$_3$ films becomes possible at high temperatures exceeding 1000 °C using GaCl-O$_2$ and InCl-O$_2$ systems, respectively. Then, based on the results of thermodynamic analyses, HVPE systems for growing Ga$_2$O$_3$ and In$_2$O$_3$ were constructed. GaCl and InCl were generated in the upstream region of the reactor maintained at 800-850 °C by introducing Cl$_2$ gas over Ga and In metal, respectively. It was clarified that homoepitaxial growth at 1000 °C on bulk β-Ga$_2$O$_3$(001) substrates is possible at a growth rate above 10 μm/h without deterioration of crystalline quality. The unintentionally doped layer showed a low effective donor concentration ($N_d - N_A$) of less than $10^{15}$ cm$^{-3}$, and it was found that n-type carrier density can be controlled in the range of $10^{15}$ to $10^{19}$ cm$^{-3}$ by intentional Si-doping using SiCl$_4$. These results indicate that the HVPE method is a suitable method for producing homoepitaxial wafers for Ga$_2$O$_3$-based vertical power devices. Also in the In$_2$O$_3$ growth, heteroepitaxy at 1000 °C on (0001) sapphire substrates showed c-In$_2$O$_3$ growth at a rate of several μm/h. These results suggest that high-temperature and high-speed growth of (In$_x$Ga$_{1-x}$)$_2$O$_3$ alloy by HVPE is also possible.

This work was partially supported by the Council for Science, Technology, and Innovation (CSTI), Cross-ministerial Strategic Innovation Promotion Program (SIP), “Next-generation power electronics” (funding agency: NEDO) and Grant-in-Aid for Scientific Research on Innovative Areas (No. 16H06417) from JSPS.

Rutile GeO$_2$—An Ultra-Wide-Band-Gap Semiconductor with Ambipolar Doping Sieun Chae$^1$, Kelsey Mengle$^1$, Hanjong Paik$^2$, John T. Heron$^1$ and Emmanouil Kioupakis$^1$;
$^1$University of Michigan, United States; $^2$Cornell University, United States

Ultra-wide-band-gap (UWBG) semiconductors have tremendous potential to advance electronic devices as device performance improves superlinearly with increasing gap. Ambipolar doping, however, has been a major challenge for UWBG materials as dopant ionization energy and charge compensation generally increase with increasing band gap. Using hybrid density functional theory, we demonstrate rutile germanium oxide (r-GeO$_2$) to be an alternative UWBG (4.68 eV) material that can be ambipolarly doped. We identify Sb$_{Ge}$, As$_{Ge}$, and F$_0$ as possible donors with low ionization energies and propose growth conditions to avoid charge compensation by native acceptor-type defects. Acceptors such as Al$_{Ge}$ have relatively large ionization energies (0.45 eV) due to the formation of localized hole polarons. Yet, we find that the co-incorporation of Al$_{Ge}$ with interstitial H can increase the solubility limit of Al and enable hole conduction in the impurity band. We also calculate electron (153.6 cm$^2$V$^{-1}$s$^{-1}$) and hole mobilities (4.7 cm$^2$V$^{-1}$s$^{-1}$) of r-GeO$_2$ at 300 K, suggesting r-GeO$_2$ has outstanding electronic properties that can compete with the state-of-the-art UWBG semiconductors such as β-Ga$_2$O$_3$. We will also discuss on our recent experimental progress on thin-film growth and electrical characterization of r-GeO$_2$. This work was supported by the Designing Materials to Revolutionize and Engineer our Future (DMREF) Program under Award No. 1534221, funded by the National Science Foundation. It used resources of the National Energy Research Scientific Computing Center, a DOE office of Science User Facility supported by the Office of Science of the U.S. Department of Energy under Contract No. DE-AC02-05CH11231.

S. Chae, J. Lee, K. A. Mengle, J. T. Heron, and E. Kioupakis, Rutile GeO$_2$ : An Ultrawide-Band-Gap Semiconductor with
The perovskite alkaline-earth stannates are gaining research attention due to their unparalleled room-temperature mobility among perovskite oxides and as wide-bandgap semiconductors. Most research attention is invested in the cubic aristotype member BaSnO$_3$ despite its unsolved challenges of large substrate-film misfit and consequent mobility disparity between thin films and bulk single crystals. The less-studied non-cubic member SrSnO$_3$ (SSO) has a smaller lattice parameter—closer to commercially available substrates—and thus has the potential to overcome the challenges associated with thin-film BaSnO$_3$. First, by using a novel radical-based hybrid molecular beam epitaxy (MBE) approach, we show that SSO can be grown coherently—free of any misfit or threading dislocations—on commercially available substrates, hence solving a longstanding challenge in the stannate community [1]. Secondly, we show—in the first strain engineering study of stannates—that epitaxial compressive strain can control the octahedral rotations in SSO, hence stabilizing a high-temperature tetragonal polymorph at room temperature by more than 700 K below its stability range in bulk. Thirdly, by combining controlled doping, Hall measurements and secondary ion mass spectroscopy (SIMS), we show that SSO can be successfully doped $n$-type with rare-earth elements showing 100% dopant activation [2]. A record-high room-temperature mobility of 70 cm$^2$V$^{-1}$s$^{-1}$ at 1 × 10$^{20}$ cm$^{-3}$ was obtained in a 12 nm La-doped SSO film, making this the thinnest perovskite oxide semiconductor with electron mobility exceeding 25 cm$^2$V$^{-1}$s$^{-1}$ at room temperature. By suppressing electron scattering using heterostructure design, we further boosted the room-temperature mobility to 80 cm$^2$V$^{-1}$s$^{-1}$ in doped SSO—the highest reported value to-date among any distorted perovskite oxide.

Finally, we discuss that the electron-electron interaction effect plays an important role in determining low-temperature transport. The quantitative analysis of the magnetoresistance data yielded a large phase coherence length of electrons exceeding 450 nm at 1.8 K and revealed the electron-electron interaction to be accountable for the breaking of electron phase coherence in La-doped SSO films. These results, while providing critical insights into the fundamental transport behavior in doped stannates, also suggest the potential application of stannates in quantum coherent electronic devices owing to their large phase coherence length [3].

x-y)2O3 alloys with high Al and In-content are not considered in this study to avoid the known phase separation issue happened to the β-Ga2O3-based ternary alloys. The band structure calculations for β-(AlxInyGa1-x-y)2O3 alloys were performed using the projector augmented wave (PAW) method. The semilocal generalized gradient approximation (GGA-PBE) is applied to treat the exchange-correlation potential in the calculations. Other computational details have also been carefully chosen to optimize the DFT calculations.

Analysis from the DFT-calculated band structures of β-(AlxInyGa1-x-y)2O3 alloys with different Al/In-content indicate that the alloys exhibit indirect band gaps, which is similar to β-Ga2O3. The direct bandgap of β-(AlxGa1-x)2O3 increases from 4.835eV to 5.171eV when the Al-content increases from 0% to 18.75%, while the direct bandgap of β-(InxGa1-x)2O3 alloys decreases from 4.835eV to 4.432eV when the In-content go up to 18.75%. In addition, the lattice parameters of the AlInGaO alloys have been investigated and analyzed. Our analysis shows that adding Al and In will reduce and increase the lattice of Ga2O3 alloys respectively. As a result, the quaternary β-(AlxInyGa1-x-y)2O3 alloys can be designed to be lattice-matching with β-Ga2O3 alloy, implying the possibility of adjusting the band properties of β-Ga2O3-based material without creating compressive or tensile strain within the material systems. In addition, electron effective mass is calculated using the energy dispersions of β-(AlxInyGa1-x-y)2O3 alloys. The electron effective mass values are generally within 0.22~0.28m0, while the addition of Al and In has an obvious effect on the effective mass changing. Our findings could be valuable for carrier transport related applications such as power electronic and deep UV photodetector devices. Experimental details on AlInGaO alloys will be further discussed.

5:00 AM *S.EL15.05.01
Dependence of Critical Electric Field on Semiconductor Bandgap—An Analytical Study Mark A. Hollis1, Oleksiy Slobodyan2, Jack Flicker2, Jeremy Dickerson2, Andrew Binder2, Trevor Smith2 and Robert J. Kaplar2; 1MIT Lincoln Laboratory, United States; 2Sandia National Laboratories, United States

An accurate understanding of the critical electric breakdown field (Ecrit) characterizing semiconductor materials is necessary for the design of power switches, power diodes, and RF power transistors. It is particularly important to understand the dependence of Ecrit on bandgap (Eg) as new ultrawide-bandgap materials are developed. Unfortunately, the reported dependencies of Ecrit on Eg cover a surprisingly wide range in the literature. Moreover, while Ecrit is often assumed to be constant for a given material, it is more accurately a function of the device depletion-region width and doping. Further, there are wide discrepancies in the literature where Ecrit values for punch-through and non-punchthrough structures are compared without regard for these differences. We report a new normalization procedure that enables an equivalent comparison of Ecrit values across materials, doping, and punch-through/non-punch-through device types. An extensive examination of many experimental avalanche-breakdown and ionization references reveals that the dependence Ecrit ~ Eg1.86 best fits the most reliable and newest data for both direct and indirect semiconductors over the range from Eg = 0.66 to 5.5 eV (comprising Ge, Si, InP, GaAs, 4H-SiC, GaN, and diamond). It may therefore be reasonable to use this Ecrit ~ Eg1.86 dependence as an approximate rule of thumb for predicting the critical electric fields of novel ultrawide-bandgap materials until precise measurements are made. Based on the Ecrit ~ Eg1.86 dependence, the relationship between specific on-resistance (Ron,sp), breakdown voltage (VBD), and Eg for power switches over this bandgap range is best described by Ron,sp ~ VBD2 Eg-5.58 for both direct- and indirect-gap semiconductors.

5:30 AM S.EL15.05.02
DFT Study of Structural and Electronic Properties of hBN/Diamond (100) Heterostructure Pegah S. Mirabedini1, Mahesh R. Neupane2, Alex Greaney1, Anthony G. Birdwell2, Dmitry Ruzmetov2, Kevin Crawford2, Pankaj Shah2, James Weit2 and Tony Ivanov2; 1University of California, Riverside, United States; 2CCDC US Army Research Laboratory, United States

Diamond has the highest breakdown field and carrier mobility among all wide band-gap semiconductors making it attractive for use in next generation high-speed and high-power electronic devices [1]. Unfortunately, unlike other semiconductors such
as Silicon, diamond cannot be doped with shallow dopants [2], and so other techniques such as surface doping and delta doping are required for doping diamond. Particularly, for the surface-doping technique, a thin-layer of acceptor layer is interfaced with the hydrogenated diamond surface which creates high-mobility hole channel at the interface. Motivated by this, we explore the possibility of using 2D materials such as graphene or hexagonal boron nitride (hBN) as acceptor layers. Though the surface lattice constants of (111) surface is nearly lattice matched and easy to create epitaxial heterostructure with h-BN, surface doped diamond field effect transistors (SDFETs) with diamond (100) surfaces are widely proposed as a next generated in p-type RF-power electronic devices [3]. Herein, we perform a first-principle study to investigate the structural alignment and electronic properties of h-BN/H-diamond (100) heterostructures. As a comparison, we also study the graphene/H-diamond (100) heterostructures. We perform a full analysis of the structural alignments of the 2D layers on Diamond (100) surface and identify optimal strain-compensated h-BN (graphene)/H-diamond (100) heterostructure. Using the optimized heterostructure, we perform electronic structure calculations and compare charge transfer through the van-der-Waal (vdW) gaps between the constituent layers in the heterostructures. Our results show that in spite of a relatively larger vdW-gap, the degree of charge transfer in h-BN and Diamond (100) is higher than that of graphene and H-diamond (100). We believe that our theoretical observations will help the fabrication of novel high-frequency and high-power electronic devices.

5:45 AM S.E.L.15.05.03
Material and Electrical Characterization of Ohmic Contacts to 4H-SiC for Stable Operation at 800 °C Robert Okojie and Dorothy Lukco; 1NASA Glenn Research Ctr, United States; 2Vantage Partners, LLC, United States

High power and high temperature electronics and sensing devices that would perform reliably on a long term basis are mostly implemented in wide bandgap (WBG) and ultra-WBG (>3 eV) semiconductors. However, critical factors that are central to their successful implementation and reliable field operations remain technologically challenging. These include the availability of relevant substrates and doped epitaxies, packaging, contact metallization (Ohmic and Schottky) and diffusion barrier systems (DBS). The DBS essentially protects the ohmic contacts to the WBG semiconductors from the inward migration of oxygen (O) from the atmosphere and gold (Au) that is typically the top bond pad layer. Reaction and diffusion kinetics are generally accelerated with increasing temperatures, resulting in corresponding short lifetime to failure of these devices. It is, therefore, imperative to develop the appropriate metallization schemes that would provide effective ohmic contact and DBS to the semiconductor.

In this work, we report the results of the material analysis and electrical characterization of Ti (100 nm)/TaSi2 (300 nm)/Ti (100 nm)/Pt (300 nm) ohmic contacts and Ti (100 nm)/Pt (300 nm) DBS on n-type 4H-SiC epilayer up to 800 °C. Device level evaluation was demonstrated on 4H-SiC micro pressure sensors to operate reliably for over 100 hours at 800 °C. Key sensor performance parameters [zero offset voltage (ZPO) and bridge resistance] that are critical to sensor measurement reliability were extracted. The results showed a strong dependency of the electrical parameters on the microstructures of the ohmic contact and DBS.

The ohmic contact sputter deposition and patterning was followed by rapid thermal anneal (RTA) at 800 °C for 10 seconds in near vacuum condition. The subsequent diffusion barrier metallization was similarly annealed. Finally, a TaSi2 (20 nm)/Pt (100 nm)/Au (1 μm) bond pad metallization was deposited and furnace annealed at 800 °C in Ar for 30 minutes. This final layer also underlaid the underlying DBS. The in-situ measured sensor resistance and output voltage during atmospheric heating up to 800 °C was matched with corresponding periodic Focused Ion Beam-Field Emission Scanning Electron Microscopy (FIB-FESEM), Energy Dispersive Spectroscopy (EDS), and Auger Electron Spectroscopy (AES) depth profiling. The depth-resolved AES and EDS revealed three prominent intermixing and reaction zones within the diffusion barrier and metal/SiC ohmic interface. The reaction products were primarily silicides and carbides of Ti, which had combined to form the ohmic contact on the n-type SiC surface. The diffusion barrier zones consisted of intermixed Ti/Pt and silicide complexes of Pt while the top zone comprised of intermixes of Pt-rich/Ti that effectively prevented O and the bond pad Au from diffusing toward the ohmic contact. The overall stability of the bridge resistance and output voltage were predicated upon the effectiveness of the diffusion barrier scheme in preventing the migration of O and Au.

During the first 100 hours of atmospheric heating at 800 °C, the changes in the resistance correlated well with the diffusion of Au and O into the Ti/Pt layer. Both the bridge resistance and the ZPO simultaneously leveled off thereafter and remained relatively stable for the remaining duration of thermal treatment. The before and after comparisons of the results of thermal activities within the metallization showed direct correlation between the ZPO characteristic trend and the microstructural changes as a result of O and Au migration and new reaction products.

This work is very significant in that future WBG based sensors and electronics can be inserted further into the hotter section
of engines, thereby eliminating the need for costly cooling and packaging schemes. It would help capture wider thermoacoustic frequency bandwidth, thereby improving the measurement needed for accurate validation of computational fluid dynamics codes.

Initial-Growth Mechanism of High-Quality Diamond Heteroepitaxial Layer on Sapphire Substrate Makoto Kasu1, Ryota Takaya1, Yuki Kawamata1, Koji Koyama2 and SeongWoo Kim2; 1Saga University, Japan; 2Adamant Namiki Precision Jewel Co., Ltd., Japan

Diamond semiconductor with a bandgap of 5.47 eV is expected to be used in high-power devices surpassing the capabilities of SiC and GaN. Diamond heteroepitaxial growth has been successfully demonstrated on cubic (001) MgO substrate [1] and yttria-stabilized zirconia / (001) Si substrate [2]. However, recently, S.-W Kim et al. demonstrated the highest quality heteroepitaxial diamond growth on a sapphire substrate. The FWHMs of (004) and (311) rocking curves were as low as 120 arcsec (0.03°) and 269 arcsec (0.07°) respectively, which are the world’s best values in heteroepitaxial diamond.

Heteroepitaxial diamond growth on sapphire [3,4] has previously been reported, but the crystal growth mechanism remains unclear. Therefore, the present research focuses on revealing the growth mechanism.

We investigated initial diamond growth initiated by bias-enhanced nucleation on an Ir buffer layer deposited on (11–20) sapphire substrate. First, we revealed the crystal orientations of diamond, Ir buffer, and sapphire substrates using X-ray diffraction. Next, we observed diamond nucleation, nucleus coalescence, and layer growth processes sequentially by using atomic force microscopy and scanning electron microscopy. In particular, using cross-sectional transmission electron microscopy, we studied the interface of diamond nuclei with the Ir buffer layer. The mechanism would be different from Ref. 2. We documented the Ir buffer layer epitaxial growth on sapphire substrate and diamond nuclei growth on the Ir buffer layer.

Deep Level Defects in LPCVD-Grown β-Ga2O3 (010) Hemant Jagannath Ghadi, Joseph McGlone, Zixuan Feng, Yuxuan Zhang, Hongping Zhao, Aaron Arehart and Steven Ringel; The Ohio State University, United States

Interest in β-phase gallium oxide (β-Ga2O3) has been growing tremendously in recent years due to its great potential for power devices and RF electronics. The major factors causing this surge are its ultra wide direct bandgap (~4.6-4.8 eV), large breakdown fields, ease of n-type doping, availability of large area, melt-grown substrates and high predicted device figures of merit compared with GaN and SiC. Most epitaxial growth efforts are focused on molecular beam epitaxy (MBE) and metalorganic chemical vapor deposition (MOCVD) but low pressure chemical vapor deposition (LPCVD) allows for high growth rates in a high temperature growth regime and with additional features like large area scalability. LPCVD can achieve growth rates as high as 10 µm/hr and growth temperatures up to 1100°C using economical and eco-friendly high purity precursors or sources. LPCVD is recently gaining significant attention due to its ability to grow β-Ga2O3 films with thicknesses as high as 40 µm, with uniform and controllable Si-doping on β-Ga2O3 substrates or sapphire. LPCVD grown β-Ga2O3 films exhibit room temperature mobilities as high as 150 cm²/Vs. However, recent studies indicate the LPCVD grown β-Ga2O3 films are still unable to achieve high mobility at low temperatures with higher background acceptor compensation compared to MOCVD or MBE grown material. This study provides the first known full-bandgap evaluation of defect states of LPCVD-grown β-Ga2O3. Here we use deep level optical spectroscopy (DLOS), deep level transient (thermal) spectroscopy (DLTS), and admittance spectroscopy (AS) to identify bandgap states in LPCVD material. By comparing with our earlier work on β-Ga2O3 grown by other methods, the goal of this work is to identify the critical defects in LPCVD material and develop correlations with possible sources in order to guide strategies to suppress them.

A 1.2 µm thick layer of Si-doped β-Ga2O3 was homoepitaxially grown at 1050°C on a Sn-doped (010) Tamura
Ga$_2$O$_3$ substrate using an in-house built LPCVD system using metallic gallium and O$_2$ sources [1]. Thin Ni Schottky diodes were fabricated to facilitate defect spectroscopy. The net doping from C-V was measured to be 2.3×10$^{17}$ cm$^{-3}$ and Hall measurements on separate samples revealed electron mobilities of ~120 cm$^2$/Vs at 300 K. Admittance spectroscopy (AS) detected a donor state at Ec-0.04 eV with a concentration of 2.3×10$^{15}$ cm$^{-3}$, which matches the doping from C-V and is the likely Si donor state. AS also revealed another state at Ec-0.12 eV with a lower concentration of 9.1×10$^{15}$ cm$^{-3}$ that was also seen by DLTS. Three other states were observed by DLTS, at Ec-0.18 eV, Ec-0.21 eV, and Ec-0.78 eV with trap concentrations of 2.1×10$^{14}$ cm$^{-3}$, 5.7×10$^{14}$ cm$^{-3}$, and 2×10$^{16}$ cm$^{-3}$, respectively. The state at Ec-0.78 eV matches prior reports attributing this to Fe impurities [2] and dominates the DTLS spectrum. States deeper in the bandgap, which cannot be detected by AS or DLTS, were seen from DLOS measurements at Ec-2.0 eV, Ec-3.7 eV and Ec-4.4 eV with concentrations of 1.6×10$^{15}$ cm$^{-3}$, 9.9×10$^{15}$ cm$^{-3}$, and 1.5×10$^{16}$ cm$^{-3}$, respectively. Of all six observed traps, only the deep level at Ec-3.7 eV appears to be unique in the LPCVD material compared to prior work on MBE, EFG and MOCVD-grown b-Ga$_2$O$_3$ [3,4] material, and is under specific investigation. Lighted C-V measurements are ongoing to correlate specific traps with the high degree of carrier compensation observed in this material, which will be compared with similar studies made on b-Ga$_2$O$_3$ grown by other methods, along with a detailed comparison of trap properties and concentration distributions from our prior work [3,4].

Polarized Transmittance and Photoluminescence Spectra of Fe-Doped Ga$_2$O$_3$ Crystals Ruijun Sun, Yukee Ooi and Michael Scarpulla; The University of Utah, United States

Fe-doped Ga$_2$O$_3$ is the only commercially available but also highly desirable semi-insulating substrates/crystal. In this work, optical properties of Fe-doped Ga$_2$O$_3$ were studied by polarized transmittance and photo-luminescence spectroscopy. The optical bandgaps of electrical field vector parallel to a* and c were 4.46 eV and 4.40 eV of (010) sample while 4.74 eV and 4.50 eV for b and c axes of (100) sample. An absorption band around 4.0 eV was observed when electrical field vector was parallel to b and a* axes. Two sharp peaks at 689nm and 697nm superimposing a broad peak at 710nm were emitted from Fe-doped Ga$_2$O$_3$ under UV laser excitation (233nm-270nm) at room temperature, while the almost zero PL intensity between 300 nm and 600nm. Temperature dependent PL showed that the broad peak diminished while two sharp peaks intensified with temperature decreasing, which matches the emission feature from transition metal Cr. ICP-MS was employing to check the existence of Cr impurity. PLE showed the 689 nm peak intensity reached its maximum when excitation wavelength was near the band gap, indicating energy transfer from electron at Ga site to this impurity site. This work demonstrates that Fe-doped Ga2O3 substrate is promising to provide zero PL background for ultra-thin epi-layer as well as to probe trace impurities.

The Influence of Polymorphism on the Electronic Structure of Ga$_2$O$_3$ Jack Swallow¹, Tim Veal¹ and Anna Regoutz²; ¹University of Liverpool, United Kingdom; ²University College London, United Kingdom

Ga$_2$O$_3$ is an ultra-wide band gap oxide material, which promises great improvements in a range of applications, including power electronics, solar blind UV photodetectors, and gas sensing devices. Its high conductivity, high breakdown field, and large band gap have led to a flurry of research in the past few years. Most of the work has focused on its most stable form, monoclinic ß-Ga$_2$O$_3$. However, Ga$_2$O$_3$ presents pronounced polymorphism and a number of other polymorphs beyond ß exist, including hexagonal ß-Ga$_2$O$_3$, cubic γ-Ga$_2$O$_3$, and orthorhombic ε-Ga$_2$O$_3$. Although this wealth of possible structures opens up opportunities to control and tune structure, electronic structure and ultimately physical characteristics, the polymorphs beyond ß-Ga$_2$O$_3$ are comparatively unexplored. In particular experimental results are scare due to the general difficulty in producing high quality materials and the lack of theoretical results for the more structurally complex polymorphs.

Here, we present an in-depth study of the electronic structure of the α, ß, γ, and ε polymorphs of Ga$_2$O$_3$. The samples investigated are either bulk single crystals or epitaxial films grown using molecular beam epitaxy (MBE) or atomic layer deposition (ALD), selecting the highest quality samples available for each of the polymorphs. We report high-resolution valence bands from hard and soft X-ray photoelectron spectroscopy (SXPS and HAXPES) which are directly compared to theoretical partial and total electronic densities of states as calculated within the framework of density functional theory (DFT). Both deep and shallow core level spectra are compared to DFT results to explore the influence of structure, rather than solely the oxidation state, on the core level behaviour. X-ray absorption spectroscopy (XAS) is used to probe the
unoccupied states and in combination with SXPS is used to gain an estimate of the changes in the band gaps of the polymorphs. Ultimately, this work presents a systematic and comprehensive study of the electronic structure of Ga$_2$O$_3$ polymorphs, providing an insight into electronic trends and their relationship to crystal structure. This comparative study helps to discern trends between the different structures and advances our understanding of this polymorphic material. It lays the foundation for further exploration of Ga$_2$O$_3$ in applications beyond its β phase.

Ultra-Wide Bandgap Oxide Semiconductors for Power Electronics and Deep-UV Optics Shizuo Fujita$^1$, Kentaro Kaneko$^1$ and Takayoshi Onuma$^2$; $^1$Kyoto University, Japan; $^2$Kogakuin University, Japan

Ultra-wide bandgap (UWBG) semiconductors have extended the opportunity for exploring novel application fields in electronics and optics. Ga$_2$O$_3$, being supported by its bandgap as wide as ~5 eV, is gaining increasing interests as a material for power electronics devices. Progress of monoclinic-structured Ga$_2$O$_3$ (β-Ga$_2$O$_3$) bulks and substrates, which is the thermodynamically most stable phase in a variety of polymorphs of Ga$_2$O$_3$, grown by solution-methods has accelerated the evolutionary research on high-performance power devices. On the other hand, our research has directed on semistable corundum-structured Ga$_2$O$_3$ (α-Ga$_2$O$_3$) grown on sapphire (α-Al$_2$O$_3$). One of the reasons for paying attention to α-Ga$_2$O$_3$ is that there are a variety of corundum-structured oxide materials, which can be combined with α-Ga$_2$O$_3$ to establish novel devices. Alloys and heterostructures of Al$_2$O$_3$, Ga$_2$O$_3$, and In$_2$O$_3$ can achieve heterostructure devices by arbitral tuning of the bandgaps. We have succeeded in the bandgap tuning from 3.7 to 8.8 eV, and the n-type conductivity control of α-Ga$_2$O$_3$ with doping Sn and Si, leading to the device-oriented research. A start-up company, FLOSFIA, Inc., has demonstrated Schottky barrier diodes with on-resistance as low as 0.1 mΩcm$^2$, their reasonable heat resistivity, and the low-loss power conversion. Heterojunctions of α-(Al,Ga)$_2$O$_3$ alloys show the type-I band lineup, and this allows fabrication of a variety of heterojunctions and quantum wells for novel devices. α-In$_2$O$_3$ showed the higher electron mobility compared to that of α-Ga$_2$O$_3$, and we demonstrated the operation of an MOSFET with the field-effect mobility of 187 cm$^2$/Vs. The bandgap of α-In$_2$O$_3$ (3.7 eV) is still wider than that of GaN and SiC, suggesting that α-In$_2$O$_3$ can also be a candidate material for power devices.

A various combination of corundum structured oxides allows unique materials properties. One of the examples is above-room temperature ferromagnetic properties of α-(Ga,Fe)$_2$O$_3$ and α-(In,Fe)$_2$O$_3$. α-Rh$_2$O$_3$ and α-Ir$_2$O$_3$ are native p-type materials. Especially, α-Ir$_2$O$_3$ is closely lattice-matched to α-Ga$_2$O$_3$. We demonstrated p-type conductivity of α-Ir$_2$O$_3$, followed by fabrication of α-Ir$_2$O$_3$/Ga$_2$O$_3$ pn junction. Efforts are continueing to control the bandngap and the hole concentration of p-type α-(Ir,Ga)$_2$O$_3$.

For optical applications of UWBG oxide semiconductors, we have focused on UWBG Mg-rich (x>0.7) rocksalt-structured Mg$_x$Zn$_{1-x}$O, whose maximum band gap can be ~7.8 eV (at x=1). This attracts its potential as deep UV light emitters in the wavelength region which cannot be reached by III-nitrides. We used mist CVD method for the growth of MgZnO with the carbon-free source precursors. The x-ray and electron-beam diffraction evidenced rocksalt structure without noticeable incorporation of other phases. For the sample with x=0.92, the CL peak blue-shifted by 1-8 nm (0.08-0.21 eV) at 6 K compared to the single MgZnO layer with decreasing the thickness of the MgZnO layer. The spectrally integrated CL intensity at 300 K over that at 6 K ($I_{300}/I_6$), which is supposed to be the internal quantum efficiency at 300 K, reached ~13%, which was apparently higher than that of the single layer. The overall results suggest that MgZnO can pave the way for deep UV photonics.
Ferroelectric Transition of Epitaxial HfO$_2$

Shang-Lin Hsu, Zimeng Zhang, Aviram Bhalla-Levine and Ramamoorthy Ramesh; University of California, United States

Hafnium oxide (HfO$_2$) is an insulator that has a wide range of applications due to its high dielectric constant and wide band gap. Recent discoveries from 2011 on emergent ferroelectricity in doped HfO$_2$ thin films, have enabled it as a candidate for ferroelectric random-access memory, ferroelectric field-effect transistors, and ferroelectric tunnel junctions. However, the origin of the ferroelectricity of HfO$_2$ and doped versions has not been systematically studied yet. Furthermore, a significant amount of work has been done only on polycrystalline thin films. We are exploring the synthesis of epitaxial Hf-Zr-O$_2$ as a function of thickness with epitaxial oxide top and bottom electrodes by pulsed laser deposition to explore these ferroelectric transitions. We utilize high-resolution transmission electron microscopy to explore the atomic structure of epitaxial HfO$_2$ thin films and identify the ferroelectric phase transition with multislice simulation. The robust ferroelectric phase of HfO$_2$ can be found at a thickness below 10nm, even below 5nm, which is identified as the non-centrosymmetric orthorhombic phase with space group Pca2$_1$. The oxygen atom plays an important role in allowing a phase transition from the monoclinic to the orthorhombic phase.

Growth of TiO$_2$ Polymorphs from RF-Sputtered, Amorphous Precursor Films

Okan Agirseven$^1$, Acacia Mariah Patterson$^1$, Joseph Kreb$^1$, Pritha Biswas$^1$, John Mangum$^2$, Brian Gorman$^2$, Bor-Rong Chen$^3$, Laura Schelhas$^3$, Arthur O. Finstad$^4$, Kelsey A. Stoorzinger$^1$ and Janet Tate$^1$; $^1$Oregon State University, United States; $^2$Colorado School of Mines, United States; $^3$SLAC National Accelerator Laboratory, United States

Titania polymorphs have been shown to crystallize when thin-film amorphous precursors deposited by pulsed laser deposition are annealed [1]. This non-equilibrium deposition method, coupled with particular oxygen partial pressure ranges [2] and film thicknesses defined a region of phase space where particular polymorphs formed. We have extended this study to investigate amorphous TiO$_2$ precursors deposited by RF-sputtering from a Ti target with an Ar/O$_2$ sputter mix of different ratios and find broadly similar trends. We can produce uniform thickness high-fraction brookite, anatase and rutile films by changing the oxygen deficiency in the precursor films and controlling the thickness in the range 30 – 200 nm. Synchrotron XRD analysis of a series of precursor and annealed films shows that the precursor films are fully amorphous and the crystallized films confirm the phases identified by the Raman analysis. We observe the growth morphology and growth rates of the three major TiO$_2$ polymorphs. We anneal amorphous precursor films in-situ in flowing nitrogen at 300 – 450°C in a heating stage mounted on a microscope attached to a Raman spectrometer. We record the crystallization on video and distinguish the phases optically due to their different refractive indices and different morphologies, confirming phase identification with Raman spectroscopy. We find a particular precursor film yields the same polymorph when annealed at different temperatures, only the rate of formation changes. With in-situ analysis we found that brookite crystallizes faster than rutile and anatase. We also observed that RF-sputtered films have more crystallization centers than pulsed laser deposited films and crystallize slower. Brookite tends to grow anisotropically, while the rutile and anatase growth habits are more symmetric. The growth morphologies are complex in mixed-phase films. Photocatalysis measurements indicate that photo-degradation of methylene blue by the polymorphs differ from each other. Some photoactive films also revealed unusual XRD spectra.

Metal-fluoride thin films have previously been investigated as gate insulators in MISFETs (CaF$_2$/Au/Diamond) and this work expands upon that investigation. AlF$_3$ is an ultra-wide-bandgap (10.8 eV) material with a low dielectric constant (2.2). These properties indicate that AlF$_3$ may be a suitable insulator for high power high frequency devices. AlF$_3$ films have been deposited on hydrogen terminated boron-doped polycrystalline diamond in a plasma enhanced atomic layer deposition (PEALD) process. PEALD is an emerging energy enhanced ALD technique that utilizes plasma radicals to drive surface reactions rather than thermal energy. PEALD allows for lower impurities, increased growth rates, improved stoichiometry, and lower deposition temperatures. The reactants used were trimethylaluminum, pyridine-hydrogen fluoride, and a hydrogen plasma. In-situ X-ray photoelectron spectroscopy was used to determine the band alignment of AlF$_3$ films on polycrystalline diamond. The valence band maxima are measured at 9.15 eV and 0.05 eV for AlF$_3$ and diamond, respectively. A type II staggered gap is formed with a conduction band offset of 3.77 eV and a valence band offset of 9.1 eV. The results indicate that AlF$_3$ should be appropriate as a dielectric on p-type diamond.

This research supported by the NSF under grant DMR-1710551.

Investigations of Ultrawide Bandgap (AlIn)$_2$O$_3$ Alloy for AlInN / GaN Devices Xiaoli Liu and Chee-Keong Tan;
Clarkson University, United States

Recent progress in wide band gap semiconductor based power electronics technology sparked humongous interest in the development of the semiconductor materials. With the aim of further reducing the cost, size, compactness while improving energy efficiency and performance of electrical systems, semiconductor materials of larger energy bandgap have been highly sought after. Recent studies show that ternary AlInN material grown lattice-matched with GaN provides access of energy bandgap of $\sim$4.5 eV, allowing theoretically higher Baliga figure of merit than GaN-based devices and similar to that of $\beta$-Ga$_2$O$_3$ based devices. However, it also poses some difficulty in controlling the field effect since insulating material with larger energy bandgap is required to create conducting channel and block electron leakage from devices. Finding an insulator material with energy bandgap larger than 4.5eV that can be grown on AlInN material is thus important towards realizing the AlInN / GaN field effect transistor based devices. Most recently, AlInO material has been proposed as a viable material that can serve as the insulator through thermal oxidation of the AlInN material. While the AlInO material is expected to exhibit chemical formula of (Al$_{1-x}$In$_x$)$_2$O$_3$, it is unclear if the AlInO material is thermodynamically stable and the information of AlInO material is extremely limited to date. Understanding the material properties of AlInO material from the viewpoint of structural and electronic properties is therefore critical for AlInN / GaN devices.

In this work, (Al$_{1-x}$In$_x$)$_2$O$_3$ alloys covering complete In compositions are investigated using Density Functional Theory (DFT) calculations. Two different phases of AlInO alloys will be investigated: corundum and hexagonal. The effect of In atoms on the electronic properties of AlInO alloys is investigated. For structural properties, lattice constants and equilibrium volume of (Al$_{1-x}$In$_x$)$_2$O$_3$ alloys are analyzed. Moreover, band alignment between AlInO and AlInN is studied, exploring possible heterojunction lineups in various orientations.

For DFT calculation, supercell approach is implemented in which a 60-atom AlInO crystal is constructed. The In composition is varied through the number of Al atoms being replaced in the crystal structure. DFT calculations were carried out using commercial package MedeA-VASP software. Band structure calculations were performed by using projector augmented wave (PAW) method, with the use of semilocal generalized gradient approximation (GGA-PBE) functional to treat the exchange correlation potential in the system. Other computational details such as the k-spacing and cutoff energy have been optimized to ensure reasonable DFT results. Surface supercells for both AlInO and AlInN alloys were also created in order to calculate the band alignment, and the parameters are set to be similar to bulk DFT calculations.

Our DFT-calculated band structures of AlInO alloys indicate the possibility of direct bandgap property crossing over to indirect bandgap property when In-content is larger than 20%. Preliminary analysis of the DFT-calculated band structures show that the energy bandgap of Al$_2$O$_3$ reduces significantly when In content is added into the alloy. The energy bandgap of AlInN with 20%-In is less than 5eV. The results are expected since In atoms are much larger than the Al atoms, and significant bowing occurs in atomic size mismatch condition. Further studies on density of states are required to understand the contribution of each orbital in the bandgap reduction. Note that Al$_2$O$_3$ and In$_2$O$_3$ have bandgap of $\sim$8.8eV and $\sim$3eV, respectively. Adding In in Al$_2$O$_3$ also results in significant reduction of lattice constants, but lattice matching condition with AlInN is possible with proper tuning of In-content. From the formation energy analysis, it is also expected that more than 20% In will result in phase separation issue in the AlInN alloys. Details on AlInN alloys will be further discussed.

S.EL15.08.09
Morphological and Electrical Study of Ga2O3-Ti Nanofilms Processed by Co-Sputtering Lucia Ivonne Juárez Amador1.
In this work an experimental study to characterize titanium (Ti) doped amorphous-Gallium Oxide (Ga2O3) nano-films embedded into a-Ga2O3 matrix when the growth process is done at low temperatures, therefore post-grown annealing processes can be used to adjust the film properties appropriately the annealing conditions, temperature or atmosphere composition. The annealing temperatures were 400, 450, 500 and 550 °C by periods of 10 min, in a high purity N2 atmosphere. When the samples were annealed at low temperatures the resistivity of the films were varied from 5.74x10^4 to 134.63 Ω-cm, electron concentration from 10^{12} to 10^{16} cm^{-3} and mobility of 0.475 to 6.689 cm^2/V-s. by annealing the samples at 550°C electrical insulating nano-films were produced by the complete oxidation of the Ti clusters. The relatively low mobility of the doped nano-films suggests the Ti dopant produces carrier dispersion suggesting the presence of Ti deep levels in the material. According to the X-ray diffraction analysis the Ti clusters in a-Ga2O3 matrix helps in reducing the required temperature to transform amorphous films to β-Ga2O3 at ~400 °C. The required temperature to produce the phase change was confirmed by SEM studies producing octahedral shape nanocrystallites with sizes from ~5 to 50 nm.

S.E.L.15.08.10

Diamond P-I-N Diodes for Receiver Protectors Mohammad Faizan Ahmad1, Harshad Surdi1, Franz A. Koeck1, Robert J. Nemanich1, Stephen M. Goodnick1, Trevor J. Thornton1 and Josephine Chang2; 1Arizona State University, United States; 2Northrop Grumman Mission Systems, United States

The intrinsic properties of diamond are attractive for use in high power receiver protector (RP) systems such as those required at the input of radar systems. At low input power, the RP device presents a low capacitance and high resistance so that it adds negligible insertion loss to the desired signals. However, at high input power levels the RP turns on with a resistance much smaller than the 50 Ω characteristic impedance and the majority of the input power is reflected away from the receiver input. P-I-N diodes made of Si and GaAs used in today’s conventional RP systems have limitations at high-power levels in the material. According to the X-ray diffraction analysis the Ti clusters in a-Ga2O3 matrix helps in reducing the required temperature to transform amorphous films to β-Ga2O3 at ~400 °C. The required temperature to produce the phase change was confirmed by SEM studies producing octahedral shape nanocrystallites with sizes from ~5 to 50 nm.

Diamond P-I-N diodes were fabricated with an n'-i-p++ structure consisting of: a heavily phosphorus-doped n-type diamond layer with a doping concentration >1x10^{19} cm^{-3} and a thickness of approximately 300 nm; an intrinsic diamond layer of thickness approximately 0.5 μm; and a heavily boron-doped diamond <111> substrate with doping concentration of 5x10^{19} cm^{-3} and a thickness of 300 μm. The sample was patterned by photolithography and Ti/Pt/Au contacts were deposited on both top and bottom surfaces of the diode. The PIN test structures consist of a total of 144 diodes with diameters of 50 μm, 100 μm, 200 μm, and 400 μm. A SiO2 hard mask of thickness 2 μm was deposited on the diamond surface prior to the isolation etch step. Reactive ion etching was used to define electrically isolated mesa regions etched to a depth of ~600 nm. The SiO2 etching was carried out using fluorine RIE with 25 sccm of CHF3 and Ar at a chamber pressure of 30 mTorr at 200 W. Diamond etching was done in the chamber with 38 sccm of O2 and 2 sccm of SF6 at a chamber pressure of 15 mTorr at 300 W. The electrical characteristics of the P-I-N diodes were measured using DC and RF probe stations. The diodes show significant forward current starting at around 10 V. The lowest specific on-resistivity at high forward bias was measured using the DC probe station and found to be 4.5x10^{-4} Ω.cm². The capacitance of the diodes at zero bias was extracted from small-signal S-parameter measurements in the frequency range 0.1 – 10 GHz and found to be 7.6 nF/cm². Taken together these values suggest a figure of merit, FOM = R_{on} C_{eff} = 6.81 ps corresponding to a frequency of 23.37 GHz.
receiver protection applications.

Defect Structure and Distribution of Electrons in Ga2O3 and IGZO Stack Yong-Seok Lee, Min-Ju Choi, Yonghee Lee, Ho Won Jang and Young-Woon Kim; Seoul National University, Korea (the Republic of)

Epitaxial Ga2O3 film was grown on the Al2O3 substrate using magnetron sputtering. Because of the lattice mismatch between Ga2O3 and substrate, epitaxial films reveal mosaic domain structure with high number density of interfacial dislocations. Interfacial Domain size has an average diameter of ~ 40 nm. On the top of the Ga2O3, without additional treatment, semiconducting indium gallium zinc oxide (IGZO) was stacked to obtain the oxide/semiconductor structure. An external electron beam control system for SEM and TEM was designed and built in house to acquire position specific physical properties – direct measurement for the electron density and luminescence characteristics from the optical energy states. External control system was successfully adopted to Electron Beam-Induced Current Imaging (EBIC) to visualize 2-dimensional distribution of electrons at the interface, which can be indirect indication of preferred electron conduction paths. Cathodoluminescence in TEM was also adopted to identify the 2-dimensional distribution of optical bandgap. Defects, originated from the interface, works as dead centers of luminescence, not wavelengths shifters as can be typically seen from the partial dislocation in GaN/InGaN lighting emitting diode structure.

Exploring the Role of Defects Produced by Ion Irradiation on Near and Sub-Surface GaN Thomas W. Pfeifer1, Ethan A. Scott2,1, David Olson1, Patrick E. Hopkins1, Khalid Hattar2 and Stuart Van Deusen2; 1University of Virginia, United States; 2Sandia National Laboratories, United States

The wide band gap and high thermal conductivity of gallium nitride semiconductors makes them ideal for high power and high frequency applications. These properties however are dependent upon the order and impurity concentration of the crystalline structure. In this study, we use Time Domain Thermoreflectance (TDTR) to investigate the role of defects on the thermal performance of GaN semiconductors. He atoms were implanted into GaN, with dosing concentrations varying between 1x1013 and 1x1019 cm-2 and implantation energies at both 400eV and 400keV. TDTR is a pump-probe technique that measures the change in thermoreflectance on the surface of a sample as a function of pump-probe delay time from picoseconds to nanoseconds; this change in thermoreflectance is related to both the temporal temperature decay from impulse heating driven by the sub-picosecond pump pulse and the frequency-dependent temperature rise induced from the modulated pump pulse train. Thus, TDTR is well suited to measure both the thermal conductance across near surface interfaces along with thermal property changes of buried damaged regions from the ion irradiation. Our TDTR apparatus includes an 800nm 80MHz femtosecond pulsed laser, the pump is modulated at 8.4MHz, and all samples included an aluminum transducer deposited on the surface. Ions implanted at low powers localize near the surface of the GaN, and their effect can be observed when measuring the Aluminum-GaN thermal boundary conductance. Ions implanted at higher powers penetrate to a depth greatly exceeded the thermal penetration depth of the TDTR measurement technique. Here, the role of defects due to the passage of the ions is observed and measured. We believe the results and trends observed in this study are not limited to GaN, and a deeper understanding of the effects of doping on thermal properties could assist in cooling of doped semiconductor devices.

Crystal Defects in GaN and Diamond Transistor Structures Aris Christou; University of Maryland, United States

The state-of-the-art power switching devices made from SiC and GaN semiconductors contain a high density of crystal defects. Most of these defects are present in starting wafers and some are generated during device processing. There is little conclusive evidence so far on the exact role that the crystal defects paly on device performance, manufacturing yield, and more importantly, long-term field-reliability especially when devices are operating under extreme stressful environments. This paper provides a review of the current state-of-the-art of Diamond and GaN power semiconductor material technology, and the potential impact crystal defects may have on power switching electronics. UWBG Nitride materials suffer from both extended and point defects, each of which will challenge the material’s application in both vertical and lateral power devices. The extended defects include vertical threading dislocations of both edge and screw type. The latter defects have been shown to be correlated to leakage in vertical two terminal device structures while the influence of the former is still undetermined and remains a critical research issue. Channel surfaces in vertical three terminal devices will also degrade due to vertical threading dislocations. These extended defects occur in all epitaxial layers grown on c-plane substrates (the predominant and
largest area substrate type) and are the result of the lack of a high quality substrate bulk material as well as substrate surface. Diamond faces the challenge of achieving n type doping. We report our results on delta doped channels in diamond CVD epitaxial layers and the achievement of delta doped field effect transistors. Finally, our recent experiments of proton and gamma radiation effects show that diamond transistors transfer characteristics do degrade as a result of radiation induced defects.

Investigating F-Doped MZO as the Emitter in CdTe Solar Cells Manoj K. Jamarkattel, Adam Phillips, Jacob Gibbs, Kamala Khanal Subedi, Fadhil K. Alfadhili, Randy J. Ellingson and Michael Heben; University of Toledo, United States

Recently, incorporation of MgZn1-xO (MZO) as the emitter in CdSeTe solar cells has resulted in improved open circuit voltage and efficiency. However, the MZO layer appears to be sensitive to subsequent device processing, possibly due to unoptimized conduction band alignment or insufficient doping in the MZO layer. Unfortunately, the carrier concentration in the MZO is dominated by oxygen vacancies, which is difficult to control. Here we investigate how doping MZO films with F affect the CdSeTe properties. We deposit the MZO:F in two ways. The first method is by depositing an MZO/MgF stack followed by high temperature anneal, while the second method will be cosputtering ZnO, MgO, and MgF. Our preliminary results on the bilayer stack show that, peak PL intensity and bulk carrier lifetime of MZO:F/CdTe device increased after annealing. There is evidence of intermixing of the MZO and MgF after annealing, suggesting that the Fermi level of the MZO is closer to the conduction band at the film interface. If this is the case, band bending in the CdSeTe layer will be enhanced, leading to reduced interface recombination. Further investigation into the cause of these results will be presented, as will the results obtained when a cosputtered MZO:F emitter is used. The findings of this study may lead to higher efficient CdTe devices.

Efficient, Stable and Scalable Perovskite Solar Cells Jangwon Seo; Korea Research Institute of Chemical Technology, Korea (the Republic of)

Power conversion efficiencies (PCE) of perovskite solar cells (PSCs) has rising from the initial 3.8% to the state-of-the-art
25.2% within the past few years. Current PSCs intended for commercialization in the near future require both high efficiency and good long-term stability. Most highly efficient PSCs utilize an n-type layer of mesoporous titanium dioxide or tin oxide in an n-i-p device configuration, in which organic conductors are widely used to transport holes into an adjoined metal. Thus far, a variety of efforts have been devoted to achieve a defectless perovskite film with high-quality morphologies to realize reduced loss-in-potential outcomes and enhanced efficiency levels. In this talk, we will discuss several challenges that need to be addressed in improving the photovoltaic performance and the stability of the perovskite solar cells, i.e. (1) preparation of high crystalline film of (FA\(\text{PbI}_3\))\(_1-(x)(\text{MAPbBr}_3)\)_\(x\) with a large grain size and a preferred orientation, (2) incorporation of wide band gap halide into narrow band gap halide perovskites, (3) development of selective charge-transporting layers (CTL) with a superior stability, (4) interfacial control between the perovskite and the CTLs, and (5) the ion migration at the interface boosted by oxygen and light. Finally, our recent works on scale-up of PSCs will be discussed. Our strategy as presented in this work will offer new directions for those involved in the fabrication of highly efficient, stable and scalable PSCs.

5:00 AM S.EN01.01.04
Elucidating the Role of a Tetrafluoroborate-Based Ionic Liquid at the n-Type Oxide/Perovskite Interface  Nakita K. Noel; Princeton University, United States

Halide perovskites are currently one of the most heavily researched emerging photovoltaic materials. Despite achieving remarkable power conversion efficiencies, perovskite solar cells have not yet achieved their full potential, with the interfaces between the perovskite and the charge-selective layers being where most recombination losses occur. In this study we employ a fluorinated ionic liquid (IL) to modify the perovskite/SnO\(_2\) interface. Using Kelvin probe and photoelectron spectroscopy measurements, we show that depositing the perovskite onto the IL results in the crystallisation of a perovskite film which has a more n-type character, evidenced by a decrease of the work function and a shift of the Fermi level towards the conduction band. We use photoluminescence spectroscopy and time-resolved microwave conductivity to investigate the optoelectronic properties of the perovskite grown on neat and IL-modified surfaces and find that the more n-type perovskite exhibits an order of magnitude lower trap density than the control film. When incorporated into solar cells, this interface modification results in a reduction in the current-voltage hysteresis and an improvement in device performance, with the best performing devices achieving steady-state PCEs exceeding 20%. Combining this modification with passivation treatments at the perovskite/HTM interfaces, allow us to achieve further enhanced PCEs (>22%) and improved long-term stability.

5:00 AM S.EN01.01.05
Interfacial Engineering in Vacuum Deposited Perovskite Solar Cells—From Metal Oxide Extraction Layers to Large Area Devices  Daniel Pérez-del-Rey, Pablo P. Boix, Michele Sessolo and Henk J. Bolink; University of Valencia, Spain

Vacuum deposition is a key technique in the field of perovskite photovoltaics because it presents significant advantages with respect to the classical solution deposition methods. In particular, avoiding the use of solvents and perovskite annealing steps makes it a good candidate for industrialization and upscaling, as it has already been demonstrated in the OLED field. Despite these advantages, tuning the interfaces is essential to reach power conversion efficiencies as high as those achieved by solution processed perovskite solar cells. Metal oxides are an interesting choice for extraction layers due to their improved properties of the perovskite grown on neat and IL-modified surfaces and find that the more n-type perovskite exhibits an order of magnitude lower trap density than the control film. In this work we present our recent advances in using metal oxides as extraction layers optimising the interfaces in order to reach record open circuit voltages in CH\(_3\)NH\(_3\)PbI\(_3\) perovskite and being able to use MoO\(_3\) as extraction layer in both PiN and NiP structures through molecular passivation improving the stability and opening new possibilities for tandem applications. The developed pinhole-free interfaces show a perfect compatibility with the intrinsically large scalable vacuum deposition, making possible the implementation of those into large area devices and mini modules with minimal losses, opening an interesting door for industrial purposes.

5:00 AM *S.EN01.01.06
Photovoltaic Performance of Metal-Halide Perovskites—What is General and What is Special?  Uwe Rau; Forschungszentrum Juelich GmbH, Germany

After many decades of photovoltaic research we would expect that there should be a common scientific understanding on the necessary ingredients to make almost perfect solar cells. However, the unprecedented success of metal-halide perovskites (MHPs) stimulated discussions on whether there could be a certain, yet non-established secret that distinguishes this material from others. The present contribution compares the performance of MHPs to other photovoltaic materials in terms of a general top-down approach. This direct comparison allows one to judge the strengths and weaknesses of different technologies but also gives some insight on the specific achievements, e.g. that, on the one hand, the radiative yield of MHPs is second only to the best GaAs solar cells, which implies open circuit voltages that come close to the thermodynamic limits. On the other hand the relative contribution of fill factor losses to the overall efficiency losses in MHPs is relatively large.
Metal halide perovskites (MHP) are the best solution-processed solar cell device technology to date. While record devices have been achieved using spin-coating, larger area prototype realization requires the translation of processing strategies to scalable deposition methods. An in-depth understanding of how solvent molecules dictate the molecular structure of solution complexes as well as define thin film morphology by being incorporated into crystalline intermediate phases enables rational process optimization. Through in-situ photoluminescence and absorption measurements during spin-coating we were able to identify the formation mechanism of several mixed cation/anion MHP semiconductors that enables us to translate film deposition strategies to scalable process techniques such as inkjet printing and slot-die coating. In-line process monitoring is used to optimize processing parameters to manufacture high-quality MHP semiconductor layers.

We will be presenting results on the fabrication of prototypes of MHP-based devices demonstrating inkjet-printed and slot-die coated small area solar cell devices with power conversion efficiencies > 15% and laser-scribed series interconnected mini-modules of > 12% on active areas > 10 cm². These results will be compared with the collected data of all MHP solar cell devices published that we are currently collecting in an open database through a crowd-sourced effort and that will be launched in spring 2020.

Study of the Anomalous Ambipolar Charge Transport at Hybrid Perovskite- Liquid Electrolyte Interface

Priya Srivastava and Monojit Bag; Indian Institute of Technology Roorkee, India

Manifested by high absorption coefficient, large carrier diffusion length, ambipolar charge transport and moderate mobility of charge carriers, organo-lead halide perovskites recently emerging as promising candidate for high efficiency and low cost solution processed solar cells, needs no introduction. Perovskite Solar Cells (PSCs) have already gathered considerable attention, showing a tremendous hike in efficiency from 3.8% by Kojima et al. (2009) to 22.1% by Yang et al. (2017). A lot of research has been done on the efficiency improvement of PSCs by optimization of the film morphology at the interfaces by various characterization techniques including electrochemical impedance spectroscopy (EIS) in a solid state active device geometry.3 Recently, the optimization of the film morphology at liquid electrolyte interface by EIS is trending as a more simplified approach. Li et. al. have measured the flat band potential, density and type of charge carrier at the perovskite-liquid interface from Mott-Schottky plot for spin coated and spray coated films of methylammonium lead tri-iodide (MAPbI3) perovskite.4 Srivastava et.al have optimized the morphology of MAPbI3 perovskite thin films at liquid interface by controlling nucleation and growth during film fabrication by spin coating the films on preheated substrates.5 However, there is a need of understanding the charge transfer at these interfaces in more detail. Here, we have studied the kinetics of charge transfer and diffusion at the hybrid organic-inorganic perovskite liquid electrolyte interface under the effect of applied bias. By applying the different dc bias from 0 to +1V and 0 to -1V, it was found that the ion diffusion at low frequency regime gets modulated due to strong accumulation. The charge transport resistance is initially increased to a maximum at around 0.4 V applied bias along with the decrease in the space charge capacitance. A transition state is observed at around 0.4 V to 0.6 V due to strong electronic-ion interaction where charge transport resistance decreases and capacitance increases. However at higher applied bias voltage charge transport resistance increases again and capacitance start to decrease due to excess ion accumulation. The perovskite films show similar trend of...
change in impedance under both positive and negative bias. The Mott-Schottky Plot for forward and reverse voltage scan shows n-type and p-type behavior which indicates the ambipolar nature of perovskite semiconductor. The significant difference in the impedance spectra can be seen in dark and light which is attributed to the high absorption coefficient of the perovskite material. We have proposed a model to explain the charge kinetics across the perovskite-liquid electrolyte interface.

Interface Engineering and Defect Passivation in Perovskite Photovoltaics by Implementing Organic Components Ali Buyruk, Thomas Bein and Tayebeh Ameri; University of Munich (LMU), Germany

so far, an enormous progress has been made for perovskite photovoltaics reaching over 23% power conversion efficiencies. The compositional engineering as well as controlling the crystallization process were key factors in achieving such highly efficient devices. However, fundamental problems, such as the toxicity of hybrid lead halide perovskites, hysteresis and structural instability remain to be solved for perovskite solar cells. Indeed, the low-temperature solution-processing of perovskite films inevitably causes formation of a certain amount of defects on the surface and at the grain boundaries, which lead to serious trapping, charge accumulation, and recombination problems as well as stability issue. In this work, we will pursue the interface engineering and defects passivation by introducing organic ammonium salts on the perovskite active layer. We will discuss the origin of crystallization changes and performance improvement of treated devices based on the results achieved from optoelectrical and structural investigations.

High Efficiency Perovskite Solar Cells Shengzhong (Frank) Liu1,2; 1Shaanxi Normal University, China; 2Chinese Academy of Sciences, China

A new type organic-inorganic hybrid perovskite has appeared to be a wonder material for its excellent optical absorption, long range charge-carrier diffusion and apparent tolerance to defects. In the last few years, it has been emerged as a primary candidate material for various photovoltaic, optoelectronic and photoelectronic applications. In just a few years, its solar cell efficiency has been improved from 3.8% to >25%. Moreover, the solar cell fabrication processes based on the planar architecture have been particularly enthusiastic thanks to their low temperature fabrication and compatibility with a range of substrates. Comparing solution deposition with vacuum deposition, the vacuum processes for thermal co-deposition and sequential deposition of PbCl2 and CH3NH3I materials are recognized as efficient means to prepare perovskite film with good uniformity and high surface coverage. A vacuum deposition process has been developed to fabricate high efficiency perovskite solar cells with high stability using alternating layer-by-layer vacuum deposition. The new deposition process allows us to relax the strict deposition monitoring and control measures, while realizing superior uniformity in film morphology, surface coverage and smoothness, together with crystalline phase purity. For the high efficiency perovskite solar cells, the power conversion efficiencies for the planar device is as high as 23.4%. More importantly, we have developed a superior low temperature modified SnO2 material for ETL and transferred the cell fabrication process onto lightweight flexible polymeric substrate. The highest cell efficiency achieved was over 20%, it is also the highest efficiency among the flexible perovskite cells reported. Meanwhile, the devices show very good stability over long term exposure in ambient with very low degradation. After a representative cell was exposed in ambient lab condition for a year, its final cell efficiency is as high as over 95% of its initial efficiency with its degradation accounts for only smaller than 5%. Further analysis on the stability of the perovskite solar cells will be discussed. We have also developed a series of single-crystalline perovskites with superior stability and optoelectronic performance.

Understanding and Tailoring Interface Microstructures of Halide Perovskites
Yuanyuan Zhou; Hong Kong Baptist University, Hong Kong

Microstructures of various interfaces (grain boundaries, heterophase interfaces, etc.) in halide perovskite materials/devices play very significant roles on the physical properties and optoelectronic functions. While enormous effort has been devoted to modifying the HP interfaces for better device performance, the insights into the interface microstructures and their exact role in devices have been obscured. In this talk, I will first present a fundamental discussion on HP interface microstructures from a materials-science perspective. Then, I will demonstrate several unique chemical approaches to tailor the HP interface microstructures in a precisely-controlled manner, which will not only lead to electronic passivation of defects, but also endow these interfaces with new functions. Finally, I will share my perspectives about future research in this promising direction.

5:00 AM *S.EN01.01.14
At the Interface—Probing the Energetic Alignment and Composition between Perovskites and Charge Extraction Layers
Selina Olthof; University of Cologne, Germany

In recent years, the interest in halide perovskites rose at a rapid pace due to their tremendous success in the area of photovoltaics; but other fields, like light emitting diodes, show great potential as well. In optoelectronic devices, the function and performance depend crucially on the proper alignment of the energy level landscape throughout the device, i.e. allowing for efficient charge transport across the various interfaces. In perovskites it turned out that these interfaces can be rather complex. On the one hand, interface dipoles and band bending occur. But more importantly, the perovskite composition and formation can be significantly influenced by chemical reactions taking place at these interfaces. In this talk I will show how UV as well as X-ray photoelectron spectroscopy measurements can help to probe and understand the processes going on at the various bottom contact materials. Intriguingly, clear differences are found between the formation of interfaces to organic materials and to metal oxide; furthermore, the perovskite processing (i.e. solution vs. evaporation) as well as the perovskite composition play significant roles as well.

5:00 AM S.EN01.01.15
Characterization of Electrical Properties of Perovskite Solar Cells—The Impact of Charge-Transport Layers
Rasha A. Awni1, Zhaoning Song1, Cong Chen1, Chongwen Li1, Changlei Wang1, Mohammed Razooqi1, Lei Chen1, Xiaoming Wang1, Randy J. Ellingson1, Jian V. Li2 and Yanfa Yan1; 1University of Toledo, United States; 2National Cheng Kung University, Taiwan

The electrical properties of metal halide perovskite solar cells (PSCs) have been intensively studied by many researchers using capacitance-based techniques such as thermal admittance spectroscopy (TAS) and capacitance–voltage (C–V) measurements. The capacitance–frequency–temperature (C–f–T) spectra of PSCs reported in the literature [1-4] typically show two capacitance signatures, one at high frequency (> 10^5 Hz) and the another at low frequency (> 10^3 Hz). These capacitance signatures have been used to evaluate the properties of defects in PSCs [1-5]. Here, we show that the charge-transport layers (CTLs) in PSCs can have significantly influence on the capacitance signatures. We find that the capacitance signature at high-frequencies and low temperatures is due to the trap and detrap of charged carriers in the hole-transport layer (HTL). We further show that high-frequency capacitance measured from HTL-free PSCs represents the geometric capacitance, allowing a reliable calculation of the dielectric constant of perovskite layers. The presence of HTL in PSCs leads to apparent temperature dependent dielectric constant [3], due to the capacitance contribution of HTL. The low-frequency capacitance signature can be used to characterize the ionic transport properties of the perovskite layer. However, to ensure meaningful results, the capacitance coupling between perovskite layer and CTLs must be carefully avoid, by choosing the appropriate CTLs and device configuration. Our results explain well the large discrepancies of electrical properties of perovskites reported in the literature.

5:00 AM S.EN01.01.18
Modeling Recombination Mechanism in Perovskite Solar Cells by Simulating Temperature-Dependent Transient Light Ideality Factor Spandankumar H. Ranpariya and Dhirendra K. Sinha; Indian Institute of Information Technology Vadodara, India

This decade witnessed rapid progress in the development of organic-inorganic hybrid lead-halide perovskite-based solar cells. In particular, this class of solar cells showed high power conversion efficiency and significant potentiality to realize a low-cost terawatt-scale power generation. This is mainly due to its high optical absorption coefficient with sharp absorption onset, long charge-carrier lifetime, tunable band-gap and low-cost fabrication. However, despite advancement in the device performance, the underlying physics of charge-carrier dynamics needs important attention to develop insight into the performance bottlenecks and thereby better control and optimization over the device performances. Among the performance bottlenecks, the charge-carrier recombination is considered to be one of the dominant mechanisms that limit solar cell behavior. Therefore, in this work, the underlying interest is to propose a phenomenological model of recombination by simulating the temperature-dependent transient light ideality factor. We consider a standard sandwich device structure with CH3NH3PbI3 as an active layer. The Spiro and TiO2 are taken as hole- and electron-transporting layers, respectively. We utilized one-dimensional drift-diffusion equation to simulate transient open-circuit voltage Voc (t) with varying light-intensity, Φ between 0.2 to 2.0 Sun-equivalent and device temperature, T between 100 to 300 K. The transient light ideality factor, nid (t) is determined by evaluating the slope of the plots between Voc (t) vs ln(Φ). The plot of temperature-dependent transient light ideality factor shows a fast rise in its value between the temperatures 100 to 150 K and tends slowly towards 2.0 at room temperature and above. The observations clearly indicate that the recombination of charge-carriers are predominantly due to trap-states, interfacial or bulk, activated at higher temperatures. The work shed light on the recombination mechanisms in such class of solar cells and their alternative variants.

5:00 AM S.EN01.01.21
Exploring Halide Perovskite Structural Tunability to Design Materials for Dynamic Photovoltaic Windows Jeffrey A. Christians and Elizabeth V. Cutlip; Hope College, United States

Halide perovskites offer exciting potential as photovoltaic materials and simply as semiconductors. Specifically, their structural tunability has become of greater interest as researchers begin to search for novel ways to tune the materials to achieve improved solar cell stability or to target new applications. One potential technology which halide perovskites could enable is dynamically switchable photovoltaic windows, windows which a user can transition between photovoltaically active (dark) and non-photovoltaic (transparent). We build toward this goal in this work by investigating the intercalation and deintercalation of methylamine gas into 2-dimensional Ruddelson-Popper phase halide perovskites. As has been shown with methylammonium lead iodide films, the intercalation of methylamine into the halide perovskite lattice results in a color change to a clear crystal phase. We find that in some 2-D perovskite systems, deintercalation of the methylamine gas is incomplete, resulting in the formation of some CH3NH3PbI3; however, other 2-D perovskite phases show reversible intercalation/deintercalation with methylamine, indicating stronger binding between the long-chain ligand and the lead halide octahedra of the 2-D perovskite sheet. When integrated into a hybrid 2-D/3-D structure of the type A’2(CH3NH3)nPbnI3n+1, where A’ is a strongly binding R-NH3+ moiety such as phenethylammonium (PEA), these materials show promising reversibility for methylamine intercalation/deintercalation with little change in absorption or morphology. This work reveals the relative affinity of various R-NH3+ molecules for the halide perovskite lattice, showing that many of these are not replaced by methylamine, and indicates that templating the 3-D CH3NH3PbI3 structure with long-chain ammonium cations could lead to better reversibility in dynamic photovoltaic windows.
We tackle the individual and combined effects of extrinsic (humidity and oxygen) and intrinsic (light, bias, and temperature) stressors on halide perovskite materials by implementing photoluminescence (PL) under environmentally controlled conditions. These experiments are critical to assess the stability of the large variety of perovskite materials available for light-absorbing and -emitting applications. We clarify the influence of distinct humidity levels on the charge carrier recombination in Cs$_x$FA$_{1-x}$Pb(I$_y$Br$_{1-y}$)$_3$ perovskites through in situ PL, where we temporally and spectrally measure light emission within loops of critical relative humidity (rH) levels. Our results demonstrate that the Cs/Br ratio strongly affects the spectral stability of light emission hysteresis, as well as its extent. The photo-emission dynamics in metal halide perovskites with both I and Br is also interrogated by environmental PL, where we find that the presence of Br suppresses hysteresis. The isolated effects of both temperature and photon excitation energy are also investigated. To pursue optimal ‘rest’ and ‘recovery’ conditions for device stable operation, we propose the implementation of a machine learning approach based on supervised learning combined with PL measurements upon exposing the samples to distinct values of humidity, oxygen, illumination, bias, and temperature, which will be discussed in details.

Commercialization of perovskite solar cells is dependent upon improving the stability of these devices. It has been shown that global average stress of a perovskite film is one significant contributing factor to its degradation rate. The global average stress of a perovskite film is mainly determined by two components: 1) the thermal expansion coefficient mismatch between the perovskite film and the substrate and 2) the temperature at which the perovskite is formed. Most perovskite films are made on a glass substrate, whose thermal expansion coefficient is about an order of magnitude smaller than the perovskite film. They are commonly formed at temperatures around or above 100°C, resulting in residual tensile stresses of over 50 MPa in the film.

We show that due to the convolution of the effects of stress on degradation with classic thermal degradation, the resulting degradation rate of a perovskite film is not Arrhenius. Stress is relieved at higher temperatures, reducing the degradation rate due to stress, which directly competes with the increasing degradation rate due to increased thermal energy for exceeding an energetic barrier associated with the degradation reaction. We use in-situ temperature dependent X-Ray Diffraction Spectroscopy to measure the degradation rate of perovskite films at multiple temperatures. The degradation rate of the perovskite film is measured by monitoring the growth of a PbI$_2$ peak and the regression of a perovskite peak.

Additionally, we directly measure the global average stress of a perovskite film as a function of temperature using in-situ temperature dependent profilometry to measure the changes in substrate curvature. The stress in a perovskite film changes with the temperature of the substrate even after the film is initially formed.

We show that the convolution of the effects of stress on degradation with classic thermal degradation, the resulting degradation rate of a perovskite film is not Arrhenius. Stress is relieved at higher temperatures, reducing the degradation rate due to stress, which directly competes with the increasing degradation rate due to increased thermal energy for exceeding an energetic barrier associated with the degradation reaction. The stress in a perovskite film changes with the temperature of the substrate even after the film is initially formed.

While the efficiency of metal halide perovskite (MHP) solar cells and light-emitting diodes continues to increase, their stability remains a critical challenge. Optical and electrical dynamics with varying degrees of reversibility arise in the presence of isolated or combined intrinsic (light, temperature, bias) and extrinsic (oxygen, water) operating factors [1]. My talk will discuss our investigations into the transient behavior of common MHP compositions, along with the ongoing implementation of statistical and machine learning techniques to predict these effects. First, we highlight our investigation into dynamics induced by environmental factors, such as light and moisture. For the archetypal MAPbI$_3$ and MAPbBr$_3$ (MA = CH$_3$NH$_3$) perovskites we investigated the impact of illumination wavelength on surface photovoltage with Kelvin probe measurements [2]. For each composition, we record the transient voltage throughout an OFF-ON-OFF light cycle. Interestingly, after turning the light OFF, MAPbBr$_3$ displays a wavelength-dependent voltage decay 10x slower than the I-containing film, which exhibits no effects due to photon energy. Concerning moisture, we evaluated the in situ light-emission response of MAPbI$_3$ and MAPbBr$_3$ across multiple humidity cycles using micro-photoluminescence (micro-PL) [3, 4]. Our results establish that the intercalation of water molecules into the perovskite lattice depends on the lattice constants, with the I-based composition showing a 6× increase at 40% relative humidity (rH) while the Br-containing samples register a 15× enhancement at 65% rH. Subsequent dehydroxylation of the MHP thin films returns the PL intensity to their original values. Our results, along with those from many other research groups, clearly establish that the issue of stability, or lack thereof, in perovskites calls for the ability to model and predict performance as a function of time. This includes times series forecasting of fundamental properties, such as photoluminescence and photoconductivity, as well as the overall macroscopic power output. With examples of their dynamics already introduced, I focus the second half of my talk on the implementation and evaluation of statistical and machine learning methods for predicting perovskite behavior. We explore and optimize standard methods, such as multiple linear regression, autoregressive integrated moving average (ARIMA), and echo state networks (ESN) on our rH-PL measurements, as well as J-V datasets from the literature. We provide a powerful analytical framework for evaluating any time-dependent MHP phenomena and, thus, tackling the open problem of stability. Our in situ measurements are a critical platform for informing the fabrication of devices with improved stability and the associated data analytics may serve as an essential tool for effectively predicting perovskite PV performance. We foresee further integration between combinatorial studies, in situ characterization, and predictive analytics, where all data streams can be collated as input for algorithms that optimize compositional tuning for sustained efficiency.

5:35 AM S.EN01.02.05
Active-Rest-Recovery Cycle in Metal-Oxide Based Semi-Transparent Perovskite Solar Cells Enabling Long-Term Stability Yuanhang Cheng$^1$, Chenchao Xie$^{1,2}$, Ho-Wa Li$^3$ and Fen Lin$^1$; 1Solar Energy Research Institute of Singapore(SERIS), National University of Singapore, Singapore; 2National University of Singapore, Singapore

Despite the rapid development in power conversion efficiency (PCE) from 3.8% to 25.2% within ten years, the long-term stability of perovskite solar cell (PVSC) severely hinders its commercial deployment. Herein, we have systematically studied the long-term stability of NiO$_x$ based p-i-n structured PVSCs. After aging at maximum power point (MPP) under AM 1.5 G illumination, the PVSCs with organic interlayer (bathocuproine, BCP) and Ag electrode exhibit permanent degradation due to BCP failure and Ag diffusion. To address the above stability issue, an aluminum-doped zinc oxide (AZO) layer was employed as buffer layer to replace BCP and an indium tin oxide (ITO) layer was sputtered as top electrode to replace Ag. With this metal-oxide based structure, the long-term stability of the PVSCs has been significantly enhanced retaining 95% of its initial PCE after 30 days aging in glovebox. Furthermore, the PCE of metal-oxide based PVSCs exhibit active-rest-recovery (ARR) cycles under MPP tracking testing. During the active phase, the PVSCs produce output power under AM 1.5 G illumination at MPP and the device performance degrades gradually. Interestingly, the PVSC recovers to its initial PCE repeatedly after a rest phase under dark condition. Optoelectronic investigations such as electroabsorption (EA) and capacitance-frequency (CF) have illustrated that the ion migration within perovskite bulk is the origin of the ARR cycle. Finally, combining with an efficient Si bottom cell, a perovskite/Si 4T tandem solar cell with over 23% efficiency has been
achieved. We anticipate the metal-oxide based PVSCs and the degradation mechanism demonstrated here would give credible impetus for developing long-term stable perovskite for both single junction and tandem applications.

In Situ Analysis and Process Control of the Drying Dynamics in Blade Coated Hybrid Perovskite Solution Films
Simon Ternes, Tobias Börnhorst, Jonas A. Schweizer, Ihteaz M. Hossain, Felix Laufer, Thomas J. Feeney, Ulrich W. Paetzold; Karlsruhe Institute of Technology, Germany

In the last decade, hybrid perovskite photovoltaics have emerged as a promising new thin-film technology, capable of solution processing, with champion power conversion efficiencies (PCEs) exceeding 25% on a laboratory scale. The ability to solution process, coupled with an abundance of precursor materials, enables the fabrication of low-cost, large-area modules, either in a single junction configuration, or as a tandem solar cell utilizing established commercial photovoltaics, such as silicon and CIGS. However, PCEs of perovskite solar cells fabricated by scalable deposition techniques such as blade coating, spray coating or inkjet printing are consistently inferior to the record PCEs obtained from lab-scale spin coated devices. To overcome losses when transitioning to scalable deposition technologies, efficient optimization strategies are required.

As a novel strategy, we demonstrate simultaneous in situ thickness monitoring at multiple probing positions and exact drying control for a blade coated perovskite film. Control of the drying is established by a laminar air flow around a wing-shaped substrate holder in a flow channel, while in situ characterization is performed by five diode lasers, each with a respective photodiode probing the reflectivity of the film over time. This unique combination, simultaneously controlling and monitoring the drying process, ensures that the environment parameters of the fabrication process are exactly defined. Therefore, it becomes possible to derive an analytical drying model for perovskite solution films, using fundamental kinetic and thermodynamics equations. This model can accurately describe the measured, dynamic shrinkage of the film thickness during solvent evaporation in line with the inherent chemical properties of the perovskite solution. Because the mass transfer coefficients are precisely controlled, the model can be applied to arbitrary industrial-scale drying machines, for which these coefficients are mostly known.

In order to illustrate the relevance of the strategy presented here, we determine the optimal drying conditions for blade coated methylammonium lead iodide films incorporated into solar cells with the planar architecture ITO/SnO2/perovskite/Spiro-MeOTAD/Au. Obtained PCEs and measured polycrystalline perovskite morphologies demonstrate a clear correlation with the drying parameters of substrate temperature and air flow velocity. Although both temperature and air flow velocity can control the drying speed, their effects on the crystal growth are fundamentally different. Obtaining a pinhole-free perovskite film and a high PCE requires restricting these variables to a distinct processing window. At optimal drying conditions, champion PCEs of 19.5% (as measured by the backward IV) and champion stabilized PCEs of about 17.3% are reached. These device PCEs do not differ significantly from those obtained from entirely spin coated devices fabricated with the same cell architecture from the same precursor solution. This equivalent device performance is evidently an example of an optimal process transfer from lab-scale spin coating to scalable blade coating fabrication method.

In summation, we provide a sophisticated upscaling strategy based on a fundamental understanding of the drying process in perovskite solution films. The derived drying model enables the prediction of the polycrystalline perovskite thin-film morphology for an arbitrary drying machine prior to experimental testing of the system. In future works, additional characterization methods will be explored to extend the model to apply beyond the onset of the crystallization process. More detail on the described work can be found in the original, open access paper "Drying Dynamics of Solution-Processed Perovskite Thin-Film Photovoltaics: In Situ Characterization, Modeling, and Process Control" published in Advanced Energy Materials / Volume 9, Issue 39, October 17, 2019.

Carbon Materials for Perovskite Solar Cell Applications
Wei Zhang; University of Surrey, United Kingdom

Perovskite solar cells are emerging candidates for next-generation thin-film photovoltaic technologies with the potential of extremely low fabrication cost and highest power conversion efficiency. Over the last decade, perovskite solar cells have gone through a rapid development in device efficiency from an initial 3.8% to a most recently certified 25.2%, though the challenges of long-term stability and lead toxicity still remain. Beyond the concerns in stability and lead toxicity, the cost of widely used materials such as ITO and Spiro-OMeTAD for high efficiency devices becomes another obstacle for the commercialization of perovskite solar cells in the near future. Carbon materials, ranging from zero-dimensional carbon quantum dots to three-dimensional carbon black materials, are promising candidates for reducing the material cost meanwhile boosting both efficiency and stability of perovskite solar cells, offering unique advantages for incorporation into various device architectures. In this talk, we will present a concise overview of important and exciting advancements of perovskite...
solar cells that incorporate different dimensions of carbon materials in their device architectures, followed by the research progress in our group utilising carbon materials (nanotubes and graphene) for a range of perovskite solar cell applications in an effort to simultaneously reduce the material cost and improve the long-term stability. We will discuss the major advantages and potential challenges of each technique that has been developed in our most recent work. Finally, we outline the future opportunities towards low-cost, efficient and stable perovskite solar cells utilising carbon materials.

Correlating Microstructure with Optoelectronic Properties to Enable Open-Air Fabrication of Stable Perovskite Solar Modules
Nicholas Rolston, Austin Flick, Hannah Elmaraghi, Justin Chen, William J. Scheideler, Oliver Zhao, Jinbao Zhang and Reinhold H. Dauskardt; Stanford University, United States

Hybrid organolead-halide perovskite materials, with their remarkable optoelectronic properties, hold real promise for use as the active layer in low-cost next-generation solar cells. High-throughput open-air fabrication methods offer low capital-expenditure routes to continuous manufacturing of perovskites, but achieving reproducibility with ambient conditions and varying relative humidity (RH) has been a persistent challenge for achieving high performance and device stability. Our group has recently developed a Rapid Spray Plasma Processing (RSPP) method, where perovskite films are spray coated and immediately exposed to an open-air plasma at an ultrafast linear processing rate > 10 cm/s. The combination of reactive species (ions, radicals, metastables, and photons) and convective thermal energy produced by the plasma enables rapid (~100 ms) crystallization with high tolerance to RH.

In this work, we first control the plasma dose to vary curing kinetics and grain size in open-air spray coated Cs$_{1.7}$FA$_{0.3}$Pb(Br$_{1.7}$I$_{0.3}$)$_3$ perovskite films. We then correlate microstructure with carrier lifetime and photoluminescence measurements to show the relationship between curing source (room-temperature gas vs plasma), grain size, and film roughness on carrier dynamics and recombination. Improved steady-state photoluminescence is observed for plasma curing, an effect that is independent of microstructure and is attributed to the quenching of trap states during film deposition from the plasma. However, a strong correlation is observed between microstructure and carrier lifetimes: increased grain size in the plasma-cured perovskite films results in lifetimes > 1000 ns—exceeding spin-coated films fabricated in a glovebox by 5X—and suggesting that RSPP perovskite films have a lower defect density.

By optimizing plasma dose to produce perovskite films in 12.5 cm$^2$ series-connected perovskite modules, we demonstrate >14% stable power output fabricated entirely with scalable deposition processes of spray coating and evaporation. We identify smooth morphologies (Rq < 30 nm) as a key parameter to enable module stability under both maximum power point tracking and accelerated humidity (25°C, 70% RH) and heating (85°C, 25% RH) conditions for >100 hours without encapsulation. The control of microstructure using RSPP therefore improves optoelectronic properties, module performance, and stability compared to traditional spin coating.

SESSION S.EN01.03: Upscaling and Industrial Considerations

Scalable Fabrication of High-Quality Crystalline and Stable FAPbI$_3$ Thin Films
Maria Antonietta Loi; University of Groningen, Netherlands

Formamidinium lead iodide (FAPbI$_3$) is one of the most extensively studied perovskite materials due to its narrow band gap and high absorption coefficient, which makes it highly suitable solar cells applications. Deposition from a solution containing lead iodide (PbI$_2$) and formamidinium iodide (FAI) or by sequential deposition of PbI$_2$ and FAI usually leads to the formation of films with poor morphology and unstable crystal structure that readily crystallizes into two different polymorphs: the yellow phase and the black phase. I will show that, 2D 2-phenylethylammonium lead iodide (PEA$_2$PbI$_4$) thin films deposited by a scalable doctor-blade coating technique can be used as a growth template for the high-quality 3D FAPbI$_3$ perovskite thin films, by organic cation exchange. I will discuss the structural, morphological and optical properties of these converted 3D FAPbI$_3$ perovskite films, comparing them to the properties of directly deposited 3D FAPbI$_3$ films. The converted FAPbI$_3$ thin
films are compact, smooth, highly oriented and exhibit better structural stability in comparison to the directly deposited 3D films. These results not only underscore the importance of the employed deposition techniques in the formation of highly crystalline and stable perovskite thin films but also reveal a strategy to easily obtain very compact perovskite layers using doctor-blade coating.

5:15 AM *S.EN01.03.03
Progress in Materials and Process of Perovskite Solar Cells toward Commercialization  
Hyun Suk Jung and Hyunjung Shin; Sungkyunkwan University (SKKU), Korea (the Republic of)

All solid-state solar cells based on organometal trihalide perovskite absorbers have already achieved distinguished power conversion efficiency (PCE) to over 25% and further improvements are expected up to 27%. Now, the research on perovskite solar cells has been moving toward commercialization. To facilitate commercialization of these great solar cells, some technical issues such as long-term stability, large scale fabrication process, and Pb-related hazardous materials need to be solved. Also, flexible perovskite solar cell using plastic substrate can be used in niche applications such as portable electrical chargers, electronic textiles, and large-scale industrial roofing.

This talk is dealing with our recent efforts to facilitate commercialization of perovskite solar cells. For examples, we introduce a recycling technology of perovskite solar cells, which covers the regeneration process of Pb contained perovskite layer as well as recycling process of Au electrodes and transparent conducting oxide glass. Also, recent interesting results regarding ultra-flexible perovskite cells will be discussed in terms of stress analysis. Finally, simple fabrication technologies for realizing large scale perovskite module is going to be introduced.

Combinatorial Sputtering and Characterization of Computationally Predicted Ternary Nitrides in the Magnesium-Antimony-Nitrogen Phase Space  
Karen Heinselman1, Stephan Lany1, John D. Perkins1, Kevin Talley2 and Andriy Zakutayev1; 1National Renewable Energy Laboratory, United States; 2Colorado School of Mines, United States

Nitrides provide a rich, and generally underexplored, field of chemistries for solar energy conversion, with many of them displaying excellent optoelectronic, electronic, and mechanical properties, as well as chemical stability. Prediction of ternary nitrides via computational modeling can significantly streamline the materials discovery process. First principles calculations were used to facilitate materials discovery within the Mg-Sb-N phase space, providing crystal structures to compare to and a predicted chemical potential phase diagram to help tune parameters. Guided by these predictions of favorable phases and the required conditions to achieve them, radio-frequency (RF) magnetron co-sputtering was used to deposit the films. The computationally predicted Mg$_2$SbN$_3$ phase, which has a wurtzite-derived structure, and a lattice constant similar to that of GaN, has been experimentally synthesized for the first time [1]. In addition, the antiperovskite Mg$_3$SbN phase, which has previously been seen only in bulk form, has been grown as a thin film. This Mg-rich phase has a variety of predicted properties ideal for photovoltaics, such as a large dielectric constant, low effective masses, and a measured near-gap PL at room temperature, at around 1.3 eV. Both of these phases show up within the same combinatorial sample across the spread of Mg to Sb.

5:40 AM S.EN01.03.05
Directed Mesoscale Self-Assembly of 3.0 nm Diameter, Fully-Inorganic Perovskite Nanocrystals into Hierarchical Superstructures  
Jacob Lee and Rajesh Sardar; Indiana University Purdue University Indianapolis, United States

Due to quantum confinement effects, nanoscale materials offer vastly different optoelectronic properties from their bulk counterpart. In the last decade, one promising nanomaterial that has emerged is the perovskite which has a crystal structure of ABX$_3$ where A and B are metallic cations and X is a halide anion. Perovskites have shown extremely large molar absorptivity, high quantum yield photoluminescence, wide visible spectral coverage, and large defect tolerance that together make them ideal for many optoelectronic applications including photovoltaics, light emitting diodes, and lasing. To maximize device applicability, monodispersed nanocrystals (NCs) must be synthesized and then assembled into superstructures over multiple length scales. Currently, most syntheses control the size of NCs by using long aliphatic surface passivating ligands which are inherently insulating molecules and create a barrier for interparticle electronic interactions. To overcome these challenges, we have synthesized nearly monodispersed (~3 nm) CsPbX$_3$ NCs (X = Cl, Br, and I) with poly(ethylene glycol)6 (PEG6–NH$_2$/COOH) surface passivating ligands. We selected PEG6 ligands because they offer several unique advantages including increased conductivity through electron dense oxygen atoms and their effectiveness to lead to hierarchical superstructure formation. Importantly, by varying the PEG concentrations in the reaction mixture, we control the mesoscale
assembly of our NCs from lamellar to nanorice structures. Interestingly, these mesoscale assemblies result in a band gap variation of 240 meV with the same ~3 nm NCs due to the delocalization of the exciton wavefunction. We believe that the dipole-dipole interactions between NCs, along with van der Waals attractions between PEGs, induce the mesoscale assemblies. Furthermore, these mesoscale assemblies form micron length twisted ribbon superstructures. Thus, by using polymer assisted forces at the nano- and meso- scales, we synthesize various CsPbX$_3$ NCs assemblies, which interact collectively through exciton wavefunction delocalization providing a pathway to enhance future device applications.

5:50 AM S.EN01.03.06
The Development of a Tamper Indicating Toolbox: Monitoring Degradation of Silica Sol-Gel Materials through the Use of Piezoelectrics Angela Suriyakumaran$^{1,1}$, Anthony J. Croxford$^1$, Sean A. Davis$^1$ and Ian Hayes$^2$; $^1$University of Bristol, United Kingdom; $^2$AWE Plc, United Kingdom

The integration of ultrasonic monitoring techniques with silica sol-gel materials, for the purpose of tamper indication, presents a novel set of challenges and with it, various solutions through integration of both fields. Tamper indication plays a vital role in the dismantlement of nuclear equipment by ensuring that the integrity of the stored equipment can be maintained.

Due to the responsive nature of sol-gel silica, it has the potential to be used as a visual indicator of tamper as sealants. In this research, the sol-gel precursor samples are synthesised using tetramethyl orthosilicate (TMOS) as a precursor and a base catalyst to amplify the effects of tamper. However, this technique can be subject to human error, therefore to alleviate such problems, ultrasounds will be explored in conjunction with the sol-gel chemistry. Ultrasounds has been used within the field of structural health monitoring (SHM) due to its high sensitivity and non-destructive nature. Piezoelectric materials are used to transmit the acoustic waves through a sample, as well as, receive any waves reflected back from the samples or any present defects. The combination of these techniques has not previously been fully explored, so the aim of this research is to develop a highly effective and accurate interdisciplinary method of tamper indication.

Metastable sol-gel formulations show shrinking and fracturing upon solvent evaporation but varying the catalyst concentration can tailor the material stability, so an appropriate concentration was decided upon. Initial experiments were then done to check compatibility of the piezoelectric transducer with the sol-gel formulations. After which, bulk wave transducers were used to test out the responsiveness of the system to sol-gel degradation. Results indicate that it is possible to use these piezoelectric transducers to monitor these sol-gel degradation points, as well as, determine the point of exposure.

The presentation will explore the capabilities of the ultrasonic components to monitor the degradation of sol-gel formulations during simulation of a tamper, as well as, the challenges overcome to ensure integration of both materials.

High-Performance Ternary Alkali Nitrides for Renewable Energy Applications Jiban Kangsabanik and Aftab Alam; Indian Institute of Technology Bombay, India

Rapid decline in fossil fuel energy necessitates the immediate need for renewable energy resources. Here, we report a previously unexplored class of nitrides AMN$_2$ (A=Na, K, Rb, Cs, M=V, Nb, Ta) keeping renewable energy applications in mind. Using a detailed structure and stability analysis using first principles simulation, we discovered twelve such compounds (few of which were already synthesized before), which are chemically, mechanically, and dynamically stable. These twelve compounds were then evaluated for their suitability for three renewable energy applications: (i) photovoltaics, (ii) water splitting, and (iii) thermoelectrics. Careful analysis of electronic structure reveals high optical transition strength resulting in a sharp rise in absorption. This in turn yields high short circuit current and hence excellent solar efficiency for a few compounds namely CsVN$_2$ and RbVN$_2$. Along with excellent absorption quality, some compounds show favorable band edge positions compared to water redox levels and hence are promising as photoelectrodes in photo(electro)chemical water
splitting devices. Mixture of flat and dispersive bands in the band structure yields both high Seebeck and electrical conductivity, thus an excellent power factor for six compounds. Simulated lattice thermal conductivity shows moderate to ultralow values and thus the possibility of achieving a high thermoelectric figure of merit (ZT), even at lower temperatures. From the experimental perspective, we discuss the possible challenges that may arise while utilizing these compounds for the desired applications and suggest possible pathways to overcome them. We believe such theoretical prediction of promising materials is extremely useful for new materials discovery and anticipate rapid response from the experimental community.

5:00 AM S.EN01.04.01
The Role of Dimethylammonium in Bandgap Modulation for Efficient All-Perovskite Tandem Solar Cells
Giles Eperon1, Tomas Leijtens2, Axel F. Palmstrom1, Taylor Moot1, Michael D. McGehee3, Joseph Luther1, David Moore1 and Joseph J. Berry1; 1NREL, United States; 2Swift Solar, United States; 3University of Colorado Boulder, United States

Multijunction all-perovskite solar cells offer a route towards efficiencies of III-V materials at low cost by combining the advantages of low thermalization loss in multijunction architectures with the beneficial properties of perovskites - namely low processing cost, high throughput fabrication, and compatibility with flexible substrates. One of the main limitations of all-perovskite tandems is the difficulty in achieving stable, high voltages with the wide bandgap subcell. Voltage losses in wide gap perovskites are generally high due to iodide-bromide segregation; mixing iodide and bromide on the X-site is the most common way to achieve the bandgaps of 1.7-1.85eV suitable for tandems. Here, we demonstrate a bandgap tuning strategy based on incorporating A-site cations of mismatched size, namely dimethylammonium (DMA) and cesium cations. This increases the bandgap and therefore reduces the amount of bromine needed to attain a certain bandgap. We achieve a band gap of 1.7eV with a bromine concentration of only 20%, minimizing photoinduced halide segregation. We find that this strategy results in higher voltages and efficiencies that are stable under operation.

Surprisingly, we find that adding either DMA or cesium alone produce increases in bandgap. While cesium shrinks the lattice (as would be expected for an increase in bandgap), adding DMA causes the lattice to expand but still produces a bandgap increase. We will discuss the nature of this unusual mechanism and its use for further advances in high voltage wide bandgap devices. We will discuss the latest results demonstrating excellent stability of the DMA-containing materials under operation, thermal stress, and the combination of the two.

The robust and efficient nature of the DMA-containing wide bandgap materials makes them perfect for use in all-perovskite tandems. By combining these cells with advances in atomic layer deposition for robust and stable interlayers, we have fabricated two-terminal all-perovskite tandem solar cells with over 23% PCE; we will also discuss the latest developments in all-perovskite tandems.

5:10 AM S.EN01.04.02
Effects of Interfacial Reaction at Metal Oxide Interface on Perovskite Stability and Degradation Pathway
Sampreetha Thampy, Boya Zhang, Weijie Xu and Julia W. Hsu; The University of Texas at Dallas, United States

Addressing the stability of organic-inorganic perovskite solar cells (PSCs) is needed to propel PSCs towards commercialization. Due to the inherent chemical reactivity of halide perovskites, most efforts have focused on improving their stability due to environmental agents. In contrast, intrinsic instability, including possible reaction between perovskite layer and contact materials in a device, has not been examined closely. Previously we showed that the stability is lowered and decomposition reaction is altered in methylammonium iodide (MAI) and methylammonium lead iodide (MAPbI3) when they are in contact with NiO, but no change was observed when contacting TiO2. In this talk, we will present a comprehensive study on thermal stability and degradation pathway in neat formamidine hydroiodide (FAI) versus when it is in contact with NiO or TiO2. Using a combined temperature programmed desorption-mass spectrometry-Fourier transform infrared spectroscopy apparatus, we observe that the bulk decomposition of FAI powders proceeds with the formation of triazine (C3H3N3) and hydrogen cyanide (HCN) as the major gas products at 265 °C while ammonia (NH3) gas evolve above 300 °C. However, when FAI is mixed with NiO nanoparticles, the decomposition temperature lowers to 172 °C with NH3 and water...
vapor releasing first, whereas C\textsubscript{2}H\textsubscript{3}N\textsubscript{3} and HCN are released at 243 °C. The releasing of NH\textsubscript{3} and water vapor at low temperature, which is absent when FAI is by itself, indicate interfacial reactions. Moreover, studies on FAI and FAI/NiO\textsubscript{x} films show that the interfacial stability of films is further lowered to ≤ 150 °C, much lower than powder samples. These findings emphasize that interfacial reactions can be significant at typical processing conditions of FAI based perovskite devices and can induce intrinsic degradation in perovskite devices. We will explain the experimental results based on thermodynamic free energy calculations and propose mitigation strategies.

5:20 AM S.EN01.04.03
Triple Halide Perovskite Absorbers for >27% Perovskite/Silicon Tandem Solar Cells with Excellent Stability

Berry\textsuperscript{2}, Joseph Luther\textsuperscript{2}, Zachary C. Holman\textsuperscript{2} and Michael D. McGehee\textsuperscript{1,2}; 1Stanford University, United States; 2National Renewable Energy Laboratory, United States; 3University of Science and Technology of China, China; 4University of Colorado Boulder, United States; 5Arizona State University, United States

Wide bandgap metal halide perovskites are promising candidates to pair with low bandgap silicon, copper indium gallium diselenide, or perovskite photovoltaics for highly efficient next-generation tandems due to their excellent optoelectronic properties, low-cost manufacturability, and bandgap tunability.(1) However, wide bandgap perovskite solar cells have larger open circuit voltage deficits than their low or medium bandgap counterparts due to both their inferior charge carrier diffusion lengths and photoinduced halide phase segregation into high bandgap (bromine-rich) and low bandgap (iodine-rich) domains.(2) Here, we overcome these material challenges by alloying chlorine into the perovskite lattice to create a triple halide perovskite absorber, a phase space that has thus far been overlooked. Using x-ray diffraction and external quantum efficiency onsets, we show that chlorine is incorporated into the lattice in molar amounts up to 15% and increases the bandgap of the alloy to a greater extent than addition of bromine or cesium, which are commonly used in perovskite bandgap tuning. Importantly, the addition of chlorine drastically improves the optoelectronic properties of the material, resulting in doubled charge carrier mobilities and lifetimes. We show that a 1.67 eV wide bandgap triple halide perovskite does not experience photoinduced halide phase segregation as determined by photoluminescence at laser intensities up to 100 suns. Finally, we incorporate the triple halide perovskite absorber into solar cells, obtaining >20% efficient single junction devices with open-circuit voltages >1.2 V and 1 cm\textsuperscript{2} monolithic perovskite/silicon tandem solar cells with voltages approaching 1.9 V and efficiencies >27%, exceeding the silicon single-junction record.(3) Solar cells with the triple halide perovskite absorber retain 95% of their initial efficiency under maximum power point tracking at 60°C under white light illumination for 1000 hours.

5:30 AM *S.EN01.04.04
Band Gap Tuning of Perovskite Semiconductors and Insights from a Device Simulator that Includes Affects Associated with Mobile Ions
Michael D. McGehee; University of Colorado, United States

Our progress at developing both low and high band gap perovskites for tandem solar cells will be presented. We have made highly stable low band gap cells with greater than 19 % power conversion efficiency and triple halide high band gap cells with > 20 % stability that do not suffer from light-induced phase separation.

We will also show drift-diffusion modeling results that take into account how mobile halogen vacancies modify the electric field within perovskites. We have input reasonable ranges of charge carrier mobilities, bulk recombination rate constants, surface recombination velocities, mobile ion density and energy levels into the simulator. We will explain mysterious trends reported in the literature and make predictions of what needs to be done to improve efficiency.

5:45 AM *S.EN01.04.05
Composition and Interface Engineering of All-Inorganic Perovskite Absorbers with Dopant-Free Carrier Transporters
Tsutomu Miyasaka; Toin University of Yokohama, Japan
Enormous efforts have been made in the last 8 years to upgrade the performance of lead halide hybrid perovskite solar cells (PSCs).\(^1\) Although efficiency level has reached 25%, PSCs face serious challenges of practical stability and durability required for industrialization. Compositional engineering of lead halide perovskites by mixing different cations and anions, using modulator molecules and mixing 2D and 3D structures have improved the stability of perovskites against heat and moisture. However, organic cations in halide perovskites (methylammonium, etc.) and use of diffusible ionic dopants in hole transport materials (HTMs) are responsible for low stability of perovskites at high temperatures (>120°C). In this respect, use of all-inorganic perovskite materials and dopant-free HTMs is highly desired.\(^2\) We have conducted some work in this direction which includes stabilization of CsPbI\(_3\) black phase\(^3\) and use of dopant-free HTMs. We could show that PSCs with all-inorganic perovskites and dopant-free HTMs are capable of efficiency up to 15%.\(^2\) Further, Open-circuit voltage was found to be enhanced over 1.4V, amply high level as a visible light absorber. In preparation of all-inorganic perovskites, a big challenge should be directed to development of lead-free perovskite materials for environmental safety in practical applications.\(^2\)

Among extensive applications of PSCs for outdoor and indoor power generation, use of PSCs in space environments is also promising because thin perovskite photovoltaic films demonstrate high stability and tolerance against exposure to severe space environment having high energy particle irradiations (proton and electron beams).\(^4\) Thin absorbers (<500 nm) avoid accumulation of particles and due to intrinsic defect tolerant nature of perovskites, radiation-induced collision damage is highly suppressed. Our current efforts in making PSCs based on both lead and lead-free perovskites, and future perspectives of perovskite photovoltaics will be introduced.

REFERENCES

in general much more stable with respect to oxidation or decomposition into the binary halides. Furthermore the doubling of the formal charge on the B site compare with the perovskites allows a range of different compositions to be explored. In addition, the vacancies at half of the B site positions have consequences for the electronic structure, charge transport and optical properties and the tolerance of the structure to non ideal ion sizes. Understanding these issues, especially how they differ compared to the ABX$_3$ perovskites, will be necessary for identifying opportunities for A$_2$BX$_6$ materials in optoelectronic applications.

In this talk I will summarise our findings on the basic crystal chemistry of A$_2$BX$_6$ materials. We have studied a range of compounds, with A = Rb$^+$, Cs$^+$, CH$_3$NH$_3^+$, B = Sn$^{4+}$, Te$^{4+}$ and X = Cl$^-$, Br$^-$, I$^-$, and mixtures of ions on the A, B and X sites. We have identified distortion mechanisms analagous to the octahedral tilting well known in the perovskites, and also new distortions that cannot occur in ABX$_3$ compounds. Local structure can be determined using Raman spectroscopy, which can identify the distribution of anions in the mixed halide materials: control of the anion distribution can lead to different optical properties in samples with the same overall chemical composition. We have studied the defect properties of these materials through divalent doping on the B site, as well as introduction of rare earth and post transition metal elements.

**5:30 AM S.EN01.05.03**

Sr and Ba Substitution in Cu$_2$XSnS$_4$—Towards Tail-Free Earth-Abundant Absorbers with New Solar Cell Structures Andrea Crovetto, Moritz Fischer, Kristine Borsting, Rasmus Nielsen, Alireza Hajiijarassar, Nicolas Stenger, Ole Hansen, Brian Seger, Ib Chorkendorff and Peter Vesborg; Technical University of Denmark, Denmark

We present fundamental characterization, single-junction solar cells, and tandem solar cells based on the kesterite-inspired Cu$_2$BaSnS$_4$ (CBTS) and Cu$_2$SrSnS$_4$ (CSTS) absorbers. While CBTS has been investigated for a couple of years, CSTS material properties and solar cells are characterized here for the first time. Both absorbers are grown by thermal conversion of sputtered oxide films (Cu$_2$BaSnO$_4$ and Cu$_2$SrSnO$_4$) in an H$_2$S atmosphere at the same temperature normally used for sulfurization of kesterite [1]. Unlike the tetrahedrally-coordinated Cu$_2$ZnSnS$_4$, the CBTS and CSTS absorbers crystallize in a trigonal structure where Cu, Ba(Sr), and Sn have distinct coordination environments, making substitutional defect formation generally less favorable than in kesterite. In fact, both CBTS and CSTS are found to have sharper absorption and emission edges than kesterite, and their room-temperature photoluminescence peaks are well aligned to the band gap. These findings indicate that changing the cation in CXTS has dramatic consequences on band tailing in the material, as also confirmed by recent experiments on the Cu$_2$CdSnS$_4$ system [2]. Aided by temperature- and intensity-dependent photoluminescence experiments, we try to identify chemical trends in the deep and shallow defects of the CXTS material system and the X cation is changed.

In CBTS and CSTS solar cells, we modify the commonly used device architecture by using the high work-function metallic back compound TaS$_2$ as a back contact. The goal is to mitigate the losses associated with carrier transport across the semiconducting MoS$_2$ layer that invariably forms on a Mo back contact. Encouragingly, the TaS$_2$ back contact yields a 10% relative efficiency improvement over the Mo back contact. As CBTS and CSTS have optimal band gaps for a top absorber in tandem cells, a proof-of-concept monolithic CBTS/Si tandem cell is fabricated to evaluate possible process incompatibilities between the two subcells. Using a thin Ti(O,N) interlayer as a diffusion barrier and as a recombination layer between the two subcells, a working tandem cell is realized. Finally, we discuss the main hurdles in the development of more efficient single-junction and tandem cells based on CBTS and CSTS.

Vapor Phase Deposited Perovskites Jorge Avila, Daniel Pérez-del-Rey, Chris Dreessen, Paz Sebastia-Luna, Pablo P. Boix, Michele Sessolo and Henk J. Bolink; University of Valencia, Spain
We will report on the progress on vapor phase deposited perovskites, including low bandgap Pb-Sn and wider bandgap multiple cation versions. The performance of these materials in both single and double junction solar cells will be reported. The influence of the use of thin organic charge extraction layers, using strong dopants, ionic compounds and conjugated polymers will be described.

Accurate Photocurrent Assessment for the Rational Design of Monolithic All-Peroxvskite Tandem Solar Cells
Zhaoning Song, Chongwen Li, Cong Chen, Biwas Subedi, Nikolas J. Podraza and Yanfa Yan; University of Toledo, United States

All-perovskite tandem solar cells, in which two perovskite solar cells with complementary bandgaps are monolithically integrated and electrically connected in series, offer a viable approach to suppress the Shockley-Queisser (SQ) radiative efficiency limits for single-junction solar cells. To date, all-perovskite solar cells have demonstrated power conversion efficiencies (PCEs) of up to ~25%. To further improve the PCE of all-perovskite tandem solar cells, it is important to accurately assess photocurrent generation in individual subcells and rationalize the tandem device architecture to maximize current output. However, accurate photocurrent assessment of individual perovskite subcells via external quantum efficiency (EQE) measurements presents some unique challenges due to the possible presence of shunting paths and unclear electric field distribution in both perovskite subcells. The accurate EQE experiments of tandem cells need to be carried out under representative illumination and electrical bias conditions to maintain accurate short-circuit condition for each subcell. Still, the detailed and accurate descriptions of EQE measurements of all-perovskite tandem solar cells have not been reported in the literature. Here, we report on a method to determine the required bias illumination and bias voltage for the EQE measurements, based on the behavior of individual subcells and optical modeling of tandem configuration. We show that the short-circuit current densities of the subcells in our all-perovskite tandem cells with PCEs of ~23% obtained from the EQE integration are consistent with those from optical modeling and current-voltage measurements under AM1.5G illumination.

Long-Range Hot Carrier Transport in Hybrid Perovskites Visualized by Ultrafast Microscopy
Libai Huang; Purdue University, United States

The Shockley-Queisser limit for solar cell efficiency of ~ 33% can be overcome if hot carriers can be harvested before they thermalize. Recently, carrier cooling time up to 100 picoseconds was observed in hybrid organic-inorganic lead halide perovskites, but it is unclear whether these long-lived hot carriers can migrate long distance for efficient collection. We report direct visualization of hot carrier migration in CH3NH3PbI3 thin films by ultrafast transient absorption microscopy, demonstrating three distinct transport regimes. Quasi-ballistic transport was observed to correlate with excess kinetic energy; resulting in up to 230 nanometers transport distance in 300 fs that could overcome grain boundaries. The nonequilibrium transport persisted over tens of picoseconds and ~ 600 nanometers before reaching the diffusive transport limit. These results suggest potential applications of hot carrier devices based on hybrid perovskites.

5:15 AM S.EN01.07.03
Heterogeneous Photon Recycling and Charge Diffusion Enhance Charge Transport in Quasi-2D Lead-Halide Perovskite Films
Silvia G. Motti1, Timothy Crothers1, Rong Yang2, Michael B. Johnston1, Jianpu Wang2 and Laura Herz1; 1University of Oxford, United Kingdom; 2Nanjing Tech University, China

The addition of large hydrophobic cations to lead halide perovskites has significantly enhanced the environmental stability of
photovoltaic cells based on these materials. However, the associated formation of two-dimensional structures inside the material can lead to dielectric confinement, higher exciton binding energies, wider bandgaps and limited charge-carrier mobilities. In this work we investigate the impact of such effects to the charge transport properties of perovskite films comprising a 3D MAPbI$_3$ perovskite layer and a self-assembled quasi-2D perovskite region on the substrate side. We apply a combination of time-resolved photoluminescence and terahertz (THz) photoconductivity spectroscopy to reveal the charge-carrier recombination and transport through the film profile, when either the quasi-2D or the 3D layers are selectively excited. Through modelling of the photoconductivity dynamics, we demonstrate that while the charge-carrier mobility is lower within the quasi-2D region, charge-carrier diffusion to the 3D phase leads to a rapid recovery in photoconductivity even when the quasi-2D region is initially photoexcited. In addition, the blue-shifted emission originating from quasi-2D regions overlaps significantly with the absorption spectrum of the 3D perovskite, allowing for highly effective heterogeneous photon recycling. We show that this combination compensates for the adverse effects of electronic confinement, yielding quasi-2D perovskite films with highly efficient charge transport properties.

Understanding Defects in Perovskite Solar Cells by Advanced Characterization Techniques Juan Pablo Correa Baena; Georgia Institute of Technology, United States

Perovskite solar cells promise to yield efficiencies beyond 30% by further improving the quality of the materials and devices. Electronic defect passivation, and suppression of detrimental charge-carrier recombination at the different device interfaces has been used as a strategy to achieve high performance perovskite solar cells. In this presentation, I will discuss the role of electronic defects and how these can be passivated to improve charge-carrier lifetimes and to achieve high open-circuit voltages. I will discuss the characterization of 2D and 3D defects, such as grain boundaries, crystal surface defects, and precipitate formation within the films, by synchrotron-based techniques. The importance of interfaces and their contribution to detrimental recombination will also be discussed. As a result of these contributions to better understanding 2D and 3D defects, the perovskite solar cell field has been able to improve device performance. Albeit the rapid improvements in performance, there is still a need to improve these defects to push the solar cells beyond the current state-of-the-art.

5:15 AM S.EN01.08.02
Crystal Phase Control toward the Perovskite Superlattice Solar Cells Satoshi Uchida¹, Naoyuki Shibayama¹, Koichi Tamaki¹, Keishi Tada¹, Miwako Furue¹, Ludmila Cojocaru² and Hiroshi Segawa¹; ¹The University of Tokyo, Japan; ²Institute des sciences Moleculaires Universite de Bordeaux, France

Recently organic–inorganic halide perovskite solar cell have great attention for its high performance together with easy production and wide variety of the process & flexibility of substrate materials. The power conversion efficiency has already reached over 25% in 2019 much beyond another solar cells such as CIGS or amorphous Si. The further performance still looks promising toward the Shockley–Queisser limit at around 30%. For that purpose, physical chemistry understanding based on the crystallography must be essential to design the good light harvesting, good charge separation and good charge transfer. Recently we reported the scientific revelation that the crystal phase of thin film CH$_3$NH$_3$PbI$_3$ consists of the mixture of tetragonal phase and cubic phase. They are about 15-20 nm well crystallized domain and randomly oriented in high resolution TEM analysis. Furthermore, multi stack sequence such as tetra-cubic-tetra resulted to form the superlattice with d-spacing 10.989Å (2θ=8.03°for CuKα). Such a superlattice may act beneficial for good charge separation & charge transfer that are well known property as a Type II superlattice. To make more efficient performance, the crystal phase control with some different approaches were examined as below.
(1) High pressure post treatment by cold isostatic pressing (CIP)
(2) Photo-flash rapid curing
(3) Crystal growth under the high voltage electrostatic field
Here in this research the results of advantage-disadvantage will be discussed.

Efficient Monolithic Perovskite/Silicon Tandem Solar Cells Based on Blade-Coated Perovskites on Textured Silicon
Bo Chen1, Zhengshan J. Yu2, Salman Manzoor2, Shen Wang1, William Weigand2, Zhenhua Yu1, Guang Yang1, Zhenyi Ni1, Xuezeng Dai1, Zachary C. Holman2 and Jinsong Huang1; 1University of North Carolina at Chapel Hill, United States; 2Arizona State University, United States

Perovskite/silicon tandem solar cells have the potential to break the single-junction efficiency limit of silicon cells and further drive down the cost of silicon photovoltaics. To date, the reported monolithic perovskite/silicon tandem cells are fabricated primarily on silicon cells with front-side-polished surface, which not only cause large reflection loss but also require a costly chemical-mechanical polishing process. Thermal evaporation-involved fabrication of perovskite/silicon tandem cells on textured silicon to reduce the reflection loss, but it sacrifices the advantage of solution processability of perovskites. Here, we develop a scalable blade-coating technique to deposit perovskite film on double-side textured silicon cells with sub-micrometer pyramids. This new tandem architecture combines the advances of textured silicon photovoltaics and solution processed perovskite photovoltaics to increase the efficiency while reducing the cost of monolithic perovskite/silicon tandem cells. The sub-micrometer pyramids are rough enough to scatter light within silicon nearly as efficiently as large pyramids but smooth enough to solution-process a perovskite film. Blade-coated perovskite film planarizes the textured silicon cell. With a textured light-scattering layer added to top of tandem to reduce front-surface reflectance, a monolithic perovskite/silicon tandem cell with an efficiency of 26% is achieved on textured silicon cells.

Thermally Co-Evaporated Perovskites—From Small Areas Solar Cells to Mini-Modules
Jia Li, Hao Wang, Herlinia Ariadna Dewi, Nripan Methews, Subodh Mhaisalkar and Annalisa Bruno; Energy Research Institute @Nanyang Technological University, Singapore

The rapid improvement in perovskite solar cells’ (PSCs) power conversion efficiency (PCE) has prompted the interest to adapt the perovskite technology in the production lines. Capitalizing on existing industrial processing methods will facilitate technology transfer from lab-scale research into mass production, thereby accelerating commercialization. In this work, we have proven the scalability of high quality thermally co-evaporation MAPbI3 active layers in perovskite solar cells up to 4 cm² and mini-modules up to 50 cm², being able to guarantee minimal PCE losses. With a combined strategy of active layer engineering based on deposition optimization, effective surface, and interfacial treatments and light-dispersion minimization, we demonstrate PSCs and mini-modules (active area 21 cm²) achieving PCEs > 20% and ~19% respectively. The unencapsulated devices were able to retain ~ 90% of the initial PCE under continuous illumination at 1 sun (AM 1.5G) without active sample cooling. Looking towards both tandem applications and building-integrated photovoltaics (BIPV), we have also demonstrated thermally evaporated perovskite semi-transparent modules and semi-transparent PSCs. Colorful thermally evaporated semitransparent PSCs show a consistent PCE of ~16% for a set of colors ranging in the whole visible range. These results demonstrate the compatibility of perovskite technology with existing industrial processes and their potential for the next generation photovoltaics.

Reduced Solvent Hazard and Deposition in Ambient Environment Conditions—Perovskite Solar Cel
Anil R. Pininti, Carlo Andrea Riccardo Perini, Annamaria Petrozza and Mario Caironi; CNST, Istituto Italiano di Tecnologia, Italy

Metal halide perovskites are of great promising candidates for optoelectronics research. Effective industrialization of
Perovskite technologies is impeded by the usage of high-boiling point, hazardous solvents, lab-scale processing techniques, and nitrogen environment processing, which significantly increases the cost. Here we propose a low-boiling point, less toxic solvent that enables to process the high-quality perovskite films at a high relative humidity (RH) and ambient atmospheric conditions. Our deposition route enables precursor dissolution and further on spin- or blade-coating, intermediate film phase is obtained. When the intermediate film is exposed to methylamine (MA) gas flow, the film immediately converts to MAPbI₃ perovskite. This method enabled deposition at moisture levels which span from 50 to 80 % RH. Incorporating the film in a low temperature processed inverted device structure, achieved stabilized PCEs up to 14%. Furthermore, the deposition is proved compatible with both spin- and blade-coating methods, to ensure scalability of the process. This method renders promising scalable, humidity robust, less hazardous, ambient atmosphere and low-temperature processing perovskite device fabrication.

5:10 AM S.EN01.09.02
Enhancing Photovoltaic Performance of Aromatic Ammonium Based Two-Dimensional Organic-Inorganic Hybrid Perovskites via Tuning CH−π Interaction Liang Yan, Jun Hu, Ninghao Zhou, Andrew Moran and Wei You; University of North Carolina at Chapel Hill, United States

Phenethylammonium (PEA) based 2D perovskite is an interesting example of 2D perovskites, serving as the gateway towards further introduction of functional conjugated organic cations into 2D perovskites for a variety of applications, for example, photovoltaics. However, the efficiency of photovoltaic devices based on PEA 2D perovskites only achieved ~ 7% for \(<n>=3\), significantly lower than what have been achieved for other cations based 2D perovskites. Here we show that, by introducing propyl ammonium (C3A) into the PEA based 2D perovskites, the device efficiency can be improved to ~10% for 1:1 C3A:PEA based 2D perovskites (\(<n>=3\)). Further investigation discloses that, tuning the CH−π interaction (between C3A and PEA or between two PEA) can have multiple beneficial impacts on such modified 2D perovskites, including (a) removal of undesirable \(n=1\) phase, (b) lowering the density of trap states, and (c) achieving rather large crystalline grains. Additionally, when substituting with 50% C3A, other aromatic ammonium cations based 2D perovskites (\(<n>=3\)) also witness similar efficiency enhancement in their photovoltaic devices, boasting the general use of such method. Our results highlight that, the strategic tuning of non-covalent interactions (such as the CH−π interaction) is a viable and important method in further developing 2D perovskites for photovoltaics.

5:20 AM S.EN01.09.03
Formulating Simultaneous Quasi Core-Shell Structure and Heterojunction for Improving Efficiency and Stability of Low-Bandgap Perovskite Solar Cells Can Li and Wallace C. Choy; University of Hong Kong, China

The highest power conversion efficiency of perovskite solar cells has reached 25.2% which is approaching the Shockley-Queisser (S-Q) limit of single-junction devices. One solid strategy to break the S-Q limit is developing perovskite-perovskite tandem devices. The low-bandgap perovskite solar cells are ideal candidates as the rear subcell in the tandem device with the advantages of tunable bandgap, solution process and low cost. However, unlike Pb-based perovskites, it is still a challenge for realizing the targets of high performance and stability in mixed Pb-Sn perovskite solar cells owing to grain boundary traps and chemical changes in the perovskites. In this work, we propose the approach of in-situ tin(II) inorganic complex anti-solvent process for particularly tuning the perovskite nucleation and crystal growth process. Interestingly, by tuning the perovskite nucleation and crystal growth process through the tin(II) process, we uniquely form the quasi core-shell structure of Pb-Sn perovskite-tin(II) complex as well as heterojunction perovskite structure with energy offset at the same time for achieving the targets. The core-shell structure of Pb-Sn perovskite crystals covered by a tin(II) complex at the grain boundaries effectively passivates the trap states and suppresses the nonradiative recombination, leading to longer carrier life time. Equally important, the perovskite heterostructure with energy offset is intentionally formed at the perovskite top region for enhancing the carrier extraction and suppressing the bimolecular recombination. As a result, the mixed Pb-Sn low-bandgap perovskite device achieves a high power conversion efficiency up to 19.03% with fill factor over 0.8, which is among the highest fill factor in high-performance Pb-Sn perovskite solar cells. The perovskite device with the tin(II) process remains 92% of its initial PCE after stored in inert environment for 22 days. Remarkably, the device fail time under continuous light illumination is extended by over 18.5 folds from 30 h to 560 h beneficial from the protection of the quasi core-shell structure [1].

5:30 AM S.EN01.09.04
Tuning the Bandgap of Cs₂AgBiBr₆ through Dilute Tin Alloying

Kurt P. Lindquist¹, Stephanie A. Mack², Adam H. Slavney¹, Linn Leppert², Aryeh Gold-Parker¹,², Jonathan F. Stebbins¹, Alberto Salleo¹, Michael F. Toney⁵, Jeffrey B. Neaton²,³,⁶ and Hemamala Karunadasa¹,⁵; ¹Stanford University, United States; ²Lawrence Berkeley National Laboratory, United States; ³University of California, Berkeley, United States; ⁴University of Bayreuth, Germany; ⁵SLAC National Accelerator Laboratory, United States; ⁶Institute at Berkeley, United States

The promise of lead halide hybrid perovskites for optoelectronic applications makes finding less-toxic alternatives a priority. The double perovskite Cs₂AgBiBr₆ (I) represents one such alternative, offering long carrier lifetimes and greater stability under ambient conditions. However, the large and indirect 1.95 eV bandgap hinders its potential as a solar absorber. Here, I will show that alloying I with Sn allows for substantial modulation of the optical absorption to absorb more sunlight in a composition free from highly toxic elements. I will then present a detailed analysis, having employed a host of experimental techniques, of the speciation and substitution pathways of Sn alloyed into I. Using this structural understanding, I will discuss the electronic consequences of Sn alloying in I as understood through band structure calculations. The understanding of heterovalent alloying in halide perovskites presented here opens the door to a wider breadth of potential alloying agents for manipulating their band structures in a predictable manner.

5:40 AM *S.EN01.09.05
Increasing the Complexity of Halide Perovskites

Kurt P. Lindquist¹, Michael Boles¹, Adam H. Slavney¹, Stephanie A. Mack², Jeffrey B. Neaton²,³ and Hemamala Karunadasa¹,⁴; ¹Stanford University, United States; ²University of California, Berkeley, United States; ³Lawrence Berkeley National Laboratory, United States; ⁴SLAC National Accelerator Laboratory, United States

Halide perovskites provide a flexible platform for tuning optoelectronic properties through changes in composition, connectivity, and dimensionality. I will present our recent studies on increasing the accessible electronic structures of this versatile family of materials by synthesizing mixed-metal perovskites. Through both stoichiometric and substoichiometric substitutions we can synthesize a variety of halide perovskites, including those with unprecedented lattices with unusual electronic structures.

5:55 AM S.EN01.09.06
Building from the Ground Up—Structural Manipulation in 2D Hybrid Halide Perovskites

Lingling Mao¹,², Constantinos Stoumpos³,², Mercurii G. Kanatzidis², Anthony K. Cheetham¹ and Ram Seshadri¹; ¹University of California, Santa Barbara, United States; ²Northwestern University, United States; ³University of Crete, Greece

Two-dimensional (2D) hybrid halide perovskites offer high chemical versatility, strong potential in optoelectronic applications, and technological improvements in stability and performance of solar cells. The 2D perovskite family has a general formula of (A')ₙ(A)ₙ₋₁BₙXₙ₊₁, where A' is a large organic spacing cation (monovalent m=2 or divalent m=1), A is a small monovalent cation, B is a metal and X is halide. Here, we report the highest layer thickness (n = 7) that has ever been crystallographically characterized, for the Dion-Jacobson (DJ) phase. The seven-layered DJ phase (4AMP)(MA)₆Pb₇I₂₂ (4AMP = 4-aminomethylpyperidinium) shows less distortion in the crystal structure compared with the Ruddlesden-Popper (RP) phase (BA)₂(MA)₆Pb₇I₂₂ (BA = butylammonium). The comparison of the DJ and RP perovskites at the n = 7 level reveals that structural details still influence the optical properties, which the DJ phase has a smaller band gap than the RP due to smaller structural distortion. Another family derived from three-dimensional double perovskite, namely the layered double perovskite halides are reported here using propylammonium (PA) cation, with a general formula of AₓMM'Xₘ (single-layered) and AₓA'MM'Xₘ (two-layered) (A = PA, A' = Cs, M = Ag, M' = Bi, In and X = Cl, Br). This system has demonstrated a high versatility, in which the layer thickness can be tuned up to two, and the organic spacer can be varied from singly protonated cations to a di-cation (1,4-butanediammonium, BDA). The band gap of the materials shows a wide tunability, varying from 2.41 eV (PA₄AgBiBr₈) to 3.96 eV (PA₄AgInCl₈). The diverse structural menu in 2D hybrid perovskite provides a wide selection in exploring the structure-property relations for better optoelectronic materials.

6:05 AM S.EN01.09.07
Improved Photo-Stability through the Incorporation of Phenyl Ethyl Ammonium Cations into Mixed Cation Perovskites

Aditya S. Yerramilli, Banashree Gogoi, Yuanqing Chen and Terry Alford; Arizona State University, United States

Organic-Inorganic halide perovskites have attracted much attention in the last few years. A certified efficiency of 23.7% has made them very attractive in the pursuit of cheaper alternatives to Si-based devices. However, the stability of the device has been a challenge given the very high moisture susceptibility in perovskites. The introduction of large cations is known to
induce two-dimensional graded perovskite structures, which improved phase and ambient stability. Very few reports have emerged in this regard that looks at the influence of introducing large cations into a mixed triple cation perovskite, on the overall properties of the device. In this work, we investigated the impact of incorporating Phenyl ethyl ammonium (PEA) into the mixed triple cation composition of FAMACsPb(I0.7Br0.3)3. For the 5% PEA in the quadruple composition, we observed improvements in the crystallinity and more uniform coverage with little to no pinholes through X-ray diffraction and electron microscopy studies. Device data showed increased V_{oc} from 0.8V to more than 1V for 5% PEA samples. Corresponding photoluminescence data also showed improvement in the intensity of absorption and charge carrier lifetimes.

6:15 AM S.EN01.09.08
The Impact of Stoichiometry on the Photophysical Properties of Ruddlesden-Popper Perovskites
Herman Duim, Sampson Adjokatse, Simon Kahmann, Gert H. Ten Brink and Maria Antonietta Loi; University of Groningen, Netherlands

Low dimensional perovskites are attracting interest for a variety of opto-electronic applications, owing to their tunable optical properties and their excellent ambient stability. In particular, metal halide perovskites of the Ruddlesden-Popper (RP) type – in which inorganic sheets are separated by relatively long organic cations - can be considered as strongly confined quantum well system. As these materials can be cast directly from solution, they hold the promise of procuring flexible and cost-effective films through large-scale fabrication techniques. However, such films typically possess a large degree of heterogeneity across different length scales, the origin and consequences of which are currently not well understood.

In this work, the influence of the stoichiometry of the precursor solution on the microscopic properties of films of the RP perovskite (PEA)2PbI4 are therefore investigated. It is found that the stoichiometry plays an important role in determining the crystallinity, morphology and optical properties of the resulting thin films. Pronounced differences in photoluminescence intensities are shown to exist even in films that are cast from stoichiometric solutions and manifest themselves on a sub-granular level. Using temperature-dependent photoluminescence mapping, an activation energy of 0.4 eV was extracted for the emergence of these local variations in non-radiative recombination rates. The spatial variation in the distribution of trap states is attributed to local fluctuations in the stoichiometry. In line with this, the surface can successfully be passivated by providing an excess of PEAI to an as-cast film, enhancing the photoluminescence intensity as much as 85% without significantly altering the film’s morphology.

6:25 AM S.EN01.09.09
Spin Dependent Charge Transport through Two-Dimensional Chiral Hybrid Lead-Iodide Perovskites
Haipeng Lu1, Jingying Wang2, Zeev V. Vardeny2 and Matthew C. Beard1; 1National Renewable Energy Laboratory, United States; 2The University of Utah, United States

Chiral-induced spin selectivity (CISS) occurs when the chirality of the transporting medium selects one of the two spin ½ states to transport through the media while blocking the other. Monolayers of chiral organic molecules demonstrate CISS but are limited in their efficiency and utility by the requirement of a monolayer in order to preserve the spin selectivity. Here we demonstrate CISS in a system that integrates an inorganic framework with a chiral organic sub-lattice inducing chirality to the hybrid system. Using magnetic conductive-probe atomic force microscopy we find that oriented chiral 2D layered Pb-iodide organic/inorganic hybrid perovskite systems exhibits CISS. The electron transport through the perovskite films depends on the magnetization of the probe tip and the handedness of the chiral molecule. The films achieve a highest spin-polarization transport of up to 86%. Magnetoresistance studies in modified spin-valve devices having only one ferromagnet electrode confirms the spin-dependent charge transport through the organic/inorganic layers.

6:35 AM S.EN01.09.10
Perovskite-Inspired 2D Antimony-Based Absorber Layers for Optoelectronic Applications
Nadja Giesbrecht; University of Muenchen, Germany

The presence of lead in novel hybrid perovskite-based solar cells remains a significant issue regarding commercial applications due to toxicity and instability issues. Therefore, perovskite-inspired new lead-free compounds are sought-after as new candidates for photovoltaic applications. However, most of the suggested substitutions are either oxidation unsteady or suffer from indirect and wide bandgaps. Here, we demonstrate the first thin-film synthesis of MA₃Sb₂I₈ in the perovskite-like 2D polymorph with narrow and direct bandgaps and their application to solar cell devices. So far, MA₃Sb₂I₈ was reported to only crystallize in the zero-dimensional dimer structure with wide indirect bandgap properties. The formation of the 2D layered polymorph with its expected direct and narrow bandgap is more suitable for solar cell application. Using in situ XRD methods, we confirm the stability of the layered phase towards high temperature and moisture. We investigated the electronic
band structure and confirmed experimentally the presence of a semi-direct bandgap at around 2.1 eV. With the incorporation of a two-valent metal cation to the 2D antimony-based structure with the general structure formula A₃SbₓX₉, the direct bandgap can be further narrowed down. The most known compound, Cs₄CuSb₂Cl₁₂, has a direct bandgap of around 1 eV with strong absorption and high stability towards temperature and polar solvents. However, the synthesis of highly crystalline material or thin-films is challenging. To overcome the limitation in the application of low-quality precipitants in optoelectronic devices, we introduce synthesis procedures requiring at least two-steps procedures. We synthesize single crystals larger than 500 µm, enabling their full characterization and application in optoelectronics. Our work shows that careful control of nucleation via processing conditions can provide access to promising perovskite-like phases for photovoltaic applications.

5:00 AM *S.EN01.10.01
Recent Advances in Integrated Perovskite Optoelectronics Anna Lena Giesecke¹, Piotr Cegielski¹, Stephan Suckow¹, Manuel Runke², Neda Pournavoud², Stefanie Neutzner³, Annamaria Petrozza³, Thomas Riedl² and Max C. Lemme¹,⁴; ¹AMO GmbH, Germany; ²University of Wuppertal, Germany; ³Center for Nano Science and Technology, Italy; ⁴RWTH Aachen University, Germany

Metal-halide perovskites as semiconductors with a direct band-gap are ideal candidates for optoelectronic on-chip devices such as lasers. These materials can be deposited onto existing chips and processed using back-end-of-line compatible techniques broadening their functionality. Recently, top-down lithographic patterning processes have been established in spite of the chemical sensitivity of perovskites. The first integrated devices show lasing thresholds that can compete with other technologies. Other recent works demonstrate continuous wave lasing operation and raising hopes for electrically pumped device concepts in the future. At the same time, monolithic integration onto different photonic substrates is feasible. This makes the integrated perovskite devices unique and, in the near future, more versatile compared to existing concepts such as hybrid-integrated III-V lasers.

In this talk we will demonstrate our latest achievements in integration of optoelectronic devices. Fabrication processes and treatment of the perovskite material has to be optimized differently in order to obtain efficient light emitting devices in comparison with photovoltaic applications. We work on a silicon nitride photonic platform and integrate perovskite processes seamlessly in our photonic fabrication line. The overall performance of the integrated devices is strongly dependent on the morphology of the used materials. First attempts of reducing the perovskite’s surface roughness and increasing the lateral dimensions of crystallites show the perspective of lowering laser threshold by order of magnitude. Scattering losses can be mitigated and thus polarization of the generated laser light can be stabilized. All devices work at room temperature and are currently optically pumped. Different types of perovskites (i.e. MAPbI₃ and CsPbBr₃) are integrated onto silicon nitride photonic chips. The generated laser light can directly be used by the photonic circuit underneath the perovskite laser. The emission is characterized after outcouppling through a silicon nitride waveguide. Furthermore, a detailed study about the optical properties of the perovskite after patterning by photolithography is carried out in order to define design optimizations needed for the future light emitting devices.

Our work focusses strongly on reproducible, mass manufacturable fabrication processes. Long term device stability is a central challenge for newly developed material and devices geometries. Possible industrial applications such as datacom and sensor devices are discussed.

5:15 AM S.EN01.10.03
Electrospun Hybrid Perovskite Fibers—Flexible Networks of One-Dimensional Semiconductors for Light Harvesting Applications Christoph Bohr, Markus Pfeiffer, Senol Öz, Florian von Toperzer, Ashish Lepcha, Thomas Fischer, Markus Schütz, Klas Lindfors and Sanjay Mathur; University of Cologne, Germany

The interest in perovskite solar cells is growing rapidly due to their versatile applicability for energy harvesting systems. In a short period of time, devices already reached efficiencies up to 25%, making them comparable to established thin-film solar
cells like Cu(In,Ga)Se₂ or CdTe. The quantity of publications dealing with planar and rigid solar cells is growing tremendously; however, fibrous solar cells have not been in focus yet. Since the 1D structure provides a greater flexibility in comparison to planar systems, applications ranging from e-textiles/wearables to lightweight applications are feasible. Here, the single step fabrication of phase-pure organic-inorganic lead halide perovskite fibers by inert electrospinning technique is presented. Morphological, as well as optical/photonic properties have been studied and demonstrate first comprehensive data on electrospun organic-inorganic hybrid materials. Substitution of the absorbing layer in planar heterojunction solar cells with perovskite fibers resulted in a photoelectric response under simulated sunlight conditions. These flexible 1D hybrid perovskite fibers are potential elements for flexible optoelectronics and mark a starting point towards competitive fibrous solar cells.

5:25 AM S.EN01.10.05

**Thermal Management for Perovskite Light Emitting Diodes** Lianfeng Zhao, Kwangdong Roh and Barry P. Rand; Princeton University, United States

Hybrid organic-inorganic perovskite semiconductors have shown potential to develop into a new generation of light-emitting diode (LED) technology with high light quality and energy efficiency. However, device operational stability is the biggest challenge for perovskite LEDs to become a commercial reality. Here we show that elevated device temperature caused by Joule heating is a major factor contributing to EQE roll-off and device degradation. Several thermal management strategies have been used to reduce Joule heating and improve thermal dissipation, such as adopting a thinner perovskite layer and doped charge transport layers, using substrates with higher thermal conductivity and optimizing device geometry. These strategies have allowed us to demonstrate perovskite LEDs with a peak EQE of 19.9%, a record high radiance of 1200 Wsr⁻¹m⁻², much reduced EQE roll-off (maintained an EQE of 5% at 4000 mA/cm²) and improved operational stability.

5:35 AM S.EN01.10.07

**Origin of Luminous Centers and Edge States in Low Dimensional Lead Halide Perovskites** Jiming Bao¹, Zhiming Wang², Liangzhi Deng³, Zhaojun Qin², Shen-yu Dai³, Shuo Chen¹, Lixin Xie¹, Chong Wang⁴, Chunzheng Wu⁵, Guang Yang¹, Guoying Feng³, Viktor Hadjiev¹, Qingkai Yu⁶, Yizhou Ni⁶, Qiang Li⁶, Haiyan Wang⁶, Kamrul Alam¹, Francisco Robles Hernandez Jie, Jie Jian⁶, Hector Calderon Benavides⁷, Yan Yao¹, Yanan Wang², Xinghua Su⁸ and Feng Lin²; ¹University of Houston, United States; ²University of Electro Science and Technology of China, China; ³Sichuan University, China; ⁴Yunnan University, China; ⁵Texas State University, United States; ⁶Purdue University, United States; ⁷Instituto Politecnico Nacional, ESFM-IPN, UPALM, Mexico; ⁸Chang’an University, China

With only a few deep-level defect states having a high formation energy and dominance of shallow carrier non-trapping defects, the defect-tolerant electronic and optical properties of lead halide perovskites have made them appealing materials for high-efficiency, low-cost, solar cells and light-emitting devices. As such, recent observations of apparently deep-level and highly luminescent states in low-dimensional perovskites have attracted enormous attention as well as intensive debates. The observed green emission in 2D CsPb₂Br₅ and 0D Cs₄PbBr₆ poses an enigma over whether it is originated from intrinsic point defects or simply from highly luminescent CsPbBr₃ nanocrystals embedded in the otherwise transparent wide bandgap semiconductors. The nature of deep-level edge emission in 2D Ruddlesden-Popper perovskites is also not well understood. In this talk, I will analyze the experimental evidences that support the opposing interpretations and discuss challenges and root causes for the controversy. I will then present experimental approaches that can better correlate property with structure of a material and help resolve the controversies. Using combined Raman-photoluminescence under hydrostatic pressure in a diamond anvil cell, we prove that CsPbBr₃ nanocrystals are responsible for the bright green emissions in both 2D CsPb₂Br₅ and 0D Cs₄PbBr₆. Finally, I will show our preliminary understanding of the edge emission in 2D R-P perovskites.

Solution-Assembled Blue Perovskite Light-Emitting Diodes Using Branched Smaller Spacer Cations as Additives

Martha J. Rivera-Medina and Maria Antonietta Loi; University of Groningen, Netherlands

Research on metal halide perovskites (MHP) has paved the way towards excellent optoelectronic materials, establishing them as a prime candidate for the forthcoming generation of large-area lighting and displays. Due to their high color purity, high radiative recombination rates, and bandgap tunability, MHP devices have been demonstrated to be in the lead for future LED applications. However, history repeats itself as for perovskite-based light-emitting diodes (PeLEDs) achieving an efficient performance for blue-emission remains a challenge. Compare to the green, red, and near-infrared, blue PeLEDs is lacking in terms of efficiency and luminance. Close attention should be paid towards the perovskite thin-film processing to ensure radiative recombination, especially in smaller grain-sized structure as in quasi-two-dimensional perovskites. Initially, these perovskites are tailored to an $n$ number of inorganic slabs surrounded by spacer cations, but during the formation of thin-films, heterogeneous values of $n$ coexist giving raised to different N-phase domains. It has been observed that by the addition of smaller organic molecules, one can suppress the formation of higher N values maintaining the excitation in the higher bandgap structures ensuring blue emission even as energy-funnelling is favored toward low bandgap domains. In this work, we report fully-solution-processed blue-light-emitting devices. Our devices have incorporated branched smaller spacer cations as additives to our PEA$_2$(MA$_{x}$Cs$_{1-x}$)$_{n-1}$Pb$_n$Br$_{3n+1}$ perovskite films to hinder the formation of higher values of $N$, while prevailing an N-phase purity of 2 for $n$ values of 1.5, 2, 2.5 in solution. This composition gave rise to devices with a dominant emission wavelength of 483 nm with color purity of 66% at a maximum operating applied voltage, and a low threshold voltage as low as 3V.

Session S.EN01.11: Surface Passivation, Upscaling and Characterisation Techniques

On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020

5:00 AM S.EN01.11.01
Passivation of Mixed Cation Perovskites through the Addition of Guanidinium Iodide Layer
Aditya S. Yerramilli, Banashree Gogoi, Yuanqing Chen and Terry Alford; Arizona State University, United States

Recent research in perovskite solar cells shows efficiencies beyond 20%. There are, however, several concerns that limit them from realizing the full potential. Defects on the surface of the perovskite are the significant reasons for non-radiative recombination, limiting the performance of the device. Several surface treatments show evidence as potential solutions to overcome these defects. Surface passivation of the perovskites is a viable option to minimize the defects and promote better charge carrier extraction. Also, the introduction of large cations into the perovskite induces a two-dimensional layered structure. In this work, we report the deposition of GUAI on mixed cation, FAMACsPb(I$_{0.7}$Br$_{0.3}$)$_3$, as a means to induce passivation and suppress non-radiative recombination. Results reveal improvements in structural properties and morphology. The open-circuit voltages ($V_{oc}$) with values >1V is indication of improvement with the addition of GUAI on the mixed cation perovskite.

5:10 AM S.EN01.11.02
Systematic Screening and Optimization of Contacts to Wide-Bandgap Perovskite through External Radiative Efficiency and Surface Photo-Voltage Measurements

Arthur Onno$^1$, Shalinee Kavadiya$^1$, Caleb Boyd$^{2,3}$, Michael D. McGehee$^{2,3}$ and Zachary C. Holman$^1$; $^1$Arizona State University, United States; $^2$University of Colorado Boulder, United States; $^3$National Renewable Energy Laboratory, United States

To achieve maximal efficiency, a photovoltaic solar cell requires:
1. an excellent absorber, with high material quality and surface passivation to maximize its quasi-Fermi-level splitting under illumination (hereafter referred to as the implied or internal open-circuit voltage $iV_{oc}$), and
2. excellent electron and hole contacts, selective enough to maximize the extraction of the $iV_{oc}$ and achieve a high external open-circuit voltage $V_{oc}$.

Consequently, deviations of the $V_{oc}$ from the detailed-balance theoretical maximum is either due to limitations of the absorber itself—because of poor material quality or surface passivation, leading to non-radiative recombination—or of the contacts—
Based on this, we use a combination of characterization techniques to systematically investigate and quantify what limits the $V_{oc}$ of wide-bandgap (1.68 eV) perovskite solar cells and screen contact schemes. First, we measure the external radiative efficiency (ERE)—also referred to as the photoluminescence quantum efficiency or yield (PLQE or PLQY)—of perovskite films and finished devices to determine their $iV_{oc}$. This voltage, which corresponds to the maximum voltage that could be extracted from the absorber if its contacts were perfect, is a metric of the material quality and the surface passivation of the absorber. Second, we measure the surface photo-voltage ($SPV$) of non-metallized devices. The $SPV$ indicates the total band bending in the device; that is, the sum of the band bending at the absorber/ETL and at the absorber/HTL interfaces. Therefore, it is a metric of the selectivity of the contacts: the higher the $SPV$, the higher the band bending and, consequently, the lower the majority-carrier quasi-Fermi level drop across each contact. Finally, we compare the $iV_{oc}$ with the $V_{oc}$. The ratio $V_{oc}/iV_{oc}$ is also a metric of the selectivity of the contact and follows the same trend as the $SPV$. By comparing these three metrics ($iV_{oc}$, $SPV$, and $V_{oc}/iV_{oc}$) between cells with different contact architectures, we can guide the cell optimization process.

In particular, bare perovskite films on glass exhibit a very high luminescence (ERE>1%), corresponding to an $iV_{oc}>1300$ mV, more than 150 mV above the $V_{oc}$ of the finished devices. Thus, the absorber material quality is not the limiting factor in the voltage of the final devices and contacts are responsible of this voltage deficit—either because of a poor surface passivation of the absorber, a poor selectivity, or a combination of both. Comparing NiOx and PTAA as hole transport layers, we show that using NiOx typically leads to a higher $iV_{oc}$ but lower $V_{oc}/iV_{oc}$ and $SPV$ than PTAA. Consequently, NiOx is more passivating but less selective than PTAA. Researchers working on NiOx contacts should consequently focus on improving its selectivity, for example through modification of its work function. Conversely, for PTAA contacts, optimization of the surface passivation should be prioritized, for example by engineering the perovskite/PTAA interface to reduce its defect density.

5:20 AM S.EN01.11.04
Investigating the $V_{oc}$ Deficit of Wide-Bandgap Perovskite Solar Cells Using Numerical Modeling Jared Friedl, Ramez Hosseinian Ahangharnejhad, Adam Phillips and Michael Heben; The University of Toledo, United States

The performance of perovskite solar cells continues to improve as progress is made in both the optimization of charge transport materials and the absorbers themselves. Mixed-halide perovskites (e.g. CH$_3$NH$_3$Pb(I$_{3-x}$Br$_x$)) are useful for their bandgap adjustment through change in chemical composition. The bandgap engineering of perovskites is of particular interest due to applications for tandem architectures in conjunction with lower-bandgap absorbers such as Si and CIGS. A notable observation in record-performance cells across the relevant bandgap range is the presence of a “bandgap deficit” for wider-bandgap perovskites. This has led to a number of studies that focus on reducing this deficit through modifying the energetics of perovskite bands at the interface with transport layers (TLs) or reducing the recombination at the perovskite/TL interfaces by incorporating passivation layers. The success of these approaches in reducing the deficit in performance with respect to thermodynamic limits points towards requirement of detailed analysis on the band alignment of perovskite/TL interfaces to realize the full potential of the device. Here we use 1-dimensional simulation of a perovskite solar cell with structure TiO$_2$/CH$_3$NH$_3$Pb(I$_{3-x}$Br$_x$)/Spiro-OMeTAD to observe the limiting factors of solar cell performance at wider bandgaps. We show that changing the bandgap of the absorber changes the band alignment at the absorber/TL interfaces, which results in increased band bending and recombination. By investigating the band positions of CH$_3$NH$_3$Pb(I$_{3-x}$Br$_x$) for intermediate values of $x$, we consistently find the optimal valence band offset to be +0.05 eV between the absorber and HTL and find differing optimal conduction band offsets for different absorber bandgaps. Most notably, the optimal CBO between the ETL and a 1.7 eV bandgap perovskite absorber is found to be -0.05 eV. A TiO$_2$ ETL and a Spiro-OMeTAD HTL form a -0.4 eV CBO and a -0.3 eV VBO, respectively, with the same absorber, significant deviations from their optimal alignments. We show that the downward trends in $V_{oc}$ and PCE for widening bandgaps can be greatly improved through optimizing band alignment of the charge transport layers alone, leading to the recommendation of alternative transport layers that better suit wider-bandgap absorbers.

5:30 AM S.EN01.11.05
Rapid and Scalable Monolithic Integration of Single-Source Laser Scribes in Perovskite Modules with Adaptive Architecture Austin Flick, Nicholas Rolston, William J. Scheideler and Reinhold H. Dauskardt; Stanford University, United States

Small area (~0.1cm$^2$) hybrid organolead-halide perovskite solar cells have made tremendous improvements in performance in recent years, approaching the efficiencies of single crystalline silicon cells. While scalable methods such as slot-die coating...
and spray coating offer the possibility of high quality large-area perovskite deposition, resistive losses across the transparent front electrode highlight the need for series interconnected module designs. Our group has developed laser scribing mechanisms for the ablation of the electrodes and active material utilizing a single wavelength (1064nm) high-frequency pulsed laser at ultrafast processing speeds (>20cm/s). This process coupled with improved module design that allows for the study of individual cell performance along with that of the complete module enables high throughput for both perovskite module development and characterization.

Our work first introduces the primary ablation mechanisms of our single-wavelength laser: direct ablation and lift-off. We demonstrate the unique characteristics of these scribing methods as they interact with the front electrode and highlight the unique capability of our single-wavelength laser system to perform each scribe step: patterning the front electrode (P1) with direction ablation, scribing the series interconnection (P2) with the lift-off mechanism, and patterning the back electrode (P3) with the lift-off mechanism. The unique lift-off characteristics for the P2 scribe result in improved efficiencies via increased short-circuit current and fill factor compared to modules utilizing direct ablation mechanisms from other laser sources. The use of a single laser system for each scribe step also allows for high repeatability and accuracy, enabling a reduction in dead area to <600μm. We address performance losses due to the requisite dead area in conjunction with the resistive losses from the series interconnections and front electrode in order to motivate a module design with optimized cell and scribe geometries. The module design incorporates an adaptive architecture that enables complete characterization of both the entire module and its constituent cells. While laser-beam induced current (LBIC) measurements are valuable in evaluating the perovskite uniformity, particularly for large-area scalable deposition methods, previous module architectures force most of the module into reverse bias throughout the scan, resulting in inaccurate current outputs and the need to scan each cell individually. Our adaptative architecture allows for the complete characterization of large-area modules with a single LBIC scan, enabling high throughput single device and complete module characterization.

5:40 AM *S.EN01.11.06
Cd-Less/Free Buffer Materials for >10% Efficiency Pure Sulphide CZTS Solar Cells Xiaojing Hao, Univ of New South Wales, Australia

The uptake in expected future markets at TW-scale of photovoltaics demands stable, abundant, non-toxic materials. In addition to traditional silicon wafer-based solar cells, thin film offers a much wider flexibility in aesthetic designing, choice of substrates and module sizes, as well as unlocking new applications through the use of flexible and light-weight substrates. In these regards, Cu2ZnSnS4 (CZTS) solar cell has been regarded as a compelling alternative of the emerging photovoltaic materials. So far the certified highest power conversion efficiency of 11% has been demonstrated for CZTS, where a layer of traditional CdS buffer material was applied. Considering the high toxicity issue of CdS, efforts have been put on partially or even fully removing the use of toxic Cd containing buffer materials. In this talk, our work on the Cd-less and Cd-free buffer based CZTS solar cells will be discussed. With SILAR-ZnxCd1-xS, we demonstrated >10% efficiency CZTS solar cells by finely tuning the chemistry process of ZnCdS and CZTS absorber composition, where the self-organised nanoscale Zn(O,S) at the initial growth process of Zn,Cd1-xS was found playing a key role in the heterojunction interface passivation and band-alignment. For ALD-Cd-free Zn,Sn1-xO buffer, we achieved >10% efficiency CZTS solar cells, which is also the first >10% efficiency fully environmentally-friendly kesterite solar cells and realised by adjusting the ratio of Zn and Sn for an optimised conduction band alignment with CZTS, and inserting ALD-Aluminum oxide (Al2O3) for heterojunction interface passivation. Our buffer materials engineering work showed that in addition to the heterojunction band alignment, combined effects from the composition of CZTS absorber (cation ratios of Cu/Zn/Sn), buffer synthesis process-induced sodium redistribution and surface modification of absorber, as well as heterojunction interface passivation play major roles in determining the final device performance.

5:55 AM S.EN01.11.07
Scalable Fabrication of Perovskites Solar Cell Using Two-Step Doctor-Blade Technique Zahrah S. Almutawah1,2, Ramez Hosseinian Ahangharnejhad1, Tamanna Mariam1, Kamala Khanal Subedi1, Adam Phillips1, Randy J. Ellingson1 and Michael Heben1; 1University of Toledo, United States; 2The University of Toledo, United States

Lead halide perovskites have attracted much interest as an emerging photovoltaic technology due to high device efficiency and low-cost preparation methods. The highest efficiency record of Perovskite Solar Cells is 23% for device area of <0.1 cm² fabricated by spin-coating. Currently, perovskite solar cells are transitioning from small area devices to large area devices that are compatible with manufacturing. Blade-coating is a promising deposition technique because it is low cost, environmentally friendly, and easily transferable to roll-to-roll processing. Many studies demonstrating high efficiency devices using this method have been performed; however, these studies use a single step to deposit perovskite, which is challenging to scale because of the required addition of an antisolvent during deposition. In our previous study we demonstrated a compact perovskite film with large grain sizes deposited with the two-step blade-coating method in air, and
we achieved solar cell with 15% efficiency for small area ~ 0.08 cm². The two-step deposition method is widely used as a route for fabricating high-quality small area perovskite films using spin-coating because of its full coverage and excellent reproducibility. However, this method has not been investigated for perovskites deposited using a scalable blade coating method. In this work we investigate the possibility of a fully scalable deposition scheme for fabricating n–i–p perovskite modules of perovskite film with the two-step process. PbI₂ layer were blade coated on substrates with a transparent conducting oxide and SnO₂ electron transport layer (ETL) deposited by atomic layer deposit (ALD). The films were converted to perovskite by blade coating with a MAI solution. Small area devices and minmodules will be completed and characterized. For minmodule fabrication, the bottom conducting electrode layer will be laser scribed to form isolated substrates for the individual sub-cells; a second scribe will remove the active material (ETL, perovskite and HTL) to allow for interconnections between the sub-cells; and in the final scribe will remove the top electrode to isolate the individual sub-cells and define the outer boundaries of the module. Encapsulation the completed devices and minmodules with an inert SiO₂ layer prepared by RF-sputtering will also be investigated as a method to increase the stability.

SESSION S.EN01.12: Poster Session: Next Steps for Perovskite Photovoltaics and Beyond

Nanoscale Degradation Mechanism of Mixed Cation Perovskite under Humidity and Light Revealed by Peak Force Infrared Microscopy
Kevin Ho and Gilbert C. Walker; University of Toronto Department of Chemistry, Canada

Light and water are well known factors that can cause degradation to organic lead halide perovskites, which hinders their commercial applications. Here, we studied the degradation mechanism of FA₀.₈₅(Cs₀.₁₅PbI₃) using peak force infrared microscopy, which enables subdiffractional spatial identification of the formamidinium (FA) cation and allows us to probe the degradation mechanism of individual grains. We found that upon exposure to light or water alone, no significant change in the spatial distribution of FA and no pure inorganic decomposition product was observed. However, upon exposure to both light and high humidity, we found that FA₀.₈₅(Cs₀.₁₅PbI₃) degrades through a multistep pathway. First, α-FA₀.₈₅(Cs₀.₁₅PbI₃) decays to δ-CsPbI₃, δ-FAPbI₃, and PbI₂ and the distribution of the FA cation became increasingly inhomogeneous. Second, the organic cations are lost and PbI₂ further photodecomposes.

S.EN01.12.06
Charge Generation Dynamics in Two-Dimensional Organic Inorganic Perovskites
Bhoj R. Gautam¹, Washat Ware¹ and Evgeny Danilov²; ¹Fayetteville State University, United States; ²North Carolina State University, United States

Two-dimensional hybrid perovskites have attracted attention due to their superior ambient stability. In addition, due to local confinement, anisotropic dimensionality and versatility of organic chemistry synthesis, 2D perovskites have flexibility for the modulation of optoelectronic properties. Therefore, these materials are very promising alternative to 3D perovskites for solar cell, thin film transistors, light emitting diode and energy upconversion applications. In this work, using ultrafast pump probe spectroscopy, we studied the charge carrier dynamics in (MA)₂Pb(SCN)₂I₂ perovskite. Carrier dynamics monitored at ~2.3 eV indicates that charges are depopulated with characteristics time constants of 3.5 ps and 57 ps. This indicates that the charge carrier recombination is finished within 100 ps. Also, transient absorption spectra suggest the less population of trap state in this structure. This work provides an improved understanding of fundamental photophysical processes in perovskite structures and provides the guideline for the design, synthesis and fabrication of optoelectronic devices including solar cells.

S.EN01.12.07
The Energy Conversion Efficiency of Perovskite/Perovskite Tandem Solar Cell Reaching 30% by Metal Oxide Optical Metasurfaces
Mohammad I. Hossain¹, Md Wayesh Qarony¹, Nivedita Yunman², Veit Wagner³, Dietmar Knipp³ and Yuen Hong Tsang¹; ¹The Hong Kong Polytechnic University, Hong Kong; ²Jacobs University Bremen, Germany; ³Stanford University, United States

Optical metasurfaces have gained a considerable attention to the research community due to their application to planar optics
with new functionality. So far most of the work has focused on implementing passive optical components like lenses and polarizers, where the optical bandwidth of the implemented structures is limited. Several optoelectronic applications like image sensors, infrared camera, and solar cells require broadband properties, which cannot be provided by most optical metasurfaces. In this study, optical metasurfaces are used to improve the light incoupling and light trapping of perovskite solar cells. Herein, a pyramid shaped metal oxide film is prepared through metal organic chemical vapor deposition (MOCVD), which later converted into optical metasurfaces. Optical metasurfaces are consist of an array of sub wavelength zinc oxide nanowires, where the incident light is controlled by the optical metasurfaces. Templated growth electrodeposition technique is used to grow sub wavelength nanowires. As a first step, metasurfaces are utilized on top of the flat perovskite single junction solar cells, which allows enhancing the short-circuit current density by >20% as compared to flat solar cell. As a second step, metasurfaces are applied to the implementation of perovskite/perovskite tandem solar cell, where materials with optimum bandgap combinations are selected to realize high energy conversion efficiency. The proposed perovskite/perovskite tandem solar cell integrated with optical metasurfaces exhibits a matched short-circuit current density beyond 18 mA/cm² and an estimated energy conversion efficiency exceeding 30%. Finite-difference Time-Domain simulations are used to investigate the optics of perovskite single junction and perovskite/perovskite tandem solar cells. Detailed guidelines for the realization of optical metasurfaces and solar cell structure will be provided.

S.EN01.12.08
On the Potential of Metal Nickel-Oxide Films for Efficient Perovskite Solar Cells Mohammad I. Hossain1, Md Wayesh Qarony1, A K Mahmud Hasan2, Md Shahiduzzaman3, M A Islam4, Nowshad Amin4, Dietmar Knipp5, M Akhtaruzzaman2 and Yuen Hong Tsang1; 1The Hong Kong Polytechnic University, Hong Kong; 2The National University of Malaysia, Malaysia; 3Kanazawa University, Japan; 4Universiti Tenaga Nasional, Malaysia; 5Stanford University, United States

An efficient hole transport material is crucial for realizing improved short-circuit current density and energy conversion efficiency of perovskite solar cells. In this study, Nickel-oxide (NiOx) thin-film was used as a potential hole transport layer for efficient perovskite solar cells. The NiOx films were prepared by electron-beam physical vapor deposition (EBPVD) at low temperatures. Necessary material characterizations were carried out to ensure high quality films and spectroscopic ellipsometry measurements allowed to determine the complex refractive indices of deposited films. Optics and optimization of perovskite solar cells were investigated by three-dimensional finite-difference time-domain simulations, where complex refractive indices were used as the input parameters. Optical simulations provided a very good agreement with the experiments in terms of quantum efficiencies and short-circuit current densities of planar perovskite solar cells. Hence, an optimized device design has been proposed, which can enhance short-circuit current density and energy conversion efficiency by 20% and over 25%, respectively in comparison to the planar perovskite solar cell. Such enhancement is due to improved light incoupling and light trapping, which allows realizing the estimated energy conversion efficiency beyond 22%. The optimized device design is further applied to the implementation of perovskite-based tandem solar cells reaching energy conversion efficiency over 30%. A detailed discussion of the proposed device structure will be provided to attain effective photon management.

S.EN01.12.09
Spray-Pyrolysis Deposition of TiO2 for Efficient Planar Perovskite Solar Cells Md Shahiduzzaman1, Mohammad I. Hossain1, Md Wayesh Qarony2, M Akhtaruzzaman3, Koji Tomita4, Yuen Hong Tsang2 and Tetsuya Taima1; 1Kanazawa Institute of Technology, Japan; 2The Hong Kong Polytechnic University, Hong Kong; 3The National University of Malaysia, Malaysia; 4Tokai University, Japan

A pin-hole free and uniformly distributed compact hole-blocking/electron-transport layer (ETL) is an essential requirement for reaching high power conversion efficiency (PCE) of planar perovskite solar cells (PSCs). In addition, the preparation of a hole-blocking layer has to be simple so that it reduces production costs and enables future commercialization of PSCs. Herein, high-performance planar PSCs were fabricated by employing spray pyrolysis deposition of TiO2 compact ETL, where necessary material characterizations ensure obtaining high-quality films. The influence of TiO2 layer thickness on the photovoltaic performance of the resulting devices was investigated by varying the precursor solution concentration from 0.15 M to 0.40 M. The photovoltaic performance is maximized for the 0.35 M TiO2 precursor solution concentration, which allows realizing a PCE of 16.55% with short-circuit current density (Jsc) of 21.3 mA/cm², open-circuit voltage (Voc) of 1.08
Three-dimensional (3D) finite-difference time-domain (FDTD) simulations were performed to investigate the mechanism of device operation from the optical point of view. Optical simulations were precisely used to model, design, and optimize the perovskite solar cells, where results from simulations provided a good agreement with experimental results which further reveal the correlation of the spray pyrolysis deposited TiO₂ thickness on the photovoltaic performance of PSCs. A detailed discussion of the proposed efficient planar PSC will be provided.

Optical Analysis of All-Perovskite Planar Tandem Solar Cells
Ahmed Mortuza Saleque¹, Mohammad I. Hossain¹, Ahmed Safayet¹ Ilhom Saidjafarzoda², Necmi Biyikli², Md Wayesh Qarony¹ and Yuen Hong Tsang¹; ¹The Hong Kong Polytechnic University, Hong Kong; ²University of Connecticut, United States

Perovskite material systems have recently attracted substantial research attention as solar energy materials owing to their excellent inherent optoelectronic properties, while the manufacturing costs are assumed to be very low. In the past decade, the energy conversion efficiency of perovskite single-junction solar cell has reached over 24%. According to the detailed balance theory, the energy conversion efficiency of tandem solar cell can go beyond 45% if the optimum bandgap materials are selected. The energy conversion efficiency of perovskite/silicon tandem solar cells has already reached to 28%, however, details of fabrication methods and device structures are not yet available. In this study, all-perovskite planar tandem solar cells are investigated, where a wide bandgap (1.72 eV) perovskite is used as a top cell absorber and a low bandgap (1.16 eV) perovskite for the bottom cell. An optimized device design is investigated to realize a high efficiency planar all-perovskite tandem solar cell, where materials used for the contacts have a comparable refractive index to the perovskite absorbers. Herein, atomic layer deposited experimentally realized metal oxide is used to prepare the contacts. Three-dimensional finite-difference time-domain optical simulations are utilized to investigate the optics and optimize individual layers in the solar cell structure. The proposed planar all-perovskite tandem solar cell exhibits a short-circuit current density of 17.6 mA/cm² at matched condition, which allows estimating the energy conversion efficiency exceeding 29%. It is assumed that the proposed planar highly efficient all-perovskite tandem solar cell can be fabricated by solution-processed method at low cost. A detailed guideline on how to determine the solar cell design will be discussed.

From Fully Self-Consistent Electro-Optical Simulations to New Resonant Photovoltaic Devices
Pyry Kivisaari, Toufik Sadi and Jani Oksanen; Aalto University, Finland

Thin-film photovoltaic devices are emerging as a serious alternative to conventional silicon solar cells. Thin films enable for example utilizing resonant modes to decrease the amount of material required for the device, and to design the solar cell for special operational circumstances. On the other hand, thin films could enable designing solar cells from unconventional earth-abundant materials, many of which have favorable light absorption properties but insatisfactory electrical conductivity. However, to enable studying the prospects of new thin-film photovoltaic devices in detail, it would be extremely beneficial to have a modeling tool that enables studying their optical and electrical properties fully self-consistently. To this end, we have recently developed an interference radiative transfer-drift-diffusion (IRTDD) model for arbitrary thin-film device structures. The IRTDD model is especially well suited to study photon recycling and luminescent coupling and how they affect the overall device characteristics of different thin-film structures under illumination and in dark current conditions. We also investigate possible ways to incorporate diffractive elements into the model, such as gratings on the device surface.
Titanium Disulfide (TiS2) Dichalcogenide Thin Films as Inorganic Hole Transport Layer for Perovskite Solar Cells Synthesized from Ionic Liquid Electrodeposition

Omar Asif, Farshad Azadian and Alok C. Rastogi; Binghamton University, The State University of New York, United States

The high efficiency organic-inorganic perovskite solar cells are generally fabricated as a multilayer structure in which the perovskite absorber layer is sandwiched between an electron transport and a hole transport thin film creating an interface on either side. So far different hole transport materials have been investigated of which the organic hole transport layers have delivered the highest efficiencies. However, these organic hole transport layers based on octakis(4-methoxyphenyl)-9,9′-spirobi[9H-fluorene]-2,2′,7,7′-tetramine (Spiro-OMeTAD) and poly[bis(4-phenyl)(2,4,6-trimethylphenyl)amine (PTAA) have displayed poor long term stability. Furthermore, their preparation involve expensive purification processes that hinders universal low-cost commercialization of perovskite solar cells. The alternative low-cost inorganic hole transport materials such as transition metal chalcogenides have been employed recently using the hot-injection method exhibiting superior device stability and high carrier mobility. However, hot-injection method has poor synthesis reproducibility and difficulty in scaling up for large-scale production.

In this work we performed an ab initio study of facile inexpensive scalable syntheses of transition metal dichalcogenide (TiS2) by electrodeposition from ionic liquids as a low-cost inorganic hole layer for perovskite solar cells. The TiS2 thin films were electrodeposited from choline chloride–urea eutectic based ionic liquid electrolytes at 80°C with Na2S2O3 as sulfur source. From the detailed cyclic voltammetry studies, the deposition potential of TiS2 was optimized at -0.79 V vs Pt. The as-deposited TiS2 hole transport layer exhibited polycrystalline structure with preferential growth along (001), (100), (002), (102), (110), (111) planes. The Raman spectroscopy investigations of these films showed peaks around 225 cm−1 and 330 cm−1 which are attribute to the E2g and A1g Raman modes respectively. The synthesized thin films demonstrated sharp optical bandgap edge along with bandgap tunability as the bandgap (direct) decreased from 1.53eV to 1.49eV, 1.40eV, and 1.34 eV with gradual change in deposition potential from -0.79V to -0.9V, -1.0V, and -1.1V vs Pt respectively. This aspect may have potential for alignment of valence band edge in facilitating the hole transport at the perovskite-TiS2 interface. The absorption coefficient of the as-deposited TiS2 thin films likewise shown a dependence of synthesis potential for visible-light range which is highly conducive for application as a hole transport layer in multilayer solar cell structure. The TiS2 thin films were observed to be p-type as shown from the Hall Effect studies with a carrier mobility up to 14.4 cm2V−1s−1. This paper will present a detailed study of the effect of the synthesis parameters on the optical and band-edge and its analysis for application as hole transport layer in perovskite solar cells.

Hole Transport Layer Free Carbon-Based Perovskite Solar Cells with SnO2 Quantum Dots as Electron Transport Layer

Vijayaraghavan Sankaranarayanan Nair, Jacob Wall and Feng Yan; University of Alabama, United States

Hybrid perovskite solar cells (PSCs) represent the hottest research topics due to its meteoric rise in its power conversion efficiency (PCE) to 25.2% since the first cell was fabricated in 2009 with PCE of ~3%. However, there is still a huge block in the form of stability and cost that hinders its path towards commercialization. The majority of the high-performance PSCs employ organic hole-transporting materials (HTMs) and precious metal as back contact (e.g. Au), which are expensive and operationally unstable. Through our work, we plan to tackle the stability and cost issues by employing cost-effective carbon as both the hole transport layer and back contact, thereby completely avoiding the organic hole HTMs. Carbon is a good replacement for the most commonly used precious metals such as gold and silver as a counter electrode as its work function (5.0 eV) is close to that of gold (5.1 eV). Our technique has the added advantage that it is suitable for the low-cost printing technology (e.g., roll-to-roll) as the material synthesis is done at low temperatures (<200 °C) and hence it gives rise to the possibility of fabricating flexible solar cell products. In this work, with SnO2 quantum dots as an electron transport layer (ETL), and carbon as the counter electrode, we fabricated stable HTM-free planar heterojunction PSCs with the structure ITO/SnO2/CSn0.05FAMA0.81PbI2.55Br0.45/Carbon. Our champion cell had an area of 0.08 cm² and recorded a PCE of 12.12% aided by a very high open-circuit voltage (Voc) of 1.07 V and a short-circuit current density (Jsc) of 20.5 mA/cm². This low-cost and highly efficient HTL free and carbon-based perovskite technology pave pathways to achieve affordable and stable perovskite thin-film solar cells.

Understanding the Effects of Moisture on Perovskite Solar Cells by Synchrotron-Based Characterization Tools

Juanita Hidalgo 1,2, Nga Phung 2, Andres Felipe Castro Mendez 2, Dennis Jones 1, Barry Lai 3, Antonio Abate 2 and Juan Pablo Correa Baena 1; 1Georgia Institute of Technology, United States; 2Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; 3Argonne National Laboratory, United States

2020 MRS Virtual Spring/Fall Meeting, November 27-December 4, 2020, Spring Abstracts Final Program 2/3/21
Lead halide perovskite solar cell efficiencies have risen dramatically, reaching a certified 25.2%, promising as low-cost solar energy alternatives. However, perovskites are highly sensitive to temperature, moisture, oxygen, and UV light, presenting an obstacle to commercialization. Therefore, it is crucial to unravel the degradation mechanisms and the ways perovskites interact with water molecules. In the path to understand how water molecules are interacting with the material, a humid treatment was performed to perovskite solar cells with different precursor stoichiometries for hybrid organic-inorganic materials. By exposing the films for 48 hours in a high relative humidity environment, improvement in efficiency for the organic excess perovskite solar cells (highly efficient) was shown. Characterization was done from the material, to the device’s performance and using synchrotron advance X-ray methods to deepen in the properties of the perovskite. Synchrotron X-ray Fluorescence was realized in parallel to X-ray Beam Induced Current technique to exhibit a correlation between the elemental mapping and electrical behavior of the devices, in which heterogeneity upon moisture was observed.

**Improved Efficiency and Stability of Inverted Planar Perovskite Solar Cell Devices by the Incorporation of an Additional Inorganic Hole Transport Layer** Banashree Gogoi, Aditya S. Yerramilli, Yuanqing Chen and Terry Alford; Arizona State University, United States

The use of poly (3,4-ethylenedioxythiophene): poly(styrene sulfonate) sulfonic acid (PEDOT: PSS) as the hole transport layer (HTL) has been commonly reported in the field of perovskite solar cells during recent years. However, these devices suffer from stability issues due to the acidic and hygroscopic characteristics of PEDOT: PSS; therefore, rendering it as an inefficient option for large scale fabrication and commercialization. In this work, we have incorporated an additional layer of CuI along with PEDOT: PSS for efficient hole transport and stability. We have investigated different concentrations of CuI in acetonitrile and prepared devices with the inverted planar architecture of ITO/CuI/PEDOT: PSS/Perovskite/PCBM/Al. From our investigation, we found that 10mg/ml of CuI is the optimum concentration for better device performance as it showed an increase in efficiency by 28 % and current density by 31 % when compared to the devices with only PEDOT: PSS as the hole transport layer. In addition, the CuI devices also showed better stability under controlled atmospheres.

**S.EN01.12.31**

**Synergistic Effect of Cooperating Solvent Vapor Annealing for High-Efficiency Planar Inverted Perovskite Solar Cells** Ahra Yi1, Sangmin Chae2, Hanbin Lee1 and Hyo Jung Kim1; 1Pusan National University, Korea (the Republic of); 2University of California, Santa Barbara, United States

Solvent vapor annealing (SVA) is an effective post-treatment process to improve the quality of crystals and grains in metal halide perovskite films. Whereas SVA has been successfully adopted for the fabrication of perovskite films via the conventional two-step method, its adaptation to the simple single-step perovskite film deposition method has been limited because of the rapid transition of the precursor to the perovskite structure. In the present study, we demonstrate highly efficient and stable single-step-based inverted perovskite solar cells fabricated with perovskite films prepared using dimethyl sulfoxide (DMSO) and water as a combined solvent in an SVA treatment. The treatment with DMSO alone resulted in the growth of large grains (~900 nm) in the lateral direction at the surface region; however, voids and defects were observed in the vertical direction at the bottom interfacial region of the CH3NH3PbI3 layer, which resulted in poor device properties. Interestingly, the combined DMSO–water induced vertical growth of almost single grains and the healing effect of water improved the grain quality. As a result, we fabricated co-SVA CH3NH3PbI3 devices with a power conversion efficiency (PCE) of 19.52%. This PCE, which is much higher than that of pristine devices, was attributed to reduced nonradiative recombination. In addition, co-SVA solar cells displayed remarkable stability and their universality in various types of perovskite materials was demonstrated. We anticipate that our proposed process and mechanism will be widely used in the future development of perovskite-based devices.

**S.EN01.12.34**

**Fabrication of a Coupled Lead Free Perovskite Oxide and Halide Layered Device—Towards Applications in Wearable Flexible Health Monitoring Devices** Mandeep Singh1, Kristina Diaz1, Mark Kovalenko1, Baltripat Singh1, Saquib Ahmed2, Soumyasanta Laha1 and Sankha Banerjee1; 1California State University, Fresno, United States; 2Buffalo State College, United States

Lead Perovskite oxide and halide based devices are especially promising when their applications in biomedical wearables. The advantages of using a perovskite oxide and halide layer for a coupled active layer include but are not limited to broad a light absorption spectrum, tunable band gaps, long charge carrier diffusion, enhanced electron mobility and low fabrication cost. The current work involves the design, fabrication, and simulation of a layered BaTiO3-PMMA-Graphene perovskite oxide and a Tin Iodide coupled active layer structure for application as signal transducers and amplifiers in led based
wearable and flexible biomedical health monitoring devices. The goal of the project is to develop a configuration that is non-toxic as well as stable in natural open air environments with a specific resistance to moisture. This design incorporates the use of organic and inorganic materials, as well as the efficient use of the perovskite crystalline structure that is produced by using the properties of the active layer. Different economical hole transport layers has also been explored to evaluate the impacts on opto-electronics, photon-to-current conversion efficiencies, variation in electron mobility and interfacial properties such as contact resistance and surface energy. The stacking structure is further modulated within the cell by progressively including a recombination-inhibiting thin BaTiO3-PMMA-Graphene layer with the FTO, followed by an electron-transport layer (various oxides) and a combination of CuO/Cu as the hole transport layer and back contact electrode. This work is intended to build up to a broader project of selecting the most optimal low-toxicity perovskite coupled layer for biomedical devices.

S.EN01.12.35
Vapor Processes for Perovskite Thin-Films Formation and Recrystallization
Isidora Susic, Michele Sessolo, Francisco Palazon and Henk J. Bolink; Instituto de Ciencia Molecular- Universidad de Valencia, Spain

Metal halide perovskites are a class of novel semiconductors, with tuneable band gap, high absorption coefficients, large charge diffusion length, and for these reasons are widely studied as absorbers in photovoltaics devices. One of the biggest challenge to achieve high-performing perovskite solar cells is the control over the perovskite film morphology. High crystallinity, low defect density, together with the formation of uniform films are important requirements in order to ensure efficient charge collection and minimize non-radiative recombination. The control over crystallization by solution techniques is challenging, due to the several parameters concurring in the film formation. For this reason, we explored solvent-free routes for the formation and post-treatment/recrystallization of perovskite thin films. Methylammonium lead iodide (MAPI) films were obtained by conversion of vacuum-deposited PbI2 films with vapours of methylammonium iodide in a vacuum oven. With this technique, we deposited MAPI films, which are typically homogeneous and flat, composed by fine (< 100 nm) grains. Furthermore, we introduce the methylamine gas post-treatment to tune the film morphology of the sequentially deposited perovskite films. Upon controlled exposure to methylamine, the perovskite film is partially recrystallized, obtaining films with different and enhanced crystallinity. In particular, by tuning the temperature and gas concentration, we are able to substantially increase the average grain size. We will present extensive morphological and structural characterization, as well as the latest advances in solar cells obtained with solvent-free, vapour treated perovskite thin films.

Giant Temperature Span in Electrocaloric Heat Exchangers  
**Alvar Torello Massana**1,2, Youri Nouchokgwe1,2, Pierre Lheritier1, Tomoyasu Usui1, Sakyo Hirose1 and Emmanuel Defay1; 
1Luxembourg Institute of Science and Technology, Luxembourg; 2University of Luxembourg, Luxembourg; 3Murata Manufacturing Co., Ltd., Japan

Cooling devices based on caloric materials have emerged as promising candidates to become the next generation of coolers. In recent years, several Electrocaloric (EC) heat exchangers have been proposed [1-5], covering different kinds of mechanisms and working principles. However, little has been told about the numerical modelling of these devices and their potential impact on improving the experimental performance. In this work, the authors highlight and prove how finite elements method could exploit and optimize EC heat exchangers. The simulations presented consisted of 2D-representations of a lead scandium tantalate multilayers capacitors (PST MLC) 22mm x 10.4mm x 1mm parallel-plates based active regenerator being developed at LIST and are used to explore new prototype’s configurations. Interestingly, results showed that by simplifying the complexity of the design and modifying the length and thickness of the parallel plates, the temperature span of the device could increase already from 1 to 9 degrees. By guidance of this outcome, the proposed new prototype’s configurations were tested in the laboratory. The maximum experimental temperature difference measured was of 9.45 degrees, which is several factors larger than the value obtained before the investigation of the numerical modelling. Furthermore, new modifications will be tested in the following months. According to our predictions, we expect to improve our actual maximum value even further.

**Direct Measurements of Electrocaloric Materials Efficiency** Emmanuel Defay1, Youri Nouchokgwe1, Alvar Torello1, Pierre Lheritier1, Wook Jo2 and Sakyo Hirose1; 1Luxembourg Institute of Science and Technology, Luxembourg; 2School of Materials Science and Engineering, Korea (the Republic of); 3Murata Manufacturing Co. Ltd., Japan

Electrocaloric (EC) materials exhibit adiabatic temperature change or isothermal entropy when triggered with electric field. Their dimensionless materials efficiency, called *EC materials efficiency*, is the ratio between the heat generated and the electrical work needed to trigger the EC effect. By direct measurements of heat using infra-red (IR) camera, Differential Scanning Calorimetry (DSC), and electrical work we report quantitative results of the efficiency of Lead Scandium Tantalum (PST). These measurements are done on two different PST samples: thick bulk ceramic and thick multi-layer capacitors (MLCs). In both cases, we observed an adiabatic temperature change delta $T_{ad}$ of 2.4 K at room temperature. For this delta $T_{ad}$, we report an efficiency of 35 and 85 respectively for MLCs and bulk. We present a comparative study on energy efficiency of different caloric materials, worked out indirectly in previous articles [1-2]. We reveal a maximum efficiency of 101 for PST (EC). Our study gives insights into the efficiency of EC materials and shows that PST is an excellent candidate for future efficient EC cooling devices.

8:20 AM S.EN02.01.14
**The Development of Electrocaloric Multilayer Capacitors** Sakyo Hirose1, Tomoyasu Usui1, Bhasi Nair2, Gian G. Guzman-Verr1,3, Xavier Moya2 and Neil D. Mathur2; 1Murata Manufacturing Co., Ltd., Japan; 2University of Cambridge, United Kingdom; 3Universidad de Costa Rica, Costa Rica

Since the discovery of giant electrocaloric (EC) effects [1-2], much effort has been made to explore new EC materials and develop prototypes EC cooling systems with high energy efficiency. However, the development of EC cooling systems has been one step behind magnetocaloric (MC) and elastocaloric (eC) cooling systems because few EC materials show comparable temperature change with MC materials. Moreover, EC working bodies with a large enough active volume and high breakdown strength have not been available.

Given this background, we have focused on developing EC multilayer capacitors (MLCs) based on various ferroelectric materials. MLCs are considered to be the ideal working bodies because a large electric field can be applied to thin EC layers without arcing, the active volume can be increased by laminating many thin EC layers, and existing MLC technologies are sufficient for mass production. The numerous internal electrodes permit EC effects to be driven by much larger electric fields than bulk ceramics, provided that the MLCs are of high quality.

Here we report EC effects driven by large electric fields in MLCs based on BaTiO3 (BTO), (1-x)Pb(Mg$_{1/3}$Nb$_{2/3}$)O$_3$-...
xPbTiO$_3$ (PMN-PT), (Pb,Ba)ZrO$_3$ (PBZ), (Pb,La)(Zr,Ti)O$_3$, and Pb(Sc,Ta)O$_3$ (PST) [3]. In 19-layer MLCs with layer thicknesses of 36-40 μm, fields exceeding 15 V μm$^{-1}$ yield adiabatic temperature changes of 2.7 K for 0.9PMN-0.1PT at 380 K [4], 3.8 K for PBZ at 430 K, and 5.1 K for PST at 300 K [5]. For MLCs of PST, process optimization and reduced EC layer thickness (18 μm) increases the breakdown strength to over 45 V μm$^{-1}$, which exceeds the 29 V μm$^{-1}$ that could be applied to MLCs of PST with thicker EC layers (38 μm) [5]. Our high quality MLCs should aid the development of prototype EC cooling systems that will be competitive with respect to their MC and eC counterparts.

Solar Thermal Source for Passive Water Desalination and Cooling Driven by Capillarity and Salinity
Gradients Matteo Morciano1, Matteo Alberghini1, Matteo Fasano1, Eliodoro Chiavazzo1 and Pietro Asinari1,2; 1Politecnico di Torino, Italy; 2Istituto Nazionale di Ricerca Metrologica, Italy

Nowadays energy-intensive and expensive processes are mainly used to desalinate contaminated water and supply cooling capacity. Developing more sustainable, robust and cost-effective technologies (e.g. powered by renewable energy or waste heat) for generating clean water and cooling effect is a crucial need. This necessity is particularly important and severe in rural countries due to the lack of infrastructure and investments. The abundant solar thermal source, which is now mainly employed to provide domestic hot water, could have a significant impact in achieving such targets, thanks to a wider engineering exploitation of innovative materials and technologies. [1,2,3] In this respect, passive distillation and cooling technologies – where all processes occur without mechanical moving parts – can make an important contribution. Unfortunately, state-of-the-art passive devices operating under one sun (that is, below 1 kW m$^{-2}$) still require efficiency enhancement, durability increase, and cost reduction to scale from lab to fab. [4,5,6] The passive technologies for solar water desalination and cooling developed at the Multi-Scale Modeling Laboratory of Politecnico di Torino (www.polito.it/small) are presented.

First, a fully passive, multistage and low-cost solar thermal device able to produce freshwater from seawater is conceived, prototyped and tested under both laboratory and outdoor conditions. The device does not require any mechanical moving parts by exploiting the capillarity of hydrophilic materials. Under realistic conditions, a distillate flow rate of almost 3 L m$^{-2}$ h$^{-1}$ from seawater at less than one sun is demonstrated. Theoretical models, under the same conditions, also suggested that the concept has the potential to further doubling the observed distillate rate, namely up to 6 L m$^{-2}$ h$^{-1}$. [7] Long-term operations of the passive distiller are then improved by optimizing the structure of evaporators towards enhanced salt-rejecting performance. [8] Finally, the passive distiller is optimized to recovery the low-temperature heat, to co-generate electricity and distilled water at the same time. [9]

Second, a passive device exploiting similar phenomena as i) capillarity of hydrophilic materials and the ii) salinity difference between multiple evaporators and condensers is experimentally demonstrated to provide cooling capacity up to 100 W m$^{-2}$. [10] The implemented prototype works at ambient pressure, employs environmentally friendly water solutions, and consists of several identical stages where the cooling effect comes from a cascade of evaporation-condensation processes driven by vapor pressure gradient. The experimentally validated model predicts that cooling capacities above 200 W m$^{-2}$ could be possibly achieved with a proper design optimization of the current lab-scale prototype.

Latest Development in Compression-Based Elastocaloric Cooling Materials and Systems Ichiro Takeuchi; University of Maryland, United States

In this talk, we will discuss our latest work on development of elastocaloric materials as well as cooling prototype systems. We have used additive manufacturing to engineer NiTi-based composites with extremely small hysteresis in stress-strain curves. Additive manufacturing allows flexible design topology of metallic refrigerants which also act as heat exchangers. The small hysteresis results in substantially enhanced materials coefficient of performance as well as long fatigue life needed for applications. On the systems front, we have demonstrated active regeneration schemes for systems with cooling capacity up to 100s of watts using commercially available NiTi tubes. The largest temperature span we have achieved for a single stage compressive regenerators is 23 K. This work is carried out in collaboration with H. Hou, J. Cui, R. Ott, A. Stebner, D. Catalini, R. Radermacher, and Y. Hwang, N. Emaikwu, and S. Qian.

8:50 AM *S.EN02.01.09
Electrocaloric Effects in Relaxor Ferroelectrics from Atomistic Simulations Zhijun Jiang1,2,3, Sergei Prokhorenko2, Yousra Nahas2, Sergey Prosandeev2, Dawei Wang4, Jorge Iniguez5, Hongjun Xiang1,6, and Laurent Bellaiche2; 1Fudan University, China; 2University of Arkansas, United States; 3Ludong University, China; 4Xi’an Jiaotong University, China; 5Luxembourg Institute of Science and Technology, Luxembourg; 6Collaborative Innovation Center of Advanced Microstructures, China

The electrocaloric (EC) effect characterizes the change in temperature induced by a change in electric field [1], with the electrocaloric coefficient being defined as $\alpha = \partial T / \partial E \mid S$, where $T$ is the temperature, $E$ is the electric field and $S$ is the entropy. It is expected that the EC effect has the potential to be an efficient solid-state cooling devices for a broad range of applications [2,3]. Up to now, fewer investigations about EC effects have been performed in relaxor ferroelectrics [4-8]. Here we study EC effect in Ba(Zr0.5Ti0.5)O3 (BZT) and PbMg1/3Nb2/3O3 (PMN) relaxor ferroelectrics. We use the first-principles-based effective Hamiltonian approach combined with Monte Carlo that has been recently developed for BZT and PMN solid solutions [9,10] to investigate the EC effects.

In the lead-free BZT systems, we investigated the electrocaloric effects subject to electric fields of different magnitude and all oriented along the pseudo-cubic [001] direction. It is found that, for any temperature, $\alpha$ exhibits a non-monotonic behavior with field that consists of small values at low fields, followed by an increase up to a maximum before decreasing for larger fields. Below the Burns temperature, this maximum of $\alpha$ is demonstrated to be correlated to a very specific microscopic feature. Finally, equalities that are derived from a simple Landau model reproduce and further help to understand the anomalous behavior of $\alpha$ with field and temperature in BZT, for any temperature above $T_m$ where the dielectric response can exhibit a peak. Our simulations also confirm that indirect and direct approaches yield similar results of the $\alpha$ EC coefficient for any temperature above the $T_m$ temperature but differ from each other for temperature below $T_m$, because of the non-ergodicity adopted by BZT at these low temperatures.

We also employed the effective Hamiltonian of Ref. [10] to shed some light on electrocaloric effects in PMN. It is particularly striking that such Hamiltonian can qualitatively reproduce not only the peculiar electric field-versus-temperature phase diagram but also the optimization of the EC coefficient near the critical point in this rather complex system. The fact that the recently developed Landau-like model, predicting that the EC coefficient is simply related to the product of temperature and the field derivative of the square of the polarization [7], also describes well the EC behavior of PMN as a function of electric field and temperature is also promising for phenomenological modelization of complex inhomogeneous systems. We therefore hope that our studies [7,8] lead to a broader knowledge of EC effects in ferroelectrics.

Barocaloric Effects in Fluorinated Polymers Jiyeob Kim1, Pol Lloveras2 and Xavier Moya1; 1University of Cambridge, United Kingdom; 2Universitat Politècnica de Catalunya, Spain

We present barocaloric studies of ferroelectric polymers of poly(vinylidene fluoride-trifluoroethylene) [PVDF-TrFE]. These copolymers are well known because of their giant electrocaloric response, but here we study pressure-driven thermal changes. PVDF-TrFE polymers undergo first-order phase transition with very large latent heats and volume changes, near room temperature. These three properties make them ideal materials for barocalorics.

1:55 PM *S.EN02.02.02
Practical Considerations for Barocaloric Cooling Enric Stern Taulats1, Juan M. Bermúdez-García1,2, Guillaume F. Nataf1 and Xavier Moya1; 1University of Cambridge, United Kingdom; 2University of A Coruna, Spain

Barocaloric materials are blossoming, with recent reports of thermal changes that compare to those observed in commercial refrigerant fluids [1-3]. The viability of future barocaloric chillers will rely on properties that go beyond the magnitude of the pressure-driven barocaloric effects. On the one hand, the challenge of effective transmission of hydrostatic pressure needs to be addressed in order to guarantee homogeneous stress distribution in the active material, and therefore optimal caloric performance. On the other hand, heat extraction needs to occur at rates that can match the practical cycling frequencies. Here, I will discuss key aspects of pressure transmission and heat transfer in barocaloric devices, and present a guide for barocaloric materials to match applications requirements.

2:05 PM *S.EN02.02.03
Colossal Reversible and Irreversible Barocaloric Effects in Plastic Crystals Araceli Aznar1, Pol Lloveras1, Maria Barrio1, Philippe Negrier2, Antoni Planes3, Lluis Mañosa4, Neil D. Mathur4, Xavier Moya1 and Josep-Lluís Tamarit1; 1Universitat Politècnica de Catalunya, Spain; 2Université de Bordeaux, France; 3Universitat de Barcelona, Spain; 4University of Cambridge, United Kingdom
The massive use of vapor-compressor-based coolers poses a serious global environmental problem due to a relatively small efficiency and the use of hydrofluorocarbons with huge greenhouse potential [1]. These devices are based on controlling the exchange of latent heat involved in liquid-vapor transitions by means of hydrostatic pressure. Alternative technologies based on driving solid-state first-order phase transitions using magnetic, electric and uniaxial stress fields avoid the use of harmful fluids and promise higher efficiencies [2], but they are limited by a relatively small magnitude of the latent heat associated with such transitions compared to evaporation. Here we show that pressure-driven caloric (i.e. barocaloric) effects at phase transitions in some plastic crystals is comparable to that in hydrofluorocarbons due to the emergence of strong molecular orientational disorder [3,4]. We also discuss the reversible barocaloric response that is obtained upon cyclic application and removal of pressure as this is key for technological implementation. In particular, we characterize reversible effects in terms of magnitude, temperature spans, and minimum required pressure. We determine that, while some of the plastic crystals under analysis are unfeasible for applications due to irreversibility within a large pressure range, others demonstrate colossal barocaloric effects that are reversible at low pressures [3,4] and therefore show aptitudes that should promote the future development of environmentally-friendly solid-state barocaloric cooling devices.

2:15 PM *S.EN02.02.04

Giant Barocaloric Effect at the Spin Crossover Transition of a Molecular Crystal Steven P. Vallone1,2, Anthony N. Tantillo1,2, António dos Santos1, Jamie J. Molaison3, Rafal Kulmaczewski4, Antonin Chapoy5, Pezhman Ahmadi5, Malcolm A. Halcrow4 and Karl Sandeman1,2
1Brooklyn College of CUNY, United States; 2CUNY, United States; 3Oak Ridge National Laboratory, United States; 4University of Leeds, United Kingdom; 5Heriot-Watt University, United Kingdom

Abstract body: Spin crossover occurs in compounds where the crystal field splitting of d-orbitals associated with a magnetic moment is of the order of $k_B T$. As a result, a change of state from low spin (LS) to high spin (HS) can occur at the so-called spin crossover temperature, $T_{SCO}$. Crucially for caloric applications, the change of state from LS to HS can be either continuous or first order, and it can occur at temperatures up to and beyond room temperature. This makes SCO transitions of interest for caloric cooling applications. Since SCO compounds are paramagnets or diamagnets, the largest caloric effects will be barocaloric rather than magnetocaloric.

In this presentation, we provide the first direct experimental demonstration of a giant, low pressure barocaloric effect (BCE) and outline future research directions for the development and optimization of the BCE associated with spin crossover.

Thermal Control Elements for Caloric Technologies Andrej Kitanovski; University of Ljubljana, Slovenia

The refrigeration and air conditioning consumes about 17% of the overall electricity used worldwide, and will drastically increase in the next 30 years. The vast majority of these systems utilize vapour-compression technology, which is actually and unfortunately still associated with the existing refrigerants and their environmental impact. Since they contribute to the 7.8% of global greenhouse gas emissions, large efforts are invested in finding appropriate future working substances. However, the options for new, environmentally friendly refrigerants are very limited. Another important step in decreasing the energy consumption is through the energy efficient refrigeration and air conditioning. The large scale vapour compression systems operate with their upper limit of about 60% of the second law efficiency. However they suffer by the low 20% efficiency especially in small appliances. The above issues represent the driver for the quest for energy efficient and environmentally friendly refrigeration and air-conditioning, which is pronounced more than ever. Among the available best alternatives to existing technologies is the caloric energy conversion. This is due to the potentially very high energy efficiency and use of environmentally friendly and safe solid-state working substances. Most of today’s caloric devices apply so-called active regeneration, which involves the oscillation of the working fluid through the matrix of the caloric material – the caloric regenerator. However, the unavoidable, irreversible viscous and heat-transfer losses apply limits to the caloric device’s performance as well as its size. The quest for better caloric-device performance has led to the development of thermal control elements, which control the heat flux on different size and time scales. Here we describe the working principles of these elements: thermal switches, thermal diodes and thermal regulators. This is followed by the critical review
of the research activities and applications of thermal control elements in all types of caloric devices. It is shown that thermal control elements have the potential to substantially improve the power density of caloric devices. Finally, we present the target features and future research guidelines for these elements in the field of caloric technologies.

Prospects and Challenges—Additive Manufacturing of Magnetocaloric Regenerators Radhika Barua1, Dustin M. Clifford1, Ravi L. Hadimani1, Hong Zhao1, Surojit Gupta2, Matthew Kramer3 and Laura Lewis4; 1Virginia Commonwealth University, United States; 2University of North Dakota, United States; 3Ames Laboratory, United States; 4Northeastern University, United States

Cooling, manifested both as air conditioning and as refrigeration, is regarded as one of the most energy-intensive technologies in demand today. Magnetic refrigeration is an energy-efficient, sustainable, environmentally-friendly alternative to conventional vapor-compression cooling technology. There are a number of magnetic refrigerator device designs in existence today that are predicted to be highly energy efficient, on condition that the suitable working materials can be developed.1 This materials challenge has proven to be daunting due to issues associated with intricate synthesis/post-processing protocols and complications related to shaping the mostly brittle magnetocaloric alloys into thin-walled, channeled regenerator structures to facilitate efficient heat transfer between the solid refrigerant and the heat exchange fluid in an active magnetic regenerator (AMR) cooling device. To this end, research centered on fabrication of functionally-graded AlFe2B2 magnetic regenerators via sophisticated additive manufacturing (AM) methods will be presented in this talk. This ferromagnetic intermetallic boride has attracted considerable attention due to its low cost, promising thermal properties that promote effective heat transfer (specific heat capacity, $C_p=115$ J/moleK; thermal conductivity, $\kappa=5.6$ W/mK) and moderate room temperature magnetocaloric response (adiabatic temperature change, $\Delta T_{ad}=1$ K and magnetic entropy change, $\Delta S=2.6$ J/kgK at $\mu_0H_{app}=2$ T).2,3

In this work, powders of single phase AlFe2B2 were synthesized using multiple conventional routes: (i) drop-casting, followed by heat treatment at 1040 °C for 72 hours and then grinding to particulate form in air, (ii) reaction sintering at 900 °C for 24 hours, followed by etching in dilute HCl for 30 min and a (ii) molten salt-assisted solid state reaction at 600 °C for 36 hours. Experimental data indicate that irrespective of processing method, powders of dimensions ranging from 5 to 40 μm demonstrate comparable structural and magnetic properties (orthorhombic $Cmmm$-type crystal structure with unit cell volume, $V=92.6 \pm 0.4$ Å; Curie temperature, $T_c=277 \pm 6$ K) as well as similar magnetocaloric response ($\Delta S=2.6 \pm 0.3$ J/kgK at $\mu_0H_{app}=2$ T). These precursor powders were used to 3D-print cylindrical AlFe2B2 samples using the established direct energy deposition AM method, laser enabled net shaping (LENS) and using an innovative magnetic-field assisted extrusion method whose prime novelty lies in the 3D ink formulation.4,5 Efforts to optimize the material and printing process parameters to maximize the magnetocaloric potential of AlFe2B2 will be discussed. Further, the feasibility of printing high-quality magnetocaloric device components with high surface area and complex porous architectures will be deliberated upon. Overall, this study provides strategies for realizing low-cost functionally graded magnetic regenerators, thus potentially eliminating one of the main barriers to commercialization of magnetic cooling technology.

SESSION S.EN02.01: Electrocaloric Materials and Systems

Giant Temperature Span in Electrocaloric Heat Exchangers
Alvar Torello Massana¹,², Youri Nouchokgwe¹,², Pierre Lheritier¹, Tomoyasu Usui³, Sakyo Hirose¹ and Emmanuel Defay¹; ¹Luxembourg Institute of Science and Technology, Luxembourg; ²University of Luxembourg, Luxembourg; ³Murata Manufacturing Co., Ltd., Japan

Cooling devices based on caloric materials have emerged as promising candidates to become the next generation of coolers. In recent years, several Electrocaloric (EC) heat exchangers have been proposed [1-5], covering different kinds of mechanisms and working principles. However, little has been told about the numerical modelling of these devices and their potential impact on improving the experimental performance. In this work, the authors highlight and prove how finite elements method could exploit and optimize EC heat exchangers. The simulations presented consisted of 2D-representations of a lead scandium tantalate multilayers capacitors (PST MLC) 22mm x 10.4mm x 1mm parallel-plates based active regenerator being developed at LIST and are used to explore new prototype’s configurations. Interestingly, results showed that by simplifying the complexity of the design and modifying the length and thickness of the parallel plates, the temperature span of the device could increase already from 1 to 9 degrees. By guidance of this outcome, the proposed new prototype’s configurations were tested in the laboratory. The maximum experimental temperature difference measured was of 9.45 degrees, which is several factors larger than the value obtained before the investigation of the numerical modelling. Furthermore, new modifications will be tested in the following months. According to our predictions, we expect to improve our actual maximum value even further.

5:10 AM S.EN02.01.03

Direct Measurements of Electrocaloric Materials Efficiency
Emmanuel Defay¹, Youri Nouchokgwe¹, Alvar Torello¹, Pierre Lheritier¹, Wook Jo² and Sakyo Hirose³; ¹Luxembourg Institute of Science and Technology, Luxembourg; ²School of Materials Science and Engineering, Korea (the Republic of); ³Murata Manufacturing Co. Ltd., Japan

Electrocaloric (EC) materials exhibit adiabatic temperature change or isothermal entropy when triggered with electric field. Their dimensionless materials efficiency, called EC materials efficiency, is the ratio between the heat generated and the electrical work needed to trigger the EC effect. By direct measurements of heat using infra-red (IR) camera, Differential Scanning Calorimetry (DSC), and electrical work we report quantitative results of the efficiency of Lead Scandium Tantalum (PST). These measurements are done on two different PST samples: thick bulk ceramic and thick multi-layer capacitors (MLCs). In both cases, we observed an adiabatic temperature change delta $T_{ad}$ of 2.4 K at room temperature. For this delta $T_{ad}$, we report an efficiency of 35 and 85 respectively for MLCs and bulk. We present a comparative study on energy efficiency of different caloric materials, worked out indirectly in previous articles [1-2]. We reveal a maximum efficiency of 101 for PST (EC). Our study gives insights into the efficiency of EC materials and shows that PST is an excellent candidate for future efficient EC cooling devices.

5:20 AM S.EN02.01.04

The Development of Electrocaloric Multilayer Capacitors
Sakyo Hirose¹, Tomoyasu Usui³, Bhasi Nair², Gian G. Guzman-Verri³, Xavier Moya² and Neil D. Mathur²; ¹Murata Manufacturing Co., Ltd., Japan; ²University of Cambridge, United Kingdom; ³Universidad de Costa Rica, Costa Rica

Since the discovery of giant electrocaloric (EC) effects [1-2], much effort has been made to explore new EC materials and develop prototypes EC cooling systems with high energy efficiency. However, the development of EC cooling systems has been one step behind magnetocaloric (MC) and elastocaloric (eC) cooling systems because few EC materials show comparable temperature change with MC materials. Moreover, EC working bodies with a large enough active volume and high breakdown strength have not been available.

Given this background, we have focused on developing EC multilayer capacitors (MLCs) based on various ferroelectric materials. MLCs are considered to be the ideal working bodies because a large electric field can be applied to thin EC layers without arcing, the active volume can be increased by laminating many thin EC layers, and existing MLC technologies are...
sufficient for mass production. The numerous internal electrodes permit EC effects to be driven by much larger electric fields than bulk ceramics, provided that the MLCs are of high quality.

Here we report EC effects driven by large electric fields in MLCs based on BaTiO_3 (BTO), (1-x)Pb(Mg_{1/3}Nb_{2/3})O_3-xPbTiO_3 (PMN-PT), (Pb,Ba)ZrO_3 (PBZ), (Pb,La)(Zr,Ti)O_3, and Pb(Sc,Ta)O_3 (PST) [3]. In 19-layer MLCs with layer thicknesses of 36-40 μm, fields exceeding 15 V μm^{-1} yield adiabatic temperature changes of 2.7 K for 0.9PMN-0.1PT at 380 K [4], 3.8 K for PBZ at 430 K, and 5.1 K for PST at 300 K [5]. For MLCs of PST, process optimization and reduced EC layer thickness (18 μm) increases the breakdown strength to over 45 V μm^{-1}, which exceeds the 29 V μm^{-1} that could be applied to MLCs of PST with thicker EC layers (38 μm) [5]. Our high quality MLCs should aid the development of prototype EC cooling systems that will be competitive with respect to their MC and eC counterparts.

Solar Thermal Source for Passive Water Desalination and Cooling Driven by Capillarity and Salinity Gradients
Matteo Morciano¹, Matteo Alberghini¹, Matteo Fasano¹, Eliodoro Chiavazzo¹ and Pietro Asinari¹,²; ¹Politecnico di Torino, Italy; ²Istituto Nazionale di Ricerca Metrologica, Italy

Nowadays energy-intensive and expensive processes are mainly used to desalinate contaminated water and supply cooling capacity. Developing more sustainable, robust and cost-effective technologies (e.g. powered by renewable energy or waste heat) for generating clean water and cooling effect is a crucial need. This necessity is particularly important and severe in rural countries due to the lack of infrastructure and investments.

The abundant solar thermal source, which is now mainly employed to provide domestic hot water, could have a significant impact in achieving such targets, thanks to a wider engineering exploitation of innovative materials and technologies. [1,2,3] In this respect, passive distillation and cooling technologies – where all processes occur without mechanical moving parts – can make an important contribution. Unfortunately, state-of-the-art passive devices operating under one sun (that is, below 1 kW m^{-2}) still require efficiency increase, durability increase, and cost reduction to scale from lab to fab. [4,5,6] The passive technologies for solar water desalination and cooling developed at the Multi-Scale Modeling Laboratory of Politecnico di Torino (www.polito.it/small) are presented.

First, a fully passive, multistage and low-cost solar thermal device able to produce freshwater from seawater is conceived, prototyped and tested under both laboratory and outdoor conditions. The device does not require any mechanical moving parts by exploiting the capillarity of hydrophilic materials. Under realistic conditions, a distillate flow rate of almost 3 L m^{-2} h^{-1} from seawater at less than one sun is demonstrated. Theoretical models, under the same conditions, also suggested that the concept has the potential to further doubling the observed distillate rate, namely up to 6 L m^{-2} h^{-1}. [7] Long-term operations of the passive distiller are then improved by optimizing the structure of evaporators towards enhanced salt-rejecting performance. [8] Finally, the passive distiller is optimized to recovery the low-temperature heat, to co-generate electricity and distilled water at the same time. [9]

Second, a passive device exploiting similar phenomena as i) capillarity of hydrophilic materials and the ii) salinity difference between multiple evaporators and condensers is experimentally demonstrated to provide cooling capacity up to 100 W m^{-2}. [10] The implemented prototype works at ambient pressure, employs environmentally friendly water solutions, and consists of several identical stages where the cooling effect comes from a cascade of evaporation-condensation processes driven by vapor pressure gradient. The experimentally validated model predicts that cooling capacities above 200 W m^{-2} could be possibly achieved with a proper design optimization of the current lab-scale prototype.

Recent Progress on Compliant Electronic and Electromechanically Responsive Materials and Device Explorations
Qibing Pei; University of California, Los Angeles, United States

The emergence of devices that combine rubbery elasticity with electronic, optoelectronic, and mechanically transductive properties offers exciting new opportunities for applications, but brings significant materials challenges. This presentation will describe our latest results in the materials efforts in developing highly compliant conductors, semiconductors, and dielectric polymers, as well as in the demonstration of integrated functional devices. Specific examples include a touch responsive sensors, a bistable electroactive polymer for tactile display, dielectric elastomer actuators, and compliant electrode for neural detection and stimulation.

Electrocaloric Effects in Relaxor Ferroelectrics from Atomistic Simulations
Zhijun Jiang1,2,3, Sergei Prokhorenko2, Yousra Nahas2, Sergey Prosandeev2, Dawei Wang4, Jorge Iniguez5, Hongjun Xiang1,6 and Laurent Bellaiche2; 1Fudan University, China; 2University of Arkansas, United States; 3Ludong University, China; 4Xi'an Jiaotong University, China; 5Luxembourg Institute of Science and Technology, Luxembourg; 6Collaborative Innovation Center of Advanced Microstructures, China

The electrocaloric (EC) effect characterizes the change in temperature induced by a change in electric field [1], with the electrocaloric coefficient being defined as α=∂T/∂Ε│S, where T is the temperature, E is the electric field and S is the entropy. It is expected that the EC effect has the potential to be an efficient solid-state cooling devices for a broad range of applications [2,3]. Up to now, fewer investigations about EC effects have been performed in relaxor ferroelectrics [4-8]. Here we study EC effect in Ba(Zr0.5Ti0.5)O3 (BZT) and PbMg1/3Nb2/3O3 (PMN) relaxor ferroelectrics. We use the first-principles-based effective Hamiltonian approach combined with Monte Carlo that has been recently developed for BZT and PMN solid solutions [9,10] to investigate the EC effects.

In the lead-free BZT systems, we investigated the electrocaloric effects subject to electric fields of different magnitude and all oriented along the pseudo-cubic [001] direction. It is found that, for any temperature, α exhibits a non-monotonic behavior with field that consists of small values at low fields, followed by an increase up to a maximum before decreasing for larger fields. Below the Burns temperature, this maximum of α is demonstrated to be correlated to a very specific microscopic feature. Finally, equalities that are derived from a simple Landau model reproduce and further help to understand the anomalous behavior of α with field and temperature in BZT, for any temperature above Tm where the dielectric response can exhibit a peak. Our simulations also confirm that indirect and direct approaches yield similar results of the α EC coefficient for any temperature above the Tm temperature but differ from each other for temperature below Tm, because of the non-ergodicity adopted by BZT at these low temperatures.

We also employed the effective Hamiltonian of Ref. [10] to shed some light on electrocaloric effects in PMN. It is particularly striking that such Hamiltonian can qualitatively reproduce not only the peculiar electric field-versus-temperature phase diagram but also the optimization of the EC coefficient near the critical point in this rather complex system. The fact that the recently developed Landau-like model, predicting that the EC coefficient is simply related to the product of temperature and the field derivative of the square of the polarization [7], also describes well the EC behavior of PMN as a function of electric field and temperature is also promising for phenomenological modelization of complex inhomogeneous systems. We therefore hope that our studies [7,8] lead to a broader knowledge of EC effects in ferroelectrics.

Barocaloric Effects in Fluorinated Polymers Jiyeob Kim1, Pol Lloveras2 and Xavier Moya1; 1University of Cambridge, United Kingdom; 2Universitat Politècnica de Catalunya, Spain

We present barocaloric studies of ferroelectric polymers of poly(vinylidene fluoride-trifluoroethylene) [PVDF-TrFE]. These copolymers are well known because of their giant electrocaloric response, but here we study pressure-driven thermal changes. PVDF-TrFE polymers undergo first-order phase transition with very large latent heats and volume changes, near room temperature. These three properties make them ideal materials for barocalorics.

5:10 AM S.EN02.02.02
Practical Considerations for Barocaloric Cooling Enric Stern Taulats1, Juan M. Bermúdez-García1,2, Guillaume F. Nataf1 and Xavier Moya1; 1University of Cambridge, United Kingdom; 2University of A Coruna, Spain

Barocaloric materials are blossoming, with recent reports of thermal changes that compare to those observed in commercial refrigerant fluids [1-3]. The viability of future barocaloric chillers will rely on properties that go beyond the magnitude of the pressure-driven barocaloric effects. On the one hand, the challenge of effective transmission of hydrostatic pressure needs to be addressed in order to guarantee homogeneous stress distribution in the active material, and therefore optimal caloric performance. On the other hand, heat extraction needs to occur at rates that can match the practical cycling frequencies. Here, I will discuss key aspects of pressure transmission and heat transfer in barocaloric devices, and present a guide for barocaloric materials to match applications requirements.

5:25 AM S.EN02.02.03
Colossal Reversible and Irreversible Barocaloric Effects in Plastic Crystals Araceli Aznar1, Pol Lloveras1, Maria Barrio1, Philippe Negrier2, Antoni Planes3, Lluis Mañosa3, Neil D. Mathur4, Xavier Moya4 and Josep-Lluís Tamarit1; 1Universitat Politècnica de Catalunya, Spain; 2Université de Bordeaux, France; 3Universitat de Barcelona, Spain; 4University of Cambridge, United Kingdom

The massive use of vapor-compressor-based coolers poses a serious global environmental problem due to a relatively small efficiency and the use of hydrofluorocarbons with huge greenhouse potential [1]. These devices are based on controlling the exchange of latent heat involved in liquid-vapor transitions by means of hydrostatic pressure. Alternative technologies based on driving solid-state first-order phase transitions using magnetic, electric and uniaxial stress fields avoid the use of harmful fluids and promise higher efficiencies [2], but they are limited by a relatively small magnitude of the latent heat associated with such transitions compared to evaporation. Here we show that pressure-driven caloric (i.e. barocaloric) effects at phase...
transitions in some plastic crystals is comparable to that in hydrofluorocarbons due to the emergence of strong molecular orientational disorder [3,4]. We also discuss the reversible barocaloric response that is obtained upon cyclic application and removal of pressure as this is key for technological implementation. In particular, we characterize reversible effects in terms of magnitude, temperature spans, and minimum required pressure. We determine that, while some of the plastic crystals under analysis are unfeasible for applications due to irreversibility within a large pressure range, others demonstrate colossal barocaloric effects that are reversible at low pressures [3,4] and therefore show aptitudes that should promote the future development of environmentally-friendly solid-state barocaloric cooling devices.

5:40 AM *S.EN02.02.04
Giant Barocaloric Effect at the Spin Crossover Transition of a Molecular Crystal Steven P. Vallone1,2, Anthony N. Tantillo1,2, António dos Santos3, Jamie J. Molaison3, Rafal Kulmaczewski4, Antonin Chapoy5, Pezhman Ahmadi5, Malcolm A. Halcrow4 and Karl Sandeman1,2; 1Brooklyn College of CUNY, United States; 2CUNY, United States; 3Oak Ridge National Laboratory, United States; 4University of Leeds, United Kingdom; 5Heriot-Watt University, United Kingdom

Abstract body: Spin crossover occurs in compounds where the crystal field splitting of d-orbitals associated with a magnetic moment is of the order of $k_B T$. As a result, a change of state from low spin (LS) to high spin (HS) can occur at the so-called spin crossover temperature, $T_{SCO}$. Crucially for caloric applications, the change of state from LS to HS can be either continuous or first order, and it can occur at temperatures up to and beyond room temperature. This makes SCO transitions of interest for caloric cooling applications. Since SCO compounds are paramagnets or diamagnets, the largest caloric effects will be barocaloric rather than magnetocaloric.

In this presentation, we provide the first direct experimental demonstration of a giant, low pressure barocaloric effect (BCE) and outline future research directions for the development and optimization of the BCE associated with spin crossover.

SESSION S.EN02.03: Elastocaloric Materials and Systems

5:00 AM *S.EN02.03.01
Latest Development in Compression-Based Elastocaloric Cooling Materials and Systems Ichiro Takeuchi; University of Maryland, United States

In this talk, we will discuss our latest work on development of elastocaloric materials as well as cooling prototype systems. We have used additive manufacturing to engineer NiTi-based composites with extremely extremely small hysteresis in stress-strain curves. Additive manufacturing allows flexible design topology of metallic refrigerants which also act as heat exchangers. The small hysteresis results in substantially enhanced materials coefficient of performance as well as long fatigue life needed for applications. On the systems front, we have demonstrated active regeneration schemes for systems with cooling capacity up to 100s of watts using commercially available NiTi tubes. The largest temperature span we have achieved for a single stage compressive regenerators is 23 K. This work is carried out in collaboration with H. Hou, J. Cui, R. Ott, A. Stebner, D. Catalini, R. Radermacher, and Y. Hwang, N. Emaikwu, and S. Qian.
The refrigeration and air conditioning consumes about 17% of the overall electricity used worldwide, and will drastically increase in the next 30 years. The vast majority of these systems utilize vapor-compression technology, which is actually and unfortunately still associated with the existing refrigerants and their environmental impact. Since they contribute to the 7.8% of global greenhouse gas emissions, large efforts are invested in finding appropriate future working substances. However, the options for new, environmentally friendly refrigerants are very limited. Another important step in decreasing the energy consumption is through the energy efficient refrigeration and air conditioning. The large scale vapor compression systems operate with their upper limit of about 60% of the second law efficiency. However they suffer by the low 20% efficiency especially in small appliances. The above issues represent the driver for the quest for energy efficient and environmentally friendly refrigeration and air-conditioning, which is pronounced more than ever. Among the available best alternatives to existing technologies is the caloric energy conversion. This is due to the potentially very high energy efficiency and use of environmentally friendly and safe solid-state working substances. Most of today’s caloric devices apply so-called active regeneration, which involves the oscillation of the working fluid through the matrix of the caloric material – the caloric regenerator. However, the unavoidable, irreversible viscous and heat-transfer losses apply limits to the caloric device’s performance as well as its size. The quest for better caloric-device performance has led to the development of thermal control elements, which control the heat flux on different size and time scales. Here we describe the working principles of these elements: thermal switches, thermal diodes and thermal regulators. This is followed by the critical review of the research activities and applications of thermal control elements in all types of caloric devices. It is shown that thermal control elements have the potential to substantially improve the power density of caloric devices. Finally, we present the target features and future research guidelines for these elements in the field of caloric technologies.

Cooling, manifested both as air conditioning and as refrigeration, is regarded as one of the most energy-intensive technologies in demand today. Magnetic refrigeration is an energy-efficient, sustainable, environmentally-friendly alternative to conventional vapor-compression cooling technology. There are a number of magnetic refrigerator device designs in existence today that are predicted to be highly energy efficient, on condition that the suitable working materials can be developed. This materials challenge has proven to be daunting due to issues associated with intricate synthesis/post-processing protocols and complications related to shaping the mostly brittle magnetocaloric alloys into thin-walled, channeled regenerator structures to facilitate efficient heat transfer between the solid refrigerant and the heat exchange fluid in an active magnetic regenerator (AMR) cooling device. To this end, research centered on fabrication of functionally-graded AlFe$_2$B$_2$ magnetic regenerators via sophisticated additive manufacturing (AM) methods will be presented in this talk. This ferromagnetic intermetallic boride has attracted considerable attention due to its low cost, promising thermal properties that promote effective heat transfer (specific heat capacity, $C_p=115$ J/moleK; thermal conductivity, $\kappa=5.6$ W/mK) and moderate room temperature magnetocaloric response (adiabatic temperature change, $\Delta T_{ad}=1$ K and magnetic entropy change, $\Delta S=2.6$ J/kgK at $\mu_0H_{app}=2$ T). In this work, powders of single phase AlFe$_2$B$_2$ were synthesized using multiple conventional routes: (i) drop-casting, followed by heat treatment at 1040 °C for 72 hours and then grinding to particulate form in air, (ii) reaction sintering at 900 °C for 24 hours, followed by etching in dilute HCl for 30 min and a (ii) molten salt-assisted solid state reaction at 600 °C for 36 hours. Experimental data indicate that irrespective of processing method, powders of dimensions ranging from 5 to 40 μm demonstrate comparable structural and magnetic properties (orthorhombic Cmmm-type crystal structure with unit cell volume, $V=92.6 \pm 0.4$ Å; Curie temperature, $T_c=277 \pm 6$ K) as well as similar magnetocaloric response ($\Delta S=2.6 \pm 0.3$ J/kgK at $\mu_0H_{app}=2$ T). These precursor powders were used to 3D-print cylindrical AlFe$_2$B$_2$ samples using the established direct energy deposition AM method, laser enabled net shaping (LENS) and using an innovative magnetic-field assisted extrusion method whose prime novelty lies in the 3D ink formulation. Efforts to optimize the material and printing process parameters to maximize the magnetocaloric potential of AlFe$_2$B$_2$ will be discussed. Further, the feasibility of printing high-quality magnetocaloric device components with high surface area and complex porous architectures will be deliberated upon. Overall, this study provides strategies for realizing low-cost functionally graded magnetic regenerators, thus potentially...
eliminating one of the main barriers to commercialization of magnetic cooling technology.

Computational Proxy Driven Identification of Magneto-Caloric Materials with Chemically Tunable Transition Temperature in the PbFCl Family
Philip Murgatroyd, Kieran Routledge, John Claridge and Jonathan Alaria; University of Liverpool, United Kingdom

Conventional refrigeration based upon the vapor compression cycle is an inefficient process when compared to the efficiency of a Carnot engine operating between the same thermal reservoirs. A viable alternative is magnetic refrigeration, which utilizes adiabatic magnetization and demagnetization to create a cooling cycle analogous to that of the vapor compression cycle through the ‘magnetocaloric effect’. A viable compound for magnetic refrigeration at ambient temperature must present a large change in magnetic entropy, with minimum hysteresis and should be composed of earth abundant and non-toxic elements.

Recently a computational proxy was developed to identify new magnetocaloric materials whereby first principle structure relaxation is carried out with and without spin polarization to ascertain the degree of magnetic deformation.[1] By applying this method to ferromagnet in the PbFCl family we found magnetic deformation of around 2% which is similar to other magnetocaloric compounds. We therefore have focussed our experimental study on MnZnSb, which is reported to be an itinerant ferromagnet with a second order phase transition and Curie temperature about room temperature.[2] Detailed magnetization measurements were carried out and Arrott analysis yields a Curie temperature of 304K, with the system being described as a 3D itinerant ferromagnet from the critical exponents of the Arrott-Noakes equation. We find a reasonably large magnetic entropy change of 4.5 Jkg⁻¹K⁻¹ with a relative cooling power of 153 Jkg⁻¹; which is comparable to second order compounds with about room temperature transition temperatures. Heat capacity measurement shows an anomaly around the magnetic transition and together with the magnetometry can be used to calculate an adiabatic temperature change of 2 K under 2 T. Temperature dependant powder neutron diffraction was used to investigate the origin of the significant magnetic entropy change around the magnetic transition. By alloying this compound with transition metal such as Fe and Cr we found a linear relationship between the c/a ratio and the magnetic transition allowing for the tuning of the operating temperature of this material from 250 K to 320 K without being too detrimental to the magnetic entropy change.

Effective Thermal Conductivity of Nickel-Polyurethane Composite Foams
Rui Dai, Gokul Chandrasekaran, Jie Chen, Chayton Jackson, Yongming Liu, Beomjin Kwon and Qiong Nian; Arizona State University, United States

Foams offer extremely large surface area per unit mass, making them competitive material for heat exchangers and energy storage systems in automotive applications. Understanding the influence of foam characteristics, i.e., size, distribution and the concentration of pores, on their effective thermal conductivity is important when designing the foam-based devices. Herein, we present the effective thermal conductivity of 15μm-thick nickel (Ni) coated open-cell polyurethane (PU) foam (20 PPI, with ~174μm truss cross-section edge length) architectures measured by transient plane source (TPS) method. A calibration methodology for TPS method is developed to ensure an accuracy in measurements. The experiment results are
compared with theoretical models including a finite element model and effective medium theory. For modeling, an X-Ray
tomography is used to accurately analyze the foam structures. We investigate how the foam characteristics, including the Ni
coating thickness, coating defects, and angular alignment of the foam truss, modulate the effective thermal conductivity.
Lastly, we discuss how the model assumptions are related to the discrepancy between the model predictions and
measurements for the polymer-metal foams.

Effective Thermal Conductivity of Nickel-Polyurethane Composite Foams Rui Dai, Gokul Chandrasekaran, Jie Chen,
Chayton Jackson, Yongming Liu, Beomjin Kwon and Qiong Nian; Arizona State University, United States

Foams offer extremely large surface area per unit mass, making them competitive material for heat exchangers and energy
storage systems in automotive applications. The influence of foam characteristics, i.e., size, distribution and
concentration of pores, on their effective thermal conductivity is important when designing the foam-based devices.
Herein, we present the effective thermal conductivity of 15μm-thick nickel (Ni) coated open-cell polyurethane (PU) foam (20
PPI, with ~174μm truss cross-section edge length) architectures measured by transient plane source (TPS) method. A
calibration methodology for TPS method is developed to ensure an accuracy in measurements. The experiment results are
compared with theoretical models including a finite element model and effective medium theory. For modeling, an X-Ray tomography is used to accurately analyze the foam structures. We investigate how the foam characteristics, including the Ni coating thickness, coating defects, and angular alignment of the foam truss, modulate the effective thermal conductivity. Lastly, we discuss how the model assumptions are related to the discrepancy between the model predictions and measurements for the polymer-metal foams.

**Reaction Mechanisms for Long-Life Rechargeable Zn/MnO2 Batteries**
Yun Li¹, Shanyu Wang¹, James Salvador², Jinpeng Wu³, Bo Liu⁴, Wanli Yang⁵, Jiong Yang⁶, Wenqing Zhang⁶, Jun Liu⁴ and Jihui Yang³; ¹University of Washington, United States; ²General Motors R&D Center, United States; ³Stanford University, United States; ⁴Shanghai University, China; ⁵Lawrence Berkeley National Laboratory, United States; ⁶Southern University of Science and Technology, China

Rechargeable aqueous Zn/MnO2 batteries are promising for large-scale grid energy storage applications owing to their low cost, environmentally benign constituents, excellent safety, and relatively high energy density. Their usage, however, is largely hampered by the fast capacity fade. The complexity of the reactions has resulted in long-standing ambiguities of the chemical pathways in Zn/MnO2. In this talk, I will discuss our latest work on discerning the reaction mechanisms of rechargeable Zn/MnO2 batteries. We find that both H+/Zn2+ intercalation and conversion reactions occur at different voltages and that the rapid capacity fading can clearly be ascribed to the rate-limiting and irreversible conversion reactions at a lower voltage. By limiting the irreversible conversion reactions at ~1.26 V, we successfully demonstrated high power and long life that are superior to most of the reported Zinc-ion Batteries or even some lithium-ion batteries.

**Transition Metal Oxide Cathodes in Aqueous Zn Batteries—Electrochemistry and Mechanism**
Esther S. Takeuchi¹,², Kenneth Takeuchi¹ and Amy Marschilok¹,²; ¹Stony Brook University, The State University of New York, United

---
States; 2Brookhaven National Laboratory, United States

Rechargeable aqueous Zn batteries are being actively explored due to the high natural abundance and safety associated with Zn, along with the intrinsic nonflammability and the high ionic conductivity of the aqueous electrolyte. While the individual cell voltage is lower than lithium systems, the benefits may be significant for some application where low cost and nonflammability are key considerations.

Several cathode systems are under exploration for zinc based batteries. The most frequently explored cathode materials are oxides based on the transition metals manganese or vanadium where both layered and tunneled structural motifs have been utilized. The discharge mechanisms can be complex where there can be a combination of H⁺ insertion and Zn²⁺ insertion. Further, the mechanisms can be highly electrolyte dependent.

This presentation will discuss exploration of cathode materials used in Zn based aqueous batteries and their electrochemistry. Characterization methods used for the analysis include cyclic voltammetry, galvanostatic discharge, scanning electrochemical microscopy, x-ray diffraction, x-ray photoelectron spectroscopy, scanning electron microscopy with energy dispersive x-ray spectroscopy mapping, and x-ray micro-fluorescence spectroscopy will be highlighted.

2:23 PM *S.EN05.01.01
Nickel-Zinc Battery Characteristics and Manufacturability Eivind Listerud, Adam Weisenstein and Michael Gordon; ZAF Energy Systems, United States

The Nickel-Zinc battery has an energy density that fits in the gap between Lead-Acid and Li-Ion batteries. Given its nonflammability, environmental friendliness, and relatively low cost, it is an attractive candidate for grid-scale storage and industrial motive applications. With tailored electrodes for optimized rate capability, Nickel-Zinc is also suitable for applications like data center storage and heavy trucking. This presentation will give an overview of this rechargeable alkaline chemistry with an emphasis on large format designs (cell capacity > 120Ah) for a variety of applications. It will cover the strengths and weaknesses of this technology when compared to Lead-Acid and Li-ion. Data will show improved deep cycle performance and superior recharge capability over Lead-Acid. Long term float charge test results will also be discussed, as well as the safety of the chemistry and how this impacts sizing, cost, and management of large-scale energy storage systems. The presentation will also discuss recent advancements in manufacturability of both positive and negative electrodes that enables high rate production of large format Nickel-Zinc batteries. Manufacturing equipment traditionally used by the Lead-Acid industry has been shown to be suitable in the production of the electrodes used in Nickel-Zinc batteries. This will have a significant impact on manufacturing rate and cost and will allow Ni-Zn to be even more competitive in terms of price.

2:31 PM *S.EN05.01.07
High Energy Density Silver-Zinc Button Cells for Wearable Devices Xia Wei; ZPower, LLC, United States

The silver (Ag)-zinc (Zn) system has the highest theoretical specific (Wh/kg) and volumetric energy density (Wh/L) amongst all rechargeable batteries with the added benefit of safety and nonflammability compared to lithium-ion or lithium metal batteries, which makes it a good and ideal candidate for portable applications like hearing-aids, ear buds and other wearable devices. However, historically, the Ag-Zn battery has suffered from poor rechargeability and low energy utilization. At ZPower, we have tailored the chemistry and engineered a new Ag-Zn battery system, which is highly energy dense and rechargeable, thus making it possible to use it portable applications and giving more power to the consumer to allow them to contribute to a greener future.

As aforementioned, enhancing the capacity of the active materials is paramount for high energy density, which we achieved by developing proprietary additives and approaches. For divalent silver oxide (AgO) cathode, we developed an optimal method of processing the raw materials and novel proprietary conductive coatings for AgO, which allowed integrity control of material properties, faster charge, high capacity utilization and retention for many cycles. The optimal process was verified by experimenting processed AgO cathode under different fast charge rate, where the results showed that it improved the charge capabilities. The role of these coatings was further studied through charge algorithm cycling, where we found that it reduced AgO cathode’s impedance compared to the control tests and maintained its active surface area. More importantly, we found that the morphology of the proprietary conductive coatings played a crucial role in efficiently utilizing the AgO cathode’s capacity.

For the Zn anode, where it has a theoretical specific capacity of 820 mA/h/g; however, Zn has a long history of poor rechargeability due to problems like shape change (zinc redistribution), dendrite formation and passivation. In the past,
previous researchers tried altering the Zn formulation to increase utilization; however, these attempts were not fruitful. We have engineered a new Zn anode that can access 94% of its theoretical capacity in a single primary discharge and 56% of its theoretical capacity rechargeably for over 300 cycles. We achieved this breakthrough by developing proprietary additives and methods that localize the Zn to the current collector and prevent dendrite formation. We showed that with incorporating these additives into Zn anode, it further helped mitigating shorting for 400+ cycles.

2:38 PM BREAK

2:43 PM *S.EN05.01.02
Development of Zn/MnO2 Alkaline Batteries for Grid Storage Timothy N. Lambert, Matthew Lim, Igor V. Kolesnichenko, David Arnot, Noah B. Schorr, Rachel L. Habing, Logan S. Ricketts, Elijah I. Ruiz and Babu Chalamala; Sandia National Laboratories, United States

For energy storage to become ubiquitous in the electric grid, safe, reliable low-cost electrochemical storage technologies manufactured at high volumes with low capital expenditures are needed. Alkaline batteries based on high capacity multi-electron conversion electrodes from low cost, abundant and safe materials, such as a Zn/MnO2 are a promising technology. These batteries have a theoretical specific energy rivaling that of Li-ion systems (Zn @820 mAh/g and MnO2 @617 mAh/g, with ~400 Wh/L) and costs reducible to <$50/kWh, when produced at scale (S. Banerjee et al.). While recent advances by Yadav et al. have demonstrated highly reversible Bi- and Cu-stabilized MnO2 electrodes that can achieve the full 2e- capacity of MnO2 in alkaline electrolyte, the ability to pair this electrode with Zn over 5000+ cycles, which equates to ~10-15 years of battery life, remains a difficult challenge.

Zn anodes suffer from irreversible shape change, the redistribution of active material, and passivation over repeated charge and discharge, limiting their achievable capacity and lifetime. Pre-saturating the electrolyte with zincate [Zn(OH)42-], which minimizes dissolution of Zn from the anode and reduces the rate of hydrogen evolution, has recently been shown to enhance cycle life for ~10-35% depth-of-discharge (DOD) Zn anodes by ~100-200% (M. Lim et al.); however, Zn(OH)42- saturated electrolyte is incompatible with high DOD MnO2, and exacerbates the formation of electrochemically inactive phases, such as ZnMn2O4 at the cathode. Hence, using zincate-blocking separators, able to entrap the zincate within the anode and effectively isolate the MnO2 cathode from Zn(OH)2+ crossover, while maintaining hydroxide/cation conductivity, is one approach to improve the reversible cycling of a Zn/MnO2 cell at high DOD of both MnO2 and Zn.

Previously, our group has shown that a ceramic Na-ion super ionic conductor (NaSICON) membrane, which completely inhibits Zn(OH)2+ crossover, increased cycle life in limited DOD batteries; however, its poor conductivity severely limited the rate capabilities and DOD of MnO2 (Duay et al.). More recently we have developed a series of permselective polymeric separators (Kolesnichenko et al.) and screened them using our newly-developed anodic stripping voltammetry crossover assay (Duay et al.) to identify those with Zn(OH)2+ blocking ability. A primary discharge of MnO2 was used to demonstrate that a sustained 2nd e' discharge plateau, indicative of the absence of zinc species at the cathode, was observed only for Zn/MnO2 batteries that utilized our selective polymeric separators. Finally, application of these polymeric separators in rechargeable Zn/MnO2 batteries increased cycle life with higher coulombic efficiencies. Various aspects involved in improving the cycle life of Zn anodes at increased DOD, and of the application of our polymeric separators in isolating the MnO2 cathode from soluble zincate and their ability to enable higher DOD cycling in Zn, will be discussed.

2:51 PM *S.EN05.01.03
From Concept through Product to Market—Rechargeable Zinc Manganese Dioxide Batteries Sanjoy Banerjee; Urban Electric Power, United States

Zinc (Zn) and manganese dioxide (MnO2) are key components of primary alkaline batteries which have dominated the market for decades. They have been demonstrated as promising electrochemical energy storage materials due to the high energy density, low cost, and outstanding safety characteristics. Transforming this non-rechargeable technology into a
rechargeable system would enable it as a revolutionary low-cost solution for grid-scale energy storage. However, the poor reversibility of the traditional Zn and MnO₂ materials, especially at high depth of discharge, has limited the achievable energy density and cycle life of this rechargeable battery system. Recent developments in rechargeable Zn/MnO₂ batteries achieved by the City University of New York Energy Institute (CUNY-EI) in partnership with Urban Electric Power, Inc. (UEP) has presented unique characteristics that could potentially disrupt existing technologies to access a $50BN market. In this talk, the challenges in developing and commercializing rechargeable Zn/MnO₂ batteries for energy storage will be presented, from initial concept through the technical breakthroughs needed to commercialize and manufacture.

2:59 PM *S.EN05.01.05
Towards Higher Utilization of Electroactive Materials in Zn-MnO₂ Alkaline Batteries Damon Turney¹, Gautam G. Yadav¹, Andrew Kiss² and Sanjoy Banerjee¹; ¹The City University of New York, United States; ²Brookhaven National Laboratory, United States

Market price points for grid-scale energy storage range from $10− $200 per kWh depending on the application. These cost targets are not possible using lithium-ion technology. Fire safety is also a concern and prohibits lithium-ion in some locations. Lead-acid, Ni-MH, and Ni-Cd currently serve as alternatives, but are too expensive, bulky, and/or contain very toxic materials. Recent research from The City College of New York shows a rechargeable alkaline Mn-Zn battery that is very low cost, very safe fire, contains no toxic materials, and has moderately high energy density. Here we review what is currently known about the materials chemistry of this Mn-Zn battery and show new results of in-operando micro-XRD and XRD-imaging chemistry of the Mn electrode. New materials evolution pathways are identified using the in-operando data.

3:07 PM *S.EN05.01.10
The Case for Zinc Debra R. Rolison¹, Brandon J. Hopkins¹,², Christopher N. Chervin¹, Megan B. Sassin¹, Jeffrey W. Long¹ and Joseph F. Parker¹; ¹U.S. Naval Research Laboratory, United States; ²National Research Council Postdoctoral Associate, United States

Realizing a next-generation battery that meets or exceeds the system energy density of lithium batteries while capturing attributes beyond the reach of lithium batteries requires a balancing act. The elements that comprise aqueous, safer-than-lithium batteries need to be reasonably naturally abundant, can be acquired through low-risk supply chains, are nontoxic, and can be fabricated, modified, and assembled using green protocols. Zinc checks all those boxes and now that monolithic spongy zinc negative electrodes open new performance terrain—rechargeably cycled at high rate, to deep utilization of the metal—a broad class of rechargeable zinc-based aqueous batteries is finally possible. We perform the systems analysis to show that zinc anodes versus either MnO₂ cathodes or air cathodes satisfy energy storage at low cost while meeting the sustainability sought for batteries beyond lithium.

8:00 AM INTRODUCTION AND ANNOUNCEMENTS

8:06 AM S.EN05.03.04
Aqueous Rechargeable Zinc Ion Batteries—Parasitic Reactions and Cycle Life Degradation Balaji Sambandam, Valiyapuri Soundharrajan, Vinod Mathew, Muhammad H. Alfaruqi, Sohyun Park, Junji Piao and Jaekook Kim; Chonnam National University, Korea (the Republic of)

Since after a new concept of mild acidic aqueous rechargeable zinc-ion batteries (ARZIBs) was introduced in 2011, the technology has been establishing gradually. ARZIBs have proven to be the most eco-friendly energy storage systems (ESSs)
as they use zinc as the negative electrode (with a notable large theoretical capacity value of 820 mAh g⁻¹). Zinc is widely available in the Earth's crust and forms a non-toxic, low-cost aqueous electrolyte, thus ensuring low principal investment and high reliability and safety. Till to date, both manganese and vanadium oxides are widely utilized as cathode for this technology and well documented. However, all these oxides have their drawbacks accompanied with their life stability through long-term cycling, particularly at low current rates. The reason is: electrolyte pH change due to metal dissolution during electrochemical reaction, resulting a reversible parasitic reaction which seriously affects the cycling life of a cathode, depending on type of electrolyte being employed. Thus a most reversible product of zinc basic sulfate (ZBS, Zn₄(OH)₆SO₄·nH₂O), an insulating material, formed/dissolved on the cathode-electrolyte interface due to change of electrolyte pH resulting from metal dissolution, when ZnSO₄ utilized as an electrolyte. Irrespective of the cathode used, this side reaction related to ZBS formation is observed in most of the reported ARZIBs. As the reason, most of the reported studies demonstrate long cyclability in metal oxides-based electrodes at very high current drains. In other words, the application of high current drain increases cycle life-span as much as it can before the electrode demonstrates capacity fading due to metal dissolution. Through Operando analyses, this work establishes the parasitic reaction during electrochemical reaction and document its consequence on the cycle life of the aqueous battery. This will be discussed in detail.

8:14 AM S.EN05.02.02
Understanding the Role and Consequence of the Mn²⁺ Additive in the Electrochemical Activity of a ZnMn₂O₄ Cathode in Aqueous Zinc-Ion Batteries Vinod Mathew, Vaiyapuri Soundharrajan, Saiful Islam, Balaji Sambandam, Seokhun Kim, Sungjin Kim, Zulkifli Zulkifli and Jaekook Kim; Chonnam National University, Korea (the Republic of)

The addition of Mn²⁺ additives in the electrolyte of aqueous zinc-ion batteries (ZIBs), in general, has shown to greatly improve the cyclability of the cathode, very recently. Despite a growing number of studies on this issue with respect to manganese-based cathodes, a complete understanding on the role of Mn²⁺ additive towards the electrochemical reaction in ZIBs has not yet been reached. In such a scenario, we studied the electrochemical activity of one such manganese-based cathode, ZnMn₂O₄ (ZMO) with zinc in a ZIB. Zinc manganese, as a ZIB cathode, is an intriguing choice due to its high theoretical capacity and voltage. We compared the electrochemical reaction of this ZMO nanorods cathode obtained through a simple co-precipitation process in the presence of a 0.1 M MnSO₄ (MS) solution as a full-time electrolyte, as an additive in zinc sulfate (ZMS) electrolyte (1 M ZnSO₄ + 0.1 M MnSO₄) and in its absence or a full-time zinc sulfate (ZS) electrolyte (1 M ZnSO₄), respectively. Systematic investigations including ex situ X-ray diffraction (XRD), scanning electron microscopy (SEM), and transmission electron microscopy (TEM) studies revealed the reasons for the superior stability and high reversibility of ZMO in the ZMS electrolyte medium. The exceptional performance was facilitated by the the electrochemical equilibrium between Zn²⁺ and Mn²⁺ ions via a stable Zn²⁺ (de)insertion in the bulk, a reversible electro-deposition/dissolution of MnO₂ from the Mn²⁺ additive in the electrolyte onto(from) the surface of the cathode and the reversible Zn-insertion into the formed surface MnO₂ layer. This finding is significant as it is contrary to the conventional understanding that the addition of Mn²⁺ merely tends to prevent manganese dissolution thereby facilitating a stable cycle-life performance of the cathode in ZIBs.

8:30 AM S.EN05.02.03
Hierarchical Porous Nickel-Doped Vanadium Dioxide (B) Nanobelts with Ultrahigh Rate Capability and Long Cycle Life for Aqueous Rechargeable Zinc-Ion Batteries Yi Cai and Rodney Chua; Nanyang Technological University, Singapore

Recently, aqueous rechargeable zinc-ion batteries (ARZIBs) have attracted great attention as compared to commercial lithium-ion batteries due to their unique advantages of high intrinsic safety (non-flammable water-based electrolyte) and low cost. [1-3] Over the past few decades, much progress has been focused on the exploration of suitable cathode materials. Among them, vanadium dioxide (B) has been considered as a potential cathode for ARZIBs owing to its unique double layers of V₄O₁₀ type with tunnels, which can facilitate rapid zinc-ions de/insertion processes. [4] However, the reported VO₂(B) displays a high initial capacity but noticeable capacity fading and especially declines drastically at a high current rate. Compositing VO₂(B) with an electrically conductive matrix has recently been introduced as an effective way to improve the power capability. However, it can only improve the external electric conductivity and the usage of expensive carbon (graphene) negates the cost advantage of vanadium oxides. Therefore, it is of great importance to construct novel VO₂(B) electrode materials with excellent electrochemical performance.

Herein, we report an alternative approach to designing and engineering a hierarchical porous Ni-doped vanadium dioxide (B)
nanobelts for ARZIBs. The as-synthesized samples were characterized by X-ray diffraction (XRD), Raman spectroscopy, scanning electron microscopy and transmission electron microscopy (TEM). The existence of Ni dopant was confirmed by the X-ray absorption near-edge structure studies (XANES) and X-ray photoelectron spectroscopy analysis. Electrochemical studies indicate that the Ni-doped VO2 nanobelts electrode exhibits superior cycling stability and ultrahigh rate capability with long cycle life, which is significantly higher than that of the undoped VO2 (B). This can be attributed to the utilization of Ni dopant to electrical wiring the electroactive material, the intrinsic conductivity of VO2 can be effectively increased. In-operando XRD measurements coupled with ex-situ TEM micrographs taken at specific potentials were exploited to gain a further understanding into the structural evolution upon cycling and ions storage mechanism. The results of the study can potentially open the doors for the widespread application of constructing other elemental doping materials as cathodes with high rate capability and long cycle life for aqueous rechargeable batteries.

8:38 AM OPEN DISCUSSION

8:54 AM *S.EN05.02.07 Flexible Zinc Ion Batteries Chunyi Zhi; City University of Hong Kong, Hong Kong

Prussian blue analogue (PBA)-type metal hexacyanoferrates have been considered as significant cathode materials for aqueous rechargeable zinc batteries (ZBs) due to the open face centered cubic framework, multiple active sites, and environmental benign. However, these PBA-type cathodes, such as cyanogroup iron hexacyanoferrate (FeHCF), suffer from ephemeral lifespan (≤1000 cycles), inferior rate capability (1A g⁻¹), and low operating voltage (ca. 1.2 V). This is because the redox active sites of multivalent iron (Fe(III/II)), which dominates its electrochemical activities, can only be very limited activated and thus utilized. The limited activity is attributed to the spatial resistance caused by the compact cooperation interaction between Fe and the surrounded six cyanogroup per unit, and the inferior conductivity. In this paper, surprisingly, we found high-voltage-scanning can effectively activate the C-coordinated Fe (redox active sites) in FeHCF cathode in ZBs. The activation spurred the increase of capacity at a high operating voltage plateau of ca. 1.5 V. Thanks to this activation, the Zn-FeHCF hybrid-ion battery achieved a record-breaking cycling performance of 5000 (82% capacity retention) and 10000 cycles (73% capacity retention), respectively, together with a superior rate capability of maintaining 53.2% capacity at super-high current density of 8 A g⁻¹ (ca. 97 C). To the best of our knowledge, this is the best cycling performance among all the Zn-PBA batteries up to now. As for the mechanism, the reversible distortion and recovering of crystalline structure caused by the (de)insertion of zinc and lithium ions was revealed. The developed strategy of applying a high-voltage-scan to trigger a greatly enhanced overall electrochemical performance of FeHCF can be easily extended to other PBA materials and other battery systems. We believe this work represents a substantial advance on PBA electrode materials and may essentially promote application of PBA materials.

9:09 AM BREAK

9:14 AM *S.EN05.04.01 Minimal Overhead Storage Technology—Living Forever By Dying Everyday Daniel Steingart; Princeton University, United States

In this work we seek to reduce cost and increase cycle life of a grid scale system by de-emphasizing the requirements for shelf life and short circuit prevention. We show a reconfiguration of the zinc-bromine system creates a system that may “live forever by dying everyday” by eliminating much of the balance-of-plant and exploiting the physical properties of the bromine and zinc. This "solution" also creates new questions. In a system that can safely short circuit at any point, what defines state
of charge and state of health? At what point is the battery now "dead"? Is this actually a useful system? The system will be illustrated and current answers to these questions will be discussed.

9:30 AM *S.EN05.04.02
Organic Electrode Materials for Aqueous Batteries—A Mechanistic Study Ye Zhang and Yan Yao; University of Houston, United States

I will present how quinone based organic materials can be designed to address the short cycle life challenges in aqueous batteries -- the structural and chemical instability of anode electrode plays a critical role. Quinone-based organic crystals can store multiple protons with high reversibility, which makes them promising candidates for the anode materials for aqueous batteries. However, the understanding of molecular structures and packing motifs on proton storage and proton-induced phase transition process is currently lacking. Recently we utilized the synchrotron-based X-ray surface scattering technique to probe the tetrachloro-p-benzoquinone (TCBQ) single crystal surface structure change during H⁺ insertion in operando. TCBQ underwent a two-phase reaction during the proton insertion process as the crystal planes of protonated TCBQ (H₂TCBQ) formed step-by-step on the crystal surface. Quinone-based polymers have also demonstrated superior performance in aqueous Na⁺, Ca²⁺, and Zn²⁺ batteries. We will also present mechanistic studies using in-situ techniques such as EQCM-D, FT-IR, and optical imaging that provide insights on how to optimize ion-solvent-polymer interactions in aqueous batteries to further improve cycle life.

9:38 AM S.EN05.02.08
Flexible Quasi-Solid-State Zinc-Ion Rechargeable Batteries for Subzero Temperature Applications Ying Wang and Yehong Chen; Louisiana State Univ, United States

The emerging zinc ion rechargeable batteries show high potential in the fast expanding market of electrochemical energy storage devices owing to their intrinsic safety and low cost, as they use aqueous electrolytes and zinc anodes that are stable and come from abundant sources, while current popular lithium ion batteries employ flammable organic electrolytes. Therefore, it would be very appealing to utilize zinc ion batteries in environments where safety is very crucial, such as ocean or space systems. However, it is challenging to use zinc ion battery in extremely cold environments due to its aqueous electrolyte. Herein we have prepared new flexible quasi-solid-state zinc ion battery consisting of anti-freezing gum-based electrolyte, high-capacity ammonium vanadate cathode and zinc foil anode, for subzero temperature applications. High concentration zinc salts are used to depress the freezing point and maintain the ionic conductivity of the quasi-solid-state electrolyte. The as-prepared battery cells exhibit a reversible capacity of 275mAh/g at 0.2 A/g at room temperature and 170mAh/g at 0 degreeC. When cycled at 0.5 A/g, the cell delivers an initial discharge specific capacity of 155mAh/g and maintains 119mAh/g after 100 cycles at 0 degreeC, and at -20 degreeC it shows an initial discharge capacity of 122mAh/g and a final capacity of 93mAh/g after 100 cycles. The capacity retention becomes higher when cycled at higher rate. As such, the high-performance quasi-solid-state zinc ion batteries with good mechanical flexibility can find potential wide applications in wearable devices and cold environments.

9:46 AM *S.EN05.04.05
Functionality Design of Nanoparticles via Surface Modification and Templated Synthesis Elena Shevchenko; Argonne National Laboratory, United States

Surface modification of nanoparticles with organic molecules and metal cations is a powerful tool to direct their assembly and catalytic properties. The composition of the inorganic cores determines the ability of nanoparticle to be modified. We will discuss the effect of surface modification and purification on catalytic and photocatalytic properties of the metal and semiconducting nanoparticles. We will also demonstrate that functional materials can be obtained using template synthesis. The sequential infiltration synthesis which involves diffusion-controlled penetration and subsequent chemisorption of inorganic precursor molecules inside polar domains of the block-copolymer template is proposed as an efficient chemo-physical approach to design highly porous all inorganic single and multi-component nanostructures. We will show that this approach can be efficiently used for the fabrication of films with a low refractive index that enables the design of single-layer and broad-band graded-index anti-reflective coatings (ARCs). The fine-tuning of the refractive index can be achieved via control over the characteristics of the block copolymer templates, and the number of infiltration cycles. We will show that modification of the block-copolymer template with cations of different elements prior to the gas-phase infiltration cycles enables the fabrication of multicomponent structures consisting of highly accessible thermally stable functional centers randomly distributed in the highly porous host matrix.

Development of Zn/MnO2 Alkaline Batteries for Grid Storage Timothy N. Lambert, Matthew Lim, Igor V. Kolesnichenko, David Arnot, Noah B. Schorr, Rachel L. Habing, Logan S. Ricketts, Elijah I. Ruiz and Babu Chalamala; Sandia National Laboratories, United States

For energy storage to become ubiquitous in the electric grid, safe, reliable low-cost electrochemical storage technologies manufactured at high volumes with low capital expenditures are needed. Alkaline batteries based on high capacity multi-electron conversion electrodes from low cost, abundant and safe materials, such as a Zn/MnO2 are a promising technology. These batteries have a theoretical specific energy rivaling that of Li-ion systems (Zn @820 mAh/g and MnO2 @617 mAh/g, with ~400 Wh/L) and costs reducible to <$50/kWh, when produced at scale (S. Banerjee et al.). While recent advances by Yadav et al. have demonstrated highly reversible Bi- and Cu-stabilized MnO2 electrodes that can achieve the full 2e- capacity of MnO2 in alkaline electrolyte, the ability to pair this electrode with Zn over 5000+ cycles, which equates to ~10-15 years of battery life, remains a difficult challenge.

Zn anodes suffer from irreversible shape change, the redistribution of active material, and passivation over repeated charge and discharge, limiting their achievable capacity and lifetime. Pre-saturating the electrolyte with zincate [Zn(OH)42-], which minimizes dissolution of Zn from the anode and reduces the rate of hydrogen evolution, has recently been shown to enhance cycle life for ~10-35% depth-of-discharge (DOD) Zn anodes by ~100-200% (M. Lim et al.); however, Zn(OH)2 saturated electrolyte is incompatible with high DOD MnO2, and exacerbates the formation of electrochemically inactive phases, such as ZnMn2O4 at the cathode. Hence, using zincate-blocking separators, able to entrap the zincate within the anode and effectively isolate the MnO2 cathode from Zn(OH)2 crossover, while maintaining hydroxide/cation conductivity, is one approach to improve the reversible cycling of a Zn/MnO2 cell at high DOD of both MnO2 and Zn.

Previously, our group has shown that a ceramic Na-ion super ionic conductor (NaSICON) membrane, which completely inhibits Zn(OH)2 crossover, increased cycle life in limited DOD batteries; however, its poor conductivity severely limited the rate capabilities and DOD of MnO2 (Duay et al.). More recently we have developed a series of permselective polymeric separators (Kolesnichenko et al.) and screened them using our newly-developed anodic stripping voltammetry crossover assay (Duay et al.) to identify those with Zn(OH)2 blocking ability. A primary discharge of MnO2 was used to demonstrate that a sustained 2nd e- discharge plateau, indicative of the absence of zinc species at the cathode, was observed only for...
Zn/MnO₂ batteries that utilized our selective polymeric separators. Finally, application of these polymeric separators in rechargeable Zn/MnO₂ batteries increased cycle life with higher coulombic efficiencies. Various aspects involved in improving the cycle life of Zn anodes at increased DOD, and of the application of our polymeric separators in isolating the MnO₂ cathode from soluble zincate and their ability to enable higher DOD cycling in Zn, will be discussed.

From Concept through Product to Market—Rechargeable Zinc Manganese Dioxide Batteries Sanjoy Banerjee; Urban Electric Power, United States

Zinc (Zn) and manganese dioxide (MnO₂) are key components of primary alkaline batteries which have dominated the market for decades. They have been demonstrated as promising electrochemical energy storage materials due to the high energy density, low cost, and outstanding safety characteristics. Transforming this non-rechargeable technology into a rechargeable system would enable it as a revolutionary low-cost solution for grid-scale energy storage. However, the poor reversibility of the traditional Zn and MnO₂ materials, especially at high depth of discharge, has limited the achievable energy density and cycle life of this rechargeable battery system.

Recent developments in rechargeable Zn/MnO₂ batteries achieved by the City University of New York Energy Institute (CUNY-EI) in partnership with Urban Electric Power, Inc. (UEP) has presented unique characteristics that could potentially disrupt existing technologies to access a $50BN market. In this talk, the challenges in developing and commercializing rechargeable Zn/MnO₂ batteries for energy storage will be presented, from initial concept through the technical breakthroughs needed to commercialize and manufacture.

Towards Higher Utilization of Electroactive Materials in Zn-MnO2 Alkaline Batteries Damon Turney¹, Gautam G. Yadav¹, Andrew Kiss² and Sanjoy Banerjee¹; ¹The City University of New York, United States; ²Brookhaven National Laboratory, United States

Market price points for grid-scale energy storage range from $10− $200 per kWh depending on the application. These cost targets are not possible using lithium-ion technology. Fire safety is also a concern and prohibits lithium-ion in some locations. Lead-acid, Ni-MH, and Ni-Cd currently serve as alternatives, but are too expensive, bulky, and/or contain very toxic materials. Recent research from The City College of New York shows a rechargeable alkaline Mn-Zn battery that is very low cost, very safe fire, contains no toxic materials, and has moderately high energy density. Here we review what is currently known about the materials chemistry of this Mn-Zn battery and show new results of in-operando micro-XRD and XRD-imaging chemistry of the Mn electrode. New materials evolution pathways are identified using the in-operando data.

6:00 AM *S.EN05.01.07
High Energy Density Silver-Zinc Button Cells for Wearable Devices Xia Wei; ZPower, LLC, United States

The silver (Ag)-zinc (Zn) system has the highest theoretical specific (Wh/kg) and volumetric energy density (Wh/L) amongst all rechargeable batteries with the added benefit of safety and non-flammability compared to lithium-ion or lithium metal batteries, which makes it a good and ideal candidate for portable applications like hearing-aid, earbuds and other wearable devices. However, historically, the Ag-Zn battery has suffered from poor rechargeability and low energy utilization. At ZPower, we have tailored the chemistry and engineered a new Ag-Zn battery system, which is highly energy dense and rechargeable, thus making it possible to use it portable applications and giving more power to the consumer to allow them to contribute to a greener future.

As aforementioned, enhancing the capacity of the active materials is paramount for high energy density, which we achieved by developing proprietary additives and approaches. For divalent silver oxide (AgO) cathode, we developed an optimal method of processing the raw materials and novel proprietary conductive coatings for AgO, which allowed integrity control of material properties, faster charge, high capacity utilization and retention for many cycles. The optimal process was verified by experimenting processed AgO cathode under different fast charge rate, where the results showed that it improved the
charge capabilities. The role of these coatings was further studied through charge algorithm cycling, where we found that it reduced AgO cathode’s impedance compared to the control tests and maintained its active surface area. More importantly, we found that the morphology of the proprietary conductive coatings played a crucial role in efficiently utilizing the AgO cathode’s capacity.

For the Zn anode, where it has a theoretical specific capacity of 820 mAh/g; however, Zn has a long history of poor rechargeability due to problems like shape change (zinc redistribution), dendrite formation and passivation. In the past, previous researchers tried altering the Zn formulation to increase utilization; however, these attempts were not fruitful. We have engineered a new Zn anode that can access 94% of its theoretical capacity in a single primary discharge and 56% of its theoretical capacity rechargeably for over 300 cycles. We achieved this breakthrough by developing proprietary additives and methods that localize the Zn to the current collector and prevent dendrite formation. We showed that with incorporating these additives into Zn anode, it further helped mitigating shorting for 400+ cycles.

The Case for Zinc Debra R. Rolison1, Brandon J. Hopkins1,2, Christopher N. Chervin1, Megan B. Sassin1, Jeffrey W. Long1 and Joseph F. Parker1; 1U.S. Naval Research Laboratory, United States; 2National Research Council Postdoctoral Associate, United States

Realizing a next-generation battery that meets or exceeds the system energy density of lithium batteries while capturing attributes beyond the reach of lithium batteries requires a balancing act. The elements that comprise aqueous, safer-than-lithium batteries need to be reasonably naturally abundant, can be acquired through low-risk supply chains, are nontoxic, and can be fabricated, modified, and assembled using green protocols. Zinc checks all those boxes and now that monolithic spongy zinc negative electrodes open new performance terrain—rechargeably cycled at high rate, to deep utilization of the metal—a broad class of rechargeable zinc-based aqueous batteries is finally possible. We perform the systems analysis to show that zinc anodes versus either MnO2 cathodes or air cathodes satisfy energy storage at low cost while meeting the sustainability sought for batteries beyond lithium.

Understanding the Role and Consequence of the Mn2+ Additive in the Electrochemical Activity of a ZnMn2O4 Cathode in Aqueous Zinc-Ion Batteries Vinod Mathew, Vaiyapuri Soundharrajan, Saiful Islam, Balaji Sambandam, Seokhun Kim, Sungjin Kim, Zulkifli Zulkifli and Jaekook Kim; Chonnam National University, Korea (the Republic of)

The addition of Mn2+ additives in the electrolyte of aqueous zinc-ion batteries (ZIBs), in general, has shown to greatly improve the cyclability of the cathode, very recently. Despite a growing number of studies on this issue with respect to manganese-based cathodes, a complete understanding on the role of Mn2+ additive towards the electrochemical reaction in ZIBs has not yet been reached. In such a scenario, we studied the electrochemical activity of one such manganese-based cathode, ZnMn2O4 (ZMO) with zinc in a ZIB. Zinc manganate, as a ZIB cathode, is an intriguing choice due to its high theoretical capacity and voltage. We compared the electrochemical reaction of this ZMO nanorods cathode obtained through a simple co-precipitation process in the presence of a 0.1 M MnSO4 (MS) solution as a full-time electrolyte, as an additive in zinc sulfate (ZS) electrolyte (1 M ZnSO4 + 0.1 M MnSO4) and in its absence or a full-time zinc sulfate (ZS) electrolyte (1 M ZnSO4), respectively. Systematic investigations including ex situ X-ray diffraction (XRD), scanning electron microscopy (SEM), and transmission electron microscopy (TEM) studies revealed the reasons for the superior stability and high reversibility of ZMO in the ZMS electrolyte medium. The exceptional performance was facilitated by the the electrochemical equilibrium between Zn2+ and Mn2+ ions via a stable Zn2+ (de)insertion in the bulk, a reversible electro-deposition/dissolution of MnO2 from the Mn2+ additive in the electrolyte onto(from) the surface of the cathode and the reversible Zn-insertion into the formed surface MnO2 layer. This finding is significant as it is contrary to the conventional understanding that the addition of Mn2+ merely tends to prevent manganese dissolution thereby facilitating a stable cycle-life performance of the cathode in ZIBs.
Hierarchical Porous Nickel-Doped Vanadium Dioxide (B) Nanobelts with Ultrahigh Rate Capability and Long Cycle Life for Aqueous Rechargeable Zinc-Ion Batteries Yi Cai and Rodney Chua; Nanyang Technological University, Singapore

Recently, aqueous rechargeable zinc-ion batteries (ARZIBs) have attracted great attention as compared to commercial lithium-ion batteries due to their unique advantages of high intrinsic safety (non-flammable water-based electrolyte) and low cost. [1-3] Over the past few decades, much progress has been focused on the exploration of suitable cathode materials. Among them, vanadium dioxide (B) has been considered as a potential cathode for ARZIBs owing to its unique double layers of V_4O_10 type with tunnels, which can facilitate rapid zinc-ions de/insertion processes. [4] However, the reported VO_2 (B) displays a high initial capacity but noticeable capacity fading and especially declines drastically at a high current rate. Compositing VO_2 (B) with an electrically conductive matrix has recently been introduced as an effective way to improve the power capability. However, it can only improve the external electric conductivity and the usage of expensive carbon (graphene) negates the cost advantage of vanadium oxides. Therefore, it is of great importance to construct novel VO_2 (B) electrode materials with excellent electrochemical performance.

Herein, we report an alternative approach to designing and engineering a hierarchical porous Ni-doped vanadium dioxide (B) nanobelts for ARZIBs. The as-synthesized samples were characterized by X-ray diffraction (XRD), Raman spectroscopy, scanning electron microscopy and transmission electron microscopy (TEM). The existence of Ni dopant was confirmed by the X-ray absorption near-edge structure studies (XANES) and X-ray photoelectron spectroscopy analysis. Electrochemical studies indicate that the Ni-doped VO_2 nanobelts electrode exhibits superior cycling stability and ultrahigh rate capability with long cycle life, which is significantly higher than that of the undoped VO_2 (B). This can be attributed to the utilization of Ni dopant to electrical wiring the electroactive material, the intrinsic conductivity of VO_2 can be effectively increased. In-operando XRD measurements coupled with ex-situ TEM micrographs taken at specific potentials were exploited to gain a further understanding into the structural evolution upon cycling and ions storage mechanism. The results of the study can potentially open the doors for the widespread application of constructing other elemental doping materials as cathodes with high rate capability and long cycle life for aqueous rechargeable batteries.

Flexible Zinc Ion Batteries Chunyi Zhi; City University of Hong Kong, Hong Kong

Prussian blue analogue (PBA)-type metal hexacyanoferrates have been considered as significant cathode materials for aqueous rechargeable zinc batteries (ZBs) due to the open face centered cubic framework, multiple active sites, and environmental benign. However, these PBA-type cathodes, such as cyanogroup iron hexacyanoferrate (FeHCF), suffer from ephemeral lifespan (≤1000 cycles), inferior rate capability (1A g⁻¹), and low operating voltage (ca. 1.2 V). This is because the redox active sites of multivalent iron (Fe(III/II)), which dominates its electrochemical activities, can only be very limited activated and thus utilized. The limited activity is attributed to the spatial resistance caused by the compact cooperation interaction between Fe and the surrounded six cyanogroup per unit, and the inferior conductivity. In this paper, surprisingly, we found high-voltage-scanning can effectively activate the C-coordinated Fe (redox active sites) in FeHCF cathode in ZBs. The activation spurred the increase of capacity at a high operating voltage plateau of ca. 1.5 V. Thanks to this activation, the Zn-FeHCF hybrid-ion battery achieved a record-breaking cycling performance of 5000 (82% capacity retention) and 10000 cycles (73% capacity retention), respectively, together with a superior rate capability of maintaining 53.2% capacity at super-high current density of 8 A g⁻¹ (ca. 97 C). To the best of our knowledge, this is the best cycling performance among all the Zn-PBA batteries up to now. As for the mechanism, the reversible distortion and recovering of crystalline structure caused by the (de)insertion of zinc and lithium ions was revealed. The developed strategy of applying a high-voltage-scan to trigger a greatly enhanced overall electrochemical performance of FeHCF can be easily extended to other PBA materials and other battery systems. We believe this work represents a substantial advance on PBA electrode materials and may essentially
promote application of PBA materials.

5:35 AM S.EN05.02.08
Flexible Quasi-Solid-State Zinc-Ion Rechargeable Batteries for Subzero Temperature Applications Ying Wang and Yehong Chen; Louisiana State Univ, United States

The emerging zinc ion rechargeable batteries show high potential in the fast expanding market of electrochemical energy storage devices owing to their intrinsic safety and low cost, as they use aqueous electrolytes and zinc anodes that are stable and come from abundant sources, while current popular lithium ion batteries employ flammable organic electrolytes. Therefore, it would be very appealing to utilize zinc ion batteries in environments where safety is very crucial, such as ocean or space systems. However, it is challenging to use zinc ion battery in extremely cold environments due to its aqueous electrolyte. Herein we have prepared new flexible quasi-solid-state zinc ion battery consisting of anti-freezing gum-based electrolyte, high-capacity ammonium vanadate cathode and zinc foil anode, for subzero temperature applications. High concentration zinc salts are used to depress the freezing point and maintain the ionic conductivity of the quasi-solid-state electrolyte. The as-prepared battery cells exhibit a reversible capacity of 275mAh/g at 0.2 A/g at room temperature and 170mAh/g at 0 degreeC. When cycled at 0.5 A/g, the cell delivers an initial discharge specific capacity of 155mAh/g and maintains 119mAh/g after 100 cycles at 0 degreeC, and at -20 degreeC it shows an initial discharge capacity of 122mAh/g and a final capacity of 93mAh/g after 100 cycles. The capacity retention becomes higher when cycled at higher rate. As such, the high-performance quasi-solid-state zinc ion batteries with good mechanical flexibility can find potential wide applications in wearable devices and cold environments.

Reaction Mechanisms for Long-Life Rechargeable Zn/MnO2 Batteries Yun Li1, Shanyu Wang1, James Salvador2, Jinpeng Wu1, Bo Liu1, Wanli Yang2, Jiong Yang3, Wenqing Zhang4, Jun Liu1 and Jihui Yang5; 1University of Washington, United States; 2General Motors R&D Center, United States; 3Stanford University, United States; 4Shanghai University, China; 5Lawrence Berkeley National Laboratory, United States; 6Southern University of Science and Technology, China

Rechargeable aqueous Zn/MnO2 batteries are promising for large-scale grid energy storage applications owing to their low cost, environmentally benign constituents, excellent safety, and relatively high energy density. Their usage, however, is largely hampered by the fast capacity fade. The complexity of the reactions has resulted in long-standing ambiguities of the chemical pathways in Zn/MnO2. In this talk, I will discuss our latest work on discerning the reaction mechanisms of rechargeable Zn/MnO2 batteries. We find that both H+/Zn2+ intercalation and conversion reactions occur at different voltages and that the rapid capacity fading can clearly be ascribed to the rate-limiting and irreversible conversion reactions at a lower voltage. By limiting the irreversible conversion reactions at ~1.26 V, we successfully demonstrated high power and long life that are superior to most of the reported Zinc-ion Batteries or even some lithium-ion batteries.

Transition Metal Oxide Cathodes in Aqueous Zn Batteries—Electrochemistry and Mechanism Esther S. Takeuchi1,2, Kenneth Takeuchi1 and Amy Marschilok1,2; 1Stony Brook University, The State University of New York, United States; 2Brookhaven National Laboratory, United States

Rechargeable aqueous Zn batteries are being actively explored due to the high natural abundance and safety associated with Zn, along with the intrinsic nonflammability and the high ionic conductivity of the aqueous electrolyte. While the individual cell voltage is lower than lithium systems, the benefits may be significant for some application where low cost and nonflammability are key considerations. Several cathode systems are under exploration for zinc based batteries. The most frequently explored cathode materials are oxides based on the transition metals manganese or vanadium where both layered and tunneled structural motifs have been utilized. The discharge mechanisms can be complex where there can be a combination of H+ insertion and Zn2+ insertion.
Further, the mechanisms can be highly electrolyte dependent. This presentation will discuss exploration of cathode materials used in Zn based aqueous batteries and their electrochemistry. Characterization methods used for the analysis include cyclic voltammetry, galvanostatic discharge, scanning electrochemical microscopy, x-ray diffraction, x-ray photoelectron spectroscopy, scanning electron microscopy with energy dispersive x-ray spectroscopy mapping, and x-ray micro-fluorescence spectroscopy will be highlighted.

Aqueous Rechargeable Zinc Ion Batteries—Parasitic Reactions and Cycle Life Degradation Balaji Sambandam,
Vaiyapuri Soundharrajan, Vinod Mathew, Muhammad H. Alfaruqi, Sohyun Park, Junji Piao and Jaekook Kim; Chonnam National University, Korea (the Republic of)

Since after a new concept of mild acidic aqueous rechargeable zinc-ion batteries (ARZIBs) was introduced in 2011, the technology has been establishing gradually. ARZIBs have proven to be the most eco-friendly energy storage systems (ESSs) as they use zinc as the negative electrode (with a notable large theoretical capacity value of 820 mAh g⁻¹). Zinc is widely available in the Earth’s crust and forms a non-toxic, low-cost aqueous electrolyte, thus ensuring low principal investment and high reliability and safety. Till to date, both manganese and vanadium oxides are widely utilized as cathode for this technology and well documented. However, all these oxides have their drawbacks accompanied with their life stability through long-term cycling, particularly at low current rates. The reason is: electrolyte pH change due to metal dissolution during electrochemical reaction, resulting a reversible parasitic reaction which seriously affects the cycling life of a cathode, depending on type of electrolyte being employed. Thus a most reversible product of zinc basic sulfate (ZBS, Zn₄(OH)₆SO₄·nH₂O), an insulating material, formed/dissolved on the cathode-electrolyte interface due to change of electrolyte pH resulting from metal dissolution, when ZnSO₄ utilized as an electrolyte. Irrespective of the cathode used, this side reaction related to ZBS formation is observed in most of the reported ARZIBs. As the reason, most of the reported studies demonstrate long cyclability in metal oxides-based electrodes at very high current drains. In other words, the application of high current drain increases cycle life-span as much as it can before the electrode demonstrates capacity fading due to metal dissolution.

Through Operando analyses, this work establishes the parasitic reaction during electrochemical reaction and document its consequence on the cycle life of the aqueous battery. This will be discussed in detail.

Minimal Overhead Storage Technology—Living Forever By Dying Everyday Daniel Steingart; Princeton University, United States

In this work we seek to reduce cost and increase cycle life of a grid scale system by de-emphasizing the requirements for shelf life and short circuit prevention. We show a reconfiguration of the zinc-bromine system creates a system that may “live forever by dying everyday” by eliminating much of the balance-of-plant and exploiting the physical properties of the bromine and zinc. This "solution" also creates new questions. In a system that can safely short circuit at any point, what defines state of charge and state of health? At what point is the battery now "dead"? Is this actually a useful system? The system will be illustrated and current answers to these questions will be discussed.

5:15 AM *S.EN05.04.02
Organic Electrode Materials for Aqueous Batteries—A Mechanistic Study Ye Zhang and Yan Yao; University of Houston, United States

I will present how quinone based organic materials can be designed to address the short cycle life challenges in aqueous batteries -- the structural and chemical instability of anode electrode plays a critical role. Quinone-based organic crystals can store multiple protons with high reversibility, which makes them promising candidates for the anode materials for aqueous batteries. However, the understanding of molecular structures and packing motifs on proton storage and proton-induced
phase transition process is currently lacking. Recently we utilized the synchrotron-based X-ray surface scattering technique to probe the tetrachloro-p-benzoquinone (TCBQ) single crystal surface structure change during H⁺ insertion in operando. TCBQ underwent a two-phase reaction during the proton insertion process as the crystal planes of protonated TCBQ (H₂TCBQ) formed step-by-step on the crystal surface. Quinone-based polymers have also demonstrated superior performance in aqueous Na⁺, Ca²⁺, and Zn²⁺ batteries. We will also present mechanistic studies using in-situ techniques such as EQCM-D, FT-IR, and optical imaging that provide insights on how to optimize ion-solvent-polymer interactions in aqueous batteries to further improve cycle life.

**Functionality Design of Nanoparticles via Surface Modification and Templated Synthesis**
Elena Shevchenko; Argonne National Laboratory, United States

Surface modification of nanoparticles with organic molecules and metal cations is a powerful tool to direct their assembly and catalytic properties. The composition of the inorganic cores determines the ability of nanoparticle to be modified. We will discuss the effect of surface modification and purification on catalytic and photocatalytic properties of the metal and semiconducting nanoparticles. We will also demonstrate that functional materials can be obtained using templated synthesis. The sequential infiltration synthesis which involves diffusion-controlled penetration and subsequent chemisorption of inorganic precursor molecules inside polar domains of the block-copolymer template is proposed as an efficient chemophysical approach to design highly porous all inorganic single and multi-component nanostructures. We will show that this approach can be efficiently used for the fabrication of films with a low refractive index that enables the design of single-layer and broad-band graded-index anti-reflective coatings (ARCs). The fine-tuning of the refractive index can be achieved via control over the characteristics of the block copolymer templates, and the number of infiltration cycles. We will show that modification of the block-copolymer template with cations of different elements prior to the gas-phase infiltration cycles enables the fabrication of multicomponent structures consisting of highly accessible thermally stable functional centers randomly distributed in the highly porous host matrix.

**Realizing Superior Energy Output for Aqueous Rechargeable Zn-Ion Batteries Using Na₂V₆O₁₆.₃H₂O Cathode**
Vaiyapuri Soundharrajan, Balaji Sambandam, Sohyun Park, Moonsu Song, Sunhyeon Park and Jaekook Kim; Chonnam National University, Korea (the Republic of)

Arguably, aqueous rechargeable Zn-ion Batteries (ARZIBs) are currently the most efficient energy storage device (ESD) for eco-friendly grid-scale applications, as associated with organic batteries such as lithium and sodium-ion batteries. However, for the long-standing storage requests the present cathode materials used in the ARZIBs are not sufficient; due to the poor rate capability and fast capacity fading issues. In the present study, a stable and robust Na₂V₆O₁₆.₃H₂O (NVO) Cathode is introduced for ARZIBs, which found to satisfy the above-said uncertainties by delivering superior electrochemical Zn storing capability. In situ synchrotron X-ray diffraction technique is used to establish the Zn storage mechanism in NVO cathode during the Zn (de)insertion stage. The constructed ARZIBs using NVO cathode and metallic Zinc anode in the presence of low-cost ZnSO₄ electrolyte delivers high specific energy of 90 Wh kg⁻¹ at a specific power of 15.8 KW kg⁻¹, and superior cycling stability (80% capacity retention after 1000 cycles) at 40°C (1c=361 mAh g⁻¹), illuminating the material rewards for an eco-friendly ambiances.

**S.EN05.05.11**

**Potassium-Pillared V₂O₅.nH₂O Nanorods with Exposed Layer Structure as High-Performance Cathode Materials for Low-Cost Aqueous Rechargeable Zinc-Ion Batteries**
Saiful Islam, Muhammad Alfaruqi, Vinod Mathew, Sohyun Park, Jun Lee, Moonsu Song and Jaekook Kim; Chonnam National University, Korea (the Republic of)

Research interest in aqueous rechargeable zinc-ion batteries (ARZIBs) is growing enormously because of their low-cost and
eco-friendly cell components. However, designing high-performance cathode materials towards practical application of ARZIBs remains a great challenge. In this contribution, ground-breaking work on the potassium-pillared V$_2$O$_5$.nH$_2$O (K$_{0.5}$V$_2$O$_5$.nH$_2$O) nanorod with exposed layer structure as high-performance cathode for ARZIB is presented. The storage mechanism of the K$_{0.5}$V$_2$O$_5$.nH$_2$O cathode in ARZIB is systematically elucidated using a combined of *in operando* synchrotron X-ray diffraction, *ex situ* synchrotron X-ray absorption spectroscopy, *ex situ* TEM analyses, and first-principle calculations. The K$_{0.5}$V$_2$O$_5$.nH$_2$O cathode exhibits a remarkable discharge capacity of 439 and 286 mA h g$^{-1}$ at current densities of 50 and 3000 mA g$^{-1}$, respectively. Furthermore, it recovers 96% of the capacity after 1500 cycles at 8000 mA g$^{-1}$. Impressively, the Zn/K$_{0.5}$V$_2$O$_5$.nH$_2$O battery offers a specific energy of 121 Wh kg$^{-1}$ at a high specific power of 6480 W kg$^{-1}$. The superior performance of the cathode is attributed to its unique exposed layer structure with high surface energy, high conductivity, and low migration barrier. This study provides an insight for designing high-performance cathode materials for ARZIBs and other electrochemical systems.

**Improving Performance of Zn Ion Battery by 3D Engineering of Zn Anodes**  
Sanket D. Bhoyate, Irsalan Cockerill, Marcus L. Young and Wonbong Choi; University of North Texas, United States

Batteries play significant role in powering modern electronic devices. Li-ion batteries are widely used in such applications. However, there are several factors such as scarcity of Li metal, major safety issues, cost and life cycle that can affect the long-term applicability of Li-batteries. Recently, aqueous Zn-ion batteries have caught research attention due to their characteristic properties such as intrinsic safety, low cost and high theoretical volumetric capacity desired for safer energy storage system. Due to high molecular weight of Zn metal, the active weight utilization of Zn anode plays major role in designing commercial batteries. Inefficient use of Zn ions from anodes can result in inferior battery performance. The active utilization of Zn anodes can be improved by decreasing the unwanted weight from Zn anodes and increasing electrochemically active surface area. In this study, we used additive manufacturing assisted technique to fabricate 3D Zn anode. Our results suggest, that 3D Zn anode show higher rate capability at high charge-discharge current as compared to commercial Zn foil. The higher performance owes to the porous surface area of designed 3D Zn anode and can be used for high-performance battery application.

Batteries play significant role in powering modern electronic devices. Li-ion batteries are widely used in such applications. However, there are several factors such as scarcity of Li metal, major safety issues, cost and life cycle that can affect the long-term applicability of Li-batteries. Recently, aqueous Zn-ion batteries have caught research attention due to their characteristic properties such as intrinsic safety, low cost and high theoretical volumetric capacity desired for safer energy storage system. Due to high molecular weight of Zn metal, the active weight utilization of Zn anode plays major role in designing commercial batteries. Inefficient use of Zn ions from anodes can result in inferior battery performance. The active utilization of Zn anodes can be improved by decreasing the unwanted weight from Zn anodes and increasing electrochemically active surface area. In this study, we used additive manufacturing assisted technique to fabricate 3D Zn anodes. Our results suggest, that 3D Zn anode show higher rate capability at high charge-discharge current as compared to commercial Zn foil. The higher performance owes to the porous surface area of designed 3D Zn anode and can be used for high-performance battery application.

Zinc Oxide Nanostructures Synthesized by a Simple Hot Water Treatment Method for Photocatalytic Degradation of Organic Pollutants in Water
Ranjitha Hariharalakshmanan, Busra Ergul, Nawzat S. Saadi, Khalidah Al-Mayalee and Tansel Karabacak; University of Arkansas at Little Rock, United States

The use of zinc oxide (ZnO) nanostructures as a photocatalyst for the degradation of organic pollutants in water has received significant attention over the recent years. However, synthesis methods for producing ZnO nanostructures are generally costly, complicated, and hazardous to the environment. In this work, we demonstrate the synthesis of zinc oxide nanostructures by a simple hot water treatment (HWT) method and the photocatalytic activity of the hence produced nanostructures. HWT is a one-step, low-cost, eco-friendly, and scalable nanostructure growth method. By HWT, various metal oxide nanostructures can be produced simply by the interaction of metals with hot water without the need for any chemical additives in the solution. Growth of metal oxide nanostructures by HWT involves the formation of metal oxides and their release from the surface of the metal into water, the migration of the metal oxides in water and their re-deposition at a different part of the metallic surface, which initiates the growth of nanostructures. In this study, we used zinc powder and plates for producing the ZnO nanostructures by HWT in DI water at 75 °C. Scanning electron microscopy images and X-ray diffraction were utilized to verify the formation of ZnO nanostructures. Zinc plates produced a suspension of ZnO nanostructures in water, while on the other hand Zn powder resulted in a predominantly core-shell geometry of Zn particle-core and ZnO nanostructures-shell also mixed in water. We used these nanostructures + water suspensions for our photocatalytic degradation studies. Methylene blue was used as a model organic pollutant. We mixed the ZnO nanostructure suspension with methylene blue and exposed it to UV light. The degradation of methylene blue was observed by measuring its absorbance values using a UV-Visible spectrophotometer over a period of four hours. We observed a 20% decrease in the concentration of methylene blue in four hours when nanostructured Zn/ZnO core-shell powder suspension was used, and a 30% decrease was achieved when ZnO nanostructure-only suspension was used. Methylene blue alone was also exposed to UV light for the same period as a control experiment and we did not observe any significant decrease in its concentration. These preliminary results indicate that hot water treatment method presents a very simple, cost-effective, scalable, and eco–friendly alternative for the synthesis of zinc oxide nanostructures for photocatalytic water treatment applications.
Mitigating atmospheric CO₂ concentration is a great challenge for the twenty-first century. It can be done only by capturing and converting CO₂ into useful fuels with the help of catalysts. Knowledge of the reaction mechanism in CO₂ hydrogenation reactions is key to the rational design of highly efficient catalysts. Here, we investigate the CO₂ conversion into methanol on Rh intercalated Graphene/SiC using density functional theory calculations and kinetic Monte Carlo simulations. The adsorption energy, bonding configuration, bond lengths, and vibrational frequencies of all the surface intermediates involved in the reaction mechanisms are studied. Present results on methanol production suggest that the hydrogenation of CO₂ to CO occurs via the reverse-water-gas shift (CO₂ + H₂ → CO + H₂O) reaction rather than formate (HCOO⁻) or direct C−O bond cleavage pathways. The produced CO can either desorb or further react with hydrogen to produce CH₄ or CH₃OH since the adsorption energy of CO is low. The intermediates of the CO₂ pathway for methanol production includes *OCOH, CO, *CHO, *CHOH, and *H₂COH. The reaction barrier energy for each elementary steps involved in CO₂ hydrogenation will be discussed, and that can provide further insights into the reaction mechanism. Finally, we will also discuss how the energetics affects the kinetics of the reaction, such as the overall rates for CO₂ conversion and the production of CO, CH₃OH, and CH₄ under reaction condition.

The utilization of fossil fuel subsidiaries, for example, coal, heavy oil, natural gas and petrol have transformed into global issue of environment concern. The use of energy is rapidly expanding with rising population in view of which there is a need of utilizing efficient green sustainable energy sources to fulfil the requirements of energy supply [1]. The solar light based energy can be converted and stored in the form of fuels, for instance, generation of hydrogen (H2) by photoelectrochemical (PEC) water splitting appears to be a potential alternative to the fossil fuels [2]. PEC water splitting is one of the most efficient solar-to-fuel conversions but photoelectrochemically unstable. These significant progresses may lead us to the practical implementation of solar fuel production. We focused on the exciting progresses achieved by using nanostructuring strategies, specifically regarding how the nanostructure influences the charge transport and separation. Special attention was paid to investigate how a nanoscale coating (overlayer) passivates the surface states, thereby reducing the surface electron hole recombination, and how a nanoscale coating (protective layer) prevents the photocorrosion or photopassivation of the semiconductors with optimal band gaps. We hope that the design strategies using these nanostructures will offer new and greater opportunities for efficient solar fuel production to existing photocatalytic and photoelectrochemical systems.

Solar Fuel Production—Opportunities for Nanostructures Zhigang Zou; Nanjing University, China

Conventional photocatalysts based on metals and semiconductors are sometimes rigid and possesses stability issues when applied in the treatment of industrial wastewater. Thus, novel photocatalysts based on polymer/nanomaterial composites are attracting more interest. Although much effort has been devoted to acquire catalysts with high efficiency and long-term durability, this work puts forward a simple and green three-steps procedure for synthesis of diethylenediamine-modified reduced graphene oxide (DD-rGO) grafted on a magnesio-thermically produced silicon carbide (SiC) to achieve one-vessel conversion of organic pollutants into useful fuels such as methanol and ethanol under simulated solar irradiation. The mechanism behind the distinct reactivity and stability of the as-prepared photocatalyst was proposed. We expect that these entirely new nanocomposite structures will not only pave way for the development of highly efficient and stable photocatalyst systems but also have a wider impact in applications (such as water treatment) where catalysts stability is essential.

Low Temperature and Green Synthesis of Diethylenediamine Functionalized Reduced-GO Grafted on SiC for Photodegradation and Conversion of Organic Pollutants to Useful Fuels Olusegun Abass; Nanyang Technological University, Singapore

The photocatalytic and photoelectrochemical reduction of water or CO2 is an intriguing approach to producing sustainable solar fuels, and has attracted growing and intense interest. Nanostructuring of photocatalysts and photoelectrodes has been proven to be a strong strategy to dramatically improve overall solar-to-fuel conversion efficiencies. Another technological barrier for the practical implementation of solar fuel production is long-term material durability, which has recently been well addressed by using conformal coatings of protective layers onto the narrow band-gap semiconductors that are suitable for efficient solar-to-fuel conversions but photoelectrochemically unstable. These significant progresses may lead us to the practical implementation of solar fuel production. We focused on the exciting progresses achieved by using nanostructuring strategies, specifically regarding how the nanostructure influences the charge transport and separation. Special attention was paid to investigate how a nanoscale coating (overlayer) passivates the surface states, thereby reducing the surface electron hole recombination, and how a nanoscale coating (protective layer) prevents the photocorrosion or photopassivation of the semiconductors with optimal band gaps. We hope that the design strategies using these nanostructures will offer new and greater opportunities for efficient solar fuel production to existing photocatalytic and photoelectrochemical systems.
is attributed to the more absorption of visible light of the solar spectra and increase the mobility of photogenerated charge carriers which improves the separation efficiency and reduces the recombination of charges. The possible mechanism responsible for the PEC water splitting have been proposed.

Non-Noble Metal Plasmonic Nanoparticles as Highly Efficient Light Absorber for Solar Steam Generation Fan Yang and Yadong Yin; University of California, Riverside, United States

Plasmonic nanoparticles have attracted great interest in harvesting solar energy due to their excellent capability in photothermal conversion. However, noble-metal-based plasmonic nanoparticles typically exhibit a narrow absorption peak, which limits their ability to fully utilize solar energy. Compared with conventional noble metal nanoparticles, transition metal nanoparticles show relatively broad resonance band, allowing absorption of a larger fraction of solar radiation. However, the application of these nanoparticles is limited due to their poor stability, especially in the presence of oxygen and water. In this presentation, we report the synthesis of Ni@C@SiO₂ core-shell nanoparticles that can be used as light absorbers. The stability of Ni nanoparticles is greatly enhanced by a layer of densified SiO₂. Moreover, by adding a carbon layer between Ni and SiO₂, the absorption peak of Ni can be expanded and red-shifted to maximize the overlapping between the absorption spectra of core-shell nanoparticles and the solar radiation spectra. The colloidal nature of the nanoparticles allows their easy processing into a thin film that can be attached to a floating melamine foam, producing an integrated solar steam generator. The three-layered core-shell nanoparticles exhibit an excellent photothermal property and high steam generation efficiency under solar illumination.

Photoelectrochemistry of Cobaloxime-Modified Gallium Phosphide and Gallium Arsenide Surfaces Nghi Nguyen, Brian L. Wadsworth, Edgar Reyes Cruz, Daiki Nishiori and Gary F. Moore; Arizona State University, United States

Photoelectrochemistry provides a strategy for creating fuels from sunlight.1-5 In this poster presentation, I will describe the chemistry of immobilizing polypyrrol coatings containing cobaloxime-type catalysts onto either GaP or GaAs surfaces. When wired in a three-electrode configuration with appropriate counter and reference electrodes, the hybrid constructs use light to power the production of hydrogen gas with near unity faradaic efficiency from aqueous solutions in the absence of sacrificial chemical reductants and with no electrochemical forward biasing. When operating at the equilibrium potential of the hydrogen evolution reaction under simulated 1-sun illumination, the modified- GaP and GaAs assemblies produce current densities of 1 and 10 mA cm⁻², respectively. Analyses of the wavelength-resolved external and internal quantum efficiencies show the modified-GaP assemblies are active over wavelengths ranging from 300 to 550 nm, and the modified-GaAs assemblies are active over wavelengths ranging from 300 to 870 nm. The cobaloxime-modified GaAs thus gives a higher rate of photoelectrochemical fuel production due to the improved spectral overlap of the semiconductor's absorption properties with the solar flux spectrum.

Human-engineered materials capable of generating fuels from sustainable energy sources provide an approach to satiating modern societies’ energy demands, with minimal environmental impact. In this poster presentation, I will describe hybrid photoelectrosynthetic assemblies composed of gallium phosphide (GaP) functionalized with metalloporphyrin complexes of five different transition metal ions: Fe(III), Co(II), Ni(II), Cu(II), and Zn(II). Surface attachment of these metalloporphyrin complexes was achieved using a previously reported UV-induced photochemical grafting method. The photoelectrochemical properties of these heterogeneous-homogeneous materials will be contrasted with electrochemical properties of the isolated, homogeneous metalloporphyrins and other previously reported heterogeneous-homogeneous constructs.

Self-Assembling Effects of NiFe Hydroxide on 3D Nano-Morphology and Enhanced Oxygen Evolution Performance

Layered double hydroxide (LDH) has been proven to have excellent performance in water splitting reactions, especially toward the oxygen evolution reaction (OER). The morphology of NiFe LDH is one of the key factors in improving its electrochemical performance. However, the controlling factors and mechanisms of morphological evolution of the nanoflower-shaped NiFe LDH remain poorly understood. In this study, NiFe LDH nanoflowers were synthesized by hydrothermal method, and the morphology and structure of NiFe LDH crystals are carefully controlled during the synthetic stage. The results indicate that NiFe LDH primary nano flakes rapidly agglomerate to form a nucleus matrix at the initial stage. Subsequently, these nano flakes are laterally aggregated and connected orderly on the substrate to form nanoflowers, and the nano-petals are generated by a rotating and edge-to-edge orientation attachment (OA) mechanism. The morphological evolution occurred by staged three-dimensional OA process plays an essential role in the self-assembly of flower-like NiFe LDH crystals. The well-formed NiFe LHD nanoflowers, grown by 10 hours of hydrothermal treatment, exhibits excellent OER performance in alkaline electrolyte, which displays very low overpotential of 190 mV at the current density of 10 mA cm$^{-2}$ and small Tafel slope of 35 mV per decade (much better than RuO$_2$ catalyst). Furthermore, the prepared NiFe LDH still showed high stability after 10,000 cycles of cyclic voltammetry tests. This work provides new insights into the relationship between catalyst morphology and OER performance, and provides new fundamental understanding of hydrothermal synthetic process of NiFe LDH.
Some emerging alloys, such as Mg alloy, are susceptible to galvanic corrosion, consequently accelerating corrosion process and resulting in severe financial loss. The galvanic corrosion potential and current obtained by experimental polarization curves could differ a lot between different literature. Herein, we proposed a semi-empirical model based on the mixed potential theory and first principles calculation to analyze the galvanic corrosion of the metal alloys. Our model is further validated in the case of Mg-Ge alloys, which is composed of anode Mg matrix and cathode Mg_2Ge second phase. The combination of the large anode equilibrium potential difference between Mg and Mg_2Ge, and the Schottky barrier across the interface indicates that the Mg_2Ge second phase can prevent the Mg grain from serving as the cathode and impede the electron transfer between the Mg grains. First principles calculations on the kinetics of hydrogen evolution reaction upon Mg_2Ge reveal that the rate-determining step is the hydrogen adsorption, which is extremely energetically unfavorable but an inevitable intermediate state. The estimated exchange current of the hydrogen evolution upon Mg_2Ge is about 3 orders of magnitude smaller than that on pure Mg, depressing the hydrogen exchange current upon Mg_2Ge and hence the galvanic corrosion of the Mg-Ge alloys. Moreover, some other Mg alloys, such as Mg-Zn and Mg-Sc, were also investigated, which is in close agreement with the experimental observations. Our model is capable of predicting the galvanic corrosion behavior and provide a promising perspective for designing better corrosion-resistant metal alloys.

Fuel cell technologies (FC) make hydrogen (H_2) a promising fuel to produce electrical energy due to their great efficiency and minimal pollution emission. However, one problem is to optimize pure H_2 production. On account of 96% global H_2 production is performed by steam reforming (SR) (76% from natural gas), H_2 purification process must be improved in SR plants to achieve a short-term hydrogen economy.

In order to avoid a cooling process from SR gas in a purification step, materials with high thermal stability and selective oxidation and chemisorption capability of CO must be developed. This work summarizes Li_2MnO_3 behavior as a selective CO oxidizing-captor to purify H_2 from SR gas. Li_2MnO_3 was synthesized by the solid-state method and characterized by XRD, N_2 adsorption-desorption and SEM. To evaluate CO chemisorption process in Li_2MnO_3, dynamic thermal analyses were performed using different gas flow compositions (CO, CO-O_2, CO_2, CO_2-O_2 and N_2). These experiments showed that CO chemisorption is only produced in oxygen absence. Furthermore, CO_2 chemisorption was not evidenced at any CO_2 partial pressure.

Based on these results, isothermal experiments were performed between 550 and 700 °C into a CO atmosphere (N_2 balanced). The isothermal products were identified as Li_2CO_3 and MnO by XRD. It must be pointed out that at temperatures lower than 625 °C Li_2MnO_3 was identified as well. These results demonstrated that CO is chemisorbed as Li_2CO_3. It may be produced by a surface CO oxidation step (into CO_2) that involves the evolution from Li_2MnO_3 (Mn^{4+}) into LiMnO_2 (Mn^{3+}).

An interesting ~2% weight loss was observed at the beginning of all the isotherms (before weight gain started). In order to elucidate the process associated to this, several thermogravimetric and catalytic experiments were carried out. Their solid and gas products were identified by XRD and mass spectrometry, respectively. The catalytic experiments showed CO_2 production at the same temperature range where Li_2MnO_3 weight loss take place. Moreover, after this ~2% weight loss occurs and before weight gain process would perform, the material composition was analyzed by XRD and ATR-FTIR, where Li_2MnO_3 was the only crystalline phase identified in addition to carbonates.

Based on these results, it may be pointed out that an oxidation step is performed at the material surface to oxidize CO into CO_2, where some part of it is chemisorbed as Li_2CO_3, while the rest is released from the material’s surface. In addition, lithium diffusion from bulk to surface in Li_2MnO_3 may be triggered by oxygen vacancies formation (at surface) due to CO oxidation. This could explain wherefore chemisorption process was not performed in CO_2 atmosphere or in oxygen presence. To further analyze Li_2MnO_3, dynamical and isothermal experiments were performed varying the CO-CO_2 partial pressures. These results demonstrated that if CO_2 is involved into the gas flow composition, the CO oxidation-capture process is displaced to higher temperatures and the total weight gain decreases as consequence of less superficial oxygen vacancies formation. Moreover, kinetic constants were calculated using the Jander-Zhang diffusion model, which can be related to ΔH° by the Eyring equation. Results showed that, in addition of CO_2, kinetics diffusion become slower than those obtained into a CO atmosphere, although the ΔH° values decreased.

Finally, Li_2MnO_3 was dynamical tested on H_2 and H_2-CO atmospheres (Ar balanced). These experiments showed a preference oxidation of CO over H_2. Nevertheless, ~10% of hydrogen was oxidized into water while CO was chemisorbed.
Evaluation of Boron Doped Reduced Graphene Oxide as IrO$_2$ Support for Efficient Oxygen Evolution Reaction

Prerna Joshi$^1$, Hsin-Hui Huang$^2$, Masanori Hara$^1$ and Masamichi Yoshimura$^1$; $^1$Toyota Technological Institute, Japan; $^2$Japan Fine Ceramics Center, Japan

With depleting fossil fuel reserves and increasing environmental problems, novel strategies have been developed based on renewable energies. A major source of renewable energy is water, which can produce hydrogen energy in large amounts. Electrochemical water splitting is an excellent way to produce hydrogen as an energy source. For generation of hydrogen at a specific rate, under ideal conditions, 1.23 V must be supplied to the water electrolyzers to allow hydrogen evolution reaction (HER) and oxygen evolution reaction (OER) in a feasible manner. In practice, OER is a complex reaction with slow kinetics and low overpotential, hence, precious metal catalysts such as iridium and ruthenium oxides (IrO$_2$, RuO$_2$) are used to reduce the overpotential for OER$^1$. However, their high cost and low natural abundance limit their extensive commercialization. One of the plausible approach can be the reduction of metal loading with the use of conductive support. For metal catalysts, the reduction in size of the catalysts (formation of nanoparticles (nps)) can help in increasing active surface area. Further, for conducting support, doped graphene can be used as a support because it can tune the electronic structure of catalysts to improve specific activity. In the current research, we have studied the electrochemical activity of IrO$_2$ nps catalyst supported on heteroatom-doped reduced graphene oxide (rGO) as the carbon support. Along with alteration of the electronic structure of the IrO$_2$ nps, heteroatom-doping of graphene$^2$ also promotes ion diffusion at the electrode-electrolyte interface, improving the overall performance of the catalyst.

Graphene oxide (GO) was prepared from synthetic graphite (Sigma Aldrich) by modified Hummers’ method$^3$. For boron doping, boric anhydride (B$_2$O$_3$, BA) was used as the precursor. Briefly, BA and GO were mixed together and ultrasonicated in water for 1 hour. The mixture was freeze dried and the obtained powder was pyrolysed at 1000 °C for 60 min in N$_2$ atmosphere. The pyrolysed sample was washed with boiling water and ethanol to yield boron-doped rGO (B-rGO). As the second step, IrO$_2$ nps were decorated onto B-rGO by hydrothermal synthesis at 150 °C for 4 h using H$_2$IrCl$_6$ as the Ir precursor. The synthesized materials were characterized for its chemical composition, morphology and electrocatalytic activity using various analytical techniques such as X-ray photoelectron spectroscopy (XPS), transmission electron microscopy (TEM), energy dispersive X-ray spectroscopy (EDX), cyclic voltammetry (CV) and linear sweep voltammetry (LSV).

XPS analysis of the synthesized catalyst, IrO$_2$-B-rGO revealed the presence of all constituent elements at their respective binding energies. The XPS spectra were deconvoluted to obtain the types of constituent C and B. Ir 4f peaks for IrO$_2$-B-rGO were obtained at lower binding energies than the unsupported IrO$_2$ powder confirming the change in electronic states of Ir due to boron doping. Further, EDX analysis indicated B to be present in ~2.0 wt% and Ir in 3.3, 7.1 and 19.6 wt%. TEM results exhibited the uniform dispersion of IrO$_2$ over the wrinkled B-rGO sheets with an average particle diameter of 1.5 nm. Electrochemical analysis in 0.5 M H$_2$SO$_4$ with Ir loading of ~140 µg cm$^{-2}$ on glassy carbon (GC) electrode showed that the onset potential was 1.41 V vs RHE for IrO$_2$-B-rGO which was ~90 mV lower than that of IrO$_2$ decorated on undoped rGO (IrO$_2$-rGO). Despite the low Ir content, higher current density was obtained for B-doped catalyst as compared to the IrO$_2$-rGO. Increase in current density for B-doped catalyst is attributed to charge redistribution in graphene lattice which alters the electronic states for Ir and provides additional active centres for catalysis.

Alkylphosphine as a Ligand for Shape-Controlled Synthesis of Metal Nanostructures

Shutang Chen and Gugang Chen; Honda Research Institute USA Inc., United States

Metal nanoparticles with high index facets and controllable shape have demonstrated excellent catalytic performance because of their unique surface chemistry. Generally, the selection of proper ligand plays an important role for the shape-control of nanoparticles. Here, different kinds of alkylphosphines with high temperature solution reduction method are adopted to synthesize metal nanostructures. With increasing chain length of alkylphosphines, different morphologies of copper nanoparticles were synthesized in a hydrophobic system, such as nanocubes, tetrahedron nanoparticles, nanowires, and nanosheets. All these copper nanostructures demonstrated excellent catalytic performance and selectivity to carbon dioxides reduction reaction. Such simple strategy is also extended to the design of other metal nanoparticles for their potential
Single atom catalysis (SAC) represents a promising design for the next generation of robust catalysts. These systems, which are commonly single metal atoms stabilized on carbonaceous materials, maximize catalytic performance while simultaneously minimizing the use of expensive and scarce platinum-group metals (PGM). While it is accepted that the molecular environment of a SAC is of crucial consequence to the chemical activity, the exact catalytic sites and chemical pathways responsible have been a matter of some controversy. For industrially practical non-PGM SAC, optimizing the defect environment stabilizing the single metal atom is necessary for enhanced performance. We will present work using a first principles approach for materials discovery to investigate three less studied earth abundant transition metals (V, Mo, Ta) stabilized on single vacancy and pyridinic N-doped defect moieties on graphene substrates to understand the role of electronic transfer, spin state and steric effects on SAC. Our results of all investigated metals demonstrate single atom stability on graphene substrates with both defect moieties. By modeling carbon monoxide oxidation, a common benchmark reaction, facilitated by these defect stabilized SAC with climbing image-nudged elastic band (CI-NEB) calculations, we find that all activation energies for transition metals stabilized on the pyridinic N-doped graphene surface defect are ~0.8 eV or lower. These low activation energy barriers suggest that the CO oxidation reaction would proceed at room temperature with pyridinic N-dopants present in the defect environment. The CI-NEB calculations further illustrate that SAC of Ta and V on pyridinic N doped graphene significantly decrease the activation energy of CO oxidation by 27% and 44%, respectively. Bader charge analysis reveals that the electronic charge transfer is surprisingly similar across the two defect moieties investigated for all four earth-abundant transition metals. However, the pyridinic N-dopant introduces an additional magnetic moment of 0.53 µB on average. Plotting the density of states of CI-NEB transition states shows spin destabilization of O2 peaks near the Fermi level, suggesting that these imparted magnetic moments could be destabilizing the O2 bond and hence lowering activation energies for CO oxidation in some cases. We will present results suggesting that magnetic moment could play a significant role in enhancing catalytic performance of SAC on nitrogen doped graphene substrates, as well as more traditionally understood mechanisms such as charge transfer and steric effects. Computational design of materials is used to define processing conditions for three-dimensional porous graphene structures. Fabrication and characterization of macroscopic graphene structures with high surface area and architectures to facilitate mass transport will also be presented.
cause deviations from local thermodynamic equilibrium. For all these reasons, synthesis of Bi-containing FeWO₄ by PLD may allow tuning of conductivity, exploration of additional co-doping with other metals, and control of defect concentrations. Using planar and cylindrical Langmuir probes, we have measured the ion density, kinetic energy distribution, and electron temperature in Fe-, W-, and O-rich plumes produced by KrF excimer laser ablation of solid targets that are suitable for growth of FeWO₄. These plasma measurements during PLD conditions show that the plasma density can be adjusted over several orders of magnitude in the 10¹⁸-10²⁰ m⁻³ range, consistent with a correspondingly broad range of deposition rates. Changes in target composition have significant impact in the kinetic energy distribution of ions in the plume. Oxygen-rich targets ablated with a typical 1.4 J/cm² laser fluence and 3.0 mm² spot area, lead to plasmas with wide ion kinetic energy distributions with high fractions of ions in the 80-90 eV range. Similar irradiation conditions for W-rich targets result in plumes dominated by kinetic energies below 5 eV. Thin films grown with changes in laser plasma conditions between these extremes show measurable variation in stoichiometry. We will discuss x-ray photoelectron results on these films that allow correlating changes in W oxidation state with plasma plume composition and kinetic energy. Thin film crystal quality, as measured by x-ray diffraction, will also be discussed in relationship to film stoichiometry and laser plasma characteristics during growth.

We report an investigation of potential kinetic limitations to the rate of hydrogenation of magnesium diboride. The metals Pd, Fe and Ti, known to be proficient at H-H bond dissociation, were introduced into MgB₂ by ball milling. Pd and Fe are directly introduced as crystalline metals, whereas Ti metal was introduced via the reaction between TiF₃ and MgB₂ to form Ti metal and MgF₂. XRD, FTIR, XAS and TEM data show that the additives persist as metals in the MgB₂ solid, free from significant oxidation of the additive itself (i.e. TiO₂, Fe₂O₃, PdO) as well oxidation of the MgB₂ material (i.e. no MgO, B₂O₃). The Pd in the MgB₂ material consists of two morphological forms: Pd particles of a size ~ 2 – 25 nm diameter with a d-spacing essentially the same as bulk Pd, as well as a highly dispersed Pd component within the MgB₂ matrix. The Fe additive decorates the MgB₂ particles as small particles with sizes ranging from ~ 11 – 34 nm diameter with comparatively little atomic-scale dispersal of the Fe additive. TiF₃ reacts with MgB₂ to form Ti metal and MgF₂, with the Ti and the F smeared out within the MgB₂ base solid. Siweverts-acquired MgB₂ hydrogenation rates for the Pd, Fe and Ti modified MgB₂ are higher than for commercial MgB₂, but the improvement is very modest, about a factor of two at most. H-D exchange studies were conducted to confirm H-H bond breaking in these materials. The data shows that H-H bond breaking is slowest for the bulk MgB₂ material, but much faster for the Fe, Pd and Ti modified samples for which H-H bond breaking reaches equilibrium in about 20 minutes. This work shows that H-H bond dissociation is not limiting the rate of hydrogenation of MgB₂ because extensive H-H bond breaking is already occurring after only 20 minutes whereas the initial hydrogenation to ~0.8 weight percent hydrogen takes about 100 hours. The results also show that surface diffusion cannot be limiting the MgB₂ hydrogenation rate because surface diffusion, a requirement for HD generation, is occurring very rapidly. We speculate that it is the intrinsic stability of the B-B extended hexagonal ring structure in MgB₂ that hinders the hydrogenation of this material. This supposition was supported by B K-edge TFY XAS measurements of the materials, which showed spectroscopically that the B-B ring was intact in these systems throughout most of the material.

Metal-Organc Framework (MOF) Derived Cobalt Oxide and Cobalt Sulfide for Efficient Electrocatalsyts in Water Splitting

Increasing global population and advancement in energy-dependent devices have caused increased use of energy in consumer and industrial appliances, electronic devices, and automobiles creating an urgent need for clean and renewable energy sources. Electrochemical water-splitting is one of the greenest ways to generate clean and high-performance fuel. Water-splitting generates hydrogen and oxygen gases. The generated hydrogen gas can be used as fuel whereas evolved oxygen gas can be used in metal-air batteries or released in the atmosphere as a clean gas. The electrocatalytic properties of most of the materials for water splitting depend upon several factors such as morphology, phase purity, defects, etc. We have synthesized metal-organic framework (MOF) derived cobalt oxide and cobalt sulfide using a facile method for their application in water-splitting as electrocatalysts. 2-methyl imidazole and cobalt nitrate were used for the synthesis of MOF-derived cobalt oxide and MOF-derived cobalt sulfide electrodes. The electrode with MOF-derived cobalt oxide was synthesized via a solvothermal process, while the electrode with MOF-derived cobalt sulfide was prepared through sulfurization using a hydrothermal process. The structural and electrochemical properties of these films were studied in detail. The electrocatalytic activities of the MOF-derived cobalt oxide and sulfide were studied in 1M KOH solution for oxygen evolution and hydrogen
evolution reactions. MOF-derived cobalt oxide showed overpotential of 375 mV and 224 mV to achieve a current density of 10 mA/cm² for oxygen and hydrogen evolution processes, respectively. A significant improvement in electrocatalytic properties was observed with the electrode after sulfurization producing MOF-derived cobalt sulfide. MOF-derived cobalt sulfide displayed overpotential of 278 mV and 220 mV at 10 mA/cm² for oxygen and hydrogen evolution processes, respectively. Our results suggest that a facile method of sulfurization of the MOF-derived compound is a way to achieve high electrocatalytic activities for oxygen and hydrogen evolution reactions in the water-splitting process.

Luminescent Solar Concentrators Based on Self-Contained Silicon Quantum Dots Films for Photovoltaic Applications

Rosendo Lopez-Delgado¹, Alejandra J. Cordova-Rubio², Roberto C. Carrillo-Torres² and Mario E. Alvarez-Ramos²; ¹Cátedras Conacyt - Universidad de Sonora, Mexico; ²Universidad de Sonora, Mexico

The incorporation of energy harvesting systems into architectural elements of buildings is gaining attention as a new possible renewable energy technology for the production of electricity. Luminescent solar concentrators (LSC) represent a promising and cost-effective complement to existing semiconductor photovoltaic (PV) technologies that could be employed as semitransparent windows to contribute to the building’s energy consumption. Typically, an LSC consist of an optical waveguide that collect sunlight from a large-area window and concentrates the emission on the smaller-area edges. The emission is obtained from luminescent materials such as organic dyes, rare earth ions or semiconductor quantum dots in the LSC that absorbs the sunlight and, by a stokes shift, emit photons at wavelengths that are better suitable for absorption by the PV devices coupled at the edges of the LSC, reducing the costs of photovoltaic power generation.

Organic dyes have been the most commonly used luminophores for LSC applications mainly due to their high quantum yield and in some cases its low degradation rate, however, organic dyes no only tend to absorb and convert only a relatively small region of the solar spectrum, but also, they present a large spectral overlap between the absorption and emission regions, which increases the reabsorption losses and prevents the viability of fabrication of large-scale efficient devices. On the other hand, colloidal semiconductor nanoparticles or quantum dots (QDs) exhibit very attractive optical properties and have attracted a lot of attention as potential luminophores for LSC applications. Colloidal QDs are promising candidates since their properties mainly arises from the materials they are made, their size and their surface passivation. Also, QDs can be engineered to manipulate their energy bandgap and the stokes shift values to suppress effectively the reabsorption losses. Here, we report the fabrication of one-pot synthesized and self-contained photoluminescent films based on silicon quantum dots (SiQDs) and its employment on luminescent solar concentrators (SiQDLSC). Silicon quantum dots were synthesized from reduction of (3-aminopropyl) triethoxysilane (APTES) by sodium ascorbate. Besides the reduction of APTES into silicon quantum dots, a silicate matrix host is obtained, which is further employed as the support for the photoluminescent film in the fabrication of the LSC. The size of the synthetized SiQDs were measured by dynamic light scattering and electron microscopy techniques obtaining an average size of 3 nm. Both SiQDs and SiQDLSCs transmittance, absorbance and photoluminescent properties were characterized. The synthesized colloidal SiQDs exhibit an abrupt increase of optical absorption below 425nm extending to the ultraviolet region while emitting photons in a broad band extending from 450 to 600 nm with maximum intensity at 525 nm. SiQDLSC were fabricated in two sets of different dimensions: 1) 50x50x3mm and 2) 25x25x1mm. Set 1 shown a transmittance above 85% while set 2 exhibited above 90% transmittance over the visible region of the electromagnetic spectrum. Both sets shown the absorbance characteristics of the SiQDs decreasing the transmittance (increasing the absorbance) below 425 nm. Photoluminescent properties of the SiQDLSC were measured at the edges of the devices, obtaining broad bands of emission that were slightly blue shifted to around 500nm due to the expected oxidation of the SiQDs surfaces. However, the fabricated SiQDLSC preserve the desired stokes shift that is necessary to prevent reabsorption losses. These results demonstrate a feasible and very attractive method of fabrication of SiQD-based luminescent solar concentrators that presents good transmittance as well as the photoluminescent stokes shift effects desired for their incorporation as PV windows.

3D Interface-Engineered Transition Metal Oxide/Carbon Hybrid Structures for Efficient Bifunctional Oxygen Electrocatalysis in Alkaline and Acidic Environments

Simranjit K. Grewal¹,²,³, Angela Andrade-Macedo¹, Zi Qi Liu¹ and Dr. Min-Hwan Lee¹,²,³; ¹University of California, Merced, United States; ²NASA, United States; ³Lawrence Berkeley National Laboratory, United States

Use of regenerative fuel cells (RFC) requires bifunctionality in oxygen electrocatalysis of oxygen reduction reaction (ORR) and oxygen evolution reaction (OER) to decrease weight and cost for efficient energy conversion. Many RFC based technologies have used noble metals such as Pt and its alloys (Pt/Ir or Pt/Ru) due to their efficient catalytic activity, selectivity and stability in harsh environments. However, their susceptibility to fast degradation during operation, as a result of catalyst agglomeration and poisoning, has driven research to find alternatives [1]. Non-precious transition metal oxides...
(TMO) including Fe₃O₄, MnOₓ and Co₃O₄ have attracted significant attention as a potential candidates [2]. We utilized a composite structure where TiO₂, ZrO₂, or CeO₂ are deposited onto conductive 3D carbon structure such as graphene oxide (GO), metal-organic frameworks (MOFs) or a combination of activated carbon (AC) with GO/MOFs. The use of carbon structures is to leverage their high surface area and excellent electronic conductivity. However, GO contains oxygen based functional groups on the edges and wrinkles that provides an anchor for nanoparticle binding while its basal plane stays relatively non-reactive. To incur a catalytically active sites between the metal oxides and carbon, we functionalize the basal surface of carbon using phosphoric, hydrobromic and/or oxalic acids. After such treatment, various types of carbon structures were hydrothermally reacted with metal precursors (Ce(NO₃)₃ or ZrOCl₂) or nanoparticles (P25). For MOF structures, due their susceptibility towards degradation after the common step of pyrolysis, a thin film of metal oxides are used. However, to adhere the metal oxides properly onto the MOF, we leverage acid treatment similar to our treatment of GO.

The hydroxylated CeO₂/GO hybrids showed the best ORR and OER performance in both alkaline (0.1 M KOH) and acidic media (0.5 M H₂SO₄), in terms of onset/half-wave potential, electron transfer number, and current density (electrochemical performances) when comparing to the performance of Pt/C (for ORR) and IrO₂ (for OER). From a series of material/experimental analyses, a strong tethering of metal oxides upon the basal plane of GO prohibits restacking, and that the particle-carbon interfaces (as oppose to the particle or GO itself) dictates the performance and reaction route, as indicated in density functional theory calculations. In addition, a hybrid catalyst where TiO₂ nanodots are uniformly anchored on phosphorylated MOF by atomic layer deposition (ALD) showed an even better ORR and OER performance in 0.1 M KOH when compared the aforementioned CeO₂/GO hybrid. Materials characterization emphasizes a strong adhesion of metal oxides upon MOF structures, thus providing ample surface interactions for favorable reaction route is important. In addition, an activation of catalytic sites can be realized by a proper engineering of interfaces in each hybrid systems. Finally, we present a facile route of improving operational durability of TMO/carbon hybrids both in alkaline and acidic media: interfacing with an activated carbon after a proper acid treatment.

Enhancing Solar Water Evaporation with Activated Carbon Sai Kiran Hota and Gerardo Diaz; University of California, United States

Thermal based desalination systems involve heating water and collecting the condensate. The use of solar energy to drive the desalination phenomena, utilizing the heat for enhancing water evaporation (steam generation) is attracting wide-spread attention. The process involves absorbing the spectral intensity of solar light and converting it to heat. This photo-thermal conversion can be enhanced by using a strong solar absorber diluted in water, which is a poor absorber of sun light. Among the solar absorbers, carbon materials have proven to enhance water desalination rate while being economical as compared to their plasmonic counterparts. Activated carbon is a carbon-rich source which has many applications such as toxic gas adsorption and industrial effluent treatment. Considering its optical quality, it has the potential to be a strong solar absorber for enhancing water evaporation rate. A series of characterization tests were performed on activated carbon. It showed 94.17% (granular) carbon composition with trace presence of hydrogen and oxygen through ultimate analysis. FT-IR analysis performed showed mostly C=C and aromatic C-H rings. Geometric (envelope) density of the sample was almost 710 kg/m³ with theoretical porosity of 0.663. The skeleton (true) density measured was 2106.9 kg/m³. The density measurements showed that activated carbon can be used as a solid dispersion in water. The granular particles sink to the bottom of the container and behave like a black bottom in enhancing water evaporation. The apparent zeta potential for nanoparticles was measured to be -47.9 mV, showing a good dispersion stability. Optical measurements showed that the absorbance of the activated carbon was 96.35%. The strength of absorbance increases with increasing concentration and can be attributed to increased extinction coefficient of the solar spectral intensity. This increases the fraction of solar absorption in the fluid dispersion system, leading to enhanced heat localization at higher concentrations. Outdoor experiments were performed to measure the mass loss of water utilizing activated carbon nanoparticle and granular activated carbon particles dispersed in DI water. The strong absorbance of the activated carbon led to increased water evaporation rate. Activated carbon particles are inexpensive compared to expensive plasmons such as copper or gold, and hence offer an economically viable solution for augmenting desalination of water.

Dinuclear Heterogeneous Catalysts as a New Platform for Catalysis Dunwei Wang; Boston College, United States

The field of catalysis has been traditionally divided into subdisciplines of homogeneous and heterogeneous catalysis, where the former primarily studies catalytic processes by molecular structures and the latter chiefly deals with surface catalysis processes. Each subdiscipline enjoys a wealth of knowledge that underpins its own respective applications. For instance, researches on homogeneous catalysis have generated a wealth of knowledge on how to tailor the reaction selectivity and specificity at the atomic level for the production of high-value chemicals such as targeted drugs. The ease of separation and processing renders heterogeneous catalysts ideal for commodity chemical synthesis. However, how to take advantage of the
two orthogonal fields and apply knowledge learned in one field to accelerate the advancements of both has remained a critical challenge. It is within this context that recent years have witnessed a surge of research activities on atomically dispersed catalysts. A prominent example is the single atom catalysts (SACs). On the one hand, such catalysts can maximize the atomic efficiency of heterogeneous catalyst materials by minimizing the amount of materials, especially precious metals such as Pt or Pd, used; on the other hand, such catalysts are reminiscent of homogeneous catalysts in that their structures tend to be better defined than conventional heterogeneous catalysts. It, therefore, opens up an opportunity to bridge the gap between the two traditional subfields. Within this context, we have focused on developing and understanding heterogeneous catalysts with dinuclear metal centers. They are similar to SACs in that the catalytically active centers are well-defined; they present a critical difference by featuring two metal atoms at the active site. This key feature enables the studies of chemical reactions that may benefit from the presence of the second metal centers. Examples of such reactions include H₂O oxidation, CH₄ activation, and preferential CO oxidation. In all cases, we have observed a clear benefit of having a second metal center at the active site. For instance, in water oxidation, we observed that the presence of the second Ir atom facilitates the proton-coupled electron transfer process so as to lower the activation energies during the rate-determining step of O-O bond formation. Similarly, for CH₄ activation, we found that the presence of the second Ir center promotes C-C bond formation for the synthesis of C₂ products. The same effect was observed for PROX, as well, where the presence of the 2nd Ir metal center was found to enable both CO adsorption and O₂ activation. Our work opens a new door to the study of atomically dispersed catalysts for the chemical transformations of significant industrial relevance. We envision that similar studies will be readily expanded to other chemical processes or other catalysts systems or both.

Rationally Designed Hierarchical Nano-Bio Assemblies for Artificial Photosynthesis Elena A. Rozhkova; Argonne National Laboratory, United States

The biological use of solar energy for the synthesis of fuels from water and carbon dioxide inspires researchers and engineers in their efforts to replace existing exhaustible energy sources with renewable energy technologies. Environmentally friendly schemes of photocatalytic visible-light hydrogen production known as artificial photosynthesis along with inorganic semiconductor material also utilize biological structures, such as enzymes, machineries of whole microorganism, capable of light-harvesting, water splitting, carbon dioxide and proton reduction. A natural membrane complex of retinal-containing proton pump bacteriorhodopsin (also known as purple membranes, PM) from the extremophile microbe has been attracting an attention of researchers owing to its minimalistic structure, exceptional robustness, excellent photophysical properties, and functional sophistication. This biological material can be assembled with inorganic nanomaterials, such as semiconductor or photonic particles, into artificial hierarchical structures and demonstrate functionality that spans far beyond its natural property. This talk will provide examples of catalytic systems based on natural proton pump for light-driven H₂ production, ATP synthesis and CO₂ reduction.

Rational Design of Photoelectrocatalytic Materials for Artificial Photosynthesis Guiji Liu and Francesca Maria Toma; Lawrence Berkeley National Laboratory, United States

Due to the rapid depletion of fossil fuels and related environmental issues, developing technologies for producing renewable, clean fuels for our future is of great importance. Artificial photosynthesis via water splitting or CO₂ reduction offers an attractive and cost-effective route to achieve this goal. 1 However, existing photoelectrocatalytic materials generally suffer from low activity or instability, thus greatly impeding the feasibility of artificial photosynthesis technologies. 2, 3 Herein, we present design strategies for the synthesis and integration of photoelectrocatalytic materials.

In Situ/Operando Study of Photocatalytic Materials Using Optical Liquid Cell Transmission Electron Microscopy

Khim Karki\textsuperscript{1}, Pawan Kumar\textsuperscript{2,2}, Antoine Verret\textsuperscript{2}, Noah Glachman\textsuperscript{2}, Rui Filipe Serra Maia\textsuperscript{2}, Deep M. Jariwala\textsuperscript{2}, Daan Hein Alsem\textsuperscript{1} and Eric A. Stach\textsuperscript{2}; \textsuperscript{1}Hummingbird Scientific, United States; \textsuperscript{2}University of Pennsylvania, United States

The clean production of hydrogen from non-fossil energy sources is highly desirable for future energy needs and realization of hydrogen fuel cell vehicles. One way of producing green hydrogen is via photoelectrochemical splitting water into hydrogen by utilizing solar energy and/or highly active catalytic materials, both subjects of much research interests.\textsuperscript{1-3} Particularly, the atomic scale mechanisms of the photocatalysts that facilitate the water splitting for efficient hydrogen generation are currently poorly understood. Further understanding of the role of various photocatalysts and the physics governing the active hydrogen evolution sites will allow for better and efficient design of photoelectrochemical devices.

We have developed a unique in situ/operando liquid cell transmission electron microscope (TEM) holder with photo-capable light source\textsuperscript{4} which can be used to study photocatalytic reactions in real time at nanometer length scales. Using some of the model materials such as Au nanoprisms and MoS\textsubscript{2} flakes, we will present the correlation of I-V characteristics with water splitting and simultaneous structural changes at the catalytically active sites. The following photocatalysts used were chosen because the proposed mechanism for each exhibits a spatial dependence: plasmonically enhanced catalysis for Au nanoprisms and catalytically active edge sites for MoS\textsubscript{2} flakes. For accurate quantitative information and reliability of materials interface in liquid, we will also present strategies for site-specific deposition/loading of sample materials in the desired electrodes of liquid cell chips for electroanalytical characterization and TEM imaging. The availability and utilization of photo stimuli in liquid cell TEM can provide important fundamental insights into the understanding of several other photoelectrochemical systems.

Si-Based Photoelectrodes Coupled with Earth-Abundant Transition Metal-Based Catalysts

Ho Won Jang; Seoul National University, Korea (the Republic of)

Harvesting solar energy for carbon-free hydrogen production via photoelectrochemical (PEC) water splitting is a promising pathway to meet the increased energy demands and deal with severe environmental pollution including climate change. Silicon is the second earth-abundant element and a narrow bandgap material which is found to be a prime candidate for water splitting photoelectrodes due to ease of high-quality wafers fabrication. Si can be doped with elements of different valence states to fabricate n-type or p-type semiconductors for photoanode and photocathode respectively. However, high light reflection, low photovoltage output due to its narrow bandgap, and severe photocorrosion in the electrolyte remain as serious limitations to manufacture efficient Si-based photoelectrodes.

In this talk, I will discuss the fabrication of Si-based photoelectrodes coupled with earth-abundant transition metal-based catalysts for efficient water splitting. We introduced two-dimensional (2D) transition metal dichalcogenides catalysts on p-type Si-photocathode for highly efficient PEC hydrogen production. 2D transition metal dichalcogenides such as MoS\textsubscript{2} and WS\textsubscript{2} are a promising materials to replace noble metal catalysts due to their high density of catalytically active edge sites and large surface-to-volume ratio. Wafer-scale transferable transition metal dichalcogenides thin-film catalysts can provide a low onset potential and high photocurrent density. I will also talk about n-type Si photoanodes with high catalytic activity in transition metal-based catalysts synthesized via facile electrodeposition method for efficient water oxidation. Si photoanodes covered with water oxidation catalysts such as layered-double hydroxides, metal nanoparticles, and thin films exhibited high photoelectrochemical property and long-term stability.

Design Principles for Photocathodes for Solar Driven Carbon Dioxide Reduction

12:26 PM *S.EN06.06.05
12:38 PM *S.EN06.06.07
Solar photovoltaic (PV) and photoelectrochemical (PEC) energy conversion share the same fundamental requirements of photon absorption, charge separation, and selective carrier collection [1]. In addition, in order to produce storabeable chemical energy, PEC systems must drive multi-electron transfer reactions, i.e. water oxidation (OER, a 4 electron process) at the anode and hydrogen evolution (HER) or carbon diode reduction (CO₂R) at the cathode (2-18 electron processes) [2]. In a small number of cases it has been possible to have a single material perform all of the requisite steps and remain stable under operation: water oxidation photoanodes composed of TiO₂ or Fe₂O₃ are examples. However, in the majority of cases, it has been beneficial to construct multi-material PEC systems, with different components chosen for optimal light absorption, selective carrier collection/passivation, and catalysis.

In this context, the design of PEC systems for CO₂R will be discussed. While it is attractive to design semiconductor absorbers based on the position of their conduction band relative to the standard state redox potentials of a given CO₂ reaction, e.g. CO₂/CO, CO₂/HCOOH, CO₂/CH₄, etc., this analysis neglects the fact that these multi-electron reactions occur via a series of elementary proton coupled electron transfers, with each step having its own redox potential [3]. For this reason, either solid state or molecular CO₂R co-catalysts are usually integrated with the absorber in PEC CO₂R studies [4,5]. These concepts will be illustrated through the design and operation of Si-based CO₂R photocathodes. Adroit use of charge selective contacts allows for considerable flexibility in design. For example, in contrast to conventional photocathode designs which employ p-type absorbers, we used a back illumination geometry with an n-type Si absorber to permit the use of absorbing metallic catalysts which would otherwise block the light. Back and front interfaces were configured by ion implantation and by surface passivation to achieve carrier selectivity. Selectivity to C-C coupled products was achieved by using hierarchical Au-Ag-Cu nanostructures as electrocatalysts. The photovoltage, 550-600 mV under simulated 1-sun illumination, and photocurrents exceeding 30 mA cm⁻² confirm the carrier selectivity and passivation of the front and back interfaces. Under simulated diurnal illumination conditions, over 60% faradaic efficiency to C₂ hydrocarbon and oxygenate products (mainly ethylene, ethanol, propanol) is maintained for several days. By coupling photocathodes to series-connected semi-transparent halide perovskite solar cells, we demonstrated stand-alone, “no-bias,” CO₂ reduction with a 1.5% conversion efficiency to hydrocarbons and oxygenates [6].

As further examples of the PEC design space for CO₂R, use of nanowire geometries which would permit the use of front illumination and the prospects of achieving cascade CO₂R [7] on the PEC surface will be discussed.

12:50 PM S.EN06.06.08
Study on Preparation and Properties of Boron-Gallium Co-Doped Multicrystalline Ingotshongzhi Luo1,2, Liang He1,2, Qi Lei1,2, Yunfei Xu1,2, Cheng Zhou1,2, Wei Mao1,2, Zhibin Fu1,2, Jianmin Li1,2, Xiaojuan Cheng1,2 and Guifu Zou2; 1Jiangxi Saiwei LDK Solar High-Tech Co., Ltd, China; 2National Photovoltaics Engineering Research Center, China

In this paper, we present the preparation of multicrystalline silicon ingots with different boron-gallium doping ratio, resistivity distribution, minority carrier lifetime, photovoltaic conversion efficiency and light-induced degradation ratio were analyzed and contrasted. The result shows that with the increase of gallium doping ratio, resistivity and minority carrier lifetime of ingot, as well as conversion efficiency of silicon wafer were both in a decreasing trend, the light-induced degradation ratio also tended to decrease as a whole, but fluctuated locally. By comparing elements tested data, it was preliminarily concluded that the fluctuation may be caused by copper, iron and other impurities. Based on the performance of resistivity, conversion efficiency and light-induced degradation ratios of gallium-doped ingots, the optimal gallium-doped ratio of multicrystalline ingots was determined to be about 25%.

1:14 PM *S.EN06.05.06
Inverse Opal Electrodes towards (Photo)Electrochemical Fuel Synthesist Julien Warnan1 and Erwin Reisner2; 1Technische Universität München, Germany; 2University of Cambridge, United Kingdom
Today, much research on water-splitting and fuel synthesis is directed at improving the efficiency of catalysts and their immobilisation on (photo)electrodes in order to be electroactive under aqueous conditions in photoelectrochemical (PEC) devices. In such hybrid configurations, metal oxide (MO) semiconductor materials hold the key to high efficiencies, as their facile preparation, stability in water and modular high surface-area architecture render them promising platforms. By greatly expanding in this area of research, our recent studies show that achieving a synergistic size parity between macromolecules and the substrate is a promising strategy to improve the electrocatalytic performance.

In this invited talk, I will present our rational development of macro-meso-porous inverse opal (IO) titanium dioxide and indium tin oxide electrodes[1], designed to host macromolecules – enzymes and polymeric catalysts – towards water-splitting and CO₂ reduction. Our recent efforts allowed the development of semi-artificial photosynthetic systems that demonstrate how, using a dye-sensitised approach, natural archetypes – photosystem II, hydrogenase and formate dehydrogenase – can be interfaced with a synthetic organic dye to achieve unassisted solar-driven water-splitting into H₂ and O₂, and CO₂-to-formate splitting.[2,3] We took further advantage of the wide pore architecture to develop catalytic copolymeric architectures capable of electrocatalysing the reduction of CO₂-to-CO.[4] Capitalising on the multifunctional capabilities intrinsically delivered by copolymer scaffolds, this work also provided a seminal example of enhanced product selectivity achieved only by tuning the environmental surroundings of the molecular catalyst. The ability of IO electrodes to host and drive large, electrocatalytically active polymers was further demonstrated on silicon-based photoelectrodes, where selective, precious metal-free, solar-driven CO₂ reduction was achieved in hydro-organic media.

Core-shell Magnetic Nanoparticles Functionalized with Copper(ii)-Loaded Dendrimer as Recoverable and Robust Magnetic-Nanoinitiator for Polymerization of Adhesive System Haruethai Kongcharoen and Pooi See Lee; Nanyang Technological University, Singapore

A cost effective synthesis route for tunable shapes and sizes of large scale monodisperse nanocrystals functionalized with copper-loaded dendrimer through a low-temperature thermal decomposition from iron (III) olate has been demonstrated for the first time as a recoverable and reusable heterogeneous magnetic-nanoinitiator for polymerization of adhesive system. Herein, the colloidal system comprised of methacrylate ester monomers, peroxide and core-shell magnetic nanoparticles functionalized with copper-loaded dendrimer are used for the polymerization of adhesives with the nanoinitiators. The effect of various morphologies of the magnetic particles such as spherical, cubic, hexagonal shape as a core of the nanoinitiators are investigated through the polymerization of anaerobic adhesive formulation. To enable the recoverability of nanoinitiators and achieve simultaneously control of the loading of Cu(II) of nanoinitiators, core-shell magnetic nanoparticles and dendrimer have been designed to initiate highly efficient and safe polymerization through redox radical initiated cationic polymerization reaction under mild condition. Moreover, core-shell magnetic nanoparticles functionalized copper-loaded dendrimer can be separated simply by either magnetic separation or centrifugation and reused for several times without any significant mass loss[1]. The core-shell magnetic nanoparticles functionalized with copper-loaded dendrimer were characterized using transmission electron microscopy (TEM), Scanning electron microscopy (SEM-EDX), X-Ray diffraction (XRD), and Fourier-transform infrared spectroscopy (FT-IR).
Even though the potential of hematite thin films for water splitting applications are widely accepted, researchers are still tackling the ‘rust challenge’. We report here on the influence of external magnetic fields applied parallel or perpendicular to the substrate during plasma enhanced chemical vapor deposition (PECVD) of hematite (α-Fe$_2$O$_3$) nanostructures and the accessibility of the very same through magnetic field assisted CVD of Fe(CO)$_5$. Hematite films grown from iron precursors showed pronounced changes in crystallographic textures depending upon whether PECVD was performed with or without the influence of external magnetic field and anisotropic film growth with higher exposure to water in case of mfCVD. In all cases, a superior photoelectrochemical (PEC) performance was obtained for hematite photoanodes synthesized under applied magnetic fields. Our experimental data on microstructure and functional properties of hematite films showed that magnetic fields have a significant effect on the crystallite size and texture with preferred growth and/or suppression of grains with specific texture in α-Fe$_2$O$_3$ films. Thereby, we are able to demonstrate magnetic field assisted gas phase depositions as new experimental playground for the ‘rust challenge’.

Solar photovoltaic (PV) and photoelectrochemical (PEC) energy conversion share the same fundamental requirements of photon absorption, charge separation, and selective carrier collection [1]. In addition, in order to produce storable chemical energy, PEC systems must drive multi-electron transfer reactions, i.e. water oxidation (OER, a 4 electron process) at the anode and hydrogen evolution (HER) or carbon dioxide reduction (CO$_2$R) at the cathode (2-18 electron processes) [2]. In a small number of cases it has been possible to have a single material perform all of the requisite steps and remain stable under operation: water oxidation photoanodes composed of TiO$_2$ or Fe$_2$O$_3$ are examples. However, in the majority of cases, selective contacts allows for considerable flexibility in design. For example, in contrast to conventional photocathode designs which employ p-type absorbers, we used a back illumination geometry with an n-type Si absorber to permit the use of absorbing metallic catalysts which would otherwise block the light. Back and front interfaces were configured by ion implantation and by surface passivation to achieve carrier selectivity. Selectivity to C-C coupled products was achieved by using hierarchical Au- Ag-Cu nanostructures as electrocatalysts. The photovoltage, 550- 600 mV under simulated 1-sun illumination, and photocurrents exceeding 30 mA cm$^{-2}$ confirm the carrier selectivity and passivation of the front and back interfaces. Under simulated diurnal illumination conditions, over 60% faradaic efficiency to C$_2$+ hydrocarbon and oxygenate products (mainly ethylene, ethanol, propanol) is maintained for several days. By coupling photocathodes to series-connected semi-transparent halide perovskite solar cells, we demonstrated stand-alone, “no-bias,” CO$_2$ reduction with a 1.5% conversion efficiency to hydrocarbons and oxygenates [6].

As further examples of the PEC design space for CO$_2$R, use of nanowire geometries which would permit the use of front illumination and the prospects of achieving cascade CO$_2$R [7] on the PEC surface will be discussed.

Structure-Property Study of Titania-PMMA Based Nanoporous Core-Shell Fibers for Waste Water Treatment
Namrata Kanth, Weiheng Xu, Dharneedar Ravichandran and Kenan Song; Arizona State University, United States

Titanium dioxide (TiO₂), or titania, is a suitable choice for environmental remediation due to its photocatalytic advanced oxidation ability which can inactivate pathogens and decompose dyes. Current researches have been focusing on titania nanoparticles impregnated in polymers, due to higher active sites for contaminant adsorption, pore size control, and easy manufacturability. Low throughput rates, however, have far limited the adoption of titania-based water-treatment systems. Our research explored a scalable manufacturing technique and achieved morphology control of core-shell fibers incorporating titania nanoparticles. The novelty of this research is that it encompasses the benefits of remote ultraviolet (UV) light accessibility and porosity-enabled enhanced adsorption sites. The fibre core was composed of UV light transparent, flexible, and oxidation-resistant polymethyl methacrylate (PMMA) that served as an optical channel for UV light transmission and was prepared by melt spinning technique. The fibre shell was composed of a porous PMMA-titania nanoparticle composite prepared by dip-coating in colloidal solution with dispersed titania nanoparticles followed by coagulation through wet phase inversion. Titania in fiber shell was photo-activated by light radially refracted from the fiber core. Photocatalytic performance was optimized by controlling the pore-size, titania concentration and the thickness of the coated shell. Pore-sizes ranging from 50 nm up to 5 µm were achieved by varying the porogen concentration and selecting different solvent and non-solvent combinations. The core-shell interfacial interactions were also characterized using static mechanical tests and dynamic mechanical analysis. Finally, the photocatalytic performance of the fibers was characterized by monitoring the decomposition of methylene blue using UV-vis spectrophotometry. This research provided an understanding of the processing-structure-property relationships in the complex, multiphase core-shell structured fibers.

5:45 AM S.EN06.01.10
Band-Gap Engineering in Perovskite Heterostrcuture for Efficient Visible Light Induced Photocatalysis—A Detailed Photophysical Study
Smruti Purohit, Soumitra Satapathi and K.L. Yadav; Indian Institute of Technology Roorkee, India

Recently, photocatalysis has emerged as a potential solution for growing energy crisis and environment pollution issues. However, higher charge recombination, slow electron transfer rate and large band-gap of photocatalytic materials remain key challenges in photocatalysis.

Here, we report a systemic study of the photocatalytic performance of K₀.₅Na₀.₅NbO₃ (KNN)-BaBiO₃ (BBO) perovskite heterostructure. KNN and BBO are synthesized by solid state reaction method and the composite is prepared by ball-milling technique with appropriate stoichiometric ratio of KNN and BBO. The materials are characterized using XRD, SEM, XPS, and Raman spectroscopy techniques. Photocatalytic degradation of Rhodamine 6G is monitored through UV-Vis absorption spectroscopy. We observed higher photocatalytic efficiency with KNN-BBO heterostructure than single junction KNN. This was attributed to the reduced band gap (approx 1.92 eV) and fast electron transfer rate in heterostructure under visible light irradiation. Moreover, the improved performance of the composite (KNN-BO) material may be attributed to heterojunction band alignment and higher ferroelectric polarization of the composite material. [3] We have also examined the effect of calcination temperature on the photocatalytic dye degradation activity of KNN-BO heterostructure. Transient absorption spectroscopy confirms the energetics and electron transfer kinetics in the composite system. Our study opens up the possibility of designing novel perovskite based materials for efficient photocatalysis.

Hierarchically Structured, Oxygen Deficient, Tungsten Oxide Morphologies for Enhanced Photoelectrochemical Charge Transfer and Stability
Peng Chen, Matthew Baldwin and Prab Bandaru; University of California, San Diego, United States

The role of non-stoichiometry in a hierarchically structured WO₃₋ₓ electrode, constituted from nanoscale fuzziness as well as microscale wire morphology, on the photoelectrochemical response is investigated. Through X-ray photoelectron
spectroscopy (XPS) studies, the relative amounts of the various oxidation states of the constituent W are probed with respect to the observed response. It is concluded that an intermediate/optimal number of vacancies, yielding a W⁶⁺/(W⁵⁺ + W⁴⁺) ratio of around 2, would be beneficial for increasing the photocurrent. It is posited that defect engineering combined with optimized band structure modulation could be used for enhanced photocurrent density as well as electrode stability. The work would help considerably elucidate the role of defects as well as charge carriers for oxygen evolution reaction (OER) efficiency increase.

Ultrafast Relaxation Dynamics in Bimetallic Plasmonic Catalysts Sangwan Sim¹, Alyssa Beierle², Philip Mantos², Steven McCrory², Rohit Prasankumar Prativadi³ and Sanchari Chowdhury²; ¹Hanyang University ERICA campus, Korea (the Republic of); ²New Mexico Tech, United States; ³Los Alamos National Laboratory, United States

Combining a plasmonic metal, such as gold, with other popular catalysts, such as Ni or Pt, can extend its benefit to many energy-extensive reactions catalyzed by those metals. The efficiency of a plasmon-enhanced the catalytic reaction is mainly determined by the light absorption cross-section and the photoexcited charge carrier relaxation dynamics of the nanoparticles. We have investigated the charge carrier relaxation dynamics of gold/nickel (Au/Ni) and gold/platinum (Au/Pt) bimetallic nanoparticles. We found that electron-phonon and phonon-phonon coupling rates in Au/Ag, Au/Ni, and Au/Pt nanoparticles are significantly different than that of pure Au nanoparticles. This is due to the large differences in their band structures and the electron-phonon coupling rate. Our findings thus provide important insights towards the rational design of bimetallic plasmonic catalysts.

5:10 AM S.EN06.02.05
Enhancing Solar Water Evaporation with Activated Carbon Sai Kiran Hota and Gerardo Diaz; University of California, United States

Thermal based desalination systems involve heating water and collecting the condensate. The use of solar energy to drive the desalination phenomena, utilizing the heat for enhancing water evaporation (steam generation) is attracting wide-spread attention. The process involves absorbing the spectral intensity of solar light and converting it to heat. This photo-thermal conversion can be enhanced by using a strong solar absorber diluted in water, which is a poor absorber of sun light. Among the solar absorbers, carbon materials have proven to enhance water desalination rate while being economical as compared to their plasmonic counterparts. Activated carbon is a carbon-rich source which has many applications such as toxic gas adsorption and industrial effluent treatment. Considering its optical quality, it has the potential to be a strong solar absorber for enhancing water evaporation rate. A series of characterization tests were performed on activated carbon. It showed 94.17% (granular) carbon composition with trace presence of hydrogen and oxygen through ultimate analysis. FT-IR analysis performed showed mostly C=C and aromatic C-H rings. Geometric (envelope) density of the sample was almost 710 kg/m³ with theoretical porosity of 0.663. The skeleton (true) density measured was 2106.9 kg/m³. The density measurements showed that activated carbon can be used as a solid dispersion in water. The granular particles sink to the bottom of the container and behave like a black bottom in enhancing water evaporation. The apparent zeta potential for nanoparticles was measured to be -47.9 mV, showing a good dispersion stability. Optical measurements showed that the absorbance of the activated carbon was 96.35%. The strength of absorbance increases with increasing concentration and can be attributed to increased extinction coefficient of the solar spectral intensity. This increases the fraction of solar absorption in the fluid dispersion system, leading to enhanced heat localization at higher concentrations. Outdoor experiments were performed to measure the mass loss of water utilizing activated carbon nanoparticle and granular activated carbon particles dispersed in DI water. The strong absorbance of the activated carbon led to increased water evaporation rate. Activated carbon particles are inexpensive compared to expensive plasmons such as copper or gold, and hence offer an economically viable solution for augmenting desalination of water.

Towards High-Performance and Low-Cost Plasmonic-Enhanced Wood-Based Solar Steam Generation
Yang Li; Hong Kong University of Science and Technology, Hong Kong

Plasmonic nanoparticles that effectively convert light into nanoscale localized heat with low radiative losses are promising photothermal materials. A lot of plasmonic-enhanced interfacial solar steam generation devices have been developed based on a broad variety of floating substrates, showing improved evaporation rates and high solar-thermal efficiency. In particular, plasmonic wood-based devices are considered as one of the ideal platforms for steam generation due to the attractive cost-effectiveness. However, up to now, the efficiency of the plasmonic wood-based device is still below 80% (evaporation rate ~1.0 kg m-2h-1) due to the considerable heat losses. In this study, by taking the full advantage of plasmonic nanoparticles in heat localization, we created nanoscale hot spots with huge light absorption and negligible heat losses in a TiN nanoparticles/wood device. Specifically, we constructed an ultrathin uniform plasmonic nanoparticle film on the micro-channels of wood using solution-processed technique. For the first time, water boiling is observed on the surface of the device under the illumination of only one sun. As a result, the 1-sun evaporation rate of such a system reaches the theoretic limit of wood-based steam generation devices (~1.5 kg m-2h-1), indicating an extremely high solar-thermal efficiency.

Inverse Opal Electrodes towards (Photo)Electrochemical Fuel Synthesis
Julien Warnan1 and Erwin Reisner2; 1Technische Universität München, Germany; 2University of Cambridge, United Kingdom

Today, much research on water-splitting and fuel synthesis is directed at improving the efficiency of catalysts and their immobilisation on (photo)electrodes in order to be electroactive under aqueous conditions in photoelectrochemical (PEC) devices. In such hybrid configurations, metal oxide (MO) semiconductor materials hold the key to high efficiencies, as their facile preparation, stability in water and modular high surface-area architecture render them promising platforms. By greatly expanding in this area of research, our recent studies show that achieving a synergistic size parity between macromolecules and the substrate is a promising strategy to improve the electrocatalytic performance. In this invited talk, I will present our rational development of macro-meso-porous inverse opal (IO) titanium dioxide and indium tin oxide electrodes1, designed to host macromolecules – enzymes and polymeric catalysts – towards water-splitting and CO2 reduction. Our recent efforts allowed the development of semi-artificial photosynthetic systems that demonstrate how, using a dye-sensitised approach, natural archetypes – photosystem II, hydrogenase and formate dehydrogenase – can be interfaced with a synthetic organic dye to achieve unassisted solar-driven water-splitting into H2 and O2, and CO2-to-formate splitting.2,3 We took further advantage of the wide pore architecture to develop catalytic copolymeric architectures capable of electrocatalysing the reduction of CO2-to-CO.4 Capitalising on the multifunctional capabilities intrinsically delivered by copolymer scaffolds, this work also provided a seminal example of enhanced product selectivity achieved only by tuning the environmental surroundings of the molecular catalyst. The ability of IO electrodes to host and drive large, electrocatalytically active polymers was further demonstrated on silicon-based photoelectrodes, where selective, precious metal-free, solar-driven CO2 reduction was achieved in hydro-organic media.

Photocatalytic and Photoelectrochemical Water Splitting by a Visible-Light-Absorbing Oxyfluoride
Kazuhiko Maeda; Tokyo Institute of Technology, Japan

Mixed-anion compounds that consist of more than two anionic species in a single-phase have attracted attention as visible-light-absorbing semiconductors, since as compared to oxygen 2p orbital, p orbitals of less electronegative anion can form a valence band that possesses more negative potential. In this regard, oxyfluorides (oxide-fluoride) are obviously unsuitable as visible-light-responsive photocatalysts because of the highest electronegativity of fluorine. However, we found that an oxyfluoride Pb2Ti2O5.4F1.2 possessed an unprecedented small band gap of ca. 2.4 eV (corresponding to ca. 510 nm absorption edge), and functioned as a stable photocatalyst for visible-light water reduction/oxidation when modified with suitable promoters. Photoelectrochemical water oxidation to O2 was also achieved with a modified Pb2Ti2O5.4F1.2 electrode under simulated sunlight. Density functional theory calculations showed that the
unprecedented visible-light-response of Pb$_2$Ti$_2$O$_5$.4F$_{1.2}$ arises from strong interaction between Pb-6s and O-2p orbitals, which is caused by a short Pb–O bond in the pyrochlore lattice due to the fluorine substitution.

Visible Light Photocatalytic Activity of Nitrogen/Fluorine Codoped Rutile TiO$_2$
Akinobu Miyoshi$^1$, Junie J. Vequizo$^2$, Shunta Nishioka$^1$, Shunsuke Yamashita$^3$, Akira Yamakata$^2$, Koji Kimoto$^3$ and Kazuhiko Maeda$^1$; $^1$Tokyo Institute of Technology, Japan; $^2$Toyota Technological Institute, Japan; $^3$National Institute for Materials Science, Japan

Significant efforts have been made to develop a photocatalyst that functions under visible light from the viewpoint of solar energy utilization. Nitrogen/fluorine doping into anatase TiO$_2$ allowed introduction of more nitrogen compared to only nitrogen-doped analogue, resulting in enhanced absorption and photocatalytic activity under visible light irradiation [K. Nukumizu et al. Chem. Lett. 2003, 32, 196; K. Maeda et al. J. Phys. Chem. C 2007, 111, 18264]. On the other hand, rutile TiO$_2$ (R-TiO$_2$), another representative polymorph of TiO$_2$, is known to possess high activity for O$_2$ evolution via water oxidation and used in Z-scheme water splitting in combination with a suitable H$_2$ evolution photocatalyst [A. Miyoshi et al. Chem. Eur. J. 2018, 24,18204]. In this work, we succeeded in introducing visible light response into R-TiO$_2$ by N/F codoping and evaluated its photocatalytic O$_2$ evolution activity.

N/F codoped R-TiO$_2$ (R-TiO$_2$;N,F) was synthesized by nitriding a mixture of R-TiO$_2$ and (NH$_4$)$_2$TiF$_6$. R-TiO$_2$ and (NH$_4$)$_2$TiF$_6$ were mixed using an agate mortar and a pestle with various molar ratios. The mixture was heated at 773 K for 1 h under NH$_3$ flow. For convenience, the nominal concentration of (NH$_4$)$_2$TiF$_6$ in the mixture is denoted as value in the unit of mol%. X-ray diffraction (XRD), scanning transmission electron microscope, and X-ray absorption fine structure (XAFS) measurements revealed that the synthesized materials mainly show R-TiO$_2$ structure. Especially, C $\leq$ 15 samples did not show any impurity phases in XRD. Presence of the anions was confirmed by elemental analysis. Shift of diffraction peaks in XRD and increase in the pre-edge peak intensity in XAFS measurements compared to pristine rutile TiO$_2$ was observed, suggesting the incorporation of nitrogen and fluorine anions into R-TiO$_2$ causing lattice distortion.

Diffuse reflectance spectra showed more pronounced absorption in visible light region for materials synthesized using (NH$_4$)$_2$TiF$_6$ (C $\geq$ 10) compared to the sample synthesized without (NH$_4$)$_2$TiF$_6$ (C = 0). Furthermore, the visible light absorption became more pronounced with increasing C value. The enhanced visible light absorption in the R-TiO$_2$:N,F is attributed to increased nitrogen content, which was confirmed by combustion elemental analysis. Photocatalytic activity of R-TiO$_2$:N,F for water oxidation was tested using AgNO$_3$ as a sacrificial electron acceptor. The C = 15 sample marked the highest activity among the synthesized R-TiO$_2$:N,F. The increase in activity up to C = 15 can be explained by increase in the visible light absorption. On the other hand the decrease in the activity for C > 15 was suspected to be caused by defect formation. To make this point clear, transient absorption spectroscopy was employed. The result revealed difference of carrier dynamics among the different C value samples. The C = 50 sample showed signals corresponding to deeply trapped electrons (~5000 cm$^{-1}$) and no free electrons (< 2000 cm$^{-1}$). On the other hand, the C = 15 sample had less deeply trapped electrons, but more free electrons. Since free electrons generally show higher reactivity compared to the trapped electrons [A. Yamakata et al. J. Photochem. Photobiol. A 2015, 313, 168], the decrease in the activity for C $\geq$ 20 is most likely attributed to the smaller population of free electrons available for reaction and/or the presence of higher concentration of trap states. This suggests enhancing visible light absorption and suppressing the defect formation with appropriate nitrogen/fluorine codoping is important for achieving high photocatalytic activity.

Finally, the C = 15 sample was loaded with RuO$_2$ and applied in Z-scheme water splitting system in combination with Ru loaded Rh doped SrTiO$_3$ (H$_2$ evolution photocatalyst) and [Co(bpy)$_3$]$^{3+}$/$^{2+}$ (redox mediator). Stoichiometric water splitting was achieved upon visible light and simulated sunlight irradiation.

In Situ/Operando Study of Photocatalytic Materials Using Optical Liquid Cell Transmission Electron Microscopy
Khim Karki$^1$, Pawan Kumar$^{2,3}$, Antoine Verret$^2$, Noah Glachman$^2$, Rui Filipe Serra Maia$^2$, Deep M. Jariwala$^2$, Daan Hein Alsem$^1$ and Eric A. Stach$^2$; $^1$Hummingbird Scientific, United States; $^2$University of Pennsylvania, United States

The clean production of hydrogen from non-fossil energy sources is highly desirable for future energy needs and realization of hydrogen fuel cell vehicles. One way of producing green hydrogen is via photoelectrochemical splitting water into hydrogen by utilizing solar energy and/or highly active catalytic materials, both subjects of much research interests.$^{1,2}$ Particularly, the atomic scale mechanisms of the photocatalysts that facilitate the water splitting for efficient hydrogen generation are currently poorly understood. Further understanding of the role of various photocatalysts and the physics governing the active hydrogen evolution sites will allow for better and efficient design of photoelectrochemical devices.

We have developed a unique in situ operando liquid cell transmission electron microscope (TEM) holder with photo-capable light source$^4$ which can be used to study photocatalytic reactions in real time at nanometer length scales. Using some of the

2020 MRS Virtual Spring/Fall Meeting, November 27-December 4, 2020, Spring Abstracts Final Program 2/3/21
model materials such as Au nanoprisms and MoS2 flakes, we will present the correlation of I-V characteristics with water splitting and simultaneous structural changes at the catalytically active sites. The following photocatalysts used were chosen because the proposed mechanism for each exhibits a spatial dependence: plasmonically enhanced catalysis for Au nanoprisms and catalytically active edge sites for MoS2 flakes. For accurate quantitative information and reliability of materials interface in liquid, we will also present strategies for site-specific deposition/loading of sample materials in the desired electrodes of liquid cell chips for electroanalytical characterization and TEM imaging. The availability and utilization of photo stimuli in liquid cell TEM can provide important fundamental insights into the understanding of several other photoelectrochemical systems.

Tailoring Layered Oxide Nanofiber Heterojunctions for Enhanced Photocatalytic Water Splitting Performance Roland Marschall; University of Bayreuth, Germany

For many semiconductors the large mismatch between their small charge carrier diffusion length and their much larger light penetration depth is one of the most critical parameters for their photocatalytic and photoelectrochemical performance. Preparation of nanofibers by electrospinning is one way to overcome this mismatch. We use this technique to prepare fibers of the (111)-layered perovskite Ba5Ta4O15.[1] The nanofiber diameter can be tailored by adjustment of the electrospinning parameters. We could show that the photocatalytic activity depends on the fiber diameter.[2] The fiber diameter for the optimum photocatalytic activity is ~160 nm. We could prepare composite nanofibers of Ba5Ta4O15−Ba3Ta5O15 and showed that this composite gives rise to strongly enhanced photocatalytic hydrogen production and water splitting performance compared to pure Ba5Ta4O15 fibers with comparable diameter due to an improved charge carrier separation. The photocurrent doubling effect with methanol as sacrificial agent with this composite could be confirmed.[3]

Generation of Hierarchically Porous Metal-Organic Frameworks through Photolysis Kunyu Wang and Hongcai Zhou; Texas A&M University, United States

Metal-organic frameworks (MOFs) are porous materials with various applications such as gas separation and photocatalysis. Currently, most MOFs have micro-pores, which hamper diffusion within the framework and limit the potential applications. The pore size of MOFs can be enlarged through linker elimination, in which labile linkers in MOFs can be removed to generate hierarchically porous frameworks with enhanced mass transfer. Here we report a facile method to remove photosensitive linkers selectively through photolysis. The formation of mesopores is confirmed by N2 sorption test and the photolytic mechanism is studied through 1H NMR, thermogravimetry (TGA) and Raman spectroscopy. The photolytic approach can engineer MOF particles in a small domain and fabricate complicated patterns on MOFs, paving a way for programmable design of MOF-based devices.
The field of catalysis has been traditionally divided into subdisciplines of homogeneous and heterogeneous catalysis, where the former primarily studies catalytic processes by molecular structures and the latter chiefly deals with surface catalysis processes. Each subdiscipline enjoys a wealth of knowledge that underpins its own respective applications. For instance, researches on homogeneous catalysis have generated a wealth of knowledge on how to tailor the reaction selectivity and specificity at the atomic level for the production of high-value chemicals such as targeted drugs. The ease of separation and processing renders heterogeneous catalysts ideal for commodity chemical synthesis. However, how to take advantage of the two orthogonal fields and apply knowledge learned in one field to accelerate the advancements of both has remained a critical challenge. It is within this context that recent years have witnessed a surge of research activities on atomically dispersed catalysts. A prominent example is the single atom catalysts (SACs). On the one hand, such catalysts can maximize the atomic efficiency of heterogeneous catalyst materials by minimizing the amount of materials, especially precious metals such as Pt or Pd, used; on the other hand, such catalysts are reminiscent of homogeneous catalysts in that their structures tend to be better defined than conventional heterogeneous catalysts. It, therefore, opens up an opportunity to bridge the gap between the two traditional subfields. Within this context, we have focused on developing and understanding heterogeneous catalysts with dinuclear metal centers. They are similar to SACs in that the catalytically active centers are well-defined; they present a critical difference by featuring two metal atoms at the active site. This key feature enables the studies of chemical reactions that may benefit from the presence of the second metal centers. Examples of such reactions include H2O oxidation, CH4 activation, and preferential CO oxidation. In all cases, we have observed a clear benefit of having a second metal center at the active site. For instance, in water oxidation, we observed that the presence of the second Ir atom facilitates the proton-coupled electron transfer process so as to lower the activation energies during the rate-determining step of O-O bond formation. Similarly, for CH4 activation, we found that the presence of the second Ir center promotes C-C bond formation for the synthesis of C2 products. The same effect was observed for PROX, as well, where the presence of the 2nd Ir metal center was found to enable both CO adsorption and O2 activation. Our work opens a new door to the study of atomically dispersed catalysts for the chemical transformations of significant industrial relevance. We envision that similar studies will be readily expanded to other chemical processes or other catalysts systems or both.

Rationally Designed Hierarchical Nano-Bio Assemblies for Artificial Photosynthesis

Elena A. Rozhkova; Argonne National Laboratory, United States

The biological use of solar energy for the synthesis of fuels from water and carbon dioxide inspires researchers and engineers in their efforts to replace existing exhaustive energy sources with renewable energy technologies. Environmentally friendly schemes of photocatalytic visible-light hydrogen production known as artificial photosynthesis along with inorganic semiconductor material also utilize biological structures, such as enzymes, machineries of whole microorganism, capable of light-harvesting, water splitting, carbon dioxide and proton reduction. A natural membrane complex of retinal-containing proton pump bacteriorhodopsin (also known as purple membranes, PM) from the extremophile microbe has been attracting an attention of researchers owing to its minimalistic structure, exceptional robustness, excellent photophysical properties, and functional sophistication. This biological material can be assembled with inorganic nanomaterials, such as semiconductor or photonic particles, into artificial hierarchical structures and demonstrate functionality that spans far beyond its natural property. This talk will provide examples of catalytic systems based on natural proton pump for light-driven H2 production, ATP synthesis and CO2 reduction.

Study on Preparation and Properties of Boron-Gallium Co-Doped Multicrystalline Ingots

Hongzhi Luo1,2, Liang He1,2, Qi Lei1,2, Yunfei Xu1,2, Cheng Zhou1,2, Wei Mao1,2, Jianmin Li1,2, Xiaojuan Cheng1,2 and Guifu Zou2; 1Jiangxi Saiwei LDK Solar High-Tech Co., Ltd, China; 2National Photovoltaics Engineering Research Center, China

In this paper, we present the preparation of multicrystalline silicon ingots with different boron-gallium doping ratio, resistivity distribution, minority carrier lifetime, photovoltaic conversion efficiency and light-induced degradation ratio were analyzed and contrasted. The result shows that with the increase of gallium doping ratio, resistivity and minority carrier lifetime of ingot, as well as conversion efficiency of silicon wafer were both in a decreasing trend, the light-induced degradation ratio also tended to decrease as a whole, but fluctuated locally. By comparing elements tested data, it was preliminarily concluded that the fluctuation may be caused by copper, iron and other impurities. Based on the performance of resistivity, conversion efficiency and light-induced degradation ratios of gallium-doped ingots, the optimal gallium-doped
Due to the rapid depletion of fossil fuels and related environmental issues, developing technologies for producing renewable, clean fuels for our future is of great importance. Artificial photosynthesis via water splitting or CO₂ reduction offers an attractive and cost-effective route to achieve this goal. However, existing photoelectrocatalytic materials generally suffer from low activity or instability, thus greatly impeding the feasibility of artificial photosynthesis technologies. Herein, we present design strategies for the synthesis and integration of photoelectrocatalytic materials.

Copper-based transition metal chalcogenide (S, Se, Te) nanocrystals provide one of the most attractive platforms for both nanophotonic and photovoltaic applications as a vast range of material properties can be realized through compositional control of these nanocrystals consisting of earth-abundant elements. In transition metal Cu-chalcogenides, the strong p-d hybridization and the small variations in size and electronegativity between the transition metal cations and the chalcogens facilitate an extraordinary range of spectral and electroluminescence properties. Additionally, the defect concentrations and the possibility of non-stoichiometric and antisite defects in the Cu-chalcogenides can be used as key parameters to further tailor optoelectronic properties of these compounds. From the perspective of photovoltaic applications, the quest for a sustainable and affordable energy material still remains. A broad spectrum of electronic band gap can be realized through compositional control in the mixed metal Cu-chalcogenides. To this end, multinary Cu-chalcogenides offer further flexibility in band gap engineering and spectral properties through compositional variation of the different elements within the compound. However, it is synthetically challenging to realize the more complex multinary compositions of the Cu-chalcogenides. To date, several binary compositions of transition metal Cu-chalcogenides have been stabilized, but few reports of ternary, quaternary, and penternary complexes are available. What if we can synthetically realize a new gamut of higher order transition metal Cu-chalcogenides for a wide range of novel optoelectronic properties?

In this study, we report a new library of penternary Cu2ZnASxSe4-x (0 < x < 4, A = Al, In, Ga) nanocrystals and thin films. The nanocrystals are synthesized via a hot injection solution process to facilitate compositional control in these complex structures. These nanocrystals with multiple chalcogens and different cross-row elements within the structure are unique from the perspective of structural and material properties. The morphology and chemical composition of the new penternary nanocrystals are investigated via scanning and transmission electron microscopy equipped with energy dispersive x-ray spectroscopy. These materials exhibit a wide range of band gap, largely influenced by the Se content and cation composition, as determined through the experimental Tauc plots. In addition, a wide range of composition-controlled photoluminescence is obtained with this group of penternary Cu-chalcogenides. Thin films of these novel chalcogenide nanocrystals were deposited on Si wafer substrates using a spin coating technique. Transport properties (resistivity and Hall effect) of the complex compounds are investigated via a hot injection solution process to facilitate compositional control in these complex structures. These nanocrystals provide one of the most attractive platforms for both nanophotonic and photovoltaic applications as a vast range of material properties can be realized through compositional control of these nanocrystals consisting of earth-abundant elements. Transport properties (resistivity and Hall effect) of the complex chalcogenide thin films were explored. This new class of semiconductor materials from readily available elements will be transformative in terms of device applications for photovoltaics and quantum dot light emitting diodes.

Si-Based Photoelectrodes Coupled with Earth-Abundant Transition Metal-Based Catalysts Ho Won Jang; Seoul National University, Korea (the Republic of)

Harvesting solar energy for carbon-free hydrogen production via photoelectrochemical (PEC) water splitting is a promising pathway to meet the increased energy demands and deal with severe environmental pollution including climate change. Silicon is the second earth-abundant element and a narrow bandgap material which is found to be a prime candidate for water splitting photoelectrodes due to ease of high-quality wafers fabrication. Si can be doped with elements of different valence states to fabricate n-type or p-type semiconductors for photoanode and photocathode respectively. However, high light reflection, low photovoltage output due to its narrow bandgap, and severe photocorrosion in the electrolyte remain as serious limitations to manufacture efficient Si-based photoelectrodes.

In this talk, I will discuss the fabrication of Si-based photoelectrodes coupled with earth-abundant transition metal-based catalysts for efficient water splitting. We introduced two-dimensional (2D) transition metal dichalcogenides catalysts on p-type Si-photoanode for highly efficient PEC hydrogen production. 2D transition metal dichalcogenides such as MoS2 and WS2 are promising materials to replace noble metal catalysts due to their high density of catalytically active edge sites and large surface-to-volume ratio. Wafer-scale transferable transition metal dichalcogenides thin-film catalysts can provide a low onset potential and high photocurrent density. I will also talk about n-type Si photoanodes with high catalytic activity in transition metal-based catalysts synthesized via facile electrodeposition method for efficient water oxidation. Si photoanodes covered with water oxidation catalysts such as layered-double hydroxides, metal nanoparticles, and thin films exhibited high photoelectrochemical property and long-term stability.

Application of Electron-Beam-Excited Surface Plasmons to Unveil Design Rules of Plasmonic Catalysts for Low-Temperature Chemical Processes Wei-Chang D. Yang1,2, Canhui Wang1,2, Henri J. Lezec1 and Renu Sharma1; 1National
Heterogeneous catalysts are used to reduce energy barrier for chemical reactions by promoting gas adsorption. Such energy barrier is commonly overcome by heating a reactor filled with gaseous reactants. On plasmonic nanostructures, optically-excited localized surface plasmon (LSP) resonances were found to induce H$_2$ or O$_2$ dissociation at a reduced temperature, mimicking photocatalysis. Energy harnessed by plasmonic nanostructures and transferred to adsorbed reactants during the dephasing of LSP resonances is theorized to initiate such reactions by compensating for the thermal energy required otherwise. Therefore, resolving sub-nanoparticle information of surface plasmon induced reactions, including (1) reactant adsorption, (2) LSP resonance energy that overcomes reaction barrier, and (3) product desorption, could elucidate design rules of plasmonic catalysts. However, such information has not been obtained under reactive environments by variants of optical spectroscopy, since their spatial resolution is diffraction-limited at best and the excitation of LSP modes by light is polarization-sensitive. Herein, we demonstrate that sub-nanoparticle information gained from electron energy-loss spectroscopy (EELS) and cathodoluminescence (CL) can be used to measure these reaction details and drive selected reactions.

Electron-beam-excited LSP resonances on shape- and size-controlled nanoparticles are exploited to drive chemical reactions in an environmental scanning transmission electron microscope equipped with a monochromated electron gun operated at 80 kV with an energy resolution of 0.08 eV. Low-loss EELS hyperspectral imaging and CL maps, combined with theoretical predictions based on electromagnetic boundary element method, reveal the spatial distribution of coupling efficiency of the convergent electron beam to the LSP modes. Coupling efficiency maps, derived by applying the non-negative matrix factorization (NMF) to an EELS hyperspectral image, shows specific LSP mode can be preferentially excited by positioning the electron beam with a nanometer-level precision. In situ core-loss EELS data is employed to measure local chemical compositions and oxidation states of the nanostructure in vacuum and the gas environments. For the first time, gas adsorption maps, were obtained using in situ EELS spectrum imaging. For shape-controlled Au nanoparticles on TiO$_2$ support in a CO environment, the adsorption maps indicate that CO is adsorbed on selective nanoparticle edges but not on the entire surfaces. Under the same CO environment, the LSP dipole mode of an Au nanoparticle is preferentially exited using electron beam to drive CO disproportionation: $2\text{CO}_{(g)} \rightarrow \text{CO}_2(g) + \text{C}_{(s)}$, at room temperature (commonly initiated above 400 °C). One of the reaction products – amorphous carbon – is deposited only at the cantilevered corner of Au nanoparticles, indicating that the active sites for the reaction are located where preferable gas adsorption sites and locations of maximum plasmonic field amplitude superimpose. Energy transferred to the adsorbed reactants is further identified based on the spectral difference between EELS and CL, acquired during the reaction. For size-controlled Al nanoparticles, elemental analysis using EELS shows a core-shell structure of Al-Al$_2$O$_3$, where a crystalline Al core is enclosed in an oxide shell. The oxide thickness modulates the LSP resonance energy and can be used to match the energy barrier for selected reactions. In one of the examples, the octupole mode on core-shell Al nanoparticles are utilized to initiate carbon etching in a CO$_2$ environment through the reverse Boudouard reaction (CO$_2(g)$ + C$_{(s)}$ → 2CO$_{(g)}$) without any additional heat in an endothermic reaction. Our methodology provides unprecedented information on LSP-induced chemical reactions at the nanometer scale, shedding light on the design principles for new hybrid plasmonic catalysts that will enable low-temperature, industry-relevant chemical processes.

Quasi-High Entropy Oxide with Ultra-Long Lifetime and Ferroelectric Catalyst- Ca(Zr,Y,Ce,Cr,Ag)O, Performing Piezo-Photo Catalytic Activity with Localized Surface Plasmonic Resonance Hsuanyu Chen$^1$ and Jyh-Ming Wu$^{1,2}$; $^1$National Tsing Hua University, Taiwan; $^2$University of California, Los Angeles, United States

This work, Ca(Zr,Y,Ce,Cr,Ag)O, modified from pristine CaZrO$_3$, owning inner heterostructure, which was sonicated with visible light has been confirmed it can enhance piezo-photo catalytic activity for organic dye degradation. CaZrO$_3$(CZO) demonstrate remarkable optical information storage application due to possessing numerous intrinsic traps and ferroelectricity, which imply long recombination lifetime. However, the large band gap (3.3eV) restrict its photo-catalytic efficiency for dye degradation. Herein introduction of several transition metal elements into CZO nanoparticles has been synthesized by a sol-gel process and forms heterojunction nanostructure(fluorite-(Zr,Y,Ce)O$_2$) & perovskite-CaZrO$_3$) The time-resolved photoluminescence (TRPL) reveals that recombination lifetime have already improved up to 620% compared to pristine CZO. CZO, which belong to Pnna group of perovskite structure, displays unique ferroelectricity which has spontaneous polarization for prolonging lifetime and enhance piezo-photo activity. Besides, modified-CZO surrounded by silver nanoparticles, demonstrating localized surface plasmon resonance (LSPR) effect as observed by surface enhanced raman spectrum(SERS). Through ultraviolet-visible (UV-Vis) spectrophotometer measurement, modified-CZO is achieving almost 200% degradation performance compared to pristine CZO. The vast enhancement arises from piezo-photo activity, which was combined through ferroelectricity, charge transfer mechanism for prolonging recombination lifetime, and induced local electric field for generating numerous electron-hole pair . The COMSOL software was employed to simulate the charge
distribution. The mechanism on LSPR enhanced piezo-photo catalytic dye degradation will be investigated.

Zinc Oxide Nanostructures Synthesized by a Simple Hot Water Treatment Method for Photocatalytic Degradation of Organic Pollutants in Water Ranjitha Hariharalakshmanan, Busra Ergul, Nawzat S. Saadi, Khalidah Al-Mayalee and Tansel Karabacak; University of Arkansas at Little Rock, United States

The use of zinc oxide (ZnO) nanostructures as a photocatalyst for the degradation of organic pollutants in water has received significant attention over the recent years. However, synthesis methods for producing ZnO nanostructures are generally costly, complicated, and hazardous to the environment. In this work, we demonstrate the synthesis of zinc oxide nanostructures by a simple hot water treatment (HWT) method and the photocatalytic activity of the hence produced nanostructures. HWT is a one-step, low-cost, eco-friendly, and scalable nanostructure growth method. By HWT, various metal oxide nanostructures can be produced simply by the interaction of metals with hot water without the need for any chemical additives in the solution. Growth of metal oxide nanostructures by HWT involves the formation of metal oxides and their release from the surface of the metal into water, the migration of the metal oxides in water and their re-deposition at a different part of the metallic surface, which initiates the growth of nanostructures. In this study, we used zinc powder and plates for producing the ZnO nanostructures by HWT in DI water at 75 °C. Scanning electron microscopy images and X-ray diffraction were utilized to verify the formation of ZnO nanostructures. Zinc plates produced a suspension of ZnO nanostructures in water, while on the other hand Zn powder resulted in a predominantly core-shell geometry of Zn particle-core and ZnO nanostructures-shell also mixed in water. We used these nanostructures + water suspensions for our photocatalytic degradation studies. Methylene blue was used as a model organic pollutant. We mixed the ZnO nanostructure suspension with methylene blue and exposed it to UV light. The degradation of methylene blue was observed by measuring its absorbance values using a UV-Visible spectrophotometer over a period of four hours. We observed a 20% decrease in the concentration of methylene blue in four hours when nanostructured Zn/ZnO core-shell powder suspension was used, and a 30% decrease was achieved when ZnO nanostructure-only suspension was used. Methylene blue alone was also exposed to UV light for the same period as a control experiment and we did not observe any significant decrease in its concentration. These preliminary results indicate that hot water treatment method presents a very simple, cost-effective, scalable, and eco-friendly alternative for the synthesis of zinc oxide nanostructures for photocatalytic water treatment applications.

Carbon Dioxide Conversion to Methanol over Rh Intercalated Graphene/SiC—A First-Principles Study Ashwin Kishore Munusamy Rajendran and Karin Larsson; Uppsala University, Sweden

Mitigating atmospheric CO2 concentration is a great challenge for the twenty-first century. It can be done only by capturing and converting CO2 into useful fuels with the help of catalysts. Knowledge of the reaction mechanism in CO2 hydrogenation reactions is key to the rational design of highly efficient catalysts. Here, we investigate the CO2 conversion into methanol on Rh intercalated Graphene/SiC using density functional theory calculations and kinetic Monte Carlo simulations. The adsorption energy, bonding configuration, bond lengths, and vibrational frequencies of all the surface intermediates involved in the reaction mechanisms are studied. Present results on methanol production suggest that the hydrogenation of CO2 to CO occurs via the reverse-water-gas shift (CO2 + H2 → CO + H2O) reaction rather than formate (HCOO-) or direct C−O bond cleavage pathways. The produced CO can either desorb or further react with hydrogen to produce CH4 or CH3OH since the adsorption energy of CO is low. The intermediates of the CO2 pathway for methanol production includes *OCOH, CO, *CHO, *CHOH, and *H2COH. The reaction barrier energy for each elementary steps involved in CO2 hydrogenation will be discussed, and that can provide further insights into the reaction mechanism. Finally, we will also discuss how the energetics affects the kinetics of the reaction, such as the overall rates for CO2 conversion and the production of CO, CH3OH, and CH4 under reaction condition.
Plasmonic Photonic Crystal Photocatalysts Consisting of TiO$_2$ Nanotube Arrays Decorated/Embedded with Noble Metal Nanoparticles

Sheng Zeng$^1$, Ryan Kisslinger$^1$, Alexander Kobryn$^2$, Sergey Gusarov$^2$, Kazi Alam$^{1,2}$ and Karthik Shankar$^1$; $^1$University of Alberta, Canada; $^2$National Research Council Canada, Canada

Plasmonic photocatalysis offers the promise of using light as the energy source to drive a variety of thermal energy-intensive phonon-driven chemical reactions close to room temperature [1]. Industrially relevant heterogeneous catalytic reactions targeted by plasmonic photocatalysis include CO$_2$ reduction, water-splitting to generate H$_2$, hydrocarbon reforming, Fischer-Tropsch reactions, synthesis of azo dyes, nitrogen fixation, hydrogenation reactions, and the oxidative degradation of organic compounds. Plasmonic catalysis also offers unique chemical bond activation mechanisms that differentiate hot carrier-driven chemical reactions from routine carrier-driven catalysis [2].

Plasmonic photocatalysis utilizes nanophotonics in the service of catalysis. Another nanophotonic architecture, namely photonic crystals (PhCs) which allow the propagation of photons of selected frequency bands, has been explored much less for catalysis. The primary reason is the impracticality of using top-down fabrication techniques such as electron beam lithography to mass-produce PhC catalysts. Bottom-up fabrication techniques for PhCs are rare, and suffer from a lack of adequate control over the optical properties of the resulting PhCs.

Herein, we present the bottom-up synthesis of large area PhCs consisting of arrays of self-organized vertically oriented TiO$_2$ nanotubes (TNTAs) with periodically modulated diameters, grown by a charge controlled pulsed electrochemical anodization (CCPEA) technique. The CCPEA technique enables superior control over the optical resonances exhibited by TNTA PhCs, compared with galvanostatic & potentiostatic pulsed anodization processes. When TNTA PhCs with well-defined photonic stop-bands are decorated or embedded with nanoparticles (NPs) of Au, Ag, CuPt, TiN, etc, plasmonic photonic crystals result.

TNTAs partially embedded with Au NPs are shown to be excellent photoanodes for visible light-driven photoelectrochemical water-splitting in alkaline electrolytes. Embedding Au NPs in the nanotube walls as opposed to decorating them results in high extinction coefficient, high Q-factor, red-shifted plasmon resonances [3] that facilitate the injection of hot electrons formed by plasmon dephasing, into the conduction band of TiO$_2$ while residual hot holes oxidize water to O$_2$. The observation of photoelectrochemical quantum yields approaching 30 % for visible wavelengths indicates surprisingly efficient hot carrier harvesting. Likewise, TNTA PhCs decorated with Au NPs are also excellent photocatalysts for the vapor phase reduction of CO$_2$ into light hydrocarbons. TNTAs conformally coated with titanium nitride exhibit near-infrared resonances and appreciable photocatalytic activity [4]. The TNTA structure provides a high density of active surface sites for reactant adsorption, and its own optical properties (PhC and Mie scattering effects) [5] interact with the plasmons to influence the photocatalytic behavior.

Solar Fuel Production—Opportunities for Nanostructures

Zhigang Zou; Nanjing University, China

The photocatalytic and photoelectrochemical reduction of water or CO$_2$ is an intriguing approach to producing sustainable solar fuels, and has attracted growing and intense interest. Nanostructuring of photocatalysts and photoelectrodes has been proven to be a strong strategy to dramatically improve overall solar-to-fuel conversion efficiencies. Another technological barrier for the practical implementation of solar fuel production is long-term material durability, which has recently been well addressed by using conformal coatings of protective layers onto the narrow band-gap semiconductors that are suitable for
efficient solar-to-fuel conversions but photoelectrochemically unstable. These significant progresses may lead us to the practical implementation of solar fuel production. We focused on the exciting progresses achieved by using nanostructuring strategies, specifically regarding how the nanostructure influences the charge transport and separation. Special attention was paid to investigate how a nanoscale coating (overlayer) passivates the surface states, thereby reducing the surface electron hole recombination, and how a nanoscale coating (protective layer) prevents the photocorrosion or photopassivation of the semiconductors with optimal band gaps. We hope that the design strategies using these nanostructures will offer new and greater opportunities for efficient solar fuel production to existing photocatalytic and photoelectrochemical systems.

Low Temperature and Green Synthesis of Diethylenediamine Functionalized Reduced-GO Grafted on SiC for Photodegradation and Conversion of Organic Pollutants to Useful Fuels
Olusegun Abass; Nanyang Technological University, Singapore

Conventional photocatalysts based on metals and semiconductors are sometimes rigid and possesses stability issues when applied in the treatment of industrial wastewater. Thus, novel photocatalysts based on polymer/nanomaterial composites are attracting more interest. Although much effort has been devoted to acquire catalysts with high efficiency and long-term durability, this work proposes a simple and green three-steps procedure for synthesis of diethylenediamine-modified reduced graphene oxide (DD-rGO) grafted on a magnesio-thermically produced silicon carbide (SiC) to achieve one-vessel conversion of organic pollutants into useful fuels such as methanol and ethanol under simulated solar irradiation. The mechanism behind the distinct reactivity and stability of the as-prepared photocatalyst was proposed. We expect that these entirely new nanocomposite structures will not only pave way for the development of highly efficient and stable photocatalyst systems but also have a wider impact in applications (such as water treatment) where catalysts stability is essential.

Sodium Niobate (NaNbO3) Nanorods Coupled with RGO Nanocomposite for Enhanced Photoelectrochemical Water Splitting
Dheeraj Kumar and Neeraj Khare; Indian Institute of Technology Delhi, India

The utilization of fossil fuel subsidiaries, for example, coal, heavy oil, natural gas and petrol have transformed into global issue of environment concern. The use of energy is rapidly expanding with rising population in view of which there is a need of utilizing efficient green sustainable energy sources to fulfill the requirements of energy supply [1]. The solar light based energy can be converted and stored in the form of fuels, for instance, generation of hydrogen (H2) by photoelectrochemical (PEC) water splitting appears to be a potential alternative to the fossil fuels [2]. PEC water splitting is one of the most attractive technology for H2 generation using a semiconductor nanocomposite materials [3, 4]. In the present work, hydrothermally grown sodium niobate nanorods (NaNbO3-NRs) has been successfully coupled with reduced graphene oxide (RGO) nanosheets by using reflux method. Furthermore, the potentiality of the synthesized nanostructures has been investigated for photoelectrochemical (PEC) water splitting. A ~4 fold enhancement in the photocurrent density is demonstrated by fabricated RGO/NaNbO3-NRs nanocomposite photoanode than that of NaNbO3-NRs photoanode under UV-visible light illumination. The enhancement in the PEC activity of RGO/NaNbO3-NRs nanocomposite is attributed to the more absorption of visible light of the solar spectra and increase the mobility of photogenerated charge carriers which improves the separation efficiency and reduces the recombination of charges. The possible mechanism responsible for the PEC water splitting have been proposed.

Non-Noble Metal Plasmonic Nanoparticles as Highly Efficient Light Absorber for Solar Steam Generation
Fan Yang and Yadong Yin; University of California, Riverside, United States

Plasmonic nanoparticles have attracted great interest in harvesting solar energy due to their excellent capability in photothermal conversion. However, noble-metal-based plasmonic nanoparticles typically exhibit a narrow absorption peak, which limits their ability to fully utilize solar energy. Compared with conventional noble metal nanoparticles, transition metal nanoparticles show relatively broad resonance band, allowing absorption of a larger fraction of solar radiation. However, the application of these nanoparticles is limited due to their poor stability, especially in the presence of oxygen and water. In this
presentation, we report the synthesis of Ni@C@SiO$_2$ core-shell nanoparticles that can be used as light absorbers. The stability of Ni nanoparticles is greatly enhanced by a layer of densified SiO$_2$. Moreover, by adding a carbon layer between Ni and SiO$_2$, the absorption peak of Ni can be expanded and red-shifted to maximize the overlapping between the absorption spectra of core-shell nanoparticles and the solar radiation spectra. The colloidal nature of the nanoparticles allows their easy processing into a thin film that can be attached to a floating melamine foam, producing an integrated solar steam generator. The three-layered core-shell nanoparticles exhibit an excellent photothermal property and high steam generation efficiency under solar illumination.

Photoelectrochemistry of Cobaloxime-Modified Gallium Phosphide and Gallium Arsenide Surfaces

Nghi Nguyen, Brian L. Wadsworth, Edgar Reyes Cruz, Daiki Nishiori and Gary F. Moore; Arizona State University, United States

Photoelectrochemistry provides a strategy for creating fuels from sunlight. In this poster presentation, I will describe the chemistry of immobilizing polypyridyl coatings containing cobaloxime-type catalysts onto either GaP or GaAs surfaces. When wired in a three-electrode configuration with appropriate counter and reference electrodes, the hybrid constructs use light to power the production of hydrogen gas with near unity faradaic efficiency from aqueous solutions in the absence of sacrificial chemical reductants and with no electrochemical forward biasing. When operating at the equilibrium potential of the hydrogen evolution reaction under simulated 1-sun illumination, the modified- GaP and GaAs assemblies produce current densities of 1 and 10 mA cm$^{-2}$, respectively. Analyses of the wavelength-resolved external and internal quantum efficiencies show the modified-GaP assemblies are active over wavelengths ranging from 300 to 550 nm, and the modified-GaAs assemblies are active over wavelengths ranging from 300 to 870 nm. The cobaloxime-modified GaAs thus gives a higher rate of photoelectrochemical fuel production due to the improved spectral overlap of the semiconductor's absorption properties with the solar flux spectrum.

Photoelectrochemistry of Metalloporphyrin-Modified Gallium Phosphide Surfaces

Daiki Nishiori, Brian L. Wadsworth, Edgar Reyes Cruz, Ngh Nguyen and Gary F. Moore; Arizona State University, United States

Human-engineered materials capable of generating fuels from sustainable energy sources provide an approach to satiating modern societies' energy demands, with minimal environmental impact. In this poster presentation, I will describe hybrid photoelectrosynthetic assemblies composed of gallium phosphide (GaP) functionalized with metalloporphyrin complexes of five different transition metal ions: Fe(III), Co(II), Ni(II), Cu(II), and Zn(II). Surface attachment of these metalloporphyrin complexes was achieved using a previously reported UV-induced photochemical grafting method. The photoelectrochemical properties of these heterogeneous-homogeneous materials will be contrasted with electrochemical properties of the isolated, homogeneous metalloporphyrins and other previously reported heterogeneous-homogeneous constructs.

Pairing Two-Electron Zinc Architectured Electrodes with Multivalent Cathodes for Enhanced Energy Storage
Debra R. Rolison1,2, Brandon J. Hopkins1,2, Samuel W. Kimmel3,4,1, Christopher N. Chervin1, Joseph F. Parker1, Jeffrey W. Long1 and Christopher Rhodes2; 1U.S. Naval Research Laboratory, United States; 2National Research Council Postdoctoral Associate, United States; 3Texas State University, United States; 4Naval Research Enterprise Internship Program (NREIP), United States

We previously demonstrated that reformulating zinc into a monolithic spongy form factor moved aqueous zinc-based batteries onto a new performance curve—one in which the zinc electrode can be rechargeably cycled at high rate, to deep utilization of the metal, all without generating separator-piercing dendrites. This breakthrough enables development of a broad class of rechargeable zinc-based aqueous batteries. Ideally a next-generation of batteries in which the accompanying cathode can match the two-electron redox of zinc. We will describe the improvement of system metrics when pairing the two-electron zinc sponge versus the two-electron silver oxide cathode, even without optimizing the silver electrode, including
electrochemical capacitor-worthy power. We then will describe the nanostructuring of α-Ni(OH)$_2$ in an attempt to stabilize the 1.67 electron redox characteristic of this precursor to the NiOOH cathode over the one-electron redox limit characteristic of β-Ni(OH)$_2$.

Development of Magnesium Electrolytes—From Chloride Mixtures to Weakly Dissociated Anions

Chen Liao$^{1,2}$; 1Argonne National Laboratory, United States; 2Joint Center of Energy Storage Research, United States

The fossil fuel energy crisis causes significant geopolitical stress, and renewable energy such and wind, tide and solar is a green solution to this problem. Energy storage is required for any renewable energy utilization as they are of intermittent nature with usually high production during off-peak hours and low production in peak hours. Lithium ion battery is the main workhorse for portable electronics and portable tools and start adopting the market of electric vehicles, as well as electrochemical energy storage. However, they are reaching their maximum performance and a new breakthrough in electrochemical energy storage is necessary for a wide adaption of renewable energy. Multivalent ion batteries, particularly Mg and Ca, are of high interest because of their very electropositive electrochemical potentials: Mg has a reduction potential of -2.4 V vs NHE, while Ca has a reduction potential of -2.9 V vs NHE. Other favorable properties include high volumetric energy density and high crustal abundance.

The development of Mg has been mostly impeded by both the cathode and electrolyte developments, unlike its counterpart Li ion, Mg is notoriously famous for formation of a strong bond with oxygen and does not move easily in the lattice of MgO. A premise for a working Mg ion battery is that the surface of the Mg metal cannot be passivated in order to facilitate reversible Mg dissolution/deposition. A classical way of conditioning or preparing the Mg metal surface is either to provide a Cl- in a Mg solution. The limited anodic stability of the Cl- would be problematic for Mg ion batteries because of corrosion issue with current collector. Using high-purity Mg salts with weakly associated anion (WCA) such as trifluorosulfonimidimide (TFSI) and carborane has been a standard practice in the field since 2015. In 2019, our group introduced a new WCA group for the MV salts, the t-butyl/perfluoroaluminate ([TPFA]$^-$ = [Al{OC(CF$_3$)$_3$}]$^-$) and demonstrated the highly reversibility of deposition/dissolution, unprecedented anodic stability, and lack of passivation layer formation during the high potentiostatic hold. The favorable properties of the salt make it a friendly anion for the quest of cathode development, especially the transition metal oxide spinels for Mg ion batteries.

We will cover the brief history of the development of Cl- containing electrolyte in our group since 2014 and will present the detailed electrochemical performance, and collaborated work on the decomposition mechanism understanding, solvation behavior in O-donor solvents, and expansion of these research

**Potential of Magnesium Batteries**

Robert Dominko¹,²,³, Jan Bitenc¹, Alen Vizintin¹, Rekha Narayan¹ and Anna Randon-Vitanova⁴; ¹National Institute of Chemistry, Slovenia; ²FKKT, University of Ljubljana, Slovenia; ³Alistore ERI, France; ⁴Honda R&D Germany, Germany

Magnesium is a promising element for future batteries due to high gravimetric (2206 mAh/g) and volumetric capacity (3834 mAh/cm³) of Mg anode. It is considered as geopolitically neutral, sustainable and abundant metal, which can be used in batteries due to non-dendritic deposition during battery operation. Besides discussed benefits, there are several challenges connected with the use of Mg metal, mainly incompatibility of the Mg metal with the electrolytes and difficult insertion of magnesium into oxide based solid state host matrix. Alternative solutions can be use of redox active polymers with different active redox groups.

In this presentation, overview of recent achievements in our group on the field of magnesium batteries will be discussed with a focus on proper selection of battery components in order to achieve electrochemical properties attractive for the commercialization.

**Electrolytes for Rechargeable Aluminum Batteries—The Complexity of Chloroaluminate Ionic Liquids**

Juchen Guo;
University of California, Riverside, United States

Reversible electrochemical reactions of aluminum (Al) that can be potentially used for energy storage technologies is an intriguing topic from both scientific and technological perspectives. The centerpiece of reversible Al electrochemistry is the electrolyte. To date, the overwhelming majority of Al battery research activities utilize Lewis acidic chloroaluminate ionic liquids as the electrolytes. However, the complex nature of these electrolytes, such as corrosiveness, proneness to oxidation, and rich coordination, can lead to unintended ambiguity. In this presentation, we demonstrate that cautions must be used to interpret results of Al electrochemical reactions using chloroaluminate ionic liquid electrolytes. We use aluminum chloride/1-ethyl-3-methylimidazolium chloride (AlCl₃-[EMIm]Cl) ionic liquid as the example. We find Lewis acidic AlCl₃-[EMIm]Cl is corrosive to many commonly used metal current collectors, and the resulting corrosion current could be mistaken as the current from the electrochemical reactions of Al. The proneness of electrochemical oxidation of AlCl₄⁻ anion (ultimately leading to chlorine evolution) causes complicated process in the previously reported reversible AlCl₄⁻ intercalation in graphite. As the results, fast self-discharge and large irreversible capacity is observed when graphite (either natural or synthetic) is used as the cathode martials. We further investigated the chemical compatibility of AlCl₃-[EMIm]Cl with V₂O₅, which is a common cathode material reported in the literature of Al battery. Our study indicates V₂O₅ chemically reacts to both Lewis neutral and Lewis acidic AlCl₃-[EMIm]Cl. By elucidating the reaction mechanisms, we conclude V₂O₅ is not a
feasible Al storage material in the chloroaluminate ionic liquid electrolytes. These findings could provide guideline for design more reliable electrolytes for rechargeable Al batteries.

Developing Advanced Electrolytes for Multivalent Mg and Ca Batteries Jian Luo and Tianbiao L. Liu; Utah State University, United States

Mg is an earth abundant and low-cost metal (ca. 24 times cheaper than Li), and as an anode material, Mg is safe to use (vs. Li, Li-ion, or Na-ion batteries). Its high gravimetric capacity (2,333 Ah/kg) and high reduction potential (-2.37 V vs SHE) allow the assembly of high-energy density batteries. However, despite rapid research progress, the lack of high performance Mg2+ conductive electrolytes still presents a primary technical hurdle for developing practical Mg batteries. The presentation will cover our research efforts in developing high performance Mg electrolytes for Mg rechargeable batteries. Specifically, we will present the synthesis and electrochemical performance of ternary Mg/MgCl2/AlCl3 (MMAC) electrolytes and a novel Cl-free perfluorinated pinacolatoborate Mg electrolyte (Mg-FPB). These MMAC and Mg-FPB electrolytes exhibited up to 100% Coulumbic efficiency, and 164 mV overpotential for Mg deposition, and 4.5 V vs Mg anodic stability. Solution and interfacial chemistry of the presented Mg electrolytes will be discussed in detail.

5:15 AM *S.EN08.01.02
Progress in Mg and Ca Batteries Maximilian Fichtner1,2, Zhenyou Li1 and Zhirong Zhao-Karger1; 1Helmholtz-Institute Ulm (HIU), Germany; 2Karlsruhe Institute of Technology, Germany

The stagnation in the development of Li ion batteries based on liquid electrolytes and resource issues associated with the current battery configuration have fueled activities which try to solve or circumvent these issues. The aim is to both increase the energy content of battery cells and to make them ready for future application. This requires a set of materials which do not only have exceptional standalone properties but can mutually interact in a harmonic manner. Multivalent batteries promise to have superior properties in terms of volumetric and gravimetric capacities, however suffer from major roadblocks such as low ionic conductivity in the solid, reversible and efficient transport in the liquid and reversibility of insertion/conversion reactions.

One concept to tap the potential of multivalent systems is using conversion electrodes, e.g. with sulfur/carbon composites as cathode. The contribution will comment on the actual state of development of sulfur-compatible electrolytes with high efficiencies, high ionic conductivities, wide electrochemical stability window, easy synthesis and excellent compatibility with electrode materials and other cell components. Recent results in the development of Mg- and Ca-sulfur batteries will be presented and the remaining challenges will be discussed. Furthermore, a new cathode material with a high capacity for Mg and a mixed storage mechanism will be presented.

Design of Charge Carriers for Multivalent Battery Electrolytes Patrik Johansson1,2; 1Chalmers Univ of Technology, Sweden; 2UPJV, France

As compared to Li-ion and Na-ion battery electrolytes the electrolytes for Mg, Ca and Al metal batteries are quite different.1,2 This is also reflected in the nature of the charge carriers e.g. the size and number of ligands coordinating to the central multivalent atom.

Furthermore the charge carriers are also affected by the salt concentration in a different way than the electrolytes based on monovalent central atoms.

We have studied several multivalent electrolyte designs3 and elucidated the preferrable local structures both by modelling (MD + DFT calculations) and by experimental methods (IR, Raman and NMR spectroscopy) in terms of stability of the first solvation shell, while also addressing other properties such as the electrochemical stabilities and the coordination of active sites at the electrode.4 These results can be used for a more general understanding of the central atom - ligand relationship for these basic electrolytes.

From the Bulk to the Interface—“Ion Solvation Spectra” of Multivalent Ions in Aprotic Solvents Artem Baskin1,2 and David Prendergast1,2; 1Lawrence Livermore National Laboratory, United States; 2Joint Center for Energy Storage Research, United States

In the journey of the ions from the bulk to the interface the changes in their solvation structures and in their relative populations determine the essential characteristics of all the most important electrochemical processes. The ion solvation energy and the stiffness of its solvation sphere determine both thermodynamics and kinetics of the charge transfer at the interfaces. However, the atomistic details and thermodynamic characteristics of ion (de-)solvation process in the confined environment (e.g., near an electrode) remain largely unknown. For example, we still lack clarity on the locus and particular ion-solvent configurations at which the charge transfer occurs. On the other hand, the current paradigm of the solvation science provides well developed concepts and tools to study the ion solvation in the bulk liquid electrolytes (molecular dynamics and quantum chemistry hybrid protocols). These rely on the fundamental assumption of the uniqueness of the ion solvation structure. However, we have recently shown [1] that some even monoatomic cations in aprotic solvents exhibit multiple minima in the free energy landscapes with respect to ion-solvent coordination. As we will demonstrate, it has profound implications for the methodology to evaluate thermodynamic characteristics of electrolytes. Here we extend our approach of using advanced molecular dynamics free energy sampling techniques – both classical and ab initio – and explore the dynamics of the solvation structures of mono- and multivalent (Li+, Mg2+, Ca2+, and Zn2+) ions as they approach electrodes from the bulk in a range of aprotic solvents.

Electrolytes for Rechargeable Aluminum Batteries—The Complexity of Chloroaluminate Ionic Liquids Juchen Guo; University of California, Riverside, United States

Reversible electrochemical reactions of aluminum (Al) that can be potentially used for energy storage technologies is an intriguing topic from both scientific and technological perspectives. corrosive to many commonly used metal current collectors, and the resulting corrosion current could be mistaken as the current from the electrochemical reactions of Al. The proneness of electrochemical oxidation of AlCl$_4^-$ anion (ultimately leading to chlorine evolution) causes complicated process in the previously reported reversible AlCl$_4^-$ intercalation in graphite. As the results, fast self-discharge and large irreversible capacity is observed when graphite (either natural or synthetic) is used as the cathode materials. We further investigated the chemical compatibility of AlCl$_3$-[EMIm]Cl with V$_2$O$_5$, which is a common cathode material reported in the literature of Al battery. Our study indicates V$_2$O$_5$ chemically reacts to both Lewis neutral and Lewis acidic AlCl$_3$-[EMIm]Cl. By elucidating the reaction mechanisms, we conclude V$_2$O$_5$ is not a feasible Al storage material in the chloroaluminate ionic liquid electrolytes. These findings could provide guideline for design more reliable electrolytes for rechargeable Al batteries.

From Magnesium to Calcium—Translating Insights across Divalent Battery Electrolytes Nathan Hahn$^1$, Kevin R. Zavadil$^1$, Trevor Seguin$^2$, Kristin A. Persson$^2$, Darren Driscoll$^3$ and Mahalingam Balasubramanian$^3$; $^1$Sandia National Labs, United States; $^2$Lawrence Berkeley National Laboratory, United States; $^3$Argonne National Laboratory, United States

Multivalent cation-based electrochemical energy storage concepts provide significant promise and challenges as beyond Li-ion technologies. In particular, chemistries based on Mg$^{2+}$ or Ca$^{2+}$ cations and their associated reactive metal anodes stretch the current limits of understanding regarding solvation and resultant electrochemistry in organic electrolytes. Furthermore, the recent discovery of semi-reversible calcium metal plating at room temperature in a very limited number of organic electrolytes provides a new and exciting opportunity to study the key aspects of solvation interactions that apply to transport and electrochemical stability across this set of alkaline earth metals. To this end, we present comparative studies of solvation phenomena and related electrochemical behavior using analogous sets of Mg$^{2+}$ and Ca$^{2+}$ salts in ethereal solvents. Differences in dication size and attendant solvation shell structures drive unique ion pairing tendencies and coordinating solvent structures, as determined through combined experimental and computational investigation. These coordination differences are further linked to both ion transport and electrochemical stability as they pertain to reversible metal plating. Based on these results, we will discuss strategies for designing electrolytes capable of maintaining efficient delivery of alkaline earth cations to and from their respective metal anodes or cathode hosts within a battery architecture.

SESSION S.EN08.03: Electrolytes and Interfaces in Multivalent Batteries
On Demand Abstracts Available for Viewing Starting On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
S-EN08

5:00 AM S.EN08.03.05
Probing Multivalent Cation Electrolytes at Dynamic Interfaces through X-Ray Spectroscopy and Modelling Ana Sanz-Matias$^1$, Jinghua Guo$^1$, Kevin R. Zavadil$^1$ and David Prendergast$^1$; $^1$Lawrence Berkeley National Laboratory, United States; $^2$Sandia National Laboratories, United States

The increasing demand of large-scale energy storage with improved performance, safety and sustainability for renewable variable energy sources and automotive applications drives the search for post-Li-ion batteries based on multivalent cation chemistries (e.g., Mg, Zn and Ca). However, poor electrolyte stability against metal anodes and high voltage cathodes has been so far one of many barriers to the development of multivalent cation rechargeable batteries. Unserstanding and controlling (electro)chemistry at the electrolyte-electrode interface is critical on improving battery performance. Multivalent cations are prone to complex formation with solvent molecules and anions, leading to different interfacial species with characteristic (electro)chemical properties. Although multivalent cation solvation/complexation structures have been investigated in the bulk, fundamental understanding of speciation at the interface is lacking.

Recently, these buried solid-liquid interfaces have been accessed experimentally via total electron yield (TEY) soft X-ray absorption spectroscopy (XAS), sensitive to just a few nanometers above the solid electrode surface, and total fluorescence yield (TFY), more sensitive to the liquid bulk electrolyte. Interfacial species identification has been realized only in a handful of systems, formed by chemically stable electrodes (Au, Pt) and water or sulfuric acid solutions, although efforts toward exploring more complex systems are ongoing.

This work explores the structure, dynamics and spectroscopic signatures of a matrix of multivalent cations (Zn$^{2+}$, Mg$^{2+}$,
Ca$^{2+}$), nonaqueous electrolytes, and the bis(trifluoromethylsulfonyl)imide anion (TFSI$^-$) through TEY/TFY soft X-ray absorption spectroscopy and atomistic simulations. While the metal K-edge may provide insight into cation coordination, the previously unexplored F K-edge contains unique information about the complexation in bulk and at the interface. The limited studies in the literature show the rich behavior of the F K-edge in materials. However, the origin of the high sensitivity of the F K-edge XAS spectral profile to the chemical environment still lacks theoretical interpretation.

TEY/TFY experiments carried out at the ALS reveal unique interfacial speciation as a function of the cation and the coordinative strength of the solvent (2-methyltetrahydrofuran, 2MeTHF; 1,2-dimethoxyethane, G1; 1,2-dimethoxyethane, G2). A recently developed many-body formalism based on Density Functional Theory (MBXAS) was used to calculate the F K-edge X-ray absorption spectroscopic signature of the counterion TFSI$^-$ in different coordination environments (contact and solvent-separated ion pairs) and in proximity to the electrode. Furthermore, the energy landscapes of the different interfacial species were probed using classical and first-principles Molecular Dynamics simulations so as to understand subsequent temperature effects on the spectra.

With this work, we intend to highlight the promise of F K-edge X-ray absorption spectroscopy in combination with computational modelling as a unique channel to detect interfacial populations of anions (and associated solvent and cations).

Functional Electrolytes and Interface Design for Multivalent-Metal Batteries Guanglei Cui and Jingwen Zhao; Chinese Academy of Sciences, China

Although lead-acid batteries managed to dominate market share of the low-cost power source, their high toxicity and negative environmental impact urge the development of low-cost batteries.[1] The divalent cation (e.g. Zn$^{2+}$ and Mg$^{2+}$ etc.) chemistries are principally advantageous for their adequate resources and improved safety. However, rechargeable divalent metal-based batteries is currently limited by the unavailability of electrolytes which must simultaneously satisfy wide enough electrochemical stability window, good compatibility with electrodes and current collector corrosion resistance.[2] Based on the precise design of electrolytes with reasonable composition and structures, we developed a series of boron-centered-anion-based Mg-ion electrolytes characterized by high ionic conductivity, non-nucleophilicity, and wide electrochemical window (Adv. Energy Mater. 2017, 1602055; Electrochem. Commun. 2017, 83, 72). Based on an in situ crosslinking reaction of magnesium borohydride and hydroxyl-terminated polytetrahydrofuran, a gel polymer electrolyte exhibits reversible Mg plating/stripping performance, high Mg-ion conductivity, and remarkable Mg-ion transfer number (Adv. Mater. 2019, 1805930; Energy Environ. Sci. 2017, 10, 2616; Small 2017, 1702277). Meanwhile, we demonstrated the solid-electrolyte interface formation on Zn anodes based on eutectic electrolytes that can optimize the stripping/deposition processes (Nano Energy 2019, 57, 625; Nat. Commun. 2019, accepted; Electrochem. Commun. 2016, 69, 6). We further creatively proposed a thermoreversible polymer-based electrolyte with the ability of cooling-recovery to repair the interfacial failure during cycling (Angew. Chem. Int. Ed. 2017, 56, 7871) and a brighter-inspired interface for suppressing Zn dendrite and side reactions (Energy Environ. Sci. 2019, 12, 1938; NPG. Asia Mater. 2019, accepted). These prospective researches on the rechargeable Zn and Mg batteries are highly in compliance with the lead-free trend in the EVs and corresponding low-cost applications.

5:25 AM *S.EN08.03.07
Electrolyte, Solvation Shell and Interphase for Ca Metal Anode Based Batteries Alexandre Ponrouch; ICMAB-CSIC, Spain

Various metals have been used as battery anodes in electrochemical cells ever since the birth of the batteries with Volta’s pile and in the first commercialized primary (Zn/MnO$_2$, Leclanché 1866) and secondary (Pb/acid, Planté 1859) batteries. Li-MoS$_2$ cells, employing Li metal anodes, with specific energies two to three times higher than both Ni/Cd and Pb/acid cells, were withdrawn from the market due to safety issues related to dendrites growth. Instead, Ca is currently being considered as safer metal anode alternative.[1] Pioneering work by Aurbach et al. in the early 1990’s showed a surface-film controlled electrochemical behavior of Ca metal anodes in electrolytes with conventional organic solvents.[2,3] The lack of metal plating was attributed to the poor diveral cation migration through the passivation layer.

Nevertheless, recent demonstration of Ca plating and stripping in the presence of a passivation layer [4,5] has paved the way for assessment of new electrolyte formulations with high resilience towards oxidation. However, several challenges remain to be tackled for the development of Ca based batteries.[1,6] Among these, the need for reliable electrochemical test protocols, mass transport limitations and high desolvation energies (due to strong cation-solvent and cation–anion interactions) are implied.[8] Here, the reliability of electrochemical set-ups involving multivalent chemistries is discussed,[9] and a systematic
investigation of the electrolyte formulation impact on the cation solvation structure and transport is presented.[10] Finally, a systematic characterization of the SEI formed on the Ca metal anode in various electrolyte formulations using complementary techniques allowed for the identification of the most suitable SEI components in terms of divalent cation mobility.

Mapping Interphasial Phenomena in Electrodeposited and Cycled Calcium Metal Anodes Scott A. McClary, Nathan Hahn, Damion Cummings, Timothy Ruggles, Mark Rodriguez, Joseph Michael and Kevin R. Zavadil; Sandia National Laboratories, United States

Secondary batteries based on divalent calcium ions are attractive due to the high theoretical capacities of calcium metal anodes, low reduction potential nearing that of lithium, and earth abundance of calcium. In a significant milestone towards calcium-based batteries, the feasibility of reversibly plating and stripping calcium at room temperature from ether-based electrolytes was recently demonstrated. However, secondary phases such as calcium hydride [1] and calcium fluoride [2] form concurrently with deposited Ca metal and accumulate over time, contributing to coulombic efficiencies far below the threshold required for a practical rechargeable battery. Determining the formation mechanisms and distribution of these secondary phases is a critical first step in understanding and harnessing potential benefits of their presence to improve reversible battery operation. In this talk, we present the results of experiments utilizing a suite of electron microscopy techniques to map the distribution of calcium metal and secondary phases throughout electrochemically deposited and cycled calcium anodes. Calcium borohydride [Ca(BH₄)₂] in tetrahydrofuran (THF) was used as the primary model electrolyte for this study. Focused ion beam-generated cross sections were extracted from deposited and cycled anodes and characterized using Scanning Transmission Electron Microscopy (STEM) and Transmission Kikuchi Diffraction (TKD), revealing the preferred locations for calcium nucleation and growth, as well as the evolving morphology and accumulation of secondary phases over time. The deposits were also characterized using XRD in an inert environment, allowing for quantification of secondary phases and revealing crystallographic texturing of the calcium metal. We also present preliminary studies of cycled calcium anodes using STEM-EELS to chemically map calcium hydride. The work presented here provides critical insights regarding the morphology of deposited calcium metal and the extent and distribution of secondary phase formation and is an important step towards increasing the coulombic efficiency of calcium plating and stripping for next-generation rechargeable batteries.

Computational Modeling of the Anode-Electrolyte Interface of Calcium-Ion Batteries Joshua Young¹ ², Stuart Shepard¹ and Manuel Smeu¹; ¹Binghampton University, United States; ²New Jersey Institute of Technology, United States

Rechargeable batteries are critical components of portable electronics, electric vehicles and grid storage. Li-ion is the dominant technology because of its low weight, large voltage and high capacity, but the demand for raw materials is putting...
strain on the supply chain, and there are several safety, ethical and environmental concerns. Therefore, developing adequate alternatives to Li-ion batteries is an active research area around the world. Multivalent ion batteries (MVIBs), utilizing Mg, Ca, Zn and Al, are promising due to being based on earth-abundant materials, and their higher weight can be compensated by their multivalent nature, which allows their ions to carry multiple charges. We are particularly interested in Ca ion batteries, which have received relatively little attention compared to Mg and Al, yet they are predicted to provide the largest voltage for a multivalent ion. However, their development has been limited by challenges in identifying adequate electrolytes to reversibly plate and strip metal Ca anodes. While there have been some encouraging recent developments, a systematic understanding of the interactions between electrolytes and Ca is needed. For example, it is not clear how the electrolyte (e.g., ethylene carbonate) decomposes at a Ca metal surface, nor are the structure and composition known of the solid-electrolyte interphase (SEI) that forms between the metal anode and the electrolyte. Furthermore, the diffusion of Ca^{2+} ions through the SEI is not well understood.

We aim to address some of these points with computational modeling that combines density functional theory (DFT) with ab initio molecular dynamics (AIMD). We investigate the electrolyte decomposition of ethylene carbonate, with and without salt, at the Ca metal interface. We then compare this process to those occurring at Li and Al metal surfaces. The DFT calculations reveal the mechanism and energy barriers associated with the possible electrolyte decomposition pathways, while the AIMD trajectories reveal how quickly molecules decompose and their location. Next, we investigate the electron conductivity of the anode-electrolyte interface region at various stages of SEI layer formation. We accomplish this with the non-equilibrium Green’s function technique combined with DFT (NEGF-DFT), which not only tells us the conductivity but also the electron pathway through the interface. Finally, we investigate the possibility of protecting the electrolyte from reacting with the anode by separating them with an artificial SEI that still allows Ca^{2+} ions to diffuse through it. We propose that this strategy can aid in the development of rechargeable Ca-ion batteries by bypassing the formation of an ionically insulating SEI due to electrolyte decomposition.

6:00 AM S.EN08.03.10
Calcium Plating and Stripping in an Alkyl Carbonate Electrolyte at Room Temperature Shreyas Pathreeker, Saeid Biria, Hansheng Li and Ian D. Hosein; Syracuse University, United States

Calcium is the 5th most abundant element in the Earth’s crust and a candidate material for next-generation non-Lithium rechargeable batteries. Its standard electrode potential of -2.87 V is close to that of Lithium and double the energy density compared to that of Lithium-ion batteries would be possible due to Calcium’s bivalent nature. Additionally, dendrite formation is alleviated with Calcium due to its high density and high thermal stability. In comparison to other multivalent ions such as Magnesium, Calcium possesses a smaller charge density and higher standard electrode potential, affording faster ion diffusion through cathode materials. However, to practically realize these advantages, Calcium metal anodes are necessary, which makes reversible plating and stripping Calcium on metallic substrates an important area of research. Recent work has successfully demonstrated electrochemical deposition of Calcium in EC/PC at elevated temperatures\(^1\), THF\(^2\), and DME\(^3\), whereas here, we report reversible plating and stripping of Calcium in an EC/PC based electrolyte at room temperature. Stable redox reactions were observed with cyclic voltammetry, and reversible plating and stripping was achieved galvanostatically at room temperature. Crystalline deposits in the form of thin films were successfully confirmed using XRD and FTIR measurements to be consisting of Calcium metal with traces of side products. Deposition on other substrates in other non-aqueous electrolytes is currently being investigated. This work provides an avenue for reliably developing Ca-metal electrodes for next-generation batteries.

Elucidating the Relationships between Performance, Transport Phenomena and Materials Properties for Functional Components of Multivalent-Ion Batteries

Hunter Ford, Peng He and Jennifer L. Schaefer; University of Notre Dame, United States

The development of new rechargeable battery systems employing novel chemistries is imperative to meet the increasing energy storage demands of emerging technologies such as electric vehicles and grid load leveling. Of particular interest is the development of battery systems employing multivalent metal anodes. Using a multivalent metal anode increases the energy density of the cell by providing an electrode consisting of entirely active material. Furthermore, many such elements such as magnesium are far more naturally abundant than lithium, ensuring they are economically viable and sustainable. Due to these benefits, multivalent-ion battery systems have recently received significant research attention. One of the outstanding challenges is dealing with the multivalency of the active cation, in regards to how the high charge density of the ion generally exacerbates traditional transport problems. For instance, conduction of multivalent cations Mg$^{2+}$ and Ca$^{2+}$ within single-ion conducting polymers is 1-3 orders of magnitude slower than their monovalent cation equivalents. This general problem of charge density presents itself in all components of the battery, from promoting decomposition on the anode to limiting the selection of electrolyte salts to the few that can adequately dissociate in solution. In regards to magnesium-sulfur batteries, poor cation diffusivity in solid discharge products makes oxidation to higher order polysulfides and sulfur difficult, a problem made worse by the low solubility of magnesium polysulfides and consequent lack of intrinsic redox mediators. Herein, we explore recent attempts within our group to provide solutions to these challenges, focusing primarily on electrolyte and conversion cathode development. We aim to link material properties to observed transport behavior, specifically in how to enhance divalent cation transport and minimize anion transport under an applied potential while maintaining electrochemical activity.

SESSION S.EN08.05: Multivalent Battery Intercalation Cathodes

On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020

Disulfide Redox Chemistry Boosts Energy Density and Divalent Ion Kinetics

Zhenyou Li$^1$, Zhirong Zhao-Karger$^1$ and Maximilian Fichtner$^{1,2}$; $^1$Helmholtz Institute Ulm, Germany; $^2$Karlsruhe Institute of Technology, Germany

Multivalent batteries are promising candidates for next generation battery technologies in terms of capacity and resource abundance. However, the theoretically high capacity of multivalent metals attributes to the multiple charge of the cations, which usually leads to a high charge density, thus causing sluggish insertion and diffusion kinetics at the corresponding cathode side. Taking rechargeable Mg batteries (RMBs) as an example, there is no report about insertion-type oxide cathode, which could provide reversible Mg storage with fair capacity at an acceptable current rate. The kinetic issue can be alleviated to some extent by using layered transition metal sulfide, due to the lower charge density of S than O. However, both diffusion kinetics and achievable capacity are not satisfying even if cointercalation of a second species is employed, which is supposed to screen the high charge density of Mg$^{2+}$. [1] In this regard, further “softening” the host structure is essential to realize fast Mg$^{2+}$ mobility. On the other hand, the realization of the high energy density requires enabling a reversible multi-electron redox reaction, which is seldom reported in insertion-type cathode for multivalent batteries. In fact, classical cationic redox with stepwise single electron reactions have not been able to fulfill the requirement for multi-electron redox reactions so far. Here, anionic redox chemistry with multi-electron transfer may be a possible solution. [2]

In this talk, we will present a new insertion-type cathode for multivalent batteries, which not only offers much more structural flexibility but also exhibits high energy density than the layered materials. Mg$^{2+}$ storage mechanism and possible diffusion pathways will be discussed in detail.

Effects of Nanoparticle Size and Solvent Molecule on Mg\textsuperscript{2+} Insertion into the Cathode Materials Wenxiang Chen\textsuperscript{1}, Xun Zhan\textsuperscript{1}, Cheng Zhang\textsuperscript{1}, Ryan Stephens\textsuperscript{2}, Hong Yang\textsuperscript{1}, Jian-Min Zu\textsuperscript{1} and Qian Chen\textsuperscript{1}; \textsuperscript{1}University of Illinois at Urbana-Champaign, United States; \textsuperscript{2}Shell International Exploration and Production Inc., United States

We study the electrochemical and structural responses of nanoparticles of different sizes as cathode materials in magnesium ion batteries. By systematically varying the electrolytes, we observe a consistent solid-solution phase transition in small nanoparticles during discharge, in contrast to the mixed-phase evolution or surface reactions in big nanoparticles. Further examination by scanning electron nanobeam diffraction (SEND) in scanning transmission electron microscope (STEM) revealed the strain and phase distribution in the small nanoparticles at nanometer resolution. We observe a non-uniform, scattered phase distribution in small nanoparticles in the non-aqueous electrolyte, in contrast to the uniform one in the aqueous electrolyte. The varied phase behaviors are associated with the co-intercalation of solvent molecules in the discharge processes. Our work shows that nanoparticle size and solvent molecules have a direct influence on Mg ion insertion processes, which rationally guide the design of Mg ion batteries with high capacity and high stability.

5:25 AM *S.EN08.05.04
Calcium Intercalation in Inorganic Materials—Pondering on Application in Rechargeable Batteries Arturo Torres, Miguel Recio-Poo and M.E. Arroyo de Dompablo; Universidad Complutense de Madrid, Spain

Li-ion batteries are currently approaching its fundamental limits in terms of energy density, which in addition to the reduced supply of Li instigate the race for the development of alternative technologies exhibiting advantages in terms of energy density, safety and cost. Although rechargeable batteries based on a Ca-metal anode are attractive, the development of such batteries is intricate due to the lack of competitive cathode materials. To the date, restricted reversible electrochemical Ca intercalation has been reported for a handful of compounds (see [1] and references therein), all of them showing poor cycling capability. Parallel experimental-computational investigations establish a link between the lack of reversible electrochemical activity (experimentally observed) and a hampered Ca diffusion (computationally estimated). Hence Ca diffusion is a key parameter, for which the migration energy barriers provide an approximate indication. In this communication we analyse the calculated DFT-energy barriers for Ca migration found for a large set of Ca-transition metal compounds including oxides, sulphiodes, phosphates, nitrates, carbonates and phosphates. The possible application of Ca intercalation materials as cathode in rechargeable batteries is further discussed considering other basic electrode characteristics.

Acknowledgments: Authors are grateful for financial support from European Union H2020-FETOPEN funded project CARBAT-766617.

5:40 AM S.EN08.05.06
Insertion Type Cathodes for Calcium-Ion Batteries Shrevas Pathreker, Sophia Figueroa, Madison E. Leiman, Seth Reed, Katharine V. Stasior and Ian D. Hosein; Syracuse University, United States

Developing batteries beyond those based on Lithium is critical to the advancement of next-generation energy storage technology with lower cost and higher energy density. To this end, Calcium has been identified as a candidate material due to its Earth-abundance, reduction potential similar to that of Lithium, and divalency, which can enable the development of high-voltage and high-energy density batteries. While various Calcium based compounds have been suggested as potential cathode materials for Ca-ion batteries using DFT calculations\textsuperscript{1}, very few have been synthesized and evaluated experimentally. Here, we report the facile synthesis and evaluation of some Calcium containing transition metal oxides as potential cathode materials for Ca-based batteries. X-ray diffractions of the as-synthesized powders are in agreement with powder patterns obtained theoretically. Electrochemical de-insertion/insertion from and into the structure of the host materials was conducted in 0.5 M CaBF\textsubscript{4} in Acetonitrile electrolyte and evaluated using X-ray diffraction. Further electrochemical evaluation of these cathode materials by galvanostatic charge/discharge measurements is currently being investigated. This work provides opportunities to identify, synthesize and evaluate low-cost cathodes for next-generation Calcium batteries.
Rechargeable Aluminum Batteries Based on 2D Transition Metal Carbide (MXene) Cathodes Armin Vahid-Mohammadi1,2, Sina Shahbazmohamadi1 and Majid Beidaghi1; 1Auburn University, United States; 2University of Connecticut, United States

The market of electric vehicles (EVs) is growing fast and is expected to take over the gas-powered vehicles in the upcoming years. However, the bottleneck for the development of EVs remains to be the battery technology, where batteries with higher energy and power densities are required. Also, battery chemistries with higher safety and lower cost must be developed to enable EVs to compete with gasoline-powered cars in the price range of under $30K. Despite the significant developments made in lithium-ion (Li-ion) batteries, their flammability and high cost, as well as concerns about the availability of economically viable lithium resources have considerably increased the need for alternative battery chemistries. Rechargeable aluminum batteries with aluminum metal anode are considered as one of the most promising alternative energy storage systems to current Li-ion batteries. Aluminum is the most abundant metal in Earth’s crust, and it can potentially offer three-electron redox reactions resulting in the highest theoretical volumetric capacity of 8040 mAh cm\(^{-3}\) among all metals and a reasonably high theoretical gravimetric capacity of 2980 mAh g\(^{-1}\). Recently, we reported on the performance of two-dimensional (2D) V\(_2\)CT\(_x\) MXene as an intercalation-type cathode for rechargeable aluminum batteries delivering exceptional capacities and rate-capabilities.\(^1\) MXenes are a family of 2D transition metal carbides and nitrides that are produced by selective etching of the A layer atoms (i.e., Al) from MAX phases (i.e., V\(_2\)AlC), a large group of layered ternary carbides and nitrides. Despite the promising performances in our early work, the V\(_2\)CT\(_x\) MXene cathode showed severe capacity decay in over hundreds of cycles. In this presentation, through a combination of various structural characterizations techniques (XRD, SEM, HRTEM, and XPS) and electroanalytical analyses such as Galvanostatic Intermittent Titration Technique (GITT) and Electrochemical Impedance Spectroscopy (EIS) we provide valuable insights about the underlying reasons for the capacity loss and further shed light on the thermodynamics and kinetics of Al\(^{3+}\) intercalation into V\(_2\)CT\(_x\) MXene cathode. We further demonstrate that by designing new electrode architectures and modifying electrolyte composition, different 2D MXenes can deliver stable cyclic performance in the aluminum battery system. The 2D MXene cathodes can also be fabricated as freestanding and binder-free electrodes with exceptional volumetric capacities and long cycle life. Considering that the family of the MXenes now includes ~30 different compositions, our research guides the preparation of an entire group of cathode materials for rechargeable aluminum batteries based on these 2D materials.

High Performance Solar Flow Batteries Song Jin, Wenjie Li and Hui-Chun Fu; University of Wisconsin-Madison, United States

Due to the intermittent nature of sunlight, practical solar energy utilization systems demand both efficient solar energy conversion and inexpensive large scale energy storage. We report novel hybrid solar-charged storage devices that integrate redox flow batteries (RFBs) and regenerative semiconductor solar cells that share the same pair of redox couples. In these integrated solar flow batteries (SFBs), photoexcited carriers are collected at the semiconductor-liquid electrolyte interface and used to convert the redox couples in the RFB to charge up the battery without external electric bias; which can be discharged to generate the electricity when electric power is needed. Carefully matching high performance III-V solar cells with various high voltage organic couples and optimizing several generations of SFB device designs enabled integrated SFB device with an overall direct solar-to-output electricity efficiency (SOEE) of 14%. We have further improved the cycling performance of the SFBs by integrating robust organic redox couples and photoelectrodes. I will also describe our recent effort in achieving a record 20% SOEE SFB with at least hundreds of hours of lifetime using novel tandem devices designed with the quantitative voltage matching model. Such highly efficient and robust SFBs that can be fabricated at low cost would enable practical distributed and standalone solar energy conversion and storage systems in remote locations.

3:15 PM *S.EN09.02.07
Electrode Chemistry for Flow Systems—Elucidating the Degradation of Redoxmer Electrolytes at the Carbon-Electrolyte Interface Using Spatially-Resolved Electrochemistry Counihan J. Michael1, Dipobrato Sarbapalli1, Tylan Watkins2, Danis Andrew1, Kevin R. Zavadil2 and Joaquin Rodriguez-Lopez1; 1University of Illinois at Urbana Champaign, United States; 2Sandia National Laboratories, United States

Non-aqueous redox flow batteries (NRFBs) are attractive technologies that offer the promise of providing higher cell voltages than their aqueous counterparts. In NRFBs, redoxmers are charged and discharged through electrodes such as carbon. Interactions between the electrode structure and concentrated redoxmer solutions cause adsorption of these species, which may lead to subsequent degradation reactions and state-of-charge dependent phenomena. Likewise, the interaction of the redoxmers with highly polarized electrodes may lead to a modified chemical reactivity at the electrochemical interface. In this work, we will describe our experiments probing the chemical and electrochemical reversibility of catholyte redoxmers such as alkoxybenzene derivatives on model carbon electrodes. Using scanning electrochemical microscopy (SECM), we probe the real-time evolution of the reactivity of the redoxmer-carbon interface by measuring the local redox kinetics, film formation processes, and the generation of reactive intermediates. Chemical interactions at the interface were further probed via in-situ Raman electrochemical measurements, and the newly developed Raman-SECM approach. We will describe the reactivity of different carbon features, as well as the interactions with model redoxmers. SECM revealed a wealth of reversible and irreversible changes in the kinetics of electron transfer, including the observation of transient enhancements in electrochemical rates and slow passivation processes. Simultaneous operation of SECM and Raman also created new opportunities to probe the impact of reactive radical cations on the chemistry of the carbon host and on film-formation processes through electropolymerization. These studies help direct the design of redoxmers with increased stability at the
electrode-electrolyte interface and reveal the complex interplay of redoxmer and electrode chemistries at NRFB structures

3:45 PM *S.EN09.04.02
Flow and Redox-Based Electrochemical Water Desalination Yanbo Pan, Abdulaziz Bentalib and Zhenmeng Peng; University of Akron, United States

Desalination of seawater has emerged as an area of critical need, but remains challenging, to solve the fresh water supply problem caused by the steady growth of human population and industry. Although the previous research efforts led to development of a number of desalination methods, for instance distillation, reverse osmosis, electrolysis and capacitive deionization, their applications were largely restricted by the inherent energy efficiency and effectiveness issues. Thus, there is a demand of new methods that allow efficient and effective separation of salt ions from water.

In this talk we review recent progress of water desalination research based on battery mechanism, and report our efforts in developing flow and redox-based electrochemical systems for water desalination application. Specifically, we have prepared FePO₄-based electrode material for sodium ion removal and copper-based electrode material for chloride ion removal. An electrochemical cell composed of the two electrode materials has been demonstrated with promising desalination capacity and efficiency.

Recent Progress in Organic-Based Aqueous Flow Batteries Michael J. Aziz; Harvard University, United States

The ability to store large amounts of electrical energy is of increasing importance with the growing fraction of electricity generation from intermittent renewable sources such as wind and solar. Wide-scale utilization of flow batteries is limited by the cost of redox-active metals such as vanadium or precious metal electrocatalysts. We have developed high performance flow batteries based on the aqueous redox behavior of small organic and organometallic molecules, e.g. [1-7]. These redox active materials can be very inexpensive and exhibit rapid redox kinetics and high solubilities, potentially enabling massive electrical energy storage at greatly reduced cost. We have developed new protocols for measuring capacity fade rates, which are particularly important for establishing very low capacity fade rates, and have discovered that the capacity fade rate is determined by the molecular calendar life, which can depend on state of charge, but is independent of the number of charge-discharge cycles imposed [6]. We will report the performance of the very few chemistries with long enough calendar life for practical application in stationary storage, and on the prospects for reversing capacity fade by recomposing decomposed molecules [7].

Redoxmer is a term coined for redox active materials with tunable architectures. In nonaqueous redox flow batteries, the properties of redoxmers often dominate the cycling performance, including energy density, power, and cycle life. However, the choice of supporting electrolytes can also dramatically impact the properties of redoxmer via tuning solvating environment; therefore it is of crucial importance to build understanding of such phenomenon. In this talk, a systemically approached was adapted to probe solvating impact of 2,1,3-benzothiadiazole (BzNSN) in various supporting electrolytes. BzNSN is an energy dense anolyte molecule with a low redox potential. When cycled in flow cells, the choice of salts significantly impact the measured redox potentials and cycling life. As shown in Figure 1, when measured in electrolytes containing Li salts, BzNSN delivers increased redox potentials, implying Li+ involved interactions. Moreover, by changing cations of different sizes, such as Na+, K+, and NEt4+, the redox potential of BzNSN shift nearly 200 mV from -1.65 V for Li+ to -1.85 V for NEt4+. For an anolyte material, the lower redox potential usually leads to worse stability as it becomes thermodynamically unstable. Surprisingly, this is not the case for BzNSN in electrolytes with different cations. Despite the lower redox potential, BzNSN radical cation delivers a much longer life time (t1/2 = 90 h) in 0.5 M KTFSI acetonitrile electrolyte than in LiTFSI acetonitrile electrolyte (t1/2 = 42 h). This is the first time that we observe an anolyte redoxmer can deliver a longer life time at a lower potential, which might be a practical approach for designing high energy density flow cells. Molecular dynamic simulation was used to explain the observed results.

Organic Redox Active Solutes in Deep Eutectic Solvents for Flow Batteries
Burcu Gurkan; Case Western Reserve University, United States

The discovery of electrolytes that have low vapor pressures, wide electrochemical window and high solubility towards redox active species with an ability to undergo multiple electron transfer reactions is a challenge to realize large-scale energy storage. Deep eutectic solvents (DESs), which are eutectic mixtures of hydrogen bond donors and acceptors, are attractive electrolytes as they have good solvent strength that is also tunable along with other physical, thermal, electrochemical and transport properties. We have examined the electrochemical behavior of various organic redox active solutes, specifically methyl viologen (MV), quinones and nitroxyl radicals, in a common DES known as ethaline; a 1 to 2 molar mixture of choline chloride and ethylene glycol. While the reactivity of most quinones investigated are found to fall outside of the
electrochemical window of ethaline, nitroxy radicals and MV provide reversible redox couples that are practical. In particular, TEMPO ((2,2,6,6-tetramethylpiperidin-1-yl)oxyl) demonstrates two single electron transfer reactions separated by 1.3 V in ethaline. However, the solubility of TEMPO in ethaline is found to be limited to 0.17 M at room temperature. The hydrogen bonding achieved by –OH substitution on TEMPO and electrostatic interactions achieved by the functionalization of halide salts with TEMPO are shown to improve solubility in ethaline close to 2 M. This study illustrates that chemical modification of redox active organic molecules impacts both their solubility in a DES electrolyte, as well as their redox performance and physical properties of the solutions.

Electrolyte Flow in Vanadium Redox Flow Battery Electrodes—A Synchrotron Imaging Study Roswitha Zeis; Karlsruhe Institute of Technology, Germany

Two major limitations of Vanadium Redox Flow Batteries (VRFBs) are (1) the transport losses of getting the electrolyte into the electrode and to the reaction sites with minimum resistance, and (2) Lack of access to all reaction sites due to relatively low saturation levels of the electrolyte [1,2]. Although the porous carbon electrodes have a high porosity, a large pressure may be required to pump the electrolyte through the electrode during operation. The flow-through porous carbon electrode can be further hampered due to the presence of hydrogen bubbles, which are formed as a parasitic side product of the V^{3+} reduction reaction at the anode in VRFBs [3]. This affects the efficiency and stability of the VRFB cells. Besides mixed potentials, the Hydrogen bubbles could also damage the pore structure of the electrode and create inaccessible surface area where otherwise the reaction would occur. To investigate the formation of gas bubbles inside the small pores of the carbon electrode, we carried out an experiment based on a novel beamline half-cell measurement setup.

During the experiment the electrolyte was injected into the cell using a peristaltic pump. Radiography was conducted during the injection process to track the flow of the electrolyte through the electrode. Simultaneously, pressure drop was measured to characterize the transport process and identify the breakthrough of the electrolyte on the opposite side of the electrode. The setup also allows us to evaluate various types of carbon electrodes such as felts, woven or paper style materials. Flow-by and flow-through geometries and manifolds can be exchanged to study their impact on the flow dynamics. These measurements help us develop theoretical models for a better understanding of the multiphase and interfacial flow phenomena within the porous electrode. These experiments are essential for the evaluation and optimization of electrode materials and manifolds currently being used in VRFBs.

PBI Based Membranes for Redox Flow Batteries Dirk Henkensmeier1,2,3; 1Korea Institute of Science and Technology, Korea (the Republic of); 2University of Science and Technology, Korea (the Republic of); 3Korea University, Korea (the Republic of)

Membranes need to balance a low resistance and a low crossover of redox-active species, and they have to be chemically stable in the electrolyte. For vanadium redox flow batteries, this implies stability against sulphuric acid and stability against VO_{2+} ions. For many years, the latter criteria strongly limited the choice of membrane materials, and perfluorinated Nafion membranes became the state of the art.[1]

A very recent development is the use of polybenzimidazole membranes, which do not conduct ions in the pure form, but become proton conductive in contact with the sulfuric acid containing electrolyte. The positive charge on the protonated polymer backbone and the narrow size of the electrolyte filled voids between the polymer chains successfully repels...
vanadium ions in ex-situ permeability measurements. Most interestingly, we observed that both voltage efficiency and coulomb efficiency increase when the membrane thickness decreases. This probably is related to the average charging potential, which increases with the membrane thickness and thus a) increases migration in the electric field, providing some vanadium ions with the energy to pass the energy barrier which hinders them from entering the membrane, and b) possibly enhances side reactions. This result suggests that cells with thin PBI films would be very efficient in terms of both voltage and coulomb efficiency; the thinner, the better [2].

Building up on this finding, we prepared porous Nafion membranes coated with a thin PBI layer [3] and porous PVDF membranes coated with a thin PBI layer [4].

Another way to improve the voltage efficiency of PBI membranes is to blend them with anion exchange ionomers [5, 6].

The very low permeability for metal ions of PBI membranes also enables the operation of iron-vanadium flow batteries (Fe-VRFB), reducing the costs of the electrolyte and increasing the upper temperature limit [7].

By alkylation PBI membranes, a permanent charge can be fixed on the PBI backbone, turning the membranes into anion exchange membranes with a high IEC [8]. While the alkyl groups may be a starting point for degradation by VO$_2^+$, this type of anion exchange membranes can be used well in aqueous organic flow batteries [9].

Hetero-Atom Functionalised Quinoidal Electrolytes for Redox Flow Batteries Rajesh B. Jethwa 1, Evan Wenbo Zhao 1, 2, Rachel Kerber 1, Erlendur Jónsson 1, 3, Dominic Wright 1 and Clare Grey 1; 1University of Cambridge, United Kingdom; 2Chalmers University of Technology, Sweden

Redox flow batteries are quickly developing as a potential solution for current grid-level electrochemical energy storage concerns where high cycle number durability, long calendar life, high efficiency, low cost and fast response times are required. However, currently low energy density and high capital costs limit the industrial implementation of such systems. It should come as no surprise therefore that electrolytes are a topic of active research, with a view to increasing the energy density while reducing the cost. Increasing energy density can be achieved in various ways: expanding the voltage window or by minimising the mass and/or volume per electron transferred. These strategies correspondingly open up various avenues through which novel electrolytes can be explored. Previous examples of electrolytes for flow batteries have included a variety of metal-based systems and a range of organic molecules. Of these, quinones are a common electroactive class of organic molecules that have been investigated due to their fast kinetics, high tunability and low cost. In the current work, benzoquinone derivatives were synthesised and investigated as potential anolytes for redox flow batteries. Benzoquinone has a higher aqueous solubility and a lower molecular weight than anthraquinone, but it is more prone to electrochemical degradation. The derivatised quinones explored in this work are anticipated to benefit, in comparison to previous anthraquinones, from a higher energy density through greater solubility, and a lower cost. Electrochemical screening was carried out using cyclic voltammetry as an initial test of redox properties and stability. Selected molecules that exhibited favourable behaviour were then run in a lab-scale full cell and through the aid of in situ NMR and EPR spectroscopy, the behaviour of the species under cycling conditions was investigated. Density functional theory modelling was used to complement the analysis. The current investigation has shown promising results towards the possibility for new routes towards functionalisation and stabilisation of such organic systems.

5:40 AM S.EN09.01.06

*In Situ* NMR Metrology Reveals Reaction Mechanisms and Electron Transfer Rates in a Flow Battery **Evan Wenbo Zhao**, Tao Liu, Erlendur Jónsson, Jeongjae Lee, Israel Temprano, Anqi Wang, Holly Smith, Javier Carretero González, Qilei Song and Clare Grey; 1University of Cambridge, United Kingdom; 2Tongji University, China; 3Chalmers University of Technology, Sweden; 4Seoul National University, Korea (the Republic of); 5Imperial College London, United Kingdom; 6ICTP-CSIC, Spain

We report two *in situ* NMR methods to study flow batteries. While flow batteries are low-cost and environmentally benign large-scale energy storage devices, an increased understanding of the battery chemistry is required to improve their energy densities, lifetimes and to reduce cost. Demonstrating the approach on two separate anthraquinones, 2,6-dihydroxyanthraquinone, DHAQ and 4,4’-((9,10-anthraquinone-2,6-diyl) dioxy) dibutyrate, DBEAQ as redox-active electrolytes, we confirm that the reduction reactions occur via a two-step, one-electron redox process coupled with a comproportionation reaction. Using the bulk magnetisation changes, observed via the 1H NMR shift of the water resonance, we determine the potential differences of the two one-electron couples. Electron transfer between radical and the diamagnetic anions is observed and is quantified via the linebroadening of the resonances of the diamagnetic anions. This linebroadening and shifting of the resonance – coupled with EPR measurements - provide direct evidence for the degree of electron delocalization of unpaired spin over the radical anions. Electrolyte decomposition and battery self-discharge is explored in real time, the results indicating that DHAQ decomposition is an electrochemical reaction which can be minimized by limiting the voltage used on charging. Applications of the new NMR metrologies to understand a wide range of redox processes in flow and other battery systems is readily foreseen.

5:50 AM S.EN09.01.07

Micellization-Enabled Ultrastability and Crossover Suppression in Aqueous RFB **Jianbing J. Jiang**, Jingchao Chai, Xiao Wang and Caroline Williams; University of Cincinnati, United States

Redox flow batteries (RFBs) are a highly promising large-scale energy storage technology for mitigating the problematic intermittency of renewable energy sources such as solar and wind. Organic redox species in aqueous RFBs have attracted substantial attention due to their facile synthesis, structural diversity, and low cost. Here, our group present the design and implementation of a micellization strategy in a pH-neutral, nontoxic, metal-free, aqueous RFB. The PEGylated micelle is constructed in an aqueous KCl solution as the anolyte. The micellization strategy (1) improves stability by protecting the redox-active molecules with the hydrophilic PEG tail to suppress parasitic reactions; and (2) increases the overall size to a mean hydrodynamic radius of 500 nm to mitigate the crossover issue via the physical blocking mechanism. Paired with a well-established potassium ferrocyanide catholyte, the micelle-based RFB in a pH-neutral aqueous electrolyte solution displayed an excellent capacity retention of 90.7% after 3600 charge/discharge cycles (28.3 days), corresponding to a capacity retention of 99.67% per day and 99.998% per cycle. Mechanistic studies of redox-active materials are also conducted during and after the cycling by proton nuclear resonance spectroscopy and cyclic voltammetry and indicate the absence of side reactions that are commonly observed in other RFBs. This work represents the longest consecutive running time and the highest charge/discharge cycles among the reported organic material-based aqueous RFBs. The outstanding performance of our RFB demonstrates the effectiveness of the micellization strategy for enhancing the performance of organic material-based aqueous RFBs.

6:00 AM *S.EN09.01.08*

Recent Progress in Organic-Based Aqueous Flow Batteries **Michael J. Aziz**; Harvard University, United States

The ability to store large amounts of electrical energy is of increasing importance with the growing fraction of electricity
generation from intermittent renewable sources such as wind and solar. Wide-scale utilization of flow batteries is limited by the cost of redox-active metals such as vanadium or precious metal electrocatalysts. We have developed high performance flow batteries based on the aqueous redox behavior of small organic and organometallic molecules, e.g. [1-7]. These redox active materials can be very inexpensive and exhibit rapid redox kinetics and high solubilities, potentially enabling massive electrical energy storage at greatly reduced cost. We have developed new protocols for measuring capacity fade rates, which are particularly important for establishing very low capacity fade rates, and have discovered that the capacity fade rate is determined by the molecular calendar life, which can depend on state of charge, but is independent of the number of charge-discharge cycles imposed [6]. We will report the performance of the very few chemistries with long enough calendar life for practical application in stationary storage, and on the prospects for reversing capacity fade by recomposing decomposed molecules [7].

Aqueous Organic Redox Flow Batteries for Energy Storage Bo Hu, Jian Luo and Tianbiao L. Liu; Utah State University, United States

Electrification of modern society including portable devices, electrical vehicles, and grid-scale storage has driven intensive research development of inexpensive, safe, long-cycling life, high performance energy storage technologies. The presentation will primarily discuss our recent research efforts in developing viologen and quinone anolyte materials for both anion and cation exchange Aqueous Organic Redox Flow Batteries (AORFBs) with a variety of catholyte materials including ferrocene, TEMPO, ferrocyanide and halides. Particularly, the presentation emphasizes that fundamental understandings of redox active electrolytes at molecular level are crucial to develop new generations of redox flow and Mg batteries for sustainable energy storage.

6:30 AM *S.EN09.01.11
High Performance Solar Flow Batteries Song Jin, Wenjie Li and Hui-Chun Fu; University of Wisconsin-Madison, United States

Due to the intermittent nature of sunlight, practical solar energy utilization systems demand both efficient solar energy conversion and inexpensive large scale energy storage. We report novel hybrid solar-charged storage devices that integrate redox flow batteries (RFBs) and regenerative semiconductor solar cells that share the same pair of redox couples. In these integrated solar flow batteries (SFBs), photoexcited carriers are collected at the semiconductor-liquid electrolyte interface and
used to convert the redox couples in the RFB to charge up the battery without external electric bias; which can be discharged to generate the electricity when electricity is needed. Carefully matching high performance III-V solar cells with various high voltage organic couples and optimizing several generations of SFB device designs enabled integrated SFB device with an overall direct solar-to-output electricity efficiency (SOEE) of 14%. We have further improved the cycling performance of the SFBs by integrating robust organic redox couples and photodelectrodes. I will also describe our recent effort in achieving a record 20% SOEE SFB with at least hundreds of hours of lifetime using novel tandem devices designed with the quantitative voltage matching model. Such highly efficient and robust SFBs that can be fabricated at low cost would enable practical distributed and standalone solar energy conversion and storage systems in remote locations.

Redox-Mediated Electrochemical Energy Conversion and Storage Qing Wang; National University of Singapore, Singapore

Redox reaction involving charge transfer at the electrode-electrolyte interface represents an essential process for various electrochemical energy conversion and storage applications, such as fuel cell, electrolyzer and battery, etc. As a result, the
operation (i.e. cell voltage, current density, number of charges, etc.) of the above devices is inherently dictated and constrained by the redox reactions. The redox-mediated process, a chemical reaction between an electrolyte-borne redox species electrochemically generated on electrode and a material (generally insoluble in electrolyte) off the electrode, provides additional flexibility in circumventing the constraints intrinsically confronted by the conventional electrochemical devices. One example is the redox targeting of energy storage materials for flow batteries. The redox-mediated reactions of high capacity solid material stored in the tank with redox electrolyte flowing through it considerably boost the energy density of redox flow battery without compromising its operation flexibility. Another example is redox-mediated oxygen evolution reaction (OER) for water electrolysis. The concurrent electrochemical-chemical cycle enables continuous reaction between an electrolyte-borne redox mediator and an OER catalyst loaded in a fixed-bed reactor spatially separated from the cell, which is believed to be advantageous to enhanced safety.

In this talk, I will report our latest advancement in the above area. In addition, I will briefly introduce some other studies on redox-mediated reactions, such as low-grade waste heat harnessing based on a thermal-electrochemical cycle and battery material recycling based on a one-way redox targeting reaction.

Low-Cost and High-Energy Redox Flow Batteries Achieved by Metal-Based Deep Eutectic Solvents Leyuan Zhang and Guihua Yu; The University of Texas at Austin, United States

Given the advantages of low cost, high concentration and potential biodegradability, the concept of deep eutectic solvents (DESs) is beneficial to developing cost-effective and sustainable batteries with high-energy density. In this talk, we will present our recent study on the Al- and Fe-based DESs as potential anolytes and catholytes, respectively, for hybrid redox flow batteries. Benefitted from special interactions between metal chlorides and urea, both Al and Fe DESs have high concentrations of active species, showing great potential to boost the energy density. Moreover, through investigating the redox chemistry and coordination chemistry of metal centers with possible additives, the stable deposition and stripping of Al and long cycling of Fe DES with high utilization are achieved. An all-DES-based hybrid flow battery taking advantages of the Al DES and Fe DES has been demonstrated with high performance. As the chemical and physical properties of DESs can be tuned by appropriate additives, it provides a new platform for developing promising redox flow batteries based on new chemistry.

5:55 AM *S.EN09.02.07
Electrode Chemistry for Flow Systems—Elucidating the Degradation of Redoxmer Electrolytes at the Carbon-Electrolyte Interface Using Spatially-Resolved Electrochemistry Counihan J. Michael1, Dipobrato Sarbapalli1, Tylan Watkins2, Danis Andrew1, Kevin R. Zavadić2 and Joaquin Rodriguez-Lopez1; 1University of Illinois at Urbana Champaign, United States; 2Sandia National Laboratories, United States

Non-aqueous redox flow batteries (NRFBs) are attractive technologies that offer the promise of providing higher cell voltages than their aqueous counterparts. In NRFBs, redoxmers are charged and discharged through electrodes such as carbon. Interactions between the electrode structure and concentrated redoxmer solutions cause adsorption of these species, which may lead to subsequent degradation reactions and state-of-charge dependent phenomena. Likewise, the interaction of the redoxmers with highly polarized electrodes may lead to a modified chemical reactivity at the electrochemical interface. In this work, we will describe our experiments probing the chemical and electrochemical reversibility of catholyte redoxmers such as alkoxybenzene derivatives on model carbon electrodes. Using scanning electrochemical microscopy (SECM), we probe the real-time evolution of the reactivity of the redoxmer-carbon interface by measuring the local redox kinetics, film formation processes, and the generation of reactive intermediates. Chemical interactions at the interface were further probed via in-situ Raman electrochemical measurements, and the newly developed Raman-SECM approach. We will describe the reactivity of different carbon features, as well as the interactions with model redoxmers. SECM revealed a wealth of
reversible and irreversible changes in the kinetics of electron transfer, including the observation of transient enhancements in electrochemical rates and slow passivation processes. Simultaneous operation of SECM and Raman also created new opportunities to probe the impact of reactive radical cations on the chemistry of the carbon host and on film-formation processes through electropolymerization. These studies help direct the design of redoxmers with increased stability at the electrode-electrolyte interface and reveal the complex interplay of redoxmer and electrode chemistries at NRFB structures.

6:10 AM *S.EN09.02.09
Organic Redox Active Solutes in Deep Eutectic Solvents for Flow Batteries Burcu Gurkan; Case Western Reserve University, United States

The discovery of electrolytes that have low vapor pressures, wide electrochemical window and high solubility towards redox active species with an ability to undergo multiple electron transfer reactions is a challenge to realize large-scale energy storage. Deep eutectic solvents (DESs), which are eutectic mixtures of hydrogen bond donors and acceptors, are attractive electrolytes as they have good solvent strength that is also tunable along with other physical, thermal, electrochemical and transport properties. We have examined the electrochemical behavior of various organic redox active solutes, specifically methyl viologen (MV), quinones and nitroxy radicals, in a common DES known as ethaline; a 1 to 2 molar mixture of choline chloride and ethylene glycol. While the reactivity of most quinones investigated are found to fall outside of the electrochemical window of ethaline, nitroxy radicals and MV provide reversible redox couples that are practical. In particular, TEMPO ((2,2,6,6-tetramethylpiperidin-1-yl)oxyl) demonstrates two single electron transfer reactions separated by 1.3 V in ethaline. However, the solubility of TEMPO in ethaline is found to be limited to 0.17 M at room temperature. The hydrogen bonding achieved by –OH substitution on TEMPO and electrostatic interactions achieved by the functionalization of halide salts with TEMPO are shown to improve solubility in ethaline close to 2 M. This study illustrates that chemical modification of redox active organic molecules impacts both their solubility in a DES electrolyte, as well as their redox performance and physical properties of the solutions.

Enhanced Voltage Generation through Electrolyte Flow on Liquid-Filled Surfaces Prab Bandaru and Bei Fan; University of California, San Diego, United States

The generation of electrical voltage through the flow of an electrolyte over a charged surface may be used for energy transduction. Here, we show that enhanced electrical potential differences (i.e., streaming potential) may be obtained through the flow of salt water on liquid-filled surfaces that are infiltrated with a lower dielectric constant liquid, such as oil, to harness electrolyte slip and associated surface charge. A record-high figure of merit, in terms of the voltage generated per unit applied pressure, of 0.04 mV/Pa is obtained through the use of the liquid-filled surfaces. In comparison with air-filled surfaces (AFS), the figure of merit associated with the liquid-filled surface (LFS) increases by a factor of 1.4. These results lay the basis for innovative surface charge engineering methodology for the study of electrokinetic phenomena at the microscale, with possible application in new electrical power sources.

Our work has experimentally demonstrated the largest figure of merit thus far, to the best of our knowledge, with primary focus on methodologies related to enhance the streaming potential \( V_s \) per unit pressure difference \( \Delta P \) through the use of LFS. The use of the LFS yields a figure of merit increase in comparison to that obtained using an AFS. It has been shown that larger voltages, through a measured streaming potential, may be achieved through careful engineering of the coupled electric field and fluid flow. The application of the related increase in the electrokinetic energy conversion efficiency would need further optimization of the fluidic and electrical impedances, in concert with the streaming conductance, as matched to an appropriate load. Concomitantly, unipolar transport (where for example, either Na\(^+\) or Cl\(^-\) ions are transported) through EDL (electrical double layer) overlap in nanoscale channels may be coupled with LFS to yield much larger voltages, comparable to that of batteries.
Generation and Modulation of the Streaming Potential and Slip Characteristics in Electrolyte Flow over Liquid-Filled Surfaces Prab Bandaru and Bei Fan; University of California, San Diego, United States

The generation of electrical voltage through the flow of an electrolyte over a charged surface may be used for energy transduction. A significant enhancement in the streaming potential ($V_s$) was obtained in experiments considering the flow of electrolyte over liquid-filled surfaces (LFSs), where the grooves in patterned substrates are filled with electrolyte immiscible oils. Such LFSs yield larger $V_s$ (by a factor of 1.5) compared to superhydrophobic surfaces, with air-filled grooves, and offer tunability of electrokinetic flow. It is shown that the density, viscosity, conductivity, as well as the dielectric constant of the filling oil, in the LFS, determine $V_s$. Relating a hydrodynamic slip length to the obtained $V_s$ offers insight into flow characteristics, as modulated by the liquid interfaces in the LFS.

5:20 AM S.EN09.03.10
Enhanced Solar Thermal Evaporation of Ethanol–Water Mixtures, through the Use of Porous Media Prab Bandaru and Fatih Canbazoglu; University of California, San Diego, United States

A significant enhancement of solar irradiation induced evaporation of water, and ethanol–water mixtures, through the use of carbon foam based porous media, is demonstrated. A relationship between the consequent rate of mass loss, with respect to the equilibrium vapor pressure, dynamic viscosity, surface tension, and density, was developed to explain experimental observations. The evaporative heat loss was parametrized through two convective heat transfer coefficients—one related to the surface and another related to the vapor external to the surface. The work promotes a better understanding of thermal processes in binary liquid mixtures with applications ranging from phase separation to distillation and desalination.

Flow and Redox-Based Electrochemical Water Desalination Yanbo Pan, Abdulaziz Bentalib and Zhenmeng Peng; University of Akron, United States

Desalination of seawater has emerged as an area of critical need, but remains challenging, to solve the fresh water supply problem caused by the steady growth of human population and industry. Although the previous research efforts led to development of a number of desalination methods, for instance distillation, reverse osmosis, electrodialysis and capacitive deionization, their applications were largely restricted by the inherent energy efficiency and effectiveness issues. Thus, there is a demand of new methods that allow efficient and effective separation of salt ions from water. In this talk we review recent progress of water desalination research based on battery mechanism, and report our efforts in developing flow and redox-based electrochemical systems for water desalination application. Specifically, we have prepared FePO4-based electrode material for sodium ion removal and copper-based electrode material for chloride ion removal. An electrochemical cell composing of the two electrode materials has been demonstrated with promising desalination capacity and efficiency.

5:15 AM S.EN09.04.05
Cascade CO2 Electroreduction to Selective C-C Coupled Products in a Flow Cell Junrui Li1,2, Linh Chung2, Gurudayal Gurudayal1,2, David Larson1, Wee-Jun Ong3,1 and Joel W. Ager1,2,1; 1Lawrence Berkeley National Laboratory, United States; 2University of California, Berkeley, United States; 3Xiamen University Malaysia, Malaysia

Electrochemical conversion of CO2 into useful products with good efficiency and high selectivity presents challenges due to the distinctive bonding strengths of the various intermediates and products. Reducing CO2 into C-C coupled products, such as ethylene, ethanol and other hydrocarbons or oxygenates with 2 or more carbon atoms, is particularly interesting technically and scientifically. However, because of the so-called “scaling relationship”, tuning the selectivity on a single catalyst surface is rather difficult as the intermediates leading to specific products have similar binding energies. Cascade catalysis breaks this scaling relationship by separating the catalysis processes into two or more steps on different catalyst surfaces with transport of the intermediates between them.
Here, we report a flow cell with a cascade configuration of two closely spaced working electrodes (Ag and Cu) for electrochemical reduction of CO2 into C-C coupled products. The Ag electrode is located upstream in the reactor to convert CO2 into CO, and CO is convectively transported to the downstream Cu electrode for further C-C coupling catalytic reactions. The porous Ag and Cu working electrodes are separately controlled by two different potentiostat channels allowing for precise control of the conversion rates in the cascade. The porosity of the metal electrodes was controlled by precision laser drilling. A COMSOL model was developed using preliminary experimental data to tune the cell design and operating conditions, such as the flow rate of electrolyte and optimal pore size of the working electrodes. When both Ag and Cu electrodes are activated, CO is generated at Ag and is transported to Cu, leading to a significant increase in generated C2-C3 oxygenates compared to control experiments with only the Cu activated. The flow cell configuration can also be extended to other working electrodes by using carbon cloth as a supporting substrate and depositing powder catalysts.

Towards TEM Observation of Ion-Current Induced Nanoprecipitation Kyle Sendgikoski1, Alokik Kanwal2, James A. Liddle2, Zuzanna Siwy3 and John Cumings1; 1University of Maryland, United States; 2National Institute of Standards and Technology, United States; 3University of California, Irvine, United States

Lime scaling, the precipitation of calcium salts, is a major hindrance encountered in desalination processes. Recently1, nanopore precipitation has been shown to cause oscillation of ion-current through nanopore membranes, a similar model system. Unfortunately, due to the geometry of the pore, direct observation of the precipitates is not possible, so the exact structure is unknown. We report on progress towards direct observation measurements, with transmission electron microscopy (TEM), of the nanoprecipitation that causes ion current oscillations. We have engineered a novel, monolithic in-situ TEM liquid cell that overcomes common shortcomings of other two-piece TEM liquid cells such as liquid thickness and alignment. The customizable geometry and reproducibility of this TEM liquid cell enables investigation of various chemistries and confinement physics.

Self-Assembling Effects of NiFe Hydroxide on 3D Nano-Morphology and Enhanced Oxygen Evolution Performance Li Ren, Jiaqi Wang, Fangfei Li, Yang Yang, Jingru Liu, Kuizhou Dou and Yongqiang Yu; Jilin University, China

Layered double hydroxide (LDH) has been proven to have excellent performance in water splitting reactions, especially toward the oxygen evolution reaction (OER). The morphology of NiFe LDH is one of the key factors in improving its electrochemical performance. However, the controlling factors and mechanisms of morphological evolution of the nanoflower-shaped NiFe LDH remain poorly understood. In this study, NiFe LDH nanoflowers were synthesized by hydrothermal method, and the morphology and structure of NiFe LDH crystals are carefully controlled during the synthetic stage. The results indicate that NiFe LDH primary nano flakes rapidly agglomerate to form a nucleus matrix at the initial stage. Subsequently, these nano flakes are laterally aggregated and connected orderly on the substrate to form nanoflowers, and the nano-petals are generated by a rotating and edge-to-edge orientation attachment (OA) mechanism. The morphological evolution occurred by staged three-dimensional OA process plays an essential role in the self-assembly of flower-like NiFe LDH crystals. The well-formed NiFe LHD nanoflowers, grown by 10 hours of hydrothermal treatment, exhibits excellent OER performance in alkaline electrolyte, which displays very low overpotential of 190 mV at the current density of 10 mA cm-2 and small Tafel slope of 35 mV per decade (much better than RuO2 catalyst). Furthermore, the prepared NiFe LDH still showed high stability after 10,000 cycles of cyclic voltammetry tests. This work provides new insights into the relationship between catalyst morphology and OER performance, and provides new fundamental understanding of hydrothermal synthetic process of NiFe LDH.
First- Principles Modeling of Galvanic Corrosion Behavior of Metal Alloys

Yaowei Wang, Tian Xie, Zhe Luo, Hong Zhu and Xiaoqin Zeng; Shanghai Jiao Tong University, China

Some emerging alloys, such as Mg alloy, are susceptible to galvanic corrosion, consequently accelerating corrosion process and resulting in severe financial loss. The galvanic corrosion potential and current obtained by experimental polarization curves could differ a lot between different literature. Herein, we proposed a semi-empirical model based on the mixed potential theory and first principles calculation to analyze the galvanic corrosion of the metal alloys. Our model is further validated in the case of Mg-Ge alloys, which is composed of anode Mg matrix and cathode Mg2Ge second phase. The combination of the large anode equilibrium potential difference between Mg and Mg2Ge, and the Schottky barrier across the interface indicates that the Mg2Ge second phase can prevent the Mg grain from serving as the cathode and impede the electron transfer between the Mg grains. First principles calculations on the kinetics of hydrogen evolution reaction upon Mg2Ge reveal that the rate-determining step is the hydrogen adsorption, which is extremely energetically unfavored but an inevitable intermediate state. The estimated exchange current of the hydrogen evolution upon Mg2Ge is about 3 orders of magnitude smaller than that on pure Mg, depressing the hydrogen exchange current upon Mg2Ge and hence the galvanic corrosion of the Mg-Ge alloys. Moreover, some other Mg alloys, such as Mg-Zn and Mg-Sc, were also investigated, which is in close agreement with the experimental observations. Our model is capable of predicting the galvanic corrosion behavior and provide a promising perspective for designing better corrosion-resistant metal alloys.
technologies offer versatile options. This presentation will provide an overview of the U.S. Department of Energy’s Hydrogen and Fuel Cell Technologies Office’s early-stage R&D activities in hydrogen production and storage and fuel cell technologies within the Office of Energy Efficiency and Renewable Energy. The presentation will focus on their relevance to the evolving energy storage needs of a modernized grid, and discuss R&D needs and challenges. Specific examples of advanced materials research relevant to address energy storage challenges will be provided. The presentation will also cover DOE’s H2@Scale initiative which will enable innovations to generate cost-competitive hydrogen as an energy carrier, coupling renewables, as well as nuclear, fossil fuels, and the grid, to enhance the economics of both baseload power plants and intermittent solar and wind, enhancing resiliency and avoiding curtailment.

Multiscale Modeling of Materials Interfaces for Hydrogen Storage, Generation and Delivery Brandon Wood; Lawrence Livermore National Laboratory, United States

Developing viable solutions for the efficient production and storage of hydrogen requires understanding chemical process occurring at solid-gas, solid-liquid, and solid-solid interfaces in advanced materials. Probing behavior of these interfaces under operating conditions presents significant challenges; however, predictive modeling offers an opportunity for providing key insights into interface chemistry, particularly when operating in tandem with high-fidelity experimental characterization techniques. Within the DOE Hydrogen Materials—Advanced Research Consortium (HyMARC) and the HydroGEN Advanced Water Splitting Materials Consortium, we are using multiscale models to understand properties of reactive interfaces for the production, storage, and delivery of hydrogen. I will provide an overview of our materials modeling strategy within these consortia, ranging from first-principles calculations of interface chemistry to continuum methods for microstructure-level properties. I will then review some of our recent activities for simulating thermodynamic and kinetic properties of hydrogen-related materials. Specific examples will be given of how these computational models have helped to elucidate mechanisms of interface chemical reactions, the formation of new phases, and the impact of solid-state interfaces on key reaction pathways. I will also show how simulations have been combined with experimental probes to improve models and obtain new understanding of materials interfaces under operating conditions. Finally, I will discuss how this understanding is being used to guide new strategies for improving materials functionality for storage, generation, and delivery of hydrogen. This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

5:51 PM *S.EN11.06.02
Techno-Economic Analysis of Hydrogen Transmission and Distribution Aikaterini Anastasopoulou and Hanna Breunig; Lawrence Berkeley National Laboratory, United States

As more nations make long-term commitments to clean infrastructure, it is critical that we better understand technologies that act at the interface of traditionally decoupled systems. Hydrogen (H2) will likely lie at the interface of energy storage, transportation, and industry. Here, we use ex-ante techno-economic analysis to characterize pathways for H2 delivery. We evaluate the impact of different process system parameters on the levelized H2 delivery cost ($/kg H2), and identify barriers and opportunities for achieving industrial competitiveness. Three carrier market applications are studied: transmission, which we define as long-distance delivery from a large H2 source to an end use; distribution, which we define as short-distance delivery from a city-gate to fueling stations within the city; and transmission-distribution, which we define as long distance delivery from a large H2 source all the way to fueling stations. For each of these market applications, we evaluate the energy intensity and other key system level performance metrics for high pressure (350 and 500 bar) truck transportation, cryogenic liquid H2 truck transportation, and carrier-based truck transportation. Ancillary equipment and operation conditions, including systems at the H2 source and refueling station which are unique to adsorption systems are included in the analysis.

For a base transmission application, where 50 Mg H2/day is delivered 100 km from a gas terminal to an end point application, the delivery cost is approximately $1.6/kg H2 and $1.8/kg H2 for 500 bar and 350 bar trucks, respectively. Liquid H2 transport is less competitive at this short distance, and costs $3.1/kg H2. A truck packed with metal organic framework (MOF) Ni2(m-dobdc) and modeled at 100 bar and 200K has a delivery cost of $7.7/kg H2. Transmission costs for the MOF-H2 system can reach as low as $1.8/kg H2 (on par with 350 bar trucks) in a scenario where driverless trucks are employed, a highly durable material is developed (15,000 cycles), material costs are $10/kg MOF, and where bed porosity and pellet porosity are substantially lower (or rather increasing H2 uptake without increasing upstream cooling requirements).

For the distribution application, the delivery cost is dominated by the CAPEX and OPEX of the refueling stations. For a base scenario where 50 Mg H2/day is delivered 1 km from a city-gate gas terminal to distributed fueling stations, the delivery cost...
is between $3.4/kg H2 and $4.6/kg H2 for 500 bar and 350 bar trucks, respectively, and $5.3/kg H2 for liquid H2 transport. Liquid trucks for distribution perform better in larger markets (40% lower costs for a 120 Mg/day market). The MOF-H2 systems studied performs poorly in this market application (above $20/kg H2) as 10x more fueling stations and trucks are required to meet the same daily H2 demand as compared to the liquid or high pressure systems.

These results demonstrate capabilities of the hydrogen delivery models developed at the Lawrence Berkeley National Laboratory for the Department of Energy HyMARC program. Any path to substantial greenhouse gas emissions (GHG) reduction will include market transformations in the transportation sector, as it remains the single largest primary source of GHGs in the United States and the third largest primary source globally. Advances in carrier materials such as liquid organic hydrogen carriers (LOHC) and MOFs, which exhibit a wide range of tunability for hydrogen storage, could radically change the way hydrogen is stored and transported globally to meet fuel demand in zero direct emission vehicles. In this research work, we present a framework for characterizing and benchmarking the performance of emerging carrier systems.

Alkylphosphine as a Ligand for Shape-Controlled Synthesis of Metal Nanostructures Shutang Chen and Gugang Chen; Honda Research Institute USA Inc., United States

Metal nanoparticles with high index facets and controllable shape have demonstrated excellent catalytic performance because of their unique surface chemistry. Generally, the selection of proper ligand plays an important role for the shape-control of nanoparticles. Here, different kinds of alkylphosphines with high temperature solution reduction method are adopted to synthesize metal nanostructures. With increasing chain length of alkylphosphines, different morphologies of copper nanoparticles were synthesized in a hydrophobic system, such as nanocubes, tetrahedron nanoparticles, nanowires, and nanosheets. All these copper nanostructures demonstrated excellent catalytic performance and selectivity to carbon dioxide reduction reaction. Such simple strategy is also extended to the design of other metal nanoparticles for their potential applications in catalysis, sensor, and electronics.
Refractory Multi-Principal-Element Alloys as Novel Solid-State Hydrogen Stores Claudia Zlotea and Jorge Montero; ICMPE CNRS, France

Among various materials for hydrogen storage, alloys and intermetallics forming hydrides are one of the most important classes due to their high volume density, reversibility and safety. Within the class of conventional metals and alloys for hydrogen storage, the body centered cubic (bcc) alloys based on early 3d transition elements (Ti, V, Cr...) represent one of the most promising class due to their high hydrogen storage capacity up to 2 Hydrogen per metal atoms (H/M). These alloys show two plateaus at low and ambient pressure in the Pressure-Composition-Isotherms. But, for practical applications only the second plateau is available reducing the reversible quantity of hydrogen that could be stored. Consequently, new metallurgical concepts and materials are stringently required to develop more efficient multifunctional hydrides. Recently, a new paradigm of alloying strategy has emerged based on the original concept of multi-principal-element alloys (MPEAs), initially proposed to develop materials with enhanced mechanical properties. The principle is laid on the mixing of elements close to the equimolar proportion for systems up to five and more containing elements. This mixing may lead to the formation of simple single-phased solid solutions (body centered cubic-bcc, face centered cubic-fcc and hexagonal close packed-hcp). The formation and the stability of such phases are still under consideration and seem to be based on several chemical and physical quantities such as, configurational entropy, mixing enthalpy, atomic misfit, valence electron concentration. Among MPEAs, alloys with at least five principal elements with atomic concentrations in the range 5 to 35 % are called high entropy alloys (HEAs). Most of reports concerning these alloys describe their structure, microstructure and mechanical properties, whereas functional properties such as, hydrogen sorption, are only scarcely investigated. We present here the study of hydrogen absorption properties of MPEAs based on refractory metals. The TiVZrNb alloy also crystallizes in a bcc phase but undergoes a two-stage hydrogen absorption reaction to a fcc dihydride phase with an intermediate tetragonal monohydride at high temperature. We suggest that the lattice distortion, δ, as defined for MPEAs, might play an important role: larger δ would favor a single-step reaction with hydrogen (bcc → bct hydride with large hydrogen content), whereas small δ would favor a two-steps phase transition (bcc → bct → fcc), as also encountered for conventional bcc alloys. The most promising alloy is the TiVZrNb composition which, despite a fading of the capacity for the first cycles, shows a stable reversible capacity around 2 wt% for further cycling.

In the light of scarce literature on the subject, hydrogen adsorption in MPEAs/HEAs is an original research topic that might open new routes for the design of promising materials for hydrogen storage.

Hydrogen Storage in Metal-Organic Frameworks Probed through Neutron Scattering Craig Brown; National Institute of Standards and Technology, United States

Adsorption of molecules in functionalized and high surface area metal-organic frameworks (MOFs) is of emergent technological importance in a multitude of areas ranging from chemical separations to energy storage. We have been studying the properties of MOFs for storage and separations of industrially important small molecules such as hydrogen, oxygen, carbon dioxide, noble gases, and short chain organics. Besides the geometrical and porosity control available in MOF chemistry, the properties of the frameworks can be tweaked to elevate electrostatic interactions by exposing open metal cation sites or functionalizing ligands. Here, we discuss the information accessible from neutron scattering experiments on hydrogen adsorbed in a selection of nominally rigid MOFs with some surprising subtle flexibility that greatly enhances metal-hydrogen interactions.

Colloidal Synthesis of Al/C-Based Composite Energetic Nanoparticles with Tunable Interfacial Activities via Laser Ablation Synthesis in Solution Dibyendu Mukherjee1,1, Seyyed A. Davari2, Jennifer L. Gottfried3 and Gerd Duscher1, 1University of Tennessee, United States; 2University of California Davis, United States; 3US Army Research Laboratory, United States

Energetic nanomaterials (ENMs) find applications in solid-state propellants and explosives. Yet, the large heat release in the Al nanoparticle (NP)-based first-generation ENMs were offset by hindered detonation rates due to the fuel-oxidizer diffusion lengths and rates being compromised by excessive oxide shell formations and NP aggregations.1-3 Efforts have been made to tune their energetic behaviors by tailoring their interfacial structures that can control the oxide shell formation while leading to excessive internal stresses within the metallic cores. Yet, there exists weak fundamental understanding and considerable challenges in the rational design and synthesis of such nanostructured architectures. To this end, carbon (C) coatings on Al NPs facilitate safe handing while promoting enhanced activities due to the added advantages of the coating itself oxidizing into gaseous products (CO2, CO etc.) without any residual ash formation, while allowing the C shell to retard NP aggregations. But, the challenge remains in the facile yet, chemically clean colloidal synthesis of these encapsulated NPs without contaminating and/or oxidizing the metal cores. Here, we address this challenge through rational design and structure-property characterizations of graphitic shell coated Al NPs (< 20 nm sizes) dispersed in pyrolyzed C matrices via laser ablation synthesis in solution (LASiS) to preserve high surface areas and interfacial properties of Al NPs. Such nanostructures allow tailored design of interfacial structures that can either lead to strain energy manifestation or, rate-controlled release of solid propellants under high pressure/temperature to prevent oxide shell-mediated surface passivation. Energetic activities of the C/Al composite NPs were tested via Laser-induced Air Shock from Energetic Materials (LASEM) technique at the US Army Research Laboratory, Aberdeen Proving Ground, MD. We demonstrate that synthesis parameters such as organic solvents, laser flux and ablation times can be tuned to provide superior control on NP sizes/aggregation, composition, crystallinity, metastable structures and, in turn, their energetic behavior with the aid of the C shell nanostructures and matrices. The study unveils synthesis-structure-property relations in LASiS-based manufacturing of composite ENMs capsuled in graphitic shells that are safe to handle and undergo kinetically controlled energy release under desired conditions. Such Al/C-based composite ENMs can be immediately employed for high energy density munitions in defense applications.

Capillary-Driven Solar-Thermal Water Desalination Using a Porous Selective Absorber Xuanjie Wang and Shankar Narayanan; Rensselaer Polytechnic Institute, United States

Freshwater is critical to humankind’s survival, as well as to global health and economic development. Providing clean water in a safe, reliable and affordable manner is a considerable challenge as demand increases with a growing population. Although 71% of the Earth’s surface is covered by water, most of it is saltwater and therefore non-potable. Therefore, large-scale and efficient deployments of seawater desalination are greatly needed. Traditional desalination technologies such as reverse osmosis (RO) and multi-stage flash (MSF) are limited by efficiency and cost. Solar vapor generation, on the other hand, is an emerging and promising technology that takes advantage of clean and abundant energy from the sun by converting the solar energy to thermal energy. More recently, efforts have been made to reduce heat loss[1][2], enhance the broadband absorption of sunlight[3], and design efficient water supply channels. Meanwhile, various materials such as carbon-based materials[4], plasmonic nanoparticles[5], polymer-based materials and metal oxides have been explored in an attempt to further increase the efficiency of solar water evaporation. However, there are only a few studies regarding the radiation loss coming from the broadband solar absorbers, which emit thermal radiation to the environment like a blackbody in the infrared region. Compared with broadband absorbers, the selective solar absorbers with strong solar absorptance and low infrared emittance can efficiently absorb the solar spectrum.
while largely suppressing the heat loss, resulting in the enhancement of solar evaporation efficiency. Nevertheless, many existing selective absorbers involve either expensive materials or complicated fabrication protocols, which limit the potential for scalable applications. Therefore, developing solar steam generation devices that takes into consideration light absorption, heat loss, and feasible scalability is challenging but also desirable.

In this study, we report on selective solar absorber with uniform self-assembled nanowires fabricated by an electrochemical deposition process. We demonstrate that the solar-thermal performance can be further enhanced by applying selective solar absorbers, compared with graphite broadband absorbers. Our results provide a feasible path for selective solar absorbers with cost-effective and scalable fabrication processes that may be beneficial for various solar-based applications.

Measuring the Dielectric Constant of Perovskite Nanoparticles Embedded in a Polymer Matrix Jackson Baker¹, Daniel Brito¹, Josh Morgan¹, Guadalupe Quirarte¹, Eleanor Rackoff², Albert Dato¹ and Todd C. Monson²; ¹Harvey Mudd College, United States; ²Sandia National Laboratories, United States

Barium titanate (BTO) is a perovskite material used in energy storage applications because of its high dielectric constant [1,2]. Wada et al. discovered that the size of BTO nanoparticles strongly affects their dielectric constant [2]. Particles with diameters above 300nm exhibited a dielectric constant of 4000, but a sharp increase in dielectric constant to over 15,000 was observed at a diameter of 70 nm [2]. These intriguing, yet highly contested results have motivated us to develop a process that further investigates the relationship between BTO nanoparticle size and their dielectric constant. With this goal in mind, we have developed novel methods of (1) functionalizing BTO nanoparticles using ball milling and (2) integrating functionalized BTO nanoparticles into a polymer matrix using injection molding. These processes enable us to create a solid colloid from which the dielectric constant of the nanoparticles can be extracted. Here we present our methods of nanoparticle functionalization and nanocomposite fabrication. We also introduce the results of our investigation, which focused on characterizing and measuring the dielectric constants of nanocomposites containing BTO nanoparticles with sizes ranging from 50 to 500 nm. We will also discuss our method of extracting the dielectric constant of the BTO nanoparticles in the polymer matrix and present the effect of nanoparticle volume loading on the dielectric constant of the nanocomposite.

Precipitating Metal Nitrate Deposition of Amorphous Metal Oxyhydroxide Electrodes Containing Ni, Fe and Co for Electrocatalytic Water Oxidation Young Kyeong Kim, Jin Hyun Kim and Jae Sung Lee; Ulsan National Institute of Science and Technology, Korea (the Republic of)
**Hydrogen** could be an ideal energy carrier for a sustainable energy supply system because it combuts cleanly without producing CO₂ or any other pollutants, and this chemical energy is easier to store than electricity. However, the current industrial production of hydrogen (most commonly by steam reforming of natural gas) is energy-intensive and produces CO₂ and other pollutants, making the overall system far from being sustainable.

Alternative environment-friendly H₂ production methods include photoelectrolysis or electrolysis of water using a renewable energy source. **Photovoltaic cell–electrochemical cell (PV–EC)** is such an approach to **solar energy-driven water splitting**, which combines PV for power generation and EC for electrochemical H₂ production from water. To realize a practical PV–EC system, both PV and EC components should be highly efficient, durable, and cost-effective. The electrochemical cell has received renewed interest recently to improve its performance as well as cost. The electrocatalytic water splitting consists of two electrochemical reactions; hydrogen evolution reaction (HER) and oxygen evolution reaction (OER) in acidic or alkaline media. Regardless of the system types and media, sluggish OER kinetics limits the efficiency of overall water splitting reaction owing to its more complex reaction mechanism and higher overpotential (0.2 V) relative to HER (0.05 V). To maximize the efficiency of a PV–EC system, reducing the overpotential of OER by developing a highly efficient oxygen evolution catalyst (OEC) is indispensable. Although noble-metal based OECs including IrOₓ and RuOₓ exhibit great OER catalytic activity in acidic media, they are not only expensive but often susceptible to corrosion and deactivation in alkaline media without proper modification.

Alternatively, many first-row transition metal oxides, hydroxides, and present great OER activity and stability in alkaline conditions in addition to the advantages of being made of earth-abundant elements and the low price compared to precious metals. Many recent studies have demonstrated great OER performance of binary and ternary mixed oxyhydroxides of Ni, Fe, and Co, synthesized by various methods. However, in order to apply these catalysts to a practical industrial scale, it is required to develop an advanced synthesis method capable of producing multicomponent electrocatalysts with a simpler synthesis step under mild conditions at ambient pressure and temperature preferably with an all-solution-based process.

In the present work, we present an ingenious synthesis method of "**precipitating metal nitrate deposition (PMND)**" to prepare amorphous phases of unary or binary transition metal oxyhydroxide (TMOH) films containing Ni, Fe, and Co. This technique can easily control the composition of the metals in the catalyst and thus is suitable to study its effects on the catalytic activity of the electrocatalysts. By examining a series of unary and binary TMOH catalysts of 30 different ratios of elements on fluorine-doped tin oxide (FTO) substrate, it is shown that their OER activity is represented by a volcano plot as a function of a single experimental descriptor, i.e., the fraction of hydroxide in the surface oxygen species. We also demonstrate the versatility of the PMND method by preparing the catalysts on various substrates of FTO, nickel foam, nickel mesh, and carbon felt. The optimized NiFe (2:8) electrocatalyst on nickel foam exhibits great OER activity in an alkaline medium superior to conventional noble metal oxides and other reported electrocatalysts of similar composition. Finally, we fabricate a PV–EC device by connecting our optimized EC with a commercial crystalline c-Si PV module, which records a **solar-to-hydrogen conversion efficiency (STH) of 9.84 %**.

A Step Change in the Cost of PEM Water Electrolysers? Gareth Hinds, Hans Becker and Luis Castanheira; National Physical Laboratory, United Kingdom

Reduction in the cost of polymer electrolyte membrane water electrolyser (PEMWE) technology is urgently required for the realisation of commercially viable green hydrogen production. However, at present up to two thirds of the manufacturing cost of a PEMWE stack is associated with the current collector components, with platinum-coated titanium a common material of choice. This presentation will describe in situ measurements of the local potential at the current collectors during PEMWE cell operation, demonstrating for the first time that the corrosion potential of the anode current collector is completely decoupled from the potential of the anode electrode due to the low ionic conductivity of the deionised water phase. This new observation opens up the possibility of using cheaper materials such as carbon and carbon-coated stainless steel for anode current collector components, which could lead to a dramatic decrease in the cost of the technology.

5:15 AM S.EN11.03.02
Embedded Ions Activating Water Oxidation Yingfang Yao1,2; 1Nanjing University, China; 2Jiangsu Key Laboratory for Nano Technology, China

Clean hydrogen from water splitting driven by electrocatalysis provides an alternative to fossil fuels. However, the oxygen evolution reaction (OER) is the rate determining step of water splitting. Therefore, there is an urgent need to develop low-cost and highly efficient OER electrocatalysts. Low-cost carbon-based materials with a high surface area that expose more active centers are the ideal candidates for OER. Challenges to reduce OER overpotentials and to increase stability still limit the practical applications of carbon-based materials. However, substantial overpotentials above thermodynamic requirements limit their efficiency and stability in OER-related energy conversion and storage technologies. Here, we embedded CrN crystals into graphene and in situ electrochemically oxidized them to construct graphene materials with encapsulated Cr$^{6+}$ ions (Cr$^{6+}$@G). These Cr$^{6+}$@G materials exhibit the lowest OER overpotential of 197 mV at 10 mA cm$^{-2}$ and excellent stability over 200 h at a high current density of about 120 mA cm$^{-2}$ in an alkaline electrolyte. Spectroscopic and computational studies confirm a stable ion coordination environment significantly benefiting the downshift of the graphene Fermi level via hybridization of C p orbitals with d orbitals of Cr$^{6+}$ ions that enhances the OER activity and stability.

Device Properties of Polymer Electrolyte Electrochemical Cells (PEEC) Influenced by the Operating Conditions of Electric Energy Management System Katsushi Fujiij, Kayo Koike, Kei Morishita, Katsushiko Tsuno and Satoshi Wada; RIKEN, RAP, Japan

Electric energy storage is an important part to establish natural energy-originate electric power like solar cells and wind power generations as a user-on-demand power supply system. Hydrogen storage is a suitable method for a long-term and a large amount of energy storage while the rechargeable battery is good for fast demand response. We proposed a new control concept of the user-on-demand electric supply system taking both advantages of hydrogen storage and rechargeable battery [1]. For the system, not only the rechargeable battery is used as a fast response device but also hydrogen storage is for a large amount of energy storage device, with DC bus voltage as the signal of the power flow balance. In such kind of system, hydrogen is stored by polymer electrolyte electrochemical cell (PEEC) and is consumed by polymer electrolyte fuel cell (PEFC). Thus, the system operating conditions influence the PEEC and PEFC properties. In this report, some of the possible
system conditions influencing the PEEC properties are mainly discussed. The evaluated PEEC was the conventional one, that is, the anodic catalyst is IrOx and the cathodic catalyst is Pt. Step-like electric power changes by the voltage and by the current for a PEEC were performed. The current by the step-like voltage change showed a large overshoot for voltage increase and undershoot for voltage decrease were observed. In contrast, the voltage by the step-like current change showed a relatively smooth increase and decrease without overshoot nor undershoot. This is explained by the EC as a capacitor, and the power change should be controlled by the current. The performance of water electrolysis is improved with increasing temperature due to the overall electric resistance decreasing and the overvoltage of water splitting decreasing. The hydrogen leakage to the oxygen evolution reaction (OER) side is also well-known properties for PEEC. The leakage was also observed to be increased with cell temperature. This means that the cell temperature must be considered because IrOx water oxidized catalyst may be reduced. This leakage may also affect device reliability, but the details are still obscured.

From the impurity analysis of the supplied water for a PEEC after the current-voltage (I-V) relationship degraded (electric resistivity increased), the component metal ions of PEEC were detected. After replacing the water with pure one, the I-V characteristic was recovered. This probably shows that the dissolved metal ions decrease the ion transferability in the proton exchange membrane. The result shows that especially for the long-term water electrolysis operation requires water purification.

release at low temperatures; however in most cases reversibility remained a challenge. The results of these investigations revealed structural limitations of existing materials as well as opportunities for future improvement.

Mono- and Bimetallic MOF-74 Frameworks as Non-Precious Metal Catalysts for Dehydrogenation of Alcohols for Energy Storage
Jonathan L. Snider1, Ji Su2,2, Pragya Verma2, Alexander Baker3, Yi-Sheng Liu2, Jinghua Guo2, David Prendergast2,2, Vitalie Stavila1, Gabor Somorjai2,4 and Mark D. Allendorf4; 1Sandia National Laboratories, United States; 2Lawrence Berkeley National Laboratory, United States; 3Lawrence Livermore National Laboratory, United States; 4University of California, Berkeley, United States

The transition to a sustainable hydrogen economy requires liquid organic hydrogen carriers (LOHCs) to enable efficient, high density storage and transportation of hydrogen-based energy. LOHCs, such as alcohols, require an effective and economical catalyst to promote the chemical reactions which store and release hydrogen from the molecule.1 In recent years, metal-organic frameworks (MOFs) have emerged as an exciting class of materials with applications in catalysis due to unsurpassed tailorability of pore size and local chemical environment and high thermal and chemical robustness required for industrial-scale processes. The MOF-74 framework (M2(dobdc), where M is a divalent metal ion and dobdc = 2,5-dioxido-1,4-benzenedicarboxylate) is a particularly versatile structure which can incorporate many different open metal sites and has been shown to perform a variety of reactions, including hydrogenolysis of aryl ethers2, dehydrogenation of ammonia borane3, and methanol-catalyzed water dissociation4. In this work, we investigate a series of mono- and bimetallic MOF-74 catalysts with activity towards the methanol dehydrogenation reaction. Reactions were carried out in a packed bed reactor with methanol vapor and nitrogen carrier gas. While Mg-MOF-74 was found to be inactive for this reaction, other M-MOF-74 (M= Zn, Co, Ni, bimetallic Ni-Mg) catalysts turnover the reaction at pressures of 1 bar with temperatures above 200 °C. At 300 °C, the Ni0.2Mg0.8 composition achieved the greatest hydrogen productivity of the sample series at 20.3 mL H2/min. This catalyst bimetallic Ni-Mg) catalysts turnover the reaction at pressures of 1 bar with temperatures above 200 °C. At 300 °C, the vapor and nitrogen carrier gas. While Mg-MOF-74 was found to be inactive for this reaction, other M-MOF-74 (M= Zn, Co, Ni, bimetallic Ni-Mg) catalysts turnover the reaction at pressures of 1 bar with temperatures above 200 °C. At 300 °C, the Ni0.2Mg0.8 composition achieved the greatest hydrogen productivity of the sample series at 20.3 mL H2/min. This catalyst demonstrated stability under the reaction conditions, maintaining the MOF-74 structure and high activity for 6 hours. In contrast, the Ni-MOF-74 catalyst had diminished hydrogen productivity and decomposed under the reaction conditions, suggesting a promotional effect was achieved by maintaining the MOF-74 framework. Ex situ X-ray absorption spectroscopy and density functional theory were used to probe the stability and properties of the open metal sites thought to play a role in the observed catalytic activity. These investigations into methanol demonstrate the catalytic activity of a variety of MOF-74 catalysts towards alcohol dehydrogenation and provide important mechanistic understanding of the factors that affect the catalytic activity and selectivity of MOFs for hydrogen generation from hydrogen carriers.

Refractory Multi-Principal-Element Alloys as Novel Solid-State Hydrogen Stores
Claudia Zlotea and Jorge Montero; ICMPE CNRS, France

Among various materials for hydrogen storage, alloys and intermetallics forming hydrides are one of the most important classes due to their high volume density, reversibility and safety. Within the class of conventional metals and alloys for hydrogen storage, the body centered cubic (bcc) alloys based on early 3d transition elements (Ti, V, Cr...) represent one of the most promising class due to their high hydrogen storage capacity up to 2 Hydrogen per metal atoms (H/M). These alloys show two plateaus at low and ambient pressure in the Pressure-Composition-Isotherms. But, for practical applications only the second plateau is available reducing the reversible quantity of hydrogen that could be stored. Consequently, new metallurgical concepts and materials are stringently required to develop more efficient multifunctional hydrides.

Recently, a new paradigm of alloying strategy has emerged based on the original concept of multi-principal-element alloys (MPEAs), initially proposed to develop materials with enhanced mechanical properties. The principle is laid on the mixing of elements close to the equimolar proportion for systems up to five and more containing elements. This mixing may lead to the formation of simple single-phased solid solutions (body centered cubic-bcc, face centered cubic-fcc and hexagonal close packed-hcp). The formation and the stability of such phases are still under consideration and seem to be based on several chemical and physical quantities such as, configurational entropy, mixing enthalpy, atomic misfit, valence electron concentration. Among MPEAs, alloys with at least five principal elements with atomic concentrations in the range 5 to 35 % are called high entropy alloys (HEAs). Most of reports concerning these alloys describe their structure, microstructure and mechanical properties, whereas functional properties such as, hydrogen sorption, are only scarcely investigated.
We present here the study of hydrogen absorption properties of MPEAs based on refractory metals. The TiVZrNbX (X = Mg, Al and Ta) alloys have been synthesized by classical metallurgical high temperature methods or mechano-synthesis by ball milling under protective atmosphere. To produce direct metal hydrides we have employed the reactive ball milling under hydrogen gas starting from the pure metal powders. The properties of TiVZrNbX (X = Mg, Al and Ta), TiZrNbHfTa and related hydrides have been studied by a large set of experimental techniques: laboratory X-ray diffraction, electron microscopy, \textit{in situ} synchrotron X-Rays or neutron diffraction, pressure-composition-isotherm, thermal desorption spectroscopy and differential scanning calorimetry. All the TiVZrNbX alloys are single-phase \textit{bcc} and undergo a one-step reaction with hydrogen at room temperature. The single-phase TiZrNbHfTa alloy also crystallizes in a \textit{bcc} phase but undergoes a two-stage hydrogen absorption reaction to a \textit{fcc} dihydride phase with an intermediate tetragonal monohydride at high temperature. We suggest that the lattice distortion, $\delta$, as defined for MPEAs, might play an important role: larger $\delta$ would favors a single-step reaction with hydrogen ($\textit{bcc} \rightarrow \textit{bct}$ hydride with large hydrogen content), whereas small $\delta$ would favor a two-steps phase transition ($\textit{bce} \rightarrow \textit{bct} \rightarrow \textit{fcc}$), as also encountered for conventional \textit{bcc} alloys. The most promising alloy is the TiVZrNb composition which, despite a fading of the capacity for the first cycles, shows a stable reversible capacity around 2 wt% for further cycling.

In the light of scarce literature on the subject, hydrogen adsorption in MPEAs/HEAs is an original research topic that might open new routes for the design of promising materials for hydrogen storage.

Colloidal Covalent Organic Frameworks for Hydrogen Storage and Delivery
Wade Braunecker$^{1,2}$, Rachel E. Mow$^{1,2}$ and Thomas Gennett$^{1,2}$; $^1$National Renewable Energy Laboratory, United States; $^2$Colorado School of Mines, United States

Several approaches for designing and synthesizing colloidal covalent organic frameworks (COFs) are discussed, along with their unique application as hydrogen storage and delivery media. Using novel catalysts and conditions, the particle size of 3D COFs can be tuned between 50 and 600 nm with surface areas > 500 m$^2$/g. Several functionalization strategies are discussed that help promote long-term colloid stability. When purified and resuspended in a bulky ionic liquid that is size excluded from entering the COF pore, the material behaves as a ‘porous liquid’, dramatically improving gas uptake in the liquid. Using temperature programmed desorption, we investigate how the frozen liquid matrix can be used to trap gas in the COF pores and effectively tune gas desorption temperatures. Finally, a technique for growing a solid-state COF monolith from densely packed COF colloids is presented, along with its characterization.

Enhanced Water Oxidation Performance by Prompting Higher Active Sites Using Transition-Metal (Co, Ni, and Cu) Oxides and CeO2 Heterointerfaces
Zahra Albu, Fahad Alzaid, Salma Alqahtani, Nawal Al Abass, Feriah Alenazey and Bandar Aloitaibi; King Abdulaziz City for Science and Technology, Saudi Arabia

Since the depletion of fossil fuel is inevitable, exploring an alternative green energy carrier is of an urgent demand. Hydrogen fuel produced from renewable resources such as photovoltaic cells coupled with electrolyzers for water splitting can offer a very attractive route to address the aforementioned issue. The major bottleneck for deploying such technology is to find a practical electrocatalyst that can efficiently oxidize water. Many research efforts have been made towards finding new electrocatalytic materials to enhance the oxygen evolution reaction (OER). However, precious metals, such as Ru and Ir, containing oxides are still the best-known electrocatalysts for OER. This entails finding a new technique to improve the electrocatalytic activity of cost-effective metal oxides. In this study, we attempt a different approach to promote more active sites for OER using transition metal oxides (i.e., Co$_3$O$_4$, NiO, and CuO) and tailoring their heterointerfaces with CeO$_2$. The metal-oxide/metal-oxide (MO/ MO) heterointerfaced nanoparticles were prepared by co-synthesizing the two MOs using wet chemistry. X-ray diffraction spectra and scanning tunneling microscope images confirm the formation of heterointerfaces between CeO$_2$ and the other MOs under study. That is, low magnification TEM images show that the synthesized particles compose of nano-sized crystallites of Co$_3$O$_4$ embedded on CeO$_2$ matrix. Electrochemical performance CeO$_2$/MOs are significantly improved compared to pure CeO$_2$ or any other MOs alone. Among all the CeO$_2$/MO structures, CeO$_2$/Co$_3$O$_4$ shows the highest cathodic shift (~ 0.65 V) and also it shows the lowest Tafel slop (~ 59 mV/dec). Mott-Schottky analysis illustrates that the presence of MOs interface with CeO$_2$ has formed an $n$-$p$ junction where CeO$_2$ has an $n$-type characteristic while the other MOs have a $p$-type characteristic. This property can be very beneficial for the separation of optically excited electron-hole pairs due to the internally induced electric field. Therefore, exploring the potential use of our MO/MO structures as photoelectrodes was conducted using chronoaomerometry under a chopped light source at 1.5 V vs. RHE. These results showed that CeO$_2$/Co$_3$O$_4$ electrode has the highest photo-response as compared to the other CeO$_2$/MOs or any single MO under this study. Additional investigations using density functional theory (DFT) of pure CeO$_2$, pure Co$_3$O$_4$, and heterointerfaced CeO$_2$/Co$_3$O$_4$ were performed. It was confirmed using DFT calculations that CeO$_2$/Co$_3$O$_4$ heterointerface has the lowest Gibbs free energy and lowest adsorption energy for OH$^-$ intermediate compared...
to pure CeO₂ and Co₃O₄. Additional characterization techniques on these MO/MO structures were conducted in this study as well.

Computational Studies of Borohydride Materials for Hydrogen Storage Bojana Ginovska, Tom Autrey and Iffat Nayyar; Pacific Northwest National Laboratory, United States

Borohydride compounds have been to have great potential for as hydrogen storage materials. Solid state density functional theory calculations were performed to identify key intermediates and gain insight into the reaction pathways involved in the release and uptake of hydrogen from the thermal decomposition of Mg(BH₄)₂. Even tough improved theoretical methods for calculating thermodynamic properties of complex BₓHᵧ borohydrides have been developed, we find that there are still limitations to understanding mechanistic details of these complex reactions, and approaches that focus on NMR and other spectroscopic characterisations are necesary to complement the thermodynamic data and provide mechanistic insight into these pathways. We will report both on molecular and solid state DFT calculations, and the gains from empolyong both approaches in these studies.

Multiscale Modeling of Materials Interfaces for Hydrogen Storage, Generation and Delivery Brandon Wood; Lawrence Livermore National Laboratory, United States

Developing viable solutions for the efficient production and storage of hydrogen requires understanding chemical process occurring at solid-gas, solid-liquid, and solid-solid interfaces in advanced materials. Probing behavior of these interfaces under operating conditions presents significant challenges; however, predictive modeling offers an opportunity for providing key insights into interface chemistry, particularly when operating in tandem with high-fidelity experimental characterization techniques. Within the DOE Hydrogen Materials—Advanced Research Consortium (HyMARC) and the HydroGEN Advanced Water Splitting Materials Consortium, we are using multiscale models to understand properties of reactive interfaces for the production, storage, and delivery of hydrogen. I will provide an overview of our materials modeling strategy within these consortia, ranging from first-principles calculations of interface chemistry to continuum methods for microstructure-level properties. I will then review some of our recent activities for simulating thermodynamic and kinetic properties of hydrogen-related materials. Specific examples will be given of how these computational models have helped to elucidate mechanisms of interface chemical reactions, the formation of new phases, and the impact of solid-state interfaces on key reaction pathways. I will also show how simulations have been combined with experimental probes to improve models and obtain new understanding of materials interfaces under operating conditions. Finally, I will discuss how this understanding is being used to guide new strategies for improving materials functionality for storage, generation, and delivery of hydrogen. This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Hydrogen Boride Sheets—Synthesis, Characterization and Application Takahiro Kondo; University of Tsukuba, Japan

Two-dimensional (2D) materials consisting of a single or a few layers of atoms have superior performance compared to conventional materials or their bulk counterparts in a variety of applications, because of their unique properties, including their flexibility, high specific surface area, and quasi-2D electron confinement. Recently, we have revealed that the hydrogen boride (HB or borophane) sheets with an empirical formula of H₇B₇ can be formed by exfoliation and complete ion-exchange between protons and magnesium cations in magnesium diboride (MgB₂) with an average yield of 42.3% at room temperature [1], as a new member of 2D sheets and boron-based nanomaterials [2]. The sheets feature an sp²-bonded boron planar structure without any long range order. A hexagonal boron network with bridge hydrogens is suggested as the possible local structure, where the absence of long range order was ascribed to the presence of three different anisotropic domains originating from the 2-fold symmetry of the hydrogen positions against the 6-fold symmetry of the boron networks. Our recent analysis with soft x-ray absorption and emission spectroscopy at the B K-shell also supports this view and show the semimetallicity of HB sheets [3]. We have then found several intriguing properties of HB sheets for the applications of hydrogen (H₂) release (as muh as 8 wt%) by UV irradiation at room temperature under mild ambient conditions [4], and the solid-acid catalyst [5] that convert C₂H₅OH to C₂H₄ and water. In the presentation, synthesis, characterization, and application of HB sheets will be introduced.

Despite the high theoretical ~15wt% hydrogen content of magnesium borohydride, reusable dehydrogenation/hydrogenation cycling of pure Mg(BH$_4$)$_2$ requires economically infeasible high temperatures and pressures in excess of 300°C and 350 bar. However, many properties of Mg(BH$_4$)$_2$, such as the melting point, are readily altered through the use of additive compounds, including metal borohydrides, metal hydrides, and organics (ethers/glymes). In the case of organic additives, both the melting point and the hydrogen evolution temperature have been shown to decrease. The zeroth order description of this behavior is that organic molecules (e.g. THF) act as ligands, attach to Mg and effectively change the cation size in the Mg(BH$_4$)$_2$ salt which disrupts the solid structure. In this work we investigated a previously unreported family of non-metallic borohydrides as Mg(BH$_4$)$_2$ additives. Of specific interest were tetramethylammonium and tetra-n-butylammonium borohydrides. These non-metallic borohydrides have low melting points (<300°C), and much larger cations than Mg$^{2+}$, similar to the zeroth order picture of Mg$^{2+}$:THF complexes. In-situ diffraction, temperature programmed desorption, mass loss, and heat flow were used to establish a full picture of the behavior of these additive systems. With regards to phase mapping, we will report the solid solubility of the additives in Mg(BH$_4$)$_2$, the presence of line compounds predicted in literature, and the initially nucleated phases during quench. We also report the phase behavior of quenched dehydrogenated samples as well as the reversibility of re-hydrogenated material. This work demonstrates a novel additive family with high cyclability and low melting points for lowering reaction and phase change temperatures of Mg(BH$_4$)$_2$.

Towards Viable Solid-State Hydrogen Storage via Bypassing Unwanted Intermediates in Complex Metal Hydrides
ShinYoung Kang, Tae Wook Heo, Keith R. Ray and Brandon Wood; Lawrence Livermore National Laboratory, United States

Complex metal hydrides have attracted great attention in the hydrogen storage community due to its high gravimetric capacity (14.9 and 8.8 wt% H$_2$ for Mg(BH$_4$)$_2$ and LiNH$_2$) and relatively small reaction enthalpy (<= 50-100 kJ /mol H$_2$). However, sluggish kinetics and the formation of stable intermediate compounds result in poor reversibility, high hydrogenation pressure and dehydrogenation temperature, hampering its application for onboard hydrogen storage. In this presentation, we propose a new concept to destabilized and bypass the formation of unwanted intermediates. In Mg(BH$_4$)$_2$ system, using first-principles calculations we explored the interplay between intermediate morphology and reaction pathways. Our results verify that the effective reaction energy landscape strongly depends on the morphological features and associated chemical environment, offering a successfully explanation of the formation of intermediates, especially Mg(B$_3$H$_8$)$_2$, which was observed in nuclear magnetic resonance (NMR) measurements, but predicted too unstable to form in conventional bulk simulations. In addition, our joint experimental-theoretical work in the LiNH$_2$ system revealed that the high interface energy suppressed the formation of Li$_2$NH intermediate in nanoscale. Our understanding introduces the possibility of tuning solid-state hydrogen-storage materials by tailoring morphology and internal microstructure, representing a new paradigm for engineering materials that could meet established performance targets.
SUNRISE—A European Horizon 2020 Flagship Project for the Defossilization of Fuels and Chemicals Artur Braun1, Ann Magnuson2, Rita Toth1 and Sophia Haussener3; 1Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; 2Uppsala University, Sweden; 3EPFL, Switzerland

Hydrogen (H2) is one of the mostly used gases in industry. The term hydrogen economy dates back to the early 1970s in the context of energy storage and electrical energy 1. Since, photoelectrochemical cells (PEC) were studied in recurring episodes for solar H2 production 2. MRS Meetings are having PEC Symposia since 2009 3. Since 2015, H2 mobility with commercial available fuel cell cars has become a reality 4, which requires a wide network of H2 fuel infrastructure 5. Most H2 for industry use today is of fossil origin, but H2 can be produced sustainable by electrolysis. The Swedish consortium for Artificial Photosynthesis is working since 1994 6. In Switzerland, PEChouse started in 2007 as an umbrella activity for the development of PEC technology for solar H2. The Joint Center for Artificial Photosynthesis (JCAP) in California is a large scale research program with a substantial hydrogen economy component 7. More clusters, centers and consortia are spreading 8. Since about 7 years, there is in Europe a large consortium 9 preparing for a large scale R&D initiative, aiming at renewable, artificial fuels and chemicals, in which hydrogen production plays a central role (SUNRISE) 10. SUNRISE aims at meeting the goals of the Paris Agreement by decarbonization of the atmosphere. By providing large scale production of green H2, and converting the CO2 with H2 to solar fuels and base chemicals, SUNRISE wants to reshape the European energy landscape towards a circular and decentralized energy system. Production, storage and conversion of hydrogen are thus key technologies, which need to be further developed and integrated in existing infrastructure and made compatible with the built environment and the natural landscape.

The SUNRISE Consortium encompasses a diverse assembly of disciplines including economy, Life Cycle Assessment, social sciences, engineering, and the basic sciences in physics, chemistry and biology. By a concerted effort, SUNRISE aims to bring disruptive technology from a low readiness level to commercial maturity within a 10-year period.

which we define as long-distance delivery from a large H2 source to an end use; distribution, which we define as short-distance delivery from a city-gate to fueling stations within the city; and transmission-distribution, which we define as long distance delivery from a large H2 source all the way to fueling stations. For each of these market applications, we evaluate the energy intensity and other key system level performance metrics for high pressure (350 and 500 bar) truck transportation, cryogenic liquid H2 truck transportation, and carrier-based truck transportation. Ancillary equipment and operation conditions, including systems at the H2 source and refueling station which are unique to adsorption systems are included in the analysis.

For a base transmission application, which 50 Mg H2/day is delivered 100 km from a gas terminal to an end point application, the delivery cost is approximately $1.6/kg H2 and $1.8/kg H2 for 500 bar and 350 bar trucks, respectively. Liquid H2 transport is less competitive at this short distance, and costs $3.1/kg H2. A truck packed with metal organic framework (MOF) Ni2(m-dobdc) and modeled at 100 bar and 200K has a delivery cost of $7.7/kg H2. Transmission costs for the MOF-H2 system can reach as low as $1.8/kg H2 (on par with 350 bar trucks) in a scenario where driverless trucks are employed, a highly durable material is developed (15,000 cycles), material costs are $10/kg MOF, and where bed porosity and pellet porosity are substantially lower (or rather increasing H2 uptake without increasing upstream cooling requirements).

For the distribution application, the delivery cost is dominated by the CAPEX and OPEX of the refueling stations. For a base scenario where 50 Mg H2/day is delivered 1 km from a city-gate gas terminal to distributed fueling stations, the delivery cost is between $3.4/kg H2 and $4.6/kg H2 for 500 bar and 350 bar trucks, respectively, and $5.3/kg H2 for liquid H2 transport. Liquid trucks for distribution perform better in larger markets (40% lower costs for a 120 Mg/day market). The MOF-H2 systems studied performs poorly in this market application (above $20/kg H2) as 10x more fueling stations and trucks are required to meet the same daily H2 demand as compared to the liquid or high pressure systems.

These results demonstrate capabilities of the hydrogen delivery models developed at the Lawrence Berkeley National Laboratory for the Department of Energy HyMARC program. Any path to substantial greenhouse gas emissions (GHG) reduction will include market transformations in the transportation sector, as it remains the single largest primary source of GHGs in the United States and the third largest primary source globally. Advances in carrier materials such as liquid organic hydrogen carriers (LOHC) and MOFs, which exhibit a wide range of tunability for hydrogen storage, could radically change the way hydrogen is stored and transported globally to meet fuel demand in zero direct emission vehicles. In this research work, we present a framework for characterizing and benchmarking the performance of emerging carrier systems.

5:15 AM S.EN11.06.07
Formates and Formic Acid as Hydrogen Carriers Mark Bowden, Kat Grübel, Jotheeswari Kothandaraman, Kriston P. Brooks and Tom Autrey; Pacific Northwest National Lab, United States

Formic acid (FA) is a potential material for transporting hydrogen with a higher volumetric density (53 g H2/L) than compressed hydrogen gas (ca. 40 g H2/L at 700 bar). Hydrogen can be released from FA in a catalytic process which is exergonic (ΔG = -33 kJ/mol) and can therefore be used to generate hydrogen pressure without a mechanical compressor. An equimolar quantity of carbon dioxide is also generated which needs to be separated from the hydrogen. Hydrogen can also be generated from formate salts (FS) in a reaction with water with close to zero free energy change. Gaseous separation is not required in this case since the product is a bicarbonate salt. In aqueous solution, faster kinetics are found for a mixture of FA and FS compared to either end member. We have studied reaction rates, the degree of conversion, and product distribution for FA, FS and their mixtures as a function of composition, pH, catalyst, and temperature. The results will provide valuable inputs techno-economic modelling to assess the suitability of these compounds as hydrogen carriers.

Density Functional Theory Investigation of Ethanol Adsorption on Ag(111) Surface Defect Sites Dariia Yehorova, Daniel Schlosser, Ashleigh Baber and Kendra Letchworth-Weaver; James Madison University, United States

In spite of the rapid development of hydrogen fuel cell (HFC) technologies, the unstable nature of hydrogen fuel presents complications for the versatile application of this energy production method. Alternatively, direct ethanol fuel cells (DEFC) are a competitive method of clean energy production due to their non-toxic, abundant, and high energy density fuel. A common barrier for modern implementations of these technologies is their dependence on high-cost precious metal catalysts. Furthermore, the search for alternative catalyst materials is limited by a poor understanding of the relationship between reactivity and structural defects. The promising performance of silver as part of heterogeneous catalytic nanoparticles, where under-coordinated sites are prevalent, motivates on investigation of ethanol on Ag(111) defects. In this study we utilize temperature programmed desorption (TPD) experiments and plane-wave density-functional theory (DFT) to investigate
fundamental electronic properties and adsorption mechanisms of ethanol on realistic metal surfaces in search for alternative lower cost catalytic materials. TPD experiments determine an analyte adsorption energy by increasing the temperature of the substrate in a high vacuum environment, showing higher adsorption energy of ethanol to defect sites on Ag(111) compared to smooth surfaces. In order to understand the atomic-scale origin of the increased reactivity of under-coordinated surface atoms we used the JDFTx software to calculate theoretical ethanol adsorption. Adsorption on Ag(111) terrace sites as well as on structural defects such as kinks, vacancies, and step edges was modeled using theory with and without van der Waals interactions to investigate the bonding character at each site. The trends in theoretical adsorption energy, geometry of the adsorbate, and bonding character at different defect sites complements and deepens our understanding of the experimental TPD spectra. Therefore, fundamental insights obtained from this study provide a pathway for development of commercially viable, effective catalysts for ethanol oxidation reactions.

Electron Microscopy of Zeolite Structural Evolution During and After Growth Andrew C. Meng¹, Ke-Bin Low², Junmei Wei², Nicholas Favate², Thomas Gegan², Ivan Petrovic² and Eric A. Stach¹; ¹University of Pennsylvania, United States; ²BASF Corporation, United States

The fluid catalytic cracking process with zeolite catalysts is used to produce a large fraction of the world’s gasoline. Although the process has been known for many years, the field remains very active as interest in the mechanism and applications involving new chemical feedstocks such as shale gas pose new challenges. In-situ electron microscopy offers new insights into the structural evolution of zeolites during chemical processes such as growth or steaming, which is used to convert the material to the catalytically active phase. We report the synthesis and characterization of a model FCC material during the different stages of growth using ex-situ scanning and transmission electron microscopy. Based on different growth conditions, zeolite-Y, which is the precursor to the active catalytic phase, defective zeolite phases, which are catalytically inactive, or other phases can be favored. Finally, we report the behavior of the different zeolites under intermediate temperature steaming in situ in an environmental scanning electron microscope. The results are promising towards method development for in-situ observation of zeolite structure evolution in both scanning and transmission electron microscopy for fundamental understanding of how nucleation and growth occur in an isolated, model system and how the structure evolves under high temperatures and pressures.

Selective Oxidation and Chemisorption of CO on Li₂MnO₃—A New Promising Material for H₂ Purification from Syngas Mixtures Carlos Hernández-Fontes and Heriberto Pfeiffer; Universidad Nacional Autónoma de México, Mexico

Fuel cell technologies (FC) make hydrogen (H₂) a promising fuel to produce electrical energy due to their great efficiency and minimal pollution emission. However, one problem is to optimize pure H₂ production. On account of 96% global H₂ production is performed by steam reforming (SR) (76% from natural gas), H₂ purification process must be improved in SR plants to achieve a short-term hydrogen economy. In order to avoid a cooling process from SR gas in a purification step, materials with high thermal stability and selective oxidation and chemisorption capability of CO must be developed. This work summarizes Li₂MnO₃ behavior as a selective CO oxidizing-captor to purify H₂ from SR gas. Li₂MnO₃ was synthetized by the solid-state method and characterized by XRD, N₂ adsorption-desorption and SEM. To evaluate CO chemisorption process in Li₂MnO₃, dynamic thermal analyses were performed using different gas flow compositions (CO, CO-O₂, CO₂, CO₂-O₂ and N₂). These experiments showed that CO chemisorption is only produced in oxygen absence. Furthermore, CO₂ chemisorption was not evidenced at any CO₂ partial pressure. Based on these results, isothermal experiments were performed between 550 and 700 °C into a CO atmosphere (N₂ balanced). The isothermal products were identified as Li₂CO₃ and MnO by XRD. It must be pointed out that at temperatures lower than 625 °C LiMnO₂ was identified as well. These results demonstrated that CO is chemisorbed as Li₂CO₃. It may be produced by a surface CO oxidation step (into CO₂) that involves the evolution from Li₂MnO₃ (Mn⁴⁺) into
LiMnO$_2$ (Mn$^{3+}$) or even into MnO (Mn$^{2+}$). An interesting ~2% weight loss was observed at the beginning of all the isotherms (before weight gain started). In order to elucidate the process associated to this, several thermogravimetric and catalytic experiments were carried out. Their solid and gas products were identified by XRD and mass spectrometry, respectively. The catalytic experiments showed CO$_2$ production at the same temperature range where Li$_2$MnO$_3$ weight loss take place. Moreover, after this ~2% weight loss occurs and before weight gain process would perform, the material composition was analyzed by XRD and ATR-FTIR, where Li$_2$MnO$_3$ was the only crystalline phase identified in addition to carbonates. Based on these results, it may be pointed out that an oxidation step is performed at the material surface to oxidize CO into CO$_2$, where some part of it is chemisorbed as Li$_2$CO$_3$, while the rest is released from the material’s surface. In addition, lithium diffusion from bulk to surface in Li$_2$MnO$_3$ may be triggered by oxygen vacancies formation (at surface) due to CO oxidation. This could explain wherefore chemisorption process was not performed in CO$_2$ atmosphere or in oxygen presence. To further analyze Li$_2$MnO$_3$, dynamical and isothermal experiments were performed varying the CO-CO$_2$ partial pressures. These results demonstrated that if CO$_2$ is involved into the gas flow composition, the CO oxidation-capture process is displaced to higher temperatures and the total weight gain decreases as consequence of less superficial oxygen vacancies formation. Moreover, kinetic constants were calculated using the Jander-Zhang diffusion model, which can be related to $\Delta H^\circ$ by the Eyring equation. Results showed that, in addition of CO$_2$, kinetics diffusion become slower than those obtained into a CO atmosphere, although the $\Delta H^\circ$ values decreased. Finally, Li$_2$MnO$_3$ was dynamical tested on H$_2$ and H$_2$-CO atmospheres (Ar balanced). These experiments showed a preference oxidation of CO over H$_2$. Nevertheless, ~10% of hydrogen was oxidized into water while CO was chemisorbed.

**Evaluation of Boron Doped Reduced Graphene Oxide as IrO$_2$ Support for Efficient Oxygen Evolution Reaction**

Prerna Joshi$^1$, Hsin-Hui Huang$^2$, Masanori Hara$^1$ and Masamichi Yoshimura$^1$; $^1$Toyota Technological Institute, Japan; $^2$Japan Fine Ceramics Center, Japan

With depleting fossil fuel reserves and increasing environmental problems, novel strategies have been developed based on renewable energies. A major source of renewable energy is water, which can produce hydrogen energy in large amounts. Electrochemical water splitting is an excellent way to produce hydrogen as an energy source. For generation of hydrogen at a specific rate, under ideal conditions, 1.23 V must be supplied to the water electrolyzers to allow hydrogen evolution reaction (HER) and oxygen evolution reaction (OER) in a feasible manner. In practice, OER is a complex reaction with slow kinetics and low overpotential, hence, precious metal catalysts such as iridium and ruthenium oxides (IrO$_2$, RuO$_2$) are used to reduce the overpotential for OER$^1$. However, their high cost and low natural abundance limit their extensive commercialization. One of the plausible approach can be the reduction of metal loading with the use of conductive support. For metal catalysts, the reduction in size of the catalysts (formation of nanoparticles (nps)) can help in increasing active surface area. Further, for conducting support, doped graphene can be used as a support because it can tune the electronic structure of catalysts to improve specific activity. In the current research, we have studied the electrochemical activity of IrO$_2$ nps catalyst supported on heteroatom-doped reduced graphene oxide (rGO) as the carbon support. Along with alteration of the electronic structure of the IrO$_2$ nps, heteroatom-doping of graphene$^2$ also promotes ion diffusion at the electrode-electrolyte interface, improving the overall performance of the catalyst.

Graphene oxide (GO) was prepared from synthetic graphite (Sigma Aldrich) by modified Hummers’ method$^3$. For boron doping, boric anhydride (B$_2$O$_3$, BA) was used as the precursor. Briefly, BA and GO were mixed together and ultrasonicated in water for 1 hour. The mixture was freeze dried and the obtained powder was pyrolysed at 1000 °C for 60 min in N$_2$ atmosphere. The pyrolysed sample was washed with boiling water and ethanol to yield boron-doped rGO (B-rGO). As the second step, IrO$_2$ nps were decorated onto B-rGO by hydrothermal synthesis at 150 °C for 4 h using H$_2$IrCl$_6$ as the Ir precursor. The synthesized materials were characterized for its chemical composition, morphology and electrocatalytic activity using various analytical techniques such as X-ray photoelectron spectroscopy (XPS), transmission electron microscopy (TEM), energy dispersive X-ray spectroscopy (EDX), cyclic voltammetry (CV) and linear sweep voltammetry (LSV).

XPS analysis of the synthesized catalyst, IrO$_2$-B-rGO revealed the presence of all constituent elements at their respective binding energies. The XPS spectra were deconvoluted to obtain the types of constituent C and B. Ir 4f peaks for IrO$_2$-B-rGO were obtained at lower binding energies than the unsupported IrO$_2$ powder confirming the change in electronic states of Ir due to boron doping. Further, EDX analysis indicated B to be present in ~2.0 wt% and Ir in 3.3, 7.1 and 19.6 wt%. TEM results exhibited the uniform dispersion of IrO$_2$ over the wrinkled B-rGO sheets with an average particle diameter of 1.5 nm. Electrochemical analysis in 0.5 M H$_2$SO$_4$ with Ir loading of ~140 µg cm$^{-2}$ on glassy carbon (GC) electrode showed that the onset potential was 1.41 V vs RHE for IrO$_2$-B-rGO which was ~90 mV lower than that of IrO$_2$ decorated on undoped rGO.
Despite the low Ir content, higher current density was obtained for B-doped catalyst as compared to the IrO2-rGO. Increase in current density for B-doped catalyst is attributed to charge redistribution in graphene lattice which alters the electronic states for Ir and provides additional active centres for catalysis.

We report an investigation of potential kinetic limitations to the rate of hydrogenation of magnesium diboride. The metals Pd, Fe and Ti, known to be proficient at H-H bond dissociation, were introduced into MgB2 by ball milling. Pd and Fe are directly introduced as crystalline metals, whereas Ti metal was introduced via the reaction between TiF3 and MgB2 to form Ti metal and MgF2. XRD, FTIR, XAS and TEM data show that the additives persist as metals in the MgB2 solid, free from significant oxidation of the additive itself (i.e. TiO2, Fe2O3, PdO) as well oxidation of the MgB2 material (i.e. no MgO, B2O3). The Pd in the MgB2 material consists of two morphological forms: Pd particles of a size ~ 2 – 25 nm diameter with a d-spacing essentially the same as bulk Pd, as well as a highly dispersed Pd component within the MgB2 matrix. The Fe additive decorates the MgB2 particles as small particles with sizes ranging from ~ 11 – 34 nm diameter with comparatively little atomic-scale dispersal of the Fe additive. TiF3 reacts with MgB2 to form Ti metal and MgF2, with the Ti and the F smeared out within the MgB2 base solid. Sieverts-acquired MgB2 hydrogenation rates for the Pd, Fe and Ti modified MgB2 are higher than for commercial MgB2, but the improvement is very modest, about a factor of two at most. H-D exchange studies were conducted to confirm H-H bond breaking in these materials. The data shows that H-H bond breaking is slowest for the bulk MgB2 material, but much faster for the Fe, Pd and Ti modified samples for which H-H bond breaking reaches equilibrium in about 20 minutes. This work shows that H-H bond dissociation is not limiting the rate of hydrogenation of MgB2 because extensive H-H bond breaking is already occurring after only 20 minutes whereas the initial hydrogenation to ~0.8 weight percent hydrogen takes about 100 hours. The results also show that surface diffusion cannot be limiting the MgB2 hydrogenation rate because surface diffusion, a requirement for HD generation, is occurring very rapidly. We speculate that it is the intrinsic stability of the B-B extended hexagonal ring structure in MgB2 that hinders the hydrogenation of this material. This supposition was supported by B K-edge TFY XAS measurements of the materials, which showed spectroscopically that the B-B ring was intact in these systems throughout most of the material.

*Graphene- and CNT- Hybrids with Metallic and Metalorganic Framework Nanostructures as Reversible and Sustainable H2 Storage Media* Suresh Kuppireddy, Anish Varghese and Georgios Karanikolos; Khalifa University, United Arab Emirates

H2 storage constitutes a barrier in decarbonizing the energy economy and expanding H2 utilization into large scale. Design of novel nanostructured materials is currently a high research priority toward a permanent solution to this challenging problem, and development of safe, dense, solid state media to substitute cryogenic storage. In this work, we present in-situ grown hybrid nanostructures based on graphene and CNTs supporting metalorganic framework (MOF) and metallic (e.g. Mg) clusters and nanocrystallites exhibiting controlled microstructure, porosity, and interface characteristics. The resulting nanohybrids exhibit increased storage capacity, while the stability of the active sites is preserved through the presence and controlled coating by the graphitic layers.

*Metal-Organic Framework (MOF) Derived Cobalt Oxide and Cobalt Sulfide for Efficient Electrocatalysts in Water Splitting* Jonghyun Choi, Tenzin Insgel, Pawan Kahol and Ram K. Gupta; Pittsburg State University, United States

Increasing global population and advancement in energy-dependent devices have caused increased use of energy in consumer and industrial appliances, electronic devices, and automobiles creating an urgent need for clean and renewable energy sources. Electrochemical water-splitting is one of the greenest ways to generate clean and high-performance fuel. Water-splitting generates hydrogen and oxygen gases. The generated hydrogen gas can be used as fuel whereas evolved oxygen gas can be used in metal-air batteries or released in the atmosphere as a clean gas. The electrocatalytic properties of most of the materials for water splitting depend upon several factors such as morphology, phase purity, defects, etc. We have synthesized...
metal-organic framework (MOF) derived cobalt oxide and cobalt sulfide using a facile method for their application in water-splitting as electrocatalysts. 2-methyl imidazole and cobalt nitrate were used for the synthesis of MOF-derived cobalt oxide and MOF-derived cobalt sulfide electrodes. The electrode with MOF-derived cobalt oxide was synthesized via a solvothermal process, while the electrode with MOF-derived cobalt sulfide was prepared through sulfurization using a hydrothermal process. The structural and electrochemical properties of these films were studied in detail. The electrocatalytic activities of the MOF-derived cobalt oxide and sulfide were studied in 1M KOH solution for oxygen evolution and hydrogen evolution reactions. MOF-derived cobalt oxide showed overpotential of 375 mV and 224 mV to achieve a current density of 10 mA/cm² for oxygen and hydrogen evolution processes, respectively. A significant improvement in electrocatalytic properties was observed with the electrode after sulfurization producing MOF-derived cobalt sulfide. MOF-derived cobalt sulfide displayed overpotential of 278 mV and 220 mV at 10 mA/cm² for oxygen and hydrogen evolution processes, respectively. Our results suggest that a facile method of sulfurization of the MOF-derived compound is a way to achieve high electrocatalytic activities for oxygen and hydrogen evolution reactions in the water-splitting process.

Chloe Groome and Regina Ragan; University of California, Irvine, United States

Single atom catalysis (SAC) represents a promising design for the next generation of robust catalysts. These systems, which are commonly single metal atoms stabilized on carbonaceous materials, maximize catalytic performance while simultaneously minimizing the use of expensive and scarce platinum-group metals (PGM). While it is accepted that the molecular environment of a SAC is of crucial consequence to the chemical activity, the exact catalytic sites and chemical pathways responsible have been a matter of some controversy. For industrially practical non-PGM SAC, optimizing the defect environment stabilizing the single metal atom is necessary for enhanced performance. We will present work using a first principles approach for materials discovery to investigate three less studied earth abundant transition metals (V, Mo, Ta) stabilized on single vacancy and pyridinic N-doped defect moieties on graphene substrates to understand the role of electronic transfer, spin state and steric effects on SAC. Our results of all investigated metals demonstrate single atom stability on graphene substrates with both defect moieties. By modeling carbon monoxide oxidation, a common benchmark reaction, facilitated by these defect stabilized SAC with climbing image-nudged elastic band (CI-NEB) calculations, we find that all activation energies for transition metals stabilized on the pyridinic N-doped graphene surface defect are ~0.8 eV or lower. These low activation energy barriers suggest that the CO oxidation reaction would proceed at room temperature with pyridinic N-dopants present in the defect environment. The CI-NEB calculations further illustrate that SAC of Ta and V on pyridinic N doped graphene significantly decrease the activation energy of CO oxidation by 27% and 44%, respectively. Bader charge analysis reveals that the electronic charge transfer is surprisingly similar across the two defect moieties investigated for all four earth-abundant transition metals. However, the pyridinic N-dopant introduces an additional magnetic moment of 0.53 μB on average. Plotting the density of states of CI-NEB transition states shows spin destabilization of O2 peaks near the Fermi level, suggesting that these imparted magnetic moments could be destabilizing the O2 bond and hence lowering activation energies for CO oxidation in some cases. We will present results suggesting that magnetic moment could play a significant role in enhancing catalytic performance of SAC on nitrogen doped graphene substrates, as well as more traditionally understood mechanisms such as charge transfer and steric effects. Computational design of materials is used to define processing conditions for three-dimensional porous graphene structures. Fabrication and characterization of macroscopic graphene structures with high surface area and architectures to facilitate mass transport will also be presented.

S.EN11.07.15
3D Interface-Engineered Transition Metal Oxide/Carbon Hybrid Structures for Efficient Bifunctional Oxygen Electrocatalysis in Alkaline and Acidic Environments

Simranjit K. Grewal1,2,3, Angela Andrade-Macedo1, Zi Qi Liu4 and Dr. Min-Hwan Lee1,2,3; 1University of California, Merced, United States; 2NASA, United States; 3Lawrence Berkeley National Laboratory, United States

Use of regenerative fuel cells (RFC) requires bifunctionality in oxygen electrocatalysis of oxygen reduction reaction (ORR) and oxygen evolution reaction (OER) to decrease weight and cost for efficient energy conversion. Many RFC based technologies have used noble metals such as Pt and its alloys (Pt/Ir or Pt/Ru) due to their efficient catalytic activity, selectivity and stability in harsh environments. However, their susceptibility to fast degradation during operation, as a result of catalyst agglomeration and poisoning, has driven research to find alternatives [1]. Non-precious transition metal oxides (TMO) including Fe3O4, MnO2, and Co3O4 have attracted significant attention as a potential candidates [2]. We utilized a composite structure where TiO2, ZrO2, or CeO2 are deposited onto conductive 3D carbon structure such as graphene oxide (GO), metal-organic frameworks (MOFs) or a combination of activated carbon (AC) with GO/MOFs. The
The use of carbon structures is to leverage their high surface area and excellent electronic conductivity. However, GO contains oxygen-based functional groups on the edges and wrinkles that provides an anchor for nanoparticle binding while its basal plane stays relatively non-reactive. To incur a catalytically active sites between the metal oxides and carbon, we functionalize the basal surface of carbon using phosphoric, hydrobromic and/or oxalic acids. After such treatment, various types of carbon structures were hydrothermally reacted with metal precursors (Ce(NO$_3$)$_3$ or ZrOCl$_2$) or nanoparticles (P25). For MOF structures, due their susceptibility towards degradation after the common step of pyrolysis, a thin film of metal oxides are used. However, to adhere the metal oxides properly onto the MOF, we leverage acid treatment similar to our treatment of GO.

The hydroxylated CeO$_2$/GO hybrids showed the best ORR and OER performance in both alkaline (0.1 M KOH) and acidic media (0.5 M H$_2$SO$_4$), in terms of onset/half-wave potential, electron transfer number, and current density (electrochemical performances) when comparing to the performance of Pt/C (for ORR) and IrO$_2$ (for OER). From a series of material/experimental analyses, a strong tethering of metal oxides upon the basal plane of GO prohibits restacking, and that the particle-carbon interfaces (as oppose to the particle or GO itself) dictates the performance and reaction route, as indicated in density functional theory calculations. In addition, a hybrid catalyst where TiO$_2$ nanodots are uniformly anchored on phosphorylated MOF by atomic layer deposition (ALD) showed an even better ORR and OER performance in 0.1 M KOH when compared the aforementioned CeO$_2$/GO hybrid. Materials characterization emphasizes a strong adhesion of metal oxides upon MOF structures, thus providing ample surface interactions for favorable reaction route is important. In addition, an activation of catalytic sites can be realized by a proper engineering of interfaces in each hybrid systems. Finally, we present a facile route of improving operational durability of TMO/carbon hybrids both in alkaline and acidic media: interfacing with an activated carbon after a proper acid treatment.

This project was funded by NASA Advanced STEM Training and Research (ASTAR) Fellowship.

*Alkylphosphine as a Ligand for Shape-Controlled Synthesis of Metal Nanostructures*  
Shutang Chen and Gugang Chen; Honda Research Institute USA Inc., United States

Metal nanoparticles with high index facets and controllable shape have demonstrated excellent catalytic performance because of their unique surface chemistry. Generally, the selection of proper ligand plays an important role for the shape-control of nanoparticles. Here, different kinds of alkylphosphines with high temperature solution reduction method are adopted to synthesize metal nanostructures. With increasing chain length of alkylphosphines, different morphologies of copper nanoparticles were synthesized in a hydrophobic system, such as nanocubes, tetrahedron nanoparticles, nanowires, and nanosheets. All these copper nanostructures demonstrated excellent catalytic performance and selectivity to carbon dioxide reduction reaction. Such simple strategy is also extended to the design of other metal nanoparticles for their potential applications in catalysis, sensor, and electronics.

*Studies in Pulsed Laser Deposition of FeWO$_4$ Thin Films*  
Chandler W. Cotton, Braden L. Spiller, Sumner B. Harris and Renato P. Camata; The University of Alabama at Birmingham, United States

Complex metal oxides such as metal tungstates, niobates, cuprates, and vanadates, have long been considered as promising absorber materials for photoelectrochemical (PEC) cells. In particular, the recent demonstration of self-passivated bismuth (Bi)-containing FeWO$_4$ thin films with suitable photovoltage for coupling to a photocathode, suggests significant potential for FeWO$_4$-based photoanodes. In this study, we explore the growth of FeWO$_4$ thin films with the laser plasma control afforded by pulsed laser deposition (PLD). In PLD, thin film growth is mediated by a laser-generated plasma that exhibits rich chemistry and spatiotemporal phenomena. The chemical diversity, variety of gas backgrounds, and shockwave characteristics of the laser plume are highly conducive to kinetic control of materials synthesis. The laser-induced plasma allows wide tunability of plasma parameters. This includes control of the strong gradients of density and temperature that cause deviations from local thermodynamic equilibrium. For all these reasons, synthesis of Bi-containing FeWO$_4$ by PLD
may allow tuning of conductivity, exploration of additional co-doping with other metals, and control of defect concentrations. Using planar and cylindrical Langmuir probes, we have measured the ion density, kinetic energy distribution, and electron temperature in Fe-, W-, and O-rich plumes produced by KrF excimer laser ablation of solid targets that are suitable for growth of FeWO₄. These plasma measurements during PLD conditions show that the plasma density can be adjusted over several orders of magnitude in the 10¹⁸-10²⁰ m⁻³ range, consistent with a correspondingly broad range of deposition rates. Changes in target composition have significant impact in the kinetic energy distribution of ions in the plume. Oxygen-rich targets ablated with a typical 1.4 J/cm² laser fluence and 3.0 mm² spot area, lead to plasmas with wide ion kinetic energy distributions with high fractions of ions in the 80-90 eV range. Similar irradiation conditions for W-rich targets result in plumes dominated by kinetic energies below 5 eV. Thin films grown with changes in laser plasma conditions between these extremes show measurable variation in stoichiometry. We will discuss x-ray photoelectron results on these films that allow correlating changes in W oxidation state with plasma plume composition and kinetic energy. Thin film crystal quality, as measured by x-ray diffraction, will also be discussed in relationship to film stoichiometry and laser plasma characteristics during growth.

**Luminescent Solar Concentrators Based on Self-Contained Silicon Quantum Dots Films for Photovoltaic Applications**

Rosendo Lopez-Delgado¹, Alejandra J. Cordova-Rubio², Roberto C. Carrillo-Torres² and Mario E. Alvarez-Ramos³; ¹Cátedras Conacyt - Universidad de Sonora, Mexico; ²Universidad de Sonora, Mexico

The incorporation of energy harvesting systems into architectural elements of buildings is gaining attention as a new possible renewable energy technology for the production of electricity. Luminescent solar concentrators (LSC) represent a promising and cost-effective complement to existing semiconductor photovoltaic (PV) technologies that could be employed as semitransparent windows to contribute to the building’s energy consumption. Typically, an LSC consists of an optical waveguide that collects sunlight from a large-area window and concentrates the emission on the smaller-area edges. The emission is obtained from luminescent materials such as organic dyes, rare earth ions or semiconductor quantum dots in the LSC that absorb the sunlight and, by a stokes shift, emit photons at wavelengths that are better suited for absorption by the PV devices coupled at the edges of the LSC, reducing the costs of photovoltaic power generation.

Organic dyes have been the most commonly used luminophores for LSC applications mainly due to their high quantum yield and in some cases its low degradation rate, however, organic dyes no only tend to absorb and convert only a relatively small region of the solar spectrum, but also, they present a large spectral overlap between the absorption and emission regions, which increases the reabsorption losses and prevents the viability of fabrication of large-scale efficient devices. On the other hand, colloidal semiconductor nanoparticles or quantum dots (QDs) exhibit very attractive optical properties and have attracted a lot of attention as potential luminophores for LSC applications. Colloidal QDs are promising candidates since their properties mainly arise from the materials they are made, their size and their surface passivation. Also, QDs can be engineered to manipulate their energy bandgap and the stokes shift values to suppress effectively the reabsorption losses.

Here, we report the fabrication of one-pot synthesized and self-contained photoluminescent films based on silicon quantum dots (SiQDs) and its employment on luminescent solar concentrators (SiQDLSC). Silicon quantum dots were synthesized from reduction of (3-aminopropyl) triethoxysilane (APTES) by sodium ascorbate. Besides the reduction of APTES into silicon quantum dots, a silicate matrix host is obtained, which is further employed as the support for the photoluminescent film in the fabrication of the LSC. The size of the synthesized SiQDs were measured by dynamic light scattering and electron microscopy techniques obtaining an average size of 3 nm. Both SiQDs and SiQDLSCs transmittance, absorbance and photoluminescent properties were characterized. The synthesized colloidal SiQDs exhibit an abrupt increase of optical absorption below 425nm extending to the ultraviolet region while emitting photons in a broad band extending from 450 to 600 nm with maximum intensity at 525 nm. SiQDLSC were fabricated in two sets of different dimensions: 1) 50x50x3mm and 2) 25x25x1mm. Set 1 shown a transmittance above 85% while set 2 exhibited above 90% transmittance over the visible region of the electromagnetic spectrum. Both sets shown the absorbance characteristics of the SiQDs decreasing the transmittance (increasing the absorbance) below 425 nm. Photoluminescent properties of the SiQDLSC were measured at the edges of the devices, obtaining broad bands of emission that were slightly blue shifted to around 500nm due to the expected oxidation of the SiQDs surfaces. However, the fabricated SiQDLSC preserve the desired stokes shift that is necessary to prevent reabsorption losses. These results demonstrate a feasible and very attractive method of fabrication of SiQD-based luminescent solar concentrators that presents good transmittance as well as the photoluminescent stokes shift effects desired for their incorporation as PV windows.

Electrolyte Design for Micro-Sized Si Anodes Chunsheng Wang; University of Maryland, United States

Li-ion batteries are the critical enabling technology for the portable devices, electric vehicles (EV), and renewable energy. However, the safety and energy density of current Li-ion batteries still need to be improved to satisfy the requirements for these applications. We systematically investigated the electrochemical performance of the nonflamable fluorinated organic electrolytes and solid state electrolytes for high energy Li and Li-ion batteries. The Li dendrite formation in liquid electrolyte and solid state Li metal batteries was proposed and validated. The critical issues of these safe electrolytes are also discussed.

7:45 PM *S.EN12.05.04
The Silicon Electrolyte Interface Stabilization Project Anthony Burrell; National Renewable Energy Laboratory, United States

Silicon is a viable alternative to graphitic carbon as an electrode in lithium-ion cells and can theoretically store >3,500 mAh/g. However, lifetime problems have been observed that severely limit its use in practical systems. The major issues appear to involve the stability of the electrolyte and the uncertainty associated with the formation of a stable solid electrolyte interphase (SEI) at the electrode. Recently, calendar-life studies have indicated that the SEI may not be stable even under conditions where the cell is supposedly static. Clearly, a more foundational understanding of the nature of the silicon/electrolyte interface is required if we are to solve these complex stability issues. A multi-lab consortium has been formed to address a critical barrier in implementing a new class of materials used in lithium-ion batteries that will allow for smaller, cheaper, and better performing batteries for electric-drive vehicles. This consortium, named the Silicon Electrolyte Interface Stabilization (SEISta) project, was formed to focus on overcoming the barrier to using such anode materials. Five national laboratories are involved: the National Renewable Energy Laboratory (NREL), Argonne National Laboratory (ANL), Lawrence Berkeley National Laboratory (LBNL), Oak Ridge National Laboratory (ORNL), and Sandia National Laboratories (SNL). The SEISta project was specifically developed to tackle the foundational understanding of the formation and evolution of the solid-electrolyte interphase on silicon. This project will have a primary goal of understanding the reactivity of the silicon and lithiated silicon interface with the electrolyte in lithium-ion systems. The overall objective for
SEISta is to understand the nature and evolution of the SEI on silicon anodes. Several issues must be addressed to enable progress in this area. Materials Standardization is critical to this project and deployment of standardized samples and experimental procedures across the team is a foundation of the project. Full characterization of any new sample that is to be used for SEI studies to ensure reproducibility and full understanding of the material. The materials standardization and model compounds will enable the researchers to systematically investigate the formation of the solid-electrode interphase using a wide variety of the spectroscopy techniques—from different optical, microscopy, and electrochemistry—to determine how the SEI forms based on the nature of the silicon surface, and how it evolves over time. This presentation will detail recent advances that the SEISta team has made to the understanding of the SEI on silicon.

Unbiased Photoelectrochemical Water Splitting Cell Exceeding >9% Solar-to-Hydrogen Conversion Efficiency with Surface Band-Modified Cu(In,Ga)(S,Se)2 Photocathode and Halide Perovskite Solar Cell Bonhyeong Koo and Byungha Shin; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Efforts to convert sustainable solar energy into a storable form of chemical fuels have generated much interest. Among various technologies, photoelectrochemical (PEC) water splitting, which is capable of producing hydrogen fuel in an environmentally friendly manner, is being intensively studied. Because PEC water splitting has an operating principle similar to that of photovoltaic devices, a good photovoltaic material must be a good candidate for a photoelectrode of PEC solar water splitting. In this talk, I will present the recent research efforts of our laboratory to produce highly efficient and stable photoelectrodes, Cu(In,Ga)Se2 (CIGS)-based heterojunction. First, I will discuss the application of functional overlayers acting as a protective layer and reduced graphene oxide as a catalyst binder to improve long-term stability of the photocathodes.[1], [2] Next, I will present the enhancement of PEC performance of CIGS photocathodes by introducing a greater degree of surface band bending with ZnS/CdS double buffer layers. Finally, we demonstrate a bias-free water splitting PEC cell consisting of the surface band-modified CIGS photocathode with the ZnS/CdS double buffer and a halide perovskite solar cell, and an IrOx anode, with a STH efficiency over 9 %.

5:15 AM S.EN12.01.03
Ionic Pumping and Salt-Rejection by Polyelectrolyte Hydrogel for Continuous Solar Desalination Jian Zeng and Renkun Chen; University of California, San Diego, United States
Efficient water pumping and selective salt rejection is highly desirable for solar or thermally driven seawater desalination, but its realization has been challenging with the typical capillary pumping mechanism. Here we proposed and demonstrated a new liquid supply mechanism, ionic pumping effect, realized using a polyelectrolyte hydrogel foam (PHF) containing poly(sodium acrylate) [P(SA)] embedded in a microporous carbon foam (CF). The PHF simultaneously possesses high osmotic pressure for efficient liquid transport and strong salt-rejection effect. The PHF was able to sustain high water flux of ~ 24 liter per m² per hour (LMH), comparable to the evaporative flux under 15 suns, and a salt rejection ratio over 80%. Compared to the porous carbon foam without the polyelectrolyte hydrogel, i.e., with only the capillary pumping effect, the PHF yielded a 42.4% higher evaporative flux, at ~ 1.6 LMH with DI-water and ~ 1.3 LMH with simulated seawater due to the more efficient ionic liquid pumping. More importantly, thanks to the strong salt-rejection effect, the PHF showed a continuous and stable solar-driven desalination flux of ~ 1.3 LMH under one-sun over 288 hours consecutively using real seawater without salt clogging in the pore and sediments on the surface, which was not achieved before. The successful demonstration of both efficient ionic pumping and strong salt rejection effects makes the PHF an attractive platform for sustainable solar-driven desalination.

5:25 AM S.EN12.01.05
Establishing Protocols for Diagnosing Defects in Photoelectrodes Using Structure-Property Analysis Rodney Smith and Yutong Liu; University of Waterloo, Canada

An inability to routinely identify, quantify and control specific structural defects in photoelectrodes leads to inconsistencies in observed photoelectrocatalytic behavior that inhibit material development. Photophysical analysis of key electron transfer processes in hematite photoanodes, for example, have provided insight into fundamental behavior and properties but have not resolved the persistent variability photoelectrocatalytic performance values reported across the literature. We aim to address such issues by developing simple methodologies to routinely identify and quantify structural defects in photoelectrodes. We initiate this work with structure-property analyses on a series of hematite photoanodes prepared by annealing lepidocrocite films under varied conditions. Raman spectroscopy reveals the presence of a formally Raman inactive vibrational mode in Raman spectra for all hematite samples. The intensity of this feature is dependent on annealing conditions and protocols and is found to correlate with behavioral descriptors extracted from photoelectrochemical, Raman and UV-visible spectroscopic datasets. Specifically, the intensity of this Raman vibrational mode correlates to the measured photocurrent density, to the position of the semiconductor band edges, and to the location of intraband trap states. Observation of such a formally Raman inactive vibration signifies a lattice distortion, and the observed correlations reveal a systematic change in the magnitude of the distortion. Analysis of the full Raman spectrum, X-ray diffraction patterns, and the synthetic conditions lead us to conclude that the lattice distortion is caused by iron vacancies that are themselves induced by the trapping of protons within the crystal lattice. These results provide the foundation for a rapid diagnostic protocol to identify and quantify specific structural defects to guide the optimization of fabrication protocols for photoelectrodes.

5:00 AM S.EN12.02.01
Effects of N-Doped Graphene and Carbon Black as Conductive Additives on Sulfur Cathodes in Lithium-Sulfur Batteries Xiaoxiao Han, Jiyu Cai, Xin Wang, Yongqiang Liu and Xiangbo Meng; University of Arkansas, United States

Lithium-sulfur (Li-S) batteries hold great potential given their theoretic energy density of 2600 Wh/kg, low cost, and S abundance. However, Li-S batteries are currently being retarded from commercialization due to several severe issues. On the S cathode side, S is highly insulating electrically and ionically. Thus, conductive materials are essential to maintain S cathodes accessible to electrons and ions. To date, many carbon materials such as carbon black, carbon nanotubes and graphene are widely used as conductive materials in various battery systems. Nevertheless, there lacks a comparative study on identifying their effects on the electrochemical properties of the S cathode. Knowing that optimizing the configuration and composition of the carbon conductive materials is the most inexpensive and simple way to improve the electrochemical performance of Li-S batteries, we recently conducted a fundamental study on the effects of a carbon black (Super P, SP) and a nitrogen-doped graphene nanosheets (NGS) on S cathodes. Experimental results showed that the S@SP (SSP) cathode and
S@NGS (SNGS) cathode have different structures, interactions with the active materials and electrochemical impedance spectra, and thus exhibited different electrochemical properties and performance. For SSP, its initial specific capacity is as twice as that of SNGS but fade rapidly. In contrast, SNGS exhibits better capacity retention and rate cyclability. We also found that by simply mixing the SP and NGS mechanically, the S@SP@NGS (SSP/NGS) cathode shows both good capacity and cyclability. The fundamental mechanisms of these phenomena are discussed and a charge transfer model for these electrodes is proposed.

5:10 AM S.EN12.02.04
Influence of Structural Changes on Sodium Storage Mechanism and Electrochemical Performance in Hard Carbons for Sodium-Ion Batteries
Hande Alptekin1, Heather Au1, Anders Jensen2, Alan Drew2 and Magdalena Titirici1; 1Imperial College London, United Kingdom; 2Queen Mary University of London, United Kingdom

Recently, Sodium-ion batteries (NIBs) have emerged as an economical alternative to lithium-ion batteries (LIBs) for large scale energy storage applications and therefore the successful implementation of renewable energy technologies. Developing optimum negative electrodes is of crucial importance to improve the energy density and stability of NIBs. Hard carbons with tunable morphologies are preferred due to their low cost, operating voltage (high energy density) and high reversible capacities.

Here, in our research work, a series of hard carbon anode materials prepared via the Hydrothermal Carbonisation (HTC) followed by high-temperature carbonisation. Applying various carbonization temperatures, templating agents and dopants results in materials with different pore morphologies, functional groups and graphitisation degrees which were characterised by HRTEM, XPS, Raman, gas adsorption, SAXS/WAXS and Total Neutron Scattering. The influence of material morphology and microstructural change during the electrochemical cycling were investigated by in-situ Electrochemical Dilatometry. By tuning the degree of graphitic regions to disordered domains, capacity obtained from slope and plateau regions of the discharge curve adjusted and a capacity up to 300 mAh/g with a very good initial Coulombic efficiency of 83% was achieved. The degree of graphitisation, pore structure, particle size and defects were found to have a significant effect on the storage mechanism and electrochemical performance of the batteries. Being able to design and modify the electrode structure and chemistry allowing us to move closer to electrochemically optimized, high performance and efficient Na-ion batteries.

5:20 AM S.EN12.02.05
A New Cathode Material for Na-Ion Batteries Made Exclusively from Abundant Elements
Arnaud J. Perez, Jacinthe Gamon, Leanne A. Jones, Rhun Morris, Luke Daniels, Tim Veal, Laurence Hardwick, Dyer Matthew, John Claridge and Matthew Rosseinsky; University of Liverpool, United Kingdom

The worldwide development of Li-ion batteries has led to a revolution in the field of consumer electronics and completely transformed the way we access information. It is currently the leading technology for the technological transition towards electricity-powered transportation and large-scale energy storage capabilities. However, it is still unclear whether the cost of Li-ion batteries will meet this challenge, as they contain non-abundant elements such as lithium, nickel, cobalt, which price is bound to vary with market and political decisions. Developing Na-ion batteries as a cheaper alternative is therefore a promising route, as it would help diversifying technology for grid or local storage applications that do not require high energy density.

Recent work on a new anti-perovskite cathode Li2FeOS1,2 has shown that oxysulfides represent a promising family of material. Oxysulfides have long been overlooked in the literature due to their complex synthesis conditions and lower voltage compared to oxides. However, they can deliver high capacities using abundant elements. We prepared a new oxysulfide material with a crystallographic structure yet unexplored in cathode materials for Li and Na-ion batteries, by a simple mechanosynthesis method in dry air, and studied its electrochemical properties. Interestingly, the material becomes amorphous upon its initial oxidation but still delivers a reversible capacity of 160 mAh/g between 1.5 and 3 V vs Na+/Na and a good capacity retention upon cycling. To understand the evolution of the material during (de)sodiation, we combined several techniques (X-ray diffraction, X-ray absorption and X-ray photoemission spectroscopies) and obtained insight on the local structure evolution and oxidation/reduction of the different elements in the material. Finally, full Na-ion cells were assembled using hard carbon anodes, showing the possibility to prepare Na-ion batteries with abundant and cheap materials. Oxysulfides, and more generally multiple anion materials, give us an opportunity to control the energy storage properties of electrode materials without relying on non-abundant transition metals.

Synergistic Engineering of Defects and Architecture in Metal Chalcogenide towards Fast and Reliable Electrocatalytic Behavior for Lithium-Sulfur Batteries Dan Luo, Gaoran Li and Zhongwei Chen; University of Waterloo, Canada

Lithium sulfur (Li-S) batteries deliver great promise to support the next-generation energy storage when the sluggish redox kinetics and polysulfide shuttling can be well addressed. The rational design of sulfur electrode plays key roles in tacking these problems and fulfilling a high-efficiency sulfur electrochemistry. Herein, we demonstrate a synergetic defect and architecture engineering strategy to design highly disordered spinel Ni-Co oxide double-shelled microspheres (NCO-HS), which consists defective spinel NiCo$_2$O$_4$-x (x=0.9 if all nickel is Ni$^{2+}$ and cobalt is Co$^{2.13+}$), as the multifunctional sulfur host material. The *in-situ* constructed cation and anion defects endow the NCO-HS with significantly enhanced electronic conductivity and superior polysulfide adsorbability. Meanwhile, the delicate nano-construction offers abundant active interfaces and reduced ion diffusion pathways for efficient Li-S chemistry. Attributed to these synergistic features, the sulfur composite electrode achieved excellent rate performance up to 5 C, remarkable cycling stability over 800 cycles and good areal capacity of 6.3 mAh cm$^{-2}$ under high sulfur loading. This proposed strategy based on synergy engineering is also promising to enlighten the material engineering in related energy storage and conversion fields.

Nanoscale Design for High Energy Batteries Yi Cui; Stanford University, United States

The demand from portable electronics and electric vehicles call for high energy batteries beyond the current lithium ion batteries. Here I will present our recent progress on materials and interfacial design to enable much high energy density batteries, which include 1) High capacity Si anodes with success in commercialization; 2) Li metal anodes: host and interface design to over the lithium metal dendrite formation and interfacial instability; 4) Sulfur as an earth abundant material for high capacity cathodes; 4) Our pioneering development of cryogenic electron microscopy for understanding the battery materials and solid-electrolyte interphase down to atomic scale resolution.

Papp$^2$, Emily Foley$^5$, Yaosen Tian$^1$, Mahalingam Balasubramanian$^4$, Haegeyoum Kim$^1$, Raphaele J. Clement$^1$, Bryan D. McCloskey$^2$, Wanli Yang$^1$ and Gerbrand Ceder$^{2,1}$; 1Lawrence Berkeley National Laboratory, United States; 2University of California, Berkeley, United States; 3Oak Ridge National Laboratory, United States; 4Columbia University, United States; 5University of California, Santa Barbara, United States; 6Argonne National Laboratory, United States

The facile transport of lithium ions in inorganic crystalline materials is a prerequisite for the many electrochemical processes in rechargeable batteries, the production of which is now being rapidly scaled up to electrify vehicles and even enable grid-scale energy storage. Achieving fast ion transport kinetics in electrode materials requires an optimized crystal structure with favorable short-range atomic arrangements, which are, in the meantime, extensively connected in the long range. In conventional electrode materials, wherein a single unit cell exactly repeats its chemistry and geometry into infinity, the two criteria conveniently become one. Such perfectly-ordered structures, though easy to characterize, lack flexibility and impose a narrowed selection in chemistry, causing significant strains on several metal resources, such as cobalt and nickel. In this talk, I will show how strategically introducing compositional and structural disorder into a simple rocksalt lattice can lead to the discovery of novel electrode materials with ultrahigh energy and power density as well as a reversible anion redox process. The design strategies might open up a vast chemical space for the search of new battery materials made from earth-abundant elements.

6:05 AM S.EN12.02.12
Controllable Fabrication of Pitaya-Like SnO$_2$/N-Doped Carbon Composite Nanospheres for Highly Rate Capability Lithium Storage Xiao Liu; Henan University, China
As one of the most important energy storage devices, lithium ion batteries (LIBs) have been widely used in portable electronic devices due to its high energy density and long cycle life. However, for commercial lithium ion batteries with graphite as anode material, a common drawback is the relatively low specific capacity (372mAh g⁻¹) and the problem of Li plating under high current density. To solve the problems, one of effective strategies is to develop anode materials with high theoretical capacity. Among them, SnO₂, with higher theoretical capacity, low toxicity and natural abundance, is widely studied as the promising alternative anode material for LIBs. However, SnO₂ is accompanied by pulverization and aggregation during charge and discharge process, resulting in its fast capacity fading and poor rate performance. Herein, we have designed and synthesized SnO₂ nanoparticle (≈10 nm) uniformly distributing in porous carbon nanosphere with a continuous N-doped carbon shell (denoted as SnO₂/po-C@NC) via a multistep method. Here, dopamine due to its excellent physicochemical property was adopted as a conductive carbon shell to provide a fast electronic transport framework and thus homogenize lithiation/delithiation, when used as anode material. This architecture demonstrate enhanced capacity and excellent rate performance, SnO₂/Po-C@NC can deliver a high reversible capacity 936.8 mAh g⁻¹ after 100 cycles at 100 mA g⁻¹, even at the high current density of 3.2 A g⁻¹, an average capacity of 460.0 mA h g⁻¹ can be achieved.

6:15 AM *S.EN12.02.13
Challenges and Benefits of Rechargeable Aluminum-Graphite and Other Dual-Ion Batteries
Maksym V. Kovalenko¹,² and Kostiantyn Kravchyk¹,²; ¹ETH Zurich, Switzerland; ²Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Rechargeable aluminum-graphite dual-ion batteries (AGDIBs) have attracted the attention of electrochemists and material scientists in recent years due to their low cost and high-performance metrics, such as high power density (up to 175 kW kg⁻¹), energy efficiency (~ 80-90%), long cycling life, and high energy density (up to 70 Wh kg⁻¹), suited for grid-level stationary storage of electricity [1]. The key feature of AGDIBs is the exploitation of the reversible oxidation of the graphite network with concomitant and highly efficient intercalation/de-intercalation of AlCl₄⁻ anionic species between graphene layers. In this talk, we discuss the utility of AGDIBs as a highly promising post-Li-ion technology for low-cost and/or large-scale storage of electricity [2,3]. In particular, we provide a balanced analysis of the overall cell-level energy density of AGDIBs. In view of its non-rocking chair operation mechanism, we show the achievable energy densities as a function of the composition of chloroaluminate ionic liquid (AlCl₃ content) and compare it with other battery electrochemistries suited for stationary storage of electricity (such as lead-acid or vanadium redox flow). Specific emphasis is given to the unbiased and correct reporting of their theoretical cell-level energy densities. Furthermore, we discuss also other issues associated with this technology, one being the incompatibility of most metallic current collectors with the corrosive AlCl₃-based ionic liquids. We then demonstrate a novel concept of flexible AGDIB using current collectors from earth-abundant elements and point to key challenges in the development and practical deployment of AGDIBs [4]. Finally, we also discuss an alternative dual-ion battery utilizing a highly concentrated electrolyte solution of 5 M potassium bis(fluorosulfonyl)imide in alkyl carbonates [5]. The resultant battery offers an energy density of 207 Wh kg⁻¹, owing to the high weight content of the electroactive species (65 wt%) in the electrolyte and a high operation voltage of 4.7 V.

References
Polymer electrolyte-based Lithium metal batteries are attractive for safe energy storage with high-energy-density. However, various material challenges present inside, such as interfacial stability with electrodes and low ionic conductivity. In this talk, I will present material characterizations and designs to understand and address some challenges inside. Specifically, a combination of stimulated Raman scattering microscopy and AFM measurements first illustrate how mechano-chemical coupling at the lithium/polymer electrolyte interface affect dendrite formation in polymer electrolyte. Second, interfacial designs are developed to suppress the oxidation of PEO electrolyte at the cathode side, and thus long-term cycling is achieved in 4V LCO or NMC-PEO-Li cells. The capacity retention reaches 85% after 200 cycles.

5:15 AM S.EN12.03.02
In-Built Solid-State Polymer Electrolytes for Rechargeable Lithium-Metal Batteries Qing Zhao and Lynden Archer; Cornell University, United States

Rechargeable metal batteries that employ metals, including Li and Na, as anodes have been gained increasing attention in recent years due to their high energy density. However, poor chemical stability of traditional liquid electrolytes in contact with the metal anode limit both the performance and safety of such cells. Solid-state electrolytes are considered particularly promising because of their inherent safety characteristics and potential to prevent dendritic deposition of the metal, in which solid polymer electrolytes (SPEs) are considered attractive from a range of perspectives, including their light-weight characteristics, lower cost, excellent mechanical toughness, and compatibility with roll-to-roll manufacturing processes. In general, a successful SPE is required to have at least two characteristics. Firstly, it should have high bulk ionic conductivity and fast interfacial transport; and secondly it should remain mechanically stable and chemically inert during extended battery cycling. In present talk, I will present our recent progresses on the preparation of in-built SPEs. Firstly, we found that the ring-opening polymerization of molecular ethers (for example, 1,3-dioxolane) inside an electrochemical cell can produce SPEs with high ionic conductivity at room temperature. These SPEs retain conformal interfacial contact with all cell components and exhibit low interfacial resistances, uniform lithium deposition and high Li plating/striping efficiencies. Secondly, we will report how to further improve cathode-electrolyte interphases of in-built SPEs. In the presence of designed fluorinated nanofillers, the designed SPEs enable the stable cycling performance in high areal capacity and high voltage LiNi0.6Mn0.2Co0.2O2 cathodes. We found the fluorinated nanofillers can plays a dual role as a Lewis acid catalyst and in building fluoridized interphase to protect both the electrolyte and aluminum current collector from degradation reactions. Finally, we will report how to maintain long-term stability for in-built SPEs by designing plasticizer. The complex kinetics of in-built SPEs with plasticizer results in nonlinear phase behavior, including the appearance of a critical transition to an entangled, solid-like electrolyte state.

High Density and Ionic Conductivity in Nanostructured Ta-Doped LLZO Synthesized by a Polymer Combustion Method Jon M. Weller and Candace Chan; Arizona State University, United States

Ta-doped LLZO (LLZTO) is of great interest due to its high ionic conductivity, electrochemical stability in contact with metallic lithium, and the fact that doping the Zr-sites with Ta does not block Li-ion conduction as is the case with other common dopants such as Al or Ga, which reside on the Li sublattice. As with most methods for synthesis of LLZO, LLZTO is primarily obtained via the solid-state reaction (SSR) method, incurring a high energy cost and producing bulk powders that require high energy milling after synthesis to promote higher reactivity towards sintering. Other methods such as sol-gel and combustion methods have also been employed seeking smaller particle sizes, but generally do not result in as good of
performance as the SSR method. Herein, a novel non-aqueous polymer combustion method is used to produce LLZTO nanopowders, which enables somewhat better control over synthesis conditions and better reproducibility than conventional nitrate-based combustion methods. Compared to SSR LLZTO, which is generally sintered at temperatures between 1150-1250 °C, as-synthesized LLZTO nanopowders are easily consolidated via conventional pressureless sintering at 1100 °C. This lower sintering temperature is enabled in part by mitigating Li2O volatility and in part by the relatively higher reactivity of nanosized LLZTO compared to coarse LLZTO powders obtained via SSR. LLZTO processed with this method exhibits relative densities up to 93.6 % with ionic conductivities as high as 0.67 mS cm⁻¹, which compares well with dense LLZTO ceramics processed at higher temperatures or via advanced consolidation processes such as hot pressing. This method can be easily extended to other doping schemes, and the ease with which nanosized LLZO can be obtained makes this polymer combustion method promising for producing active fillers for composite polymer electrolytes.

5:35 AM S.EN12.03.05
A Composite NASICON (Na₃Zr₂Si₂PO₁₂) Solid-State Electrolyte with Enhanced Na⁺ Ionic Conductivity by Liquid Phase Sintering Jin An Sam Oh¹,², Li Lu¹ and Kaiyang Zeng¹; ¹National University of Singapore, Singapore; ²Singapore Institute of Manufacturing Technology, Singapore

Solid-state battery is one of the most discussed next generation energy storage devices in both industry and academia. While Li-ions battery has been popularised by the success in mobile electronics, Na-ions battery has higher potential in stationary energy storage system due to the cost and availability of raw materials. Among the solid-state electrolyte, NASICON (NASic IOnic CONductor), Na₃Zr₂Si₂P₂O₁₂, possesses high mechanical strength, large electrochemical stability, and good chemical and thermal stability makes it one of the potential materials to be utilised. However, the processing of NASICON involves long exposure at high temperature thermal treatment. In addition, the lower grain boundary ionic conductivity limits the total ionic conductivity to be around 0.64 mS cm⁻¹. In this study, sodium metasilicate, Na₂SiO₃, was added into the NASICON matrix and facilitated the sintering process. The addition of Na₂SiO₃ has effectively reduced the sintering duration and temperature. Furthermore, the diffusion of cation from Na₂SiO₃ into the bulk NASICON resulted in changes in the stoichiometry and improve the bulk ionic conductivity. More importantly, as Na₂SiO₃ melt pool penetrate through the grain boundary, it formed a Si-rich secondary phase that significantly improve the grain boundary ionic conductivity. The highest ionic conductivity measured at room temperature is when 5wt% of Na₂SiO₃ was added into the NASICON at 1.48 mS cm⁻¹. This study has shown facile addition of liquid-phase during sintering can effectively achieve high ionic conductivity.

Solid-State Materials to Enable Molten Sodium Batteries Erik D. Spoerke, Martha M. Gross, Stephen Percival, Leo J. Small and Amanda Peretti; Sandia National Laboratories, United States

In the expanding search for safe, sustainable, low-cost large scale energy storage solutions, molten sodium batteries have been recognized as an attractive candidate technology. The relatively high operating temperature (near 300°C) of traditional molten sodium-sulfur and sodium-nickel chloride batteries, however, has discouraged the widespread adoption of these battery chemistries. We are developing a new, lower temperature molten sodium battery that operates near 100°C, based on a sodium anode, a solid state separator, and a sodium iodide-based molten halide salt catholyte. This new lower temperature system opens the door to lower materials costs, improved material lifetimes, and simplified, less costly operation. The reduced operating temperature, however, introduces new material and electrochemical challenges to not only the key molten components of the battery, but also critical interfaces and functional materials associated with the solid state separator, the current collectors, and even the material packaging of the battery. Here, we will discuss creative engineering solutions to emergent low temperature-specific problems related to interfacial wetting, ionic conductivity, chemical compatibility, and charge transfer efficiency. We highlight new approaches to solid state separator development, manipulating not only ceramic or composite chemistry but also separator structure and interfacial chemistry to enhance low temperature ionic conductance. Meanwhile, efforts to tailor high surface area, low resistance current collectors show progress toward higher efficiency battery cycling. Addressing the specific solid state materials in this functionally molten battery system allows us to accelerate the development of this potentially safe and sustainable sodium-based energy storage option.

Electrolyte and Interface Design for High Voltage Solid-State Batteries Xin Li; Harvard University, United States
In this talk, we show how mechanically-induced metastability greatly widens the voltage window and modulates the dynamic interface decomposition of sulfide solid electrolyte at high voltage, going beyond our recent work [1,2,3]. By comparing ab-initio simulation and XPS measurement, the thermodynamic pathway of decomposition is determined. Beyond this thermodynamic stability window, kinetic effects are also discussed. We show both experimentally and theoretically how the decomposition of LGPS at high voltage is largely prohibited by these effects via mechanical constraint. We further discuss the potential of this effect on the cathode-electrolyte interface design to enable high voltage solid state batteries beyond the commercial level.

5:00 AM S.EN12.04.01
Electrolyte Design for Micro-Sized Si Anodes Chunsheng Wang; University of Maryland, United States

Li-ion batteries are the critical enabling technology for the portable devices, electric vehicles (EV), and renewable energy. However, the safety and energy density of current Li-ion batteries still need to be improved to satisfy the requirements for these applications. We systematically investigated the electrochemical performance of the nonflammable fluorinated organic electrolytes and solid state electrolytes for high energy Li and Li-ion batteries. The Li dendrite formation in liquid electrolyte and solid state Li metal batteries was proposed and validated. The critical issues of these safe electrolytes are also discussed.

Materials Degradation Trends from Systematic Long-Term Cycling of Commercial Li-Ion Batteries Reed Wittman, Yuliya Preger, Sergei Ivanov, Armando Fresquez and Babu Chalamala; Sandia National Laboratories, United States

Li-ion batteries are complex systems whose long-term performance is still the subject of much research. Of particular interest is the degradation of electrode materials during long term cycling under a variety of cycling rates and operating temperatures. Electrode degradation in Li-ion batteries has been the focus of much study in recent years and mechanisms for degradation have been proposed. These proposed mechanisms have not been tied to performance of commercial cells during long term cycling under a variety of operating conditions. Determining and understanding systematic trends in degradation is crucial to further improvement of Li-ion battery performance and safety.

Previously, researchers at Sandia National Labs conducted a systematic study of commercially available battery cycling behavior. Dozens of commercial NCA (LiNi1/2Co1/2Al1/2O2) and NMC (LiNi1/3Mn2/3Co1/3O2) cells were cycled to 80% capacity and end of life across a range of temperatures, discharge rates, and depth of discharge windows. To better understand the reasons for the observed degradation trends, postmortem analysis was carried out at pristine condition, 80% capacity, and end of life. As such, multiple cells were started at the same operating conditions but stopped at different points to be analyzed. Postmortem analysis of the anode and cathode of each cell included X-ray Diffraction (XRD), Scanning Electron Microscopy (SEM), Differential Scanning Calorimetry (DSC), and Brunauer-Emmett-Teller Isotherms (BET). Each provided different insights into crucial changes in the electrodes of these batteries, including phase changes in the cathode, micro-cracking, SEI layer formation, and Li plating. Critically, DSC in combination with BET showed changes in reactions and reaction rates that contribute to thermal runaway and generally indicates changes in chemical properties of the electrode. Materials properties were correlated to whole cell electrochemical performance to understand the causes of performance fade and failure of the cell. The breadth of operating conditions and duration of cycling considered in this study fills a substantial gap in the literature, enabling optimization of Li-ion batteries for application beyond 80% capacity.
Bio-Inspired Nanospiky Metal Particles Enable Thin, Flexible and Responsive Polymer Nanocomposites for Thermal Regulation Mingqian Li and Zheng Chen; University of California, San Diego, United States

Safety issue remains a major obstacle towards large-scale applications of high-energy lithium-ion batteries. Embedding thermo-responsive polymer switching materials (TRPS) into batteries is a potential strategy to prevent thermal runaway, which is a major cause of battery failures. Here, we report thin, flexible, highly responsive polymer nanocomposites enabled by bio-inspired nanospiky metal (Ni) particles. These unique Ni particles were synthesized by a simple aqueous reaction at gram-scale with controlled surface morphology and composition to optimize electrical properties of the nanocomposites. The Ni particles provide TRPS films with a high room-temperature conductivity of up to 300 S cm\(^{-1}\). Such TRPS composites also have a high rate (<1 s) of resistance switching within a narrow temperature range, good reversibility upon on/off switching and a tunable \(T_c\) (75 to 170 oC) that can be achieved by tailing their compositions. The small size (~500 nm) of Ni particles enables ready fabrication of thin and flexible TRPS films with thickness approaching 5 µm or less. These features suggest the great potential of using this new type of responsive polymer composites for more effective battery thermal regulation without sacrificing cell performance.

5:35 AM S. EN12.04.04
Draining over Blocking—Nano-Composite Janus Separators for Mitigating Internal Shorting of Lithium Batteries Matthew Gonzalez, Qizhang Yan, Zhaohui Wu, Hongyao Zhou, Nicholas Patterson, Victoria Petrova, Haodong Liu and Ping Liu; University of California, San Diego (UCSD), United States

Catastrophic battery failure due to internal short is extremely difficult to detect and mitigate. In order to enable next generation lithium-metal batteries, a “fail safe” mechanism for internal short will be highly desirable. We introduce a novel separator design and approach to mitigate the effects of an internal short circuit by limiting the self-discharge current to prevent cell temperature rise. A nano-composite Janus separator—with a fully electronically insulating side contacting the anode and a partially electronically conductive (PEC) coating with tunable conductivity contacting the cathode—is implemented to intercept dendrites, control internal short circuit resistance, and slowly drain cell capacity. Galvanostatic cycling experiments demonstrate Li-metal batteries with the Janus separator perform normally before shorting, which then results in a gradual increase of internal self-discharge over >25 cycles due to PEC mitigated shorting. Abuse charge testing of Li metal batteries containing the Janus separator shows a remarkable ability to reduce short circuit current and heat generated during internal shorting incidents. This new separator design can not only greatly improve battery safety, but also lower battery costs by relaxing manufacturing tolerance and accelerate the adoption of high-energy next-generation batteries.

5:45 AM S. EN12.04.06
Dual Ion Organic Batteries Based on Conducting Redox Polymers Guiomar Hernández1, Nerea Casado2, Lisa Åkerlund1, Rikard Emanuelsson1, Fernando Ruipérez2, Daniel Brandell1, Maria Strömme1, Martin Sjödin1 and Davis Mecerreyes2; 1Uppsala University, Sweden; 2University of the Basque Country, Spain

The electrochemical performance of lithium-ion batteries has been substantially improved in the last decades. However, with the increasing demand of electrochemical energy storage technologies, other challenges such as scarcity of raw materials, toxicity, and recyclability ought to be considered. In this regard, redox active polymers are promising materials thanks to their abundance, low cost, low toxicity and environmentally friendly disposal.[1-3] In addition, their redox properties can be tailored to be used as negative electrodes storing cations (Li\(^+\), Na\(^+\), H\(^+\)) as well as positive electrodes incorporating anions (PF\(_6^-\), TFSI\(^-\)). However, redox active polymers also possess some limitations, such as dissolution into the electrolytes, poor conductivity and low operational voltage.[4] To overcome some of those limitations, we have investigated different redox active conducting polymers with enhanced conductivity and reduced solubility to be used as positive and negative electrodes. As negative electrode, we have chosen a polypyrrole-polyether block copolymer that combines the versatile redox activity and electronic conductivity of aromatic imide groups with the ion conducting polyether. As positive electrode, we have studied a PEDOT-lignin biopolymer composite combining the PEDOT conducting backbone with redox active lignin to increase the capacity. These two materials have been paired to build an all-organic aqueous battery with long cycle life at high current densities.[5] Additionally, another positive electrode based on PEDOT with hydroquinone and pyridine pendant groups has been investigated as a proton trap material. In this system, the redox reaction occurs in the hydroquinone moieties and the protons are transferred to the pyridine sites preventing its diffusion to the electrolyte. This material is very versatile as it can be used in many different electrolytes (conventional liquid electrolytes and ionic liquids), regardless of the coordinating salt (lithium or sodium based).[6] Overall, redox active polymers can be tailored with specific backbones and redox active moieties to feature the desired properties and to be used as negative and positive electrodes towards more sustainable and environmentally friendlier energy storage technologies.
Exploiting Mechanistic Solvation Kinetics for Dual-Graphite Batteries with High Power Output at Extremely Low Temperature

John Holoubek, Ping Liu and Zheng Chen; University of California, San Diego, United States

Improving the extremely low temperature operation of rechargeable batteries is vital to the operation of electronics in extreme environments, where systems capable of high-rate discharge are in short supply. Herein, we demonstrate the holistic design of dual-graphite batteries, which circumvent the sluggish ion desolvation process found in typical lithium-ion batteries during discharge. These batteries were enabled by a novel electrolyte, which simultaneously provided high electrochemical stability and ionic conductivity at low temperature. The dual-graphite cells, when compared to industry-type graphite | LiCoO2 full-cells demonstrated an 11 times increased capacity retention at -60 °C for a 10 C discharge rate, indicative of the superior kinetics of the “dual-ion” storage mechanism. These trends are further supported by GITT and EIS measurements at reduced temperature. This work provides a new design strategy for extreme low-temperature batteries.

Porous Si and CNT@Si@C Microspheres from Self-Assembly of Colloidal SiO2 Nanoparticles as High-Performance Li-Ion Battery Anodes

Xiaolin Li, Haiping Jia and Jiguang Zhang; Pacific Northwest National Laboratory, United States

Silicon has been regarded as the most promising high energy density anode for Li-ion batteries. However, it suffers from large volume expansion upon full lithiation and fast capacity fade. Si of porous structure has been known to accommodate the volume change and improve the cycling stability and hence has attracted extensive attention. Here, we report the synthesis of porous Si microspheres by thermite reduction of SiO2 microspheres (500nm to 10 micron) from self-assembly of 70 nm SiO2 colloidal particles. The porous Si microspheres have uniform mesopores and Si crystallites of ~20 nm. The fine primary particles can shorten the Li+ transport route and avoid the pulverization of Si. The obtained porous silicon delivers a reversible capacity of 1900 mAh g-1 at 0.5C and 85% capacity can be retained after 100 cycles. In another effort, CNT@SiO2 coaxial cables were synthesized using sol-gel method and then self-assembled into microspheres in microemulsion. Hierarchical porous CNT@Si@C microspheres obtained after thermite reduction reaction demonstrated excellent electrochemical performance. The anodes deliver 90% capacity retention over 100 cycles at the areal loading of ~3 mAh/cm2. These works represent significant steps in the development of Si anodes and provide guidance for battery material synthesis.

Non-Equilibrium Tungsten Oxide Hydrates via Selective Ion Etching for Aqueous Energy Storage

Veronica Augustyn; North Carolina State University, United States

The search for electrochemical energy storage that provides good safety as well as high energy storage performance has reignited interest in materials that operate in aqueous electrolytes. In these electrolytes, protons are increasingly identified as the relevant intercalating species into the vacant sites of transition metal oxide electrodes. Using selective ion etching of a bismuth tungsten oxide, we synthesized a non-equilibrium tungsten oxide hydrate (W₂O₆*H₂O) that exhibits both high proton intercalation capacity (~ 55 mAh/g) and excellent kinetics enabling charge/discharge times of just 12 seconds. The capacity is significantly higher than what can be attained with tungsten oxide hydrates obtained via typical acid precipitation routes or the anhydrous tungsten oxide. Intriguingly, the performance is attained with thick electrodes consisting of large particles tens of microns in diameter. Utilizing a combined experimental and theoretical approach, this talk will discuss how the structure of the non-equilibrium hydrate influences its proton intercalation kinetics. Finally, we will discuss future opportunities in the use of selective-ion etching of transition metal oxides for the synthesis of non-equilibrium structures for energy storage.

An In Situ Testing Platform for the Multi-Dimensional Diagnostic of the Solid-State Li Batteries

Zheng Fan; University
Global demand for high-performance energy storage systems has grown tremendously in recent years. The all-solid-state lithium-ion batteries (ASSLIBs) are promising for such storage solutions on account of the lithium metal anodes with high areal capacity and the solid-state electrolytes (SSEs) with critical safety. However, the interfacial failure of the ASSLIBs posed a major hurdle towards the design of high-performance solid-state batteries. Time-resolved in operando techniques (e.g. in situ microscopy, synchrotron X-ray tomography) are ideal for the direct and quantitative characterization of the interfacial deteriorations. However, the in situ analysis of solid-state batteries is still in its primary stage due to the difficulties in probing the buried interfacial layer. The specific causes of the high interfacial impedance and the lithium dendrite growth that deteriorates the battery in a few cycles remain nebulous.

To this end, we developed a multi-dimensional diagnostic platform that allows the direct probe of the chemical and spatial distribution on the interface while the cell operates. Parameters such as pressure and temperature, which have a strong influence on cell behavior, are also enabled by the platform. Moreover, the platform can be transferred between analytical instruments, including SEM, ToF-SIMS, and Raman, for a synergistic diagnose of the structural and chemical evolutions in solid-state Li batteries. A deeper understanding of interfaces and dendrites evolutions has been acquired by the testing platform, including (1) correlation between void formation and electrolyte decomposition, and (2) creeping mechanical properties of the lithium metal during the cell operations. These in-depth understandings will allow us to effectively optimize and enable further enhancements of solid-state Li batteries.

Sustainable Energy Storage Technologies Beyond Li-Ion Batteries Jie Xiao and Chaojiang Niu; Pacific Northwest National Laboratory, United States

Abstract: The thermodynamically unstable nature of lithium metal in liquid electrolytes significantly plagues the implementation of the high-energy rechargeable lithium battery technology in electrical vehicles. Although many approaches have been proposed to rescue Li metal anodes, most of the work are performed in small-scale coinellsand tested in the conditions drastically different from the reality. A full knowledge of Li metal activities at the cell level is lacking but extremely critical for the success of developing next-generation rechargeable Li metal batteries. This talk will discuss the fundamental challenges of utilizing Li metal anode in at cell-level and demonstrate a prototypic 350 Wh/kg lithium metal pouch cell > 250 stable cycling.

Controlled Synthesis of Disordered Carbon Anodes for Na-Ion Battery Yaxiang Lu, Yuruo Qi, Chenglong Zhao, Qingshi Meng, Yuqi Li, Hong Li, Xuejie Huang, Liquan Chen and Yong-Sheng Hu; Chinese Academy of Sciences, China

Na-ion batteries (NIBs) have been recently reconsidered for storing the electricity from renewable energy due to the abundant sodium resources and low cost. The progress of NIBs intensively relies on the application of appropriate cathode and anode materials, especially, the anode side has become the main bottleneck in enhancing the batteries’ performance. Among all available anode candidates, disordered carbon still shows the best overall performance in terms of capacity, cycling stability and cost. In this talk, I will present several superior low cost disordered carbon anodes made from pitch, focusing on the strategies adopted to suppress the graphitization degree of pitch-derived carbon at high carbonization temperature. Besides,
pore structures of a porous biomass-derived carbon are regulated to enhance the Na storage performance. Furthermore, two kinds of carbon anodes demonstrate a high Na storage capacity ≥400 mAh/g through controlled synthesis, which help unravel the Na storage mechanism in disordered carbon. The understanding gained potentially provides reference for the design and development of high-performance disordered carbon materials for NIBs.

The Silicon Electrolyte Interface Stabilization Project Anthony Burrell; National Renewable Energy Laboratory, United States

Silicon is a viable alternative to graphite/carbon as an electrode in lithium-ion cells and can theoretically store >3,500 mAh/g. However, lifetime problems have been observed that severely limit its use in practical systems. The major issues appear to involve the stability of the electrolyte and the uncertainty associated with the formation of a stable solid electrolyte interphase (SEI) at the electrode. Recently, calendar-life studies have indicated that the SEI may not be stable even under conditions where the cell is supposedly static. Clearly, a more foundational understanding of the nature of the silicon/electrolyte interface is required if we are to solve these complex stability issues. A multi-lab consortium has been formed to address a critical barrier in implementing a new class of materials used in lithium-ion batteries that will allow for smaller, cheaper, and better performing batteries for electric-drive vehicles. This consortium, named the Silicon Electrolyte Interface Stabilization (SEISta) project, was formed to focus on overcoming the barrier to using such anode materials. Five national laboratories are involved: the National Renewable Energy Laboratory (NREL), Argonne National Laboratory (ANL), Lawrence Berkeley National Laboratory (LBNL), Oak Ridge National Laboratory (ORNL), and Sandia National Laboratories (SNL). The SEISta project was specifically developed to tackle the foundational understanding of the formation and evolution of the solid-electrolyte interphase on silicon. This project will have a primary goal of understanding the reactivity of the silicon and lithiated silicon interface with the electrolyte in lithium-ion systems. The overall objective for SEISta is to understand the nature and evolution of the SEI on silicon anodes.

Several issues must be addressed to enable progress in this area. Materials Standardization is critical to this project and deployment of standardized samples and experimental procedures across the team is a foundation of the project. Full characterization of any new sample that is to be used for SEI studies to ensure reproducibility and full understanding of the material. The materials standardization and model compounds will enable the researchers to systematically investigate the formation of the solid-electrode interphase using a wide variety of the spectroscopy techniques—from different optical, microscopy, and electrochemistry—to determine how the SEI forms based on the nature of the silicon surface, and how it evolves over time. This presentation will detail recent advances that the SEISta team has made to the understanding of the SEI on silicon.

5:45 AM S.EN12.05.08
Low-Temperature Formation of Lithium Conducting Garnets via Basic Molten Salt Synthesis Jon M. Weller and Candace Chan; Arizona State University, United States

Lithium conducting garnets in the family of lithium lanthanum zirconate (nominally Li7La3Zr2O12, LLZO) are of great interest as oxide solid electrolytes for solid-state lithium-metal batteries. Various synthetic approaches have been investigated to date, including sol-gel, co-precipitation, thin film deposition, spray pyrolysis, combustion, and molten salt synthesis, not to mention the standard solid-state reaction (SSR) method. Most of the aforementioned methods can generate LLZO with expected good properties, but nearly all have drawbacks including cost, high processing temperatures, complexity, poor properties (in the case of vacuum deposition of thin films), or difficulty of producing fine powders for thin films of LLZO, which are necessary for practical solid-state batteries. Thus, despite the promising properties of LLZO in terms of electrochemical stability and ionic conductivity, processing of garnet powders into dense solid electrolytes in practically useful forms is still a challenge. Herein, submicron (200-500 nm) powders of doped LLZO of nominal composition Li0.65La0.35Zr2Ti0.5O7 are demonstrated to form at an unprecedented low temperature of 400 °C using a basic molten salt synthetic approach, ameliorating two main challenges of processing temperature and particle size. However, a curious
phenomenon is observed: the composition of individual LLZO particles can vary considerably from the nominal composition, producing a distribution in the ratio of Zr and Ta that is difficult to detect during routine characterization (requiring the high spatial resolution of analytical transmission electron microscopy) but may have deleterious consequences on performance. Indeed, LLZTO synthesized via SSR exhibits higher ionic conductivity despite comparable relative density and sintering conditions. Backscatter electron imaging and energy dispersive spectroscopy shows that this compositional inhomogeneity persists even after sintering at high temperatures, indicating that interdiffusion between Zr and Ta does not go to completion at relevant sintering times if a distribution in composition exists in the feedstock powder. Variation in composition between individual grains implicates subcritical doping in some percentage of grains in a dense ceramic as the source of poorer performance relative to SSR LLZTO. The thermodynamic and kinetic origins of compositional inhomogeneity are discussed in Ta-doped LLZO and addressed by use of novel elementally homogeneous precursors. Implications of compositional inhomogeneity on performance of garnet solid electrolytes via this and other common synthesis methods are discussed.

Development of High Potential Negative Electrode for Lithium-Ion Batteries Benjamin Mercier-Guyon, Jean-François Colin and Sebastien Martinet; Univ. Grenoble Alpes, CEA, LITEN, France

Rechargeable lithium ion batteries (LiBs) are commonly used as power sources, and they became the dominant energy storage technology for various range of applications including portable electronic, electrical vehicles, and large-scale energy storage. Used as negative electrode for most of commercial cells because of its low cost and good theoretical capacity (372 mAh.g⁻¹), graphite, suffers from important stability issues. The passivating layer formed on graphite electrode, well-known as solid electrolyte interphase (SEI), occurring because of the decomposition of organic liquid electrolyte can lead to capacity fading, electrolyte consummation and low lifetime. Despite the presence of the “stable” SEI layer, lithium plating, dendrite formation and in some case thermal run away may occur depending on the charging conditions. This poor interface, especially sensitive to low temperature and high currents poses an important challenge for the development of electric vehicles (EVs).

For some years, with safety and performance in mind, titanates composites have been studied as anode material. The lithium titanate spinel Li₄Ti₅O₁₂ (LTO) has drawn attention of many research groups, due to its high operating voltage preventing lithium plating, its long cycle life and its ultra-low volume change during the lithium insertion. This material might have been perfect for hybrid electric vehicles requiring high rate cycling and fast charge even with low temperature. However, a low specific capacity (175mAh.g⁻¹) leading to a low energy density associated as well with a gassing phenomenon drastically hinder the deployment of this material. Another family of material exhibiting Wadsley-Roth shear structures, mainly composed of mixed Ti and Nb was introduced during the 50s and has shown the ability to intercalate lithium ions [1]. Later, Goodenough et al. showed in 2011 that TiNb₂O₇ (TNO) can be used as negative electrode material in a full cell system [2], keeping LTO’s advantages (high working potential and safety) but offering a theoretical capacity of 387.6 mAh.g⁻¹ that is comparable to the one of graphite.

Many groups report advanced ways to synthesize this material such as solvothermal synthesis [3] and spray drying [4] but only little consideration was given to the study of the lithiation and degradation mechanisms [5]. In this work, we report that TNO electrodes present important differences of performances at high rates following their cycling history. Indeed, we notice that, when previously cycled at low rate (C/10 or below), the material exhibits less than the half of the discharge capacity obtained when directly cycled at high rate.

To understand this phenomenon, many investigations have been carried, in particular using in situ and post-mortem X-ray diffraction. In situ and operando X-ray diffraction can be a powerful tool to characterize crystalline evolution upon cycling and pushing forward the understanding of lithiation reactions. We used a cell fitted with thin beryllium windows, with a mix of TNO and black carbon, a lithium metal as counter electrode and using EC/PC/DMC (1/1/3v) +1M LiPF₆ electrolyte. Different conditions of cycling where used and diffractograms obtained were compared for a same lithiation rate. Clear and important evolutions of peak positions, shapes and intensities can be followed all along the lithiation process and allowed us to refine the lattice parameter.

We have been able to follow the lithiation process in the materials at different cycling conditions. We also try to stabilize and improve the comportment of the material with different solutions such as carbon coating or doping and we will present the results of these studies.

Graphene-Wrapped Cu$_2$S as a Promising Anode for Sodium-Ion Batteries

Jiyu Cai$^1$, Chengjun Sun$^2$, Hua Zhou$^2$, Yang Ren$^2$, Zonghai Chen$^2$ and Xiangbo Meng$^1$; $^1$University of Arkansas, United States; $^2$Argonne National Laboratory, United States

Among electrical energy storage (EES) systems, sodium-ion batteries (SIBs) are very promising and have been attracting an ever-growing research interest in the past decade, due to the low cost and natural abundance of sodium element. Compared to the success of cathodes in SIBs, one main challenge is seeking high-performance anodes. To this end, in this work we investigated copper(I) sulfide (Cu$_2$S) as a promising SIB anode through mixing with nitrogen-doped graphene nanosheets (NGS) via a facile high-energy ball milling route. The resultant Cu$_2$S@NGS composite could achieve a sustainable high capacity of 300 mAh g$^{-1}$ over 500 cycles and accomplish a high rate capability up to 10 C (1C = 337 mA/g). Compared to all studies reported so far, our Cu$_2$S@NGS composite electrodes demonstrated the highest electrode capacity. Our analyses revealed that the substitution of NGS for carbon black has produced multiple beneficial effects: (i) inhibiting polysulfide shuttling effect, (ii) suppressing the formation of SEI layer, (iii) offering high electron and ion conductivity, and (iv) enhancing mechanical integrity of electrodes. We also systematically investigated the effects of voltage windows and surface coatings on enhancing the stable electrochemical performance of Cu$_2$S@NGS composite electrodes. This work represents a great advance in seeking high-performance anodes in SIBs.
and the electrolyte and recombined in the other electrode, accomplished through the redox reactions occurred in the electrodes. Material design that lead to better charge separation, transport, and recombination, in this context, holds great promise towards better electrochemical-energy-storage devices. In this presentation, the design of electrode materials and electrolytes, which lead to better performance lithium-ion batteries, lead acid batteries, and fuel cells will be discussed.

Direct Recycling of Lithium-Ion Battery Materials Jack Vaughey, Anthony Montoya and Fulya Dogan; Argonne National Lab, United States

Lithium-ion batteries have been manufactured for nearly three decades and represent an excellent example of the role steady improvements in design and science can have on end users and research opportunities. As more uses become viable the number of cells produced increases and puts a strain on the metals and mining industry to maintain the supplies of component metals, such as cobalt. Some reports have noted that for cobalt, almost 25% of the world's yearly output is used in lithium ion batteries creating the need to vary the amount of metals used and identify new compositions made of more abundant materials. In addition to new supplies, the opportunity exists with previously manufactured lithium ion cells to recover and reuse the metals and components. As with the lead-acid battery industry, collection of end-of-life lithium ion cells (automotive, consumer, or medical) can act as a supply of reusable materials. In this talk we will discuss the role Direct Recycling has on these pathways and highlight methods to relithiate lithium-deficient samples and deal with the need for compositional changes as market needs change over time with advances in chemistry and technology.

Towards Safe and Sustainable Energy Storage by New Approaches and Materials for Future Dual-Ion Batteries Jens M. Wrogemann¹, Martin Winter²,¹ and Tobias Placke¹; ¹University of Münster, Germany; ²Forschungszentrum Jülich GmbH, Germany

Lithium ion batteries are the dominating energy storage technology for various applications, especially in the field of portable electronics as well as for large scale applications like electric mobility, due to an outstanding mix of high energy density, high power density and long cycle life. However, a growing demand of rechargeable batteries for automotive and stationary applications raises also concerns about resources, growing costs, and sustainability aspects. Especially for stationary grid storage and large-scale applications, sustainability aspects and low installation and lifetime costs are mandatory requirements in order to compete with other energy storage technologies.[1] Driven by that motivation, a huge number of several alternative energy storage technologies raised up in the last decade. One prominent candidate are dual-ion batteries (DIBs), which gained increased attention as alternative energy storage recently. [2] DIBs are characterized by the simultaneous uptake of both, anions and cations from the electrolyte into the respective host materials during charge and their release during discharge. This working principle allows to use non-lithium as well as non-heavy metal containing positive electrode materials like graphite, organic cathodes or even metal organic frameworks for anion storage. [2-4] Due to the promising high working potential of graphite for anion intercalation of ≥4.5 V vs. Li|Li⁺ especially dual-graphite batteries (DGB) achieved an increased attention in the last years. However, the high working potential generates new issues and requirements like high oxidative stability of the electrolyte. Therefore, ionic liquids as well as highly concentrated electrolytes were studied and show promising results. [2,5] However, in terms of cost, safety and sustainability these cell chemistries need further improvement.

The presented work shows first approaches by introducing water-based electrolytes in DIBs as well as new electrode materials for anion insertion. In the first part, a water-based DIB using graphite as cathode material is presented. The impact of different anode materials on the electrochemical performance as well as structural changes during charge and discharge are systematically investigated by ex situ studies as well as in situ X-Ray diffraction and other techniques. In a second part, new organic/inorganic positive electrode materials for reversible anion insertion are presented and evaluated for application in DIB cells with regard to their electrochemical and structural properties.

Advanced Characterization and Diagnosis of Sulfide Based Solid Electrolytes and Their Interfaces  Y. Shirley Meng; University of California, San Diego, United States

Enabling long cyclability of high-voltage oxide cathodes is a persistent challenge for all-solidstate batteries, largely due to their poor interfacial stabilities against sulfide solid electrolytes. While protective oxide coating layers such as LiNbO3 (LNO) have been proposed, its precise working mechanisms are still not fully understood. Existing literature attributes reductions in interfacial impedance growth to the coating’s ability to prevent interfacial reactions. However, its true nature is more complex, with cathode interfacial reactions and electrolyte electrochemical decomposition occurring simultaneously, making it difficult to decouple each effect. Herein, we utilized various advanced characterization tools and first-principles calculations to probe the interfacial phenomenon between solid electrolyte and high-voltage cathode. We segregated the effects of spontaneous reaction between the electrode and electrolyte at the interface and quantified the intrinsic electrochemical decomposition of LPSCI during cell cycling. We will also discuss a few important aspects related to the mechanical compatibility of electrode and electrolyte in all solid state batteries.

5:15 AM *S.EN12.08.03
Developing Materials and Structural-Chemical-Mechanical Diagnostics Tools for Understanding Interface Evolutions in Solid-State Metal Batteries  Yan Yao; University of Houston, United States

The performance deterioration of a solid-state Li battery is the result of a combination of interfacial events. Characterization of these interfaces has been an ongoing challenge, and solid-state batteries are considered by some as a “black box”. Only during the past few years has been there exponential growth in the efforts to apply a variety of microscopic and spectroscopic techniques to characterizing solid-state batteries, but the interfacial phenomena are still far from being well understood. We will report the progress of establishing a structural-chemical-mechanical diagnostics toolset to investigate the interface evolutions in solid-state Li batteries. We will acquire detailed information of interfaces and dendrites evolutions including but not limited to (1) real-time visualization of Li dendrites growth within the whole thickness of electrolyte layer, (2) chemical composition, mechanical property, and evolution of electrolyte decomposition products, including intermediate and metastable ones, at both cathode and anode interfaces, and, (3) quantitative correlation between electrolyte decomposition, void formation, and cell performance. These in-depth understandings will allow us to effectively predict and optimize the physical and chemical changes of components within solid-state Li batteries during charge and discharge.

In addition to tool development, we have studied new cathode and electrolyte materials that form reversible cathode-electrolyte interfacial resistance evolution during cycling as the result of the reversible conversion between the superionic conductor Na3PS4 and the resistive oxidation products Na2P2S6/Na2P2S8. Structural and mechanical analyses further showed that a low- modulus cathode material like PTO (Young’s modulus = 4.2 ± 0.2 GPa) can effectively accommodate interfacial stress and maintain intimate interfacial contact with solid electrolytes. The reversible electrolyte decomposition, revealed by time-of-flight secondary ion mass spectrometry (ToF-SIMS), the consistently intimate interfacial contact, visualized by focused ion beam-scanning electron microscopy (FIB-SEM), and the soft nature of cathode material, characterized by nanoindentation, are all first-time reports in the field of solid-state batteries, and they have collectively led to a high specific energy (587 Wh kg-1) at the active-material level and an 89% capacity retention over 500 cycles, a record cycling stability among all-solid-state Na batteries.

Atomic-Scale Reactivity and Degradation of Electrode Materials During Liquid-Phase Electrochemical Reactions through In Situ/Operando Transmission Electron Microscopy  Rui Filipe Serra Maia and Eric A. Stach; University of Pennsylvania, United States

Liquid-phase Transmission Electron Microscopy (TEM) provides a unique platform to perform time-resolved analysis of
Stability and Evolution of Solid Electrolyte Interphase on Lithium-Ion Anodes Chunmei Ban; University of Colorado Boulder, United States

Solid electrolyte interphase (SEI), which forms at the interface between the electrolyte and the electrode, can passivate the surface of graphite anodes and finally facilitate the intercalation of lithium ions into graphite electrodes. The concept of using SEI protects the electrode surface from the reductive electrolyte has been used for developing other Lithium-ion (Li-ion) applications with worldwide impact, such as ion batteries, hydrogen fuel cells and reduction of CO\textsubscript{2} to biofuels. Moreover, approach here developed opens the opportunity to study and develop nanomaterials with enhanced performance in

Electrode performance is largely determined by the structure of active materials, and thus can be advanced by synthesis of

Solid electrolyte interphase (SEI), which forms at the interface between the electrolyte and the electrode, can passivate the surface of graphite anodes and finally facilitate the intercalation of lithium ions into graphite electrodes. The concept of using SEI protects the electrode surface from the reductive electrolyte has been used for developing other Lithium-ion (Li-ion) anodes, such as intermetallic silicon (Si) anodes. Different from the intercalation chemistry in graphite anodes, Si anodes experience alloying/dealloying reactions during electrochemical process, leading to phase transformation, morphology and volumetric changes. It generates great complexity in understanding the formation and the structural/composition evolution of the SEI layer during electrochemical process. Considering the high theoretical capacity Si anodes can offer, the investigation of SEI behavior on Si anodes is critical for developing next-generation anode materials. This presentation, which is based on recent results from advanced electrochemical and spectroscopy characterization, systematically elaborates the chemical and physical properties of SEI chemistry, towards developing mitigation strategies for stabilizing SEI on Li-ion anodes.

Synthesis of High-Ni Cathode Materials by Design Feng Wang; Brookhaven National Laboratory, United States

Electrode performance is largely determined by the structure of active materials, and thus can be advanced by synthesis of phase-pure materials, and control of their stoichiometry, morphology, surface properties. However, synthesizing materials with desired structure and properties has been difficult due to the complexity associated with chemical reaction and involvement of metastable intermediates. Additional challenge comes from the fact that synthesis is often undertaken under non-equilibrium conditions, making it hard to predict the synthesis process by theoretical computations. Herein, we report development and application of in situ spectroscopy techniques for real-time studies of synthesis to capture intermediates, thereby elucidating how synthesis parameters affect the kinetic reaction pathways and, consequently, the structural properties of the final products both in the bulk and at particle surface. By coupling with electrochemical characterization of the synthesized materials, such studies elucidate how structure, composition and synthesis affect electrochemical performance and therefore provide a basis for synthesis of cathode materials by design. Specific examples will be given on developing LiNi\textsubscript{0.8}Mn\textsubscript{0.1}Co\textsubscript{0.1} (NMC811) and other high-Ni cathodes for Li-ion batteries.

ACKNOWLEDGMENT. This work was supported by the U.S. Department of Energy (DOE) Office of Energy Efficiency and Renewable Energy, Vehicle Technologies Office, Contract No. DE-SC0012704.

The Formation of Li-Mg-Si Zintl Phase by Magnesium Coating on Si Thin-Film as Anode for Lithium-Ion Batteries Zhifei Li\textsuperscript{1}, Caleb Stetson\textsuperscript{1,2}, Glenn Teeter\textsuperscript{1}, Andrew Norman\textsuperscript{1}, Bertrand Tremolet de Villers\textsuperscript{1}, Yeyoung Ha\textsuperscript{1}, Zoey Hue\textsuperscript{1,2}, Sang-Don Han\textsuperscript{1}, Chun-sheng Jiang\textsuperscript{1}, Anthony Burrell\textsuperscript{1} and Andriy Zakutayev\textsuperscript{1}; \textsuperscript{1}National Renewable Energy Laboratory, United States; \textsuperscript{2}Colorado School of Mines, United States

Si anode with high theoretical capacity has shown its promise as the next generation anode for high energy density lithium ion batteries. The large volume change of Si anode during cycling has been well accepted as the main reason that leads to its poor cycling stability. However, the high reactivity of lithiated Si, namely Li$_x$Si, is also responsible for the fast consumption of electrolyte and therefore, the quick capacity decay. To address this issue, we coated Si anode with Mg where the Mg can diffuse into the bulk Si anode and involve in the formation of ternary Li-Mg-Si Zintl phase upon lithiation. The ternary Zintl phase had been proved to be more stable toward electrolyte than Li$_x$Si. The formation of this new phase by Mg coating suppressed the decomposition of electrolyte, altered the solid electrolyte interphase, and resulted in a significantly improved cycling performance of Si anode. This work provides a new approach to tuning the compositions and properties of Si anodes.

6:20 AM S.EN12.08.12
Change in the Crystal Structure of Lithium-Intercalated Graphite at Elevated Temperature Studied by Synchrotron X-Ray Diffraction
Hideaki Oka, Yoshinari Makimura, Chikaaki Okuda, Takamasa Nonaka, Takeshi Uyama and Tsuyoshi Sasaki; Toyota Central R&D Labs., Inc., Japan

The growth of the lithium-ion battery market is being fueled by the expansion of its use in electric vehicles. To achieve long cycle life and high reliability, lithium-ion batteries have to be operated in the limited conditions as for voltage, current, and temperature. Above all, it is important for using lithium-ion batteries safety that understanding and improvement of the thermal stabilities of active materials with electrolyte under elevated temperature. In this study, the thermal stability of the graphite electrode used in Li-ion batteries was studied by in-situ X-ray diffraction (XRD) during elevating the temperature. The in-situ XRD measurements clarified that phase transitions from C$_6$Li to C$_{12}$Li and from C$_{12}$Li to graphite occurred in the temperature range of 250-305 degree C and 305-320 degree C, respectively, which corresponds to the exothermic behaviors detected by differential scanning calorimetry. The de-lithiation behavior under anomalous elevated temperature might be passed with an intermediate state between C$_6$Li and C$_{12}$Li, which is not observed in electrochemical processes.

6:30 AM S.EN12.08.13
Emerging Electron Microscopy Techniques for Probing Interfaces in Battery Materials
Miaofang Chi; Oak Ridge National Laboratory, United States

Interfaces play a fundamental role in defining the performance of batteries, regardless of the type of battery configuration. However, the localized nature of interfaces requires high spatial resolution characterization techniques to fully understand their structure and properties. State-of-the-art atomic-resolution and/or in situ scanning transmission electron microscopy (STEM) and electron energy-loss spectroscopy (EELS) are indispensable tools for characterizing the local structure and chemistry of materials but they are difficult to use to measure many properties that dictate the cycling performance of batteries. For example, it is challenging to directly observe the lithium distribution at lattice sites, to probe electrostatic potential drop at interfaces, to measure electronic and ionic conductivity of local features, and to detect interfacial dynamic evolution under in situ electrochemical cycling conditions. Further, current techniques are largely limited to electron-beam irradiation and samples that do not contain liquids. Here, we outline emerging electron microscopy techniques that allow us to overcome these limitations and highlight several recent studies that have been enabled by techniques such as 4D-STEM, monochromated EELS, cryo-STEM, and new integrated in situ stages. The limitations of these techniques and the pitfalls in data interpretations will be discussed. We provide a perspective as to how these methods can be paired to deliver new insights into the static and dynamic behavior of functional interfaces in batteries.

Under the influences from both classical analytical electrochemistry pursuing ideal ionic behavior at infinitely diluted state and classical physical electrochemistry pursuing the most conductive ionics, the study of non-aqueous electrolytes have been confined within the narrow concentrations around 1 molarity. This confinement was only breached in recent years when investigators discovered that unexpected properties often arise from excessively concentrated electrolytes, benefitting mechanical, thermal, transport, interfacial structure as well as interphasial chemistries. The most extreme examples of the super-concentrated electrolytes include the high voltage (4 V) aqueous electrolytes and non-aqueous electrolytes that enables highly aggressive battery chemistries (Li-metal, high NMC, etc).

Aside from their various novelties in physical, transport and electrochemical/interphasial properties, super-concentrated electrolytes enhances the overall safety of batteries, primarily because solvent molecules therein were bound by new liquid structures that never exists previously.

In this talk, I will briefly summarize the current status of these battery chemistries.

5:15 AM *S.EN12.09.02
Does Spinel Serve as a Rigid Framework for Oxygen Redox? Xiang-Mei Shi¹, Kosuke Kawai¹, Eriko Watanabe¹, Masashi Okubo¹² and Atsuo Yamada¹²; ¹The University of Tokyo, Japan; ²Kyoto University, Japan

The discovery of a large-capacity cathode material is a major task for developing batteries of high energy density, and an additional oxygen redox capacity has recently been regarded as a new impetus. From the electronic-structure point of view, lithium-rich layered oxides, typical oxygen-redox cathode materials, possess oxide ions with a nonbonding O 2p state along the Li-O-Li coordination axis, which provides the oxygen redox activity. After oxygen oxidation, either a π-type M t2g-O 2p interaction (M: transition metal) or a O-O bond formation should stabilize oxidized oxide ions. However, the layered structure is generally unstable after extracting an excess amount of Li ions, leading to the capacity fade and potential decay upon cycling. Therefore, for achieving the stable additional oxygen-redox capacity, of particular importance is to implement oxide ions with nonbonding O 2p state into a stable host framework against excess Li-ion extraction. As layered to spinel transformation has been claimed as a origin of a voltage drop and the latter have a stable three-dimensional framework, it is attractive to explore for spinel oxides capable of the oxygen-redox reactions.

Here, we diagnose the oxygen-redox activity of spinel oxides with combined experimental and density functional theory (DFT) calculations. 

5:30 AM S.EN12.09.03
Temperature Effect and Thermal Analysis of Battery Package for Harsh Space Environment Amani Alhammadi, Amarsingh Bhabu Kanagaraj, Prerna Chaturvedi, Hamda Alshibli and Daniel Choi; Khalifa University, United Arab Emirates

The main challenge that hinders the use of Li-ion batteries in space applications is its low performance at ultra-low temperatures. This is due to the low ionic conductivity and freezing of the electrolyte which leads to the loss of battery’s capacity. Another challenge is the moisture absorption of the electrodes and polymer electrolyte. In this research, a protective packaged case is designed and fabricated using 3D printing technique to enhance the ionic conductivity and restrict moisture absorption from the surrounding. This pack is made of polyether–ether–ketone (PEEK) which can withstand temperature range from -100 to 260°C and hence improve the ionic conductivity and prevent freezing of the electrolyte. Furthermore, the full cell battery is coated with a protective layer made of polydopamine to decrease the moisture absorption and improve the performance and lifetime of the battery. The battery case is simulated using COMSOL software to study the thermal and mechanical effect under space environment. In addition, the full cell packaged battery will be tested in terms of mechanical, electrical, and electrochemical performance using battery test setup. Moreover, thermal and radiation tests will be conducted in the vacuum thermal chamber to analyze the battery’s performance in harsh space environment. Parameters such as weight, lifetime and capacity loss are taken into consideration.

Co-intercalation for Increased Performance of Dual-Carbon Battery Using Mixed Salt Electrolyte Tatsumi Ishihara, Kotaro Nakamura, Jun Tae Song and Taner Akbay; Kyushu University, Japan

Long cycle life, high rate properties, sustainable active materials, reduced manufacturing cost, and improved safety aspects of dual-carbon batteries (DCBs) make them promising alternatives for the state-of-the-art rechargeable battery technologies. The DCB chemistry exploits the redox-amphoteric host capability of graphite as both electrodes for Faradaic charge storage.
by intercalating active species such as alkaline cations (typically Li+) and fluorinated anions (e.g., PF6-) into anode and cathode respectively. Recently, as part of the quest for elevating discharge potentials of DCBs, intercalation properties of larger sized anions such as bis(trifluoromethanesulfonyl)imide (TFSI-) into the graphitic carbon cathode have been investigated. However, rather low coulombic efficiency values obtained by using the LiTFSI salts in DCBs prove to be a greater challenge.

Co-intercalation of PF6- and TFSI- anions as a result of the use of a mixed salt of LiPF6 and LiTFSI was studied for the increased performance of a dual-carbon battery (DCB). Unlike the fluorine- or the imide-based anions (e.g., PF6- and TFSI-), the cluster formation between co-intercalated PF6- and TFSI- in the positive electrode of a dual carbon battery resulted in achieving high discharge capacities with significant increased cycle properties. A reversible discharge capacity of 90 mAh/g-cathode over 350 cycles with no significant degradation is presented. The Coulombic efficiency of almost 100% is reached after the initial 10 cycles and suitable rate property is also observed. F-NMR analysis on graphitic carbon intercalated with PF6- and TFSI- suggested the interaction between two anions resulting in the increased stability of the intercalated structure which is also supported by first principles calculations. Gas formation at high potential during charge step is also suppressed by using mixed salt of LiPF6-LiTFSI.

Nicotinamide Cofactor as an Energy Storage Compound for Biologically Inspired Rechargeable Batteries

Sunghyun Ko1, Jihyeon Kim2, Chanwoo Noh2, Heechan Kim2, Sechan Lee2, Dodam Kim2, Hyeokjun Park2, Giyun Kwon2, Giyeon Son1, Jong Wan Ko2, YoonJoon Jung2, Dongwhan Lee2, Chan Beum Park1 and Kisuk Kang2; 1Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of); 2Seoul National University, Korea (the Republic of); 3Korea Institute of Industrial Technology, Korea (the Republic of)

Rising concerns on sustainability have brought great interest for ecofriendly energy storage solutions and motivated searching for sustainable electrode chemistry for lithium ion batteries (LIBs), most widely used portable power sources. Organic materials, which are derived from biomass or naturally abundant resources, are attractive electrode candidates for LIBs due to their minimal environmental footprint. The chemical tunability of organic materials can additionally allow a design flexibility required for electrodes in various types of rechargeable batteries. Especially, exploiting redox-active molecules in biological energy transduction, which have been optimized over many years of natural selection, is an appealing approach to green energy storage combined with the demonstrated efficiency. Biological energy transductions share many aspects with rechargeable battery operation in underlying redox mechanism with respect to unidirectional transportation of charged ions (H+ or Li+) and electrons to a redox-active center, resulting in reversible energy storage. This analogy suggests a potential feasibility for utilizing new redox center from biological reactions to energy storage in rechargeable batteries.

Nicotinamide adenine dinucleotide (NAD+) is one of the most well-known redox cofactors carrying electrons. The redox-active NAD+ motif is involved in over 80% of all biotransformations and electron transfer reactions in natural systems by carrying charged ions and electrons from one reaction to another. The versatility of NAD+ motif may present promises in its electrochemical activity in other energy storage systems such as LIBs. Nevertheless, the exploration of its applicability as an electrode in conventional LIB setup is not trivial, since its charged state (NAD+) and the dissolved nature are not compatible with the electrode fabrication requirements, where active compounds are generally in neutral state and ready for process into solid electrode. While significant portion of the energy carrying molecules are in charged states and/or dissolved states in the biocells, a general fixation strategy would aid in expediting the exploration of these bio redox molecules.

Herein, we exploited the NAD+ motif, one of the most versatile redox centers in nature, to facilitate reversible electrochemical energy storage in LIB system for the first time. To exploit the redox reaction of NAD+ motif in LIBs, nicotinamide cofactor was modified into a simple structure bearing the redox-active part to produce nicotinamide analogue (mNAD+). The charged mNAD+ were crystallized using counter anions such as I-, Br-, and Cl-, resulting in a neutral and solid-state powder. It is demonstrated that these NAD+ -derivatives (mNAD-X, X= I-, Br-, and Cl-) are capable of reversibly facilitating lithium coupled electron transfer in solid electrode form, exhibiting the intrinsic redox capability of NAD+.
Combined experimental and theoretical calculations revealed that mNAD-X retains the intrinsic redox activity of natural NAD⁺ motif, accompanying lithium coupled electron transfer which is similar to the proton-coupled electron transfer mechanism in the biological systems. Furthermore, the operating voltage and capacity are tunable by altering the anchoring anion species without modifying the redox center itself. This work not only demonstrates the redox capability of NAD⁺, but also suggests that anchoring the charged molecules with anion incorporation is a viable new approach to exploit various charged biological cofactors in rechargeable battery systems.

Bio-Templated Tubular MCo2O4 (M= Mn, Ni, Cr) Microstructure and Their Electrochemical Performance
Deepa Guragain¹, Camila Zequine², Sanjay R. Mishra¹ and Ram K. Gupta²; ¹University of Memphis, United States; ²Pittsburg State University, United States

Binary oxides with novel nanoarchitectures are increasingly explored for their application in energy storage devices. The nanoarchitecture of these oxides is usually varied via synthesis route, which usually requires complex technologies, expensive equipment, and harmful organic reagents or surfactants, which might further hinder their application. Hence, it is highly desirable to explore facile synthesis strategies, which are cost-effective, simple, and environmentally friendly to get “green” nanomaterials. Recently, bio-templating has emerged as a promising technique for the synthesis of Co₃O₄ capacitors [i]. Nature offers us various and excellent bio-templates [ii],[iii],[iv] such as bamboo, pig bone, crab shells, lotus pollen grains, bacteria [v], leaf [vi], sorghum straw [vii], butterfly wing [viii], jute fibers [ix], and cotton [ix]. Such bio-templates exhibit precise widths and lengths, complex exterior and interior surfaces, and uniform geometries, all of which have inspired researchers to produce multiscale hybrid inorganic materials that exhibit hierarchical morphologies.

In this work, we present a comparative study of the electrochemical performance of tubular MCo2O4 (M= Mn, Ni, Cr) microstructures prepared using cotton fiber as a biotemplate. The as-obtained templated MCo2O4 (M= Mn, Ni, Cr) structures inherit the morphology and microstructure of cotton fiber. The electrochemical performance of the electrode made up of tubular MCo₂O₄(M= Mn, Ni, Cr) structure was evaluated in 3M KOH aqueous electrolytes. The large-surface-area of tubular MCo₂O₄(M= Mn, Ni, Cr) microstructures has a noticeable pseudocapacitive performance with a capacitance of 161 F/g, 190 F/g, and 231 F/g at 1 A/g current density and 378.13 F/g, 407.16 F/g, and 403.39 F/g at 2 mV/s scan rate for MnCo₂O₄, NiCo₂O₄, and CrCo₂O₄ respectively. Also a Coulombic efficiency ~100%, and excellent cycling stability with capacitance retention of about 91%, 100%, and 92% for MnCo₂O₄, NiCo₂O₄, and CrCo₂O₄ respectively even after 5,000 cycles. These obtained tubular MCo₂O₄(M= Mn, Ni, Cr) microstructure display superior electrochemical performance in aqueous 3M KOH electrolyte with peak power density reaching 295.5 W/Kg, 296.3 W/Kg, and 293.5 W/Kg, and energy density 7.8 Wh/kg, 9.3 Wh/kg, and 11.1 Wh/kg, for MnCo₂O₄, NiCo₂O₄, and CrCo₂O₄ respectively. The superior performance of tubular MCo₂O₄(M= Mn, Ni, Cr) microstructure electrode is attributed to their high surface area and adequate pore volume distribution, which allows effective redox reaction and diffusion of hydrated ions.

The preparation of transition metal oxides has attracted the interest of many research groups in recent years because of their unique properties and envisioned applications in electronics, optics, magnetic materials, and energy storage devices. Co$_3$O$_4$ belongs to a class of complex oxides known as spinels with the chemical formulas of AB$_2$O$_4$ in which A ions are generally divalent cations occupying tetrahedral sites, and B ions are trivalent cations in octahedral sites. Co$_3$O$_4$ has been explored for its good pseudocapacitance along with other established materials, in which charge is stored using redox-based Faradic reactions. Many synthesis techniques such as solvothermal synthesis, sol-gel method, electrospinning method, and lithography technique, a hydrothermal technique, have been explored for the synthesis of nanostructured materials. However, many of these strategies generally require complex technologies, expensive equipment, and harmful organic reagents or surfactants, which might further hinder their application. In the present work, we used a one-step facile procedure for the synthesis of biomorphic Co$_3$O$_4$ using cotton fiber as a bio-template.

Template-assisted facile synthesis of tubular Co$_3$O$_4$ microstructures and its electrochemical performance was studied to understand its use as a potential electrode material for supercapacitors. Tubular porous Co$_3$O$_4$ microstructures were synthesized using cotton fibers as bio-template. The as-obtained templated Co$_3$O$_4$ structure inherits the morphology and microstructure of cotton fiber. The electrochemical performance of the electrode made up of tubular Co$_3$O$_4$ structure was evaluated in 3M KOH, NaOH, and LiOH aqueous electrolytes. The large-surface-area of tubular Co$_3$O$_4$ microstructure has a noticeable pseudocapacitive performance with a capacitance of 401 F/g at 1 A/g and 828 F/g at 2 mV/s, a Coulombic efficiency averaging ~100%, and excellent cycling stability with capacitance retention of about 80% after 5,000 cycles. Overall, the tubular Co$_3$O$_4$ microstructure displayed superior electrochemical performance in 3M KOH electrolyte with peak power density reaching 5,500 Wh/kg and energy density exceeding 22 Wh/kg. The superior performance of tubular Co$_3$O$_4$ microstructure electrode is attributed to its high surface area and adequate pore volume distribution, which allows effective redox reaction and diffusion of hydrated ions. The facile synthesis method can be adapted for preparing various metal oxide microstructures for possible applications in catalysis, electrochemical, sensors, and fuel cells applications.
Morphological and Theoretical Study of Ni$_{1-x}$Ca$_x$Co$_2$O$_4$ (0 ≤ x ≤ 0.8) Nanostructures as High-Performance Electrode Materials for Supercapacitors

Deepa Guragain$^1$, Camila Zequine$^2$, Romakanta Bhattarai$^1$, Jonghyun Choi$^2$, Ram K. Gupta$^2$ and Sanjay R. Mishra$^1$; $^1$University of Memphis, United States; $^2$Pittsburg State University, United States

Nowadays the binary metal oxides are highly use as supercapacitor electrodes in energy storing devices. Particularly NiCo$_2$O$_4$ has shown promising electrocapacitive performance with high specific capacitance and energy density. The electrocapacitive performance of these oxides largely depends on their morphology and electrical properties governed by their energy band-gaps and defects. The morphological structure of NiCo$_2$O$_4$ can be altered via synthesis route while energy band-gap could be altered by doping. Also, doping can enhance crystal stability and bring in grain refinement, which can further enhance the much-needed surface area for high specific capacitance. In view of the above, this study evaluates the electrochemical performance of Ca-doped Ni$_{1-x}$Ca$_x$Co$_2$O$_4$ (0 ≤ x ≤ 0.8) compounds. The Ni$_{1-x}$Ca$_x$Co$_2$O$_4$ samples were prepared via a facile and cost effective hydrothermal technique by varying Ca to Ni molar ratio. Physical, morphological, and electrochemical properties of Ni$_{1-x}$Ca$_x$Co$_2$O$_4$ were observed on the variation of Ca. The increase of Ca concentration in Ni$_{1-x}$Ca$_x$Co$_2$O$_4$ leads to the morphological transformation from nanoplates to urchin-like structure with an increase in the surface area reaching up to 73.2 m$^2$/g for x = 0.2. The higher specific capacitance of 247.5 F/g at a current density of 1 A/g, 934.4 F/g at 2 mV/s scan rate, the energy density of 14.8 Wh/kg and power density of 136.3 W/kg in 3M KOH electrolyte was observed for x = 0.6 sample. An increased retention capacity ∼255% measured at 5 A/g current density and Coulombic efficiency of 99%. The density functional theory (DFT) calculations of the electronic density of states identified Ni$_{1-x}$Ca$_x$Co$_2$O$_4$ with optimal band-gap varies from 2.67 eV to 3.88 eV for x = 0 to x = 0.8. Such impressive electrocatalytic activity results in the high intrinsic electronic conductivity and can largely improve the interfacial electroactive sites as well as charge transfer rates. This work of doping NiCo$_2$O$_4$ by calcium is very novel which will stipulates promising applications for electrodes in future supercapacitors.

NOEL—Innovative Nanostructured Electrodes for Energy Storage Concepts

Maria Bernechea$^{1,2,3}$, M. Pilar Lobera$^{1,2}$, Robert Dominko$^4$, Alen Vizintin$^4$, Elzbieta Frackowiak$^2$ and Krzysztof Fic$^5$; $^1$INA - Institute of Nanoscience of Aragon, Spain; $^2$Networking Biomedical Research Centre of Bioengineering, Biomaterials and Nanomedicine (CIBER-BBN), Spain; $^3$ARAID, Spain; $^4$National Institute of Chemistry, Slovenia; $^5$Poznan University of Technology, Poland

Energy Storage Systems (ESS) will play a central role in reducing fossil fuel consumption and greenhouse gas emissions by providing solutions to store energy produced from renewable sources and to implement electrical vehicles.

Graphite is the traditional material employed in standard rechargeable batteries or hybrid electrochemical capacitors, but it shows restrictions because of its limited intrinsic capacity, moderate Li-ion intercalation and capacity rate. Also, Li and Co, all standard materials for hybrid capacitors and Li-ion batteries, are limited resources, and the European Union (EU) is dependent on external supply.

To solve these shortcomings, NOEL aims at developing new, low-cost and environmentally friendly layered semiconductor-carbon composites for their use as innovative electrodes in the next generation of batteries or supercapacitors. Specifically, NOEL will provide new carbon substrates and carbons decorated with layered sulfide nanoparticles and will test their performance as electrodes for supercapacitors and post-Li batteries (Na, Mg, or Ca), looking for improved performance, low price, high material availability being locally produced in EU, and environmentally friendly properties.

For that purpose, NOEL consists of 2 European universities (Zaragoza University, UNIZAR, in Spain, and Poznan University of Technology, PUT, in Poland), and 1 European research institution (National Institute of Chemistry, NIC, in Slovenia). The balancing expertise includes development and characterization of nanomaterials (UNIZAR), and manufacture and testing of batteries (NIC), or supercapacitors (PUT).

Nanoconfined Iron (III) Fluoride Cathode in NaDFOB Electrolyte towards High-Performance Sodium-Ion Batteries

Zifei Sun, Wenbin Fu, Michael Liu, Peilin Lu, Enbo Zhao, Alexandre Magasinski, Mengting Liu, Shunrui Luo, Jesse McDaniel and Gleb Yushin; Georgia Institute of Technology, United States

Iron (III) fluoride (FeF$_3$) is considered as a potential cathode for sodium-ion batteries (SIBs) due to its high capacity and low cost. However, the particle pulverization upon cycling generally results in rapid degradations in its structure and capacity.
Here, we introduce a free-standing nanoconfined FeF₃ cathode and a novel electrolyte salt sodium-difluoro(oxalato)borate (NaDFOB) for SIBs. The assembled cells show high discharge capacity up to ~230 mAh g⁻¹ at the rate of 20 mA g⁻¹ (~200 mAh g⁻¹ at 100 mA g⁻¹) and capacity retention up to ~70% after 100 cycles, which represent the best results reported on FeF₃ in Na-ion electrolytes. The achieved high performance can be attributed to the synergic protection provided by the nanoconfined FeF₃ electrode and the NaDFOB electrolyte. Post-mortem analysis and quantum mechanics show that DFOB anion facilitated the formation of a thin cathode electrolyte interphase (CEI) at the surface of FeF₃-carbon nanofibers (CNFs) via oligomerization.

Upgrading Coal to Multifunctional Graphene-Based Materials by Directlaser Scribing Chi Zhang and Jian Lin; University of Missouri-Columbia, United States

Despite much progress, developing a cost-effective and environmental-friendly method to upgrade earth-abundant coal into high value-added products is still a grand challenge. Here, we report a one-step and facile approach to synthesize graphene based materials from coal under ambient conditions via direct CO₂ laser scribing. The obtained laser scribed graphene from coal (C-LSG) has been well characterized, showing good electrical conductivity (120 U/square), high electrochemical sensitivity and ionic storage properties. These properties make C-LSG a multifunctional material for applications in Joule heating, electrochemical dopamine sensing, and supercapacitors. Moreover, when electrochemically deposited with FeNi hydroxide, the hybridized FeNi/C-LSG shows impressive electrocatalysis performance toward oxygen evolution reaction. As such, this direct laser scribing of coal into graphene based materials can not only potentially expand new business opportunities by adding coal into the value-chain of industries that usually do not use coal as the starting materials in their manufacturing processes but also brings down the cost of the graphene based materials, which would make their deployment in various fields more economically attractive.

Facile Fabrication of a Polyaniline Electrode with a Hierarchical, 3-D Porous Network for High Performance Supercapacitors Hyung-Jun Koo, Ji-Hye Kim, Ju-Hee So and Sung-Kon Kim; ¹Seoul National University of Science & Technology, Korea (the Republic of); ²Korea Institute of Industrial Technology, Korea (the Republic of); ³Chonbuk National University, Korea (the Republic of)

Since any electrochemical reactions occur at the interface between electrodes and electrolytes, an electrode with well-defined open pores and high surface area is preferred for an efficient electrochemical system, such as supercapacitors and batteries. Recently, it has been reported that a conducting polymer, polyaniline, can be crosslinked by phytic acid, to form a conducting hydrogel with hierarchical open pores. Here, we present a facile fabrication method of a conducting porous electrode, by a doctor-blading technique of the polyaniline hydrogel paste and successive dehydration process. We carefully investigated the effect of compositions in preparation of PANI on its pore morphology and electrical property. It turns out that as initiator/crosslinker contents increase or monomer content decreases, the PANI conducting hydrogel has denser morphology with decreased pore size, resulting in higher electrical conductivity. Notably, hierarchical pores, ranging from tens of micrometers to tens of nanometers in size, are well developed, even in the dense porous PANI film. Due to its characteristic pore morphology and redox activity, the PANI film could serve as an efficient electrode for a pseudo-capacitor. In the 3-electrode configuration, the porous PANI electrode prepared at the optimized composition, in the pristine form without any conducting additive, exhibited ~690 F/cm³ of volumetric capacitance, which is much higher than those of the PANI based capacitors reported so far. Finally, we fabricated a practical capacitor with two symmetric PANI hydrogel electrodes, which shows 110 mF/cm³ of volumetric capacitance with improved cycle stability of 80% retention rate for 5000 cycles.

Molten Salt Catholytes for Low-Temperature Molten Sodium Batteries Leo J. Small, Stephen Percival, Martha M. Gross and Erik D. Spoerke; Sandia National Laboratories, United States

Molten sodium batteries offer a promising technology for grid scale energy storage. The molten sodium anode minimizes dendrite formation, while the elevated operating temperature minimizes hazards associated with assembly of MWh capacities at room temperature. Typical molten sodium battery chemistries such as Na-S and Na-NiCl₂ (ZEBRA) operate near 300 and 200 °C, respectively. Driving operating temperatures down to 100 °C would decrease operating costs, minimize materials aging effects, and enable use of low temperature polymeric seals. Successful development of a molten sodium battery that operates near 100 °C, however, requires significant reengineering of the catholyte. Besides being molten at 100 °C, such a catholyte must possess (1) electrochemically reversibility, (2) chemical stability, (3) high ionic conductivity, and (4) minimal reactivity to molten sodium metal. Herein we describe the development of fully inorganic molten salt catholytes based on...
mixtures of NaI and group 13 halide salts that satisfy these requirements. The NaI enables use of the facile, energy-dense I⁻/I₃⁻ redox couple, while targeted group 13 halide salts engender sufficiently low melting points over a wide range of NaI concentrations. These molten salts demonstrate good electrochemical I⁻/I₃⁻ reversibility and at high I⁻ concentrations near 100 °C, without use of any organic solvent. We characterize the ionic conductivity and electrochemical kinetics of these salts for a variety of compositions and electrode materials. Full cell cycling using a molten sodium anode and a ceramic NaSICON separator demonstrates promising performance and indicates points for further electrolyte refinement. Together, these molten salts offer a pathway for safe, reliable, grid-scale energy storage.

S.EN12.10.21
Fabrication and Characterization of Glassy Carbon on Flexible Substrate Interdigitated Supercapacitor Omar Nunez Cuacuas, Sammuel Kassegne and Surabhi Nimbalkar; San Diego State University, United States

Improved energy storage technologies have received intense attention since there is a fast-growing market for portable electronic devices such as the internet of things. Micro-supercapacitors possess a remarkable feature of high electrochemical performance and relatively small volume in which they can reach high power density and fast charge-discharge rates. In contrast to batteries, these next-generation energy storage devices are fast, efficient and environmentally friendly with longer life cycles without losing performance. We developed a novel integrated, flexible glassy carbon micro-supercapacitor technology with 30 interdigitated fingers as seen in figure 1. We compacted the complete electrical routing path and contact pads within the device's area, utilizing through-via bottom electrodes. The glassy carbon electrode achieved a surface area of 0.1655 and mass of 0.278 mg. The device showed a specific capacitance of 963.979 μF/cm² for a scan rate of 0.1 V/s, which is greater than the values reported for vertically aligned carbon nanotubes. In addition, it achieved an energy density of, and a power density of, higher than those reported from multilayer reduced graphene oxide.

S.EN12.10.24
Ni₁₋ₓAlₓCo₂O₄ (0 ≤ x ≤ 0.8) Nanostructures as High-Performance Supercapacitor Applications—Theoretical and Morphological Study Deepa Guragain¹, Jonghyun Choi², Wang Lin², Subash C. Bhandari¹, Ram K. Gupta² and Sanjay R. Mishra¹; ¹The University of Memphis, United States; ²Pittsburg State University, United States

Nowadays nickel cobaltite, NiCo₂O₄ with excellent electrochemical properties has become good source of energy storage electrode for electrochemical supercapacitor. NiCo₂O₄ has shown promising electrocapacitive performance with high specific capacitance and energy density. The electrocapacitive performance of these oxides highly depends on their morphology and electrical properties governed by their energy band-gaps and defects. The variation of morphological structure can be occur via synthesis route, on the other hand energy band-gap could be changed by doping. Also, doping can enhance crystal stability and bring in grain refinement, which can further enhance the much-needed surface area for high specific capacitance. This study evaluates the electrochemical performance of Al-doped Ni₁₋ₓAlₓCo₂O₄ (0 ≤ x ≤ 0.8) compounds. These Ni₁₋ₓAlₓCo₂O₄ samples were prepared via a hydrothermal technique by varying Al to Ni in molar ratio. Physical, morphological, and electrochemical properties of Ni₁₋ₓAlₓCo₂O₄ were observed on the variation of Al. The characterization was performed by using X-ray diffraction (XRD), Scanning Electron Microscopy (SEM), Fourier Transform Infrared Spectroscopy (FTIR), Quantumchrode Image, and X-Ray Photoelectron Spectroscopy (XPS). XRD confirms the formation of phase pure Ni₁₋ₓAlₓCo₂O₄ (0 ≤ x ≤ 0.8). The increase of Al concentration in Ni₁₋ₓAlₓCo₂O₄ leads to the morphological transformation from urchin like spheres to nanoplates like structure with an increase in the surface area reaching up to 107.2 m²/g for x=0.4. XPS give the elemental composition of Al dope Ni₁₋ₓAlₓCo₂O₄ (0 ≤ x ≤ 0.8). The electrochemical performance was observed using Cyclic Voltammetry (CV), Galvanostatic Charge Discharge (GCD), and Electrochemical Impedence Spectroscopy (EIS) measurement. The higher specific capacitance of 511.5 F/g at 2 mV/s scan rate, 267.9 F/g at a current density of 0.5 A/g, and the energy density of 12.4 Wh/kg in 3M KOH electrolyte was observed for x = 0.0 sample. The power density of 4660.4 W/kg was observed for x = 0.8 sample. The capacitance retention ~97%, 108.52% and Coulombic efficiency of 100%,
99.24% for x=0.0 and x=0.8 respectively. All these results indicate Al dope NiCo2O4 composites electrode shows promising electrocatalytic activity results in the high intrinsic electronic conductivity, can largely improve the interfacial electroactive sites, increase charge transfer rates and help to stabilize the structure of compound.

S.EN12.10.25
Synthesis of NiCo2O4 Nanoparticles Decorated with g-C3N4 by Using Urea as a High-Performance Electrode Material for Supercapacitor
Deepa Guragain, Subash C. Bhandari and Sanjay R. Mishra; University of Memphis, United States

Transition metal oxides have been extensively studies as an electrode material for the energy storage devices including fuel cell, Li-ion batteries, and electrochemical capacitors. Nowadays, it has been found that ternary metal oxides with two different metal cations exhibit much higher electrochemical activities because of their complex chemical composition and effect of multiple metal ions [[1]]. NiCo2O4 urchin like Nano-flower are decorated by graphitic carbon nitride (g-C3N4). Graphitic carbon nitride is a graphene derivative, has been explored due to its interesting electronic feature, low price, and high environmental-friendly features [[2], [3]]. We have prepared first NiCo2O4 by hydrothermal method and decorated NiCo2O4 by g-C3N4 composite material by calcination of urea. The structural property of NiCo2O4 was confirmed by X-ray diffraction (XRD) and found phase pure crystalline structure. On the other hand, presence of g-C3N4 is confirmed by Scanning Electron Microscopy (SEM) which show the NiCo2O4 with g-C3N4 have thicker urchin Nano-flowers compare to NiCo2O4 without it. X-ray Photoelectron Spectroscopy (XPS) confirm the presence of graphitic carbon on NiCo2O4 composition. The obtained surface area by using Quanta-chrome surface area analyzer is 40.1 m²/gm for NiCo2O4 and 63.7 m²/gm for NiCo2O4 decorated with g-C3N4. Higher surface area could provide more channels for the access of hydrated electrolyte ions, so we can assume that g-C3N4 decorated NiCo2O4 have shown better electrochemical performance compare to NiCo2O4 alone. The electrochemical performance was observed using Cyclic Voltammetry (CV), Galvanostatic Charge Discharge (GCD), and Electrochemical Impedance Spectroscopy (EIS) measurement. The higher specific capacitance of 601 F/g and 712 F/g at 2 mV/s scan rate, specific capacitance of 289 F/g and 394F/g at a current density of 0.5 A/g, and the energy density of 13 Wh/kg and 14.5 Wh/kg observed for NiCo2O4 and g-3N4 decorated NiCo2O4 respectively, when measure in 3M KOH electrolyte. Furthermore, the observed power density of 4740 W/kg and 5010 W/Kg, capacitance retention ∼97% and 99% and Coulombic efficiency of 97% and 99.5% for NiCo2O4 and g-3N4 decorated NiCo2O4 respectively. This project will be promising for future energy storing devices.

S.EN12.10.28
Fabrication and Characterization of Flexible MWCNTs/LTO Nanocomposites-Based Electrodes for Battery Applications
Prerna Chaturvedi1, Amarsingh Bhabu Kanagaraj1, Aman Alihammad1, Maraim S. Al Nahyan1, Hamda Alshibli1, Boohyun An1, Sultan Al Dahmani2, Hamed Fadaq2 and Daniel Choi1; 1Khalifa University of Science and Technology, United Arab Emirates; 2United Arab Emirates Space Agency, Space Missions’ Science and Technology Directorate, United Arab Emirates

The investigation and development of flexible power sources has motivated the development of flexible, lightweight, binder and current-collector-free electrodes for Li-ion batteries (LIB). For the fabrication of conventional LIB electrode, binder and current collector are introduced to inhibit the collapse of the active materials and maintain the electrode conductivity, respectively. The usage of binders and current collectors contributes nothing but dead weight to the lithium storage, which decreases the energy density of LIBs. Free-standing carbon nanotube ‘buckypaper’ can be fabricated by using both single-walled carbon nanotubes and multi-walled carbon nanotubes (MWCNTs), and their composites with other active electrode materials and then can be used as working electrodes for LIBs. Compared with conventional electrode material in the bulky form, free-standing paper type electrodes have several advantages. First of all, with the removal of the binders and current
collector, the dead weight of an electrode is decreased, leading to the increase of usable capacity and specific energy density for the overall battery design. Secondly, the ease of handling the ‘buckypaper’ makes them readily shaped into various forms required in a variety of flexible and lightweight electronic devices. Here, we are proposing the fabrication of free-standing, flexible and foldable MWCNTs/ lithium titanate oxide (Li4Ti5O12, LTO) based composite ‘buckypaper’ by a facile, scalable, cost-effective and environmental friendly surface-engineered tape casting (SETC) method. The SETC technique has several advantages such as tunable length, thickness, density, composition and implementation in both batch and roll to roll process. The composite ‘buckypaper’ is demonstrated as anode material for LIB. Electrical conductivity was found to be $4.4 \times 10^2$ Scm$^{-1}$ at room temperature. The composite electrode shows the specific capacity of ~150 mAhg$^{-1}$ at 0.2 C rate which is mainly attributed to enhanced electric and ionic transfer during electrochemical reactions.

Acknowledgements
This project is part of the implementation plan for the United Arab Emirates Space Agency’s ST&I Roadmap and it falls under Level 1 ST&I area of "space power and energy storage" and level 2 "energy storage". The project is aimed at developing enabling technologies for promising mission and system concept; in particular, an in-house prototype of lithium-ion battery. The project can potentially result in a commercially viable lithium-ion battery technology for spacecrafts/satellites. This work is funded by the United Arab Emirates Space Agency, Space Missions’ Science and Technology Directorate, Reference M04-2016-001.

Fabrication of Freestanding Mn$_2$O$_3$ Web Electrode for Supercapacitor Applications Molly Brockway and Jack L. Skinner; Montana Tech, United States

Supercapacitors have the potential to bridge the gap between traditional capacitors and secondary batteries, providing high power and energy densities that may be used for clean energy storage, hybrid vehicles, and other applications. Manganese oxides, including Mn$_2$O$_3$, are inexpensive, environmentally benign materials that have shown promising performances as supercapacitor electrodes. Inherent low conductivity limits application of Mn$_2$O$_3$ in bulk form; however, nanostructured oxides demonstrate enhanced charge-transfer capabilities that render them feasible electrode materials. Additionally, the increased specific surface areas of nanomaterials provide a route for further enhancement of electrode performance, as electrochemical capacitors store charge through surface interactions with the electrolyte. However, in the fabrication of electrodes from nanostructured manganese oxides, the active materials are mixed with binders and conductive agents before pasting onto a charge-collecting substrate. By eliminating additives, mass can be minimized, and the specific capacitance of assembled devices can be improved. Free-standing web electrodes have been reported in several materials systems but have primarily been carbon-fiber based. A similarly independent structure for manganese oxides may improve performance to allow for enhanced widespread use.

In this work, a free-standing Mn$_2$O$_3$ web electrode is fabricated directly onto a charge collector using a facile, two-step electrospinning and thermal treatment process. To fabricate freestanding web electrodes, polymer fibers containing manganese salts are electrospun directly onto foil charge collecting substrates. The fibers are calcined in air to remove the carrier polymer and convert the manganese salts to an oxide. X-ray diffraction is used to confirm the oxide phase produced during calcination so that comparison of electrochemical performance to literature values may be performed. The fabricated electrodes are imaged with scanning electron microscopy; fiber mat morphology and structure are qualitatively observed, while quantitative image analysis is used to calculate the active mass of oxide in the electrodes. The web electrodes are tested in an electrochemical system using cyclic voltammetry and galvanostatic charge-discharge to measure specific capacitance and capacity fading over many cycles. Contact angle measurements are performed to analyze electrode wettability and determine whether poor wettability and the accompanying reduced interfacial area present a barrier to optimized capacitance. After electrochemical cycling, the electrodes are again imaged with electron microscopy, and morphological changes are qualified with electron microscopy and comparison to the as-fabricated structures. Electrodes prepared using pre-calcination processing steps such as hot-pressing and chemical melting are examined alongside untreated fiber mats to determine the effects of multiple processing steps on final manganese oxide electrode morphology and performance.

S.EN12.10.33
Decoding the Oil Dependent Properties of Soot’s Composition and Optimization Strategies for Its Application in EDLC Supercapacitors Anurag Tyagi$^{1}$, Manish Gupta$^{1}$, Chetna Gola$^{2}$, Surender K. Sharma$^{2}$, Vivek Shukla$^{1}$ and Chhaya Ravikant$^{2}$; $^{1}$Gautam Buddha University, India; $^{2}$Indira Gandhi Delhi Technical University for Women, India

EDLC supercapacitors have drawn wide-ranging consideration and significant scientific interest in recent years due to their rapid charging and discharging capabilities, high energy density, large capacity and better performance in terms of
Supercapacitors are emerging as an alternative to batteries particularly for applications where rapid charging/discharging is needed. Another reason for their advent is their increased energy density that is approaching to the leading competitive technology of lithium ion battery. However the major drawback of lithium-ion cell is its electrochemistry that causes the rapid degradation in its performance in addition to its high failure rate that puts the user at high risk. On the other hand the energy storage mechanism of EDLC supercapacitors does not involve any electrochemical reaction therefore it offers more charging discharging cycles and more safe operation compared to Li-Ion batteries. However a key component of their performance is activated carbon whose electrical and morphological property plays a crucial role in governing the performance of supercapacitor. The newer techniques to synthesize activated carbonaceous material having a precise control on their morphological and electrical properties could be more useful for improvement in their capacity and energy density. In present investigations use of carbonaceous materials with different dimensions and aspect ratio obtained from soot generated by controlled burning of various oils derived from plant/animal sources such as coconut oil, mustard oil, olive oil, wax, kerosene etc are explored for their application in EDLC supercapacitor. A systematic study has been carried out to understand the dependence of soot’s composition and its properties on composition of oil and further optimizing the properties of as obtained soot by several measures including its activation to accomplish the improved performance. Although the present study is focused on supercapacitor application, the work may have broad technological scope because the soot synthesized in this work has potential to be used in various other applications also such as sensors, conductive additives for EMI shielding applications etc.

3D-Printed Flexible Energy Storage for Soft Robotics Christian Romero; University of Bristol, United Kingdom

Novel methods to fabricate bendable and stretchable energy storage devices with improved performance for flexible and wearable electronics are of great current interest. Scalable manufacturing procedures are crucial for practical application in the fabrication of complete functional electronic devices.[1] Here we report a scalable hybrid fabrication process of 3D printing combined with laser engraving to construct highly flexible and stretchable supercapacitors. CAD-designed supercapacitors were manufactured with a customized commercial 3D-printer equipped with a 460 nm commercial laser. In addition, we present our route to the development, formulation and preparation of the main components required for a fully 3D-printed flexible and stretchable supercapacitor. A range of functional 3D-printable inks were developed to enable printing of the current collectors, electroactive electrode materials, the electrolytes, as well as the flexible and stretchable housing. In addition to the development of such inks, we have combined printing with laser-scribing of the functional inks. Specifically, high areal capacitance is achieved with conductive current collectors obtained by simple laser-scribing reduction of graphene oxide (GO) flakes in a 3D-printed polyethylene oxide (PEO)/GO-based material.[2],[3] The resulting reduced GO-based 3D microstructures are transferred onto a commercial UV-curable silicon rubber to obtain flexible current collectors.[4] The flexible conductive collectors were coated with a 3D-printed PEO/polyaniline-based electroactive material.[5] These component are integrated with a polyvinyl alcohol/sulphuric acid-based gel electrolyte to obtain a flexible and stretchable supercapacitor.

Impacts of Oxygen on the SEI Formation and Electrochemical Cycling of Si Anodes Zhifei Li, Glenn Teeter, Anthony Burrell and Andriy Zakutayev; National Renewable Energy Laboratory, United States

Si anodes are one of the most promising anodes for the next generation high energy density lithium-ion batteries (LIBs) because of its high theoretical capacity, low operating potential and high abundance of Si. However, the large volume expansion and continuous electrolyte consumption during lithiation and delithiation leads to a poor cycling performance of Si anodes. It is critical to understand how the electrolyte is consumed, how to stabilize the interface and form a stable solid electrolyte interphase (SEI) in order to develop Si anodes with good cycling stability. Oxygen is almost inevitable in Si anodes where the surface of Si forms a native oxide layer when it exposes to air. In addition, the different preparation
processes of Si anodes may also lead to different levels of oxygen content [1,2]. Thus, a better understanding about how the oxygen would affect the surface SEI formation, (ir)reversible capacity, and electrochemical cycling of Si anodes is needed.

In this study, we synthesized a series of model Si anodes with different oxygen levels by sputtering on Cu foils, to investigate SEI formation and electrochemical cycling in GEN-2 electrolyte with FEC additive in half-cells configuration with Li-metal counter electrode. The obtained Si anodes clearly showed different lithiation/delithiation behaviors and cycling performance with different oxygen level, where higher oxygen level leads to a longer plateau at around 0.6 V during the first lithiation and better cycling performance. Via comprehensive in situ and ex situ characterization techniques, such as XPS, AFM and EQCM, we revealed how oxygen affects the SEI formation and electrochemical performance of Si anodes.

Role of Thin and Uniform Solid Electrolyte Interface in High-Rate Sodium Storage of Sb2Te3/CNT and Sb2Se3/CNT Composite Anodes
Muhammad Ihsan Ul Haq, Baoling Huang and Jang Kyo Kim; The Hong Kong University of Science and Technology, Hong Kong

Metal chalcogenides (MCs) are widely studied for low cost and high performance sodium ion batteries (SIBs). However, the thickness and morphology of solid electrolyte interface (SEI) formed on MC based electrodes still remain to be elucidated because the formation of SEI is highly sensitive to ambient conditions and electron beam in vacuum. Herein, two Sb-based MCs, Sb2Te3 and Sb2Se3, are selected to study the SEI formed on their pristine particles and composites assembled with functionalized CNTs through high energy ball milling. The ex-situ cryogenic electron microscope (cryo-EM) is employed to distinguish the morphologies and dimensions of the SEI layers formed on pristine Sb2Te3, Sb2Se3 and their composite electrodes. Uniform and thin SEI layers of ~19.1 and ~35.7 nm are observed for the Sb2Te3/CNT and Sb2Se3/CNT composite electrodes, respectively. In contrast, irregular SEI films with maximum thicknesses of ~67.3 and ~71.8 nm are revealed for the pristine Sb2Te3 and Sb2Se3 electrodes, respectively. The ex-situ electrochemical impedance spectroscopy (EIS) analysis corroborates the effect of thin and uniform SEI on reduced charge transfer resistances of 126.9 and 290 Ω for the Sb2Te3/CNT and Sb2Se3/CNT composite electrodes, respectively, which are much lower than 556.1 and 466.3 Ω of the pristine Sb2Te3 and Sb2Se3 counterparts, respectively. The significant increase in electrochemical kinetics of the composite electrodes results in outstanding high-rate capabilities. The sodium-ion full cells (SIFCs) are assembled by pairing the Sb2Te3/CNT and Sb2Se3/CNT composite anodes with a Na3V2(PO4)2F3 cathode, which deliver high energy densities of ~229 and ~176 Wh kg⁻¹, respectively, at 0.5 C together with remarkable power densities of 5384 W kg⁻¹ at 40 C and 5760 W kg⁻¹ at 80 C. These findings may shed new insight into the important role played by the optimal SEI layers on the rationally designed composite electrodes in giving rise to high-rate capabilities.

Three-Dimensional Sn-Based Anodes for All-Solid-State Rechargeable Batteries
Arailym Nurpeissova1, Gulnur Kalimuldina2 and Zhumabay Bakenov1,2; 1National Laboratory Astana, Kazakhstan; 2Nazarbayev University, Kazakhstan

Recently a rapid technological progress in various fields of industry and daily life has been driven by miniaturization of electronics. Components such as medical devices, logic and memory circuits, and various sensors have been drastically reduced to smaller dimensions with vastly improved performance. Limited performance of batteries is one of the most critical problems to be tackled for sustainable technological advances and to allow for further development of novel and future technologies.

Lithium-ion batteries (LIBs) exhibit excellent cycle performance and high energy capacity and thus are the best choice to power miniaturized devices. However, the current architecture used in LIBs’ electrodes limits the energy and power densities in electrodes. Furthermore, safety issues arising from flammable liquid electrolytes and lithium dendrite growth upon cycling still remain as the major challenges for implementation of LIBs in this area. Advanced architectures and materials are needed to design high performance LIBs with increased energy storage capacity per unit volume while maintaining a small footprint area.

A three-dimensional (3D) architecture design of the battery electrodes is believed to enhance the energy and power densities of conventional LIBs. In this regard, we report a unique 3D architecture anode designed for all-solid battery and fabricated by electrodeposition of ultrathin Ni3Sn4 intermetallic alloy onto a commercially available nickel foam current collector from an aqueous electrolyte. The X-ray diffraction results obtained from three-dimensional electrodes indicated that the main phase of
electrodeposited alloys was Ni$_3$Sn$_4$. The designed three-dimensional electrode demonstrated a high discharge capacity of 843.75 mAh g$^{-1}$ during initial cycles and an improved cycle performance over 100 cycles. The high surface area of the electrode and short Li$^+$-ions diffusion paths along with suppression of volume expansion provided by the proposed 3D structure and Ni inactive matrix play a key role in improving the performance of the electrode.

Efficient and Stable TiNxOy Thin-Film Catalysts for Oxygen Evolution Reaction Nikhil R. Mucha$^1$, Jacob Som$^1$, Surabhi Shaji$^1$, Felipe Martins Desouza$^2$, Ram K. Gupta$^2$, Corson Cramer$^3$, Harry Meyer$^3$, Amy Elliott$^3$ and Dhananjay Kumar$^1$; $^1$North Carolina A&T State University, United States; $^2$Pittsburg State University, United States; $^3$Oakridge National Laboratory, United States

A TiN$_x$O$_y$ (TiNO) material system has been synthesized in a thin film form using a pulsed laser deposition process with a wide range of x and y realized by varying the oxygen pressure from 5 to 50 mTorr. X-ray diffraction, x-ray photoelectron spectroscopy, and transmission electron microscopy measurements have been carried out to confirm the phase purity, partial oxidation, and chemical bonding information. The XPS compositions of the TiNO film deposited in 5, 15, 25, and 50 mTorr oxygen pressures were found to be TiN$_{0.57}$O$_{0.76}$, TiN$_{0.44}$O$_{0.99}$, TiN$_{0.37}$O$_{1.19}$, and TiN$_{0.29}$O$_{1.25}$ after 15 seconds of Ar-ions surface etch which was performed to remove carbon as well physically adsorbed O 1s and N 1s signals. The XPS depth profile study has shown that O and N profiles act opposite, i.e., when the O goes down, N goes up; when O goes up, N goes down. The electrocatalytic activities of these films were performed in 1M KOH solution for oxygen evolution reaction. It was observed that the electrocatalytic activities of these films depend on the growth conditions. Films grown under low oxygen partial pressure (5 mTorr) showed an overpotential of 390 mV to achieve a current density of 10 mA/cm$^2$, whereas the TiNO film grown under high oxygen partial pressure of 50 mTorr displayed the lowest overpotential of 320 mV at 10 mA/cm$^2$. This range of overpotential observed in this study is among the lowest values reported for any oxynitride systems. In addition to low overpotentials, these TiNO based films showed a stable electrocatalytic performance over 24 hours of chronoamperometric testing. Thus, our results suggest that a very high level electrocatalytic activity can be accomplished in TiNO films for the oxygen evolution reaction in the water-splitting process by controlling the substitutional defects in the starting TiN material.

Definition of Redox Centers in Reactions of Lithium-Intercalation in Li$_3$RuO$_4$ Polymorphs Haifeng Li$^1$, Srinivasan Ramakrishnan$^2$, John Freeland$^3$, Bryan D. McCloskey$^2$ and Jordi Cabana$^4$; $^1$University of Illinois at Chicago, United States; $^2$University of California, Berkeley, United States; $^3$Argonne National Laboratory, United States

Cathodes based on layered LiMO$_2$ are the limiting components in the path toward Li-ion batteries with high energy density. Introducing an over-stoichiometry of Li increases storage capacity beyond a conventional mechanism of formal transition metal redox. Yet the role and fate of the oxide ligands in such intriguing additional capacity remain unclear. This reactivity is hypothesized in Li$_3$Ru$_5^+$O$_4$, making it a valuable model system. A comprehensive analysis of the redox activity of both Ru and O under different electrochemical conditions was carried out, and the effect of Li/Ru ordering was evaluated. Li$_2$RuO$_4$ displays highly reversible Li intercalation to Li$_i$RuO$_4$ below 2.5 V vs. Li$^+$/Li$^0$, with conventional reactivity through the formal Ru$^{5+}$-Ru$^{4+}$ couple. In turn, it can also undergo anodic Li extraction at 3.9 V, which involves of O states to a much greater extent than Ru. Although the associated capacity is reversible, reintercalation subsequently unlocks a conventional pathway involving the formal Ru$^{5+}$-Ru$^{4+}$ couple despite operating above 2.5 V, leading to chemical hysteresis. This new pathway is both chemically and electrochemically reversible. This work exemplifies both the challenge of stabilizing highly depleted O states, and the ability of solids to access the same redox couple at two very different potential windows depending
on the underlying structural changes. It highlights the importance of properly defining the covalency of oxides when defining charge compensation in view of the design of materials with high capacity for Li storage.

One-Step Low Temperature Synthesis of Carbon Free Pure Phase Orthorhombic Li₂MnSiO₄ and Its Electrochemical Activity

Meetesh Singh, Nagesh Kumar and Yogesh Sharma; Indian Institute of Technology Roorkee, India

Li₂MnSiO₄ (LMS) offers a promising opportunity as a high capacity potential cathode for next generation lithium ion battery because of its high theoretical capacity 333 mAhg⁻¹ which is ascribed to the possible deintercalation/deintercalation of two lithium ions per formula unit through the excursion of Mn⁰/MnIII and MnIII/MnIV redox couples within the voltage range of used electrolyte (1 M LiPF₆ in EC: DC, 1:1 vol. %) However, the main drawbacks associated with LMS are its poor electronic conductivity (5x10⁻¹⁶ Scm⁻¹), low Li-ion diffusion coefficient (10⁻¹⁷-10⁻¹⁸ cm²s⁻¹), unstable crystallographic structure, and poor cyclability, which hinder its possibility to be used as a commercial cathode material. Additionally, only a small difference in the formation energy of its polymorphisms, namely, orthorhombic Pmn₂₁, Pmnb, and monoclinic P2₁/n, further challenges its pure phase synthesis, and the investigation of its electrochemical behaviour. In view of this, although various synthesis approaches have been adopted in the recent past to get reproducible pure phase LMS yet still not facile, and the formation of some impure phases such as MnO, Li₂SiO₃, and Mn₂SiO₄ usually appear along with LMS phase. In most of the reported synthesis approaches, a little amount of carbon has been used, which suppresses the growth of impurity phases in the sample. In this study, carbon free pure phase orthorhombic Li₂MnSiO₄ cathode with space group Pmn₂₁ has been prepared at low temperature (180 °C) via facile one-step hydrothermal approach. The pure phase formation has been confirmed by Rietveld refinement followed by other characterizations like TGA, FE-SEM, EDAX, XPS, HR-TEM, FTIR, Raman, and EPR at room temperature. Further, the electrochemical activity of such synthesized LMS as a prospective cathode for LIBs has been investigated thoroughly via galvanostatic charge-discharge (GCD) and electrochemical impedance spectroscopy (EIS). We believe our findings can be utilized in exploring the possible commercial utility of the Li₂MnSiO₄ as cathode material for Li-ion batteries.

Nanostructured Low Bandgap Perovskite Oxides for Artificial Photosynthesis

Pawan Kumar¹, Sheng Zeng², Suresh Mulmi², Kazi Alam¹, Venkataraman Thangadurai² and Karthik Shankar¹; ¹University of Alberta, Canada; ²University of Calgary, Canada

YMnO₃ (and related compositions) is a multiferroic perovskite oxide, which is recently attracting attention as a visible light driven photocatalyst due to optical absorption that extends to ~900 nm. Similarly, quinary and senary non-stoichiometric double perovskite oxides such as BCNF (Absorption edge ~800 nm) have been used for gas sensing, solid-state ionics and thermochemical CO₂ reduction. Herein, we examined the potential of both non-stoichiometric YMnO₃ and BCNF-family of compounds, as narrow bandgap semiconductors for use in solar energy harvesting.

Both YMnO₃ and BCNF showed p-type conduction and a distinct photoresponse upto red wavelengths. Due to poor carrier transport in these materials, these perovskite oxides need to be nanostructured in order to ensure that the critical dimension is roughly comparable to the minority carrier diffusion length. While YMnO₃ was nanostructured through solvothermal processing, BCNF was nanostructured by forming composites with few-layer sheets of g-C₃N₄. For both types of nanostructured perovskites, scanning Kelvin probe force microscopy (KPFM) and photoluminescence measurements indicated efficient charge separation following visible light illumination. In this poster, we will be presenting our preliminary results exploiting these materials in photocatalytic CO₂ reduction and photoelectrochemical water splitting.
Selective and Efficient Gd-Doped BiVO₄ Photoanode for Two-Electron Water Oxidation to H₂O₂

Thomas Gill, Jihyun Baek and Xiaolin Zheng; Stanford University, United States

Photoelectrochemical oxidation of water presents a pathway for sustainable production of hydrogen peroxide (H₂O₂). Two-electron water oxidation toward H₂O₂, however, competes with the popular four-electron process to form oxygen and one-electron water oxidation to form OH radical. To date, bismuth vanadate (BiVO₄) has been shown to exhibit promising selectivity toward H₂O₂, especially under illumination, but it suffers from high overpotential and notoriously poor stability. Herein, using density functional theory calculations, we predict that doping BiVO₄ with optimal concentrations of gadolinium (Gd) not only enhances its activity for H₂O₂ production but also improves its stability. Experimentally, we demonstrate that intermediate amounts of Gd doping (6–12%) reduce the onset potential of BiVO₄ for H₂O₂ production by ~110 mV while achieving a Faradaic efficiency of ~99.5% under illumination and prolonging the catalytic lifetime by more than a factor of 20 at 2.0 V vs RHE under illumination.

Influence of the Solvent and Precursors in the Formation of CuS and CuInS₂ Nanoparticles by Controlled Precipitation

Daniela E. Ortiz Ramos¹ and Luis Alfredo González-López²; ¹Universidad Autonoma de Coahuila, Mexico; ²CINVESTAV Saltillo, Mexico

Nowadays, many applications of optoelectronics require materials with tailored properties. Chalcogenide metallic materials have become an important research field in order to get semiconductors. Specifically, CuS and CuIn₂ are a promising materials for device applications like in solar energy conversion, lighting, display technology, or biolabelling. However, it is important to avoid the use of toxic heavy metals as cadmium or lead, one of the possible alternatives are copper sulfide and Copper indium disulfide.

Copper sulfide is a p-type semiconductor with a a bandgap in the range of 2.0-2.36 eV and a low resistivity with a value of 1x10⁴ Ωcm, has a covellite structure with a hexagonal arrangement. Copper indium disulfide (CuInS₂), a direct semiconductor with a bandgap in the bulk of 1.45 eV, it has a chalcopyrite type crystalline structure, this metal chalcogenide has a high absorption coefficient of 10⁵ cm⁻¹.

Here, we show preliminary results of the influence of the solvent in the formation of CuS and CuInS₂ nanoparticles by controlled precipitation, also we studied de influence of the metallic precursors and the source of the sulfur ions in the formation of the nanoparticles. The solvents used were ethanol, ethylene glycol and deionized water. The metal precursors were Cu(NO₃)₂ 2.5H₂O and CuCl₂H₂O for CuS nanoparticles, Cu(NO₃)₂ 2.5H₂O , CuCl₂ H₂O, In(C₂H₃O₂)₃ and InCl₃ for CuInS₂ nanoparticles. Sulfur ion sources were CH₃CSNH₂, NaS₂ 9H₂O and NaSH xH₂O at low temperature 80°C and 1 hour stirring. It is important to note that the addition of the solution containing the sulfur ions to the solution containing the metal ions should be drop by drop, otherwise an abrupt reaction and rapid precipitation occurs, resulting in metal oxides and sulfur ions not react with copper ions.

First, a formulation was made to obtain CuS nanoparticles, using Cu(NO₃)₂ 2.5H₂O as a metal salt and a variation of the sulfur ion precursor was made CH₃CSNH₂, NaS₂ 9H₂O and NaSH xH₂O using water and ethanol as solvents, with the objective of obtaining CuS with covellite crystalline structure. The results obtained by an XRD analysis show that when using NaS₂ 9H₂O as a source of sulfur ions, the desired crystalline structure for CuS is obtained. Subsequently ethylene glycol was used as a solvent, to obtain CuS and CuInS₂, the characterization by DRX and EDAX in the nanoparticles of CuS and CuInS₂ showed contamination by oxides and in the case of CuInS₂ showed low content of atomic In%. Finally, deionized water was used as a solvent, in this case the optical properties, the crystalline structure and the morphology of the CuS and CuInS₂ nanoparticles are related to the results reported in the literature. The objective was achieved, the nanoparticles were analyzed structurally, morphologically and optically to study the effect of using different sources of metal ions and vary the solvent used in the obtention of CuS and CuInS₂ nanoparticles.

Nanodiamond Production and Surface Manipulation
Oliver A. Williams, Soumen Mandal and Laia Gines; Cardiff University, United Kingdom

Diamond nanoparticles have a diverse array of applications from single photon sources and biomarkers to the seeds for diamond growth. Although there are a wide range of commercial suppliers, the purity of diamond nanoparticles is insufficient for some specific applications such as optical levitation and Coherent Anti-Stokes Raman Spectroscopy (CARS). There is also no commercial supplier for nanodiamonds containing the silicon vacancy centre or newer single photon sources. In this work the production and purification of novel diamond nanoparticles containing custom colour centres will be detailed. First a diamond film containing NV/SiV centres was grown onto a substrate. Colour centre incorporation was confirmed by Photoluminescence and Hanbury Brown and Twiss measurements. The resulting diamond film was removed from the substrate and milled using a planetary mill based on either steel or SiN. The milled material was purified by acid reflux. To measure particle sizes, different slurries containing the diamond nanoparticles obtained were prepared and characterized by using Dynamic Light Scattering (DLS) and Nanoparticle Tracking Analysis (NTA). XPS was also used to qualify the milling process contamination.

The control of surface sp² and zeta potential will also be demonstrated. Positive zeta potentials in hydrogenated nanostructured carbons could be explained due to the presence of basal planes of graphite which can become protonated. At the same time, sp² carbon creation on diamond nanoparticles surface eases low temperature (500°C) diamond nanoparticles hydrogenation and amination, previously demonstrated for detonation diamond (5nm). Applications of the positive zeta potential in nanodiamond will be proposed.

Measuring and Controlling Temperature at The Nanoscale—Current Strategies and Future Challenges
Carlo Bradac; Trent University, Canada

Color centers in solids are the fundamental building blocks of various applications ranging from lasers to light emitting diodes and sensors, as well as the foundation of advanced quantum information and communication technologies. Their photoluminescence properties are usually studied under Stokes excitation, in which the emitted photons are at a lower energy than the excitation ones. We explore the opposite Anti-Stokes process, where excitation is performed with lower energy photons. The process is sufficiently efficient to excite even a single quantum system—the germanium-vacancy center in diamond. As a proof of concept, we propose using Anti-Stokes excitation of diamond color centers for nanoscale thermometry. We leverage the temperature-dependent, phonon-assisted mechanism to realize an all-optical nanoscale thermometry scheme that outperforms any homologous optical method employed to date. We discuss other potential applications and show that our results frame a promising approach for exploring fundamental light-matter interactions in isolated quantum systems.
**Nanodiamonds in Biological Environment—From Selective Cell Targeting to Control of Cell Signalling** Petr Cigler; Institute of Organic Chemistry and Biochemistry of the CAS, Czechia

Nanodiamond is a biocompatible nanomaterial which can accommodate various photoluminescent crystal defects. Nitrogen-vacancy (NV) centers show particularly high photostability and unique electronic sensitivity to magnetic and electric fields. Their spin properties can be read by optical means, which enables construction of various probes based on quantum mechanical interactions. For application in biological environment, a proper interface of the particles is required. Two conceptually different design of nanodiamond surface design will be discussed [1-3]. These includes polymer and biomimetic lipid terminations enabling further modification by chemically reactive groups. Selectivity of cell surface receptors targeting will be discussed.

Furthermore, specific and efficient regulation of the family of extracellular signaling molecules known as fibroblast growth factors (FGFs) using positively charged detonation nanodiamonds without any synthetically installed (bio)organic interface will be presented [4]. The FGF-based regulation of cell signalling using nanodiamonds can be performed in full sera. This nanotherapeutic approach can be potentially applied to mitigation of pathological FGF signaling and neutralization of disease-related activities of FGFs.

**Surface Reactivity of Hydrogenated Nanodiamonds in Water** Franziska Buchner¹, Christoph Merschjann¹, Robert Seidel¹, Benjamin Kiendl², Peter Knittel¹, Hugues Girard³, Jean-Charles Arnault³, Anke Krueger² and Tristan Petit¹; ¹Helmholtz Zentrum Berlin, Germany; ²Julius-Maximilians-Universität Würzburg, Germany; ³Fraunhofer Institute for Applied Solid State Physics (IAF), Germany; ⁴CEA, LIST, Diamond Sensors Laboratory, France

The nanodiamond-water interface plays a central role in nanodiamond reactivity in aqueous environment, which is relevant for nanomedicine, photocatalysis or environmental applications. Especially, the generation of solvated electrons can trigger N₂ or CO₂ reduction in aqueous environment, and probably strongly depend on the nanodiamond-water interface.

In this presentation, our latest results related to different spectroscopic approaches to probe the nanodiamond-water interface will be shown. In particular, the different surface reactivity with water related to hydrogen-termination will be compared to oxidized nanodiamond surfaces.

First, the vibrational and electronic structures of water molecules around nanodiamoneds were probed by Fourier Transform Infrared spectroscopy (FTIR) and X-ray absorption spectroscopy (XAS) directly in aqueous environment.¹ X-ray Photoelectron Spectroscopy (XPS) was also applied under near ambient pressure conditions (few mbar of water) to probe changes of the surface chemistry of nanostructured diamond upon exposure to water.

Finally, transient absorption spectroscopy (TAS) was applied to nanodiamond dispersions. The evolution of the visible light absorption spectra over time with a sub-picosecond time resolution was monitored after excitation of electrons into the diamond valence band using a UV laser pulse. This enables the observation of the emission of solvated electrons from nanodiamonds in water. The effect of surface chemistry on the electron emission will also be discussed.

This work has received funding from the European Union’s Horizon 2020 Program under Grant Agreement number 665085 (DIACAT).

Progress in Nanodiamonds for Novel Composites and Biomedical Applications Vadym Mochalin; Missouri University of Science and Technology, United States

Nanodiamond powders produced by detonation synthesis offer a great potential in many applications¹, including novel nanocomposites² and biomedical applications³. In the area of nanocomposites, much of work has been focused on polymer matrix composites, while significantly less has been done with other matrices, such as ceramics and metals⁴. At the same time, nanodiamonds have great potential in reinforcing as well as improving optical properties and wear behavior of metal- and ceramic-matrix composites.

We will review our progress in developing well dispersed nanodiamonds⁵ for composite applications with emphasis on novel and less studied nanodiamond-ceramic and nanodiamond-metal composites. Manufacturing and processing techniques, as well as properties of the composites will be discussed.

Another hot area of applications for nanodiamond is biomedical imaging and drug delivery. We will discuss our recent progress in drug delivery with nanodiamonds, emphasizing the effects of nanodiamond surface chemistry, and present novel processing techniques to produce luminescent nanodiamond particles from HPHT luminescent diamond for bioimaging, labeling, and other applications.

Dynamic Nuclear Polarization of 13C Spins in Diamond Nanoparticles Carlos Meriles¹ and Ashok Ajoy²; ¹The City College of New York, United States; ²University of California, Berkeley, United States

Diamond particles hosting negatively charged nitrogen vacancy (NV-) centers have recently emerged as an intriguing platform to dynamically polarize nuclear spins both inside and outside the crystal lattice. This presentation surveys some recent work on the topic by our groups including the development and implementation of spin polarization methods insensitive to the orientation of the diamond particles, as well as proof-of-principle applications such as dual fluorescence and magnetic resonance imaging of diamond particles arrays. Further, we introduce recent observations using particles of varying dimensions down to nm sizes, and show that diamond annealing at elevated temperatures has important effects on the hyperpolarization levels, enhancing them by above an order of magnitude over materials annealed through conventional means. Electron and nuclear spin resonance measurements show this response correlates with NV- and 13C relaxation and coherence times, which points to improved recovery of the diamond lattice from radiation damage.

5:15 AM *S.NM01.01.03
Diamond Magnetometry with Nanodiamonds in Cells Romana Schirhagl; Groningen University, University Medical Center Groningen, Netherlands

Diamond magnetometry has led to impressive results in physics. The technique provides magnetic resonance signals with nanoscale resolution. It is so sensitive that even the faint signal of single electrons can be detected. Here we have first applied the technique to measure free radical generation in cells. These radicals play a critical role in the natural metabolism of cells. Examples of processes relying on radicals include, signalling, immune responses or cell death or ageing. However, they are also involved in numerous processes which indicate disease. Diseases where radicals play a key role includes cancer, cardiovascular diseases, bacterial or viral infection or arthritis. Despite their relevance and prevalence, we know very little about free radical generation. The reason is that they are small, short lived and reactive and thus difficult to measure for the state of the art.

For diamond magnetometry they are well visible due to their free electron spin. With this new technology we are able to detect stimulation and inhibition of radical production with subcellular resolution. On top of that we can differentiate different knock out cells (where certain metabolic processes have been turned off) as well as different production in mitochondria compared to the cytosol. The signals we receive are in principle equivalent to conventional MRI signals. However, the resolution and sensitivity are significantly improved.

5:30 AM *S.NM01.01.04
Optically Hyperpolarized Nanodiamonds—New Avenues for Signal Enhanced NMR and MRI Ashok Ajoy¹,²; ¹UC Berkeley, United States; ²Carnegie Mellon University, United States

I will describe new quantum-assisted modalities to deliver enormous signal enhancements in conventional MRI and NMR mediated by quantum defects in nanodiamond powder. This relies on the use of Nitrogen-Vacancy (NV) center spins within the diamond particles that can be optically polarized at room temperature with modest laser powers. This polarization can be transferred to nuclei surrounding the NV spins to hyperpolarize them to levels far above Boltzmann levels, manifesting in a highly enhanced NMR signature. Nanodiamonds are particularly suited for this task, given their large surface areas, and the ability to arrange for close physical contact between the polarized NVs and analyte molecules of interest.

I will discuss our experimental effort in this direction, particularly focusing on the ability for ¹³C hyperpolarized nanodiamonds to serve as dual-mode (optical and MRI) imaging agents, and as transduced and deployable magnetometers.
Beyond Superlubricity—Manipulating Friction and Wear at an Unprecedented Level

Anirudha Sumant; Argonne National Laboratory, United States

The mechanical energy dissipation between two sliding objects at macroscopic level leads to friction and wear and is explained by Amonton’s law where friction is directly proportional to the load applied but independent of the contact area. However, at nanoscale, contact area becomes dominant factor in controlling friction due to the nanoscale interactions at single asperity level and therefore interpretation of friction at nanoscale and macroscale has always been somewhat ambiguous due to the missing mesoscopic link that bridges nanoscale phenomenon with that of macroscopic world. Our research at CNM has always been focused on understanding atomic scale origin of the friction and how that can be linked to the macroscopic world. Our recent work utilizing combination of 2D materials and nanodiamond as a nanoscale lubricant have broken that barrier between nanoscale and macroscale world demonstrating near zero friction (superlubricity) at engineering scale for the first time [1-2]. We have further shown that it is possible to control friction at macroscale by manipulating nanoscale interactions at the tribological interface involving combination of various 2D materials and nanoparticles that generates superlubric tribolayer within the wear track resulting in near zero friction and negligible wear [3-4]. With the help of newly installed multifunctional tribometer at CNM in the superlubricity lab, we systematically study evolution of tribochemical changes in the wear track using integrated Raman spectroscopy and 3D confocal microscopy and wear debris using HRTEM and EELS techniques. Combining that with the molecular dynamic simulation we elucidate the mechanism of friction and show possible pathways to manipulate friction at nanoscale that can directly influence friction at macroscale. The implications of this discovery are profound and already demonstrating its potential for some commercial applications that we are exploring with the industry. I’ll also discuss some new results on achieving superlubrcity in rolling/sliding contacts [5] that will have great potential in bearings industry.

Self-Assembly of Elementary Diamond Nanoparticles from their Aqueous Solutions #2—Hybrid Ultra-Thin Films of Fatty Acid and Diamond Nanoparticles

Yasuhiro F. Miura1, Yoshiya Akagi1, Toshihiko Tanaka2,3, Tetsuya Aoyama3, Kazunori Miyamoto3, Masaya Nemoto2, Masanobu Uchiyama3,4 and Eiji Osawa5; 1Hamamatsu University School of Medicine, Japan; 2National Institute of Technology, Fukushima College, Japan; 3RIKEN Cluster for Pioneering Research (CPR), Japan; 4The University of Tokyo, Japan; 5NanoCarbon Research Institute Co., Ltd., Japan
Detonation nanodiamonds (DNDs) attract much attention due to the exceptional colloidal properties in aqueous media. In particular, the elementary particles of detonation nanodiamonds (EPDNDs), whose size is within a lower single-digit nanometer, should be a promising component in various fields that include nanoscale medicine. Whereas the characterization of EPDNDs is progressing rapidly\(^1,2\), one of the remaining subjects is the fabrication of organized films of EPDNDs to confirm the agglutination mechanism as predicted based on the interfacial Coulombic interactions\(^3\) and to obtain clues to identify the surface structure. Furthermore, it is also beneficial if we can make heterojunctions between organized two-dimensional assemblies of EPDNDs and those of other chemical species.

We have already reported that nanosheets of DNDs are formed at the air/water interface by injecting a well-dispersed solution of DNDs (NanoAmando\(^6\)) below a Langmuir monolayer of arachid acid (CH\(_3\)(CH\(_2\))\(_{18}\)COOH, C\(_{20}\)) at the interface. We have also reported that the floating nanosheets can be transferred onto solid substrates, such as glass, quartz or Si wafers by the modified horizontal lifting method, during which the substrate is lifted up below the nanosheets keeping the substrate surface horizontally to the air/water interface. Since each nanosheet is strip-like or rectangular in shape and is birefringent, we postulate that they are colloidal crystals of EPDNDs.

By our fabrication technique reported so far, however, we were not be able to fabricate continuous films based on EPDNDs (each nanosheet is isolated on the substrate surface). Therefore, it was practically impossible to perform layer-by-layer depositions to make multi-layered structures. Here we report a successful layer-by-layer depositions of the hybrid EPDND-C\(_{20}\) films onto solid substrates by the Langmuir-Schaefer method, where the substrate is lowered toward the floating film keeping the substrate surface horizontally to the air/water interface and after the substrate touches the film surface, the substrate is lifted up. We would like to discuss the structure and properties of the hybrid EPDND-C\(_{20}\) film based on FT-IR and Raman spectra together with morphological characterizations by atomic force microscopy and optical microscopy.

Over the past two decades, solid-state defects have emerged as one of the leading systems for a wide variety of quantum technologies. Solid-state hosts such as diamond are well studied, and a wide spectrum of fluorescing crystal defects have been identified and characterized. Nanodiamonds enable efficient control and readout of color centers within. Furthermore, nanodiamonds offer surface functionalization, nanometer-scale spatial positioning, and the compatibility with optical levitation. The fabrication of non-aggregated and uniformly-sized nanodiamonds with systematic integration of single quantum emitters has so far been lacking. Here, we present a top-down fabrication method to produce ~30 nm uniformly-sized single-crystal nanodiamonds by block copolymer self-assembled nanomask patterning together with directional and isotropic reactive ion etching. We show detected emission from bright single nitrogen vacancy centers hosted in the fabricated nanodiamonds. The lithographically precise patterning of large areas of diamond by self-assembled masks and their release into uniformly sized nanodiamonds open up new possibilities for quantum information processing and sensing. (Scientific Reports 9, 6914 (2019))

Research carried out in part at the Center for Functional Nanomaterials, Brookhaven National Laboratory, which is supported by the U.S. Department of Energy, Office of Basic Energy Sciences, under Contract No. DE-SC0012704.

Enhancing the Strength of Polyester with Nanodiamonds Taylor Sloop, Nathan Sunbury, Dithi Ganjam, Red Willow Coleman and Albert Dato; Harvey Mudd College, United States

Polyester is used as a matrix material in fiber-reinforced composites that have a wide range of applications, which include naval vessels, storage tanks, and pipelines. Improving the strength of polyester is highly desirable in these applications. Detonation nanodiamond is a promising filler material for polymer reinforcement because of its superior mechanical...
properties, small size, and chemical stability. Here we show that incorporating low concentrations (0.1 wt%) of commercially-available detonation nanodiamonds (3-10 nm in diameter) into isophthalic polyester results in significant enhancements in the strength of the polymer. A facile method of fabricating nanodiamond-polyester composites will be discussed. The method does not require additional nanodiamond purification steps or surface modification strategies to enhance the bonding of nanodiamond to polyester. Results from the uniaxial tensile testing of nanodiamond-polyester composites will be presented, and scanning electron microscopy images of specimen fracture surfaces will be shown. The results reveal the mechanical properties, dispersion, and possible strengthening mechanisms of nanodiamond-polyester composites.

5:30 AM S.NM01.02.04
Self-Assembly of Elementary Diamond Nanoparticles from Their Aqueous Solutions #1—Anisotropy of Whiskers or Nanosheets Toshihiko Tanaka1,2, Yasuhiro F. Miura3, Tetsuya Aoyama2, Kazunori Miyamoto4, Yoshiya Akagi5, Masaya Nemoto1,2, Masanobu Uchiyama2,3 and Eiji Osawa5; 1National Institute of Technology, Fukushima College, Japan; 2RIKEN, Japan; 3Hamamatsu University School of Medicine, Japan; 4The University of Tokyo, Japan; 5Nano Carbon Research Institute Ltd., Japan

The anisotropy of the precipitates from nanodiamond (ND) solutions suggests the existence of elementary diamond nanoparticles (EDIANs). The rectangular shapes of whiskers [1], nanocrystals[2], sheets[3], or nanosheets[4-6] should be formed from the particles being similar both in shape and size. We believe that there is a peculiar kind of similarity in the colloidal particles consisting the precipitates and that hydrated colloidal crystals are formed from them. We demonstrate herein two kinds of the rectangular precipitates, the whiskers and the nanosheets both of which were prepared from the solutions of NanoAmando® (Nano Carbon Research Institute Ltd.).

The former was prepared at the three-phase contact between air, an ND solution, and glass on the sidewall of its tubes[4]. The whiskers have the fine geometry of rectangular shapes as well as uniaxial uniform optical anisotropy. A laser microscopy image exhibited the surprisingly fine shape and crossed nicol polarized microscopic observations with a Berek compensator demonstrate the uniaxial birefringence of Δn=0.0016. The curvature of the sidewall is needed to show the birefringence and recent procedures furthermore provided a small ring (φ~7 mm) of a curved whisker on the wall. Although the ring was brittle, it was slightly elastic, being able to deform a little without breaking.

The nanosheets were crystallized from a diluted ND solution to the adsorbed ND particles on a Langmuir monolayer of arachidic acid (C19H39COOH). After opening the trough of the monolayer, we found innumerable ultra thin rectangular sheets on the water surface [4-6]. We postulate that the monolayer induces the crystallization under the PTFE bars of a Langmuir trough and that the precipitates of ultrathin rectangular nanosheets (~26 nm thick) are squeezed out from the undersurface of the bars to the water surface. Raman spectra showed that the nanosheets contain a negligible amount of the acid and such a process should result in the low content of it. We think that the quality of NanoAmando® contributes to the self-assembly; recent small diameter values (2.6 nm) from dynamic light scattering (DLS) measurements also suggest its appreciable content of EDIANs, considering that Rayleigh scattering should force us to overestimate the diameters. We will discuss the origin of the self-assembly with respect to the colloidal nature of the multi-polar ND polyhedrons predicted by DFT calculations [7].

Three-Dimensional Imaging of Self-Assembled Lacey Network of Detonation Nanodiamond in Water Shery Chang, Dewigt Williams, Toby Sanders and Christian Dwyer; Arizona State University, United States

Detonation nanodiamonds (DND) are diamond nanoparticles synthesized through detonation process with sizes ranging 3-5nm. It's small size, non-toxic and biocompatibility has drawn huge interests, particularly in the biomedical field. In order to capitalize the large total surface areas afforded by the small particle size, dispersing DND have been one of the endeavor for the better utilizing DND for its applications. The consensus of DND dispersion has been that detonation nanodiamond is mono-dispersed single digit nanoparticles in water, largely based on the dynamic light scattering (DLS) measurements.
We have recently shown that DND dispersion in water, without any surface modification, exhibit striking lacey network, formed dynamically by self-assembled chain-like superstructure. This discovery was carried out by a combination of DLS, small-angle x-ray scattering (SAXS) as well as cryo-TEM imaging. Our analysis shows that the superstructure morphology has strong size and particle shape dependence.

To further understand the three dimensional distribution of the lacey network, electron tomography was conducted on the plunge-freezing samples of DND dispersion. Using a cryo-TEM (Krios) equipped with a single-electron-detection camera, a series of 65 images with specimen tilts ranging from -65°to +65° was acquired, with a dose rate of 3 e-/pixel/sec to avoid melting of the vitreous ice. Our initial result suggests that there is a preferential orientation of the chain-superstructure. We speculate that the reason behind the oriented chains is the screening effect from the interactions between water molecules surrounding the nanodiamond chains.

Self-Assembly of Diamond-Gold Conjugates for Plasmonic Enhancement of NV Centers Davida Simpson1, Nedah Basravi1, Karen Lopez1, Camron Stokes1, Trisha Fabillaran1, Camilla Hanson1, Virginia Altoe2, D. Nordlund3 and Abraham Wolcott1; 1San Jose State University, United States; 2Lawrence Berkeley National Laboratory, United States; 3SLAC National Accelerator Laboratory, United States

Nitrogen vacancy center (NVC) nanodiamonds (NDs) are useful for applications in biolabeling and biosensing due to their electron spin properties, biocompatibility and photostability. However, NVC imaging requires high photon fluxes (1 mW/um²), increasing autofluorescence from cells and tissues and reducing signal-to-noise ratios. Generating gold-diamond nanoarchitectures in a hexagonal packing geometry can lead to a 200X fold increase in fluorescence based on finite-dimension time-domain (FDTD) simulations. For maximum fluorescence enhancement these simulations also require a dielectric (SiO₂) to separate the diamond-gold assembly. Here, we satisfy these conditions using a core-shell diamond-SiO₂ nanoparticle using self assembly to generate a gold-nanodiamond heterostructures that is driven by gold-thiolate bond formation. Here we use 65nm gold nanoparticles to plasmonically enhance the far field emission of NV centers. Au NPs were synthesized via a seeded growth mechanism to yield 60-80nm citrate capped AuNPs. 15nm SiO₂ shells were synthesized on nanodiamond cores with sulfyl-hydryl and stabilizing moieties to provide a chemically inert dielectric platform. Both AuNPs and SiO₂ coated nanodiamonds were imaged via scanning electron microscopy (SEM) and probed in-situ via Dynamic Light Scattering (DLS). Self-assembly was found to be driven by entropic forces and the ratio of gold-chelating ligands to stabilizing moieties is discussed. These fundamental findings are a key metric in designing, preparing and deploying nanoscale NV diamond under low-light conditions.

Nanodiamond Production and Surface Manipulation Oliver A. Williams, Soumen Mandal and Laia Gines; Cardiff University, United Kingdom

Diamond nanoparticles have a diverse array of applications from single photon sources and biomarkers to the seeds for diamond growth. Although there are a wide range of commercial suppliers, the purity of diamond nanoparticles is insufficient for some specific applications such as optical levitation and Coherent Anti-Stokes Raman Spectroscopy (CARS). There is also no commercial supplier for nanodiamonds containing the silicon vacancy centre or newer single photon sources. In this work the production and purification of novel diamond nanoparticles containing custom colour centres will be detailed. First a diamond film containing NV/SiV centres was grown onto a substrate. Colour centre incorporation was confirmed by Photoluminescence and Hanbury Brown and Twiss measurements. The resulting diamond film was removed from the substrate and milled using a planetary mill based on either steel or SiN. The milled material was purified by acid reflux. To measure particle sizes, different slurries containing the diamond nanoparticles obtained were prepared and characterized by using Dynamic Light Scattering (DLS) and Nanoparticle Tracking Analysis (NTA). XPS was also used to qualify the milling process contamination.
The control of surface sp² and zeta potential will also be demonstrated. Positive zeta potentials in hydrogenated nanostructured carbons could be explained due to the presence of basal planes of graphite which can become protonated. At the same time, sp² carbon creation on diamond nanoparticles surface eases low temperature (500°C) diamond nanoparticles hydrogenation and amination, previously demonstrated for detonation diamond (5nm). Applications of the positive zeta potential in nanodiamond will be proposed.

5:15 AM S.NM01.03.03
Degradation of Perfluorooctane Sulfonate by Sub-Bandgap Irradiation of Hydrogen Terminated Detonation Nanodiamond William A. Maza, Vanessa M. Breslin, Tatyana Feygelson, Paul DeSario, Bradford B. Pate, Jeffrey C. Owrutsky and Albert Epshteyn; US Naval Research Laboratory, United States

The extraordinary stability of the C-F bond imparts many commercially useful properties to poly- and per-fluoroalkyl substances (PFASs). Among the properties imparted by the stability of the C-F bond is a high resistance to degradation via traditional oxidative/reductive processes. As a consequence PFAS is a persistent contaminant upon environmental exposure; especially in water. In this work, we examine the impact of nanodiamond photochemistry on the degradation of one of the more resilient in the class of PFASs, perfluorooctane sulfonate (PFOS). Using nanosecond transient absorption we find that hydrated electrons result by photodetachment from hydrogen-terminated (negative electron affinity) detonation nanodiamond (HDND) suspensions in water upon sub-bandgap (266nm) irradiation. Hydrated electron photogeneration from oxygen-terminated (positive electron affinity) detonation nanodiamond (ODND), on the other hand, is not observed. The transient absorption data suggest the presence of an interaction between PFOS and HDND and, more so, an interaction between PFOS and the hydrated electrons. Finally, we show that prolonged sub-bandgap (254nm) irradiation of aqueous HDND in the presence of PFOS leads to full decomposition of PFOS by reductive fragmentation, consistent with hydrated electron reductive chemistry.

Sonication-Assisted Hydrolysis of Ozone Oxidized Detonation Nanodiamond Atsushi Kume1,2 and Vadym Mochalin2; 1Daicel Corporation, Japan; 2Missouri University of Science and Technology, United States

Detonation of TNT/RDX in oxygen-deficient conditions produces nanodiamonds terminated by various oxygen containing surface functional groups, which enable single digit state dispersion in aqueous media via deaggregation methods such as zirconia micro bead milling. We quantitatively investigated ozone oxidized DNDs by acid-base back potentiometric titration and XPS, revealing a large amount of oxygen containing surface groups in comparison to air oxidized DNDs. The most prominent feature of the ozone oxidized DNDs is its high tolerance to re-aggregation during horn sonication process, allowing longer sonication times to produce smaller particles (down to a single digit DND dispersion) without any milling media. Additionally, the deaggregated DNDs were investigated by UV-Raman and FTIR, suggesting that a large number of oxygen-containing surface groups (mainly anhydrides) produced by ozonation were further hydrolyzed to COOH during horn sonication. We will introduce the sonication-assisted hydrolysis of ozone oxidized DND as potentially a commercially viable technique to obtain single-digit COOH-terminated DND colloids due to a better control, milder conditions, and a lower burn-off of the smallest DND particles as compared to air oxidation.
a remarkable single photon emitter whose advantageous optoelectronic properties are utilized in all these applications. Current technologies employ a top down approach of chemical vapor deposition grown (CVD) diamond in combination with ion irradiation and implantation to form the desired color center. CVD grown diamond is very pure, but because of the high energies of the implantation technique, the diamond crystal lattice becomes damaged which requires post processing techniques to correct. Doping diamond at high temperatures and pressures is also difficult due to diamond’s compact atomic lattice and low atomic diffusivities. In this work, we demonstrate a versatile, bottom-up approach to SiV− fabrication based on molecular doping of amorphous carbonaceous precursors which are converted to diamond at high-pressure, high-temperature (HPHT) conditions (>15 GPa, >1800K) within a laser-heated diamond anvil cell. A molecular dopant, tetraethyl orthosilicate (TEOS), incorporates silicon heteroatoms into the HPHT grown nanodiamond compared to non-doped samples fabricated under similar conditions. Pressure dependent photoluminescence confirms not only the formation of SiV− (λ ~ 738 nm), it also provides experimental juxtaposition for ab initio quantum cluster calculations modeling the pressure dependence of the center’s zero phonon line (~0.9 meV/GPa). Aberration corrected scanning transmission electron microscopy provides images of the silicon heteroatoms on the surface and the interior of converted diamond material. Scanning transmission x-ray absorption microscopy (STXM) measurements, along with electron energy loss spectroscopy (EELS), suggest limited graphitic surface reconstruction of the diamond nanocrystals, as compared to other nanodiamond synthetic avenues. Ab initio quantum cluster calculations also support the possibility of a graphitic reconstruction of the diamond nanocrystal’s surface along with significant distortions of the cubic diamond crystal lattice adjacent to the reconstruction. These results demonstrate the versatility of this approach to doping diamond and that it can be extended to the formation of more complex color centers in diamond.

5:15 AM *S.NM01.04.02 Biological Impact and Selective Optical Detection of Functionalized and Luminescent Nanodiamond Robert J. Hamers1, Kelly Zhang1, Zachary Jones1, Natalie Hudson-Smith2, Christy Haynes2 and Olga A. Shenderova5; 1University of Wisconsin-Madison, United States; 2University of Minnesota Twin Cities, United States; 3Adamas Nanotechnologies, United States

The biological impact of nanoparticles is largely controlled by the properties of their surfaces. However, on times scales relevant to most biological studies most nanoparticles undergo chemical changes, including oxidation and loss of surface functional groups. Nanodiamond is a nearly ideal system for investigation of nano-bio interactions because diamond can be functionalized with a wide range of organic molecules via "all-carbon" scaffolding with unprecedented chemical stability, and because defects such as Nv centers in nanodiamond provide a way to detect nanodiamond via optical methods. In this talk I will present recent results investigating how the chemical structure of surface ligands affects the interaction of nanodiamond with cells and model membranes, and recent efforts using magnetically modulated Nv imaging to selectively identify nanoparticles within complex matrices. Together, the ability to functionalize nanodiamond and observe it with high selectivity and high sensitivity provides a nearly idea system for understanding nano-bio interactions in environmental systems.

5:30 AM S.NM01.04.03 Effect of Surface Treatment to the Optical Properties of Nitrogen-Vacancy Containing Fluorescent Nanodiamond Particles Haotian Wen1, Huan-Cheng Chang2, Christian Dwyer1 and Shery L-Y Chang3; 1Arizona State University, United States; 2Academia Sinica, Taiwan

Fluorescent nanodiamonds (FNDs) are diamond nanoparticles containing color centers that emit visible light at room temperature. Among the color centers in FNDs, the negatively charged nitrogen-vacancy centers (NV−) have drawn the most attention due to its excellent optical properties and great prospect in sensing and biomedical diagnostic applications. Thus, it is of great significance to further expand the potential of the NV− centers in FNDs by understanding the effect of various factors including the NV distribution, particle morphology and surface properties of the particles.

Recently, it has been reported that the brightness of the FND particles can be increased by etching the particles with molten salt (KNO3). The increase of the brightness was attributed to the roundness and smoothness of the FND surface, as well as the removal of non-sp3 species after the surface treatment. In order to understand how the surface treatment impacts the surface structure and particle morphology, high-resolution transmission electron microscopy (TEM) and electron energy loss spectroscopy (EELS) were employed to reveal the detailed surface atomic and electronic structures.

We have previously demonstrated that it is possible to measure the electronic transitions of the NV center in nanodiamond using high-energy resolution EELS in a scanning transmission electron microscope (STEM). Using a crushed type 1a natural diamond with a nominal size of 70 nm, we detected signals at the ~1.3 and 2.16 eV assigned to [NVN] and [NV]. The high
spatial resolution afforded by this STEM also allows us to observe the atomic structure of the particles.

Here, we compare the different surface processing methods for FND (irradiation, acid treatment, molten salt treatment), and correlate the photoluminescence (PL) mapping with the transmission electron microscope (TEM) mapping of the same area. In addition, high-energy resolution EELS in a STEM at low voltage (30-60 kV) was used to measure the surface state of the FND particles, in combination with the high-resolution TEM images on the same particles.

Our initial finding from the PL and TEM mappings suggests that most of the molten salt (KNO₃) treated FND particles are photoluminescent, and the PL intensity has a correlation with particle size: the bigger the particle the higher PL intensity. High-resolution imaging shows that the molten salt (KNO₃) treated FND particles tend to have less rough surfaces, with fewer sharp-angle edges and less surface unevenness. The particle morphology population displays more round and polygonal shaped particles compared to the non-molten salt treated particles. However, we found a thin layer (1-2 nm) of amorphous carbon and graphite layers present on the particle surfaces. The EELS mapping also confirms this finding.

5:40 AM S.NM01.04.04
Alkyl-Bromide Formation on HPHT Surfaces Enables Room Temperature Catalyst-free Functionalization Chemistry Jorge Rosas¹, Cynthia Melendrez¹, Jocelyn Valenzuela¹, Tyanna Supreme¹, Daniel Labunsky¹, James Titus², Sang-Jun Lee³, Virginia Altoe⁴, D. Nordlund³, Kent Irwin² and Abraham Wolcott¹; ¹San Jose State University, United States; ²Stanford University, United States; ³SLAC National Accelerator Laboratory, United States; ⁴Lawrence Berkeley National Laboratory, United States

Bulk and nanoscale diamond host the nitrogen vacancy center, a unique atomic defect, a photostable emitter that has been used for magnetometry, electrometry and quantum computation. Wet chemical modification of 25-50 nm diamond surfaces, the typical host for nitrogen vacancy centers, is challenging and carboxylate moieties are the common target of nucleophiles for chemical protocols. Here we produce a carbocation-rich diamond surface by converting high-pressure high-temperature nanoscale diamond with tertiary-alcohols to highly reactive alkyl-bromides. The chemical reactivity of the brominated surface allows for carbon-nitrogen bond formation at room temperature without catalysts using low-cost amine precursors. We report that alkyl-bromine moieties are highly labile on diamond, prone to hydrolysis and intracrystallite Williamson ether-type reactions occur. Additionally, in contrast to traditional organic chemistry reactivity, alkyl-bromides on nanoscale diamond are more reactive than acyl-bromides and an explanation is given. The chemical lability of the alkyl-bromide surface leads to efficient amination with NH₃-THF at 298 K and weak conversion rates with condensed NH₃ at 195K. Other amine precursors were also probed to guage a range of nucleophilicities. Overlapping surface sensitive spectroscopies confirm our chemical assignments. Peptide bond formation with FND-NH₂ and folic acid was demonstrated using sulfos-NHS/EDC coupling reagents and reveals that chemical reactivity is maintained. Our work demonstrates that a robust pathway now exists to transform a chemically inert diamond surface into a highly reactive surface at room temperature and broadens the pathways of carbon-heteroatom covalent bond formation.

Progress in Nanodiamonds for Novel Composites and Biomedical Applications Vadym Mochalin; Missouri University of Science and Technology, United States

Nanodiamond powders produced by detonation synthesis offer a great potential in many applications¹, including novel nanocomposites² and biomedical applications³. In the area of nanocomposites, much of work has been focused on polymer matrix composites, while significantly less has been done with other matrices, such as ceramics and metals⁴. At the same time, nanodiamonds have great potential in reinforcing as well as improving optical properties and wear behavior of metal- and ceramic-matrix composites.

We will review our progress in developing well dispersed nanodiamonds⁵ for composite applications with emphasis on novel and less studied nanodiamond-ceramic and nanodiamond-metal composites. Manufacturing and processing techniques, as well as properties of the composites will be discussed.
Another hot area of applications for nanodiamond is biomedical imaging and drug delivery. We will discuss our recent progress in drug delivery with nanodiamonds, emphasizing the effects of nanodiamond surface chemistry, and present novel processing techniques to produce luminescent nanodiamond particles from HPHT luminescent diamond for bioimaging, labeling, and other applications.

5:15 AM *S.NM01.05.02*

**Polyglycerol Grafted Nanodiamond Avoids Protein Corona Formation, Evades Macrophage Uptake and Images Tumor Fluorescently**

Naoki Komatsu and Yajuan Zou; Kyoto Univ, Japan

In biological fluids, proteins are adsorbed onto the surface of nanoparticles (NPs) to form a coating known as protein corona. Most of the corona proteins act as opsonin which activates the macrophage from immune system to uptake NPs, leading to the rapid removal of NPs. This restricts the development of nanomedicine. Although conjugation with linear polyethylene glycol (PEG) is the standard approach to reduce protein attachment and to avoid non-specific uptake, it cannot fully prevent the opsonization. On the other hand, we have demonstrated polyglycerol (PG) as a promising alternative to PEG, because PG enhanced the aqueous dispersibility and gave stealth effect to NPs [1]. In order to understand the role of PG, we compare protein affinity and macrophage uptake of PG and PEG grafted nanodiamond (ND-PG and ND-PEG, respectively) with different polymer content in this paper. Protein analyses by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) indicated that PG was much more resistant than PEG to adsorption of the opsonin proteins such as IgG and complement protein. In particular, there was almost no protein on the PG layer with high content. In addition, almost no ND-PG was observed in the TEM images of U937 macrophage, while there was ND-PEG in the macrophage. This indicates that PG has much better stealth effect than PEG [2]. Finally, the stealth effect was confirmed in vivo by preferential tumor accumulation of the ND-PG functionalized with near infrared fluorescence dye (Cy7) [3].

5:30 AM S.NM01.05.03

**Synergistic Integration of Ultrananocrystalline Diamond (UNCD)-Coatings on Chemical Mechanical Surface Nano-Structured Titanium-Based Dental Implants**

G. Bahar Basim1, Debashish Sur1, Orlando Auciello2, Pablo Tirado2 and Jesus Alcantar2; 1University of Florida, United States; 2The University of Texas at Dallas, United States

This paper focuses on describing a synergistic combination of ultrananocrystalline diamond (UNCD) coating on chemical mechanical nanostructured metallic dental implants to optimize the biocompatibility by a synergistic integration of both processes to optimize the performance of the particular implant.

UNCD films, with grain size in the range of 3-5 nm, exhibit excellent biocompatibility in addition to a unique set of complementary properties including much smoother surface as compared to microcrystalline and nanocrystalline diamond (NCD) (10-100 nm grain size), a superior conformal growth on 3-D structures such as the dental implants and protection of the coated metal-based implants from the chemical attack by oral fluids, enabling enhanced hermeticity [1]. Chemical mechanical nano-structuring (CMNS) is a new complementary technique that can be synergistically utilized to induce nano-scale smoothness or nano/micro-scale roughness on the bioimplant surfaces [2]. Furthermore, implementation of the CMNS process on titanium bio-implants helps cleaning the implant surface from potentially contaminated surface layers by removing a nano-scale top layer, limits any further contamination by creating a non-porous and continuous protective oxide film to minimize the risk of infection and prevent corrosion.

It is demonstrated by surface characterization through SEM imaging and Raman analyses that the CMNS process can be effectively implemented before the UNCD coating to modify surface roughness. Electrochemical evaluations in the simulated
body fluid were also performed to demonstrate corrosion resistance improvements in addition to enhanced biocompatibility by adjustable surface nano-structuring, depending on the cell attachment requirements on the various parts of the dental implants.

SESSION S.NM01.06: Chemical and Structural Characterisation of Nanodiamonds

5:00 AM *S.NM01.06.02
Surface Reactivity of Hydrogenated Nanodiamonds in Water Franziska Buchner¹, Christoph Merschjann¹, Robert Seidel¹, Benjamin Kiendl², Peter Knittel³, Hugues Girard⁴, Jean-Charles Arnault⁴, Anke Krueger² and Tristan Petit¹; ¹Helmholtz Zentrum Berlin, Germany; ²Julius-Maximilians-Universität Würzburg, Germany; ³Fraunhofer Institute for Applied Solid State Physics (IAF), Germany; ⁴CEA, LIST, Diamond Sensors Laboratory, France

The nanodiamond-water interface plays a central role in nanodiamond reactivity in aqueous environment, which is relevant for nanomedicine, photocatalysis or environmental applications. Especially, the generation of solvated electrons can trigger N₂ or CO₂ reduction in aqueous environment, and probably strongly depend on the nanodiamond-water interface.

In this presentation, our latest results related to different spectroscopic approaches to probe the nanodiamond-water interface will be shown. In particular, the different surface reactivity with water related to hydrogen-termination will be compared to oxidized nanodiamond surfaces.

First, the vibrational and electronic structures of water molecules around nanodiamonds were probed by Fourier Transform Infrared spectroscopy (FTIR) and X-ray absorption spectroscopy (XAS) directly in aqueous environment.¹ X-ray Photoelectron Spectroscopy (XPS) was also applied under near ambient pressure conditions (few mbar of water) to probe changes of the surface chemistry of nanostructured diamond upon exposure to water.

Finally, transient absorption spectroscopy (TAS) was applied to nanodiamond dispersions. The evolution of the visible light absorption spectra over time with a sub-picosecond time resolution was monitored after excitation of electrons into the diamond valence band using a UV laser pulse. This enables the observation of the emission of solvated electrons from nanodiamonds in water. The effect of surface chemistry on the electron emission will also be discussed.

This work has received funding from the European Union’s Horizon 2020 Program under Grant Agreement number 665085 (DIACAT).

SESSION S.NM01.07: Fluorescent Nanodiamonds and Sensing
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
S-NM01

5:00 AM *S.NM01.07.01
Measuring and Controlling Temperature at The Nanoscale—Current Strategies and Future Challenges Carlo Bradac;
Color centers in solids are the fundamental building blocks of various applications ranging from lasers to light emitting diodes and sensors, as well as the foundation of advanced quantum information and communication technologies. Their photoluminescence properties are usually studied under Stokes excitation, in which the emitted photons are at a lower energy than the excitation ones.

We explore the opposite Anti-Stokes process, where excitation is performed with lower energy photons. The process is sufficiently efficient to excite even a single quantum system—the germanium-vacancy center in diamond.

As a proof of concept, we propose using Anti-Stokes excitation of diamond color centers for nanoscale thermometry. We leverage the temperature-dependent, phonon-assisted mechanism to realize an all-optical nanoscale thermometry scheme that outperforms any homologous optical method employed to date. We discuss other potential applications and show that our results frame a promising approach for exploring fundamental light-matter interactions in isolated quantum systems.

5:15 AM *S.NM01.07.02
Nanodiamond Quantum Sensing and Its Application to Biological Thermometry Masazumi Fujiwara; Osaka City University, Japan

Fluorescent nanodiamonds (FNDs) have a great promise as robust and biocompatible fluorescent probes. Their most distinct property is the optically detected magnetic resonance of nitrogen vacancy color centers, which enables nanoscale sensing of surrounding physical properties, such as magnetic field, electric field and temperature.

I will talk about our recent activity to build up such microscope-based thermometry for biological applications. Temperature is a fundamental physical parameter of any biological activity, and in most cases, current biology assumes that temperature is uniform over the living space (including organisms themselves). However recent studies have revealed that sub-cellular temperature information is crucial to understand various biological events, such as embryogenesis, physiological thermogenesis, and thermotaxis. The FND quantum thermometry may tackle these biological issues.

I first present our effort to understand the basic spin properties of FND sensors when they are surface treated [1] or placed in various pH and ionic-strength solutions to quantify the sensor stability [2]. Second, we present a bio-dedicated ODMR measurement system to perform quantum thermometry assay for number of biological specimens [3]. Third, with these development, we demonstrate real-time subcellular quantum thermometry of live worms of *C. elegans* [4].

Fabrication Technique, Mechanical and Optical Properties of Nanodiamond-Silica Glass Composite Ibrahim M. Abdullahi and Vadym Mochalin; Missouri University of Science and Technology, United States

Due to the high refractive index and unique optical and mechanical properties of diamond, the nanodiamond (ND) glass composites are of great interest for advanced photonic devices and other applications [1]. However, it is difficult to employ conventional processing techniques to achieve good dispersion of NDs in glass. This is because most of these techniques start from solid powder precursors that may result in serious ND aggregation, leading to degradation of the properties of the composites.

In this presentation, an alternative fabrication method for ND-silica glass composites via sol-gel chemistry will be discussed. Optical and mechanical properties of the resulting ND-silica glass composites at various ND contents will be presented. Single digit (~4-10 nm) ND colloidal solutions in water were prepared by salt assisted ultrasonic deaggregation (SAUD) technique [2]. These colloidal solutions were then used to produce excellent dispersions of ND in ND-silica aerogels that were subsequently sintered into glass at 1100 °C. This proposed method for the integration of ND into silica glass has great potential for fabrication of ND-silica glass composites and could be extended to other nanoparticles and materials produced via sol gel chemistry. The improvements in mechanical properties, optical transmittance in ultraviolet (UV) and visible regions of the spectrum, as well as the refractive index of the ND-silica glass composites at various ND contents will be further discussed.

Nanodiamond NanoMRI for Intracellular Detection of Free Radical Species Alina Sigaeva, Felipe Perona, Nikos Mougios and Romana Schirhagl; Department of Biomedical Engineering, University Medical Center Groningen, Netherlands

Free radicals, by definition containing unpaired electrons, constitute one of the major sources of magnetic signal in live cells. While these molecules are usually considered to be deleterious and are associated with ageing and pathological conditions, certain types of free radicals, such as nitric oxide (NO), perform important signaling functions in live systems. One of the major challenges in understanding the role of free radicals in health and disease is their high reactivity, which makes it hard to detect these molecules with desired spatial and temporal resolution. Moreover, the majority of methods of free radical detection rely on the reaction between the radical and the probe, thus interfering with the natural effects of the radicals [1]. Nitrogen vacancy (NV) centers of nanodiamonds allow for direct optical quantum-based sensing of the magnetic signal coming from the radic.

We apply nanodiamond magnetometry for intracellular sensing of free radical production. As FNDs possess excellent biocompatibility and can be internalized by live cells [2], they can be used for in situ detection of radicals (nanoMRI on subcellular level). As a proof-of-concept model, we used J774 murine macrophages, which produce large amounts of free radicals as part of the normal immune response. One of these radical species is NO, which is generated by a specific enzyme, inducible nitric oxide synthase (iNOS). iNOS activity can be inhibited, resulting in lower levels of NO present in the cell. We have for the first time recorded T1 relaxation curves from FNDs internalized by live macrophages. During the T1 acquisition, the cells were exposed to the iNOS inhibitor, L-NAME. We then assessed the dynamic changes of T1 relaxation of the NV centers, for the first time observing the lengthening of T1 constant of FNDs internalized by the cells, as the NO production in the system was abolished. The changes in intracellular NO levels were confirmed with the conventional fluorescent assay (DAF-2 DA) by the means of microplate reader and confocal microscopy.

Our study shows the potential of nanodiamond-based nanoMRI for the direct optical monitoring of free radical production on a single-cell level with nanoscale sensitivity and a resolution in the second range.

Nanodiamonds in Biological Environment—From Selective Cell Targeting to Control of Cell Signalling Petr Cigler;
Institute of Organic Chemistry and Biochemistry of the CAS, Czechia

Nanodiamond is a biocompatible nanomaterial which can accommodate various photoluminescent crystal defects. Nitrogen-vacancy (NV) centers show particularly high photostability and unique electronic sensitivity to magnetic and electric fields. Their spin properties can be read by optical means, which enables construction of various probes based on quantum mechanical interactions. For application in biological environment, a proper interface of the particles is required. Two conceptually different design of nanodiamond surface design will be discussed [1-3]. These includes polymer and biomimetic lipid terminations enabling further modification by chemically reactive groups. Selectivity of cell surface receptors targeting will be discussed.

Furthermore, specific and efficient regulation of the family of extracellular signaling molecules known as fibroblast growth factors (FGFs) using positively charged detonation nanodiamonds without any synthetically installed (bio)organic interface will be presented [4]. The FGF-based regulation of cell signalling using nanodiamonds can be performed in full sera. This nanotherapeutic approach can be potentially applied to mitigation of pathological FGF signaling and neutralization of disease-related activities of FGFs.

Characterization of Lattice Displacement Using In Situ and Operando Bragg Coherent X-Ray Diffractive Imaging Wonsuk Cha1, F. Joseph P. Heremans2,1 and Stephan O. Hruszkewycz3; 1Argonne National Laboratory, United States; 2University of Chicago, United States

Because of unique sensitivity to lattice, Bragg coherent x-ray diffractive imaging (BCDI) is a powerful characterization tool to image three-dimensional map of strain and defect distribution inside nano-scaled materials with non-destructive measurements [1]. In-situ and operando imaging became a major driver for BCDI to address scientific questions on metal, metal oxide, and mineral in recent years. In this talk, I will introduce basic concept and current state-of-art of BCDI and recent experimental results on in-situ and operando BCDI. High temperature BCDI reveals unique lattice distortion in ZSM-5 zeolites [2], annealing effect on gold grains on gold thin films [3] and relaxation of strain inside quantum materials such as nanodiamonds and silicon carbides [4, 5]. In addition, some estimates of BCDI in the future will be discussed

5:25 AM S.NM01.09.03
Effects of Nanodiamond Size and Surface Chemistry on the Spin-Lattice Relaxation Times of the NV-Center Thea A. Vedelaar1,2, Sandeep Kumar Padamati1,2, Thamir Hamoh1,2, Felipe Perona1,2 and Romana Schirhagl1,2; 1University of Groningen, Netherlands; 2University Medical Center Groningen, Netherlands

The NV-center in nanodiamonds has been applied as a sensor for different applications. They are ideal for this application due to their sensitivity, low cytotoxicity and ability to work at room temperature. However, a limitation of using nanodiamonds to measure a change in the environment, is that one has to use the same nanodiamond. This is due to large variations between nanodiamonds. This study aims to address the differences between nanodiamonds and to develop a method which allows us to understand what contributes to the variation between T1 relaxation times of nanodiamonds. We aim to do this by controlling the size and surface chemistry of the nanodiamonds.
Previous studies in our group have shown that there is large size variation between nanodiamonds. We assume that the size of the diamonds does not only affect the brightness of the fluorescence, but also the T1 relaxation time of the diamonds. The NV-centers in smaller diamonds are in general closer to the surface than in larger diamonds. Therefore, the NV-centers in smaller diamonds are more sensitive to magnetic noise around the diamond compared to larger diamonds. Hence, larger diamonds have a longer T1 relaxation time compared to smaller diamonds. Magnetic noise closest to the NV-center is noise that originates on the surface. We assume that by controlling the surface chemistry of the nanodiamonds, we can study the effects of the surface chemistry on the NV-centers. We assume that the T1 relaxation time will vary depending on the properties of chemical compounds on the surface of the nanodiamonds. We assume that the T1 will become longer or shorter depending on the magnetic properties of the chemicals bound to the surface of the nanodiamond.

The T1 relaxation times are measured on dry nanodiamonds. The procedure is to initialize the system by shining a green laser (532nm) onto the nanodiamonds. Afterwards the laser is turned off which allows the system to relax. This sequence is repeated for varying time of the laser being turned off. During this time the red photoluminescence of the nanodiamonds is recorded. The whole procedure is repeated approximately 10000 times to obtain sufficient statistics. To obtain the T1-value, the initial part of each pulse is integrated to obtain a T1-curve which is then fitted by the bi-exponential model. To account for size, the nanodiamonds are centrifuged to select the average size of the diamonds in the suspension. Afterwards the T1 of the nanodiamonds is measured. The surface chemistry is controlled by applying plasma treatment to the diamonds. The diamonds are treated with different types of plasma (O2, H2, N2 and NH3) for 2, 5 and 10 minutes. Similarly as for size separation, the T1 relaxation times for different plasma treated nanodiamonds have been measured. The T1 curves were recorded for 9 nanodiamonds before plasma treatment and 8 diamonds after 5 minute plasma treatment with NH3. The plasma treated nanodiamonds showed a lower fluorescence than the pre-treatment nanodiamonds. The average T1 value of the bare nanodiamonds is 601(±170) μs and for NH3 treated nanodiamonds is 306(±66) μs. The observed T1 relaxation times pre- and post-treatment show a clear difference between the T1 relaxation times. However, the proportional error for the plasma treated nanodiamonds only reduces by 6% (28% pre-treatment and 22% post-treatment). This shows that the plasma treatment with NH3 decreases the T1 relaxation time, but does not account for the variation between the nanodiamonds. This experiment was preliminary, therefore we did not account for the size variation between the nanodiamonds yet.

Clot Imaging Using Photostable Fluorescent Nanodiamonds Marco Torelli1, Nicholas Nunn1, Gowthami Arepally2, Olga A. Shenderova1 and Sam Francis2; 1Adamas Nanotechnologies, Inc., United States; 2Duke University, United States

Thrombosis is the leading cause of morbidity and mortality in the United States. However, there is still a low understanding of its triggers, progression, and response to anticoagulant therapy. Fluorescence microscopy provides targeted, multi-color contrast, which has advanced the study of thrombus formation. However, photodegradation of fluorophores limits the application in processes that occur over longer periods of time (e.g. clot progression and/or dissolution). Fluorescent nanodiamond (FND) is a fluorophore which utilizes the intrinsic fluorescence of color centers located within and protected by the diamond crystalline lattice. Recent developments in diamond processing have allowed for the controlled production of nanodiamond emitting in multiple colors. In this work, FND is used to visualize clots and their degradation, and this imaging capability is compared to commonly used organic fluorophores. The use of FND for thrombus imaging paves the way for longitudinal studies to investigate biomarker expression in acute thrombosis, with the hope to ultimately improve clinical outcomes. These results represent the initial translation of FND research to clinical applications.
A nanocarbon film consisting of nanocrystallites with mixed sp² and sp³ bonds formed by unbalanced magnetron sputtering was studied with respect to the changes in characteristics caused by surface oxygen concentration. Electrochemical pretreatment (ECP) was conducted to change the surface oxygen concentration of the nanocarbon film. X-ray photoelectron spectroscopy (XPS) measurements revealed that nanocarbon films with different amounts of surface oxygen could be prepared. In addition, we observed no significant increase of surface roughness (Rₐ) at the angstrom level after ECP, owing to stable structure containing 40% of sp³ bonds. Electrode characteristics including potential window, and electrochemical properties for some redox species such as Ru(NH₃)₆⁴⁺, Fe(CN)₆³⁻/⁴⁻ and some biomolecules were investigated. The anodic potential limit became wider and ΔEₚ of Fe(CN)₆³⁻/⁴⁻ became smaller at the treated nanocarbon film electrode than that of the electrode before the treatment. Based on these results, we realized to measure uridylic acid (UMP) and inosine triphosphate (ITP) with high oxidation potential by direct oxidation, which was difficult to measure at as-deposited nanocarbon film electrode.

Magnetic Resonance Study of Lightly Boron-Doped Diamond Alexander Panich¹, Alexander I. Shames¹, Shaul D. Goren¹, Natalya Froumin² and Olga A. Shenderova³; ¹Ben-Gurion Univ of the Negev, Israel; ²Ben-Gurion University of the Negev, Israel; ³Adámas Nanotechnologies, United States

To study the properties of diamond at the initial stages of boron doping, we conducted XPS, EPR,¹¹B and¹³C NMR study of a lightly boron-doped high pressure – high temperature (HPHT) microdiamond with 0.27% of boron. The total content of localized paramagnetic defects is 24 ppm, among them 12 ppm are due to substitutional nitrogen defects (P1). The P1 content is found to be much smaller than that usually observed in conventional HPHT diamonds.¹¹B NMR shows two components assigned to boron atoms substituting carbon and those located within the conducting regions, respectively. The latter component demonstrates exceptionally short spin-lattice relaxation time (T₁ = 2.4 ms) characteristic of conductive compounds. Increase in the boron concentration would increase the number and size of the conductive clusters and would finally lead to connectivity between them. This will result in conductivity and superconductivity in the heavily B-doped regime.

Selective Imaging of Diamond Nanoparticles in Complex Matrices Using Magnetically Induced Fluorescence Contrast Zachary Jones¹, Nicholas Neimuth², Margaret Robinson¹, Olga A. Shenderova³, Rebecca Klaper² and Robert J. Hamers¹; ¹University of Wisconsin - Madison, United States; ²University of Wisconsin–Milwaukee, United States; ³Adamas Nanotechnologies, United States

The use of fluorescence microscopy to study fate and transport of nanoparticles in the environment can be limited by the presence of background signals such as autofluorescence and scattered light. Fluorescent diamond nanoparticles offer a solution to these limitations through the unique spin-related luminescence properties of nitrogen vacancy (NV) centers in diamond nanoparticles (NVND). NV centers have spin properties which affect their fluorescence, and which can be altered using applied magnetic or radio-frequency fields. I will present recent studies using magnetic fields to modulate the fluorescence of NVND for background-subtracted imaging of nanoparticles ingested by a model organism, C. elegans. By using small magnetic fields from an inexpensive electromagnet, the fluorescence of 40 nm NVND can be modulated by 10% in a widefield imaging configuration. We use differential imaging of magnet-induced changes in NVND fluorescence intensity to image and to isolate the emission arising from nanodiamond within the gut of C. elegans. This method represents a promising approach to probing the uptake of nanoparticles by organisms and to assessing the environmental fate and transport of nanoparticles in the environment.

Oxime-Functionalized Nanodiamonds as a Platform for Treatment of Organophosphate Poisoning Yevgen Karpichev¹, Denys Bondar¹, Pavel Starkov¹, Ivo Heinmaa², Ondrej Soukup³, Daniel Jun³, Kamil Kuca³ and Vadym Mochalin³; ¹Tallinn University of Technology, Estonia; ²National Institute of Chemical Physics and Biophysics, Estonia; ³University of Hradec Kralove, Czechia; ⁴University of Defence, Czechia; ⁵Missouri S&T, United States

Nanodiamonds (ND) have emerged since about a decade ago as a key platform for many developments in nanoscience and
nanotechnology due to their outstanding mechanical performance, biocompatibility and unique properties. The NDs bearing biologically active fragments or immobilized on biomolecules are remarkably suitable for biomedical application [1]. Recently, NDs were reported to affect endothelial permeability to deliver anticancer drugs [2, 3]. The main strategy to manage acute poisoning with organophosphorus agents include, either for pre-treatment or for ex-post therapy, administration of oxime AChE reactivator, along with atropine and anticonvulsant drug. The reactivators based on mono- or bis-pyridinium scaffold are not able to diffuse readily into the central nervous system to restore activity of inhibited AcChE. A challenging issue is to design a scaffold providing as high antidotal efficiency towards inhibited AcChE as quaternary oximes along with their ability to come across the blood-brain barrier (BBB). The NDs with a surface modified with the pyridinium oxime moieties have been synthesized. Using carboxylated NDs (ND-COOH) as starting material, there was elaborated method of attaching 4-oximino pyridinium (4-PAM) fragment via variable linkers. The amino-PEG3-amine linker has been selected for studying counterion effect on the modified ND properties. Using 3-chloropropionyl chloride instead of 2-bromoethyl bromide sufficiently increases yield and purity of the final material. The FTIR, elemental analysis, and solid state NMR (13C MAS and 13C CP-MAS) confirm the structure of the substituents and conversion of ND-COOH. Following our green chemistry approach applied recently for the synthesis of inherently biodegradable ionic liquid-derived oxime surfactants [4] and antidotes [5], the closed bottle test was adapted to estimate biodegradability of the organic material covalently attached to of the nanoparticle and therefore evaluate potential impact of the transformation products on the environment. The MDCK assay, an example of the tight junction cell line modelling BBB, has been selected to evaluate the ability of oxime-modified NDs to diffuse from the donor compartment through the MDCK cell membrane into the acceptor compartment. An separate experiment included noncovalent loading of the quaternary oximes on the ND-COOH. Concentrations of HI-6 or 2-PAM in acceptor wells (when the cell monolayer was exposed to NDs) were not elevated in comparison to untreated cell monolayers showing that noncovalent binding is not effective enough to come across the cellular barrier, compared to covalently bound oxime-functionalized NDs. The AcChE reactivation have been performed against three toxic OP: banned insecticide paraoxon and two CWA – sarin (GD) and VX. Our study demonstrates that, as compared to obidoxime, 800 μg/ml of Ox-ND (bromide salt) demonstrate 25-30% of its activity (taken as 0.1 mM aq. solution). For GD and paraoxon, the reactivation with 800 μg/ml is similar to that in the presence of 400 μg/ml; for VX, obidoxime reveals 3 times higher percentage of reactivation. Switching to chloride remarkably elevates the antidotal potency. The molecular docking was applied to estimate optimal distance between the oxime moieties attached to the ND and spacer properties (length, hydrophobicity, rigidity) to get the active cite of human AcChE and act as the antidote.

Air Driven Electrospinning of CNT Doped Conductive Polymer Fibers for Electronics Emily Kooistra-Manning, Lane G. Huston, Jessica M. Andriolo and Jack L. Skinner; Montana Technological University, United States

Electrospinning (ES) is a rapid and simple manufacturing process for producing polymer materials with high surface-area-to-volume ratios. Traditional ES fabrication involves an electrostatic force that pulls polymer from a grounded spinneret tip to a charged metallic deposition surface held at high voltage. Due to the high voltages and the charged electrodes required for ES fiber creation, ES conductive polymers presents a great challenge. During ES of conductive materials, a circuit is completed from the ES spinneret to the deposition substrate, resulting in electrical arcing and non-predictable deposition. In the work presented here, a handheld ES device that incorporates directed airflow was used for deposition of conductive polymer fiber materials directly onto substrates regardless of dielectric charges. In the portable ES device described, deposition occurs by placing a conductive, ring electrode between a spinneret and a deposition surface. The resulting electrostatic force pulls polymer from the spinneret and toward the ring electrode. Directed airflow then carries the polymer fiber through the center of the ring electrode and onto a non-conductive surface beyond the device. Such a system prevents electrical arcing, thereby improving predictability and allowing for the creation of a fiber mat capable of carrying electrical current ranging from direct to alternating. Electrically conductive polymer fiber mats are desirable due to their mechanical compliance, high surface area, potential for optical transparency, and a variety of electrical, optical, and mechanical applications. These applications include but are not limited to materials for water filtration, photocatalysis, light polarization, light energy harvesting, sensors, actuators, and miniature electrical components.

The portable, electrostatic and air driven (EStAD) ES device presented includes enclosed electrodes and a fiber propulsion system that provides several additional benefits as compared to other portable ES devices including improved safety for the
user and predictable deposition with controllable directionality. A highly desirable and novel application of the ES\textsuperscript{STAD} device is that it can be used to electrospin conductive materials onto non-conductive substrates without the drawbacks of traditional ES. In the proposed work, the ES\textsuperscript{STAD} device will be used to deposit conductive sensors onto non-conductive substrates. Carbon nanotube (CNT) polymer composites will consist of multi-walled CNTs (MWCNTs) treated with amphiphilic surfactants or untreated single and double-walled CNTs dispersed in the neat polymer. Previously, amphiphilic surfactants were used to create homogeneously dispersed MWCNT in an aligned nanofiber network with improved conductivity. The feasibility of using untreated single and double-walled CNTs will also be investigated for sensor creation on non-conductive substrates. The preparation process will include a solution-based purification process (ultracentrifugation) in order to inexpensively achieve high purity, metallic CNTs that have been used in high-performing electronic devices. High-purity metallic CNTs are more suitable for superior optical transparency because poorly conducting, strongly absorbing impurities, and semiconducting CNTs will be eliminated through the purification process. Both amorphous nanofiber mats and aligned fiber arrays will be created for subsequent testing. A four-point probe will be used to measure conductivity across the composite CNT nanofiber mats or arrays. The electronic response of nanofiber sensors to analytes (e.g. water vapor and ammonia) will be characterized through current-voltage (I-V) measurements. Morphological surface characterization will be performed through scanning electron microscope (SEM) imaging and analysis, and CNT dispersion within the composite matrix will be analyzed through transmission electron microscope (TEM) imaging and analysis.

Quantum Coupling of Spatially Patterned Guanine Defects in DNA Functionalized Carbon Nanotubes

Youngehee Kim\textsuperscript{1}, Yu Zheng\textsuperscript{1}, Sergei Bachilo\textsuperscript{2}, R. Bruce Weisman\textsuperscript{2}, Stephen K. Doorn\textsuperscript{1} and Han Htoon\textsuperscript{1}; \textsuperscript{1}Los Alamos National Laboratory, United States; \textsuperscript{2}Rice University, United States

Chemical functionalization of the sidewalls of semiconducting single-wall carbon nanotubes (SWCNTs) has attracted intense attention because of the localization of tightly bound excitons at defect sites on the nanotube surface, allowing single-photon emission (SPE) at room temperature. Such covalently functionalized SWCNTs hold the potentials as single-photon sources (SPSs) for the applications of quantum photonics and quantum information processing. Aryl \textit{sp}\textsuperscript{3} defects have been sparsely and covalently implanted to the random positons of SWCNT sidewalls through diazonium chemistry, leading to the trapping of mobile band-edge excitons in the aryl defects and causing spectrally shifted photoluminescence (PL). Single photon has been emitted through the radiative recombination of localized excitons at the defect sites in the altered nanotube with ultrahigh single-photon purity (99%).

Previous reports about chemically functionalized SWCNTs as single-photon emitters are based on sparse and random placement of oxygen atom or aryl group on the nanotube surface. Incorporation of multiple defects with spatial pattern in nanotube sidewalls has not been achieved until recent discovery of covalently functionalizing SWCNTs with single-stranded DNA (ssDNA). The coating agents such as surfactants, polymers, or DNA are required for individualizing nanotube particles. ssDNA oligomers have been found to helically wrap around nanotube surfaces through noncovalent interactions. Recently, a room-temperature chemical reaction in samples of ssDNA-suspended SWCNTs has been found between the guanine nucleotides in the ssDNA coating and the nanotube sidewall in the presence of singlet oxygen (\textit{O}_2). Therefore, introducing and controlling spatially patterned guanine defects on nanotube surfaces is easily achieved by manipulating ssDNA sequences. Such DNA-templated covalent functionalization allows smooth modulation of SWCNT electronic energy levels along the nanotube axis with customized spatial pattern and depth.

Each reacted guanine nucleotides creates a defect with shallow trapping depth in the nanotubes. The axial separation between guanines in the (GT)_\textit{n} ssDNA coating is estimated to be ~0.4 nm, which is at least 5 times smaller than the exciton size. Therefore, excitons in the DNA-tailored SWCNTs are capable of sensing the cumulative potential of several nearby guanine-introduced defects. On the contrary, the exciton is localized in a defect site with deep trapping depth for SWCNT samples with sparse chemical doping of oxygen atom or aryl group on the nanotube surface. We have found that single photon can be generated from the defect-state emission in DNA-altered SWCNTs. Notably, quantum coupling of multiple defect-states has been achieved, resulting from multiple guanine defects with spatial patterning on the nanotube surface.

Superparamagnetic Properties of Metal-Free Nitrogen Doped Graphene Quantum Dots Synthesized by Pulsed Laser Ablation

Muhammad Shehzad Sultan, Vladimir I. Makarov, Brad R. Weiner and Gerardo Morell; University of Puerto Rico - Rio Piedras, United States

In this study, we developed a novel approach to synthesize high-quality metal-free Nitrogen-doped graphene quantum dots (N-GQDs) with high quantum yield, via irradiation of s-triazene in a solution with benzene by using pulsed laser. The TEM, HRTEM, XPS, XRD, Raman spectroscopy and FTIR were carried out to observe the morphology, size distribution, crystalline structure and to prove successful doping of GQDs with nitrogen atoms. Furthermore, for the first time, to our
knowledge, their magnetic properties were investigated. The results indicate that N-GQDs exhibit superparamagnetic behavior. The specific size, shape and zigzag edge structure of N-GQDs were considered to explain the origin of the observed magnetism. The magnetization dependence led to estimating the N-GQD material magnetic permeability for different ambient temperatures. From the zero-field-cooled (ZFC) and field-cooled (FC) magnetization measurements, carried out at 50 Oe magnetic field strength, we estimated the blocking temperature $T_B$ to be around 300 K. Based on the experimental data analysis, the magnetic permeability, number of correlated spins per single N-GQD, and number density of superparamagnetic N-GQD per gram of material were estimated. The excellent superparamagnetic properties together with optical properties manifested by N-GQDs have the potential to lead to high performance biomedical applications.

Optical Response of Ultrathin Periodically Aligned Single-Wall Carbon Nanotube Films Chandra Adhikari and Igor Bondarev; North Carolina Central University, United States

Finite-thickness films of aligned single-wall carbon nanotubes (SWCNT) are recently demonstrated to have extraordinary optoplasmonic properties including a tunable negative dielectric response in a wide photon energy range[1]. We explain this theoretically using the Maxwell-Garnett (MG) mixing[2] for the dielectric responses of planar periodic arrays of identical SWCNTs. We start with the calculation of the conductivity for an individual SWCNT using the (k*p)-method of band structure calculations[3]. Then we use the low-energy plasmonic response calculation technique earlier proposed by one of us for finite-thickness metallic films with periodic cylindrical anisotropy[4], to derive an analytical expression for the dynamical dielectric response tensor of an ultrathin finite-thickness periodically aligned SWCNT array. The dielectric responses of about a dozen of SWCNT arrays with different chiralities and very close diameters are then mixed using the MG method to obtain the anisotropic optical response of the finite-thickness SWCNT film which explains the experimental ellipsometry measurements reported[1]. We also note that in such SWCNT films the inhomogeneously broadened interband plasmon resonance of individual SWCNTs overlaps with the broadened exciton resonance, thus making the exciton-plasmon coupling and associated photon bandgap formation possible[5] for these and similar cylindrically anisotropic compound systems including double-walled carbon nanotubes.

Flexible Configurable Multifunctional Electronics Based on Carbon Nanotube Dual-Material Gate Devices Fan Xia, Li Xiang and Youfan Hu; Peking University, China

Electronic devices with configurability to providing multiple functions are of great interests for their superior adaptability to the ever-changing and multifarious application scenarios. Here, we report flexible integrated circuits possessing configurable functions constructed with dual-material gate (DMG) devices based on carbon nanotube thin films, which can serve as either transistors or diodes, on a 2-μm-thick parylene substrate. When configured as a transistor, the DMG device has great advantages over the normal-gated devices regarding the current on/off ratio, the subthreshold swing and the drain-induced barrier lowering due to the regulated energy band distribution in channel area. When operating as a diode, a typical DMG device demonstrates a sufficient rectification ratio of approximately five orders and a diode-on-current of over 26μA. Scalable manufacturing of DMG devices was also demonstrated with great uniformity both in diode and transistor configurations. Finally, multifunctional integrated circuits, which can dynamically switch their function from rectifier to follower or from OR gate to voltage adder by changing controlling signals, were constructed. The functional-configurability, together with scalable manufacturing and the realization on ultrathin flexible substrates, will open up great opportunity for the future environmentally-adaptive system in the field of flexible electronics.

Pseudocarbynes—Stabilization of Polyynes in Solid-State by Gold Clusters Hyunsub Kim, Pilarisetty Tarakeshwar, Peter Buseck and Scott G. Sayres; Arizona State University, United States
Carbyne, the structure consisting of one-dimensional (1D) chain of $sp$-hybridized carbons is predicted to have greater tensile strength than graphene, making it a highly sought material. However, the highly reactive $sp$-hybridized carbon chains convert to the more stable $sp^2$-hybridized phase through cross-linking reactions and ozonolysis by exposure to oxygen. We have developed a new class of molecules/materials, “pseudocarbynes”, that we define as $sp$-hybridized carbon chains that are stabilized through non-covalent interactions with small metal clusters. Here, I will present our progress in synthesizing pseudocarbynes through two distinct experimental techniques: 1) through direct laser ablation of a gold target submerged in liquid, and 2) through the self-assembly of conjugated carbon chains with a colloidal solution of gold nanoparticles. Pseudocarbynes remain stable in the solid-state (tested for up to several months). We characterize the $sp$-hybridized carbon structure by analyzing FT-IR and Raman spectroscopies, as well as X-ray powder diffraction directly in the solid state. By securing stability in the solid state, pseudocarbynes are expected to be a good candidate for a diverse set of optical or electronic applications.

Design, Solution Synthesis and Characterization of Graphene Nanoribbons and Heterojunctions Mamun Sarker and Alexander Sinitskii; University of Nebraska-Lincoln, United States

Graphene nanoribbons (GNRs) are known for their highly tunable physical properties and great promise for a broad spectrum of electronic applications. The current study focuses on the chemical design of novel molecular precursors for the bottom-up solution synthesis of atomically precise GNRs. As semiconducting properties of GNRs are highly dependent on their width, edge geometry, and heteroatom doping, here we report on the design, synthesis, and characterization of three different GNRs, which include C4N- and C8N-GNR heterojunctions derived from the pristine with nitrogen-substituted chevron-based monomers, laterally extended chevron GNRs (LecGNRs) and edge-modulated chevron GNRs (EmcGNRs). The XPS-data for C4N- and C8N-GNR heterojunctions confirms the presence of nitrogens and suggests the random positions of pristine and nitrogen-doped GNR segments. The data on the structural, optical and electronic properties of all three GNRs will be presented. In particular, LecGNRs showed an expected lower optical bandgap than their counterparts, while EmcGNRs demonstrate a higher optical bandgap than the pristine chevron GNRs. While this study has a particular focus on the solution synthesis of nanoribbons, the developed molecular precursors may also be compatible with the established on-surface synthesis approaches for GNRs.

Low-Power Carbon Nanotube-Based Flexible Integrated Circuits with Bio-Integration Capabilities Li Xiang and Youfan Hu; Peking University, China

Carbon nanotubes (CNTs) is one of the most promising candidates for next-generation electronics for its extraordinary intrinsic properties, including high carrier mobility, excellent mechanical flexibility and solution processability, which are desirable in unique application scenarios, from smart sensing to biomedical implants. However, the integrated circuits (ICs) with enough complexity and integration scale for signal processing, which is the core units in modern electronic systems, are still lacking, which is mainly due to the nonuniformity of the devices, low yield manufacturing and large power consumption. This presentation would detail approaches for wafer-scale, high-yield and highly-uniform manufacturing of CNT devices and ICs. Chips using CNTs as semiconducting materials are 100% successfully transferred to water-soluble substrates with average device yield of 96.6%. Great uniformity is also demonstrated with minimum standard deviation of 55 mV in threshold voltage. The ICs could be successfully transferred onto biological surfaces, such as human wrist, biodegradable polymers and plant leaf. Integrated with other sensors, the CNT based flexible ICs could demonstrate system-level environmental monitoring. In addition, to further push forward the CNT based flexible electronic devices, we propose a gate engineering approach to boost the electrical performance of the carbon nanotube transistors, to make them more energy-efficient and fit for the low power consumption requirement in practical biological or environmental applications.

Wearable Two-Dimensional Thermoelectric Imaging Sensor Array Based on Carbon Nanotube Nabila Fairuz, Fariba Islam and Ahmed Zubair; Bangladesh University of Engineering and Technology, Bangladesh
Thermal imaging has applications in non-destructive imaging, testing, detection, and many more areas. Here, we demonstrate a thermal imaging sensor design made of carbon nanotubes (CNTs) using the thermoelectric effect. We designed the sensor device consisted of an array of p-type CNT fibers that crisscross with another array of n-type CNT fibers. Temperature differences between different p-n fiber knots produce voltage differences. Measuring the voltage differences between p and n terminals of each knot, the temperature of each knot can be determined and the thermal image of the object can be obtained. For a 7×7 sensor array, the p-n terminal voltage difference of ~0.22 mV was attained for a temperature difference of 100 K. As CNT gives flexibility and tunability of the Seebeck coefficient in the device, this thermal sensor device can be made wearable with nanorange thermal imaging with extreme precision.

Density Control of Vertically Aligned Carbon Nanotubes Grown Directly on Stainless Steel through Nanosphere Lithography and Its Effect on Field Emission Properties Arun Thapa and Wenzhi Li; Florida International University, United States

The direct contact of vertically aligned carbon nanotube (VACNT) based field emitter arrays (VACNT-FEAs) to their growth substrate and their structurally controlled morphology are critical factors for applications in vacuum micro/nano-electronic devices. Here, we propose a method for fabricating a high-performance VACNT-FEAs by controlling the morphology of VACNT micro/nano-pillars synthesized directly on stainless steel substrates without external metal catalyst particles via nanosphere lithography (NSL). Exposure of carbon precursor gas to the limited space, created after the NSL using polystyrene spheres of different sizes, on the surface of the thermally heated bulk catalytic substrate was a key for manipulating the morphology of the VACNT-FEAs. Field emission properties of the as-synthesized VACNT-FEAs were measured and found fascinating field emission properties along with high emission current stability. The correlation between the number of emitters in a pillar structure and their field emission behavior has been investigated. The proposed method may be used to fabricate the cold cathodes for vacuum electronic devices requiring high emission current density along with extended emission current stability.

High Pressure Raman Spectroscopy of Linear Carbon Chain Encapsulated in Isolated Multiwall Carbon Nanotube Keshav Sharma1, Paulo T. Araujo1, Nathalia L. Costa2 and Alexandre R. Paschoal2; 1The University of Alabama, United States; 2Universidade Federal do Ceará, Brazil

Elusive measurements of the Longitudinal optical (LO) phonon mode frequency of isolated Cn@MWCNT systems (linear carbon chains encapsulated by multi-wall carbon nanotubes) were studied under extreme high pressure via Resonance Raman spectroscopy. The pressure-dependent frequency softening with increasing pressure is discussed in terms of a simple force constant model in which the spring constants present a dependence with pressure. The model allowed us to easily obtain both the Young's modulus and the Gruneisen parameter associated to such LO mode. In particular, the Gruneisen parameter was found to be much higher than that of Graphene and CNTs. Additionally, the LO phonon lifetime was found to be decrease with increasing stress.

Hybrid Integration of CNT Logic and Analog RRAM towards Monolithic 3DSoC Yijun Li, Jianshi Tang, Zhenxuan Zhao, Jian Yuan, Bin Gao, He Qian and Huaqiang Wu; Tsinghua University, China

With the fast development of emerging technologies such as artificial intelligence and internet of things, there has been higher and higher demand for future chips in terms of computing power, speed, and energy efficiency. Amid the slowdown of Moore's law, new chip architecture is needed to alleviate or overcome the so-called von Neumann bottleneck. Monolithic three-dimensional (3D) integration of multiple layers of functional components, such as emerging memory, logic and sensors, through high-density interlayer interconnects, provides a promising approach to build highly energy-efficient system-on-chip (SoC). On one hand, carbon nanotube (CNT) has been demonstrated as a superior candidate for high-speed logic technology that can be fabricated with low-temperature process. On the other hand, resistive random-access memory (RRAM) has been extensively studied for energy-efficient computing-in-memory (CIM) by taking advantage of its analog switching characteristics. In this work, we report the monolithic integration of CNT logic circuits and analog RRAM array using back-end-of-line (BEOL) compatible low-temperature fabrication processes. The performance of CNT integrated circuits and analog RRAM devices have been carefully optimized. Hybrid circuits such as ternary content-addressable memory (TCAM) are also fabricated. Our work represents a critical step towards 3DSoC with CIM capability.
The motivation behind this project is to study the structure of complex hetero ion based lamellar materials and their physical properties, including ferroelectricity and ferromagnetism, at the 2D limit. By mechanically exfoliating bulk single crystals of CuInP$_2$S$_6$, CuCrP$_2$S$_6$, and CuCrP$_2$Se$_6$, a top down approach is used to obtain flakes that are as thin as possible. By isolating a monolayer of these materials, future studies will be conducted to probe for the existence of subnanometer ferroelectric, ferromagnetic, or magnetoelectric multiferroic responses from each respective material systems. Furthermore, studies on heterostructures formed from stacking different monolayers of material in order to study the coupling between different layers are also considered. In hope of its success, we can formulate a device that can take advantage of its magnetoelectric coupling in applications of spintronics and capacitors for more advanced computing.

Using Atomic Force Microscope (AFM) and Raman Spectroscopy, I developed a system to measure the thickness of flakes and to correlate them to Raman spectra and optical images. Despite its challenges, I have successfully measured a range of flake thickness that correlates to a trend in the intensity of the Raman spectra. This allows us a way to identify thin flakes of materials to pursue future studies on the multiferroic character of these materials systems at the 2D limit.

Among the many chemical and physical processes capable of modifying 2D materials, laser plasma processing provides an attractive suite of unique experimental parameters. Using appropriate laser irradiation conditions of a solid target, the ionization fraction, density, temperature, and kinetic energy of a laser-generated plasma can all be adjusted. These plasmas can be used to modify atomically-thin materials. This approach has been employed in the use of a laser-generated sulfur plume for alloying and creation of lateral heterostructures in transition metal dichalcogenides (TMDs) [1]. Further development in this area may be possible with a quantitative understanding of the formation/expansion process of laser-produced chalcogen plumes. In this work, we report on full-scale fluid dynamic simulations of laser-generated chalcogen ion plasmas from initial light-matter interactions to long-range expansion away from a solid target. Contrary to previous studies, our simulation is carried out to centimeter distances, which is the length scale relevant for materials modification. The simulation makes use of implicit partial differential equation solvers and is implemented in a state-of-the-art, multidimensional adaptive Cartesian mesh (ACM) framework. The ACM approach is essential since the spatial resolution required in the early stage of laser-matter interaction is a fraction of a micron while the entire computational domain is several centimeters. As the plasma begins to expand, the fine resolution at the target surface is no longer required, allowing the grid to be coarsened. A dense mesh is still required at the moving plasma front throughout the entire domain and so the ACM follows the front, and allows a coarse mesh elsewhere. The ACM technique makes the computation fast and enables large scale, multidimensional simulations. We simulate the plasma produced during pulsed nanosecond ablation (e.g., KrF excimer) of elemental tellurium and selenium and calculate the kinetic energy distribution of neutral and ionic species, analyzing in detail the evolution of their spatial dynamics. Compared to other metals like copper, bulk tellurium and selenium have drastically lower melting and boiling points as well as mass density. The result of these physical properties is that plasma absorption of the laser pulse begins earlier in the ablation process, and is sustained for longer times, leading to greater vapor densities and temperatures. For instance, at the surface of a copper target, vapor densities are in the 10$^{23}$ m$^{-3}$ range while a selenium or tellurium target irradiated with the same laser power exhibits vapor densities that are an order of magnitude higher, with a greater number of highly ionized species. Both 1D and 2D-axisymmetric simulations show that singly and doubly ionized species expand outwards with high kinetic energy ahead of the high-density neutral vapor. At high vacuum conditions, reducing the laser irradiance below the plasma absorption threshold minimizes the number of energetic species and the thermal component of the plume is dominant. Simulations such as these provide quantitative understanding of the physical properties of chalcogen ion plasmas and can guide experiments in laser plasma modification of TMDs.

The emergence of two dimensional (2D) materials opened up many potential avenues for novel device applications such as nanoelectronics, topological insulators, field effect transistors, microwave and terahertz photonics and many more. To date there are over 1,000 theoretically predicted 2D materials. Of those theoretical materials, only 55 have been experimentally synthesized. The incorporation of this technology into device applications has been hindered due to the difficulty synthesizing and stabilizing the 2D materials. Traditional methods such as chemical vapor deposition result in films with defects and grain boundaries. Controlling the growth of these films requires a systematic understanding of the crucial factors of the film-substrate adhesion strength and mismatch strain. In this work, we present a multi-scale computational approach to model the mesoscopic growth mechanisms of 2D materials on various substrates using density functional theory calculations with van der Waals corrections and phase field methods capturing both atomistic and mesoscopic materials properties.

Various 2D materials are placed epitaxially on substrate surfaces which possess hexagonal symmetry. The 2D materials are pre-screened to ensure that each 2D material will not possess a strain that is more than 10%. For all substrate-2D systems the binding and formation energy is computed using a high-throughput approach to density functional theory performed within the atomate framework. These parameters, coupled with the elastic constants for the 2D material are used to fit phase field models to predict the mesoscopic growth of various 2D materials.

From last decade, the interest of graphene is rising spanning almost all research areas due to its outstanding electrical, optical, mechanical, etc. properties inherited by its 2D structure [1]. Due to this remarkable discovery, the material graphene oxide (GO) became famous as a precursor for graphene synthesis, even though it was discovered about 150 years ago [2]. The GO is oxygenated form of graphene with many oxygen-containing groups (O-groups) and lattice defects. Hence, to fabricate graphene from GO, removal of these O-groups and repairing of the lattice defects is vital. This process is known as reduction [3]. However, to obtain pristine graphene from GO is the most challenging task due to the difficulty in complete removal of O-groups and repairing of lattice defects by conventional reduction method.

It has been reported that, reduction of GO by high temperature annealing (>1500 °C) is an effective reduction method, particularly in producing conducting RGO films [4]. However, high temperature annealing transforms into high-energy consumption. Further, high temperatures cannot be used on all types of substrates in making graphene films. Therefore, the road to make pristine graphene like material by reducing GO still poses obstacles. As an alternative strategy, thermal annealing of GO in the presence of a carbon source (C-source) such as, ethanol, methane, ethylene, and acetylene via chemical vapour deposition (CVD) has been reported (<1000 °C) [5,6]. In our previously published work, fabrication of conducting RGO films by the restoration of graphitic structure via ethanol-CVD was reported [7]. As a continuation of this work, here we report, with the objective to understand the restoration behaviour of lattice defects, thermal annealing of GO in the presence of various organic solvents such as ethanol, methanol, isopropanol, tert-butanol, ethylene glycol, and toluene.

To mention the methodology in brief, first a dispersion of GO was spin-coated on SiO2/Si substrates and thermal annealing was done in the presence of the above solvents using a CVD device. Characterization of the synthesized samples was done by Raman spectroscopy, atomic force microscopy (AFM) along with Kelvin probe force microscopy (KPFM), and X-ray photoelectron spectroscopy (XPS). Preliminary results showed that there is a significant effect on restoration of lattice defects depending on the organic solvent used. Particularly, the Raman spectroscopic results show the evolution of the G’-peak, which is an indication of restoration of lattice defects, and depending on the C-source the spectral properties change (intensity of G’-peak increases with more carbon atoms). The AFM results showed that the thickness of a single GO sheet has reduced from 1 nm to 0.4 nm due to removal of O-groups upon thermal treatment. Further, conductivity measurements of the synthesized RGO films will be carried out to clarify the solvent dependence on the restoration of lattice defects.

Symmetry Dependent Kinetics of 2D Materials’ Growth and Etching

Jichen Dong¹ and Feng Ding¹,²; ¹Center for Multidimensional Carbon Materials, Institute for Basic Science, Korea (the Republic of); ²Ulsan National Institute of Science and Technology, Korea (the Republic of)

The unique structures of 2D materials make them to show many excellent electronic, chemical and thermal properties that are absent from their 3D counterparts. To date, tremendous efforts have been devoted to the synthesis of large-area high-quality 2D materials. Moreover, studies have shown that etching, which has been one of the key techniques in the semiconductor society, can be used to create various structures in 2D materials, which can not be obtained by direct growth (PNAS 110 20386 (2013)). Therefore, A deep understanding on the growth and etching behaviors of 2D materials is crucial for their controllable fabrication. Here, we propose a general model for the growth and etching of two dimensional (2-D) crystals. In this model, low index edges are treated as the basis, while high index ones are described to be composed of terraces along the basis directions and kinks that connect the terraces. Considering the high formation energy penalty of forming a 1D nucleus on a terrace and the easy addition or removal of atoms to or from the kink sites, symmetry dependent edge growth and etching rate profiles of 2D crystals are constructed. By applying the kinetic Wulff construction (KWC) for growth and our modified KWC for etching, we simulated the shape evolutions of 2-, 3-, 4- and 6-fold symmetric 2D crystals during their growth and etching processes, which are well consistent with many experimental observations. This proposed model is expected to be a standard model for the growth of 2D crystals.

Robustness of Atomic Scale Phosphorous Delta Layers—Toward Room Temperature Operation

David A. Scrymgeour, Connor Halsey, Daniel Ward, DeAnna Campbell, Evan Anderson, Scott W. Schmucker, Jeffrey A. Ivie, Ezra Bussmann, Suzey Gao, Tzu-Ming Lu and Shashank Misra; Sandia National Labs, United States

Atomic precision phosphorus doping of silicon by scanning tunneling microscope (STM) based hydrogen resist lithography is a promising fabrication platform for creating advanced silicon based electrical and quantum structures. In this process, termed atomic precision advanced manufacturing (APAM), the doping is accomplished by selective depassivation of bound hydrogen with the STM tip, incorporation of phosphine molecules, and capping with epitaxial silicon. APAM devices could provide a platform to learn about the device physics relevant to future transistor technologies. Moreover, these structures can carry a surprising 2 mA/μm of current, potentially enough to integrate APAM structures and devices with modern CMOS transistors. However, these devices have limited applicability because they only operate at cryogenic temperatures, and their ability to withstand the operational environments of CMOS is an open question. In this work, we report on our attempts to demonstrate room temperature devices realized in silicon-on-insulator devices and delta layer analogs, and the discuss the robustness and failure mechanisms at elevated temperature and current densities. These results show utility and challenges of this material platform for future discovery platforms.

This work was supported by the Laboratory Directed Research and Development Program at Sandia National Laboratories and was performed, in part, at the Center for Integrated Nanotechnologies, a U.S. DOE, Office of Basic Energy Sciences user facility. Fabrication and Characterization of DNA Origami-Based Metal-Semiconductor Junctions

Basu R. Aryal, Dulashani R. Ranasinghe, Tyler R. Westover, Robert C. Davis, John N. Harb and Adam T. Woolley; Brigham Young University, United States

DNA-assisted bottom-up nanofabrication has demonstrated promise in creating both metal and non-metal nanostructures with diverse applications. To date, different-shaped and electrically connected metal nanostructures have been created and
electrically characterized. However, the self-assembly and electrical measurement of semiconducting materials on DNA at the nanoscale have not been demonstrated. We have examined the fabrication yield and electrical properties of various Au nanowire structures created on DNA origami tiles by site-specific attachment of Au nanorods to molecularly programmed sites. We are now working with metals and semiconductors on these DNA nanostructures. We have attached Au and Te nanorods to designed locations on individual DNA origami templates and connected the nanorods via electroless Au deposition technique to create metal-semiconductor junctions. In addition, two-point probe electrical measurements were performed to verify the electrical continuity of the junctions, and non-linear current vs voltage curves were obtained. This work is a step toward self-assembling metals and semiconductors at the nanoscale using DNA origami structures, with potential future nanoelectronics applications.

**Tailoring the Electronic Transport Properties of MoS2 Thin Film by Oxygen Plasma Treatment** Bhim Cham lagain and Saiful I. Khondaker; University of Central Florida, United States

Controlled and meticulous tunability of electronic properties of layered two-dimensional (2D) transition metal dichalcogenides (TMDs) is essential challenge to fabricate TMDs functional devices for the specific applications. Structural defects, crystallinity of the film and dopants used in two-dimensional (2D) transition metal dichalcogenides (TMDs) can significantly modify the material properties. Significant effort has been done to tune the optical and electrical properties of MoS2 with plasma exposure by manipulating the defects, doping and band structure. However, the observation of structural defects repair and phase change of MoS2 by plasma exposure has been still debatable. In this study, we will present the tunability of the electrical properties MoS2 thin film prepared by low pressure chemical vapor deposition (LPCVD) method with low power oxygen plasma treatment. Our electrical transport measurements elucidate the effect of the mild oxygen to the MoS2 film and able to tune the transport properties of the MoS2.

**Non-Destructive Thickness Mapping of Insulating 2D Materials Down to a Monolayer** Andrea Crovetto1, Patrick Whelan1, Rui zhi Wang2, Miriam Galbiati1, Stephan Hoffmann2 and Luca Camilli1; 1Technical University of Denmark, Denmark; 2Cambridge University, United Kingdom

Characterization of the thickness and continuity of wide band gap 2D materials with monolayer sensitivity over large areas has proven to be very challenging. A prime example is 2D hexagonal boron nitride (hBN). Optical contrast methods suffer from the lack of visible absorption in the material; Raman spectral signatures are weak and often not conclusive; and electrical measurements are not possible due to a high electrical resistivity. In this contribution, we will demonstrate an experimental method based on the ellipsometry technique, which makes it possible to map the thickness and continuity of large-area hBN monolayers and bilayers transferred to Si/SiO2 substrates. The method has sub-monolayer thickness sensitivity, is relatively fast, non-destructive, and can be easily automated. Importantly, artifacts in the measured thickness due to polymer residuals from the transfer process can be deconvolved under most conditions. With some assumptions on the optical functions of hBN, the thickness of an as-transferred hBN monolayer on SiO2 is measured as 4.1 Å ± 0.1 Å, whereas the thickness of an air- annealed hBN monolayer on SiO2 is measured as 2.5 Å ± 0.1 Å. The most likely cause of this discrepancy is the presence of a water layer trapped between the SiO2 surface and the hBN layer in the latter case. The number of hBN layers measured in this study has been confirmed by Raman spectroscopy, x-ray photoemission spectroscopy, and by a series of ellipsometry control experiments. We will present a workflow of our experimental procedure, so that other researchers can extend this characterization method to other 2D materials and hopefully accelerate their development.

**Molecular Modeling of Biomaterial Degradation in Two Dimensions** Falk Hoffmann, Rainhard Machatschek, Stefanie Barbirz and Andreas Lendlein; Helmholtz-Zentrum Geesthacht, Germany
Modern medical applications require the design of multifunctional polymers. These substances shall fulfill several roles while implanted in the human body, for example as mechanically supporting devices that can release a drug, followed by a full, non-toxic degradation. A concept for implanting multiple functions is molecular integration through well-defined polymer architectures. Here, structure parameters, which can be varied include composition and ratio of different molecular building blocks as well as the branching type. Moreover, the aqueous biological environment can influence polymer behavior, like hydrogel swelling in water that may trigger both drug release and subsequent degradation. Material design therefore implies knowledge on structure-function relationships that enable rapid prediction of material properties under specific conditions and external stimuli over sufficiently long time scales. Especially, polymer degradation has major impact on material physicochemical properties and requires thorough understanding of the molecular processes [1]. Importantly, degradation at the polymer surface links to medical applications. For example, medical drugs are delivered in the human body without functional loss if they are encapsulated in a polymer matrix which degrades at the surface without effecting its bulk composition. Recent experimental studies have shown that defined two-dimensional thin film polymer layers are highly suitable to quantitatively study degradation kinetics with Langmuir techniques [2]. In this work we now apply computational simulations to provide an all-atomistic description of the polymer degradation process at the two dimensional interface. A molecular modeling approach is used to show how a molecular monolayer polymer surface film at the water interface behaves at different stages of the degradation process. The models are validated by exploring chemically established commercially available implant materials such as PLGAs (poly(lactide-co-glycolide)s and PCL (poly(ε-caprolactone)). The validation takes random chains as well as end-chain cutting as degradation mechanisms into consideration. Finally, the model will be used as a predictive tool for digitally assembled copolyesters comprising the same repeating units, but aligned in sequence structure, which in part are challenging to synthesize such as strictly alternating structures. The gained knowledge will form the basis for the design of the next generation of degradable implant materials.

Exploring the Role of Dimensional Variation in Molybdenum Disulphide (MoS2) by Relating the Structural, Morphological and Optical Characteristics
Margi Jani, Dhyey Raval, Abhijit Ray and Indrajit Mukhopadhyay; Pandit Deendayal Petroleum University, India

Molybdenum disulphide (MoS2) as a transition metal dichalcogenides (TMDCs) sketching a wide research interests with unique optical and electronic properties then a bulk. Bandgap engineering technique is a potential way for tuning to its optimization. MoS2 owing to band gap tailoring from 1.3 to 1.9 eV for bulk (indirect) and single-layered (direct) structures makes it a promising material in the field of energy applications. The present article deals with variation in the properties along with dimensional (1-3D) change in molybdenum disulphide nanostructure. Syntheses, structural, morphological, optical properties of bulk to few layers of nanostructures are investigated. The exfoliation of MoS2 Flake like nanostructure has been studied for its unique properties. Uniform 3D flower like nanostructures has been prepared by one-pot hydrothermal method. Nanostructure flakes by a solution based exfoliation method are compared with a bulk MoS2. Structural, morphological and optical properties were investigated by XRD, FESEM, EDAX, UV–Visible for the bulk and nanostructures properties.

Enhanced Intracellular Uptake of Quantum Dots and Gold Nanocrystals Promoted by an Antimicrobial Peptide

Hedi M. Mattoussi; Florida State Univ, United States

There has been much interest in developing multimodal imaging platforms, using colloidal nanocrystals made of luminescent quantum dots and plasmonic nanomaterials. Such approach is highly promising. However, the lack of adequate and effective strategies to deliver these nanocrystals into the cytoplasm of live cells has been a major challenge. We have designed a set of high affinity hydrophilic polymer ligands and tested them for the stabilization of various inorganic nanocrystals (e.g., luminescent quantum dots and Au nano-colloids) in biological media. Furthermore, introducing additional reactive groups facilities easy coupling of the polymer-coated nanocrystals to specific cell targeting peptides or/and NMR-active labels. Here, we report on the ability of an anti-microbial peptide to promote the uptake of three types of nanomaterials (QDs, AuNPs and AuNRs) into mammalian cells. Using fluorescence microscopy experiments, we found that incubation with these conjugates yielded nanocrystal staining throughout the cell volumes. Additional experiments showed that uptake persisted under endocytosis inhibition conditions, such as incubation at low temperature and in the presence of hypertonic sucrose solution. These findings were complemented with flow cytometry measurements and confocal microscopy imaging. Overall, the imaging data support the hypothesis of physical translocation of these conjugates through the membrane rather than endocytosis.

Intracellular Transport of TiO₂ Nanoparticles—Single Particle Tracking and Modeling of Stochasticity

Keisha Cook¹, Nathan T. Rayens², Scott A. McKinley¹ and Christine K. Payne²; ¹Tulane University, United States; ²Duke University, United States

Titanium dioxide nanoparticles (TiO₂ NPs) are indispensable in consumer products due to their function as pigments and photocatalysts. For example, TiO₂ NPs are included in food products and cosmetics to brighten white colors and in sunscreen to block UV rays from reaching the skin. Previous work has shown that the effects of TiO₂ NP exposure on human cells through food consumption and skin contact are negligible, but the effects of TiO₂ NP inhalation are unknown. Using fluorescence microscopy and transmission electron microscopy, we have found that TiO₂ NPs are internalized by human lung cells (A549). In these cells, TiO₂ NPs accumulate in lysosomes, membrane-bound organelles responsible for the transport and degradation of cell cargo. Enlargement of these organelles can have significant effects on cell health. We have found that TiO₂ NP-containing lysosomes are 1.85 times larger on average than lysosomes in untreated cells when compared through representative distributions of size.

We used single particle tracking fluorescence microscopy to follow the motion of TiO₂ NP-containing lysosomes in living cells. Lysosomes were fluorescently labeled with fluorescent proteins and by the absorption of fluorescently-labeled proteins on the TiO₂ NPs. In both of these cases, and for any single particle tracking experiment, observation time is limited by photobleaching, cell viability, and microscope stability. As such, a stochastic model of lysosome motion is warranted to extrapolate beyond trajectory limitations and establish confidence in data validity.

Our goal was to determine the trajectory length necessary to establish confidence in the validity of the observed velocity and diffusivity of lysosome motion. Using Bayesian methods, we estimated unknown information given a set of single particle trajectories. With this information from lysosome trajectories, we could then assign a likelihood that each lysosome was in a specific state of motion (e.g., active transport or diffusion) during a given time interval. This provides insights on the mobility distribution of lysosomes in the cell as a function of TiO₂ NP transport. Based on the inferred relative frequencies of the various states of motion, we then built a forward simulation to explore what the long-term distributions of enlarged lysosomes might be compared to normal lysosomes. Our stochastic model, in combination with experimental data, verifies the validity of our observed trajectories and predicts lysosome transport modes for both untreated control and TiO₂ NP-
containing cells. This confidence in the stochastic modeling of particle tracking is useful not only for TiO$_2$ NP-containing lysosomes, but also broad questions of cellular transport studied with single particle tracking.

Application of Combined Computational and Machine Learning Based Cheminformatics Approaches towards Nanomaterials Toxicity Assessment Bakhtiyor Rasulev; North Dakota State University, United States

For the last two decades, breakthrough research has been going on in all aspects of materials science, including nanotechnology at an accelerated pace. New nanomaterials of unprecedented functionality and performance are being developed and characterized. However, environmental exposure to nanomaterials is inevitable as nanomaterials become part of our daily life, and as a result, nanotoxicity assessment is getting increasingly important.

Here we show the adaptation and application of various computational and cheminformatics methods in nanomaterials toxicity prediction. Since nanomaterials are complex entities from a chemical point of view and the study of these kind of materials requires an interdisciplinary approach, involving multiple aspects ranging from physics and chemistry to biology, informatics and medicine. We show how the combination of computational chemistry, available experimental data, machine learning and cheminformatics approaches can help in nanomaterials toxicological risk assessment. We discuss here a few case studies where data-driven models developed help to decode the relationships between the toxicity of nanomaterials and their physicochemical characteristics, by application quantum chemical, protein-ligand docking, developed nanodescriptors and cheminformatics approaches, including a quantitative multi-nano-read-across approach that combines interspecies correlation analysis.

Flame-Based Fabrication of Superhydrophobic Surfaces from Silicones Souvik Banerjee$^1$, Xin Chun Tian$^1$, Deyny L. Mendivelso-Perez$^1$, Kara Lind$^2$, Santosh Shaw$^3$, Emily Smith$^1$ and Ludovico Cademartiri$^4$; $^1$Iowa State University, United States; $^2$Ochsner LSU Health Shreveport, United States; $^3$Intel Corporation, United States

Outdoor applications of superhydrophobic coatings require synthetic approaches that allow their simple, fast, scalable, and environmentally benign deployment on large, heterogeneous surfaces and their rapid regeneration in situ. We show that the thermal degradation of silicones by flames fulfills these characteristics by spontaneously structuring silicone surfaces into a hierarchical, textured structure that provides wear-resistant, healable superhydrophobicity. We will elucidate how flame processing is a simple, rapid, and out-of-equilibrium process that is counterintuitively reliable and robust in producing such a complex structure. A comprehensive study of the effect of the processing speed and flame temperature on the chemical and physical properties of the coatings yielded three surprising results. (i) Three thermal degradation mechanisms drive the surface texturing: depolymerization (in the O$_2$-rich conditions of the surface), decomposition (in the O$_2$-poor conditions found a few micrometers from the surface), and pyrolysis at excessive temperatures. (ii) The operational condition is delimited by the onset of the depolymerization at low temperatures and the onset of pyrolysis at high temperatures. (iii) The remarkably wide operational conditions and robustness of this approach result from self-limiting growth and oxidation of the silicone particles that are responsible for the surface texturing and in the extent of their deposition. As a result of this analysis, we show that superhydrophobic surfaces can be produced or regenerated with this approach at a speed of 15 cm s$^{-1}$ (i.e., the length of an airport runway in $\sim$4.5 h).

A Highly Selective Sensor Based on Fluorescent Fe2O3-CdSe Nanocomposite for Detection and Removal of Picric Acid

Vishal Kumar and Soumitra Satapathi; Indian Institute of Technology Roorkee, India

Detection of the nitro-fragrant compound at trace level is critical in combating terrorism, for keeping up national security and for providing environmental and clinical safety. Among various nitroaromatics compounds (NACs), the importance of picric acid (PA) owes to its extensive usage in the manufacture of rocket fuels, fireworks, deadly explosives, leather processing and sensitizers in photographic emulsions.[1] As of now, many fluorescence chemosensors/probes have been effectively applied for the detection of PA with functional specificity based on its characteristic properties, particularly resonance energy transfer and electron-deficient nature of the nitro group (-NO2), yet only a few appeared closer to the practical applications. Late reports on CdSe nanoparticles and expedient to surface modification showed its fate in the detection of NACs. Quantum dots have a clear advantage over molecule-based emitters; however, these multi-model sensors are inconvenient for the removal of the target species, which might cause secondary contamination. Towards this end, the incorporation of a fluorescent and magnetic functionality in a single nanocomposite particle would be a promising alternative.[2]

Here, we present a methodology and promising novel hybrid nano-structure that comprises of magnetic core encapsulated inside a thin silica shell (Fe2O3@SiO2 NPs), electrostatically adsorbed through the free anionic carboxyl group with a positively charged spacer arm of florescent Cysteamine-capped CdSe quantum dot (QD) (particle size ≈ 12.7 nm). This multimodal nanosensor provides an efficient sensitive and selectivity detection of PA over a number of other explosive (NACs) in DMSO, (LOD ≈ 2.2 µM) (Quenching constant KPA ≈ 4.3×10^4 M⁻¹) in solution via photo-induced electron transfer mechanism. The sensing mechanism is probed via UV-Vis spectroscopy, steady-state and time-resolved fluorescence spectroscopy which was found to be a mixture of immediate dynamic and static quenching as the lifetime of nanosensor (0.98 ns) is reduced to 0.63 in presence of PA. In addition to solution-phase sensing, this magneto-fluorescent nanosensor also showed an excellent ability for the removal of detected PA molecules with the use of an external magnet, staging as a possibility for the potential application of low-cost and stand-off sensor. In summary, this elegant architecture results in an ultra-small magneto-fluorescent nanoparticle offering a novel platform for the development of a field-based PA sensor.

Effects of Polyethylene Particles from 0.2 μm - 0.9 μm in Size on Synechococcus sp. PCC 7002

Mary Machado¹, Gina Vimbela¹, Tania Silva de Oliveira², Arijit Bose² and Anubhav Tripathi¹; ¹Brown University, United States; ²University of Rhode Island, United States

Microplastics or plastic particles less than 5 mm in size are a common and damaging pollutant in the marine ecosystem. However, the full adverse impacts of these particles on marine microorganisms are just starting to be understood. Polyethylene is one of the most abundant microplastics found within the marine environment, but few studies have been performed on microorganisms exposed to these particles. Additionally, little work has been done to identify the cytotoxic, genetic, enzymatic and morphological effects that nanoplastics and microplastics have on marine microorganisms. This study used molecular techniques such as High-Resolution Automated Electrophoresis and RT-PCR to quantitatively analyze expression changes in characteristic marine organism (*Synechococcus sp. PCC 7002*) exposed to polyethylene nanoparticles and polyethylene microparticles. Novel visualization techniques such as scanning electron cryomicroscopy (CryoSEM) were also used by this investigation to measure morphological changes in bacterial colonization on these particles. Results of this study showed significant differences between nanoparticle, microparticle and control samples. A viability analysis using neutral red showed decreases in the number of viable cells after 5 days of exposure to polyethylene nanoparticles that were not seen in microparticle or control samples. RT-PCR analyses showed differences in the expression of esterase and hydrolase genes. For samples exposed to polyethylene nanoparticles, increases in expression occurred at 5 days of exposure. In samples exposed to polyethylene microparticles, however, expression increased more substantially at 10 days of exposure. A plate based enzymatic assay showed increased esterase activity at the 5 day time point in the nanoparticle exposed samples. Cryo-scanning electron microscopy results identified changes in exopolymers formation in all samples exposed to polyethylene particles. These results illustrate that exposure to polyethylene microparticles and nanoparticles results in genetic, enzymatic and morphological changes in *Synechococcus sp. PCC 7002* and argue for further molecular study of the effects of anthropogenic stressors on marine microorganisms.

**Atomically Precise Graphene Nanoribbons—From Synthesis to Electronic Applications** Alexander Sinitskii; University of Nebraska - Lincoln, United States

Atomically precise graphene nanoribbons (GNRs) are at the forefront of nanocarbon research and hold great promise for electronic and optoelectronic applications. Theoretical studies have shown that narrow GNRs possess interesting electronic and magnetic properties that strongly depend on the nanoribbon’s width and edge structure. GNRs with different structures can be synthesized with atomic precision and fine-tuned properties by coupling properly designed molecular precursors and planarization of the resulting polymers.

In this talk, I will discuss our recent results on solution and on-surface synthesis and characterization of atomically precise GNRs. The solution approach is based on Yamamoto coupling of pre-synthesized molecular precursors followed by cyclodehydrogenation using Scholl reaction. This approach can be applied to the synthesis of a variety of GNRs, including pristine and nitrogen-doped GNRs with the chevron structure. The on-surface approach is based on the coupling of halogenated molecular precursors on metal substrates and subsequent cyclodehydrogenation of the resulting polymers at elevated temperatures.

Both solution and on-surface approaches were used to synthesize laterally extended chevron GNRs (eGNRs). The ribbons grown on Au(111) were used for extensive scanning tunneling microscopy (STM), noncontact atomic force microscopy (nc-AFM) and scanning tunneling spectroscopy (STS) characterization. They were found to exhibit a bandgap of about 2.2 eV, which is considerably smaller than the values reported for chevron GNRs in similar studies. The solution-synthesized eGNRs were processed into uniform thin films that exhibited improved electrical conductivity compared to similar films of regular chevron GNRs. The eGNR films were employed in gas sensors that showed very high responsivity to low molecular weight alcohols compared to similar sensors based on benchmark graphitic materials, such as graphene and graphene oxide. Finally, we demonstrated the first electronic nose system based on atomically precise GNRs that could reliably recognize analytes of nearly the same chemical nature, such as methanol and ethanol. Overall, this work demonstrates the entire path from designing new atomically precise GNRs with improved properties to their bottom-up synthesis, characterization, processing and implementation in electronic devices.

**High Performance Graphene Nanoribbon Transistors** Jeffrey Bokor1, Zafer Mutlu1, Juan Pablo Llinás1, Gabriela Borin Barin2, Peter Jacobse1, Ilya Piskun1, Raymond Blackwell1, Andrew Fairbrother1, Xinliang Feng4, Klaus Müllen2, Felix R. Fischer1, Pascal Ruffieux2, Michael Crommie1 and Roman Fasel2; 1University of California, United States; 2Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; 3National Institute of Standards and Technology,
Recent advances in on-surface organic synthesis have led to the development of bottom-up graphene nanoribbon (GNR) growth with atomic precision. Bottom-up synthesized GNRs have promising electronic properties for high performance field effect transistors (FETs) and ultra-low power devices such as tunneling FETs. However, the short length, wide band gap, and random spatial orientation of GNRs have impeded the fabrication of devices with the expected performance and switching behavior. Here, recent progress in integrating bottom-up synthesized GNRs into devices will be presented. High on-current and high on-off ratio FETs with a nine-atom wide GNRs as the channel material were successfully fabricated. Strategies to further improve FET device yield and performance with the parallel arrays of GNRs transferred from single crystal Au (788) will be discussed. Finally, a new approach for the transfer-free fabrication of GNR devices has been developed.

References
simulations picture how electron correlations result in spin-polarized radical states with the experimentally observed spatial distributions. Extra hydrogen atoms bound to radical sites quench their magnetic moment and switch the spin of the nanostructure in half-integer amounts.

I will also review other methods for activating magnetic ground states in graphene. For example, spin states can be created on a ribbon simply by substitutional doping or by incorporating magnetic species into a ribbon using on-surface synthesis routes (see included image of a Fe porphyrin contacted to chiral nanoribbons). In this last case, we proved that the molecular spin survives in the ribbon by using spin-excitation inelastic spectroscopy [2]. By proper selecting the position of the halogen functionalization, we fabricated linear GNR-FeTPP-GNR structures and performed electronic transport measurements [3], detecting spin-excitation fingerprints in transport mode.

Bottom-Up Solution Synthesis of Structurally Well-Defined Graphene Nanoribbons—Modulation of the Width and Edge Functionalization Akimitsu Narita[2], 1Okinawa Institute of Science and Technology Graduate University, Japan; 2Max Planck Institute for Polymer Research, Germany

In contrast to zero-bandgap graphene, structurally confined graphene nanoribbons (GNRs) features open bandgaps due to the quantum confinement effect, which render them highly promising for nanoelectronic and optoelectronic applications.[1] The properties of the GNRs are determined by their chemical structures, in particular the width and the edge configuration, which makes their precise structural control essential. Whereas such precision cannot be achieved by “top-down” fabrication methods such as “cutting” of graphene, bottom-up chemical synthesis can afford atomically precise GNRs with various structures.[1,2] The synthesis is carried out through polymerization of a tailor-made monomer leading to a polymer precursor, which can be “planarized” and “graphitized” into GNRs by oxidative cyclodehydrogenation. While it is challenging to obtain very long GNRs through transition-metal-catalyzed or metal-surface-assisted polymerization, we have demonstrated solution synthesis of GNRs with average lengths larger than ~600 nm through AB-type Diels-Alder polymerization.[2,3] Solubilizing alkyl chains can be attached on the GNR edges through the solution synthesis, making them dispersible in organic solvents and thus allowing for the liquid-phase processing for the device integration.[1,4] By modifying the monomer structure, laterally extended GNRs with the width of up to ~2 nm could be obtained, revealing the lowering of the optical bandgap down to ~1.2 eV.[2,3] We have also achieved edge functionalization of the GNRs by introducing a bromo group on the monomer. For example, introduction of perylene monoimide units led modulation of the self-assembly behavior, providing intriguing “rectangular” networks of GNRs.[6] Moreover, introduction of spin-bearing organic radicals on the GNR edges allowed for spin injection to the aromatic core, inducing a delocalized magnetic state, which might have potential for application in the quantum computers.[7] These results form a fundamental basis for applications of such GNRs in the future nanotechnology.

Controlling Carbon Nanotubes by DNA—From Separation to Integration Ming Zheng; National Institute of Standards and Technology, United States

A unique feature of single-wall carbon nanotube (SWCNT) material is its structure diversity: within the same rolled-up graphene sheet structure framework one finds SWCNTs of different electronic bandgaps: metals with zero bandgap, quasi-metals with meV bandgap and semiconductors with ~ 1 eV bandgap. However, making use of SWCNT structure diversity requires a method to obtain SWCNTs of defined structures. In this contribution, we present our current state of DNA-based sorting of SWCNTs. In particular, we show our ability to put any DNA sequence on any SWCNT species, enabling DNA-based assembly of high-density SWCNT devices. In the end, we discuss the design of a device we call Photon Perceptron Array (PPA). PPA is an array of micron-sized spectrometer units that can measure the spectrum of incoming photon in the wavelength range of 200 nm to 2000 nm (and possibly going all the way to THz), with a spatial resolution comparable to the size of a single spectrometer unit. Each spectrometer unit is composed of a set of distinct photodetectors made of SWCNTs of defined atomic structures, placed in parallel with tube-to-tube separations controlled at nanometer precision by DNA origami technology. A high-density array of identical spectrometers can be constructed by placing DNA origami/carbon nanotube complexes in photolithographically-defined locations. PPA may be used in spectral imaging in many fields of science and technology.

Flexible, Wearable and High-Temperature Devices Based on Aligned Carbon Nanotubes Junichiro Kono; Rice University, United States

The remarkable flexibility, stable chemical structure, and extraordinary thermal, electrical, and optical properties of carbon nanotubes (CNTs) are promising for a variety of applications in flexible and/or high-temperature electronics, optoelectronics, and thermoelectrics, including wearables, refractory photonics, and waste heat harvesting. However, the long-standing problem in the preparation of CNT ensembles is to maintain the extraordinary properties of individual CNTs on a macroscopic scale; the polydispersity and randomness remain two main challenges. Here, we will discuss three ways of creating wafer-scale aligned CNTs: direct growth of aligned CNTs by chemical vapor deposition, production of ultrahigh-conductivity CNT fibers through solution spinning and coating, and spontaneous formation of wafer-scale aligned CNT films via controlled vacuum filtration. We will then describe flexible and high-temperature applications of these materials, such as flexible CNT broadband detectors, spectrally selective thermal emitters, and thermoelectric devices.

5:40 PM *S.NM05.02.02
Self-Assembly of Carbon Nanotubes into Tunable Hyperbolic Metamaterials Abram Falk; IBM T.J. Watson Research Center, United States

Plasmon resonance in carbon nanotubes is an exciting resource for confining light to the nanometer scale [1]. In this talk, I will discuss how dense films of carbon nanotubes have emergent optical properties related to these resonances. We assemble our films with a simple vacuum filtration technique and find that optimal assembly leads to the nanotubes crystallizing into monolithic, two-dimensionally ordered films. Using Mueller-matrix ellipsometry, we then characterize the films’ optical properties and find a broadband, electrostatically tunable hyperbolic region in the mid-infrared [2]. Another fascinating property of dense nanotube films is that excitons in the nanotubes can couple to the nanotubes’ own plasmon resonances – that is, cavity quantum electrodynamics (cQED) without an external cavity [3]. In fact, this coupling strength can reach the ultrastrong light-matter interaction regime. Technologically, crystallized nanotube films could provide a materials-driven pathway from fundamental concepts in cQED to advanced telecommunications hardware, including tunable thermal emitters,
super-resolution imaging systems, and active, nonlinear optical devices like modulators and nanolasers.

6:00 PM *S.NM05.07.02
Transforming Ideas to Reality—Emerging Nanotechnologies from the “Lab” to the “Fab” Max Shulaker and Christian Lau; Massachusetts Institute of Technology, United States

At this exact moment when future applications are demanding massive improvements in computing performance, conventional approaches to improving computing are becoming increasingly challenging. Nanosystems – leveraging unique properties of emerging nanotechnologies to realize new systems and architectures – promise to enable the next wave of computing gains for next-generation applications as well as provide the means for developing rich new functionalities that lie beyond the scope of traditional computing today. Yet despite this promise, imperfections and variations inherent in beyond-silicon emerging nanotechnologies have made realizing large-scale integrated systems infeasible. In this talk, I describe how by combining advances across the entire stack – from nanomaterial synthesis to new processing techniques, circuit design methodologies, and architectures – these challenges can be overcome to realize the first large-scale and complex electronic systems leveraging beyond-silicon emerging nanotechnologies. As a case-study, I will describe the journey of transforming carbon nanotubes from an interesting scientific nanomaterial into the foundation for realizing the first beyond-silicon microprocessor built entirely from carbon nanotube transistors – RV16X-NANO, a 16-bit microprocessor based on the RISC-V instruction set. I will conclude by describing how emerging nanotechnologies are beginning to be transferred from the “lab” to the “fab,” promising a new and exciting age for nanoelectronics and computing.

6:20 PM *S.NM05.07.01
Carbon Nanotube Based High Performance CMOS and Optoelectronic Devices Lian-mao Peng1,2 and Yang Liu2; 1Peking University, China; 2Columbia University, United States

Carbon nanotube (CNT)-based electronics has been considered one of the most promising candidates to extend Si complementary metal-oxide-semiconductor (CMOS) technology. In particular CNTs have been investigated for various electronic and optoelectronic device applications, such as sub-10nm CMOS devices which outperform that of state-of-the-art Si based CMOS devices in both speed and power consumption [1-5], as well as idea material for monolithic optoelectronic integration with complementary MOS-compatible signal processing circuit [6-8]. Prototype device studies on individual CNTs revealed that CNT based devices have the potential to outperform Si CMOS technology in both performance and power consumption. With a well-designed device structure and in combination with graphene, we showed that high-performance top-gated CNT FETs with a gate length of 5 nm can be fabricated. Significant progress has also been made in fabricating carbon nanotube low-power devices. An efficient way to reduce the power is to lower the supply voltage VDD, but this voltage is restricted by the 60 millivolts per decade thermi-onic limit of subthreshold swing (SS) in FETs. A Dirac source (DS) with a much narrower electron density distribution around the Fermi level than that of conventional FETs was recently proposed and demonstrated using CNT to reduce SS [2].

Nanomaterials for Printable Electronics Patrick R. Malenfant; National Research Council Canada, Canada

The National Research Council (NRC) is Canada’s premier organization for research and technology development. NRC’s Printable Electronics (PE) program develops materials and inks for additive manufacturing in order to enable a sustainable PE sector in Canada. Progress has been made over the last 15 years, yet many challenges remain at the materials, fabrication and integration level, limiting performance and commercialization. This presentation covers our progress in high purity semiconducting single-walled carbon nanotube (sc-SWCNT) enrichment and transistor fabrication via solution based processes as well as conductive molecular ink development [1-11]. I will highlight our recent progress in understanding sc-SWCNT enrichment using conjugated polymers, with special consideration given to the effects of solvent parameters and doping on the mechanism and yield/purity of the final product [2-4]. Removal of the wrapping polymer using a dry process on-wafer will also be described [5]. Developments in conductive molecular inks and progress towards the commercialization of new applications will be described such as in-mold electronics [6-8]. Challenges and advances associated with using polymer-based dielectrics and encapsulants will be discussed as well [9-10]. Such transistor packages have enabled the realization of fully inkjet-printed transistors as a result of the excellent electrical properties of sc-SWCNTs [2,11]. A demonstration of a fully additive process to make TFT backplanes via R2R printing will also be highlighted. The development of new functional nanomaterials and their successful integration into devices will enable additive manufacturing of TFT arrays and in-mold electronics.

considered to be the main reason for obtaining the excellent field emission performance.

Uniform Alignment of Carbon Nanotubes via Interfacial Assembly Katherine R. Jinkins, Vivek Saraswat, Robert M. Jacobberger, Padma Gopalan, Arganthaël Berson and Michael Arnold; University of Wisconsin-Madison, United States

In order to achieve a sufficiently high on-current, carbon nanotube based electronic devices must be comprised of highly aligned, densely packed arrays of nanotubes. One technique that has demonstrated immense promise for aligning nanotubes at optimal packing densities across technologically relevant substrates is floating evaporative self-assembly (FESA). The FESA process is a fluid-based method to align carbon nanotubes from solution post-synthesis and electronic sorting.1–3 FESA aligned carbon nanotube films exhibit exceptional local alignment and packing density, which has enabled the fabrication of field-effect transistors (FETs) with current densities exceeding that of GaAs and Si.4 However, globally, FESA carbon nanotube films are highly non-uniform, as the films are comprised of alternating stripes of aligned and unaligned nanotubes.
In the work presented here, we demonstrate a new technique in order to overcome the shortcomings of the FESA method and produce uniform films of aligned carbon nanotubes at desired packing densities, in a scalable technique.

In our technique, nanotubes are continuously deposited onto planar surfaces by sweeping a nanotube ink/water interface over a target substrate. The ink/water interface serves to collect and confine the carbon nanotubes, which aids in their alignment across the substrate during deposition. By translating the substrate vertically through the flowing nanotube ink/water interface, we fabricate uniform films of highly aligned (within ±5.7°) carbon nanotubes on the wafer-scale. Carbon nanotube ink concentration is varied from 0.1 to 100 µg mL⁻¹ to control the film packing density from 0.3 to 50 µm⁻¹, near those required for electronics. Using optimized conditions, we align carbon nanotubes 60 mm laterally across a 100 mm wide wafer, with no limit on the deposition in the vertical/lift direction. The high uniformity of nanotube alignment leads to excellent FET characteristics—high on-state current density averaging 520 µA µm⁻¹ at -0.6 V and FET to FET variation of only 19%. In contrast, FETs fabricated across FESA films demonstrate variation of 52%, due to the stripes of aligned and unaligned nanotubes.

5:40 AM S.NM05.02.04
**Aligned and Spatially Localized Semiconducting Single-Walled Carbon Nanotube Arrays**
Jonathan H. Dwyer, Zhizhang Shen, Katherine R. Jinkins, Michael Arnold, Reid Van Lehn and Padma Gopalan; University of Wisconsin–Madison, United States

Conjugated polymers have been extensively utilized to isolate semiconducting single-walled carbon nanotubes (s-CNTs) to greater than 99.9% purity in organic solvents creating a high-purity s-CNT “ink”. Solution deposition of s-CNTs from these inks onto target substrates has been widely studied in the literature for fabricating field-effect transistors (FETs). However, s-CNT-based FETs have so far underperformed compared to conventional silicon- and gallium arsenide-based FETs. One limiting factor is the difficulty in fabricating ideal s-CNT arrays using scalable methods. The ideal morphology of s-CNTs in array FET consists of perfectly aligned s-CNTs (i.e. 0° orientation difference between all s-CNTs in the array) with a pitch of 5-10 nm between nanotubes. Even with the plethora of alignment and spatially localized s-CNT deposition methods designed to control s-CNT deposition, fundamental understanding of the driving forces for s-CNT deposition is still lacking. The individual roles of the polymer wrapper, solvent, target substrate composition, and the s-CNT itself are not completely understood because it is difficult to decouple the deposition parameters.

In order to understand and control s-CNT deposition onto substrates, we present our studies to understand the multitude of factors driving polymer wrapped s-CNT deposition onto substrates. Chemical modification of the substrate with self-assembled monolayers (SAMs) presents an ideal platform to explore these parameters. We use poly[(9,9-dioctylfluorenyl-2,7-diyl)-alt-co-(6,6’-{2,2’-bipyridine})] (PFO-BPy) wrapped s-CNTs and study their interactions with chemically modified substrates. Experimentally, we characterize number density of s-CNT deposition on different chemically modified surfaces from toluene and chloroform. To gain a molecular level understanding we use atomistic molecular dynamics simulations to examine the driving forces for s-CNT adsorption. Multiple parameters are considered including substrate surface energy, substrate chemistry, solvent type, and the interactions that arise from the polymer wrapper PFO-BPy. We find that the global free-energy minimum associated with favorable s-CNT adsorption occurs for a configuration in which the minimum of the solvent density around the s-CNT coincides with the minimum of the solvent density above a SAM-grafted surface. This configuration indicates that solvent structure near a SAM-grafted surface determines the adsorption free-energy landscape driving s-CNT deposition.

Knowledge gained from these simulations and experiments guides substrate surface pattern designs for spatially localized s-CNT deposition. We use scalable s-CNT alignment techniques in combination with surface patterned substrates to fabricate aligned and spatially localized s-CNT arrays for integrated device structures. These s-CNTs arrays are characterized by s-CNT alignment degree for use in s-CNT-based FETs.
Controlled Surface Grafting of 3D Carbon Nanotube Structure—Nanomanipulation for Hydrophobic to Hydrophilic Tunability

Mostakima M. Lubna, Jakub Sciora and Philip Bradford; North Carolina State University, United States

Three-dimensional (3D) assemblies of super porous carbon nanotube (CNT) structure is the recent focus of nano-carbon research for the unique properties offered by the interconnected conductive network in multifunctional applications like flexible sensors, energy storage, ultra-low-density electromagnetic interference (EMI) shielding, and selective organic compound absorption. In a 3D macroscopic assembly not only the purity, size and diameter of the CNTs are major variables also the orientation, alignment, and stability of the CNT-CNT junctions play a crucial role in the final structural performance. We developed a 3D free-standing CNT sponge from high purity, similar-sized (length 1mm, diameter ~ 23 ±4 nm) spinnable CNTs with complete control over the CNT network alignment technique. And the CNT-CNT junctions within the 3D sponge were secured by conformal coating with atomic layer by layer infiltration of amorphous pyrolytic carbon (PyC) inside the CVD furnace at 800 °C. The density (as low as 6 mg cm⁻³) and porosity (as high as 99.8 %) of the CNT/PyC sponge can be tuned by varying the PyC coating time and regulated consolidation of aligned CNTs. The CNT sponges are super compressible with quick recovery of the structure even after as high as 80 % compressive strain and showed negative poison ratio auxetic compression behavior. Further, nanomanipulation of the superhydrophobic surface of the CNT sponge is done by controlled pulse corona treatment, which allows initiating certain hydrophilic polymer grafting on the surface. The surface modification changes the water contact angle from 153 ° to 0° and enables us to directly incorporate different polymers (polyvinyl chloride, polycarbonate, polydimethylsiloxane) into CNT sponge to fabricate CNT/PyC-polymer sponges without interrupting the stable alignment of the CNTs. The conformal polymer wrapping around the CNT/PyC can be easily controlled from a very few nanometres to hundreds of nanometres. All the CNT/PyC and CNT/PyC-polymer sponges were fully characterized using SEM, TEM, FTIR, Raman, and TGA. The polymer coating on the CNT/PyC sponges not only help to prevent the nano-release into the environment during dynamic use also showed very promising sensing and EMI shielding capabilities. This tunable nanomanipulation of the CNT/PyC sponge surface chemistry open-up a platform for easier multi-material hybrid structure construction in bulk without disrupting the pre-formed super aligned nano conductive network.

Controlling Carbon Nanotubes by DNA—From Separation to Integration

Ming Zheng; National Institute of Standards and Technology, United States

A unique feature of single-wall carbon nanotube (SWCNT) material is its structure diversity: within the same rolled-up graphene sheet structure framework one finds SWCNTs of different electronic bandgaps: metals with zero bandgap, quasi-metals with meV bandgap and semiconductors with ~ 1 eV bandgap. However, making use of SWCNT structure diversity requires a method to obtain SWCNTs of defined structures. In this contribution, we present our current state of DNA-based sorting of SWCNTs. In particular, we show our ability to put any DNA sequence on any SWCNT species, enabling DNA-based assembly of high-density SWCNT devices. In the end, we discuss the design of a device we call Photon Perceptron Array (PPA). PPA is an array of micron-sized spectrometer units that can measure the spectrum of incoming photon in the wavelength range of 200 nm to 2000 nm (and possibly going all the way to THz), with a spatial resolution comparable to the size of a single spectrometer unit. Each spectrometer unit is composed of a set of distinct photodetectors made of SWCNTs of defined atomic structures, placed in parallel with tube-to-tube separations controlled at nanometer precision by DNA origami technology. A high-density array of identical spectrometers can be constructed by placing DNA origami/carbon nanotube complexes in photolithographically-defined locations. PPA may be used in spectral imaging in many fields of science and technology.

Engineering Supramolecular Polymer Conformation for Efficient Carbon Nanotube Sorting

Theodore Gao¹, Zehao Sun², Xuzhou Yan¹, Hung-Chin Wu¹, Hongping Yan¹ and Zhenan Bao¹; ¹Stanford University, United States; ²Peking University, China
Supramolecular polymer sorting is a promising approach to separating single-walled carbon nanotubes (CNTs) by electronic type. Unlike conjugated polymers, they can be easily removed from the CNTs after sorting by breaking the supramolecular bonds, allowing for isolation of electronically pristine CNTs as well as facile recycling of the sorting polymer. However, little is understood about how supramolecular polymer properties affect CNT sorting. Herein we use chain stoppers to engineer the conformation of a supramolecular sorting polymer. Through NMR and UV-vis spectroscopy, SAXS, and thermodynamic modeling, we show that this supramolecular polymer exhibits ring-chain equilibrium, and that this equilibrium can be skewed towards chains by the addition of chain stoppers. We also demonstrate that by controlling the stopper-monomer ratio, we can double the sorting yield without compromising the purity or properties of sorted CNTs.

Temperature Dependent Thermoelectric Transport in Polymer-Sorted Semiconducting Carbon Nanotube Networks with Different Diameter Distributions Martin Statz¹, Severin Schneider¹, Felix Berger², Lianglun Lai¹, William A. Wood¹, Jana Zaumseil² and Henning Sirringhaus¹; ¹University of Cambridge, United Kingdom; ²Heidelberg University, Germany

In the past decade tuning the chirality distribution of single-walled carbon nanotube (SWCNT) networks has led to rapid advances of their optoelectronic, electronic and thermoelectric applications. Nevertheless, the full potential of this design freedom in those networks is yet to be explored, both in terms of the processes governing charge transport as well as their performance in applications. Here we report on charge carrier density and temperature dependent field-effect mobility and on-chip Seebeck coefficient measurements of polymer-sorted small diameter (6,5) SWCNT (0.76 nm) networks, 1,2,4,5-tetrakis(tetramethylguanidino)benzene (ttmgb) treated (6,5) networks as well as large diameter plasma torch SWCNT (1.17-1.55 nm) networks with different network densities to provide insights into their charge transport mechanisms and potential for thermoelectric applications. The Seebeck coefficient offers insights into transport energetics, potential contributions from electron-electron and electron-phonon interactions and the relative contributions of inter- versus intra-CNT transport. Contrary to previous studies we conclude that a pure percolation theory and variable-range hopping description of transport is insufficient to explain the charge density and temperature dependence of both transport coefficients. Instead intrananotube transport that depends on the chirality of the CNTs composing the network needs to be considered as well. All untreated networks show remarkable ambipolar behaviour in both the mobility and the Seebeck coefficient, emphasizing the purity of our samples suitable to study their intrinsic transport mechanisms. Interestingly, in the high network density regime, the network density influences neither electric nor thermoelectric transport strongly, indicating both are dominated by the tubes rather than the tube-tube junctions. Furthermore, we emphasize the importance of density of states (DoS) engineering via chirality selection for thermoelectric generators. Despite their generally lower mobilities (6,5) SWCNTs show comparable power factors to large diameter, small bandgap networks with a broad chirality distribution. These findings provide design guidelines towards narrow DoS distribution, large diameter SWCNT networks for both electronic and thermoelectric applications.²

SESSION S.NM05.04: Carbon Nanotube Flexible Electronics

Flexible Sensor Sheets Using Carbon Nanotube-Based Composite Materials Kuni Takei¹,²; ¹Osaka Prefecture University, Japan; ²JST PRESTO, Japan

Flexible and stretchable electronics are now widely studied for a next class of electric devices replaced from the silicon-based conventional inflexible devices. In particular, multi-functional sensor sheets can contribute to a variety of applications for Internet of Things (IoT) including wearable healthcare. For this flexible device concepts, one of the potential materials is nanocarbons including carbon nanotube and graphene due to their unique electrical and mechanical properties. Furthermore, material handling to pattern these on a macroscale flexible film is readily conducted which is an important factor for practical flexible electronics. By utilizing the advantages of nanocarbon, in this study, macroscale, multi-functional flexible sensor sheets fabricated by mainly printing methods of nanocarbon composite materials are introduced for healthcare and IoT
applications. Firstly, fundamental characteristics of strain, tactile pressure, temperature, and humidity sensors are discussed, followed by the device demonstrations. Healthcare, wind flow mapping, and soft-robotic applications are mainly discussed in this talk. Finally, to move forward to building the platform of flexible electronics, stability and reliability of sensors in terms of sensitivity and long-time measurements will be briefly introduced.

Although a lot of researches and developments are still required for practical application, these studies may help to open a door for the next step of flexible electronics.

Energy Harvesting Technologies Based on Low-Dimensional Materials for Self-Powered Sensing Devices Yutaka Ohno; Nagoya University, Japan

There is a movement to realize a more efficient and energy-saving society by utilizing a vast amount of data obtained by a huge number of sensors installed in various places of our society. In order to construct such a sensor network, it is essential to realize self-powered sensor devices that do not require wirings. Energy harvesting technology is expected as one of the power sources. The energy harvesting technology gains a power source for driving sensors from small energy existing in the environment. Recently, researches to realize energy harvesters using graphene and carbon nanotubes has extensively being conducted. The nanocarbon materials is a highly conductive film with excellent flexibility and transparency so as to have installation flexibility. In this presentation, we introduce our research on flexible energy harvesting technologies and ultra-low power sensing circuit technologies.

5:30 AM S.NM05.04.03
Ultra-Thin Flexible Tactile Pressure Sensor Network by Integrating Large-Area Carbon Nanotube Active Matrix with Highly Sensitive Piezoresistive Thin Film Zhenxuan Zhao¹, Jianshi Tang¹,², Jian Yuan¹, Xiao Li³, Ning Suo³, Huaping Liu³, Yuan Dai², Yijun Li¹, Bin Gao¹,², He Qian¹,² and Huaqiang Wu¹,²; ¹Tsinghua University, China; ²Beijing National Research Center for Information Science and Technology (BNRist), Tsinghua University, China; ³Institute of Physics, Chinese Academy of Sciences, China; ⁴Robotics X lab, Tencent, China

The rapid development in smart robotics and prosthetic solutions calls for large-area and low-cost tactile sensor networks with high performance in both electrical and mechanical properties. Tremendous progress has been made recently on the research of flexible pressure sensors using various nanomaterials including organic and oxide semiconductors, carbon nanotube (CNT), semiconductor nanowire, etc. However, several key challenges remain, such as the fabrication of high-performance flexible transistor arrays with high density as well as the synthesis of ultra-thin piezoresistive film with high sensitivity. In this work, we report the integration of large-area CNT active matrix and highly sensitive piezoresistive thin film into a functional flexible tactile pressure sensor network. The 16×16 CNT active matrix was fabricated using highly purified (99.9%) semiconducting single-walled CNT solution, achieving a high density of 7 pixels per inch (ppi) over 4-inch area. A novel piezoresistive thin film was made with low-temperature processed multi-walled CNT composite, showing excellent pressure sensitivity with tunable thickness and flat surface. The highly integrated flexible tactile pressure sensor network was built on ultra-smooth polyimide with a surface roughness less than 1 nm, and it can be easily delaminated from the silicon substrate while maintaining the integrity and performance of the integrated system fabricated on top. The thickness of the entire flexible tactile sensor system can be controlled around 50 μm, leading to excellent flexibility. The demonstration in this work paves the road to build large-area electronic skins with high integration density and superior performance for future applications in smart robotics.

Synthetic Electronics Chagaan Baatar; Office of Naval Research, United States

Building electronic circuitry with atomic precision is beyond the capability of current, and in the foreseeable future, top-down lithographic techniques. In recent years, the US Office of Naval Research (ONR) has championed several research initiatives that sought to address this key challenge. One of the most exciting development and initial success that resulted
from these initiatives is a bottom-up chemical synthesis technique that has proven highly effective at assembling two-dimensional (2D) graphene nanostructures with spatial precision control down to single atom and single bond level. In this presentation, I will briefly review the current status of this exciting new research field, and also the challenges that still remain. I will share some personal perspectives and speculate on possible future directions. The motivation behind the discussion is to socialize the basic ideas and capabilities with, and get feedback from, the relevant research communities, in order to further refine and improve future research agenda.

5:15 AM *S.NM05.05.02
Engineering Electronic Properties in Graphene Nanoribbons Pascal Ruffieux; Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

On-surfaces synthesis has become a versatile tool for the fabrication of atomically precise graphene nanostructures. Recent studies have successfully focused on the controlled synthesis of graphene nanoribbons (GNRs) (1), which offer a wide range of physical properties depending on edge structure and width. For instance, width-control in armchair GNRs gives access to band gap tuning in a wide range and allows, owing to the deterministic selection of a single width, for the preparation of an electronically homogenous material. For the case of nine atom wide armchair GNRs, the band gap is of 1.4 eV and allows, together with the development of suitable GNR transfer procedures, for the realization of field effect transistors with high on-currents (~1 µA) and high on/off current ratios (10^6) (2).

Some particularly appealing properties of graphene nanostructures are achieved when the sublattice symmetry is broken. For zigzag GNRs this gives rise to spin-polarized edge states and opens new opportunities for spintronic applications. For the case of six atom wide zigzag GNRs (6-ZGNRs), we have recently identified suitable molecular building blocks and have confirmed the existence of edge-localized states for electronically decoupled 6-ZGNRs (3).

Such localized states also emerge from short zigzag segments embedded in armchair GNRs. By periodically positioning these zigzag segments along the GNR axis, this can be used to design one-dimensional lattices of coupled states yielding electronic bands in the band gap of the hosting armchair GNR (4). These bands are fully described by the Su-Schrieffer-Heeger (SSH) model, from which all relevant electronic properties can be derived by considering two coupling constants. Depending on the relative strength of these coupling constants, topologically trivial and non-trivial electronic quantum phases can be realized and give rise to characteristic topological boundary states in heterostructures consisting of topologically trivial and non-trivial segments. Tuning of the coupling constants of the SSH model also allows for the design of low-bandgap GNRs. In this limit, charge carrier properties can be approximated by the dispersion of massive Dirac fermions. The experimental realization of such a system together with its electronic characterization will be presented.

Finally, recent achievements in the on-surface synthesis of magnetic nanographenes will be discussed. Using inelastic scanning tunneling spectroscopy, the unambiguous identification of robust antiferromagnetic order in specific nanographenes is achieved and opens new opportunities for carbon-based magnetism.

5:30 AM S.NM05.05.03
Bottom-Up Synthesis of Edge-Functionalized Graphene Nanoribbons Manabu Ohtomo1, Hironobu Hayashi2, Hideyuki Jippo1, Junichi Yamaguchi1, Kenjirou Hayashi1, Juanjuan Zhu2, Ryunosuke Hayashi2, Xiaoxi Pang1, Tong Wang1, Mari Ohfuji1, Richiro Saito1, Hiroko Yamada2 and Shintaro Sato1; 1Fujitsu Labs Ltd. and Fujitsu Ltd., Japan; 2Nara Institute of Science and Technology, Japan; 3Tohoku University, Japan

Bottom-up synthesis of graphene nanoribbons (GNR) enables us to obtain atomically-precise GNRs with well-defined edges [1]. The GNR heterojunction is one of the key elements required for realizing promising electronic devices, such as tunneling field-effect transistors and backward diodes. One of the promising applications of extremely narrow GNRs is a detector diode, which rectifies THz-waves into a direct-current (DC) output voltage [2]. Due to its small junction capacitance of sub-nm wide GNR p-n junction, it was predicted that the backward diode with GNR heterojunction can outperform the state-of-the-art diodes made from III-V compound semiconductors [2]. Among various techniques of manipulating electronic states of GNRs, we focus on the edge-functionalization of GNRs in this study. While a couple of edge-functionalized GNRs have been reported to date [3, 4], the edge-functionalization is still challenging mainly due to protonation of edges during cyclo-dehydrogenation [5, 6]. In this research, we report on some of our recent attempts for realizing edge-functionalized GNRs.
from molecular precursors.
First, we refer to the effect of edge-functionalization on the on-surface polymerization. It was found that the on-surface reaction of newly-developed precursor named 5-bromo-11(10-bromoanthracene-9-yI)anthra[2,3-b:7,6-b']dithiophene (BABAT) with isomers, which has a similar structure as 10,10'-Dibromo-9,9'-bianthryl (DBBA) with one anthracene substituted with anthradithiophene, ends in intramolecular cyclodehydrogenation [7]. Unlike DBBA, which is widely known to form anthracene polymers and armchair-edge graphene nanoribbons on Au(111), BABAT was found to make planar nanographene with intramolecular C-C bonding after annealing at 200°C on Au(111). The mechanism was investigated using first-principle density functional theory, which revealed that on-surface polymerization is not kinetically preferred in the case of BABAT. The intramolecular C-C bonding in DBBA biradicals, on the other hand, does not take place because of a faster reverse reaction. By referring to the electron density of BABAT biradicals, it was concluded that thiophene functionalization modifies the distribution of electron density in BABAT biradicals and facilitates electrophilic addition, leading to intramolecular C-C bonding after 200°C annealing. These results indicate that the design of radical moiety is particularly important in the on-surface Ullmann-type coupling.

The second part of our presentation is dedicated to the bottom-up synthesis of GNRs with edges functionalized by methylenedioxy functional groups. Unlike BABAT, it was confirmed by STM measurement that GNRs functionalized by methylenedioxy were obtained from anthracene trimer precursor functionalized by methylenedioxy. Unlike fluoride, which was detached during cyclodehydrogenation [5], methylenedioxy groups seem to be robust and survive cyclodehydrogenation process, while co-existence of hydroxyl groups was also confirmed by XPS. The GNR formation process was studied using the nudged elastic band (NEB) method within the density functional theory (DFT). One of the important findings is that methylenedioxy substitution opens an alternative path for dehydrogenation, which protects methylenedioxy groups from protonation. Due to electron-donating nature of methylenedioxy groups, it was also confirmed, by first-principles simulations, that the ionization potential and electron affinity of Medioxy-7AGNR differ from those of pristine 7AGNR, which may lead to the formation of a Type II heterojunction of GNRs.

This work was supported by CREST JST (no. JPMJCR15F1) and MEXT/JSPS KAKENHI grant nos. 26105004, 16H02286.

5:40 AM *S.NM05.05.04
Bottom-Up Solution Synthesis of Structurally Well-Defined Graphene Nanoribbons—Modulation of the Width and Edge Functionalization Akimisu Narita[2]; 1Okinawa Institute of Science and Technology Graduate University, Japan; 2Max Planck Institute for Polymer Research, Germany

In contrast to zero-bandgap graphene, structurally confined graphene nanoribbons (GNRs) features open bandgaps due to the quantum confinement effect, which render them highly promising for nanoelectronic and optoelectronic applications.[1] The properties of the GNRs are determined by their chemical structures, in particular the width and the edge configuration, which makes their precise structural control essential. Whereas such precision cannot be achieved by “top-down” fabrication methods such as “cutting” of graphene, bottom-up chemical synthesis can afford atomically precise GNRs with various structures.[1,2] The synthesis is carried out through polymerization of a tailor-made monomer leading to a polymer precursor, which can be “planarized” and “graphitized” into GNRs by oxidative cyclodehydrogenation. While it is challenging to obtain very long GNRs through transition-metal-catalyzed or metal-surface-assisted polymerization, we have demonstrated solution synthesis of GNRs with average lengths larger than ~600 nm through AB-type Diels-Alder polymerization.[2,3] Solubilizing alkyl chains can be attached on the GNR edges through the solution synthesis, making them dispersible in organic solvents and thus allowing for the liquid-phase processing for the device integration.[3,4] By modifying the monomer structure, laterally extended GNRs with the width of up to ~2 nm could be obtained, revealing the lowering of the optical bandgap down to ~1.2 eV.[2,3] We have also achieved edge functionalization of the GNRs by introducing a bromo group on the monomer. For example, introduction of perylene monoimide units led modulation of the self-assembly behavior, providing intriguing “rectangular” networks of GNRs.[6] Moreover, introduction of spin-bearing organic radicals on the GNR edges allowed for spin injection to the aromatic core, inducing a delocalized magnetic state, which might have potential for application in the quantum computers.[7] These results form a fundamental basis for applications of such GNRs in the future nanotechnology.

Hierarchical Graphene Nanoarchitechtionics

Aran Garcia-Lekue1,2 and Aitor Mugarza1,3; 1Catalan Institute of Nanoscience and Nanotechnology (ICN2), CSIC and BIST, Spain; 2Ikerbasque, Basque Foundation for Science, Spain; 3Institució Catalana de Recerca i Estudis Avançats (ICREA), Spain

On-surface synthesis has emerged as an efficient strategy for the synthesis of 1D and 2D covalent nanostructures (1). The vast variety of graphene nanoribbons (GNR) that have been synthesized during the last decade represent the most successful case of this bottom-up approach. GNRs have indeed been synthesized with atomic scale control over the edge structure, width, or chemical composition (3). However, extending dimensionality to 2D nanostructures has revealed itself as a paramount challenge for on-surface chemistry. In this talk, I will report on some novel 2D graphene nanostructures obtained by a hierarchical onsurface method. The method relies on the stepwise synthesis of polymeric chains that turn into arrays of aligned graphene nanoribbons that then couple into nanoporous graphene (NPG), which combines 1nm size ribbons and pores (4). As demonstrated by combining scanning tunneling (STM) and density functional theory (DFT), the peculiar topology of the NPG imprints a band-gap, novel electronic pore states and high electronic in-plane anisotropy. Our calculations have also predicted that the anisotropic electron propagation within the mesh gives rise to Talbot interference effects (5), analogous to photons in coupled waveguides. Moreover, as I will show with particular examples, all these unique properties of NPG can be tuned by controlling the geometry and/or composition of the pores.

Longitudinal Vibrational Modes in Atomically Precise Graphene Nanoribbons

Jan Overbeck1, Gabriela Borin Barin1, Colin Daniels2, Perrin L. Mickael1, Oliver Braun1, Pascal Ruffieux1, Vincent Meunier2, Roman Fasel1 and Michel Calame1; 1Empa, Switzerland; 2Rensselaer Polytechnic Institute, United States

Graphene nanoribbons (GNRs) exhibit an electronic bandgap due to the lateral confinement of charge carriers and edge effects. They can be fabricated by bottom-up on-surface synthesis from molecular precursors resulting in atomically precise structures [1]. This approach promises tunable optical and electronic properties [2]. Their integration into functional devices will require an in-depth understanding of their structural properties, in particular after transfer from their metallic growth substrates to the target device substrate. We use Raman spectroscopy to characterize GNRs with a large area Raman mapping approach on optimized substrates exhibiting interference enhancement [3]. This allows the investigation of low-intensity geometry dependent Raman modes. We show that a longitudinal compressive mode (LCM) is particularly suited to investigate the length of bottom-up synthesized GNR, probe the effects of device processing as well as their interaction with different types of substrates [4].

Graphene nanoribbons (GNRs) are narrow strips of graphene, with exciting properties deriving from electron confinement and related band gap tunability[1]. The ability to tune GNRs’ electronic and magnetic properties by structural design at the single atom level makes them an ideal platform for a wide range of device applications, from classical transistors to spintronics. Despite their exceptional properties, significant challenges remain for GNR fabrication, processing and characterization. This contribution addresses some of the critical challenges in the further development of GNR technologies in particular on GNR fabrication, transfer, and characterization.

Bottom-up synthesis of graphene nanoribbons is most commonly performed under ultra-high vacuum conditions, which is one of the bottlenecks in the further technological advancement of this material. Additionally, little is known about the stability of ultra-narrow GNRs under ambient conditions or during device processing. In this work we focused on 9- and 5-atom wide armchair GNRs (9-AGNR and 5-AGNR, respectively) grown under ultra-high vacuum conditions on Au(111) and on vicinal gold surfaces Au(788), which promotes GNR's unidirectional growth on the narrow (111) terraces along the step edges. We first investigate the role of halogen functionalization of the precursor monomer in the final GNR length. Using different precursor monomers and synthesis protocols we show an increase in the average length for the 9-AGNR from 15 nm to 45 nm[2] and for the 5-AGNRs from 8 nm to 20 nm. GNRs grown on Au(111) substrates are transferred using a polymer-free method[3]. Raman spectra indicate no significant degradation of GNRs' quality, reveal their homogeneous distribution on the target surface and also show that GNRs have remarkably stability under ambient conditions tracked over a 2-year period[3]. GNRs grown on Au(788) are transferred via electrochemical delamination method[4], and Polarized Raman of the G mode show that GNRs retain their orientation after transfer with maximum Raman intensity along the ribbon axis and minimum intensity perpendicular to it.

These process steps allowed us to integrate both 9- and 5-AGNR into short channel field-effect transistors (FETs). Using the 9-AGNRs as channel material we demonstrate FETs with high on-current $I_{on}>1\mu A$ at $V_d=-1\ V$, high $I_{on}/I_{off}$ ratios of ~$10^3$ and 10% device yield[5]. In a next step, aligned 9-AGNR-FET devices are produced using graphene electrodes, and a performance of $I_{on}>6\mu A$ at $V_d=0.1\ V$ and high $I_{on}/I_{off}$ ratios of ~$10^3$ is observed along with an increase of device yield to 80-100%, due to the GNRs' orientation along the source-drain axis of the devices. GNR-FET devices using short 5-AGNRs (2-10 nm) as channel material and graphene as electrodes show linear I-V curves (metal-like behavior) at room temperature, while long 5-AGNRs (>20 nm) integrated into FETs with Pd as contacts behave as a semiconductor. The role of GNRs' surface coverage and length on the transfer efficiency and electronic/transport properties will be discussed.

**Atomically Precise Graphene Nanoribbons—from Synthesis to Electronic Applications**

Alexander Sinitskii; University of Nebraska - Lincoln, United States

Atomically precise graphene nanoribbons (GNRs) are at the forefront of nanocarbon research and hold great promise for electronic and optoelectronic applications. Theoretical studies have shown that narrow GNRs possess interesting electronic and magnetic properties that strongly depend on the nanoribbon’s width and edge structure. GNRs with different structures can be synthesized with atomic precision and fine-tuned properties by coupling properly designed molecular precursors and planarization of the resulting polymers.

In this talk, I will discuss our recent results on solution and on-surface synthesis and characterization of atomically precise GNRs. The solution approach is based on Yamamoto coupling of pre-synthesized molecular precursors followed by cyclodehydrogenation using Scholl reaction. This approach can be applied to the synthesis of a variety of GNRs, including pristine and nitrogen-doped GNRs with the chevron structure. The on-surface approach is based on the coupling of halogenated molecular precursors on metal substrates and subsequent cyclodehydrogenation of the resulting polymers at...
Both solution and on-surface approaches were used to synthesize laterally extended chevron GNRs (eGNRs). The ribbons grown on Au(111) were used for extensive scanning tunneling microscopy (STM), noncontact atomic force microscopy (nc-AFM) and scanning tunneling spectroscopy (STS) characterization. They were found to exhibit a bandgap of about 2.2 eV, which is considerably smaller than the values reported for chevron GNRs in similar studies. The solution-synthesized eGNRs were processed into uniform thin films that exhibited improved electrical conductivity compared to similar films of regular chevron GNRs. The eGNR films were employed in gas sensors that showed very high responsivity to low molecular weight alcohols compared to similar sensors based on benchmark graphitic materials, such as graphene and graphene oxide. Finally, we demonstrated the first electronic nose system based on atomically precise GNRs that could reliably recognize analytes of nearly the same chemical nature, such as methanol and ethanol. Overall, this work demonstrates the entire path from designing new atomically precise GNRs with improved properties to their bottom-up synthesis, characterization, processing and implementation in electronic devices.

6:45 AM S.NM05.05.09
Chemical Vapor Deposition of Semiconducting Armchair Graphene Nanoribbons Robert M. Jacobberger, Austin J. Way, Vivek Saraswat and Michael Arnold; Univ of Wisconsin-Madison, United States

Graphene nanoribbons with sub-10 nm widths and ultra-smooth armchair edges are exciting candidates for next-generation semiconductor electronics because of their potential to exhibit exceptional charge and thermal transport properties. However, widespread integration of nanoribbons into commercial applications has been limited by challenges in producing nanoribbons with a high degree of structural precision and assembling the nanoribbons into large-area arrays on technologically-relevant substrates.

Here, we present a promising scalable approach for producing nanoribbons with sub-10 nm widths, smooth armchair edges, and excellent charge transport properties directly on conventional semiconductor wafer platforms via chemical vapor deposition (CVD). We have discovered that by exploiting highly anisotropic crystal growth of graphene from hydrocarbon precursors on Ge(001), narrow nanoribbons with high-aspect ratios can be synthesized. Due to the bottom-up, self-defining nature of growth, the nanoribbons have nearly atomically smooth armchair edges. The nanoribbon width can be continuously tuned to virtually zero by controlling the growth time and growth rate, which depends on the precursor flux and substrate temperature, and nanoribbons with sub-10 nm widths can be hundreds of nanometers in length. Breaking the symmetry of the Ge(001) surface by introducing a miscut results in wafer-scale unidirectional nanoribbon alignment. Control over both the alignment as well as the placement of individual nanoribbons is realized by initiating growth from lithographically-defined nanoscale seeds, enabling large-area hierarchical nanoribbon arrays. This nanoribbon synthesis is also adapted onto Si(001) wafers by utilizing epitaxial Ge interlayers.

Nanoribbons grown on Ge(001) via CVD have sizeable bandgaps and display high-performance charge transport properties at room temperature. For example, field-effect transistors with nanoribbon channels can simultaneously exhibit on/off conductance ratio of $2 \times 10^4$ and on-state conductance of 5 µS. Therefore, this bottom-up nanoribbon synthesis may provide a high-throughput route for realizing future state-of-the-art technologies based on semiconducting graphene.

Towards Chirality Control of Graphene Nanoribbons Embedded in Hexagonal Boron Nitride Haomin Wang, Lingxiu Chen, Huishan Wang, chen chen and Chengxin Jiang; Shanghai Institute of Microsystem and Information Technology Chinese Academy of Sciences, China

Ideal graphene nanoribbons (GNRs) have been shown to exhibit extreme chirality dependence as metals or semiconductors.
Therefore, the capability to precisely produce GNRs with defined chirality at the atomic level is required in order to engineer their band gap and electrical properties. It is obvious that earlier approaches have fundamental limitations for further electronic investigation. Electronics always require scalable transfer-free approaches for growing GNRs and conducting band gap engineering. Controlled fabrication of oriented GNRs embedded on hexagonal boron nitride (h-BN) has the capability to overcome the above difficulties. With proper control, the band gap and magnetic properties can be precisely engineered. Most desired features for GNRs can be automatically attained using this approach.

Here we developed a two-step growth method and successfully achieved sub-5 nm zigzag and armchair GNRs embedded in h-BN, respectively. Further transport measurements reveal that the sub-7 nm zigzag GNRs exhibit openings of the bandgap inversely proportional to their width, while narrow armchair GNRs exhibit some fluctuation in the bandgap-width relationship. Transistors made of these GNRs with large bandgaps (>0.4 eV) exhibit excellent electronic performance even at room temperature (e.g. conductance on-off ratio more than 10E5 and carrier mobility more than 0.15m2 per volt per second ). An obvious conductance peak is observed in the transfer curve of 8-10 nm-wide zigzag GNRs while it is absent in most of armchair GNRs of similar width. Magneto-transport experiments show that zigzag GNRs exhibit relatively small magneto-conductance (MC) while armchair GNRs have much higher MC than zigzag GNRs. This integrated lateral growth of edge-specific GNRs in h-BN brings more robust and orientation-controlled edges than previously demonstrated, and will enable exciting future investigations into the physics and applications of edge-specific GNRs.

Electronic and Vibrational Properties of 1D Carbon Nanostructures from First-Principles Vincent Meunier1, Colin Daniels1 and Liangbo Liang2; 1Rensselaer Polytechnic Institute, United States; 2Oak Ridge National Laboratory, United States

I will provide an overview of the recent progress made in my group on the understanding of the electronic and vibrational properties of 1D carbon nanostructures based on a combination of theoretical and computational methods. In the first part of the presentation, I will first focus on providing a model to account for the significant screening caused by the presence of a substrate on the electronic properties of graphene nanoribbons. In the second part of the talk, I will present a broad and detailed overview of the intrinsic vibrational properties of 1D carbon nanostructures with a variety of edge configurations, sizes, and shapes. These results will be systematically compared to experiment (notably, Scanning Tunneling Spectroscopy and Raman Spectroscopy). While theory and experiment are found to usually be in excellent agreement, I will also discuss a number of unresolved issues and will suggest a roadmap to tackle them.

5:25 AM S.NM05.06.05
Progress in Extending the Pseudocarbyne Library Hyunsub Kim, Pilarisetty Tarakeshwar, Peter Buseck and Scott G. Sayres; Arizona State University, United States

Using the high energy environment of laser ablation, we have synthesized several new materials composed of 1D carbon chains stabilized through interaction with small metal clusters, that we have named “Pseudocarbynes”. These new materials are expected to approach the unprecedented strength, elastic modulus, and stiffness of carbyne, which has defied isolation and characterization for over a century. Our spectroscopic characterization suggests that pseudocarbynes self-assemble from colloidal solutions into new mesomaterials that bridge the molecular and materials realms. These measurements are supported by density functional theory (DFT) calculations that highlight a strong tendency of small metal clusters to interact with the sides of the -C≡C- chains. X-ray powder diffraction and high-resolution electron microscopy demonstrate the long-range material crystallinity. I will discuss our recent experimental results aimed at extending the pseudocarbyne library to include a variety of transition metals, cluster sizes, and lengths of carbon chain. Our results suggest that pseudocarbynes have potential to become a platform for developing an array of materials with tunable electronic properties.

5:35 AM S.NM05.06.06
Tunable, Bottom-up Synthesis of Semiconducting Graphene Nanoribbons on Germanium Virtual Substrates Vivek Saraswat1, Nathan Guisinger2, Yuji Yamamoto1, Robert M. Jacobberger1, Austin J. Way1 and Michael S. Arnold2; 1University of Wisconsin-Madison, United States; 2Argonne National Laboratory, United States; 3IHP GmbH, Germany

Graphene nanoribbons (GNRs) are quasi-1D strips of graphene that are tunable semiconductors and can exhibit excellent electronic, thermal and mechanical properties. Field effect transistors (FETs) made of sub-10 nm wide GNRs with smooth, armchair edges can outperform silicon-FETs in drive current and suppress short channel effects due to ultra-thin geometry. However, in order to become a viable contender to silicon based high volume manufacturing, compatibility with existing
CMOS processes is of paramount importance. Although, the synthesis of GNRs has been demonstrated on Ge(001),\textsuperscript{4,5} owing to the lack of availability of 300 mm Ge wafers and relatively higher cost, a promising alternative is to synthesize graphene nanoribbons on Ge virtual substrates, which can be epitaxially grown on 300 mm Si wafers.

Here we explore the concept of transfer-free growth of armchair graphene nanoribbons on a Si(001) platform by conducting the GNR synthesis on germanium virtual substrates by CVD.\textsuperscript{6} By tuning the thickness of the Ge epilayer, growth temperature, methane flow rate and the synthesis duration, we are able to achieve sub-10 nm wide GNRs that possess a semiconducting bandstructure and are several hundred nanometers long. Scanning tunneling microscopy reveals that these GNRs possess smooth armchair edges, which is critical to achieving high on/off ratios and drive currents. We also find that GNR growth kinetics on Ge virtual substrates is identical to Ge(001) and that Si diffusion from the bulk can be suppressed for as long as 9 h, preventing SiC formation on the surface. Furthermore, the threading dislocations, which are inevitably present in heteropitaxially mismatched systems as Ge-Si are also not found to influence GNR nucleation and/or growth. These results indicate that all previous advances of GNR growth on Ge(001) (e.g. seeding initiated synthesis)\textsuperscript{7,8} can be readily scaled to Ge virtual substrates, overcoming a substantial barrier for adoption of GNRs in novel semiconductor technologies. This demonstration also opens up the possibility of achieving nanoribbons directly on a Si surface via selective vapor phase etching of Ge.\textsuperscript{9}

**Carbon Nanotube Based High Performance CMOS and Optoelectronic Devices** Lian-mao Peng\textsuperscript{1,2} and Yang Liu\textsuperscript{2}; \textsuperscript{1}Peking University, China; \textsuperscript{2}Columbia University, United States

Carbon nanotube (CNT)-based electronics has been considered one of the most promising candidates to extend Si complementary metal-oxide-semiconductor (CMOS) technology. In particular CNTs have been investigated for various electronic and optoelectronic device applications, such as sub-10nm CMOS devices which outperform that of state-of-the-art Si based CMOS devices in both speed and power consumption [1-5], as well as idea material for monolithic optoelectronic integration with complementary MOS-compatible signal processing circuit [6-8].

Prototype device studies on individual CNTs revealed that CNT based devices have the potential to outperform Si CMOS technology in both performance and power consumption. With a well-designed device structure and in combination with graphene, we showed that high-performance top-gated CNT FETs with a gate length of 5 nm can be fabricated. Significant progress has also been made in fabricating carbon nanotube low-power devices. An efficient way to reduce the power is to
lower the supply voltage VDD, but this voltage is restricted by the 60 millivolts per decade thermi-onic limit of subthreshold swing (SS) in FETs. A Dirac source (DS) with a much narrower electron density distribution around the Fermi level than that of conventional FETs was recently proposed and demonstrated using CNT to reduce SS [2].

Transforming Ideas to Reality—Emerging Nanotechnologies from the “Lab” to the “Fab” Max Shulaker and Christian Lau; Massachusetts Institute of Technology, United States

At this exact moment when future applications are demanding massive improvements in computing performance, conventional approaches to improving computing are becoming increasingly challenging. Nanosystems – leveraging unique properties of emerging nanotechnologies to realize new systems and architectures – promise to enable the next wave of computing gains for next-generation applications as well as provide the means for developing rich new functionalities that lie beyond the scope of traditional computing today. Yet despite this promise, imperfections and variations inherent in beyond-silicon emerging nanotechnologies have made realizing large-scale integrated systems infeasible. In this talk, I describe how by combining advances across the entire stack – from nanomaterial synthesis to new processing techniques, circuit design methodologies, and architectures – these challenges can be overcome to realize the first large-scale and complex electronic systems leveraging beyond-silicon emerging nanotechnologies. As a case-study, I will describe the journey of transforming carbon nanotubes from an interesting scientific nanomaterial into the foundation for realizing the first beyond-silicon microprocessor built entirely from carbon nanotube transistors – RV16X-NANO, a 16-bit microprocessor based on the RISC-V instruction set. I will conclude by describing how emerging nanotechnologies are beginning to be transferred from the “lab” to the “fab,” promising a new and exciting age for nanoelectronics and computing.

5:30 AM *S.NM05.07.03
Nanomaterials for Printable Electronics Patrick R. Malenfant; National Research Council Canada, Canada

The National Research Council (NRC) is Canada’s premier organization for research and technology development. NRC’s Printable Electronics (PE) program develops materials and inks for additive manufacturing in order to enable a sustainable PE sector in Canada. Progress has been made over the last 15 years, yet many challenges remain at the materials, fabrication and integration level, limiting performance and commercialization. This presentation covers our progress in high purity semiconducting single-walled carbon nanotube (sc-SWCNT) enrichment and transistor fabrication via solution based processes as well as conductive molecular ink development[1-11]. I will highlight our recent progress in understanding sc-SWCNT enrichment using conjugated polymers, with special consideration given to the effects of solvent parameters and doping on the mechanism and yield/purity of the final product[2-4]. Removal of the wrapping polymer using a dry process on-wafer will also be described [5]. Developments in conductive molecular inks and progress towards the commercialization of new applications will be described such as in-mold electronics [6-8]. Challenges and advances associated with using polymer-based dielectrics and encapsulants will be discussed as well[9,10]. Such transistor packages have enabled the realization of fully inkjet-printed transistors as a result of the excellent electrical properties of sc-SWCNTs [2,11]. A demonstration of a fully additive process to make TFT backplanes via R2R printing will also be highlighted. The development of new functional nanomaterials and their successful integration into devices will enable additive manufacturing of TFT arrays and in-mold electronics.

Developing an Advanced Integration Technology for Condition Monitoring with Pre-Strained Carbon Nanotubes

Simon Böttger1, Eric Pankenin1, Martin Hartmann1,2 and Sascha Hermann1,2,3; 1Chemnitz University of Technology, Germany; 2Center for Advancing Electronics Dresden CFAED, Germany; 3Fraunhofer Institute for Electronic Nano Systems ENAS, Germany

Giant piezoresistivity of Carbon Nanotubes (CNTs) is a unique feature promoting further miniaturization of strain sensors. In the context of condition monitoring for safety relevant applications, Industry 4.0, or robotics, especially integrated scalable solutions are overdue. CNT-based electro-mechanical transducers were already shown in proof-of-principle studies [1, 2] and recently also scalable technologies were applied [3]. However, there are still remaining challenges hindering reproducible device fabrication. To emphasize, on the material side a lack of control over chirality and length distribution of single-walled CNTs leads to a distribution of sensor properties. On the other side, an undefined initial CNT-strain condition makes reliable and controlled operation of sensors very challenging.

Here, we have addressed several in-depth studies along a reproducible CNT integration technology, such as length separation, role of CNT/metal contacts, pre-straining CNTs, and their impact on CNT device performance. This integration technology was consequently utilized on wafer-level in order to enable a scalable fabrication of CNT-based piezoresistive sensors in the perspective of forthcoming heterogeneous system-integration in e.g. safety-relevant ASICs. We found significant improvements on the CNT-FET performance by integrating pre-sorted long CNTs which is mainly correlated to reduced network effects, since less amount of CNT to CNT intersections are formed in the transistor channel [4]. In particular, we statistically revealed improvements in terms of fabrication yield, charge carrier mobility and subthreshold controllability. Moreover, we identified tunneling-related contact effects in CNT-based piezoresistive sensors to enhance the intrinsic gauge factor up to 165% [5]. The gauge factor can further be controlled by the input drain-source and gate-source voltage.

In addition, we realized pre-straining of integrated CNTs, which was verified by a significant blue-shift of the CNT-specific phonon mode G+ of up to 6.2 cm⁻¹, with respect to un-strained CNTs. Based on previous literature [6], we assessed the built-in strain ranging from 0.4% up to 0.8%.

In conclusion, we emphasize several technological aspects of the process value-chain and their relevance for a successful manufacturing of miniaturized CNT-based piezoresistive sensors for condition monitoring of forthcoming smart systems.

Carbon Nanotube Transistors for Highly Energy-Efficient Digital Systems

Carlo Gilardi1, Gage Hills2, Qing Lin1, Rebecca Park1, Gregory Pitner1, H.S. Philip Wong3 and Subhasish Mitra1; 1Stanford University, United States; 2Massachusetts Institute of Technology, United States

Carbon nanotube field-effect transistors (CNFETs) are a promising candidate for implementing highly energy-efficient future digital systems. This is due to the superior transport properties of carbon nanotubes (CNTs) together with small body
thickness. Furthermore, low-temperature (< 200°C) fabrication of CNFETs enables new monolithic three-dimensional (3D) architectures with computation immersed in memory, enabling up to 1,000-fold system-level energy-delay-product benefits for abundant-data applications (such as deep learning). In this talk, we will present ways in which many challenges traditionally associated with CNFETs have been overcome in the recent years. At the device-level, hysteresis in CNFET electrical characteristics is reduced to < 0.5% of the VGS sweep range by studying charge impurities around CNTs. CNT PFET with low contact resistance of 6.5 kΩ (10 nm contact length) has been successfully demonstrated. At the circuit-level, a combination of fabrication and design techniques (the imperfection-immune paradigm) overcomes substantial inherent imperfections and variations traditionally associated with CNTs. The imperfection-immune paradigm has been key to the demonstration of CNFET digital VLSI circuits, as well as monolithic 3D NanoSystems that will also be highlighted in this talk.

SESSION S.NM05.08: Graphene Nanoribbon Device
On Demand Abstracts Available for Viewing Starting On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
S-NM05

5:00 AM *S.NM05.08.01
High Performance Graphene Nanoribbon Transistors Jeffrey Bokor¹, Zafer Mutlu¹, Juan Pablo Llinás¹, Gabriela Borin Barin², Peter Jacobs¹, Ilya Piskun¹, Raymond Blackwell⁴, Andrew Fairbrother¹, Xinliang Feng⁴, Klaus Müllen⁴, Felix R. Fischer¹, Pascal Ruffieux², Michael Crommie¹ and Roman Fasel²; ¹University of California, United States; ²Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; ³National Institute of Standards and Technology, United States; ⁴Technische Universität Dresden, Germany; ⁵Max Planck Institute for Polymer Research, Germany

Recent advances in on-surface organic synthesis have led to the development of bottom-up graphene nanoribbon (GNR) growth with atomic precision⁵. Bottom-up synthesized GNRs have promising electronic properties for high performance field effect transistors (FETs) and ultra-low power devices such as tunneling FETs⁶. However, the short length, wide band gap, and random spatial orientation of GNRs have impeded the fabrication of devices with the expected performance and switching behavior⁷. Here, recent progress in integrating bottom-up synthesized GNRs into devices will be presented. High on-current and high on-off ratio FETs with a nine-atom wide GNRs as the channel material were successfully fabricated⁸. Strategies to further improve FET device yield and performance with the parallel arrays of GNRs transferred from single crystal Au (788) will be discussed. Finally, a new approach for the transfer-free fabrication of GNR devices has been developed.

Integrated Synthesis of Millions of Suspended Graphene Nanoribbons and Its Non-Volatile Memory Applications Toshiaki Kato¹,² and Toshiro Kaneko¹; ¹Tohoku University, Japan; ²JST-PRESTO, Japan

We have developed a new, simple, scalable method based on novel plasma catalytic reaction [1-3] for directly fabricating narrow graphene nanoribbons (GNRs) devices on an insulating substrate [4]. Since the establishment of our novel GNRs fabrication method, direct conversion of a Ni nanobar to a suspended GNR is now possible. Indeed, GNRs can be grown at any desired position on an insulating substrate without any post-growth treatment, and the wafer-scale synthesis of suspended GNRs arrays with a very high yield (over 98%) is realized [5]. The growth dynamics of suspended GNRs is also investigated through the systematic experimental study combined with molecular dynamics simulation and theoretical calculations for phase diagram analysis. Unique optoelectrical property, known as persistent photoconductivity (PPC), is also observed in our suspended GNRs devices. By using the PPC, GNRs-based non-volatile memory operation is demonstrated [6]. High thermoelectric performance is also shown in our as-grown suspended GNRs [7]. We believe that our results can contribute to pushing the study of atomically thin layered materials from basic science into a new stage related to the optoelectrical applications [8-11] in industrial scale.
Controlled Quantum Dot Formation in Atomically Engineered Graphene Nanoribbons Field-Effect Transistors

Maria El Abbassi, Perrin L. Mickael, Gabriela Borin Barin, Sara Sangtarash, Jan Overbeck, Oliver Braun, Colin Lambert, Qiang Sun, Thorsten Prechtli, Akimitsu Narita, Klaus Müllen, HSJ van der Zant, Pascal Ruffieux, Roman Fasel, Akimitsu Narita, Klaus Müllen, HSJ van der Zant, Pascal Ruffieux, Roman Fasel, HSJ van der Zant.

Graphene nanoribbons (GNRs) have attracted a strong interest from researchers worldwide, as they constitute an emerging class of quantum-designed materials [1-4]. Some of the major challenges towards their exploitation in electronic applications are their reliable contacting due to their small size (< 50 nm), as well as the preservation of their physical properties upon device integration.

In this combined experimental and theoretical study, we report on the first demonstration of quantum dot (QD) transport in atomically precise GNRs [5]. The devices consist of a film of aligned 5-atoms wide GNRs (5-AGNRs) transferred onto graphene electrodes with a sub 5-nm nanogap [6-8]. We demonstrate that the narrow-bandgap 5-AGNRs exhibit metal-like behavior resulting in linear IV curves for low bias voltages at room temperature and single-electron transistor behavior at 13 K. By performing spectroscopy of the molecular levels, we obtain addition energies in the range of 200-300 meV. DFT calculations predict comparable addition energies, and reveal that, due to the finite length of the 5-AGNRs, two states at the termini of the 5-AGNRs are formed within the bandgap of the infinite ribbons. The properties of the obtained QD reflect the band-structure and therefore demonstrate the preservation of the GNR properties upon device integration, a critical step in the realisation of more exotic GNR-based nano-electronic devices.

**Probing the Magnetism of Topological End-States in Armchair Graphene Nanoribbons**
**Dimas de Oteyza**

1Donostia International Physics Center, Spain; 2Centro de Física de Materiales (CFM-MPC), CSIC-UPV/EHU, Spain; 3Ikerbasque, Basque Foundation for Science, Spain

Materials purely made up of non-magnetic atoms can display magnetic properties. One such example are aromatic hydrocarbon structures. Following Lieb’s theorem, if the number of atoms in each carbon sublattice is different, the molecular structure will hold a net spin. However, even in the absence of net spin, polyradicals can be generated on graphitic structures subject to particular edge topologies. In addition to the edge topologies, also the structure’s size determines the presence or absence of such radical states, whose corresponding spin, if present, is furthermore predicted to display a specific relative alignment. These interesting predictions are hard to verify because of the difficulty in the synthesis of appropriate nanographic structures with atomic precision. In this respect, on-surface synthesis under vacuum conditions has appeared as an extremely promising approach. Making use of it, we have synthesized a variety of nanosized aromatic hydrocarbon structures with well-determined shapes and sizes, including graphene nanoribbons with different edge morphologies, widths and lengths. For the particular case of 5 atoms wide armchair graphene nanoribbons we describe, based on scanning tunneling microscopy and spectroscopy, and combined with theoretical calculations, their electronic properties and the magnetism associated to its topologic end-states.

5:15 AM *S.NM05.09.02

**Emergence of Spin States in Graphene Nanostructures**
**José Ignacio Pascual**; CIC nanoGUNE, Spain

Graphene can spontaneously develop intrinsic paramagnetism. Crucial examples are the magnetization of zig-zag edges in graphene, or the emergence of paramagnetism in open shell graphene nanostructures. I will show that graphene nanoribbons (GNR), fabricated with atomic precision on a metal surface exhibit fingerprints of π-paramagnetism on a metal surface, which can be detected and spatially localized using low temperature scanning tunneling spectroscopy and microscopy, and combined with theoretical calculations, their electronic properties and the magnetism associated to its topologic end-states.

I will also review other methods for activating magnetic ground states in graphene. For example, spin states can be created on a ribbon simply by substitutional doping or by incorporating magnetic species into a ribbon using on-surface synthesis routes (see included image of a Fe porphyrin contacted to chiral nanoribbons). In this last case, we proved that the molecular spin survives in the ribbon by spin-excitation inelastic spectroscopy [2]. By proper selecting the position of the halogen functionalization, we fabricated linear GNR-FeTPP-GNR structures and performed electronic transport measurements [3], detecting spin-excitation fingerprints in transport mode.

5:30 AM S.NM05.09.03

**Magnetotransport Spectroscopy of Graphene Nanoribbon Devices**
**Simen Sopp**

1Alessandro Lodi, Tian Pei, Akimitsu
A long-standing challenge in nanoscience has been to fabricate devices of only a few nanometers with single-atom accuracy. The necessary structural control can be provided by bottom-up fabricated molecular graphene nanoribbons with atomically precise edges. Only such control of the graphene nanoribbons should allow derived field-effect transistors that exhibit magnetic and topological effects. Here we report the observation of magnetic, topological, and electronic effects on the quantum transport of hitherto unexplored molecular graphene nanoribbons. This includes magnetic shifting of molecular energy levels, topology and time-reversal symmetry breaking in a universality-class transition, negative differential conductance, and quantum transport effects up to near-room temperature.

Forging Symmetry Protected Topological States into Metallic Graphene Nanoribbons  
Felix R. Fischer$^{1,2,3}$, Michael Crommie$^{1,2,3}$ and Steven G. Louie$^{1,2}$;  
$^1$University of California, Riverside, United States; $^2$Lawrence Berkeley National Laboratory, United States; $^3$Kavli Energy NanoScience Institute, United States

We have recently demonstrated the rational design and experimental realization of a graphene nanoribbon (GNR) superlattices that hosts a 1D array of symmetry-protected topological states, thus generating otherwise inaccessitable electronic structure. This new class of materials can be thought of as an extended form of poly-acetylene wherein highly localized half-filled topological states replace the familiar single occupied p-orbitals along a conjugated p-system. Experimental results and first-principles calculations reveal that the frontier band structure of these GNR superlattices is defined purely by the coupling between adjacent topological interface states and can be tuned all the way from a semiconductor to a metal. This novel manifestation of 1D topological phases presents an entirely new route to band engineering in 1D materials based on precise control of their electronic topology, and is a promising new platform for future studies of 1D quantum spin physics.

Quantum Interference Engineering of Nanoporous Graphene for Carbon Nanocircuitry  
Isaac Alcon$^{1,2}$, Gaetano Calogero$^{3,2}$, Nick Papior$^2$, Anti-Pekka Jauho$^2$ and Mads Brandbyge$^2$;  
$^1$Freie Universitat Berlin, Germany; $^2$Technical University of Denmark, Denmark; $^3$Università degli Studi di Pisa, Italy

Bottom-up prepared carbon nanostructures appear as promising platforms for future carbon-based nanoelectronics due to their atomically precise and versatile structure. An important breakthrough is the recent preparation of nanoporous graphene (NPG) as an ordered covalent array of graphene nanoribbons (GNRs). Within NPG, the GNRs may be thought of as 1D electronic nanochannels through which electrons preferentially move, highlighting NPG’s potential for carbon nanocircuitry. However, the π-conjugated bonds bridging the GNRs give rise to electronic crosstalk between the individual 1D channels, leading to spatially dispersing electronic currents. In this talk, we propose a chemical design of the bridges resulting in destructive quantum interference, which blocks the crosstalk between GNRs in NPG, electronically isolating them. Our multiscale calculations reveal that injected currents can remain confined within a single, 0.7 nm wide, GNR channel for distances as long as 100 nm. The concepts developed in this work thus provide an important ingredient for the quantum design of future carbon nanocircuitry. In addition, our latest results demonstrating an external control of these characteristics will also be presented.

SESSION S.NM05.11: Carbon Nanotube Transport
On Demand Abstracts Available for Viewing Starting On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
S-NM05

5:00 AM S.NM05.11.02
Asymmetric CNT Transistors for Enhanced High Frequency Performance Martin Hartmann1,2, Simon Böttger1, Georg Heldt1, Martin Claus2, Michael Schroter3 and Sascha Hermann1,2,3; 1Chemnitz University of Technology, Germany; 2Center for Advancing Electronics Dresden (cfaed), Germany; 3Fraunhofer Institute for Electronic Nano Systems, Germany; 4University of Technology Dresden, Germany

A strong driving force for future communication systems is the improvement of transceiver electronics efficiency. Carbon nanotube-based field effect transistors (CNTFETs) are promising electronic components1, since high intrinsic speed and linearity due to their high charge carrier mobility, current carrying capability and one-dimensional charge transport are prospected2-4. We report on design rules for the high frequency (HF) CNTFETs device architecture with improved operating speed. Therefore, the spacer between the gate and the source electrode (S-spacer) and gate to drain electrode (D-spacer) was investigated with respect to the HF performance. It will be discussed to which extent the spacer variation is balancing the device electrostatics in the CNT-metal contact area which influences the charge carrier injection and reflection by the Schottky barriers (SBs) that form between the metal covered CNT ends and the uncovered CNT channel region. Theoretically the dependence of the S-spacer and D-spacer on speed and linearity has been shown by simulations4 but was not yet investigated in an experimental study. Mothes et al. point out that especially within the S-spacer the fringing fields are needed to modulate the SBs, which is essential to gain highest speed and linearity. Therefore a small finite SB is essential to reduce the impact of charge carrier back-scattering from the source electrode. In contrast to FET geometry variations reported in literature, where additional gate electrodes or asymmetrical gate oxide trenches were introduced and investigated with respect to their DC performance5,6, we report on the impact of S-spacer and D-spacer variations on the HF performance of CNTFETs. In terms of HF performance, inspiring results were obtained with symmetrical gate arrangements, using a self-aligned T-shape top gate electrode7 where Cao et al. realized CNTFETs with a transit frequency f_T as well as maximum frequency of oscillation f_max of up to 70 GHz at 100 nm channel length. In contrast, a buried gate helps minimizing parasitic capacitances and thus improving the HF performance further8. We present HF CNTFETs with a buried gate fabricated by an additional lithography step enabling to realize devices with asymmetrical S-spacer and D-spacer. Thereby we followed scalable device fabrication procedures based on a wafer-level prototyping platform allowing to fabricate sufficiently large device counts for systematic and conclusive studies. The studies exposed a speed increase, measured by the external f_T and f_max, of up to 20% for a specific asymmetrical gate electrode position in the channel. The fabricated devices show transit frequencies up to 16 GHz for 280 nm long channels with randomly oriented CNTs and a tube density of up to 30 CNTs/µm.

Hybrid Integration of CNT Logic and Analog RRAM towards Monolithic 3DSoC  Yijun Li, Jianshi Tang, Zhenxuan Zhao, Jian Yuan, Bin Gao, He Qian and Huaqiang Wu; Tsinghua University, China
With the fast development of emerging technologies such as artificial intelligence and internet of things, there has been higher and higher demand for future chips in terms of computing power, speed, and energy efficiency. Amid the slowdown of Moore's law, new chip architecture is needed to alleviate or overcome the so-called von Neumann bottleneck. Monolithic three-dimensional (3D) integration of multiple layers of functional components, such as emerging memory, logic and sensors, through high-density interlayer interconnects, provides a promising approach to build highly energy-efficient system-on-chip (SoC). On one hand, carbon nanotube (CNT) has been demonstrated as a superior candidate for high-speed logic technology that can be fabricated with low-temperature process. On the other hand, resistive random-access memory (RRAM) has been extensively studied for energy-efficient computing-in-memory (CIM) by taking advantage of its analog switching characteristics. In this work, we report the monolithic integration of CNT logic circuits and analog RRAM array using back-end-of-line (BEOL) compatible low-temperature fabrication processes. The performance of CNT integrated circuits and analog RRAM devices have been carefully optimized. Hybrid circuits such as ternary content-addressable memory (TCAM) are also fabricated. Our work represents a critical step towards 3DSoC with CIM capability.

S.NM05.12.03
Low-Power Carbon Nanotube-Based Flexible Integrated Circuits with Bio-Integration Capabilities Li Xiang and Youfan Hu; Peking University, China
Carbon nanotubes (CNTs) is one of the most promising candidates for next-generation electronics for its extraordinary intrinsic properties, including high carrier mobility, excellent mechanical flexibility and solution processability, which are desirable in unique application scenarios, from smart sensing to biomedical implants. However, the integrated circuits (ICs) with enough complexity and integration scale for signal processing, which is the core units in modern electronic systems, are still lacking, which is mainly due to the nonuniformity of the devices, low yield manufacturing and large power consumption. This presentation would detail approaches for wafer-scale, high-yield and highly-uniform manufacturing of CNT devices and ICs. Chips using CNTs as semiconducting materials are 100% successfully transferred to water-soluble substrates with average device yield of 96.6%. Great uniformity is also demonstrated with minimum standard deviation of 55 mV in threshold voltage. The ICs could be successfully transferred onto biological surfaces, such as human wrist, biodegradable polymers and plant leaf. Integrated with other sensors, the CNT based flexible ICs could demonstrate system-level environmental monitoring. In addition, to further push forward the CNT based flexible electronic devices, we propose a gate engineering approach to boost the electrical performance of the carbon nanotube transistors, to make them more energy-efficient and fit for the low power consumption requirement in practical biological or environmental applications.

Wearable Two-Dimensional Thermoelectric Imaging Sensor Array Based on Carbon Nanotube Nabila Fairuz, Fariba Islam and Ahmed Zubair; Bangladesh University of Engineering and Technology, Bangladesh
Thermal imaging has applications in non-destructive imaging, testing, detection, and many more areas. Here, we demonstrate a thermal imaging sensor design made of carbon nanotubes (CNTs) using the thermoelectric effect. We designed the sensor device consisted of an array of p-type CNT fibers that crisscross with another array of n-type CNT fibers. Temperature differences between different p-n fiber knots produce voltage differences. Measuring the voltage differences between p and n
terminals of each knot, the temperature of each knot can be determined and the thermal image of the object can be obtained. For a 7×7 sensor array, the p-n terminal voltage difference of ~0.22 mV was attained for a temperature difference of 100 K. As CNT gives flexibility and tunability of the Seebeck coefficient in the device, this thermal sensor device can be made wearable with nanorange thermal imaging with extreme precision.

Density Control of Vertically Aligned Carbon Nanotubes Grown Directly on Stainless Steel through Nanosphere Lithography and Its Effect on Field Emission Properties Arun Thapa and Wenzhi Li; Florida International University, United States

The direct contact of vertically aligned carbon nanotube (VACNT) based field emitter arrays (VACNT-FEAs) to their growth substrate and their structurally controlled morphology are critical factors for applications in vacuum micro/nano-electronic devices. Here, we propose a method for fabricating a high-performance VACNT-FEAs by controlling the morphology of VACNT micro/nano-pillars synthesized directly on stainless steel substrates without external metal catalyst particles via nanosphere lithography (NSL). Exposure of carbon precursor gas to the limited space, created after the NSL using polystyrene spheres of different sizes, on the surface of the thermally heated bulk catalytic substrate was a key for manipulating the morphology of the VACNT-FEAs. Field emission properties of the as-synthesized VACNT-FEAs were measured and found fascinating field emission properties along with high emission current stability. The correlation between the number of emitters in a pillar structure and their field emission behavior has been investigated. The proposed method may be used to fabricate the cold cathodes for vacuum electronic devices requiring high emission current density along with extended emission current stability.

High Pressure Raman Spectroscopy of Linear Carbon Chain Encapsulated in Isolated Multiwall Carbon Nanotube Keshav Sharma¹, Paulo T. Araujo¹, Nathalia L. Costa², and Alexandre R. Paschoal²; ¹The University of Alabama, United States; ²Universidade Federal do Ceará, Brazil

Elusive measurements of the Longitudinal optical (LO) phonon mode frequency of isolated Cn@MWCNT systems (linear carbon chains encapsulated by multi-wall carbon nanotubes) were studied under extreme high pressure via Resonance Raman spectroscopy. The pressure-dependent frequency softening with increasing pressure is discussed in terms of a simple force constant model in which the spring constants present a dependence with pressure. The model allowed us to easily obtain both the Young’s modulus and the Gruneisen parameter associated to such LO mode. In particular, the Gruneisen parameter was found to be much higher than that of Graphene and CNTs. Additionally, the LO phonon lifetime was found to be decrease with increasing stress.

Optical Response of Ultrathin Periodically Aligned Single-Wall Carbon Nanotube Films Chandra Adhikari and Igor Bondarev; North Carolina Central University, United States

Finite-thickness films of aligned single-wall carbon nanotubes (SWCNT) are recently demonstrated to have extraordinary optoplasmic properties including a tunable negative dielectric response in a wide photon energy range[1]. We explain this theoretically using the Maxwell-Garnett (MG) mixing[2] for the dielectric responses of planar periodic arrays of identical SWCNTs. We start with the calculation of the conductivity for an individual SWCNT using the (k*p)-method of band structure calculations[3]. Then we use the low-energy plasmonic response calculation technique earlier proposed by one of us for finite-thickness metallic films with periodic cylindrical anisotropy[4], to derive an analytical expression for the dynamical dielectric response tensor of an ultrathin finite-thickness periodically aligned SWCNT array. The dielectric responses of about a dozen of SWCNT arrays with different chiralities and very close diameters are then mixed using the MG method to obtain the anisotropic optical response of the finite-thickness SWCNT film which explains the experimental ellipsometry measurements reported[1]. We also note that in such SWCNT films the inhomogeneously broadened interband plasmon resonance of individual SWCNTs overlaps with the broadened exciton resonance, thus making the exciton-plasmon coupling and associated photon bandgap formation possible[5] for these and similar cylindrically anisotropic compound systems including double-walled carbon nanotubes.

Electronic devices with configurability to providing multiple functions are of great interests for their superior adaptability to the ever-changing and multifarious application scenarios. Here, we report flexible integrated circuits possessing configurable functions constructed with dual-material gate (DMG) devices based on carbon nanotube thin films, which can serve as either transistors or diodes, on a 2-μm-thick parylene substrate. When configured as a transistor, the DMG device has great advantages over the normal-gated devices regarding the current on/off ratio, the subthreshold swing and the drain-induced barrier lowering due to the regulated energy band distribution in channel area. When operating as a diode, a typical DMG device demonstrates a sufficient rectification ratio of approximately five orders and a diode-on-current of over 26μA. Scalable manufacturing of DMG devices was also demonstrated with great uniformity both in diode and transistor configurations. Finally, multifunctional integrated circuits, which can dynamically switch their function from rectifier to follower or from OR gate to voltage adder by changing controlling signals, were constructed. The functional-configurability, together with scalable manufacturing and the realization on ultrathin flexible substrates, will open up great opportunity for the future environmentally-adaptive system in the field of flexible electronics.

**Pseudocarbynes—Stabilization of Polyynes in Solid-State by Gold Clusters**

Hyunsub Kim, Pilarisetty Tarakeshwar, Peter Buseck and Scott G. Sayres; Arizona State University, United States

Carbyne, the structure consisting of one-dimensional (1D) chain of sp-hybridized carbons is predicted to have greater tensile strength than graphene, making it a highly sought material. However, the highly reactive sp-hybridized carbon chains convertto the more stable sp2-hybridized phase through cross-linking reactions and ozonolysis by exposure to oxygen. We have developed a new class of molecules/materials, “pseudocarbynes”, that we define as sp-hybridized carbon chains that are stabilized through non-covalent interactions with small metal clusters. Here, I will present our progress in synthesizing pseudocarbynes through two distinct experimental techniques: 1) through direct laser ablation of a gold target submerged in liquid, and 2) through the self-assembly of conjugated carbon chains with a colloidal solution of gold nanoparticles. Pseudocarbynes remain stable in the solid-state (tested for up to several months). We characterize the sp-hybridized carbon structure by analyzing FT-IR and Raman spectroscopies, as well as X-ray powder diffraction directly in the solid state. By securing stability in the solid state, pseudocarbynes are expected to be a good candidate for a diverse set of optical or electronic applications.

**Design, Solution Synthesis and Characterization of Graphene Nanoribbons and Heterojunctions**

Mamun Sarker and Alexander Sinitskii; University of Nebraska-Lincoln, United States

Graphene nanoribbons (GNRs) are known for their highly tunable physical properties and great promise for a broad spectrum of electronic applications. The current study focuses on the chemical design of novel molecular precursors for the bottom-up solution synthesis of atomically precise GNRs. As semiconducting properties of GNRs are highly dependent on their width, edge geometry, and heteroatom doping, here we report on the design, synthesis, and characterization of three different GNRs, which include C4N- and C8N-GNR heterojunctions derived from the pristine with nitrogen-substituted chevron-based monomers, laterally extended chevron GNRs (LecGNRs) and edge-modulated chevron GNRs (EmcGNRs). The XPS-data for C4N- and C8N-GNR heterojunctions confirms the presence of nitrogens and suggests the random positions of pristine and nitrogen-doped GNR segments. The data on the structural, optical and electronic properties of all three GNRs will be presented. In particular, LecGNRs showed an expected lower optical bandgap than their counterparts, while EmcGNRs demonstrate a higher optical bandgap than the pristine chevron GNRs. While this study has a particular focus on the solution synthesis of nanoribbons, the developed molecular precursors may also be compatible with the established on-surface synthesis approaches for GNRs.
Electrospinning (ES) is a rapid and simple manufacturing process for producing polymer materials with high surface-area-to-volume ratios. Traditional ES fabrication involves an electrostatic force that pulls polymer from a grounded spinneret tip to a charged metallic deposition surface held at high voltage. Due to the high voltages and the charged electrodes required for ES fiber creation, ES conductive polymers presents a great challenge. During ES of conductive materials, a circuit is completed from the ES spinneret to the deposition substrate, resulting in electrical arcing and non-predictable deposition. In the work presented here, a handheld ES device that incorporates directed airflow was used for deposition of conductive polymer fiber materials directly onto substrates regardless of dielectric charges. In the portable ES device described, deposition occurs by placing a conductive, ring electrode between a spinneret and a deposition surface. The resulting electrostatic force pulls polymer from the spinneret and toward the ring electrode. Directed airflow then carries the polymer fiber through the center of the ring electrode and onto a non-conductive surface beyond the device. Such a system prevents electrical arcing, thereby improving predictability and allowing for the creation of a fiber mat capable of carrying electrical current ranging from direct to alternating. Electrically conductive polymer fiber mats are desirable due to their mechanical compliance, high surface area, potential for optical transparency, and a variety of electrical, optical, and mechanical applications. These applications include but are not limited to materials for water filtration, photocatalysis, light polarization, light energy harvesting, sensors, actuators, and miniature electrical components.

The portable, electrostatic and air driven (EStAD) ES device presented includes enclosed electrodes and a fiber propulsion system that provides several additional benefits as compared to other portable ES devices including improved safety for the user and predictable deposition with controllable directionality. A highly desirable and novel application of the EStAD device is that it can be used to electrosinpin conductive materials onto non-conductive substrates without the drawbacks of traditional ES. In the proposed work, the EStAD device will be used to deposit conductive sensors onto non-conductive substrates. Carbon nanotube (CNT) polymer composites will consist of multi-walled CNTs (MWCNTs) treated with amphiphilic surfactants or untreated single and double-walled CNTs dispersed in the neat polymer. Previously, amphiphilic surfactants were used to create homogenously dispersed MWCNT in an aligned nanofiber network with improved conductivity. The feasibility of using untreated single and double-walled CNTs will also be investigated for sensor creation on non-conductive substrates. The preparation process will include a solution-based purification process (ultracentrifugation) in order to inexpensively achieve high purity, metallic CNTs that have been used in high-performing electronic devices. High-purity metallic CNTs are more suitable for superior optical transparency because poorly conducting, strongly absorbing impurities, and semiconducting CNTs will be eliminated through the purification process. Both amorphous nanofiber mats and aligned fiber arrays will be created for subsequent testing. A four-point probe will be used to measure conductivity across the composite CNT nanofiber mats or arrays. The electronic response of nanofiber sensors to analytes (e.g. water vapor and ammonia) will be characterized through current-voltage (I-V) measurements. Morphological surface characterization will be performed through scanning electron microscope (SEM) imaging and analysis, and CNT dispersion within the composite matrix will be analyzed through transmission electron microscope (TEM) imaging and analysis.

Quantum Coupling of Spatially Patterned Guanine Defects in DNA Functionalized Carbon Nanotubes

Younghee Kim¹, Yu Zheng¹, Sergei Bachilo², R. Bruce Weisman², Stephen K. Doorn¹ and Han Htoon¹; ¹Los Alamos National Laboratory, United States; ²Rice University, United States

Chemical functionalization of the sidewalls of semiconducting single-wall carbon nanotubes (SWCNTs) has attracted intense attention because of the localization of tightly bound excitons at defect sites on the nanotube surface, allowing single-photon emission (SPE) at room temperature. Such covalently functionalized SWCNTs hold the potentials as single-photon sources (SPSs) for the applications of quantum photonics and quantum information processing. Aryl sp³ defects have been sparsely and covalently implanted to the random positions of SWCNT sidewalls through diazonium chemistry, leading to the trapping of mobile band-edge excitons in the aryl defects and causing spectrally shifted photoluminescence (PL). Single photon has been emitted through the radiative recombination of localized excitons at the defect sites in the altered nanotube with ultrahigh single-photon purity (99%).

Previous reports about chemically functionalized SWCNTs as single-photon emitters are based on sparse and random placement of oxygen atom or aryl group on the nanotube surface. Incorporation of multiple defects with spatial pattern in nanotube sidewalls has not been achieved until recent discovery of covalently functionalizing SWCNTs with single-stranded DNA (ssDNA). The coating agents such as surfactants, polymers, or DNA are required for individualizing nanotube particles. ssDNA oligomers have been found to helically wrap around nanotube surfaces trough noncovalent interactions. Recently, a room-temperature chemical reaction in samples of ssDNA-suspended SWCNTs has been found between the guanine
nucleotides in the ssDNA coating and the nanotube sidewall in the presence of singlet oxygen ($^1\text{O}_2$). Therefore, introducing and controlling spatially patterned guanine defects on nanotube surfaces is easily achieved by manipulating ssDNA sequences. Such DNA-templated covalent functionalization allows smooth modulation of SWCNT electronic energy levels along the nanotube axis with customized spatial pattern and depth. Each reacted guanine nucleotides creates a defect with shallow trapping depth in the nanotubes. The axial separation between guanines in the (GT)$_n$ ssDNA coating is estimated to be ~0.4 nm, which is at least 5 times smaller than the exciton size. Therefore, excitons in the DNA-tailored SWCNTs are capable of sensing the cumulative potential of several nearby guanine-introduced defects. On the contrary, the exciton is localized in a defect site with deep trapping depth for SWCNT samples with sparse chemical doping of oxygen atom or aryl group on the nanotube surface. We have found that single photon can be generated from the defect-state emission in DNA-altered SWCNTs. Notably, quantum coupling of multiple defect-states has been achieved, resulting from multiple guanine defects with spatial patterning on the nanotube surface.

**Superparamagnetic Properties of Metal-Free Nitrogen Doped Graphene Quantum Dots Synthesized by Pulsed Laser Ablation**

Muhammad Shehzad Sultan, Vladimir I. Makarov, Brad R. Weiner and Gerardo Morell; University of Puerto Rico - Rio Piedras, United States

In this study, we developed a novel approach to synthesize high-quality metal-free Nitrogen-doped graphene quantum dots (N-GQDs) with high quantum yield, via irradiation of s-triazene in a solution with benzene by using pulsed laser. The TEM, HRTEM, XPS, XRD, Raman spectroscopy and FTIR were carried out to observe the morphology, size distribution, crystalline structure and to prove successful doping of GQDs with nitrogen atoms. Furthermore, for the first time, to our knowledge, their magnetic properties were investigated. The results indicate that N-GQDs exhibit superparamagnetic behavior. The specific size, shape and zigzag edge structure of N-GQDs were considered to explain the origin of the observed magnetism. The magnetization dependence led to estimating the N-QGD material magnetic permeability for different ambient temperatures. From the zero-field-cooled (ZFC) and field-cooled (FC) magnetization measurements, carried out at 50 Oe magnetic field strength, we estimated the blocking temperature $T_B$ to be around 300 K. Based on the experimental data analysis, the magnetic permeability, number of correlated spins per single N-QGD, and number density of superparamagnetic N-GQD per gram of material were estimated. The excellent superparamagnetic properties together with optical properties manifested by N-GQDs have the potential to lead to high performance biomedical applications.

Atomic Electrostatic Maps of Defect Structures in 2D TMDs Yi Wen1, Colin Ophus2, Christopher S. Allen1,3, Shiang Fang1,4, Efthimios Kaxiras4,4, Angus I. Kirkland1,3 and Jamie Warner1; 1University of Oxford, United Kingdom; 2National Center for Electron Microscopy, Molecular Foundry, Lawrence Berkeley National Laboratory, United States; 3Electron Physical Sciences Imaging Center, Diamond Light Source Ltd., United Kingdom; 4Harvard University, United States

The atomic scale studies on the pristine lattice of TMDs have been carried out with aid from aberration-corrected (scanning) transmission electron microscope (AC-(S)TEM), enabling detailed studies on the evolution of atomic scale defect structures, but their perturbation on local electronic properties, which is essential for understanding their functionality in electronic and optoelectronic devices, are not readily available from direct imaging. Here, we reported the detailed analysis on adatoms, vacancies, line defects, nanopores, nanowires and edge structures in MoS2 and WS2 using 4D STEM, which record not only the scattering information, but also the direct beam, and this allows us to extract phase shift, atomic electric field and charge density map based on the shift of center of mass of direct beam.1 We showed that the electric field map and phase reconstructed imaging are sensitive in detection of abnormal 1D states2 and low atomic number atoms,3 and together provide a comprehensive anatomy on the electronic properties of these defect structures, which is of great importance for the theoretical study of 2D electronic devices.

Study of Atomic and Electronic Structures of Black Arsenic Using Analytical Scanning Transmission Electron Microscopy Hwanhui Yun, Supriya Ghosh, Prafful Golani, Steven Koester and K. Andre Mkhoyan; University of Minnesota, United States

Black arsenic (bAs) is a two-dimensional layered material with similar atomic structures to black phosphorus (bP), and it is expected to exhibit attractive properties for future applications such as high carrier mobility, high anisotropy, tunable band structures by varying the number of layers, etc. [1]. Despite the theoretical predictions, it has only recently gained attention due to difficulties in synthesis of high-quality bAs [2]. Recent experimental reports have shown intriguing nature of bAs including high anisotropy [1,3]. Here, we explore the atomic and electronic structures of exfoliated high-quality bAs using high-angle annular dark-field (HAADF)-scanning transmission electron microscopy (STEM) imaging and spectroscopy and demonstrate changes in optical properties in few-layered bAs. Additionally, a stability study on bAs is conducted to gain insight on the key parameters affecting bAs at ambient conditions.

STEM experiments were carried out using an FEI Titan G2 60-300 (STEM) at 200 keV equipped with energy dispersive X-ray (EDX) and monochromated electron energy-loss spectroscopy (EELS). HAADF-STEM image simulation was carried out using the TEMSIM code based on the Multislice approach [4,5]. Atomic resolution HAADF-STEM images of bulk bAs were obtained from five different orientations including three major crystallographic directions - armchair direction (x-axis), zigzag direction (y-axis), and plan-view direction (z-axis) - confirming anisotropic atomic structures of bAs. Plan-view images were also obtained from few-layered bAs and compared with simulated images that are computed as a function of the number of layers, by which the thickness of the examined layers was measured precisely. The electronic structure of bAs was investigated by using EELS. Low-loss EELS reveals bulk and surface plasma excitation energies and interband transitions, and characteristics of core-loss EELS are described. Low-loss EELS spectra are then acquired as a function of the number of bAs layers and evidence the changes in optical properties in few-layered bAs from bulk bAs. Lastly, degradation of bAs accompanying structure change is analyzed using HAADF-STEM, EDX, and diffraction pattern of specimens. The effect of air, i.e. O2, and water on the degradation is further investigated and discussed.

Two-dimensional (2D) materials and heterostructures are promising systems for soft robotics, deformable electronics, and nanoelectromechanical systems because they combine the high charge carrier mobilities of hard materials with the pliability of soft materials. Understanding their bending properties is crucial for the development of these next-generation devices. However, experimental measurements of bending stiffness in 2D materials have been widely divergent; for example, the reported bending stiffnesses of bilayer and trilayer graphene range from 3.4-160 eV and 7-690 eV, respectively [1-3]. Even less is known about the bending stiffness of 2D heterostructures. Here, we show that electron microscopy can provide a powerful platform for measuring the bending properties of 2D materials. We use aberration-corrected scanning transmission electron microscopy (STEM) to image graphene and 2D heterostructures draped over a series of atomically sharp hexagonal boron nitride steps. This approach enables atomic-resolution studies of their bending conformation, producing insight into both the bending stiffness and mechanisms of bending. In combination with density functional theory (DFT) and continuum mechanics modeling, we derive a unifying model for bending in 2D materials and their heterostructures.

First, we investigated the bending stiffness of single and few-layer graphene [4]. We derive mechanical models that relate the bending stiffness to geometric parameters—such as the radius of curvature, bending angle, and step height—measured directly from STEM images. For monolayer graphene, we obtain bending stiffness values of 1.2-1.7 eV, consistent with DFT predictions [5] and the experimental value of 1.2 eV derived from graphite phonon modes [6]. In multilayer graphene, we find that the bending stiffness varies strongly as a function of bending angle, tuning by almost 400% for trilayer graphene. For ten-layer graphene, we show that the bending stiffness can be as low as 18 eV, three orders of magnitude lower than the bending stiffness predicted by conventional thin-film mechanics. This unusual behavior results from the atomic-scale bending mechanism in 2D multilayers, which is dominated by interlayer shear and slip.

Our findings have profound implications on 2D heterostructures, where we demonstrate that the bending stiffness can be controlled by tailoring the interfacial interactions between vertical homo- and heterointerfaces. We investigated heterostructures and showed that, by simply changing their stacking order, we can dramatically tune their bending stiffnesses. Using a combination of DFT and classical simulations, we produce a model to predict the bending stiffness of arbitrary 2D heterostructures. Together, our results provide a new lower limit of bending stiffness for the fabrication of ultrasoft, high mobility electronics and demonstrate new methods to fabricate 2D heterostructures with tailored bending stiffnesses.

SESSION S.NM06.12: Live Keynote I: Theory and Characterization of 2D Materials—Bridging Atomic Structure and Device Performance
Molecule Functionalization and Intercalation in 2D Materials

Judy Cha; Yale University, United States

Owing to the large surface area and layered nature, the electrical and catalytic properties of 2D materials can be tuned greatly by surface functionalization with tailored molecules with specific redox potentials and intercalation of various intercalants. The utility of surface functionalization and intercalation has been amply demonstrated in 2D transition metal dichalcogenides (TMDCs), including the modulation of carrier densities in monolayer MoS2 field-effect transistors (FETs) and the enhancement of catalytic activities of hydrogen evolution reaction in Li+-intercalated WS2. However, fundamental mechanistic understandings that govern molecule-TMDC interactions or intercalation-induced structural and electrical phase transformations remain basic.

In this talk, I will present our approach to elucidate the underlying mechanisms that govern surface functionalization and intercalation in 2D TMDCs, using MoS2 as a material choice. For surface functionalization, we compare doping powers of a family of organic electron donors (OEDs) on MoS2 to understand the OED-MoS2 interactions. This requires accurate knowledge of surface coverage of OEDs, change in the carrier density after functionalization, and the nature of the OED bonding to MoS2. For intercalation, we electrochemically intercalate Li+ ions into individual monolayer or heterostructure FETs and follow the change in crystal structure and electrical properties of the host 2D systems as a function of intercalation. We uncover a host of interesting phenomena, such as the role of a hBN/MoS2 interface on intercalation kinetics and physics, phase transformation in WSe2 by intercalation, and competition between intercalation kinetics and thermodynamics in MoS2/graphene heterostructures. A central theme of our approach to understanding surface functionalization and intercalation is the integration of device physics with electrochemistry.

Ambient Stable Phosphorenes and Covalently Linked Phosphorene-MoX2 (X = S or Se) Nanocomposites with Enhanced H2 Evolution Activity

Pratap Vishnoi1,2 and C. N. R. Rao1; 1Jawaharlal Nehru Centre for Advanced Scientific Research, India; 2University of California Santa Barbara, United States

The phosphorene is a 2D puckered sheet composed of sp3 phosphorus with each P atom is covalently bonded to three P atoms in the plane. The phosphorus atoms contain lone-pair electrons. It exhibits high charge carrier mobility as well as a thickness tuneable band-gap in the 0.3-2.0 eV range.[1] The conduction band minimum of phosphorene is appropriately positioned to effectively catalyze the H2 evolution reaction by water splitting. Besides, phosphorus is an earth-abundant and environmentally benign non-metal element. Therefore, it is of great interest to exploit the potential of phosphorene as a metal-free photocatalyst for H2 evolution. However, pristine phosphorene is ambient unstable and it produces trace amounts of H2 by water splitting.[2,3]

The advantage of the lone-pair electrons is that they can be utilized for chemical functionalization of phosphorene without significantly affecting its intrinsic properties. In this work, we present synthesis of ambient stable η–ν adducts of phosphorene, covalently cross-linked phosphorene-MoX2 (X = S or Se) nanocomposites, and their HER activity. The
phosphorenes functionalized with InCl\textsubscript{3} and B(C\textsubscript{6}F\textsubscript{5})\textsubscript{3} as well as ylide with a benzyl group are ambient stable and disperse well in aqueous medium.[3] Their photocatalytic HER activity is enhanced significantly exhibiting H\textsubscript{2} yields of 6.6 mmol h\textsuperscript{-1}g\textsuperscript{-1} in the case of phosphorene-B(C\textsubscript{6}F\textsubscript{5})\textsubscript{3} (hydrogen yields for pristine phosphorene is 0.6 mmol h\textsuperscript{-1}g\textsuperscript{-1}). Phosphorene-MoX\textsubscript{2} nanocomposites are synthesized by forming amide as the cross-linkages.[4] Due to improved charge-transfer and suppressed charge recombination rate, phosphorene-MoS\textsubscript{2} exhibits excellent photochemical HER activity with H\textsubscript{2} yields of 26.8 mmol h\textsuperscript{-1}g\textsuperscript{-1}, while only a negligible amount is produced by their physical mixture. The phosphorene-MoS\textsubscript{2} composite shows high electrochemical HER activity with an onset overpotential of 110 mV, closer to that of Pt/C catalyst. The onset overpotential of a 1:1 physical mixture of phosphorene and MoS\textsubscript{2} is 450 mV. The enhanced HER activity of phosphorene-MoS\textsubscript{2} nanocomposite can be attributed to the ordered cross-linking of the 2D sheets, leading to increased interfacial area as well as the charge-transfer interaction between phosphorene and MoS\textsubscript{2} layers.

9:40 AM S.NM06.07.02
Accurate Molecular Models for MoS\textsubscript{2} and Battery Oxides (NMC) to Predict Interfacial Properties up to the Large Nanometer Scale
Juan Liu and Hendrik Heinz; University of Colorado Boulder, United States

We introduce reliable force fields and applications to electrolyte and organic interfaces for molybdenum sulfide and battery oxides, including lithium cobalt oxide as well as nickel and manganese substituted lithium cobalt oxides. Such models, except for MoS\textsubscript{2}, have not been available and are necessary to understand the dynamics and charge transport properties up to the large nanometer scale. Specifically, the parameters for MoS\textsubscript{2} reliably account for structural, interfacial, and mechanical properties and are compatible with many force fields for molecular simulations (Interface force field, CVFF, PCFF, CHARMM, AMBER, OPLS-AA, TEAM). We reproduce chemical bonding, X-ray structure, cleavage energy, infrared spectrum, bulk modulus, Young’s modulus, and interfacial properties with polar and nonpolar solvents within 0.1% to 5% deviation from measurements. Compared to prior models, structural and mechanical instabilities of the nanoscale layers were eliminated, and large deviations in computed interfacial properties (>50%) were reduced to quantitative agreement with experiment (<5%).

The parameters rely on quantitative representation of chemical bonding using atomic charges, using methods that reach much higher accuracy than DFT calculations, bonded parameters from experimental data, and a consistent interpretation of Lennard-Jones parameters that lead to wide compatibility for multiphase materials. All parameters are supported by a physical chemical interpretation. As an example, we discuss the binding mechanism and adsorption energies of peptides on the MoS\textsubscript{2} basal plane using strongly binding and weakly binding sequences derived from phage display. Adsorption is driven by direct surface contact and replacement of surface-bound water molecules, with very widely tunable adsorption energies between -86 and -6 kcal/mol. Weak electrostatic interactions of backbone and side chains with the surface, hydrogen bonds between electrolyte-facing side groups and water, and contributions by hydrophobic groups play a key role to tune the interaction strength.

The models can be applied to any biomaterials and nanomaterials including these 2D compounds, including embedding in electrolytes, polymer matrices, understanding of charge transport, local defects and changes in stoichiometry. The accuracy is comparable to DFT methods at millionfold larger time and length scales, and extensions are feasible for reactive simulations (IFF-R). The models for battery oxides can help overcome problems in designing materials with a higher storage capacity.

5:15 PM INTRODUCTION

5:20 PM *S.NM06.05.01  
Keynote: Interfacial Engineering of Chemically Reactive Two-Dimensional Materials  
Mark C. Hersam; Northwestern University, United States

Following the success of ambient-stable two-dimensional (2D) materials such as graphene, hexagonal boron nitride, and transition metal dichalcogenides, new classes of chemically reactive layered solids are being explored since their unique properties hold promise for improved device performance [1] and quantum phenomena [2]. For example, chemically reactive 2D semiconductors (e.g., black phosphorus (BP) and indium selenide (InSe)) have shown enhanced field-effect mobilities and optoelectronic properties under controlled conditions that minimize ambient degradation [3,4]. In addition, 2D boron (i.e., borophene) is an anisotropic metal with a diverse range of theoretically predicted phenomena including confined plasmons, charge density waves, and superconductivity [5], although its high chemical reactivity has limited experimental studies to inert ultrahigh vacuum conditions [6-9]. Therefore, to fully study and exploit the vast majority of 2D materials, methods for mitigating or exploiting their relatively high chemical reactivity are required [10]. In particular, covalent organic functionalization of BP minimizes ambient degradation, provides charge transfer doping, and enhances field-effect mobility [11], while noncovalent organic functionalization of borophene leads to the spontaneous formation of electronically abrupt lateral borophene-organic heterostructures [12]. On the other hand, sequential deposition of atomic carbon and boron on silver substrates results in rotationally commensurate vertical borophene-graphene heterostructures where the graphene adlayer provides robust encapsulation for the underlying borophene [13]. By combining organic and inorganic encapsulation strategies, even highly chemically reactive 2D materials (e.g., InSe and CrI3) can be studied and utilized in ambient conditions [14].

Exploring Strain-Stabilization of the Conducting 1T Phase in Pulsed Laser Deposited MoS2 Thin Film on Different Single Crystal Substrates  
Swati Parmar1,2, Suresh Gosavi1 and Satishchandra Ogale2; 1Savitribai Phule Pune University, United States
The metallic 1T phase of MoS$_2$ has excellent electrical conductivity but it is thermodynamically unstable. Hence there is great interest in realization and stabilization of this phase in different forms such as nanomaterials and thin films for various device applications. The thin film platform affords the element of substrate-induced strain as a tunable parameter that can control the phase equilibria. In the work reported here, we therefore examine the possibility of stabilizing the desirable 1T phase of MoS$_2$ in the case of thin films grown by pulsed laser deposition (PLD) on different crystalline substrates, namely c-Al$_2$O$_3$ (0001), LaAlO$_3$ (001), SrLaAlO$_4$ (001), SrTiO$_3$ (001) and MgO (001). The percent (%) lattice parameter mismatch between the most favorable growth planes of MoS$_2$ and these different substrates varies from 5% to 16%. c-Al$_2$O$_3$, LaAlO$_3$, SrLaAlO$_4$ are noted to induce tensile strain whereas SrTiO$_3$ and MgO cause compressive strain in MoS$_2$ thin film. Interestingly, Raman and X-ray Photoelectron spectroscopy reveal much enhanced and stable 1T phase contribution in MoS$_2$ thin films grown on SrTiO$_3$ and SrLaAlO$_4$ substrates. The X-ray diffraction, X-ray reflectivity, and atomic force microscopy data reveal high crystalline quality of MoS$_2$ thin films. The most enhanced 1T phase film of MoS$_2$ is noted in the case of the film grown on SrLaAlO$_4$, which also shows a reduction in room temperature resistivity and semi-metal behavior. The valence band spectroscopy (VBS) data for this case are also consistent with the expected metal-like nature of the 1T phase MoS$_2$ thin film. Furthermore, while increasing the thickness, structural transition from mixed 1T/2H phase to pure 2H hexagonal phase is observed; a consequence of strain relaxation, which clearly establishes the role of substrate-induced strain in 1T phase stabilization via octahedral rotation. This study will pave the way for making the vast family of transition-metal chalcogenides tetragonal phase thin films and brings out the potential of 1T phase thin film for unfolding phenomenon and technological applications.

Pulsed Laser Deposition of Two-Dimensional Materials

Denys Miakota$^1$, Huu Phuoc Le$^1$, Yu-Chuan Lin$^2$, Raymond R. Unocic$^2$, Fabian Bertoldo$^1$, Kristian Thygesen$^1$, Alexander Puretzky$^2$, Ilia N Ivanov$^2$, Jorgen Schou$^1$, David B. Geohegan$^2$ and Stela Canulescu$^1$; $^1$Technical University of Denmark, Denmark; $^2$Oak Ridge National Laboratory, United States

Two-dimensional of transition metal dichalcogenides (2D-TMDCs) stand out from the class of 2D materials due to their appealing properties, including atomic-scale thickness, direct band gap and strong spin-orbit coupling. The precise control of the atomic layer structure can pave new avenues for the integration of TMDCs in future optoelectronic devices, such as light-emitting diodes and van der Waals photovoltaics. In this paper, we present our recent progress on the growth of 2D-TMDCs including MoS$_2$, WS$_2$, MoSe$_2$ and their alloys, by a bottom-up approach, namely Pulsed Laser Deposition (PLD). PLD is a well-established technique for the growth of functional oxide structures$^1$ and superlattices$^2$. It relies on vapor-phase transfer of a material from a target to substrate$^3$. Furthermore, this catalyst-free approach has recently been used for the growth of layered TMDCs$^4$. Nevertheless, the optoelectronic properties of 2D-TMDCs, particularly photoluminescence (PL) emission, are often poor. A good control of the chalcogenide vacancies at the monolayer limit is important to realize the full potential of 2D materials and their heterostructures in devices. In this paper we will discuss the PLD-synthesis of large area, crystalline 2D-TMDCs on sapphire and SiO$_2$/Si. PLD synthesis at high temperature (~600$^\circ$C and above) using this one-step approach results in the formation of continuous monolayers with grain boundaries, as compared to the triangular-shaped structures, specific to the chemical vapor deposition process. We profile the vacancy concentration in MoS$_2$ monolayer on an atomic scale using annular-dark-field electron microscopy, with an absolute detection sensitivity of one to two sulfur vacancies. A rich variety of defects, including single and double sulfur vacancies, anti-site defects, as well as grain boundaries with periodic rings 8-4-4- rings defects are revealed. Room temperature PL spectra of MoS$_2$ monolayer exhibit two-distinct exciton peaks that can be used to qualitatively assess the as-grown monolayers. Finally, we will discuss the PLD growth of 2D materials using chalcogen-enriched targets as a path towards defect engineering of 2D materials.

Spatial and Temporal Imaging of Exciton Transport in Two-Dimensional Heterostructures Libai Huang; Purdue University, United States

Charge-transfer (CT) excitons at hetero-interfaces play a critical role in light to electricity conversion using nanostructured materials. However, how CT excitons migrate at these interfaces is poorly understood. Atomically thin and two-dimensional (2D) nanostructures provide a new platform to create architectures with sharp interfaces for directing interfacial charge transport. Here we investigate the formation and transport of interlayer CT excitons in van der Waals (vdW) heterostructures based on semiconducting transition metal dichalcogenides (TMDCs) employing transient absorption microscopy (TAM) with a temporal resolution of 200 fs and spatial precision of 50 nm.

We have recently imaged the transport of interlayer CT excitons in 2D organic-inorganic vdW heterostructures constructed from WS₂ layers and tetracene thin films. To investigate driving force for exciton dissociation, we perform measurements on heterostructures constructed with different WS₂ thickness ranging from 1 layer to 7 layers. Photoluminescence (PL) measurements confirm the formation of interlayer excitons with a binding energy of ~ 0.3 eV. Electron and hole transfer processes at the interface between monolayer WS₂ and tetracene thin film are very rapid, with time constant of ~ 2 ps and ~ 3 ps, respectively. TAM measurements of exciton transport at these 2D interfaces reveal coexistence of delocalized and localized CT excitons, with diffusion constant of ~ 1 cm²s⁻¹ and ~ 0.04 cm²s⁻¹, respectively. The high mobility of the delocalized CT excitons could be the key factor to overcome large CT exciton binding energy in achieving efficient charge separation.

We have also investigated interlayer exciton dynamics and transport modulated by the moiré potentials in WS₂-WSe₂ heterobilayers in time, space, and momentum domains using transient absorption microscopy combined with first-principles calculations. Experimental results verified the theoretical prediction of energetically favorable K-Q interlayer excitons and unraveled exciton-population dynamics that was controlled by the twist-angle-dependent energy difference between the K-Q and K-K excitons. Spatially- and temporally-resolved exciton-population imaging directly visualizes exciton localization by twist-angle-dependent moiré potentials of ~100 meV. Exciton transport deviates significantly from normal diffusion due to the interplay between the moiré potentials and strong many-body interactions, leading to exciton-density- and twist-angle-dependent diffusion length. These results have important implications for designing vdW heterostructures for exciton and spin transport as well as for quantum communication applications.

Stable Long-Range Diffusion of Photocarriers in 2D MoS₂ Injected by 0D Charge Sources Ilka Kriegel¹, Michele Ghini¹, Nicholas Borys², Kehao Zhang³, Adam W. Jansons⁶, Brandon M. Crockett⁶, Kristopher W. Koskela⁶, Edward S.
We present stable long-range diffusion of photocarriers in an innovative 0D-2D heterostructure through contactless all solid state photodoping. We implement 0D indium tin oxide nanocrystals (ITO NCs) as light-driven charge injection sources for localized contactless injection of carriers into the underlying monolayer of molybdenum disulfide (2D MoS2). This technique gives us the opportunity to follow carrier diffusion in the 2D transition metal dichalcogenide without the need of invasive and broad physical contacts. With light beyond the bandgap we locally excite the nanocrystals within a diffraction limited excitation spot, promoting electrons from the valence band to the conduction band of ITO. The photogenerated holes spontaneously transfer to the underlying 2D material with charge injection densities comparable to p-type doping in electronically gated MoS2 samples (in the range of 6 \times 10^{12} \text{cm}^{-2}). We collect hyperspectral maps of the 0D-2D hybrid, before and after light-driven charge injection to spatially resolve variations in the emission of the monolayer MoS2. We observe a blue-shift of more than 35 meV of the photoluminescence peak energy and a significant variation in the relative contribution of excitons and trions to the emission, as a consequence of the annihilation of negatively charged excitons. Remarkably, the injected carriers diffuse tens of microns through the monolayer, covering long distances away from the local micron sized excitation spot. The excited holes accumulate preferably in regions that are initially higher in n-doping and preferentially along edges and grain boundaries, following the initial local electronic landscape of the two-dimensional layer. The comparison between hyperspectral maps collected immediately after the photodoping and after months shows no significant variation in the photoluminescence, indicating that the photodoping process is irreversible and stable up to, at least, 73 days. These works demonstrate a new possibility to remotely and locally dope two-dimensional transition metal dichalcogenides in a contact-less way. The accumulation of carriers in specific regions of the monolayer, as observed by us, might play an important role in unveiling the contributions of structural defects, vacancies and strain to the optical properties of 2D materials and in the same time open novel design principles for future applications in the field of energy storage and contactless light-driven nanoelectronics.

Quasiparticle Electronic Structure, Exciton and Optical Absorption of Atomically Thin Blue Phosphorus
Ju Zhou, Tian-Yi Cai and Sheng Ju; Soochow University, China

Two-dimensional (2D) van der Waals layered materials have attracted wide interest in condensed matter physics, materials, chemistry and engineering. For allotropes of phosphorus, besides black phosphorus with narrow band gap, a single layered phosphorus with bulked honeycomb structure and wide band gap was studied recently and was called blue phosphorus. Here, by considering many-body effects arising from strong electron-electron and electron-hole interactions in low-dimensional systems, we have studied the electronic and optical properties of 2D blue phosphorus. The intrinsic indirect quasiparticle band gap is 3.76 eV, with a sharp bright and strongly bound exciton located at 2.85 eV, with a binding energy of 0.9 eV. By applying the isotropic strain within 6%, the 1s exciton could be tuned effectively from 2.4 eV to 3.2 eV. In addition, the band topology and winding numbers have been illustrated, explaining the existence of p-like excitons with relatively high oscillator strength. Given recent advances in the successful production of two-dimensional blue phosphorus crystals, we expect them to be profoundly applied in sensor, solar, and lighting technologies.

Correlative Mapping of Photonic Properties in 2D Semiconductor-Based Optoelectronics
Timothy Ismael1, Kazi Islam1, Nathan Grinalds2 and Matthew Escarra1; 1Tulane University, United States; 2High Point University, United States

A variety of techniques have proven to be important in characterizing the optical and electronic properties of atomically thin transition metal dichalcogenides (TMDs). Among these two-dimensional (2D) materials, molybdenum disulfide (MoS2) is considered a good candidate for applications in optoelectronics and photovoltaics. However, predicted device performance is significantly affected by localized defects such as grain boundaries and non-uniformity in large-area films, including regions with varying number of atomic layers. Improvement of techniques for spatially localized investigation of these materials will help accelerate device development from these materials. In this work, we demonstrate an optical microscope setup capable of transmittance, photoluminescence (PL), and photocurrent spectroscopy with ~1 μm spatial resolution. This spectral-spatial mapping of 2D materials is shown for the visible and near-infrared part of the spectrum. By correlating each of these measurements over the same material and device region, we can draw connections between material properties and device performance. We do this by studying optoelectronic and photovoltaic (PV) devices fabricated on chemical vapor-deposition (CVD) grown MoS2 samples. We concurrently

2020 MRS Virtual Spring/Fall Meeting, November 27-December 4, 2020, Spring Abstracts Final Program 2/3/21
measure the fundamental properties of various excitons, e.g. transmission at the A, B and C peaks, and identify spatial regions of peak photoreponsivity leading to efficient photocurrent generation in MoS2 photodetectors. Our light source is a supercontinuum laser (Fianium/NKT Photonics) with laser line tunable filter, facilitating wavelength dependent excitation and optical studies of our MoS2. PL mapping of MoS2 flakes and films within the device active area is carried out by exciting single and few-layer thick MoS2 samples with a monochromatic 532 nm excitation; emitted PL is measured using an Ocean Optics QePro spectrometer. Transmittance measurements are carried out with Thorlabs FDS1010-CAL calibrated photodiode mounted 1mm beneath the sample on a transparent stage. Device photocurrent is measured using a Keithley 2450 sourcemeter.

While each technique individually yields insightful information on the uniformity and properties of the 2D material, the integrated setup enables spatial correlation of properties as they relate to the performance of 2D PV, photodetectors, and other optoelectronics. From correlated PL and transmission measurements we extract absorption and photogeneration information that enables mapping localized external radiative efficiency. Transmittance measurements probe wavelength dependent absorption and reflectance and their dependence on local defects, while correlated spatial mapping of absorption and photocurrent vs. wavelength reveals the effects on carrier collection and device performance resulting from material uniformity, contact choice, grain boundaries, surface treatments, and defects. Localized layering of materials is visualized through mapping PL intensity and percentage transmittance. We are using this correlative mapping of photonic properties to better understand, design, model, and prototype advanced optoelectronics from 2D materials.

Emerging Two-Dimensional Materials for Memory and Sensing Applications Han Wang; University of Southern California, United States

In this talk, I will discuss our recent research progress in understanding the electronic, photonic and ferroelectric properties of emerging low-dimensional materials, and in developing them for sensing and memory applications. The first part of the talk will focus on discussing the basic properties of emerging 2D materials such as black phosphorus and our progress in developing the material for mid-infrared optoelectronics application. I will also discuss our work on utilizing 4-dimensional imaging techniques to study carrier dynamics in two-dimensional materials, including a study using the newly developed scanning ultrafast electron microscopy (SUERM) technique to image the photo-carrier transport in black phosphorus. In the second part of the talk, I will discuss our recent research on the ferroelectric monolayer materials for memory device applications. I will conclude with remarks on promising future research directions of low-dimensional material properties and devices, and how the emerging materials may benefit future generations of electronics and photonics technology in sensing and memory.

Quasi-1D TiS3 Nanoribbons—Mechanical Exfoliation, Thickness-Dependent Raman Spectroscopy and Device Prospects Michael J. Loes, Alexey Lipatov, Haidong Lu, Jun Dai, Nataliia Vorobeva, Xiao Cheng Zeng, Alexei Gruverman, Peter Dowben and Alexander Sinitskii; University of Nebraska - Lincoln, United States
Two-dimensional layered materials have received much interest in recent years due to their ease of miniaturization by mechanical exfoliation along with strong light-matter interactions and tunable electronic properties. Quasi-one-dimensional (Quasi-1D) materials, however, have seen considerably less interest, but can express many of the same desirable properties as conventional layered materials, with an added dimension of anisotropy. A representative example of this Quasi-1D subclass is Titanium Trisulfide (TiS₃). We demonstrate similar ease of mechanical exfoliation of TiS₃ accompanied with theoretical calculations and show that these materials exfoliate into few-atomic-layer nanoribbons with very smooth edges. We emulated macroscopic exfoliation experiments on the nanoscale by applying a local shear force to TiS₃ crystals in different crystallographic directions using a tip of an atomic force microscopy (AFM) probe. In the AFM experiments, it was possible to slide the 2D TiS₃ layers relative to each other as well as to remove selected 1D chains from the layers. Further, their characterization by Raman spectroscopy shows a reliable, internally standardized shift of a few cm⁻¹ from monolayer to bulk demonstrating tunability typical of conventional layered materials. Devices made from this material show promising electronic properties with predicted mobilities in excess of 10,000 cm²V⁻¹s⁻¹ with low edge-scattering, as well as in optoelectronics with strong light-matter interactions, particularly along the crystallographic b-axis (anisotropic). Orientation-dependent properties of this nature show promise as filters and polarizers, while high surface areas associated with 2D materials hint towards gas-sensing and energy storage applications.

2:10 PM S.NM06.09.02
Encapsulation and Transfer Schemes for Epitaxial Xenes Deepyanti Taneja¹, Gabriele Faraone²,³, Md. Hasibul Alam¹, Christian Martella², Carlo Grazianetti², Emiliano Bonera³, Alessandro Molle² and Deji Akinwande¹; ¹The University of Texas at Austin, United States; ²CNR IMM, Unit of Agrate Brianza, Italy; ³Università degli Studi di Milano-Bicocca, Italy

Epitaxial Xenes are an emerging class of two-dimensional crystals made of elements spanning group III to group VI of the periodic table (e.g. borophene, silicene, phosphorene, antimomene, tellurene etc) [1]. These materials are synthesized by epitaxy on various substrates and are subject to degradation in environmental conditions. Our work is centered around Xenes grown on noble metal surfaces that are supported by mica, as they can readily undergo delamination and transfer on other substrates for device related studies. In particular, we focus on silicene-on-silver [2] and epitaxial phosphorene [3] as representative cases to establish a stabilization and transfer scheme. Encapsulation of the unstable Xenes is a critical step for achieving transfer of the Xene layer from its pristine growth substrate to a device or functional substrate. We propose the use of an Al₂O₃ encapsulation as a stabilization strategy that can be universally applied to the whole class of Xenes. The integrity of the Xene layer after encapsulation is validated by means of Raman spectroscopy and X-ray photoelectron spectroscopy. We then propose a few different transfer schemes and present experimental results of film transfer. A technical step in the delamination and transfer process is the time-controlled etching of the metal substrate. We achieve this using an optimized KI/I₂ silver etchant with a controllable etch rate. Finally, we demonstrate the stability of air-exposed multilayer silicene, prepared using our developed methods, via Raman spectroscopy, validating our successive delamination and transfer protocol.

Improving the Electrical Performance of MoS₂ Transistors Using Tensile Strain Isha Datye¹, Alwin Daus¹, Kevin Brenner¹,², Ryan W. Grady¹ and Eric Pop¹; ¹Stanford University, United States; ²Southern Methodist University, United States

Transition metal dichalcogenides (TMDs) such as molybdenum disulfide (MoS₂) have gained much interest for scaled nanoelectronics, but their mobilities and drive currents must be improved in order to compete with existing technologies. Theoretical studies predict that tensile strain can increase the mobility of TMDs due to changes in band structure, leading to reduced intervalley scattering [1]. However, such mobility improvement has not yet been experimentally demonstrated. In this work, we utilize uniaxial tensile strain to improve the electrical performance of monolayer (1L) MoS₂ transistors on flexible substrates. Using a two-point bending apparatus, we apply multiple strain levels between 0% and ~0.7%, which we estimate from the curvature radius of the bent substrates. We confirm these strain levels by Raman spectroscopy, using the known red-shift of the MoS₂ in-plane E’ Raman peak of ~2 cm⁻¹ per percent of tensile strain [2]. We fabricate our devices on polyethylene naphthalate (PEN) flexible substrates. First, the gate metal is lithographically patterned, and then we form the gate dielectric with ~20 nm of Al₂O₃ by atomic layer deposition (ALD). Monolayer
MoS2 grown by chemical vapor deposition (CVD) on separate SiO2/Si substrates [3] is then transferred to the flexible substrates using a polymer scaffold [4]. Finally, we pattern source and drain contacts onto the MoS2 films, followed by an O2 plasma etch to define the channels.

We characterize the effects of tensile strain on MoS2 transistors with channel lengths from 1 to 15 μm, by extracting the field-effect mobility. Relatively long channels are used to limit extrinsic contributions of contact resistance. We obtain a continuous mobility improvement up to ~85% with increasing tensile strain up to ~0.7%, leading to a drain current $I_D$ increase of ~2x at the same carrier density. Furthermore, we find that the effects are fully reversible as the device characteristics return to their initial state after strain release. The mobility increase with tensile strain also indicates that these devices could be used as strain sensors. An $I_D$ change of ~2x at 0.7% strain corresponds to a gauge factor of nearly ~150, which is the highest value reported so far for piezoresistive 1L CVD MoS2 strain sensors [5-6].

These results demonstrate the largest mobility and on-state current improvements to MoS2 transistors using strain to date, revealing that strain engineering is a promising way to tune the electrical performance of TMD-based devices. Furthermore, using MoS2 transistors as strain sensors can facilitate the realization of flexible and transparent sensor systems for strain mapping.

jumps in frequency which do not appear in monolayer resonators. We find the magnitude of the frequency jumps follows a simple model for changes in stress due to the dynamics of solitons at the interface. Moreover, we find enhanced structural dissipation in twisted 2D interfaces due to the inelastic sliding between layers. Finally, we examine the evolution of buckle and fold instabilities in 2D membranes and heterostructures under compression, and examine the behavior of stretchable electronics made from crumpled 2D heterostructure devices.

Taken together, these experiments show that interfacial slip strongly impacts the mechanics of 2D materials and heterostructures and leads to membranes which are orders of magnitude more deformable than conventional 3D materials.

Structural Damping in Superlubric Twisted Bilayer Graphene Resonators Paolo F. Ferrari, SunPhil Kim and Arend M. van der Zande; University of Illinois at Urbana-Champaign, United States

A major drawback in shrinking down mechanical components to the nanoscale is the excessive dissipation coming from friction at contacting surfaces. A physical regime where this could be substantially avoided is structural superlubricity, wherein an atomically flat and incommensurate van der Waals interface will lead to ultra-low coefficients of friction of $<0.001$, less than $1\%$ of conventional interfaces. Superlubricity has been experimentally observed via scanning probe measurements of 2D material surfaces, as well as in static sliding of twisted bilayer graphene [1,2] and heterostructure interfaces [3,4]. Moreover, many theoretical studies have predicted and proposed superlubricity in a variety of systems. Yet, nearly three decades after being predicted, superlubric behavior has not been demonstrated in a nanoelectromechanical system, nor has the energy dissipation from superlubric friction ever been directly measured.

In this study, we directly probe the dissipation due to incommensurate interfaces by engineering and comparing mechanical drumhead resonators made from twisted (incommensurate) bilayer, Bernal-stacked (commensurate) bilayer, and monolayer graphene. Because of the ultra-low mass of graphene, the total energy in the resonators is orders of magnitude less than in conventional MEMS systems, making their response extraordinarily sensitive to changes in the energy dissipation. We find that the incommensurate bilayer graphene resonators have damping coefficients more than twice that of the commensurate counterparts. The extra dissipation in the twisted interface is well described by a structural damping model common in macroscale vibrating components arising from small slips at mechanical joints [5,6]. In the twisted bilayer graphene, the damping arises from inelastic sliding between layers during vibration. From this structural damping model, we extract an upper limit for the interlayer friction stress to be 0.86 mN/m, in good agreement with the reported value obtained in static measurements of interlayer sliding [2]. Additionally, by measuring the mechanical quality factor versus temperature, we observe that friction decreases with decreasing temperature, down to a value $< 0.1$ mN/m, in agreement with theoretical predictions of a phonon limiting mechanism for superlubric friction. These results unveil the important role of the superlubric interface in mechanical dissipation and provides a principle for designing nanoelectromechanical systems with 2D heterostructures.

3:10 PM S.NM06.04.04
Mechanical Behavior of Strain Engineered Transition Metal Dichalcogenides for Phase Change Transistors Shoieb Ahmed Chowdhury, Ahmad Azizimanesh, Stephen Wu and Hesam Askari; University of Rochester, United States
Switching mechanism in transistors based on transformation of transition metal dichalcogenides (TMD) between semiconducting and semi-metallic phases may offer superior performance by eliminating static and dynamic power consumption problems associated with scaling of conventional field effect transistors. It has been shown recently that the transformation between semi-metallic TMD 1T'-MoTe₂ and semiconducting MoTe₂ using nanoscale strain engineering results in such switching behavior at device scale. Since strain is the key factor in controlling such electrical properties in these multilayer materials, we use a combination of modelling and experimental approaches to examine and quantify the efficiency of strain transfer in multilayer TMDs and how strain is tied to electrical properties. In this study, molecular dynamics (MD) models are used to predict properties of both monolayer and multilayer structured TMDs under different mechanical loading such as uniaxial, biaxial strain, and nanoindentation. Using the reactive empirical bond order (REBO) potential available in literature along with local structural identification methods such as polyhedral template matching, phase transformation behavior is studied under mechanical loading. Additionally, nanoindentation is used for experimental measurement of properties of different structure types of TMDs (2H and 1T') for verifying, as well as developing, interlayer van der Waals interaction parameters for atomistic models. Results from the atomistic model coupled with experimental observations using optical microscopy and Raman spectroscopy reveals the mechanism of strain transfer at device scale and its efficiency in various setups.

Atomic Electrostatic Maps of Defect Structures in 2D TMDs Yi Wen¹, Colin Ophus², Christopher S. Allen¹,³, Shiang Fang¹,⁴, Efthimios Kaxiras⁴,⁵, Angus I. Kirkland¹,² and Jamie Warner¹; ¹University of Oxford, United Kingdom; ²National Center for Electron Microscopy, Molecular Foundry, Lawrence Berkeley National Laboratory, United States; ³Electron Physical Sciences Imaging Center, Diamond Light Source Ltd., United Kingdom; ⁴Harvard University, United States

The atomic scale studies on the pristine lattice of TMDs have been carried out with aid from aberration-corrected (scanning) transmission electron microscope (AC-(S)TEM), enabling detailed studies on the evolution of atomic scale defect structures, but their perturbation on local electronic properties, which is essential for understanding their functionality in electronic and optoelectronic devices, are not readily available from direct imaging. Here, we reported the detailed analysis on adatoms, vacancies, line defects, nanopores, nanowires and edge structures in MoS₂ and WS₂ using 4D STEM, which record not only the scattering information, but also the direct beam, and this allows us to extract phase shift, atomic electric field and charge density map based on the shift of center of mass of direct beam.¹ We showed that the electric field map and phase reconstructed imaging are sensitive in detection of abnormal 1D states² and low atomic number atoms,³ and together provide a comprehensive anatomy on the electronic properties of these defect structures, which is of great importance for the theoretical study of 2D electronic devices.

Atomic Structure and Dynamics of Defects and Grain Boundaries in 2D Pd₂Se₃ Monolayers Jun Chen and Jamie Warner; Department of Materials, University of Oxford, United Kingdom

We report the distinctive defect structures and electron-driven dynamics of a novel 2D monolayer Pd₂Se₃ at the atomic level, which is controllably produced from restructuring few-layered PdSe₃ by thermal stimulation at an in-situ heating stage in scanning transmission electron microscopy (STEM). A rich variety of point vacancies, one-dimensional defects, grain boundaries (GBs) and defect ring complex, which are distinctly different from those in typical transition metal chalcogenides,
are directly observed on monolayer Pd$_2$Se$_3$. The self-healing point vacancies, gradually consumed edges, and the fast-evolved peculiar defect complex and voids suggest the high mobility of the Se vacancies mobility under electron beam. Multiple unique defects without losing atoms are rendered by the behaviours of special covalent Se−Se dumbbells, which can elastically shift in a staggered way to buffer strains, forming the wave-like one-dimensional defects, and can also undergo Stone-Wales bond rotations which constitute the significant defect behaviour in Pd$_2$Se$_3$. The GBs can flexibly form in a meandering pathway and migrate by a sequence of Se−Se bond rotations without vacancies formation, and in the GB-rich corners and tilt GBs, the other highly symmetric vacancy-involved defects also occur to adapt to orientation turning. This report gives insights into the novel defects in new 2D materials featuring high adaptability, rich diversity and dynamics, which opens up more possibilities for exploiting versatile properties of new 2D material systems.

5:20 AM S.NM06.01.04
Structure/Function of MoS$_2$ Thin Films by Atom Probe Tomography and Beyond

Manuel A. Ramos¹, Oscar Alberto López Galán¹, John Nogan², Carlos Ornelas³, Abel Hurtado-Macias³, Torben Boll¹, Jose L. Enríquez Carrejo¹ and Martin Heilmaier¹; ¹Universidad Autonoma de Ciudad Juarez, Mexico; ²Center for Integration of Nanotechnologies, United States; ³Centro de Investigaciones en Materiales Avanzados, Mexico; ⁴Karlsruhe Institute of Technology, Germany

We present experimental evidence of extensive characterization for MoS$_2$ thin films. Our findings include: in-situ oxidation by induced Raman spectroscopy, scanning electron microscopy and grazing incidence x-ray diffraction and atom probe tomography. Results indicate Results confirm that nanowires plated shape with the 110-orientation are aligned perpendicular to the film substrate principal reflections at (002), (100), (101), (201), and Raman spectroscopy vibrational modes at E$_{12g}$ at 378 cm$^{-1}$ and A$_{1g}$ at 407 cm$^{-1}$ correspond to 2H-MoS$_2$. APT reveals MoS$^{2+}$, MoS$^{3+}$ as predominant evaporated molecular ions on the sample, indicating no significant diffusion/segregation of Mo or S species within the ITO layer in correlation with STEM measurements. Mechanical properties indicate a harness value of 10 GPa and elastic modulus value of 136 GPa. Finally, some density functional theory calculations reveal honey-comb superlattices can possess ultra-rapid transitions from semiconducting to metallic as reported previously.

5:30 AM S.NM06.01.05

Hwanhui Yun, Supriya Ghosh, Prafful Golani, Steven Koester and K. Andre Mkhoyan; University of Minnesota, United States

Black arsenic (bAs) is a two-dimensional layered material with similar atomic structures to black phosphorus (bP), and it is expected to exhibit attractive number of layers, etc. [1]. Despite the theoretical predictions, it has only recently gained attention due to difficulties in synthesis of high-quality bAs [2]. Recent experimental reports have shown intriguing nature of bAs including high anisotropy [1,3]. Here, we explore the atomic and electronic structures of exfoliated high-quality bAs using high-angle annular dark-field (HAADF)-scanning transmission electron microscopy (STEM) imaging and spectroscopy and demonstrate changes in optical properties in few-layered bAs. Additionally, a stability study on bAs is conducted to gain insight on the key parameters affecting bAs at ambient conditions.

STEM experiments were carried out using an FEI Titan G2 60-300 (S)TEM at 200 keV equipped with energy dispersive X-ray (EDX) and monochromated electron energy-loss spectroscopy (EELS). HAADF-STEM image simulation was carried out using the TEMSIM code based on the Multislice approach [4,5]. Atomic resolution HAADF-STEM images of bulk bAs were obtained from five different orientations including three major crystallographic directions - armchair direction (x-axis), zigzag direction (y-axis), and plan-view direction (z-axis) - confirming anisotropic atomic structures of bAs. Plan-view images were also obtained from few-layered bAs and compared with simulated images that are computed as a function of the number of layers, by which the thickness of the examined layers was measured precisely. The electronic structure of bAs was investigated by using EELS. Low-loss EELS reveals bulk and surface plasma excitation energies and interband transitions, and characteristics of core-loss EELS are described. Low-loss EELS spectra are then acquired as a function of the number of bAs layers and evidence the changes in optical properties in few-layered bAs from bulk bAs. Lastly, degradation of bAs accompanying structure change is analyzed using HAADF-STEM, EDX, and diffraction pattern of specimens. The effect of air, i.e. O$_2$, and water on the degradation is further investigated and discussed.

Two-dimensional (2D) materials and heterostructures are promising systems for soft robotics, deformable electronics, and nanoelectromechanical systems because they combine the high charge carrier mobilities of hard materials with the pliability of soft materials. Understanding their bending properties is crucial for the development of these next-generation devices. However, experimental measurements of bending stiffness in 2D materials have been widely divergent; for example, the reported bending stiffnesses of bilayer and trilayer graphene range from 3.4-160 eV and 7-690 eV, respectively [1-3]. Even less is known about the bending stiffness of 2D heterostructures. Here, we show that electron microscopy can provide a powerful platform for measuring the bending properties of 2D materials. We use aberration-corrected scanning transmission electron microscopy (STEM) to image graphene and 2D heterostructures draped over a series of atomically sharp hexagonal boron nitride steps. This approach enables atomic-resolution studies of their bending conformation, producing insight into both the bending stiffness and mechanisms of bending. In combination with density functional theory (DFT) and continuum mechanics modeling, we derive a unifying model for bending in 2D materials and their heterostructures.

First, we investigated the bending stiffness of single and few-layer graphene [4]. We derive mechanical models that relate the bending stiffness to geometric parameters—such as the radius of curvature, bending angle, and step height—measured directly from STEM images. For monolayer graphene, we obtain bending stiffness values of 1.2-1.7 eV, consistent with DFT predictions [5] and the experimental value of 1.2 eV derived from graphite phonon modes [6]. In multilayer graphene, we find that the bending stiffness varies strongly as a function of bending angle, tuning by almost 400% for trilayer graphene. For ten-layer graphene, we show that the bending stiffness can be as low as 18 eV, three orders of magnitude lower than the bending stiffness predicted by conventional thin-film mechanics. This unusual behavior results from the atomic-scale bending mechanism in 2D multilayers, which is dominated by interlayer shear and slip.

Our findings have profound implications on 2D heterostructures, where we demonstrate that the bending stiffness can be controlled by tailoring the interfacial interactions between vertical homo- and heterointerfaces. We investigated heterostructures and showed that, by simply changing their stacking order, we can dramatically tune their bending stiffnesses. Using a combination of DFT and classical simulations, we produce a model to predict the bending stiffness of arbitrary 2D heterostructures. Together, our results provide a new lower limit of bending stiffness for the fabrication of ultrasoft, high mobility electronics and demonstrate new methods to fabricate 2D heterostructures with tailored bending stiffnesses.

References:
to low friction and low interlayer electrical transport. Using our recent nanomanipulation technology, based on atomic force microscopy, we show that combined electro-mechanical characterization can uniquely address open fundamental questions related to the dielectric interlayer interactions and electronic charge transport through stacking faulted structures.

In addition, we studied experimentally and theoretically the interlayer charge transport in twisted bilayer graphene systems separately for edges and bulk parts. We find that interlayer edge currents are several orders of magnitude larger than in the bulk and therefore govern the transport up until very large critical diameters depending on the potential across the adjacent layers.

Collective Manipulation of Gold Nanoclusters on Mono- and Multilayer MoS$_2$
Enrico Gnecco$^1$, Felix Trillitzsch$^1$, Alper Özogul$^1$, Arkadiusz Janas$^2$, Roberto Guerra$^3$ and Franciszek Krok$^2$; $^1$Friedrich Schiller University Jena, Germany; $^2$Jagiellonian University, Poland; $^3$University of Milan, Italy

Apart from being a powerful imaging technique, atomic force microscopy allows a talented user to forge nanostructures out of tiny objects (e.g. metal clusters) deposited and manipulated on atomically flat surfaces. This is important for fundamental investigations in nanotribology as well as for building up conductive networks with potential applications in molecular electronics. Due to the length scales involved, the control over the morphology of these structures remains, nevertheless, very problematic. Generally speaking, one has to distinguish between nanomanipulations performed by displacing the nano-objects one by one in a time-consuming way or collectively. In this talk we will focus on the second case and discuss "scan-induced-assembly" experiments on Au nanoclusters on mono- and multilayer MoS$_2$ aimed to (i) understand if the direction of manipulation can be controlled by a proper choice of the scan pattern, and (ii) using the information so obtained for fabricating structures with a desired morphology, such as long but tiny Au stripes [1,2]. While the first goal could be reached with the motion of the clusters precisely related to the angle of attack of the tip on both mono- and multilayers, this is not (yet) the case with the second goal. On MoS$_2$ monolayers the Au could be indeed rearranged in the form of crumpled stripes with a separation depending on the cluster size and concentration, but the clusters within each stripe remain slightly disconnected, which is possibly due to the roughness of the underlying SiO$_2$ substrate and/or to charge transfer effects. The presentation is supplemented by molecular dynamics simulations reproducing the displacement of single Au clusters on MoS$_2$. Differences with collective manipulation experiments on larger and irregularly shaped Sb islands forming incommensurate contacts with MoS$_2$ [3] will be also discussed.

Spatial and Temporal Imaging of Exciton Transport in Two-Dimensional Heterostructures Libai Huang; Purdue University, United States

Charge-transfer (CT) excitons at hetero-interfaces play a critical role in light to electricity conversion using nanostructured materials. However, how CT excitons migrate at these interfaces is poorly understood. Atomically thin and two-dimensional
(2D) nanostructures provide a new platform to create architectures with sharp interfaces for directing interfacial charge transport. Here we investigate the formation and transport of interlayer CT excitons in van der Waals (vdW) heterostructures based on semiconducting transition metal dichalcogenides (TMDCs) employing transient absorption microscopy (TAM) with a temporal resolution of 200 fs and spatial precision of 50 nm.

We have recently imaged the transport of interlayer CT excitons in 2D organic-inorganic vdW heterostructures constructed from WS$_2$ layers and tetracene thin films. To investigate driving force for exciton dissociation, we perform measurements on heterostructures constructed with different WS$_2$ thickness ranging from 1 layer to 7 layers. Photoluminescence (PL) measurements confirm the formation of interlayer excitons with a binding energy of $\sim 0.3$ eV. Electron and hole transfer processes at the interface between monolayer WS$_2$ and tetracene thin film are very rapid, with time constant of $\sim 2$ ps and $\sim 3$ ps, respectively. TAM measurements of exciton transport at these 2D interfaces reveal coexistence of delocalized and localized CT excitons, with diffusion constant of $\sim 1$ cm$^2$s$^{-1}$ and $\sim 0.04$ cm$^2$s$^{-1}$, respectively. The high mobility of the delocalized CT excitons could be the key factor to overcome large CT exciton binding energy in achieving efficient charge separation.

We have also investigated interlayer exciton dynamics and transport modulated by the moiré potentials in WS$_2$-WSe$_2$ heterobilayers in time, space, and momentum domains using transient absorption microscopy combined with first-principles calculations. Experimental results verified the theoretical prediction of energetically favorable K-Q interlayer excitons and unraveled exciton-population dynamics that was controlled by the twist-angle-dependent energy difference between the K-Q and K-K excitons. Spatially- and temporally-resolved exciton-population imaging directly visualizes exciton localization by twist-angle-dependent moiré potentials of $\sim 100$ meV. Exciton transport deviates significantly from normal diffusion due to the interplay between the moiré potentials and strong many-body interactions, leading to exciton-density- and twist-angle-dependent diffusion length. These results have important implications for designing vdW heterostructures for exciton and spin transport as well as for quantum communication applications.

**Stable Long-Range Diffusion of Photocarriers in 2D MoS$_2$ Injected by 0D Charge Sources** Ilka Kriegel$^{1,2}$, Michele Ghini$^1$, Nicholas Borys$^{3,4}$, Kehao Zhang$^{5,6}$, Adam W. Jansons$^6$, Brandon M. Crockett$^6$, Kristopher W. Koskela$^4$, Edward S. Barnard$^5$, Erika Penzo$^2$, James E. Hutchison$^6$, Joshua A. Robinson$^{5,6}$, Liberato Manna$^1$ and P James Schuck$^3$; 1Italian Institute of Technology, Italy; 2Lawrence Berkeley National Laboratory, United States; 3Columbia University, United States; 4Montana State University, United States; 5The Pennsylvania State University, United States; 6University of Oregon, United States

We present stable long-range diffusion of photocarriers in an innovative 0D-2D heterostructure through contactless all solid state photodoping. We implement 0D indium tin oxide nanocrystals (ITO NCs) as light-driven charge injection sources for localized contactless injection of carriers into the underlying monolayer of molybdenum disulfide (2D MoS$_2$). This technique gives us the opportunity to follow carrier diffusion in the 2D transition metal dichalcogenide without the need of invasive and broad physical contacts. With light beyond the bandgap we locally excite the nanocrystals within a diffraction limited excitation spot, promoting electrons from the valence band to the conduction band of ITO. The photogenerated holes spontaneously transfer to the underlying 2D material with charge injection densities comparable to p-type doping in electronically gated MoS$_2$ samples (in the range of 6x10$^{12}$cm$^{-2}$). We collect hyperspectral maps of the 0D-2D hybrid, before and after light-driven charge injection to spatially resolve variations in the emission of the monolayer MoS$_2$. We observe a blue-shift of more than 35 meV of the photoluminescence peak energy and a significant variation in the relative contribution of excitons and trions to the emission, as a consequence of the annihilation of negatively charged excitons. Remarkably, the injected carriers diffuse tens of microns through the monolayer, covering long distances away from the local micron sized excitation spot. The excited holes accumulate preferably in regions that are initially higher in n-doping and preferentially along edges and grain boundaries, following the initial local electronic landscape of the two-dimensional layer. The comparison between hyperspectral maps collected immediately after the photodoping and after months shows no significant variation in the photoluminescence, indicating that the photodoping process is irreversible and stable up to, at least, 73 days. These works demonstrate a new possibility to remotely and locally dope two-dimensional transition metal dichalcogenides in a contact-less way. The accumulation of carriers in specific regions of the monolayer, as observed by us, might play an important role in unveiling the contributions of structural defects, vacancies and strain to the optical properties of 2D materials and in the same time open novel design principles for future applications in the field of energy storage and contactless light-driven nanoelectronics.

**Correlative Mapping of Photonic Properties in 2D Semiconductor-Based Optoelectronics** Timothy Ismael$^1$, Kazi Islam$^1$, Nathan Grinalds$^2$ and Matthew Escarra$^1$; 1Tulane University, United States; 2High Point University, United States
A variety of techniques have proven to be important in characterizing the optical and electronic properties of atomically thin transition metal dichalcogenides (TMDCs). Among these two-dimensional (2D) materials, molybdenum disulfide (MoS$_2$) is considered a good candidate for applications in optoelectronics and photovoltaics. However, predicted device performance is significantly affected by localized defects such as grain boundaries and non-uniformity in large-area films, including regions with varying number of atomic layers. Improvement of techniques for spatially localized investigation of these materials will help accelerate device development from these materials.

In this work, we demonstrate an optical microscope setup capable of transmittance, photoluminescence (PL), and photocurrent spectroscopy with ~1 μm spatial resolution. This spatial-spectral mapping of 2D materials is shown for the visible and near-infrared part of the spectrum. By correlating each of these measurements over the same material and device region, we can draw connections between material properties and device performance. We do this by studying optoelectronic and photovoltaic (PV) devices fabricated on chemical vapor-deposition (CVD) grown MoS$_2$ samples. We concurrently measure the fundamental properties of various excitons, e.g. transmission at the A, B and C peaks, and identify spatial regions of peak photoresponsivity leading to efficient photocurrent generation in MoS$_2$ photodetectors.

Our light source is a supercontinuum laser (Fianium/NKT Photonics) with laser line tunable filter, facilitating wavelength dependent excitation and optical studies of our MoS$_2$. PL mapping of MoS$_2$ flakes and films within the device active area is carried out by exciting single and few-layer thick MoS$_2$ samples with a monochromatic 532 nm excitation; emitted PL is measured using an Ocean Optics QePro spectrometer. Transmittance measurements are carried out with Thorlabs FDS1010-CAL calibrated photodiode mounted 1mm beneath the sample on a transparent stage. Device photocurrent is measured using a Keithley 2450 sourcemeter.

While each technique individually yields insightful information on the uniformity and properties of the 2D material, the integrated setup enables spatial correlation of properties as they relate to the performance of 2D PV, photodetectors, and other optoelectronics. From correlated PL and transmission measurements we extract absorption and photogeneration information that enables mapping localized external radiative efficiency. Transmittance measurements probe wavelength dependent absorption and reflectance and their dependence on local defects, while correlated spatial mapping of absorption and photocurrent vs. wavelength reveals the effects on carrier collection and device performance resulting from material uniformity, contact choice, grain boundaries, surface treatments, and defects. Localized layering of materials is visualized through mapping PL intensity and percentage transmittance. We are using this correlative mapping of photonic properties to better understand, design, model, and prototype advanced optoelectronics from 2D materials.

Quasiparticle Electronic Structure, Exciton and Optical Absorption of Atomically Thin Blue Phosphorus
Ju Zhou, Tian-Yi Cai and Sheng Ju; Soochow University, China

Two-dimensional (2D) van der Waals layered materials have attracted wide interest in condensed matter physics, materials, chemistry and engineering. For allotropes of phosphorus, besides black phosphorus with narrow band gap, a single layered phosphorus with bulked honeycomb structure and wide band gap was studied recently and was called blue phosphorus. Here, by considering many-body effects arising from strong electron-electron and electron-hole interactions in low-dimensional systems, we have studied the electronic and optical properties of 2D blue phosphorus. The intrinsic indirect quasiparticle band gap is 3.76 eV, with a sharp bright and strongly bound exciton located at 2.85 eV, with a binding energy of 0.9 eV. By applying the isotropic strain within 6%, the 1s exciton could be tuned effectively from 2.4 eV to 3.2 eV. In addition, the band topology and winding numbers have been illustrated, explaining the existence of $p$-like excitons with relatively high oscillator strength. Given recent advances in the successful production of two-dimensional blue phosphorus crystals, we expect them to be profoundly applied in sensor, solar, and lighting technologies.
specific conductivity wiring [1], chemiresitive sensors [2], nanoscale strain gauges, and nanoelectromechanical systems. Despite considerable experimental and computational research, understanding of electromechanical coupling effects in GNR is limited. Recent computational research [3] has developed a general description of electron transmission along circular arcs in semiconducting (3M-1) aGNRs. The computational results suggest that: (1) length and total rotation (along a circular arc) are orthogonal generalized coordinates which determine the resistance of a semiconducting nanowire, (2) the ratio of the curved GNR conductance to that of a corresponding flat nanowire is a linear function of the total rotation over a wide operating range, and (3) at low rotations, the current in a curved GNR can exceed that of a corresponding flat nanowire, due to bandgap effects. The computational results have been shown to be consistent with published data obtained from lifting experiments on 5-aGNRs. An analytical conductance model developed from the computational results generalizes the well known exponential decay law for semiconducting nanowires, and may be applied in the design of experiments and new nanoscale devices.

This work was supported by the Office of Naval Research (Grant N00014-16-2357). Phase and Quantum Confinement Dependent Structural, Electronic and Magnetic Properties of Layered CrTe2 Yuhang Liu1, Hang Chi2,3, Yunbo Ou2, Mahesh R. Neupane3,4, George D. Coster3, Charles Rong3, Patrick Folkes3 and Jagadeesh Moodera2,2; 1University of California, Riverside, United States; 2Massachusetts Institute of Technology, United States; 3CCDC US Army Research Laboratory, United States

CrTe2 is a novel magnetic layered transition metal dichalcogenide that has been recently synthesized in a metastable 1T bulk form [1]. While promising strain-tunable magnetic ordering has been proposed in 1T monolayers [2], detailed theoretical insights into the phase and layer thickness dependent electronic and magnetic properties are imperative [3]. In this work, we have investigated the effect of phase type and quantum confinement on the structural, electronic, and magnetic properties of CrTe2-based systems using first-principle simulations. In the 1T phase, although the inclusion of spin-orbit coupling (SOC) opens up a gap at the K-point in the Brillouin zone, the relaxed structures appear to be insensitive to quantum confinement and maintain metallic from the bulk towards the monolayer limit. This weak metallic behavior is generally consistent with thickness dependent resistivity measurements in the few-monolayer regime on e.g., exfoliated 1T-CrTe2 flakes as recently reported in the literature [4], as well as on our in-house prepared CrTe2-based thin films. The 1H and 2H phases, on the other hand, typically have finite and thickness-tunable energy gaps. Surprisingly, the 1H-CrTe2 is nonmagnetic with a finite gap of 0.3-0.4 eV with thickness ranging from 1 to 5 layers, which becomes ferromagnetic and metallic at and above six layers. These tunable, anomalous electronic and magnetic properties controlled by the layer thickness and phase make the extended family of chromium tellurides a particularly rich and intriguing platform for further exploration of spintronic and topologically enabled devices.

Due to their unparalleled mechanical strength and high electronic mobility, two-dimensional (2D) materials represent the ultimate limit in size for both mechanical atomic membranes and molecular electronics. Bringing these capabilities together make 2D materials and heterostructures promising for emerging technologies like origami robotics, stretchable electronics and mechanically reconfigurable nanoelectromechanical systems. Additionally, many of the most interesting properties of 2D materials and new functionality arise from the interfaces between layers and in engineering multilayer heterostructures. Building an understanding of the mechanics of the van der Waals interface is critical to these next generation devices. In this study, we will examine the role of the van der Waals interface in determining the mechanics of deformation in atomic membranes under bending, stretching, and shear and the impact on the behavior of 2D electromechanical systems. First, we use aberration-corrected scanning transmission electron microscopy to image multilayer graphene and 2D heterostructures draped over a series of atomically sharp hexagonal boron nitride steps and extract. Combining the measurements with atomistic simulations and energy conservation models we extract the bending stiffness over a range of thicknesses and step heights. We find an bending angle and interface orientation dependent bending stiffness. At high bending angles, the bending stiffness scales linearly with the number of layers due to free slip between layers. At low angles, materials made from commensurate interfaces become stiffer, converging to the cubic scaling with thickness predicted from continuum mechanics. In contrast, heterostructures with an incommensurate interface maintain the linear scaling at all bending angles due to the low interfacial friction. By tailoring the ordering of layers within the heterostructure, we demonstrate tuning of the bending stiffness. These results provide a united description for bending in 2D materials which resolve several years of contradictory measurements and enable the design of bending stiffness in 2D heterostructures with mixed commensurate and incommensurate interfaces.

Next, we engineer electromechanical drumhead resonators from 2D membranes such as twisted bilayer graphene, commensurate bilayer graphene and graphene/MoS2 bimorphs. In the commensurate bilayer graphene, we observe discrete jumps in frequency which do not appear in monolayer resonators. We find the magnitude of the frequency jumps follows a simple model for changes in stress due to the dynamics of solitons at the interface. Moreover, we find enhanced structural dissipation in twisted 2D interfaces due to the inelastic sliding between layers. Finally, we examine the evolution of buckle and fold instabilities in 2D membranes and heterostructures under compression, and examine the behavior of stretchable electronics made from crumpled 2D heterostructure devices. Taken together, these experiments show that interfacial slip strongly impacts the mechanics of 2D materials and heterostructures and leads to membranes which are orders of magnitude more deformable than conventional 3D materials.
common in macroscale vibrating components arising from small slips at mechanical joints [5,6]. In the twisted bilayer graphene, the damping arises from inelastic sliding between layers during vibration. From this structural damping model, we extract an upper limit for the interlayer friction stress to be 0.86 mN/m, in good agreement with the reported value obtained in static measurements of interlayer sliding [2]. Additionally, by measuring the mechanical quality factor versus temperature, we observe that friction decreases with decreasing temperature, down to a value < 0.1 mN/m, in agreement with theoretical predictions of a phonon limiting mechanism for superlubric friction. These results unveil the important role of the superlubric interface in mechanical dissipation and provides a principle for designing nanoelectromechanical systems with 2D heterostructures.

Mechanical Behavior of Strain Engineered Transition Metal Dichalcogenides for Phase Change Transistors Shoaeb Ahmed Chowdhury, Ahmad Azizimanesh, Stephen Wu and Hesam Askari; University of Rochester, United States

Switching mechanism in transistors based on transformation of transition metal dichalcogenides (TMD) between semiconducting and semi-metallic phases may offer superior performance by eliminating static and dynamic power consumption problems associated with scaling of conventional field effect transistors. It has been shown recently that the transformation between semi-metallic TMD 1T’-MoTe2 and semiconducting MoTe2 using nanoscale strain engineering results in such switching behavior at device scale. Since strain is the key factor in controlling such electrical properties in these multilayer materials, we use a combination of modelling and experimental approaches to examine and quantify the efficiency of strain transfer in multilayer TMDs and how strain is tied to electrical properties. In this study, molecular dynamics (MD) models are used to predict properties of both monolayer and multilayer structured TMDs under different mechanical loading such as uniaxial, biaxial strain, and nanoindentation. Using the reactive empirical bond order (REBO) potential available in literature along with local structural identification methods such as polyhedral template matching, phase transformation behavior is studied under mechanical loading. Additionally, nanoindentation is used for experimental measurement of properties of different structure types of TMDs (2H and 1T’) for verifying, as well as developing, interlayer van der Waals interaction parameters for atomistic models. Results from the atomistic model coupled with experimental observations using optical microscopy and Raman spectroscopy reveals the mechanism of strain transfer at device scale and its efficiency in various setups.

Lattice Green’s Function for Atomistic Scale Modeling of Strain Field Due to a Vacancy in a 2D Material Vinod K. Tewary and Edward J. Garboczi; National Institute of Standards and Technology, United States

Modern 2D (two-dimensional) materials such as graphene and beyond are nanoscale materials of strong topical interest. They are recognized as materials with strong potential for diverse industrial applications ranging from quantum to structural material systems. In order to exploit their full potential, it is necessary to develop efficient techniques for their characterization and for atomic-scale understanding of lattice defects in these materials. One lattice defect of primary importance in 2D materials is a monovacancy. It can be treated as a building block of more complicated and extended defects in the materials.

Vacancies and their aggregates, such as antidots and Stonewall defects, play a pivotal role in determining mechanical, thermal, as well as electronic characteristics of 2D materials. One parameter that plays an important role in aggregation and coalescence of vacancies, is the strain field in the material due to the vacancy. Modeling of a monovacancy and its strain field is, therefore, of central interest for 2D materials.

Over the last several years, we have developed powerful techniques at NIST for calculation of Green’s functions (GF) for multiscale modeling of different materials and their application to mechanical and thermal problems. A major advantage of a GF based technique is its computational efficiency. Using this technique, we can model large crystallites containing several
million atoms even on a desktop. Modeling large crystallites is especially important for 2D materials because these materials show a significant size effect. It arises because of the logarithmic nature of the response of these materials to a point stimulus. Lattice GF method makes it numerically convenient to account for the size effect. Further, since the GF gives the response of the whole solid at multiscales, it has been shown to seamlessly link the atomistic structure and bulk material performance.

In this talk, we will describe the lattice GF and its application to calculation of the lattice distortion and the strain field in 2D materials. We will present numerical results for silicene, phosphorene and, of course, graphene. Our model crystallite consists of about 2 million atoms. An important input to the GF calculation is the interatomic potential. We have used the functional form of the potentials as available in the literature.

One especially interesting feature of the GF is the possibility of its direct measurement. It has been proposed that the GF is not just a mathematical artefact but a physical entity that can be measured for 2D materials [Tewary et. al., “Green's function modeling of response of two-dimensional materials to point probes for scanning probe microscopy”; Physics Letters A380 (2016) 1750]. If this can be verified, the GF will become a very practical tool for characterization and atomistic scale modeling of 2D materials. This work is another step in that direction.

Improving the Electrical Performance of MoS2 Transistors Using Tensile Strain
Isha Datye1, Alwin Daus1, Kevin Brenner1,2, Ryan W. Grady1 and Eric Pop1; 1Stanford University, United States; 2Southern Methodist University, United States

Transition metal dichalcogenides (TMDs) such as molybdenum disulfide (MoS2) have gained much interest for scaled nanoelectronics, but their mobilities and drive currents must be improved in order to compete with existing technologies. Theoretical studies predict that tensile strain can increase the mobility of TMDs due to changes in band structure, leading to reduced intervalley scattering [1]. However, such mobility improvement has not yet been experimentally demonstrated. In this work, we utilize uniaxial tensile strain to improve the electrical performance of monolayer (1L) MoS2 transistors on flexible substrates. Using a two-point bending apparatus, we apply multiple strain levels between 0% and ~0.7%, which we estimate from the curvature radius of the bent substrates. We confirm these strain levels by Raman spectroscopy, using the known red-shift of the MoS2 in-plane E’ Raman peak of ~2 cm⁻¹ per percent of tensile strain [2].

We fabricate our devices on polyethylene naphthalate (PEN) flexible substrates. First, the gate metal is lithographically patterned, and then we form the gate dielectric with ~20 nm of Al2O3 by atomic layer deposition (ALD). Monolayer MoS2 grown by chemical vapor deposition (CVD) on separate SiO2/Si substrates [3] is then transferred to the flexible substrates using a polymer scaffold [4]. Finally, we pattern source and drain contacts onto the MoS2 films, followed by an O2 plasma etch to define the channels. We characterize the effects of tensile strain on MoS2 transistors with channel lengths from 1 to 15 μm, by extracting the field-effect mobility. Relatively long channels are used to limit extrinsic contributions of contact resistance. We obtain a continuous mobility improvement up to ~85% with increasing tensile strain up to ~0.7%, leading to a drain current ID increase of ~2x at the same carrier density. Furthermore, we find that the effects are fully reversible as the device characteristics return to their initial state after strain release. The mobility increase with tensile strain also indicates that these devices could be used as strain sensors. An ID change of ~2x at 0.7% strain corresponds to a gauge factor of nearly ~150, which is the highest value reported so far for piezoresistive 1L CVD MoS2 strain sensors [5-6].

These results demonstrate the largest mobility and on-state current improvements to MoS2 transistors using strain to date, revealing that strain engineering is a promising way to tune the electrical performance of TMD-based devices. Furthermore, using MoS2 transistors as strain sensors can facilitate the realization of flexible and transparent sensor systems for strain mapping.

Keynote: Interfacial Engineering of Chemically Reactive Two-Dimensional Materials
Mark C. Hersam; Northwestern University, United States

Following the success of ambient-stable two-dimensional (2D) materials such as graphene, hexagonal boron nitride, and transition metal dichalcogenides, new classes of chemically reactive layered solids are being explored since their unique properties hold promise for improved device performance [1] and quantum phenomena [2]. For example, chemically reactive 2D semiconductors (e.g., black phosphorus (BP) and indium selenide (InSe)) have shown enhanced field-effect mobilities and optoelectronic properties under controlled conditions that minimize ambient degradation [3,4]. In addition, 2D boron (i.e., borophene) is an anisotropic metal with a diverse range of theoretically predicted phenomena including confined plasmons, charge density waves, and superconductivity [5], although its high chemical reactivity has limited experimental studies to inert ultrahigh vacuum conditions [6-9]. Therefore, to fully study and exploit the vast majority of 2D materials, methods for mitigating or exploiting their relatively high chemical reactivity are required [10]. In particular, covalent organic functionalization of BP minimizes ambient degradation, provides charge transfer doping, and enhances field-effect mobility [11], while noncovalent organic functionalization of borophene leads to the spontaneous formation of electronically abrupt lateral borophene-organic heterostructures [12]. On the other hand, sequential deposition of atomic carbon and boron on silver substrates results in rotationally commensurate vertical borophene-graphene heterostructures where the graphene adlayer provides robust encapsulation for the underlying borophene [13]. By combining organic and inorganic encapsulation strategies, even highly chemically reactive 2D materials (e.g., InSe and CrI3) can be studied and utilized in ambient conditions [14].

First Principles Electronic and Lattice Dynamics Calculations of TiSe2 and TiTe2
Warda Rahim1, Phil King2 and David O. Scanlon1; 1University College London, United Kingdom; 2University of St. Andrews, United Kingdom

Charge density wave (CDW) instabilities are a common phenomenon in many of the layered transition metal dichalcogenides which make them interesting both from a theoretical viewpoint and for practical applications.1 Bulk TiTe2 is a semimetal and does not undergo any CDW distortion but according to recent reports its monolayer undergoes a CDW instability very similar to TiSe2 bulk and monolayer.3,4 We performed electronic structure and lattice dynamics calculations (using Phonopy code)5 for both of these Ti(IV) dichalcogenides using hybrid (HSE06) density functional theory. We also mapped the
potential energy surfaces$^6$ spanned by the imaginary mode eigenvectors to estimate the barrier associated with the transition and to track the route to the CDW phase. By treating these structures all at the same high level of theory, we can try to explain why specific phases undergo CDW transition and what the driving force is.

Our results successfully show that though TiTe$_2$ bulk has no lattice instability, its monolayer has an instability similar to but much weaker than that present in TiSe$_2$, highlighting the origin of a very weak coupling CDW. The semimetallic overlap in the electronic band structure of TiTe$_2$ monolayer is only 0.2 eV smaller than that in the bulk supporting the idea that narrow band overlaps thermodynamically drive the CDW distortion. This is the first attempt to perform a complete study of \textit{ab-initio} electronic and lattice dynamics calculations of the two compounds within the same level of theory. The presence of phonon instability only in the structures that undergo CDW transition shows that the CDW distortion in these compounds is brought about by a lattice instability, and the semimetallic overlap is the key factor that determines how favoured the transition is. These results could have impact in prediction and understanding of CDW instabilities in other systems, particularly the methodology of following imaginary modes to track the transitions between phases.

\textbf{Lattice Dynamics of Moire Pattern Graphene} Ben Xu$^1$, Nan Feng$^1$, Ce-Wen Nan$^1$, Dong Zhang$^2$ and Kai Chang$^3$; $^1$Tsinghua University, China; $^2$Institute for Semiconductors, Chinese Academy of Science, China

Recent experiments found signatures of superconductivity in 'magic angle' twisted bilayer graphene and ABC-trilayer graphene/hexagonal boron nitride moiré superlattice. Several theoretical works point that the electron-phonon coupling is strong enough to introduce this superconducting phenomenon. In our presentation, phonon spectrum and corresponding phonon modes will be demonstrated by molecular dynamics simulation. These illustrations will help the understanding the interaction between electron and phonon in these multi-layered materials.

\textbf{SESSION S.NM06.07: 2D Systems for Electrochemical Energy Storage}

\textbf{Accurate Molecular Models for MoS$_2$ and Battery Oxides (NMC) to Predict Interfacial Properties up to the Large Nanometer Scale} Juan Liu and Hendrik Heinz; University of Colorado Boulder, United States

We introduce reliable force fields and applications to electrolyte and organic interfaces for molybdenum sulfide and battery oxides, including lithium cobalt oxide as well as nickel and manganese substituted lithium cobalt oxides. Such models, except for MoS$_2$, have not been available and are necessary to understand the dynamics and charge transport properties up to the large nanometer scale. Specifically, the parameters for MoS$_2$ reliably account for structural, interfacial, and mechanical properties and are compatible with many force fields for molecular simulations (Interface force field, CVFF, PCFF, CHARMM, AMBER, OPLS-AA, TEAM). We reproduce chemical bonding, X-ray structure, cleavage energy, infrared spectrum, bulk modulus, Young’s modulus, and interfacial properties with polar and nonpolar solvents within 0.1% to 5% deviation from measurements. Compared to prior models, structural and mechanical instabilities of the nanoscale layers were eliminated, and large deviations in computed interfacial properties (>50%) were reduced to quantitative agreement with experiment (<5%). Computed contact angles of water and diiodomethane agree within ±2° with experimental measurements on freshly cleaved MoS$_2$ surfaces. Similarly, new force field parameters for lithium cobalt oxide as well as Co-Ni-Mn mixed oxide phases are shared that reproduce lattice constants, surface energies, contact angles, and mechanical properties in excellent agreement with experiment. The models can be used as part of multiple force fields (IFF, CHARMM, AMBER, OPLS-AA, PCFF, TEAM) for accurate predictions of fully dynamic, large scale interfacial properties and local analysis by quantum mechanics.
The parameters rely on quantitative representation of chemical bonding using atomic charges, using methods that reach much higher accuracy than DFT calculations, bonded parameters from experimental data, and a consistent interpretation of Lennard-Jones parameters that lead to wide compatibility for multiphase materials. All parameters are supported by a physical chemical interpretation. As an example, we discuss the binding mechanism and adsorption energies of peptides on the MoS2 basal plane using strongly binding and weakly binding sequences derived from phage display. Adsorption is driven by direct surface contact and replacement of surface-bound water molecules, with very widely tunable adsorption energies between -86 and -6 kcal/mol. Weak electrostatic interactions of backbone and side chains with the surface, hydrogen bonds between electrolyte-facing side groups and water, and contributions by hydrophobic groups play a key role to tune the interaction strength.

The models can be applied to any biomaterials and nanomaterials including these 2D compounds, including embedding in electrolytes, polymer matrices, understanding of charge transport, local defects and changes in stoichiometry. The accuracy is comparable to DFT methods at millionfold larger time and length scales, and extensions are feasible for reactive simulations (IFF-R). The models for battery oxides can help overcome problems in designing materials with a higher storage capacity.

Molecule Functionalization and Intercalation in 2D Materials Judy Cha; Yale University, United States

Owing to the large surface area and layered nature, the electrical and catalytic properties of 2D materials can be tuned greatly by surface functionalization with tailored molecules with specific redox potentials and intercalation of various intercalants. The utility of surface functionalization and intercalation has been amply demonstrated in 2D transition metal dichalcogenides (TMDs), including the modulation of carrier densities in monolayer MoS2 field-effect transistors (FETs) and the enhancement of catalytic activities of hydrogen evolution reaction in Li+-intercalated WS2. However, fundamental mechanistic understandings that govern molecule-TMD interactions or intercalation-induced structural and electrical phase transformations remain basic.

In this talk, I will present our approach to elucidate the underlying mechanisms that govern surface functionalization and intercalation in 2D TMDs, using MoS2 as a material choice. For surface functionalization, we compare doping powers of a family of organic electron donors (OEDs) on MoS2 to understand the OED-MoS2 interactions. This requires accurate knowledge of surface coverage of OEDs, change in the carrier density after functionalization, and the nature of the OED bonding to MoS2. For intercalation, we electrochemically intercalate Li+ ions into individual monolayer or heterostructure FETs and follow the change in crystal structure and electrical properties of the host 2D systems as a function of intercalation. We uncover a host of interesting phenomena, such as the role of a hBN/MoS2 interface on intercalation kinetics and physics, phase transformation in WSe2 by intercalation, and competition between intercalation kinetics and thermodynamics in MoS2/graphene heterostructures. A central theme of our approach to understanding surface functionalization and intercalation is the integration of device physics with electrochemistry.

Effect of Structural Disorder and Nitrogen Doping on the Li Storage Capacity of Graphene Nanomaterials—A First-Principles Study Yu-Jen Tsai and Chin-Lung Kuo; National Taiwan University, Taiwan

We employed first-principles calculations based on density functional theory to investigate the effect of structural disorder and nitrogen doping on the Li storage capacity of graphene nanomaterials as the anodes of Li-ion batteries. Our calculated results first revealed that the Li storage capacity of monolayer graphene does not necessarily increase with the number of carbon vacancy created but highly depends on the local geometry of the defect sites. The achievable Li capacity limit per vacancy contributed was found to decrease from four to one as the monovacancy grows into a hexavacancy complex, which implies that the coalescence of vacancy defects may tend to lower down the Li storage capacity of monolayer graphene. Our electronic structure analysis further revealed that the enhanced Li storage capacity by the carbon vacancy is mainly attributed to the increased amount of density of states lying just above the Fermi level, which can be much more increased by the local structural disorder around the vacancy sites. Moreover, our calculations also showed that the Li storage capacity of monolayer graphene can be effectively enhanced by the local ring disorder such as the Stone-Wales defect without the...
presence of any carbon vacancy, which appeared to increase proportionally to the number of the Stone-Wales defect on the basal plane. Our calculations further demonstrated that the amorphous graphene structure can possess a relatively high Li storage capacity primarily owing to the presence of many non-hexagonal ring defects therein. These topological disorders were found to create many electron-deficient regions on the basal plane, which can effectively induce p-type doping on graphene to accommodate more electrons from Li, thereby greatly enhancing the Li storage capacity of the graphene-based nanomaterials. On the other hand, our calculated results also indicate that nitrogen-doping can effectively reduce the vacancy formation energy in graphene, thereby increasing the amount of carbon vacancy to enhance the Li storage capacity. Moreover, the migration energy barriers of vacancy defects were found to increase by nitrogen-doping, which can thus suppress the Li capacity loss induced by the coalescence of vacancy defects in graphene. Nevertheless, our calculations also indicated that it is energetically favorable for nitrogen dopants to aggregate on the vacancy sites, which can thus result in significant irreversible capacity loss of Li because of its extremely high adsorption energy on the vacancy site. Our theoretical findings suggest that the concentration of nitrogen-doping should be carefully controlled in order to obtain optimal Li storage capacity of graphene-based materials.

Dimensionality-Dependent Electrochemical Kinetics at the Single-Layer Graphene–Electrolyte Interface Prab Bandaru1, Hidenori Yamada1 and Rajaram Narayanan2;1; 1University of California, San Diego, United States; 2Applied Materials, Inc., United States

The theories to describe the rate at which electrochemical reactions proceed, to date, do not consider explicitly the dimensionality or the discreteness and occupancy of the energy levels of the electrodes. We show experimentally that such quantum mechanical aspects are important for dimensionally confined nanostructured materials and yield unusual variation of the kinetic rate constants with applied voltage in single-layer graphene. The observed divergence from conventional electrokinetics was ascribed to the linear energy dispersion as well as a nonzero density of states at the Dirac point in the graphene. The obtained results justify the use of density of states-based rate constants and considerably add to Marcus–Hush–Chidsey kinetics. The talk includes theoretical, computational, and experimental results.

Influence of Atomic Vacancies on Catalytic and Transport Properties of 2D Transition Metal Dichalcogenides Manish Chhowalla; University of Cambridge, United Kingdom

Single atom chalcogen vacancies are common in chemical vapor deposited monolayer transition metal dichalcogenides (TMDs). In some ways, the properties of two dimensional TMDs appear to be not influenced by the presence of up to 1-3% vacancies in the monolayers. That is, it is possible to achieve gate modulation and mobilities of tens of cm²-V⁻¹-s⁻¹ at room temperature in field effect transistors (FETs) with single layer TMD channels. Here, we describe the evolution of photoluminescence and FET characteristics as a function of single atom vacancy defects concentration. We find that the monolayer TMDs are defect tolerant – capable of preserving their properties up to defect concentration of ~ 10¹⁴ cm⁻². We also measure the catalytic properties of monolayer TMDs and find that the overall activity increases with number of atomic vacancies – with the best performance (lowest overpotential and highest turnover frequency for the reaction) occurring at a concentration where semiconductor to metal transition occurs. I will describe how our results provide new insights into the defect tolerance of 2D TMDs and how atomic structure engineering can be used to tune their properties.

6:00 AM S.NM06.07.09
Ambient Stable Phosphorenes and Covalently Linked Phosphorene-MoX₂ (X = S or Se) Nanocomposites with Enhanced H₂ Evolution Activity Pratap Vishnoi1,2 and C. N. R. Rao1; 1Jawaharlal Nehru Centre for Advanced Scientific Research, India; 2University of California Santa Barbara, United States

The phosphorene is a 2D puckered sheet composed of sp³ phosphorus with each P atom is covalently bonded to three P atoms in the plane. The phosphorus atoms contain lone-pair electrons. It exhibits high charge carrier mobility as well as a thickness tuneable band-gap in the 0.3-2.0 eV range.[1] The conduction band minimum of phosphorene is appropriately positioned to effectively catalyze the H₂ evolution reaction by water splitting. Besides, phosphorus is an earth-abundant and environmentally benign non-metal element. Therefore, it is of great interest to exploit the potential of phosphorene as a metal-free photocatalyst for H₂ evolution. However, pristine phosphorene is ambient instable and it produces trace amounts of H₂ by water splitting.[2,3]

The advantage of the lone-pair electrons is that they can be utilized for chemical functionalization of phosphorene without
significantly affecting its intrinsic properties. In this work, we present synthesis of ambient stable η–ν adducts of phosphorene, covalently cross-linked phosphorene-MoX₂ (X = S or Se) nanocomposites, and their HER activity. The phosphorenes functionalized with InCl₃ and B(C₆F₅)₃ as well as ylide with a benzyl group are ambient stable and disperse well in aqueous medium.[3] Their photocatalytic HER activity is enhanced significantly exhibiting H₂ yields of 6.6 mmol h⁻¹g⁻¹ in the case of phosphorene-B(C₆F₅)₃ (hydrogen yields for pristine phosphorene is 0.6 mmol h⁻¹g⁻¹). Phosphorene-MoX₂ nanocomposites are synthesized by forming amide as the cross-linkages.[4] Due to improved charge-transfer and suppressed charge recombination rate, phosphorene-MoS₂ exhibits excellent photochemical HER activity with H₂ yields of 26.8 mmol h⁻¹g⁻¹, while only a negligible amount is produced by their physical mixture. The phosphorene-MoS₂ composite shows high electrochemical HER activity with an onset overpotential of 110 mV, closer to that of Pt/C catalyst. The onset overpotential of a 1:1 physical mixture of phosphorene and MoS₂ is 450 mV. The enhanced HER activity of phosphorene-MoS₂ nanocomposite can be attributed to the ordered cross-linking of the 2D sheets, leading to increased interfacial area as well as the charge-transfer interaction between phosphorene and MoS₂ layers.

Revealing the Full Spectrum Layered Materials with Super-Human Predictive Abilities Gowoon Cheon and Evan J. Reed; Stanford University, United States

We have utilized data mining approaches to elucidate over 1000 2D materials and several hundred 3D materials consisting of van der Waals bonded 1D subcomponents, or molecular wires. We find that hundreds of these 2D materials have the potential to exhibit observable piezoelectric effects, representing a new class of piezoelectrics. A further class of layered materials consists of naturally occurring vertical hetero structures, i.e. bulk crystals that consist of stacks of chemically dissimilar van der Waals bonded layers like a 2-D super lattice. We further combine this data set with physics-based machine learning to discover the chemical composition of an additional 1000 materials that are likely to exhibit layered and two-dimensional phases but have yet to be synthesized. This includes two materials our calculations indicate can exist in distinct structures with different band gaps, expanding the short list of two-dimensional phase change materials. We find our model performs five times better than practitioners in the field at identifying layered materials and is comparable or better than professional solid-state chemists. Finally, we find that semi-supervised learning can offer benefits for materials design where labels for some of the materials are unknown.

5:15 AM *S.NM06.08.03
Water-Based and Biocompatible 2D Inks for Printed Electronics Cinzia Casiraghi; University of Manchester, United Kingdom

Solution processing of graphene [1] allows simple and low-cost techniques such as inkjet printing [2, 3] to be used for fabrication of heterostructures of arbitrary complexity. However, the success of this technology is determined by the nature and quality of the inks used.

In this work we show a general formulation engineering approach to achieve highly concentrated, and inkjet printable water-based 2D crystal formulations, which also provide optimal film formation for heterostructure fabrication [4]. Examples of all-inkjet printed devices, such as large area arrays of photosensors on plastic [4], programmable logic memory devices [4], strain sensors on paper [5], capacitors [6] and transistors [7] will be discussed. In addition, our approach allows easy production of defects-free and biocompatible graphene flakes with positive or negative charge [4,8-10], which can find use in biomedical applications.

Low Temperature NbS2/NbS3 Heterostructure Fabrication by Atomic Layer Deposition Saravana Balaji Basuvalingam, Yue Zhang, Matthew Bloodgood, Jan P. Hofmann, Marcel Verheijen, Erwin Kessels and Ageeth A. Bol; Eindhoven University of Technology, Netherlands

Two-dimensional transition metal dichalcogenides (TMDCs) such as MoS2 and WS2, among others, have gained a lot of attention due to their phase and thickness dependent electrical and optical properties. There is also another class of two-dimensional materials involving similar elements as in TMDCs, which are known as transition metal trichalcogenides (TMTCs). Contrary to TMDCs, TMTCs are quasi-1D materials, which gives added benefits for applications as they have strong anisotropy in both electrical and optical properties. Among the various transition metal chalcogenides systems, some TMDCs exhibits metallic properties, while their TMTCs counterparts exhibits semiconducting properties (or vice versa). An example are Nb based sulfides: NbS2 is metallic, whereas NbS3 is semiconducting.

Lately, the prospects of combining metal-semiconductor transition metal chalcogenides to form heterostructures have gained momentum for future applications in opto-electronics. However, there are many challenges associated with the current heterostructure synthesis processes, such as process scalability, control over the thickness of the individual layers and high processing temperatures. Atomic layer deposition (ALD) can address most of the aforementioned challenges as it offers uniformity over large area substrates, precise thickness control, and low-temperature processing.

In this work, we focus on fabricating metallic NbS2, semiconducting NbS3 heterostructures by ALD. NbS2 and NbS3 thin films were synthesized with control over the phase by plasma-enhanced atomic layer deposition (PE-ALD) using a metalorganic precursor and H2S (+H2) plasma at low temperatures (200 – 450 °C). The phase-control between NbS2 and NbS3 was achieved by two methods, first by varying the temperature (which we have also shown for TiS2/TiS3). Second, by careful optimization of H2S:H2 gas mixture ratio in the plasma co-reactant while maintaining a constant deposition temperature. For demonstrating this, the deposition temperature was maintained at 300 °C. The H2S:H2 ratio was varied from 1:0 to 0:1 while maintaining a constant total flow. A high H2S gas fraction led to the synthesis of NbS3, otherwise, NbS2 was deposited. It was observed with optical emission spectroscopy that the increased H species in the plasma mixture could act as an S reducing agent and cause NbS2 growth at low temperatures. We used this phase-controlled growth of NbS2 on NbS3 (or vice versa) by modulating the H2S:H2 ratio as a function of ALD cycles to form NbS2/NbS3 heterostructures. The formation of heterostructures was confirmed by high-resolution transmission electron microscopy (TEM) along with electron diffraction. Our experiments demonstrate that ALD enables the controlled synthesis of both TMDCs and TMTCs, while also enabling metal-semiconductor heterostructure formation at low temperatures over large scale substrates. This opens up new avenues to include both TMDCs and TMTCs in nano- or optoelectronic applications.

5:40 AM S.NM06.08.05
Transition from 3D to 2D and Fractal to Compact Domains of CVD Grown MoSe2 Sayema Chowdhury, Anupam Roy and Sanjay K. Banerjee; University of Texas at Austin, United States

Atomically thin two-dimensional transition metal dichalcogenides (TMDs) have been extensively researched in recent years
due to their unique thickness dependent optical and electronic properties, showing remarkable applications in FETs, digital logic circuits, memory devices, photovoltaics, sensors, flexible devices etc. The selenides are garnering a greater interest particularly for the applications in optoelectronics owing to a narrower bandgap and higher optical absorbance compared to sulfides [1]. Although mechanically exfoliated monolayer TMDs are widely used for different proof-of-concept experiments, scaling up the production of large area uniform TMDs to an industrial level still requires an optimized growth method. Several bottom up synthesis processes such as molecular beam epitaxy (MBE) [2] and chemical vapor deposition (CVD) [3] have already been reported in literature, but while the low grain sizes in MBE grown TMDs limits device performances [4], CVD comes with its own challenges e.g., poor control over thickness, low repeatability of growth results etc. In order to achieve large area repeatable growth of TMDs with precise thickness control, a detailed understanding of the role of different parameters influencing the growth dynamics is of utmost importance.

In this work we demonstrate atmospheric pressure CVD (APCVD) growth of MoSe2 on Si/SiO2 substrates, and investigate the effect of growth temperature and metal/chalcogen flux. We observe that the growth temperature strongly influences the morphology of the domains and the compact triangular or hexagonal domains ramify into fractals as the growth temperature is decreased. We also observe that higher substrate temperature helps reduce the formation of grain boundaries, which hinder carrier mobilities and introduce defects in the crystal domains by suppressing the nucleation density. The effect of chalcogen environment is studied where growth in a Se-rich environment helps restrict Mo-rich nuclei formation promoting lateral growth. Raman and Photoluminescence (PL) spectroscopy confirms the formation of crystalline monolayer MoSe2. For the growth in Se-deficient environment, several multilayer islands are seen to form on the domains, showing vertical growth of multilayer MoSe2 which can be attributed to insufficient Se-passivation. Atomic force microscopy (AFM) study confirms the lateral (monolayer) versus vertical growth under Se-rich and Se-deficient conditions, respectively. XPS analysis show a near perfect stoichiometry (Mo:Se=1:1.97) of MoSe2 under Se-rich growth environment, whereas in the Se-deficient condition a ratio of Mo:Se=1:1.77 is observed indicating a deviation from the stoichiometric MoSe2. This also supports our claim of forming metal rich nuclei (Mo1+xSe2-x) under Se-deficient condition leading to 3D island formation. This work offers a deeper understanding of the effects of several important growth parameters and proposes an optimized growth window for synthesizing large area 2D TMD compounds.

This work was supported in part by the Army Research Office (ARO) Grant # W911NF-17-1-0312 (MURI) and NSF NNCl (done at the Texas Nanofabrication Facility at the University of Texas at Austin supported by NSF grant NNCl-1542159).

Engineering Atomic Structures of MoS2 for Neuromorphic Applications

Zhi Gen Yu1, Shuai Chen1, Hangbo Zhou1, Lin Wang2, Xuewei Feng2, Yongqing Cai1, Xiangjun Liu4, Gang Zhang1, Kah Wee Ang22 and Yong-Wei Zhang1, 1Institute of High Performance Computing, Singapore; 2National University of Singapore, Singapore; 3University of Macau, China; 4Donghua University, China

Two-dimensional (2D) semiconducting materials, such as MoS2, WS2, phosphorene, etc., hold great potential for many important applications, such as in nanoelectronics, molecular and bio-sensors, thermoelectric conversion and solar energy harvesting. It is well recognized that structures and defects of these 2D materials play an import role in dictating the electronic, optical, magnetic and thermal properties. To fully explore the functionalities and potentials of 2D materials, their structure and defect engineering is often required, which can greatly widen their applications.

Neuromorphic computing, which mimics the biological neural architectures, is promising to address some of the challenges facing von Neumann computing system, such as energy efficiency, computational power, and robust learning. 2D materials are promising materials for use in such new computational paradigm.

In this talk, we report on our work on the development of multi-terminal MoS2-based memtransistor for neuromorphic computing. By combining first-principles calculations and theoretical modelling, we investigate the structures and energetics of intrinsic point defects in MoS2, their evolution and reaction under thermal and electric fields, and their effects on the changes in electrical properties, such as electrical conductivity and Schottky barrier. We further examine the origin of synaptic behavior in the MoS2-based multi-terminal memtransistor and the performance of such memtransistors, such as, long-term potentiation, long-term depreciation, etc. We also report our realization of an aerosol jet printed Ag/MoS2/Ag
memristor capable of storing and processing data on flexible substrates. This memristor is realized in a cross bar structure by developing a scalable and low-temperature printing technique utilizing a functional MoS$_2$ ink platform. Interestingly, the MoS$_2$ memristor exhibits both volatile and nonvolatile resistive switching behavior. By using first-principles calculations and kinetic Monte Carlo simulations, we further examine the role of defects and structures in the functionalities and performance of the memristor.

Our studies here show that these nanodevices are capable of efficiently mimicking many interesting behaviors of biological synapses, demonstrating their potential to enable energy efficient artificial neuromorphic computing.

6:05 AM S.NM06.08.08
Exploring Strain-Stabilization of the Conducting 1T Phase in Pulsed Laser Deposited MoS$_2$ Thin Film on Different Single Crystal Substrates Swati Parmar$^{1,2}$, Suresh Gosavi$^1$ and Satishchandra Ogale$^2$; $^1$Savitribai Phule Pune University, India; $^2$Indian Institute of Science Education and Research, India

The metallic 1T phase of MoS$_2$ has excellent electrical conductivity but it is thermodynamically unstable. Hence there is great interest in realization and stabilization of this phase in different forms such as nanomaterials and thin films for various device applications. The thin film platform affords the element of substrate-induced strain as a tunable parameter that can control the phase equilibria. In the work reported here, we therefore examine the possibility of stabilizing the desirable 1T phase of MoS$_2$ in the case of thin films grown by pulsed laser deposition (PLD) on different crystalline substrates, namely c-Al$_2$O$_3$ (0001), LaAlO$_3$ (001), SrLaAlO$_4$ (001), SrTiO$_3$ (001) and MgO (001). The percent (%) lattice parameter mismatch between the most favorable growth planes of MoS$_2$ and these different substrates varies from 5% to 16%. c-Al$_2$O$_3$, LaAlO$_3$, SrLaAlO$_4$ are noted to induce tensile strain whereas SrTiO$_3$ and MgO cause compressive strain in MoS$_2$ thin film. Interestingly, Raman and X-ray Photoelectron spectroscopy reveal much enhanced and stable 1T phase contribution in MoS$_2$ thin films grown on SrTiO$_3$ and SrLaAlO$_4$ substrates. The X-ray diffraction, X-ray reflectivity, and atomic force microscopy data reveal high crystalline quality of MoS$_2$ thin films. The most enhanced 1T phase film of MoS$_2$ is noted in the case of the film grown on SrLaAlO$_4$, which also shows a reduction in room temperature resistivity and semi-metal behavior. The valence band spectroscopy (VBS) data for this case are also consistent with the expected metal-like nature of the 1T phase MoS$_2$ thin film. Furthermore, while increasing the thickness, structural transition from mixed 1T/2H phase to pure 2H hexagonal phase is observed; a consequence of strain relaxation, which clearly establishes the role of substrate-induced strain in 1T phase stabilization via octahedral rotation. This study will pave the way for making the vast family of transition-metal chalcogenides tetragonal phase thin films and brings out the potential of 1T phase thin film for unfolding phenomenon and technological applications.

Pulsed Laser Deposition of Two-Dimensional Materials Denys Miakota$^1$, Huu Phuoc Le$^1$, Yu-Chuan Lin$^2$, Raymond R. Uncic$^2$, Fabian Bertoldo$^1$, Kristian Thygesen$^1$, Alexander Puretzky$^2$, Ilia N Ivanov$^2$, Jorgen Schou$^1$, David B. Geohegan$^2$ and Stela Canulescu$^1$; $^1$Technical University of Denmark, Denmark; $^2$Oak Ridge National Laboratory, United States

Two-dimensional of transition metal dichalcogenides (2D-TMDCs) stand out from the class of 2D materials due to their appealing properties, including atomic-scale thickness, direct band gap and strong spin-orbit coupling. The precise control of the atomic layer structure can pave new avenues for the integration of TMDCs in future optoelectronic devices, such as light-emitting diodes and van der Waals photovoltaics. In this paper, we present our recent progress on the growth of 2D-TMDCs including MoS$_2$, WS$_2$, MoSe$_2$ and their alloys, by a bottom-up approach, namely Pulsed Laser Deposition (PLD). PLD is a well-established technique for the growth of functional oxide structures$^1$ and superlattices$^2$. It relies on vapor-phase transfer of a material from a target to substrate$^3$. Furthermore, this catalyst-free approach has recently been used for the growth of layered TMDCs$^4$. Nevertheless, the optoelectronic properties of 2D-TMDCs, particularly photoluminescence (PL) emission, are often poor. A good control of the chalcogenide vacancies at the monolayer limit is important to realize the full potential of 2D materials and their heterostructures in devices. In this paper we will discuss the PLD-synthesis of large area, crystalline 2D-TMDCs on sapphire and SiO$_2$/Si. PLD synthesis
at high temperature (~600°C and above) using this one-step approach results in the formation of continuous monolayers with grain boundaries, as compared to the triangular-shaped structures, specific to the chemical vapor deposition process. We profile the vacancy concentration in MoS₂ monolayer on an atomic scale using annular-dark-field electron microscopy, with an absolute detection sensitivity of one to two sulfur vacancies. A rich variety of defects, including single and double sulfur vacancies, anti-site defects, as well as grain boundaries with periodic rings 8-4-4- rings defects are revealed. Room temperature PL spectra of MoS₂ monolayer exhibit two-distinct exciton peaks that can be used to qualitatively assess the as-grown monolayers. Finally, we will discuss the PLD growth of 2D materials using chalcogen-enriched targets as a path towards defect engineering of 2D materials.

Encapsulation and Transfer Schemes for Epitaxial Xenes

Deepyanti Taneja, Gabriele Faraone, Md. Hasibul Alam, Christian Martella, Carlo Grazianetti, Emiliano Bonera and Deji Akinwande; 1The University of Texas at Austin, United States; 2CNR IMM, Unit of Agrate Brianza, Italy; 3Università degli Studi di Milano-Bicocca, Italy

Epitaxial Xenes are an emerging class of two-dimensional crystals made of elements spanning group III to group VI of the periodic table (e.g. borophene, silicene, phosphorene, antimomene, tellurene etc) [1]. These materials are synthesized by epitaxy on various substrates and are subject to degradation in environmental conditions. Our work is centered around Xenes grown on noble metal surfaces that are supported by mica, as they can readily undergo delamination and transfer on other substrates for device related studies. In particular, we focus on silicene-on-silver [2] and epitaxial phosphorene [3] as representative cases to establish a stabilization and transfer scheme. Encapsulation of the unstable Xenes is a critical step for achieving transfer of the Xene layer from its pristine growth substrate to a device or functional substrate. We propose the use of an Al₂O₃ encapsulation as a stabilization strategy that can be universally applied to the whole class of Xenes. The integrity of the Xene layer after encapsulation is validated by means of Raman spectroscopy and X-ray photoelectron spectroscopy. We then propose a few different transfer schemes and present experimental results of film transfer. A technical step in the delamination and transfer process is the time-controlled etching of the metal substrate. We achieve this using an optimized KI/I₂ silver etchant with a controllable etch rate. Finally, we demonstrate the stability of air-exposed multilayer silicene, prepared using our developed methods, via Raman spectroscopy, validating our successive delamination and transfer protocol.

Optical Properties of Group-14 Xenes on Al₂O₃(0001)

Carlo Grazianetti, Christian Martella, Stefano Lupi and Alessandro Molle; 1CNR-IMM, Italy; 2CNR-IOM, Italy

The class of two-dimensional (2D) graphene-like lattices made of atoms out of carbon, collectively known as Xenes, today
includes elements from the lightest boron to the heaviest tellurium [1]. The Xenes flow started with silicene that first paved the way to the chance of mimicking the graphene’s properties in an artificial way [2]. Although the widely studied silicene on Ag(111) looks promising for applications in electronics [3], conversely on such a substrate the optical properties can be hardly accessed [4]. The synthesis by molecular beam epitaxy (MBE) of silicene and silicon nanosheets on a transparent substrate like Al₂O₃(0001) allowed for the survey of the thickness-dependent behavior of the optical conductivity obtained from transmittance measurements via Kramers-Kronig constrained fit [5]. At the 2D limit, the optical conductivity is characterized by two main features at 1.4 and 4.5 eV that closely resemble those arising from π-π* and σ-σ* interband transition in freestanding silicene. Two distinct behaviors can be recognized: at the 2D limit, the optical conductivity is consistent with a Dirac-like energy bandstructure, whereas, conversely, for thicker silicon layers an anomalous optical behavior shows up suggesting a different energy bandstructure with respect to that of conventional silicon. On the other hand, limited to the group-14 (i.e. column-IVA) of the periodic table, it turns out that increasing the mass of the X element from carbon to tin, the spin-orbit coupling (SOC), a relativistic effect that scales as \( Z^3 \) in elements of atomic number \( Z \), converts a honeycomb lattice from an ideal 2D semimetallic state to a quantum spin Hall insulator (as predicted first for graphene) characterized by large bandgap opening and conductive dissipationless edge channels [6]. In this framework, the choice of a heavier element than silicon, like tin, would intriguingly afford to unravel the topological properties of the Xenes giving rise to the emergence of non-trivial topological properties even at room temperature. Interestingly, the Al₂O₃(0001) substrate turns out to be also well-suited even for stanene as predicted by theoretical modeling [7]. In close analogy with silicon [5], we investigated the optical properties of tin deposited by MBE on Al₂O₃(0001). The absorbance from THz to ultraviolet (6 meV - 5 eV) photon range measured on ultra-thin tin nanosheets show two spectral features centered at ~1.25 and 4 eV that can be related to π-π* and σ-σ* interband transition in freestanding stanene albeit broadened and shifted towards lower frequency. Remarkably, as also confirmed by means of optical conductivity, ultra-thin tin nanosheets show hints of a bandgap opening of ~40 (0.5 nm-thick) and ~90 (1.5 nm-thick) meV being consistent with SOC induced predicted values. Moreover in the 0.25-1.10 eV range the optical conductance are linear following a power-law frequency dependence that universally describes the interband optical response of D-dimensional Dirac electrons. By and large, the Xenes made of silicon and tin atoms grown on Al₂O₃(0001) might potentially pave the way to a new era in high-speed and low-power nanophotonics based on 2D materials.

Emerging Two-Dimensional Materials for Memory and Sensing Applications Han Wang; University of Southern California, United States

In this talk, I will discuss our recent research progress in understanding the electronic, photonic and ferroelectric properties of emerging low-dimensional materials, and in developing them for sensing and memory applications. The first part of the talk will focus on discussing the basic properties of emerging 2D materials such as black phosphorus and our progress in developing the material for mid-infrared optoelectronics application. I will also discuss our work on utilizing 4-dimensional imaging techniques to study carrier dynamics in two-dimensional materials, including a study using the newly developed scanning ultrafast electron microscopy (SUEM) technique to image the photo-carrier transport in black phosphorus. In the second part of the talk, I will discuss our recent research on the ferroelectric monolayer materials for memory device applications. I will conclude with remarks on promising future research directions of low-dimensional material properties and devices, and how the emerging materials may benefit future generations of electronics and photonics technology in sensing and memory.

Quasi-1D TiS₃ Nanoribbons—Mechanical Exfoliation, Thickness-Dependent Raman Spectroscopy and Device Prospects Michael J. Loes, Alexey Lipatov, Haidong Lu, Jun Dai, Natalia Vorobeva, Xiao Cheng Zeng, Alexei Gruverman, Peter Dowben and Alexander Sinitskii; University of Nebraska - Lincoln, United States

Two-dimensional layered materials have received much interest in recent years due to their ease of miniaturization by mechanical exfoliation along with strong light-matter interactions and tunable electronic properties. Quasi-one-dimensional
(Quasi-1D) materials, however, have seen considerably less interest, but can express many of the same desirable properties as conventional layered materials, with an added dimension of anisotropy. A representative example of this Quasi-1D subclass is Titanium Trisulfide (TiS₃). We demonstrate similar ease of mechanical exfoliation of TiS₃ accompanied with theoretical calculations and show that these materials exfoliate into few-atomic-layer nanoribbons with very smooth edges. We emulated macroscopic exfoliation experiments on the nanoscale by applying a local shear force to TiS₃ crystals in different crystallographic directions using a tip of an atomic force microscopy (AFM) probe. In the AFM experiments, it was possible to slide the 2D TiS₃ layers relative to each other as well as to remove selected 1D chains from the layers. Further, their characterization by Raman spectroscopy shows a reliable, internally standardized shift of a few cm⁻¹ from monolayer to bulk demonstrating tunability typical of conventional layered materials. Devices made from this material show promising electronic properties with predicted mobilities in excess of 10,000 cm²V⁻¹s⁻¹ with low edge-scattering, as well as in optoelectronics with strong light-matter interactions, particularly along the crystallographic b-axis (anisotropic). Orientation-dependent properties of this nature show promise as filters and polarizers, while high surface areas associated with 2D materials hint towards gas-sensing and energy storage applications.

Manipulation of Molecules with Tuned-Oscillator Atomic Force Microscopy—A New Pathway to Catalysis
Research Omur E. Dagdeviren¹²; ¹Yale University, United States; ²McGill University, Canada

Since the first demonstration of atomic resolution in ultrahigh vacuum conditions more than twenty years ago, frequency modulation-based noncontact atomic force microscopy (FM-NC-AFM) has significantly matured and is now routinely applied to study problems that benefit from high-resolution surface imaging. In FM-NC-AFM, control of the tip’s vertical position is accomplished by detecting a shift in the cantilever’s resonance frequency upon approach to the sample. Consistently ensuring reliable distance control during extended data acquisition periods has nevertheless remained challenging, as most FM-mode-based control schemes employ three feedback loops that may interfere. As a consequence, sample throughput in FM-NC-AFM is often low compared to ambient condition AFM, where the easy-to-implement amplitude-modulation (AM) control scheme is predominantly used. Transfer of the AM methodology to high-resolution measurements in vacuum is, however, difficult as with AM-AFM, instabilities during approach are common; in addition, the lack of viscous air damping and the related significant increase of the cantilever’s quality factor generates prolonged settling times that cause the system’s bandwidth to become impractical for many applications. Here we introduce a greatly simplified approach to NC-AFM imaging and quantitative tip-sample interaction force measurement that prevents instabilities while simultaneously enabling data acquisition with customary scan speeds by externally tuning the oscillator’s response characteristics [1]. After discussing the background and basic measurement principles, examples for its application to controlled manipulation of molecules are provided. We will show that the manipulation path can be chosen at will and energy barriers between potential minima on that pathway can be quantified, as can the energy landscape around the molecule before and after manipulation. To explore the practicality of this novel pathway to catalysis research, we selected benzene molecules on a Cu (100) surface as a model system. We first choose a specific manipulation path and then move the tip at constant but continuously reduced heights along this path (x-coordinate) while recording the oscillation amplitude A and phase phi with the microscope operated in our recently developed tuned-oscillator (TO) detection scheme [1]. To preserve the accuracy of recovered tip-sample interaction potentials and forces, we use oscillation amplitudes significantly larger than the decay length of the tip-sample interaction potential [2-5]. Analyzing the full (x, z, A, phi) data array then allows recovery of the potential energy \( U(x,z) \) acting between the tip and the sample, the force on the tip normal to the surface vertical tip-sample force \( F_n(x,z) \), and the force \( F_l(x,z) \) that acts on the tip along the manipulation path (i.e., lateral) with meV, pN, and pm resolution [4,5]. In 54 distinct manipulation events, the molecules were either pushed, pulled, jumped to the tip, or did not move depending on the chemical surrounding of the molecule and the chemical identity of the tip. For further insight, we compared the experimentally measured energy landscapes and manipulation outcomes with computational results, which highlights the decrease of the energy barrier with the variation of the chemical environment of the molecule.

Energy Dissipation on Suspended Graphene Quantum Dots Marcin Kisiel, Alexina Ollier, Urs Gysin and Ernst Meyer;
Understanding nanoscale energy dissipation is nowadays among few priorities particularly in solid state systems. Breakdown of topological protection, loss of quantum information and disorder-assisted hot electrons scattering in graphene are just few examples of systems, where the presence of energy dissipation has a great impact on the studied object [1]. It is therefore critical to know, how and where energy leaks. Pendulum geometry Atomic Force Microscope (pAFM), oscillating like a pendulum over the surface, is perfectly suited to measure such tiny amount of dissipation [2,3], since a minimum detectable power loss is of the order of aW.

Here we report on a low temperature (T=5K) measurement of striking singlets or multiplets of dissipation peaks above graphene nanodrums surface. The stress present in the structure leads to formation of few nanometer sized graphene quantum dots (GDS) and the observed dissipation peaks are attributed to tip-induced charge state transitions in quantum-dot-like entities. The dissipation peaks strongly depend on the external magnetic field (B=0T-2T), the behavior we attributed to crossover from quantum dot carrier confinement to the confinement by magnetic field.

SESSION S.NM06.10: Poster Session: Theory and Characterization of 2D Materials—Bridging Atomic Structure and Device Performance

S.NM06.10.01 Structural Characterization of 2D Layered Complex Hetero-Ion Systems Ryan Mbagna Nanko¹, Matthew Cheng² and Vinayak Dravid²; ¹University of Maryland, Baltimore County, United States; ²Northwestern University, United States

The motivation behind this project is to study the structure of complex hetero ion based lamellar materials and their physical properties, including ferroelectricity and ferromagnetism, at the 2D limit. By mechanically exfoliating bulk single crystals of CuInP₂S₆, CuCrP₂S₆, and CuCrP₂Se₆, a top down approach is used to obtain flakes that are as thin as possible. By isolating a monolayer of these materials, future studies will be conducted to probe for the existence of subnanometer ferroelectric, ferromagnetic, or magnetoelectric multiferroic responses from each respective material systems. Furthermore, studies on heterostructures formed from stacking different monolayers of material in order to study the coupling between different layers are also considered. In hope of its success, we can formulate a device that can take advantage of its magnetoelectric coupling in applications of spintronics and capacitors for more advanced computing.

Using Atomic Force Microscope (AFM) and Raman Spectroscopy, I developed a system to measure the thickness of flakes and to correlate them to Raman spectra and optical images. Despite its challenges, I have successfully measured a range of flake thickness that correlates to a trend in the intensity of the Raman spectra. This allows us a way to identify thin flakes of materials to pursue future studies on the multiferroic character of these materials systems at the 2D limit.

S.NM06.10.03 Simulation of Chalcogen Ion Laser Plasma Plumes—Fine-Tuning Plasma Conditions for Modification and Heterostructure Formation in Transition Metal Dichalcogenides Joseph A. Edoki¹, Jacob H. Paiste², Sumner B. Harris², Robert R. Arslanbekov³ and Renato P. Camata²; ¹Alabama A&M University, United States; ²The University of Alabama in Huntsville, United States; ³CFD Research Corporation, United States
Among the many chemical and physical processes capable of modifying 2D materials, laser plasma processing provides an attractive suite of unique experimental parameters. Using appropriate laser irradiation conditions of a solid target, the ionization fraction, density, temperature, and kinetic energy of a laser-generated plasma can all be adjusted. These plasmas can be used to modify atomically-thin materials. This approach has been employed in the use of a laser-generated sulfur plume for alloying and creation of lateral heterostructures in transition metal dichalcogenides (TMDs) [1]. Further development in this area may be possible with a quantitative understanding of the formation/expansion process of laser-produced chalcogen plumes. In this work, we report on full-scale fluid dynamic simulations of laser-generated chalcogen ion plasmas from initial light-matter interactions to long-range expansion away from a solid target. Contrary to previous studies, our simulation is carried out to centimeter distances, which is the length scale relevant for materials modification. The simulation makes use of implicit partial differential equation solvers and is implemented in a state-of-the-art, multidimensional adaptive Cartesian mesh (ACM) framework. The ACM approach is essential since the spatial resolution required in the early stage of laser-matter interaction is a fraction of a micron while the entire computational domain is several centimeters. As the plasma begins to expand, the fine resolution at the target surface is no longer required, allowing the grid to be coarsened. A dense mesh is still required at the moving plasma front throughout the entire domain and so the ACM follows the front, and allows a coarse mesh elsewhere. The ACM technique makes the computation fast and enables large scale, multidimensional simulations. We simulate the plasma produced during pulsed nanosecond ablation (e.g., KrF excimer) of elemental tellurium and selenium and calculate the kinetic energy distribution of neutral and ionic species, analyzing in detail the evolution of their spatial dynamics. Compared to other metals like copper, bulk tellurium and selenium have drastically lower melting and boiling points as well as mass density. The result of these physical properties is that plasma absorption of the laser pulse begins earlier in the ablation process, and is sustained for longer times, leading to greater vapor densities and temperatures. For instance, at the surface of a copper target, vapor densities are in the \(10^{23}\) m\(^{-3}\) range while a selenium or tellurium target irradiated with the same laser power exhibits vapor densities that are an order of magnitude higher, with a greater number of highly ionized species. Both 1D and 2D-axisymmetric simulations show that singly and doubly ionized species expand outwards with high kinetic energy ahead of the high-density neutral vapor. At high vacuum conditions, reducing the laser irradiance below the plasma absorption threshold minimizes the number of energetic species and the thermal component of the plume is dominant. Simulations such as these provide quantitative understanding of the physical properties of chalcogen ion plasmas and can guide experiments in laser plasma modification of TMDs.

Influence of Strain on Mesoscopic 2D Film Growth from Phase Field Methods Tara M. Boland, Gabriel Munro-Ludders and Arunima Singh; Arizona State University, United States

The emergence of two dimensional (2D) materials opened up many potential avenues for novel device applications such as nanoelectronics, topological insulators, field effect transistors, microwave and terahertz photonics and many more. To date there are over 1,000 theoretically predicted 2D materials. Of those theoretical materials, only 55 have been experimentally synthesized. The incorporation of this technology into device applications has been hindered due to the difficulty synthesizing and stabilizing the 2D materials. Traditional methods such as chemical vapor deposition result in films with defects and grain boundaries. Controlling the growth of these films requires a systematic understanding of the crucial factors of the film-substrate adhesion strength and mismatch strain. In this work, we present a multi-scale computational approach to model the mesoscopic growth mechanisms of 2D materials on various substrates using density functional theory calculations with van der Waals corrections and phase field methods capturing both atomistic and mesoscopic materials properties.

Various 2D materials are placed epitaxially on substrate surfaces which possess hexagonal symmetry. The 2D materials are pre-screened to ensure that each 2D material will not possess a strain that is more than 10%. For all substrate-2D systems the binding and formation energy is computed using a high-throughput approach to density functional theory performed within the atomate framework. These parameters, coupled with the elastic constants for the 2D material are used to fit phase field models to predict the mesoscopic growth of various 2D materials.

Restoration of Lattice Defects in Graphene Oxide by Organic Solvent-Assisted Thermal Annealing Kanishka De Silva and Masamichi Yoshimura; Toyota Technological Institute, Japan

From last decade, the interest of graphene is rising spanning almost all research areas due to its outstanding electrical, optical, mechanical, etc. properties inherited by its 2D structure [1]. Due to this remarkable discovery, the material graphene oxide (GO) became famous as a precursor for graphene synthesis, even though it was discovered about 150 years ago [2]. The GO is oxygenated form of graphene with many oxygen-containing groups (O-groups) and lattice defects. Hence, to fabricate graphene from GO, removal of these O-groups and repairing of the lattice defects is vital. This process is known as reduction [3]. However, to obtain pristine graphene from GO is the most challenging task due to the difficulty in complete removal of O-groups and repairing of lattice defects by conventional reduction method. It has been reported that, reduction of GO by high temperature annealing (>1500 °C) is an effective reduction method, particularly in producing conducting RGO films [4]. However, high temperature annealing transforms into high-energy consumption. Further, high temperatures cannot be used on all types of substrates in making graphene films. Therefore, the road to make pristine graphene like material by reducing GO still poses obstacles. As an alternative strategy, thermal annealing of GO in the presence of a carbon source (C-source) such as, ethanol, methane, ethylene, and acetylene via chemical vapour deposition (CVD) has been reported (<1000 °C) [5,6]. In our previously published work, fabrication of conducting RGO films by the restoration of graphitic structure via ethanol-CVD was reported [7]. As a continuation of this work, here we report, with the objective to understand the restoration behaviour of lattice defects, thermal annealing of GO in the presence of various organic solvents such as ethanol, methanol, isopropanol, tert-butanol, ethylene glycol, and toluene.

To mention the methodology in brief, first a dispersion of GO was spin-coated on SiO2/Si substrates and thermal annealing was done in the presence of the above solvents using a CVD device. Characterization of the synthesized samples was done by Raman spectroscopy, atomic force microscopy (AFM) along with Kelvin probe force microscopy (KPFM), and X-ray photoelectron spectroscopy (XPS). Preliminary results showed that there is a significant effect on restoration of lattice defects depending on the organic solvent used. Particularly, the Raman spectroscopic results show the evolution of the G’-peak, which is an indication of restoration of lattice defects, and depending on the C-source the spectral properties change (intensity of G’-peak increases with more carbon atoms). The AFM results showed that the thickness of a single GO sheet has reduced from 1 nm to 0.4 nm due to removal of O-groups upon thermal treatment. Further, conductivity measurements of the synthesized RGO films will be carried out to clarify the solvent dependence on the restoration of lattice defects.

Symmetry Dependent Kinetics of 2D Materials’ Growth and Etching Jichen Dong1 and Feng Ding1,2; 1Center for Multidimensional Carbon Materials, Institute for Basic Science, Korea (the Republic of); 2Ulsan National Institute of Science and Technology, Korea (the Republic of)

The unique structures of 2D materials make them to show many excellent electronic, chemical and thermal properties that are absent from their 3D counterparts. To date, tremendous efforts have been devoted to the synthesis of large-area high-quality 2D materials. Moreover, studies have shown that etching, which has been one of the key techniques in the semiconductor society, can be used to create various strictures in 2D materials, which can not be obtained by direct growth (PNAS 110 20386 (2013)). Therefore, A deep understanding on the growth and etching behaviors of 2D materials is crucial for their controllable fabrication. Here, we propose a general model for the growth and etching of two dimensional (2-D) crystals. In this model, low index edges are treated as the basis, while high index ones are described to be composed of terraces along the basis directions and kinks that connect the terraces. Considering the high formation energy penalty of forming a 1D nucleus on a terrace and the easy addition or removal of atoms to or from the kink sites, symmetry dependent edge growth and etching rate profiles of 2D crystals are constructed. By applying the kinetic Wulff construction (KWC) for growth and our modified KWC for etching, we simulated the shape evolutions of 2-, 3-, 4- and 6-fold symmetric 2D crystals during their growth and etching processes, which are well consistent with many experimental observations. This proposed model is expected to be a standard model for the growth and etching of 2D crystals.
Robustness of Atomic Scale Phosphorous Delta Layers—Toward Room Temperature Operation

David A. Scrymgeour, Connor Halsey, Daniel Ward, DeAnna Campbell, Evan Anderson, Scott W. Schmucker, Jeffrey A. Ivie, Ezra Buusmann, Suzey Gao, Tzu-Ming Lu and Shashank Misra; Sandia National Labs, United States

Atomic precision phosphorus doping of silicon by scanning tunneling microscope (STM) based hydrogen resist lithography is a promising fabrication platform for creating advanced silicon based electrical and quantum structures. In this process, termed atomic precision advanced manufacturing (APAM), the doping is accomplished by selective depassivation of bound hydrogen with the STM tip, incorporation of phosphine molecules, and capping with epitaxial silicon. APAM devices could provide a platform to learn about the device physics relevant to future transistor technologies. Moreover, these structures can carry a surprising 2 mA/μm of current, potentially enough to integrate APAM structures and devices with modern CMOS transistors. However, these devices have limited applicability because they only operate at cryogenic temperatures, and their ability to withstand the operational environments of CMOS is an open question. In this work, we report on our attempts to demonstrate room temperature devices realized in silicon-on-insulator devices and delta layer analogs, and the discuss the robustness and failure mechanisms at elevated temperature and current densities. These results show utility and challenges of this material platform for future discovery platforms.

This work was supported by the Laboratory Directed Research and Development Program at Sandia National Laboratories and was performed, in part, at the Center for Integrated Nanotechnologies, a U.S. DOE, Office of Basic Energy Sciences user facility. Sandia National Labs is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC. Fabrication and Characterization of DNA Origami-Based Metal-Semiconductor Junctions

Basu R. Aryal, Dulashani R. Ranasinghe, Tyler R. Westover, Robert C. Davis, John N. Harb and Adam T. Woolley; Brigham Young University, United States

DNA-assisted bottom-up nanofabrication has demonstrated promise in creating both metal and non-metal nanostructures with diverse applications. To date, different-shaped and electrically connected metal nanostructures have been created and electrically characterized. However, the self-assembly and electrical measurement of semiconducting materials on DNA at the nanoscale have not been demonstrated. We have examined the fabrication yield and electrical properties of various Au nanowire structures created on DNA origami tiles by site-specific attachment of Au nanorods to molecularly programmed sites.1 We are now working with metals and semiconductors on these DNA nanostructures. We have attached Au and Te nanorods to designed locations on individual DNA origami templates and connected the nanorods via electroless Au deposition technique to create metal-semiconductor junctions. In addition, two-point probe electrical measurements were performed to verify the electrical continuity of the junctions, and non-linear current vs voltage curves were obtained. This work is a step toward self-assembling metals and semiconductors at the nanoscale using DNA origami structures, with potential future nanoelectronics applications.

Tailoring the Electronic Transport Properties of MoS2 Thin Film by Oxygen Plasma Treatment

Bhim Chamlagain and Saiful I. Khondaker; University of Central Florida, United States

Controlled and meticulous tunability of electronic properties of layered two-dimensional (2D) transition metal dichalcogenides (TMDs) is essential challenge to fabricate TMDs functional devices for the specific applications. Structural defects, crystallinity of the film and dopants used in two-dimensional (2D) transition metal dichalcogenides (TMDs) can significantly modify the material properties. Significant effort has been done to tune the optical and electrical properties of MoS2 with plasma exposure by manipulating the defects, doping and band structure. However, the observation of structural defects repair and phase change of MoS2 by plasma exposure has been still debatable. In this study, we will present the tunability of the electrical properties MoS2 thin film prepared by low pressure chemical vapor deposition (LPCVD) method with low power oxygen plasma treatment. Our electrical transport measurements elucidate the effect of the mild oxygen to
the MoS$_2$ film and able to tune the transport properties of the MoS$_2$.

This work was supported by U.S. National Science Foundation under grant No. 1728309.

Non-Destructive Thickness Mapping of Insulating 2D Materials Down to a Monolayer Andrea Crovetto$^1$, Patrick Whelan$^1$, Ruizi Wang$^2$, Miriam Galbiati$^1$, Stephan Hofmann$^2$ and Luca Camilli$^1$; $^1$Technical University of Denmark, Denmark; $^2$Cambridge University, United Kingdom

Characterization of the thickness and continuity of wide band gap 2D materials with monolayer sensitivity over large areas has proven to be very challenging. A prime example is 2D hexagonal boron nitride (hBN). Optical contrast methods suffer from the lack of visible absorption in the material; Raman spectral signatures are weak and often not conclusive; and electrical measurements are not possible due to a high electrical resistivity. In this contribution, we will demonstrate an experimental method based on the ellipsometry technique, which makes it possible to map the thickness and continuity of large-area hBN monolayers and bilayers transferred to Si/SiO$_2$ substrates. The method has sub-monolayer thickness sensitivity, is relatively fast, non-destructive, and can be easily automated. Importantly, artifacts in the measured thickness due to polymer residuals from the transfer process can be deconvolved under most conditions. With some assumptions on the optical functions of hBN, the thickness of an as-transferred hBN monolayer on SiO$_2$ is measured as 4.1 Å ± 0.1 Å, whereas the thickness of an air-annealed hBN monolayer on SiO$_2$ is measured as 2.5 Å ± 0.1 Å. The most likely cause of this discrepancy is the presence of a water layer trapped between the SiO$_2$ surface and the hBN layer in the latter case. The number of hBN layers measured in this study has been confirmed by Raman spectroscopy, x-ray photoemission spectroscopy, and by a series of ellipsometry control experiments. We will present a workflow of our experimental procedure, so that other researchers can extend this characterization method to other 2D materials and hopefully accelerate their development.

S.NM06.10.27
Molecular Modeling of Biomaterial Degradation in Two Dimensions Falk Hoffmann, Rainhard Machatschek, Stefanie Barbirz and Andreas Lendlein; Helmholtz-Zentrum Geesthacht, Germany

Modern medical applications require the design of multifunctional polymers. These substances shall fulfill several roles while implanted in the human body, for example as mechanically supporting devices that can release a drug, followed by a full, non-toxic degradation. A concept for implanting multiple functions is molecular integration through well-defined polymer architectures. Here, structure parameters, which can be varied include composition and ratio of different molecular building blocks as well as the branching type. Moreover, the aqueous biological environment can influence polymer behavior, like hydrogel swelling in water that may trigger both drug release and subsequent degradation.

Material design therefore implies knowledge on structure-function relationships that enable rapid prediction of material properties under specific conditions and external stimuli over sufficiently long time scales. Especially, polymer degradation has major impact on material physicochemical properties and requires thorough understanding of the molecular processes [1]. Importantly, degradation at the polymer surface links to medical applications. For example, medical drugs are delivered in the human body without functional loss if they are encapsulated in a polymer matrix which degrades at the surface without effecting its bulk composition. Recent experimental studies have shown that defined two-dimensional thin film polymer layers are highly suitable to quantitatively study degradation kinetics with Langmuir techniques [2]. In this work we now apply computational simulations to provide an all-atomic description of the polymer degradation process at the two-dimensional interface. A molecular modeling approach is used to show how a molecular monolayer polymer surface film at the water interface behaves at different stages of the degradation process. The models are validated by exploring chemically established commercially available implant materials such as PLGAs (poly(lactide-co-glycolide)s and PCL (poly(ε-caprolactone)). The validation takes random chains as well as end-chain cutting as degradation mechanisms into consideration.

Finally, the model will be used as a predictive tool for digitally assembled copolyesters comprising the same repeating units, but aligned in sequence structure, which in part are challenging to synthesize such as strictly alternating structures. The gained knowledge will form the basis for the design of the next generation of degradable implant materials.

Exploring the Role of Dimensional Variation in Molybdenum Disulphide (MoS$_2$) by Relating the Structural, Morphological and Optical Characteristics Margi Jani, Dhyey Raval, Abhijit Ray and Indrajit Mukhopadhyay; Pandit
Deendayal Petroleum University, India

Molybdenum disulphide (MoS₂) as a transition metal dichalcogenides (TMDCs) sketching a wide research interests with unique optical and electronic properties then a bulk. Bandgap engineering technique is a potential way for tuning to its optimization. MoS₂ owing to band gap tailoring from 1.3 to 1.9 eV for bulk (indirect) and single-layered (direct) structures makes it a promising material in the field of energy applications. The present article deals with variation in the properties along with dimensional (1-3D) change in molybdenum disulphide nanostructure. Syntheses, structural, morphological, optical properties of bulk to few layers of nanostructures are investigated. The exfoliation of MoS₂ Flake like nanostructure has been studied for its unique properties. Uniform 3D flower like nanostructures has been prepared by one-pot hydrothermal method. Nanostructure flakes by a solution based exfoliation method are compared with a bulk MoS₂. Structural, morphological and optical properties were investigated by XRD, FESEM, EDAX, UV–Visible for the bulk and nanostructures properties.

S.NM07

2:45 PM *
Topological Quantum Materials for Quantum Electronic Devices Philip Kim; Harvard University, United States

Modern electronics has been heavily relied on the technology to confine electrons in the interface layers of materials. The unique properties of these low dimensional systems are generally understood by considering enhanced quantum effects and increased correlations due to the reduction of available phase space. Quantum effect in low dimensional materials also provides topological states of matter where entangled quantum states that can be transformed smoothly with protected symmetries, resulting in robust invariants. In this presentation, we will discuss some of the key physical phenomena such as the Berry phase, quantum Hall, and the quantum spin Hall effect. Topology and collective phenomena give quantum materials emergent functions that provide a platform for developing next-generation quantum devices with novel functionality, such as electronics without power dissipation and fault-tolerant quantum computing. We will discuss the prospect of quantum technology based on topological quantum materials.

3:45 PM BREAK

Terahertz Light Control and Nano-Imaging of Quantum Materials Jigang Wang; Iowa State University, United States

The recent development of ultrafast THz spectroscopy and nano-imaging tools facilitates discovering and understanding collective excitations and emergent phenomena in quantum materials. In this tutorial, I will discuss strategic advantages, with recent examples, of applying single- and few-cycle THz pulses to probe and control several systems of current focus, including unconventional superconductors, topological matter and perovskite photovoltaic semiconductors. Particularly, THz light-driven coherence and dynamic symmetry breaking allows the observation of quantum beats forbidden by equilibrium symmetry and quantum phases hidden by conventional tuning methods. Finally I will discuss far-reaching consequence of THz spectroscopy tools at the space-time limit on quantum matter discovery and dynamic control.

5:00 PM BREAK

5:15 PM *
Magnetism in Quantum Materials—Computation Approach Liqin Ke; Ames Laboratory, United States

The magnetic 2D van der Waals materials have received great attention due to their potential applications in spintronics. In this tutorial, I will give an introduction to computational magnetism. In particular, I will focus on the ab initio methods that used to compute and resolve intrinsic magnetic properties, such as exchange coupling, magnetocrystalline anisotropy, and magnetic susceptibility. We will discuss the underlining magnetic mechanisms that may guide the bandstructure engineering to improve the magnetic properties in these systems.
coherence into topological matter may become a universal light control principle for reinforcing the protected quantum transport.

12:54 PM *S.NM07.09.03
Manipulating Valley-Selective Photon Dressed States in Monolayer Semiconductors Nathaniel P. Stern; Northwestern University, United States

Control over the interactions between light and matter underlies many classical and quantum applications. In recent years, 2D layered semiconductors have gained prominence for optoelectronics because of their strong excitonic features and capacity for van der Waals assembly in layered heterostructures. Through integration with various photonics devices, the interactions between these materials and light can be tailored and new physical regimes can be achieved, highlighting the importance of understanding photonic dressed states of 2D materials. One of the unique features of monolayer materials such as transition metal dichalcogenides is the valley pseudospin addressable by circularly-polarized light. Understanding how this valley polarization can be manipulated is an exciting goal with implications for devices and quantum information science. Here, I discuss hybrid light-matter dressed states, or exciton-polaritons, in transition metal dichalcogenides embedded in dielectric microcavities. These strongly-coupled polaritons preserve the valley pseudospin known from bare monolayers [1]. Distinct behavior of valley-polarized exciton-polaritons can be accessed with microcavity engineering by tuning system parameters such as cavity decay rate and exciton-photon coupling strength. In the opposite dressed state regime of weak light-matter coupling, intense off-resonant light can be used to shift energy levels though the Stark effect [2]. Applied to valley-sensitive states, this shift can be used for coherent manipulation of valley pseudospin. I will show how this approach can be translated to valley-selective exciton-polaritons. Cavity reflectance spectra exhibit a simultaneous shift of both polariton branches when ultrafast coincident pump and probe pulses are co-circularly-polarized, and no appreciable shift when they are cross-polarized. This valley-selective polariton Stark shift combines both dressed state regimes of strong, near resonant interactions with weak, off-resonant optical interactions, providing a new tool for state control in coherent valleytronics. Exploiting photonic dressed states can be viewed as another approach in the toolbox for manipulating the optoelectronic properties of 2D materials and their heterostructures.

Local Site Magnetic Susceptibility on Quantum Materials by Polarized Neutron Diffraction Huibo Cao; Oak Ridge National Laboratory, United States

Understanding the interactions leading to magnetic quantum phenomena in a wide range of quantum materials is extremely important for development of new quantum materials and future technologies. Although neutron scattering is a powerful tool for this purpose, it also faces a range of challenges, such as the lack of sizable high-quality crystals, limited high pressure capabilities, and the difficulty in disentangling the intrinsic quantum phenomena versus effects from defects and site-disorder. Recently we have introduced the local magnetic susceptibility methods for studying quantum materials, which can be used for small crystals and powder samples. A single crystal neutron diffractometer DEMAND at the High Flux Isotope Reactor at the Oak Ridge National Laboratory has been upgraded for studying magnetic materials under various extreme sample environment conditions. In this talk, I will introduce the local site magnetic susceptibility methods, the current capabilities at the DEMAND, and our recent studies on two-dimensional quantum materials.

1:18 PM *S.NM07.09.05
Quantum Oscillations in Resistivity and Magnetization in Kondo Insulators Lu Li; University of Michigan, United States

In metals, orbital motions of conduction electrons on the Fermi surface are quantized in magnetic fields, which is manifested by quantum oscillations in electrical resistivity. This Landau quantization is generally absent in insulators. Here we report a notable exception in an insulator — ytterbium dodecaboride (YbB_{12}). The resistivity of YbB_{12} exhibits distinct quantum oscillations despite having a much larger magnitude than in metals. This unconventional oscillation is shown to arise from the insulating bulk, even though the temperature dependence of the oscillation amplitude follows the conventional Fermi liquid theory of metals. The large effective masses indicate the presence of a Fermi surface consisting of strongly correlated
electrons. Quantum oscillations are also observed in the magnetization of YbB12. Our result reveals a mysterious dual nature of the ground state in YbB12: it is both a charge insulator and a strongly correlated metal.

**Spin Excitations in Magnetic 2D van der Waals Materials—Nonlocal Electron Correlation Effects** Liqin Ke; Ames Laboratory, United States

The recent experimental realization of magnetic two-dimensional van der Waals (m2DvdW) materials has generated significant interest in exploiting such systems for novel 2D magnetism and for developing applications such as energy-efficient ultra-compact spin-based electronics. A better understanding of the magnetic interactions in these systems may help to accelerate the discovery of materials with higher magnetic ordering temperatures, moving these novel systems closer to practical applications. Using linear-response ab initio methods, we investigate the magnetic interactions and spin excitations in various m2DvdW systems, such as CrI3, CrGeTe3, V13, and Fe3GeTe2. Dynamical transverse spin susceptibility is calculated to directly compare with available Inelastic Neutron Scattering (INS) measurements. Accurate descriptions of electronic structure can provide reliable predictions of electronic and magnetic properties. Due to confinement, electrons in these 2D systems are likely to be strongly correlated, and electron screening anisotropic, so that their description may require advanced ab initio methods beyond density functional theory (DFT). Therefore, we also use the quasiparticle self-consistent GW (QSGW) method, a self-consistent many-body perturbation method, to describe the electronic structure and calculate magnetic properties. In contrast to DFT, the electron-electron interaction is evaluated explicitly by calculating the dynamically-screened Coulomb interaction W. We found that the nonlocal electron correlations, which are not included in methods such as DFT+U, have profound effects on the electronic and magnetic properties in these m2DvdW materials. A more elaborate description of electron interactions helps better describe the magnetic interactions in these 2D quantum systems. By comparing the electronic structures obtained in QSGW and DFT, we discuss the applicability and limitations of the widely-used DFT+U methods for these systems. We will also discuss the effects of spin-orbit coupling, the Dzyaloshinskii-Moriya interaction, impurities, pressure, and electric fields on the magnetic interactions and excitations in relevant systems.

**High Pressure Driven Structural and Electronic Phase Transitions in 2D Materials and Structures** Junqiao Wu, Yang Gao and Penghong Ci; University of California, Berkeley, United States

High pressure is a powerful, reversible and “clean” way to drive materials away from equilibrium, exposing new phases, new states, new effects and new physics that would not exist in ambient condition. For layered materials where neighboring layers are held together by weak van der Waals forces, high pressure are particularly effective in creating these new effects. In this talk, we will discuss some of our findings in using high hydrostatic pressure to modulate the structure and electronic/optical properties of a variety of 2D materials, ranging from single or few layers of transition metal dichalcogenides, and their heterostructures, to new 2D materials created by intercalating non-2D materials.

**Fluctuations in Quantum Materials—From Skyrmions to Superconductivity** Joshua J. Turner1,2; 1Stanford University, United States; 2SLAC National Accelerator Laboratory, United States

Quantum materials offer not only a vast array of potential for technological advancement, but also provide a testbed for the laws of nature in condensed matter. One area to advance the frontier in this area is through the measurement of fast, spontaneous fluctuations of quantum order. This is at the heart of the essential physics in these types of solids, but has remained largely unexplored. The key component we use is the application of a newly developed coherent scattering method which can access these fluctuations on the relevant energy scales. This new tool has been demonstrated on a topological magnetic material, and early results point to the tremendous potential for this approach to provide important new insight into fundamental open questions in condensed matter. It allows for the direct, element-specific and momentum-resolved measurement of the fluctuations of a complex material and to connect them to the requisite response functions calculated from first principles. By analyzing subtle X-ray variations known as "speckle", statistics is used to extract the stochastic fluctuation information of the system. This offers the ability to address a range of important current problems in materials. In this talk, we will first discuss the newly developed tools which are used to measure the material properties, based on short pulses from an x-ray free electron laser. We will then present how this has been applied to skyrmions and the measurement of nanosecond fluctuations. This will be followed by an examination of new results on skyrmion physics near the critical point of the skyrmion ordered lattice phase. We will end with an outlook of how this progress can help to tackle the question of fluctuations in unconventional superconductors.

Investigation of Coherent Magnons in Antiferromagnetic Iridate Sr₂IrO₄ Richard D. Averitt; University of California, San Diego, United States

The spin-orbit coupled Mott insulator Sr₂IrO₄ has attracted considerable interest because of its exotic \( J_{\text{eff}} = 1/2 \) Mott state arising from the interplay of on-site Coulomb repulsion and strong spin-orbit coupling. We have investigated magnetization dynamics of this enigmatic compound. Specifically, we measured coherent magnons of the \( J_{\text{eff}} = 1/2 \) Mott state using Kerr rotation following excitation with either mid-infrared 9 \( \mu \)m (below the charge gap), or near-infrared 1.3 \( \mu \)m (above the charge gap) circularly polarized pulses. For both pump wavelengths, the 2D in-plane \( B_{2g} \) coherent magnon oscillation of frequency \( \sim 0.5 \) THz is observed. In this talk, we show that the excitation pathways are different for these two excitation wavelengths. In particular, coherent magnon excitation with 9 \( \mu \)m pulses arises from the inverse Faraday effect that, microscopically, is related to two-magnon processes. Notably, coherent magnon generation with 9 \( \mu \)m pulses is nearly an order of magnitude more efficient in comparison to 1.3 \( \mu \)m pulses, without excitation of carriers across the Mott gap.

Non-Equilibrium Effects in Quantum Magnets Kate Ross and Steffen Saeubert; Colorado State University, United States

The study of non-equilibrium properties of quantum phases of matter is important in the context of future quantum technologies, since all devices operate in the non-equilibrium limit. Theoretically, the transverse field Ising model (TFIM) and its disordered variants provide a tractable platform to study effects of quantum quenches (a rapid variation of a non-thermal parameter, leading to interesting transient effects), or quantum annealing (a slow variation of a non-thermal parameter, leading to efficient optimization). While there is enormous theoretical interest in these ideas, they have not yet been thoroughly tested on real Ising magnetic systems. There are well-known magnetic material realizations of the TFIM, CoNb₂O₆ and LiHoYF₄, which display quantum critical points in accessible transverse magnetic field ranges. We have studied these materials following various protocols of time variation of the magnetic field, using ac susceptibility and neutron scattering as probes. I will discuss the non-equilibrium effects we have observed in these TFIM materials.

Magnetic Field Induced Berezinskii-Kosterlitz-Thouless Correlations in Three-Dimensional Manganites Subray Bhat¹, Bhagyashree KS¹ and Arjun Ashoka²; ¹Indian Institute of Science, India; ²University of Cambridge, United Kingdom

Ideal two-dimensional (2D) Heisenberg magnets lack long range order [1]. However, the XY model with spins confined to a plane shows a topological phase transition at a finite temperature corresponding to binding and unbinding of vortices [2,3]. Experimental evidence for such Berezinskii-Kosterlitz-Thouless (BKT) transitions has been difficult to obtain in condensed matter systems, where, even a weak interlayer coupling that is invariably present leads to long-range order, pre-empting the BKT transition. The BKT signatures are still discernible above the long-range ordering temperature, however, in the characteristic exponential temperature dependence of the coherence length of the fluctuations. In this work we report that an applied magnetic field can induce such BKT correlations not only in quasi 2-dimensional systems but also in nominally 3-dimensional manganites undergoing antiferromagnetic transitions. We arrive at this unexpected conclusion based on our
studies of temperature dependence of electron spin resonance (ESR) linewidth $\Delta H(T)$ of Cr$^{3+}$ doped bismuth strontium manganite Bi$_{0.5}$Sr$_{0.5}$Mn$_{1-x}$Cr$_x$O$_3$ ($x=0.04, 0.1$) (BSMCO).

BSMCO [4] belongs to the family of mixed valent manganites of the type ReAMnO$_3$ where Re is a trivalent rare earth ion or Bi$^{3+}$ and A is a divalent alkaline earth ion, which are intensely studied in the last few years [5]. $\Delta H(T)$ provides the most important probe to study the spin interactions in these strongly correlated spin systems. We find that $\Delta H(T)$ observed in BSMCO (current work), as well as in La$_{0.5}$Ca$_{0.5}$MnO$_3$ and CaMnO$_3$ [6] is better (than the usually adopted critical state model) described by the BKT scenario which predicts [7]

$$\Delta H_{\text{BKT}}(T) = \Delta H_\infty \exp \left[ \frac{3b}{T/T_{\text{BKT}} - 1}^{0.5} \right] + mT + \Delta H_{\text{ind}}, \quad T > T_{\text{BKT}}$$

where $T_{\text{BKT}}$ is the BKT transition temperature and $b = \pi/2$ for a square lattice and the last two terms are included to account for the high temperature and temperature independent behaviour. This is unexpected as these manganites have a 3D structure and the BKT model addresses systems with spin and spatial dimensions of two. We understand this result in terms of an effective symmetry reduction induced by i) the magnetic field applied in the ESR experiment and ii) the intrinsic anisotropy arising from microscopic details such as doping and phase separation - contributing to an effectively 2-dimensional XY easy plane anisotropy. Nanometric scale spin clusters similar to the ones observed in La doped CaMnO$_3$ [8] could conceivably play the role of vortices in these 3D materials. The sensitivity of the BKT behaviour to applied field is also supported by a re-analysis of the field dependence of the $\Delta H(T)$ in the quasi-2D antiferromagnetic compound BaNi$_2$V$_2$O$_8$ reported by Heinrich at al., [9]. For undoped manganites we find $T_{\text{BKT}}$ is of the order of the magnetic interaction energy, suggesting that the applied field could be the sole origin of the BKT behaviour [10]. We shall also address the interesting observation that in BSMCO ($x=0.04, 0.1$), $T_{\text{BKT}}$ is composition-independent while the magnetic properties are quite sensitive to composition.

Ultrafast Energy- and Momentum-Resolved Dynamics of Magnetic Correlations in the Photo-Doped Iridates

Mark P. Dean; Brookhaven National Laboratory, United States

Measuring how the magnetic correlations evolve in doped Mott insulators has greatly improved our understanding of the pseudogap, non-Fermi liquids and high-temperature superconductivity. Recently, photo-excitation has been used to induce similarly exotic states transiently. However, the lack of available probes of magnetic correlations in the time domain hinders our understanding of these photo-induced states and how they could be controlled. This talk will describe our implementation of magnetic resonant inelastic X-ray scattering at free-electron lasers to directly determine the magnetic dynamics after photo-doping the Mott insulators Sr$_2$IrO$_4$ and Sr$_3$Ir$_2$O$_7$ [1-3]. We find that the non-equilibrium states host strong 2D magnetic correlations even in cases where 3D long-range magnetic order is completely suppressed [1]. The marked difference in these 2D and 3D timescales implies that the dimensionality of magnetic correlations is vital for our understanding of ultrafast magnetic dynamics. We also uncover distinct differences in the magnetic dynamics between insulators Sr$_2$IrO$_4$ and Sr$_3$Ir$_2$O$_7$, which we attribute to a “spin-bottle-neck” effect [3].

Keynote: Topological Defects in Twisted van der Waals Interfaces Philip Kim; Harvard University, United States

Controlling the interlayer twist angle in artificial two-dimensional (2D) van der Waals (vdW) heterostructures offers an experimental route to create moire superlattice. One can create exotic electronic states by minimizing electronic band width with tunable moire length scale. However, in the small twist angle regime, vdW interlayer interaction can cause significant structural reconfiguration at the interface, creating the arrays of domain structures. In this presentation, we will discuss the atomic reconstruction at twisted vdW interfaces and its effect on electronic structure and electrical transport behavior. Furthermore, we note that multiple domain boundaries at the reconstructed interface join together to create energetically unfavorable nodes forming vortex-like structures. We will discuss our recent efforts to understand the topological nature of those defects.

8:48 AM *S.NM07.03.04
Tracking Non-Equilibrium Magnetism in Quantum Materials John Freeland; Argonne National Laboratory, United States

Non-equilibrium phases have developed as an important topic in the realm of layered materials, especially in the two-dimensional limit. Of particular interest is the case of magnetism in the single layer limit[1]. Using external inputs ranging from static to dynamic, the states in these systems can be strongly manipulated to drive transitions between different spin configurations[2]. However, the challenge is to follow the emergent or collapses of specific phases in systems that are at the two-dimensional limit. Here I will focus on using X-rays to explore the magnetic order parameter directly for the cases involving antiferromagnetic and ferromagnetic states. The use of polarized X-rays in either scattering or absorption experiments, has a long history of probing magnetic states. With synchrotron and free-electron laser sources, we can extend this to the ultrafast domain to follow the dynamic response of the magnetic configuration. Here I will present examples involving dynamic collapse of antiferromagnetic order in nickelates to the optical conversion of antiferromagnetic to ferromagnetic order in manganites[3]. I will use these ultrathin oxide films as examples of exploration of magnetism in the two-dimensional limit using X-rays.

Keynote: Light-Matter Interaction in Two-Dimensional Semiconductors Vinod Menon; City College and Graduate Center of CUNY, United States

Owing to their large oscillator strength and strong exciton binding energy, two-dimensional (2D) transition metal dichalcogenides (TMDs) have emerged as an attractive material platform for studying strong light-matter coupling and associated phenomena. Following up on our previous work on strong light-matter coupling in 2D TMDs [1, 2], here we will present results on enhancing the nonlinear interaction between the quasiparticles (exciton-polaritons). This is achieved using excited states of excitons (Rydberg states) which have larger Bohr radii. We will also present our recent results on controlling the valley pseudospin via the pseudomagnetic fields in optical cavities and our work on realizing an electrically pumped polariton LED [3]. Finally, we will first present our work on realizing single photon emitters (SPEs) in hexagonal boron nitride (hBN), a van der Waals material, via strain engineering [4] and coupling of these SPEs to high Q silicon nitride microresonators [5].

Uniaxial Stress Effect on a Transition Metal Dichalcogenide, WTe2 Na Hyun Jo, Lin-lin Wang, Peter P. Orth, Sergey L. Bud'ko, Adam Kaminski and Paul C. Canfield; Ames Laboratory/Iowa State University, United States

Strain describes the deformation of a material as a result of applied stress. It has been widely employed to probe transport properties of materials, ranging from semiconductors to correlated materials. In order to understand, and eventually control, transport behavior under strain, it is important to quantify the effects of strain on the electronic band structure, carrier density and mobility. Here, we demonstrate that much information can be obtained by exploring a novel experimental observable: magneto-elastoresistance (MER), which refers to magnetic field-driven changes of the elastoresistance. We use this powerful approach to study the combined effect of strain and magnetic fields on the semi-metallic transition metal dichalcogenide WTe2. We discover that WTe2 shows a large and temperature non-monotonic elastoresistance, driven by uniaxial stress, that can be tuned by magnetic field. Using first-principle and analytical low-energy model calculations, we provide a semi-quantitative understanding of our experimental observations. We show that in WTe2 the strain induced change of the carrier density dominates the observed elastoresistance. In addition, the change of the mobilities can be directly accessed using MER. Our analysis also reveals the importance of a heavy hole band near the Fermi level on the elastoresistance at intermediate temperatures.
Microscale Synthesis of Photoluminescent Silicated Quantum Dots for Particulate-Flow Tracking

Clara Reed, Lance Hubbard, Nic Uhnak, Trevor Cell, Ryan Sumner, Martin Liezers, Nathaniel Smith, Michael Foxe, April Carman and Caleb Allen; Pacific Northwest National Laboratory, United States

Particulate flow measurements require environmentally inert and size-selected particles, with unique identifiers. Agglomerated microscale silica covered quantum dots (QDs) were synthesized and used for explosive mass-deposition measurements within fabricated enclosures. Experimental determination of luminescent intensity, as well as chemical-environmental tolerance, were conducted to ensure the inert nature and unique identifier for each size-selected band. Reagent concentration control was used to produce silicated/QD luminescent particles with bands centered from 100 nm to 4 microns. The ability to uniformly size particles and link the size to an easily identifiable characteristic, such as luminescence, allows for the creation of flow-based particle distribution description. This is a valuable tool for the analysis of turbulent flow in highly variable cavities. Future modeling with these particles can be used to predict the deposition and settling location of particulates and the environmental flow of debris in turbulent fluid environments.

Ultrafast Optical Studies of Two-Dimensional Quantum Materials

Rohit Prasankumar; Los Alamos National Laboratory, United States

Ultrafast optical spectroscopy has attained prominence due to its ability to resolve dynamics in conventional metals and semiconductors at the fundamental time scales of electron and lattice motion. In recent years, ultrafast optical techniques have become more sophisticated, making it possible to directly access fundamental material parameters in a non-contact manner. In this talk, I will discuss the use of ultrafast optical spectroscopy to track and potentially control carrier dynamics through both space and time in two-dimensional (2D) quantum materials. This will include unraveling charge transfer and diffusion across the interface between lateral transition metal dichalcogenide (TMD) monolayers as well as driving structural dynamics in a topological insulator with intense terahertz (THz) pulses, along with other studies of these fascinating nanosystems.
At the time of its discovery, antiferromagnetic (AFM) order was considered as an interesting but essentially useless phenomenon in terms of application. Now, however, the AFM state is being regarded as highly promising for spintronic applications. The fully compensated magnetic order makes it robust against external magnetic fields and at the same time leads to vanishing magnetic stray fields, thus reducing crosstalk between neighbouring AFM domains. Furthermore, the AFM order permits spin dynamics in the THz-regime with AFM switching processes on the picosecond timescale. Because of the absence of a macroscopic magnetization, ultrafast detection of the AFM state is challenging, however. In my talk, I present various laser-optical approaches to overcome this. On the one hand, linear and nonlinear laser-optical processes allow us to track the ultrafast three-dimensional motion of the AFM order parameter through space. By doing that, we show that, in stark contrast to ferromagnets, damping effects play an important role during the optical excitation of the AFM state and offer an efficient handle for all-optical AFM order-parameter switching ("writing an AFM bit") [1]. Furthermore, THz time-domain spectroscopy offers a novel approach for studying the competition of AFM order and a magnetically screened spin-liquid state with the formation of heavy fermions and their disintegration near the quantum-critical points in materials like CeCu$_6$-$_x$Au$_x$ and YbRh$_2$Si$_2$ [2, 3].

Non-equilibrium phases have developed as an important topic in the realm of layered materials, especially in the two-dimensional limit. Of particular interest is the case of magnetism in the single layer limit[1]. Using external inputs ranging from static to dynamic, the states in these systems can be strongly manipulated to drive transitions between different spin configurations[2]. However, the challenge is to follow the emergent or collapses of specific phases in systems that are at the two-dimensional limit. Here I will focus on using X-rays to explore the magnetic order parameter directly for the cases involving antiferromagnetic and ferromagnetic states. The use of polarized X-rays in either scattering or absorption experiments, has a long history of probing magnetic states. With synchrotron and free-electron laser sources, we can extend this to the ultrafast domain to follow the dynamic response of the magnetic configuration. Here I will present examples involving dynamic collapse of antiferromagnetic order in nickelates to the optical conversion of antiferromagnetic to ferromagnetic order in manganites[3]. I will use these ultrathin oxide films as examples of exploration of magnetism in the two-dimensional limit using X-rays.

Ultra-Thin van der Waals Crystals as Semiconductor Quantum Wells Samuel Magorrian, Johanna Zultak, Vladimir Falko and Roman Gorbachev; National Graphene Institute, University of Manchester, United Kingdom

The confinement of electrons in semiconductor quantum wells, and the resulting quantization of motion and energy, allows the engineering of electronic band structure and resulting device properties. However, this possibility has remained largely unexplored for the case of ultra-thin two-dimensional (2D) van der Waals crystals. Here, we apply the quantum well concept to 2D materials, using the thickness of exfoliated 2D crystals to control the quantum well dimensions in few-layer indium selenide. This approach allows high-precision control of the subband energies, with their uniformity giving high quality electronic transport properties to the system.

Here, for the first time, we present a comprehensive study of the full subband structure of atomically thin 2D semiconductors, applied to InSe[1]. The subbands of the conduction band are fully mapped using resonance tunneling spectroscopy, in agreement with theoretical density of states calculations. On the valence band side, we map the subbands using photoluminescence excitation (PLE), interpreting the results using theoretical calculations of the optical absorption and comparing them with ARPES data. Further evidence of quantum confinement is explored, including quantum-confined Stark shifts of the subbands on application of a bias across the crystal, and an increase in the binding energy of the excitonic resonance in absorption in the thinnest films is seen.

The analogy between ultra-thin van der Waals crystals and conventional semiconductor quantum wells can be clearly traced, with this work paving the way to the application of 2D materials in infrared and terahertz light sources employing intersubband optical transitions.

Exciton Polarons in Two-Dimensional Hybrid Metal-Halide Perovskites Ajay Srimath Kandada1,2, Felix Thouin3 and Carlos Silva2; 1Wake Forest University, United States; 2Istituto Italiano di Tecnologia, Italy; 3Georgia Institute of Technology, United States

Owing to strong electronic and dielectric confinement effects, strongly bound two-dimensional excitons are observed in layered hybrid organic-inorganic perovskites[1,2]. Given the relevance of polaronic effects in their 3D counterparts, here we ask if such effects are consequential for excitons in 2D HOIPs. We argue that the peculiar lattice interactions are manifested intrinsically in the exciton spectral structure, which is comprised of multiple non-degenerate resonances with distinct photophysical characteristics[2]. We highlight their population[3] and dephasing dynamics[4] that point to the apparently deterministic role of polaronic effects. We contend that an interplay of long-range and short-range exciton-lattice couplings give rise to exciton polarons, which fundamentally establishes their effective mass and radius, and consequently, their quantum dynamics[2]. Finally, we highlight opportunities for developing rigorous description of exciton polarons in 2D-HOIPs to advance their fundamental understanding as model systems for materials with strong lattice-mediated correlations.

Optical Properties of Two-Dimensional Electron Gas (2DEG) in Black Phosphorus Souvik Biswas¹, William S. Whitney¹, Meir Y. Grajower¹, Joeson Wong¹, Hans Bechtel², George Rossman¹ and Harry A. Atwater¹; ¹California Institute of Technology, United States; ²Lawrence Berkeley National Laboratory, United States

Two dimensional electron gases (2DEG) in graphene¹ have been explored in quantum transport measurements, yet unlike graphene, the optical properties 2DEGs in bP are relatively unknown. The crystal structure of bP is anisotropic¹, so it is a candidate material to exhibit naturally-occurring tunable hyperbolic dispersion. According to calculations⁴, plasmons (low energy collective mode excitations) in bP exist in the mid to far-infrared regime and exhibit hyperbolic dispersion and anisotropy in different frequency windows.

In order to probe plasmonic resonances we have performed far-field infrared spectroscopy measurements (with both thermal source and synchrotron beam at ALS, Berkeley) to observe gate-tunable polarized absorption in patterned bP nano-resonators encapsulated with hBN (to prevent oxidation). Ribbons of bP 100-150nm wide were fabricated via electron beam-lithography and reactive ion etching, aligned to its two principal crystal axes identified with polarized Raman spectroscopy and characterized with SEM. A vertical Fabry-Perot resonator was also used to enhance the weak plasmonic absorption. Polarized infrared extinction shows clear anisotropy in the 35-50µm regime, along with characteristic Fabry-Perot (F-P) peaks. Finite difference time domain (FDTD) simulations show good agreement with experimental results. However, these measurements are limited by two factors – patterning bP induces scattering centers leading to higher damping; dry etching of bP limits the accessible wave vectors, leading to resonances in the far IR with poor signal to noise ratio. To circumvent these limitations we designed a structure comprised of unpatterned bP (giving much higher quality 2DEGs) placed close to metallic resonators, which can be made at the 30-50nm scale, cladded by hBN spacer layers, enabling excitation of acoustic plasmons. FDTD simulations predict gate-tunable anisotropic/hyperbolic plasmonic resonances in 10-20µm range. Higher order optical modes from the metallic resonators and bP plasmon-hBN phonon coupling are observed. Fabrication techniques for such devices will be discussed, along with characterization techniques like polarized Raman spectroscopy, SEM and two-terminal field effect transport measurements. Also, polarization infra-red extinction and its dependence on charge density, duty cycle and hBN spacer thickness will be shown if time permits. Taken together, these optical studies offer a thorough understanding of low energy excitations in bP and suggest the potential for infrared fingerprinting in the THz range.

Ultrafast Enhancement of Magnetic Exchange Interactions in an Optically Excited van der Waals Ferromagnet David Hsieh; California Institute of Technology, United States

In this talk I will discuss how ultrafast optical techniques can be used to probe magnetic correlations and modify magnetic interactions in van der Waals materials. As a testbed I will discuss CrSiTe₃, which is composed of van der Waals bonded sheets of ferromagnetic interacting Heisenberg spins that, in isolation, would be impeded from long-range order by the Mermin-Wagner theorem. Using an optical second harmonic generation based probe of spin correlations, I will show how CrSiTe₃ evades this law via a two-step crossover from two- to three-dimensional magnetic short-range order above its Curie temperature. Having understood the interplay between short-range correlations and magneto-elastic distortions, I will then demonstrate, using coherent phonon spectroscopy, how optically induced ligand-to-metal charge transfer excitations can be used to transiently enhance magnetic super-exchange in CrSiTe₃.

6:40 AM S.NM07.03.11
Light Driven All-Solid-State Capacitive Charging of a 0D-2D Heterostructure Ilka Kriegel¹, Michele Ghini¹, Nicholas Borys², Sebastiano Bellani¹, Kehao Zhang¹, Adam W. Jansons³, Brandon M. Crockett⁴, Kristopher W. Koskela⁵, Edward Barnard⁶, Erika Penzo⁷, James E. Hutchinson⁴, Joshua Robinson⁴, Liberato Manna⁴ and P James Schuck⁶; ¹Italian Institute Technology, Italy; ²Montana State University, United States; ³The Pennsylvania State University, United States; ⁴University of Oregon, United States; ⁵Lawrence Berkeley National Laboratory, United States; ⁶Columbia University, United States
We report a novel 0D-2D hybrid heterostructure displaying light-driven capacitive charging dynamics through solid state photodoping. We exploit the coupling between indium tin oxide (ITO) nanocrystals and two-dimensional molybdenum disulfide (MoS2) to absorb and directly store the energy of the incoming light as extra charges within the ultra-thin heterostructure. By illuminating this hybrid system with light beyond the bandgap of ITO photo-electrons and holes are generated inside the nanocrystal and rapidly separated from each other. Photo-generated holes are quenched at the surface of the semiconductor and injected into the MoS2 monolayer, which acts as a hole collector. The photo-excited electrons accumulate in the ITO nanocrystal leading to the photodoping of the hybrid nanostructure. Multiple electrons can be excited and permanently stored displaying the behavior of a light-driven miniaturized capacitor. During the photodoping process we detect variations in the relative contributions of excitons and trions to the emission of 2D-MoS2: while the overall photoluminescence peak shifts over time to higher energies the exciton population is enhanced and the trion population suppressed. We extract the temporal evolution of the free carriers in the MoS2, which mimics the charging kinetics of a capacitive system. Further studies unveiled that the solid state photodoping process occurs over two main timescales, with most of the variations happening in the first 30 seconds and remaining established after the photoexcitation is switched off. Moreover, by probing the system with light at different wavelengths we identify two distinct processes competing with each other: one reversible due to the interaction between the MoS2 and air molecules and one irreversible due to the injection of extra holes transferred from the ITO nanocapacitors. Quantitative analysis suggests that each nanocrystal can store, in average, 40 optically generated electrons and that the p-type photodoping of 2D MoS2 reaches values compatible with electrostatic gating. These studies present an innovative step towards a light-driven hybrid 0D-2D nanocapacitor, opening prospects for the development of new solutions to directly store the solar energy.

6:50 AM  S.NM07.03.12

Ultrafast Manipulation of Surface Transport in Topological Insulators by Mid-Infrared and Terahertz Pulses  Jigang Wang; Iowa State Univ and Ames Lab, United States

The demand for disorder-tolerant quantum logic and spin electronics can be met by generating and controlling dissipativeless spin currents protected by topology. Dirac fermions with helical spin-locking surface transport offer a way of achieving such goal. Yet a challenge remains on how to selectively control surface helical spin transport and surface-bulk coupling. Here we use the mid-infrared and terahertz (THz) photoexcitation of intraband transitions and/or coherence optical phonons to enable ultrafast manipulation of surface THz conductivity in a topological insulator. We will also discuss how to extend the ultra-broadband, wavelength-selective pumping to emerging topological semimetals. Imposing electronic and vibrational coherence into topological matter may become a universal light control principle for reinforcing the protected quantum transport.

7:05 AM  S.NM07.03.13

Many-Body Contributions to the Valley-Selective Optical Stark Effect in Monolayer WS2  Paul D. Cunningham¹, Aubrey Hanbicki¹,², Thomas L. Reinecke¹, Kathleen M. McCreary¹ and Berend T. Jonker¹; ¹U.S. Naval Research Laboratory, United States; ²University of Maryland, United States

Valley pseudo-spin and broken inversion symmetry leads to valley-specific optical and transport properties in monolayer transition metal dichalcogenides (TMDC). Selective population of the degenerate K and K' valleys via right- and left-hand circularly polarized light has fueled interest in the potential of TMDCs for Valleytronic applications, where the momentum state is manipulated to perform logical operations.

Intense circularly polarized light fields can break the valley degeneracy, allowing the energy levels of each valley to be independently tuned via a valley-selective form of the optical Stark effect.¹² These strong light-matter interactions have historically been described by a two-level dressed-atom picture, which works well for semiconductors far from resonance where the Rabi frequency is larger than the exciton formation rate. Recently, the need to extend this model to include the additional energy levels associated with intervalley biexcitons has been demonstrated,³ however the basic assumption of non-interacting particles remained. Here, we report that this assumption is not applicable for excitation near resonance in monolayer WS2,⁴ where an excitonic model⁵ of the optical Stark effect that includes many body effects is required.

We use ultrafast transient absorption spectroscopy to show that the valley-selective optical Stark effect produces a blue shift for both below- and above-resonant excitation.⁶ This coherent light-matter interaction is inconsistent with the two-level dressed-atom picture, which predicts a change in the direction of the optical Stark shift when tuning through resonance.
Instead, our observations are well described by an excitonic model\(^5\) of the optical Stark effect that includes exciton-exciton interactions in addition to the exciton photon interaction. Here, we confirm the prediction from this theory that repulsion between virtual excitons will be the dominant contribution to the optical Stark effect when the excitation wavelength is detuned from resonance by less than the exciton binding energy. This observation demonstrates the need to include many-body Coulomb effects when describing the optical Stark effect in low-dimensional semiconductors that support bound excitons.

\textbf{Optical Control of Interlayer Exchange Interaction and Tunneling through Floquet States} \textbf{Wang-Kong Tse}; University of Alabama, United States

Floquet states are photon-dressed electronic states that emerge when driven by a time-periodic optical excitation. The presence of these states changes the equilibrium picture of electronic transitions into one where transitions between Floquet states are allowed. We have recently studied the indirect exchange (RKKY) interaction between ferromagnetic chains mediated by itinerant electrons that are driven strongly out of equilibrium by circularly polarized light. Emergence of non-equilibrium Floquet states leads to new and qualitatively different regimes of RKKY coupling, in which the sign (ferromagnetic or antiferromagnetic) and the period of the RKKY oscillation become tunable through the frequency and amplitude of the laser. Another phenomenon where Floquet driving plays a distinctive role is the tunneling dynamics in a tunneling junction. We have investigated the tunneling current between graphene layers under strong polarized radiation, predicting periodic suppression of the photon-assisted tunneling current when the bias voltage is equal to integer multiples of the photon frequency. Our findings on these Floquet systems demonstrate the feasibility of optically controlling the indirect exchange interaction and tunneling in van der Waals materials with coherent laser fields.

\textbf{Tuning the Kinetic Energy of Pulsed Laser Deposition Plasmas to Selectively Convert Atomically Thin Transition Metal Dichalcogenides and Form Janus Monolayers} \textbf{Yu-Chuan Lin}\(^1\), Yiling Yu\(^1\), Chenze Liu\(^1,2\), Eva Zarkadoula\(^1\), Mina Yoon\(^1\), Alexander Puretzky\(^1\), Ilia N Ivanov\(^1\), Christopher Rouleau\(^1\), Harry Meyer\(^1\), Matthew Chisholm\(^1\), Gerd Duscher\(^1,2\), Kai Xiao\(^1\) and David B. Geohegan\(^1\); \textsuperscript{1}Oak Ridge National Laboratory, United States; \textsuperscript{2}The University of Tennessee, Knoxville, United States

Janus two-dimensional (2D) materials present a new form of quantum materials predicted to exhibit topological phases and the Rashba-type spin-orbit-coupling. Despite the fact that Janus monolayers have now been experimentally realized, the reliable synthesis of these metastable materials requires precise synthetic control. Pulsed laser deposition (PLD) plasma plumes offer hyperthermal kinetic energies that have been used for decades to synthesize thin films of many materials and are currently being explored for the growth of 2D transition metal dichalcogenides (TMDC) in metastable phases, alloys, and heterostructures. Here, we demonstrate PLD for the selective replacement of sulfur by selenium in monolayer (ML) WS\(_2\) crystals at low (250-600 °C) temperatures to form 2D Janus TMDCs. Using \textit{in situ} plasma diagnostics, the kinetic energy of Se species generated by pulsed laser ablation of Se targets was moderated in the < 20 eV/atom range by collisions with inert Ar atoms in order to determine the thresholds for top- and bottom-layer selenization of monolayer WS\(_2\) crystals on both TEM grids and SiO\(_2\)/Si substrates. Subsequent analysis by Z-contrast STEM images, XPS, PL, and Raman spectroscopy were used to measure the degree of alloying and confirm the Janus monolayer formation as a function of kinetic energy, revealing discrete kinetic energy thresholds: (1) for irreparable damage to the monolayers, (2) for replacement of S atoms on both the top and bottom of the monolayer to enable full or partial conversion into WSe\(_2\); and (3) for the selective replacement of only the top S atoms (facing the Se beam), enabling the formation of high-quality Janus WSe\(_2\) and MoSe\(_2\) monolayers. The experimental thresholds are consistent with both density functional theory calculations of energy barriers for Se migration through WS\(_2\), and with molecular dynamic simulations the selenization process. The generalization of this synthetic approach to many other Janus monolayer systems will be described. Synthesis science was supported by the U.S. Department of Energy, Office of Science, Basic Energy Sciences (BES), Materials Sciences and Engineering Division. Characterization science at CNMS was supported by the Scientific User Facilities Division, BES.
Disorder-induced magnetoresistance (MR) effect is quadratic at low perpendicular magnetic fields and linear at high fields. This effect is technologically appealing, especially in the two-dimensional (2D) materials such as graphene, since it offers potential applications in magnetic sensors with nanoscale spatial resolution. However, it is a great challenge to realize a graphene magnetic sensor based on this effect because of the difficulty in controlling the spatial distribution of disorder and enhancing the MR sensitivity in the single-layer regime. Here, we report a room-temperature colossal MR of up to 5,000% at 9 T in terraced single-layer graphene. By laminating single-layer graphene on a terraced substrate, such as TiO$_2$ terminated SrTiO$_3$, we demonstrate a universal one order of magnitude enhancement in the MR compared to conventional single-layer graphene devices. Strikingly, a colossal MR of >1,000% was also achieved in the terraced graphene even at a high carrier density of $\sim 10^{12}$ cm$^{-2}$. Systematic studies of the MR of single-layer graphene on various oxide- and non-oxide-based terraced surfaces demonstrate that the terraced structure is the dominant factor driving the MR enhancement. Our results open a new route for tailoring the physical property of 2D materials by engineering the strain through a terraced substrate.

characteristic lengths of interlayer charge-transfer in correlated oxide heterostructures

Electronic devices in the form of high mobility conducting channel with charge carriers can be regulated through the internal charge transfer or chemical doping. Using interlayer interaction through the internal charge transfer to control functional heterostructures with atomic-scale design has become one of the most effective interface-engineering strategies nowadays. Here, we demonstrate the effect of a crystalline LaFeO$_3$ buffer layer on amorphous and crystalline LaAlO$_3$/SrTiO$_3$ heterostructures with different characteristic length of interlayer charge transfer. The LaFeO$_3$ buffer layer acts as an energetically favored electron acceptor in both LaAlO$_3$/SrTiO$_3$ systems, resulting in modulation of interfacial carrier density and hence metal-to-insulator transition. For the amorphous and crystalline LaAlO$_3$/SrTiO$_3$ heterostructures, the corresponding metal-to-insulator transition is found when the LaFeO$_3$ buffer layer thickness crosses 3 and 6 unit cells, respectively. Such different critical LaFeO$_3$ thicknesses are explained in terms of distinct characteristic lengths of the redox-reaction-mediated and polar-catastrophe-dominated charge transfer, controlled by the interfacial atomic contact and Thomas-Fermi screening effect, respectively. Our results not only shed light on the complex interlayer charge transfer across oxide heterostructures, but also establish a new route to precisely tailor the charge-transfer process at a functional interface by atomically engineered buffer layers.

magnetic field induced berezinskii-kosterlitz-thouless correlations in three-dimensional manganites

Ideal two-dimensional (2D) Heisenberg magnets lack long range order [1]. However, the XY model with spins confined to a plane shows a topological phase transition at a finite temperature corresponding to binding and unbinding of vortices [2,3]. Experimental evidence for such Berezinskii-Kosterlitz-Thouless (BKT) transitions has been difficult to obtain in condensed matter systems, where, even a weak interlayer coupling that is invariably present leads to long-range order, pre-empting the BKT transition. The BKT signatures are still discernible above the long-range ordering temperature, however, in the characteristic exponential temperature dependence of the coherence length of the fluctuations. In this work we report that an applied magnetic field can induce such BKT correlations not only in quasi 2-dimensional systems but also in nominally 3-dimensional manganites undergoing antiferromagnetic transitions. We arrive at this unexpected conclusion based on our studies of temperature dependence of electron spin resonance (ESR) linewidth $\Delta H(T)$ of Cr$^{3+}$ doped bismuth strontium manganite Bi$_{0.5}$Sr$_{0.5}$Mn$_{1-x}$Cr$_x$O$_3$ ($x=0.04, 0.1$) (BSMCO).
BSMCO [4] belongs to the family of mixed valent manganites of the type \( \text{ReAMnO}_3 \) where \( \text{Re} \) is a trivalent rare earth ion or \( \text{Bi}^{3+} \) and \( \text{A} \) is a divalent alkaline earth ion, which are intensely studied in the last few years [5]. \( \Delta H(T) \) provides the most important probe to study the spin interactions in these strongly correlated spin systems. We find that \( \Delta H(T) \) observed in BSMCO (current work), as well as in \( \text{La}_{0.95}\text{Ca}_{0.05}\text{MnO}_3 \) and \( \text{CaMnO}_3 \) [6] is better (than the usually adopted critical state model) described by the BKT scenario which predicts [7]

\[
\Delta H_{\text{BKT}}(T) = \Delta H_\infty \exp \left[ \frac{3b}{T/T_{\text{BKT}} - 1} \right] + mT + \Delta H_{\text{ind}}, \quad T > T_{\text{BKT}}
\]

where \( T_{\text{BKT}} \) is the BKT transition temperature and \( b = \pi/2 \) for a square lattice and the last two terms are included to account for the high temperature and temperature independent behaviour. This is unexpected as these manganites have a 3D structure and the BKT model addresses systems with spin and spatial dimensions of two. We understand this result in terms of an effective symmetry reduction induced by i) the magnetic field applied in the ESR experiment and ii) the intrinsic anisotropy arising from microscopic details such as doping and phase separation - contributing to an effectively 2-dimensional XY easy plane anisotropy. Nanometric scale spin clusters similar to the ones observed in \( \text{La} \) doped \( \text{CaMnO}_3 \) [8] could conceivably play the role of vortices in these 3D materials. The sensitivity of the BKT behaviour to applied field is also supported by a re-analysis of the field dependence of the \( \Delta H(T) \) in the quasi-2D antiferromagnetic compound \( \text{BaNi}_2\text{V}_2\text{O}_8 \) reported by Heinrich at al., [9]. For undoped manganites we find \( T_{\text{BKT}} \) is of the order of the magnetic interaction energy, suggesting that the applied field could be the sole origin of the BKT behaviour [10]. We shall also address the interesting observation that in BSMCO (\( x = 0.04, 0.1 \)), \( T_{\text{BKT}} \) is composition-independent while the magnetic properties are quite sensitive to composition.

Magnetic Properties of Proton Irradiated van der Waals Mn₃Si₂Te₆ Luis M. Martinez¹, Rubyann Olmos¹, Hector Iturriaga¹, Lin Shao², Yu Liu², Cedomir Petrovic³ and Srinivasa Rao Singamaneni¹; ¹The University of Texas at El Paso, United States; ²Texas A&M University, United States; ³Brookhaven National Laboratory, United States

Van der Waals (vdW) magnetism is the topic of intense research interest in the community of 2D magnetic materials. Proton irradiation is an effective tool in controlling the magnetic properties of vdW magnets by modifying the spin-lattice coupling. In the present work, the magnetic properties of vdW magnet, such as Mn₃Si₂Te₆ (MST) have been studied at varying proton irradiation fluences of \( 1 \times 10^{15}, 5 \times 10^{15}, 1 \times 10^{16}, \) and \( 1 \times 10^{18} \text{ H+/cm}^2 \). The magnetization changes more prominently in the ferrimagnetic region (temperature < 74 K, where the saturation magnetization (\( M_S \)) reaches a maximum value of 25.1 emu/g (53% increase) at the fluence of \( 5 \times 10^{15} \text{ H+/cm}^2 \)) and decreases with further increase in the fluence. Electron Paramagnetic Resonance (EPR) spectroscopy was used to probe whether proton irradiation caused defects that may alter the magnetic properties of MST. From the EPR measurements taken at 80 K and 50 K, no signals corresponding to defects arose from the pristine and all the fluence rate spectra except for two intrinsic Mn signals. Raman spectroscopy suggests a change in the in-plane Tellurium vibrational modes, as reflected from a similar trend between the \( M_S \) and the Raman \( E_g \) peak. Additionally, XPS spectroscopy shows a decrease in the Te 3d5 peaks' intensity as the fluence changes. The changes observed in the \( M_S \) are suggested to come from the modified Mn-Te interactions through spin-lattice coupling.

Multi-Frequency Electron Spin Resonance Studies of van der Waals Layered CrX₃ (X = Cl, Br, I) Christian Saiz¹, Sohan Hennadige¹, Michael A. McGuire², Fazel Fallah Tafti³, Johan van Tol⁴ and Srinivasa Rao Singamaneni¹; ¹The University of Texas at El Paso, United States; ²Texas A&M University, United States; ³Boston College, United States; ⁴Florida State University, United States
van der Waals layered magnets such as CrX₃ (X = Cl, Br, I) have received a great deal of research excitement in the recent past due to their exfoliable nature and layer dependent magnetic properties, as well as their potential applications in future data storage devices. Interestingly, these compounds reveal strong halogen size dependent magnetic properties due to the introduction of strong spin-orbit coupling as one moves from Cl to I. This variation can be perfectly captured by employing electron spin resonance (ESR) spectroscopy, which is highly sensitive to underlying magnetic interactions. In this work, we report the ESR properties of these compounds such as g-value, line broadening, and signal intensity as a function of microwave frequency (9-240 GHz), temperature (4-500 K), and angle of rotation (0-360°). We compare and contrast the ESR properties of these three compounds and discuss their two-dimensional correlations across the magnetic ordering temperature, magnetic exchange interactions, and spin dynamics. The experimental findings collected from this work will have greater implications in understanding the few-layer magnetism in these materials, which is being intensely researched in the 2D magnetism community.

Controlling Charge Density-Wave States in Single-Layer Transition-Metal Dichalcogenides Phil King; University of St Andrews, United Kingdom

Control over materials thickness down to the single-atom scale has emerged as a powerful tuning parameter for manipulating not only the single-particle band structures of solids, but increasingly also their interacting electronic states and phases. A particularly attractive materials system in which to explore this is the transition-metal dichalcogenides, both because of their naturally-layered van der Waals structures as well as the wide variety of materials properties which they are known to host. Yet, how their interacting electronic states and phases evolve when thinned to the single-layer limit remains a key open question in many such systems. Here, we use angle-resolved photoemission to investigate the electronic structure and charge density wave (CDW) phases of monolayer TiSe₂, TiTe₂, and VSe₂ epitaxial thin films grown by molecular-beam epitaxy. Three-dimensionality is a core feature of the electronic structure of all of these parent compounds, but we show how their CDW phases not only persist, but are strengthened, in the monolayer limit. In TiSe₂, we observe a strong-coupling and orbital-selective CDW, necessarily without a k_z-selectivity in band hybridisation that is of key importance for the bulk instability. TiTe₂ is driven into a charge-ordered phase in the monolayer which is not stable in the bulk at all, but our measurements indicate that it is a much weaker-coupling instability than for the Se-based sister compound. In VSe₂, we show how the monolayer hosts a much stronger-coupling CDW instability than for the bulk compound, which in turn drives a metal-insulator transition, removing a competing instability to ferromagnetism. We show how ferromagnetism can, however, be re-established via proximity coupling. Together, these studies point to the delicate balance that can be realized between competing interacting states and phases in monolayer transition-metal dichalcogenides, and suggest new strategies for controlling these.

Fluctuations in Quantum Materials—From Skyrmions to Superconductivity Joshua J. Turner; 1Stanford University, United States; 2SLAC National Accelerator Laboratory, United States

Quantum materials offer not only a vast array of potential for technological advancement, but also provide a testbed for the laws of nature in condensed matter. One area to advance the frontier in this area is through the measurement of fast,
spontaneous fluctuations of quantum order. This is at the heart of the essential physics in these types of solids, but has remained largely unexplored. The key component we use is the application of a newly developed coherent scattering method which can access these fluctuations on the relevant energy scales. This new tool has been demonstrated on a topological magnetic material, and early results point to the tremendous potential for this approach to provide important new insight into fundamental open questions in condensed matter. It allows for the direct, element-specific and momentum-resolved measurement of the fluctuations of a complex material and to connect them to the requisite response functions calculated from first principles. By analyzing subtle X-ray variations known as "speckle", statistics is used to extract the stochastic fluctuation information of the system. This offers the ability to address a range of important current problems in materials. In this talk, we will first discuss the newly developed tools which are used to measure the material properties, based on short pulses from an x-ray free electron laser. We will then present how this has been applied to skyrmions and the measurement of nanosecond fluctuations. This will be followed by an examination of new results on skyrmion physics near the critical point of the skyrmion ordered lattice phase. We will end with an outlook of how this progress can help to tackle the question of fluctuations in unconventional superconductors.

Strong Correlation in Low-Dimensional Materials of TMPS3 Je-Geun Park1,2; 1Institute for Basic Science (IBS), Korea (the Republic of); 2Seoul National University, Korea (the Republic of)

One of the most pressing questions in condensed matter physics is how electron correlations play out on two-dimension. For this question, the newly emerged magnetic van der Waals material can be helpful. In particular, TMPS3 with TM=transition metal elements have attracted significant attention as it exhibits all three fundamental magnetic models of magnetism; Ising (FePS3), XY (NiPS3) and Heisenberg (MnPS3) Hamiltonian. Using these materials, we have studied some of the fundamental theorems of modern magnetism: Onsager solution for the Ising model, The Berezinskii–Kosterlitz–Thouless transition for the XY model, and Mermin-Wagner theorem for the Heisenberg model. Besides, we have also investigated how correlation physics plays a role in optical spectroscopy data. In this talk, I will demonstrate how we can use this unique magnetic property of these materials to learn of the old physics.

5:15 AM *S.NM07.06/S.NM09.05.02
Keynote: Topological Defects in Twisted van der Waals Interfaces Philip Kim; Harvard University, United States

Controlling the interlayer twist angle in artificial two-dimensional (2D) van der Waals (vdW) heterostructures offers an experimental route to create moire superlattice. One can create exotic electronic states by minimizing electronic band width with tunable moire length scale. However, in the small twist angle regime, vdW interlayer interaction can cause significant structural reconfiguration at the interface, creating the arrays of domain structures. In this presentation, we will discuss the atomic reconstruction at twisted vdW interfaces and its effect on electronic structure and electrical transport behavior. Furthermore, we note that multiple domain boundaries at the reconstructed interface join together to create energetically unfavorable nodes forming vortex-like structures. We will discuss our recent efforts to understand the topological nature of those defects.

Pressure Induced Magnetic Properties of Crystal Cobalt-Ferrite

Dawn S. Blazer¹, Kinjal Gandha², Hector Iturriaga¹, Rubyann Olmos¹, Denis Prodius², Srinivasa Rao Singamaneni¹ and Cajetan Nlebedim²; ¹The University of Texas at El Paso, United States; ²Ames Laboratory, United States

Hydrostatic pressure is an effective way in tuning the physical properties of materials. This study examines the impact of hydrostatic pressure on the magnetic properties of 3-d transition metal oxide; CoFe₂O₄. The high cubic magnetocrystalline anisotropy, coercivity, moderate saturation magnetization, chemical stability, wear resistance, electrical insulation, and photomagnetic properties of CoFe₂O₄ have resulted in its study for engineering applications. The ease with which cobalt ferrite can be synthesized makes it suitable for scientific investigations and also increases its potential for cost-effective engineering applications. Our results show that the coercive field is decreased from 1600 Oe to 1000 Oe upon the application of 0.2 GPa, and the saturation magnetization is decreased from 91 emu/g to 88 emu/g, measured at cryogenic temperatures (4 K). The modification in the magnetic exchange interaction upon the application of pressure is believed to alter the magnetic properties. We will present our results based on magnetic experiments collected as a function of pressure (0-1 GPa), temperature (4-400 K), and magnetic field (3T).

S.NM07.10.02
Phase Transitions in Novel Li-Containing Honeycombs, Li₈M₂(Te/Sb)₂O₁₂

Hector C. Mandujano¹, Sandra L. Gonzalez¹, Narayan Poudel², Krzysztof Gofryk², Stuart A. Calder³ and Harikrishnan S. Nair¹; ¹The University of Texas at El Paso, United States; ²Idaho National Laboratory, United States; ³Oak Ridge National Laboratory, United States

Octahedral layers of metal atom separated and charge-compensated by alkali-metal ions have the ideal architecture to be used as electrodes for Li-ion batteries, ionic conductors, and visible light photocatalysts. Li₈M₂(Te/Sb)₂O₁₂ (M = transition metal) are relatively new members of this class. Forming honeycomb frameworks, they present interesting magnetic phenomena related to frustrated two-dimensional lattices of spins. In the present work, polycrystalline Li₈Cr₂(Sb/Te)₂O₁₂ were synthesized by standard solid-state route. Powder X ray diffraction patterns were recorded to check the phase formation and purity. C₂ᵥm space group was confirmed using Rietveld analysis and lattice parameters are determined to be a = 5.141 Å, b = 8.884 Å, c = 5.143 Å, β = 109.5 Å for Li₈Cr₂Sb₂O₁₂, and a = 5.128 Å, b = 8.850 Å, c = 5.151 Å, β = 109.8 Å for Li₈Cr₂Te₂O₁₂, presenting diminished unit cell sizes compared to that of Li₈Co₂Te₂O₁₂. In the case of Li₈Cr₂Sb₂O₁₂ a magnetic phase transition is present at 7.4 K as determined from the derivative, dCp/dT. A similar transition is found in Li₈Co₂Te₂O₁₂ at 9.5 K. Neutron diffraction is underway for comprehending cationic ordering, crystal, and magnetic structure of Li₈Cr₂(Te/Sb)₂O₁₂ as well as its mixed occupancy of the 4g Wyckoff position in the C₂ᵥm space group. Our experimental results will highlight the magnetism of the honeycomb layers of Cr and the ionic diffusion of inter-layer Lithium and will be of interest to magnetism as well as battery research.

Fluence Dependent Magnetic Properties of Proton Irradiated CrSiTe₃

Hector Iturriaga¹, Rubyann Olmos¹, Dawn S. Blazer¹, Luis M. Martinez¹, Samir A. Muniz¹, Kinjal Gandha², Cajetan Nlebedim², Yu Liu³, Cedomir Petrovic³, Lin Shao⁴, Qiang Wang⁵ and Srinivasa Rao Singamaneni¹; ¹The University of Texas at El Paso, United States; ²Ames Laboratory, United States; ³Brookhaven National Laboratory, United States; ⁴Texas A&M University, United States; ⁵West Virginia University, United States

Proton irradiation as a means of modifying the magnetic properties of layered van der Waals (vdW) materials has considerable, yet unexplored potential. Although vdW crystals display strong correlation and stability, their susceptibility to various kinds of stimuli promotes research into the flexible control of magnetism via proton irradiation for various applications. In this study, layered ferromagnetic vdW CrSiTe₃ (CST) crystals were subjected to proton irradiation at fluences ranging from 10¹⁶ to 10¹⁸ protons/cm². Low-temperature and isothermal magnetometry was conducted with a Quantum Design MPMS 3 on both pristine and irradiated samples. Direction dependent isothermal magnetization confirms the presence of magnetocrystalline anisotropy, with a stable easy axis along the in-plane direction. Furthermore, at the fluence of 5 x 10¹⁶ protons/cm², we have observed a 35% increase in saturation magnetization from 25 emu/g to 34 emu/g at T = 2 K. We will present and discuss our experimental findings on saturation magnetization, coercive field, magnetocrystalline anisotropy, and Curie temperature on proton irradiated CST.

Pressure Dependent Magnetic Properties of CrBr₃ Bulk Crystals
Rubyann Olmos, Hector Iturriaga, Kinjal Gandha, Caetan Nlebedim, Fazel Fallah Tafti and Srivinasa Rao Singamaneni; University of Texas at El Paso, United States; 2Ames Laboratory, United States; 3Boston College, United States

The van der Waals (vdW) class of materials offer a new approach for two-dimensional magnetism allowing spin fluctuations to be tuned upon exfoliation of layers. The magnetic properties with pressure are investigated for the highly anisotropic MX₃ (M = Cr, V; X = Cl, Br, I) family. A clear understanding of the bulk magnetic structure and its tunability can be used as a means towards predicting material properties upon exfoliation. As research on pressure induced magnetic properties of exfoliated CrX₃ is at its nascent stage, hydrostatic pressure as a probe to induce a change in magnetic properties is employed in this study of bulk CrBr₃. Furthermore, pressure studies on CrI₃, VI₃, and Cr₂Ge₃Te₆ have appeared in literature reporting that pressure can modify the spin-lattice coupling and long-range magnetic order, however, the origin of magnetic behavior and whether pressure increases or decreases the long-range magnetic ordering is under debate. This study as a whole will take a deeper look into characterizing the magnetic properties of these crystals to understand the underlying magnetic behavior. Results for CrBr₃ upon the application of 0.4 and 0.8 GPa show a decrease in magnetization with no significant change in Curie temperature (T_C) with pressures of 0, 0.4, 0.8 GPa with T_C = 33, 32, 31 K, respectively. In the future, further insight will be collected by looking at the local electronic and magnetic structure of these materials by employing x-ray magnetic circular dichroism (XMCD) (Cr L2,3 edge) measurements upon the application of pressure (0-10 GPa). In this work we will present all comprehensive experimental findings.

S.NM07.10.05
Magnetism in the Honeycomb Layers of Na₂Ni₂TeO₆ with Chiral Layers of Na
Nathan C. Episcopo, Kinley Wangmo, Narayan Poudel, Krzysztof Gofryk, Po-Hao Chang, Rajendra R. Zope, Ryan Kleim, Craig Brown, Thomas W. Heitmann and Hari Nair; 1The University of Texas at El Paso, United States; 2Idaho National Laboratory, United States; 3National Renewable Energy Laboratory, United States; 4National Institute of Standards and Technology, United States; 5University of Missouri Research Reactor, United States

Low dimensional magnetic lattices offer the possibility of realizing flatbands in the magnon spectrum which can then lead to dissipation-less spin transport and associated magnon Hall effect. One could expect to find a magnon insulator, similar to a topological insulator. In the present work we present a rather less-studied honeycomb material Na₂Ni₂TeO₆ where our preliminary density functional theory calculations of magnetic structure shows departures from reported structures. Our samples of Na₂Ni₂TeO₆ confirmed hexagonal P6₃/mcm space group with refined lattice parameters, a=5.2023(1)Å and c=11.1552(8)Å. The bulk magnetism for the present sample is characterized using magnetic susceptibility and specific heat, both of which confirm a phase transition at 28 K. Application of 8 T magnetic field only slightly polarizes the transition. We obtain a Curie-Weiss temperature of -9.7(2)K and effective paramagnetic moment of 2.24(4)mB/Ni. This matches well with the spin-only moment of Ni²⁺. Elastic and inelastic neutron scattering experiments are currently underway and reveal a rather flat spin wave excitation at 5 meV. Combining neutron diffraction with the DFT results, we would arrive at an accurate estimation of the exchange constants for Na₂Ni₂TeO₆.

S.NM07.10.06
Thermodynamically Driven Stacking of All-Inorganic Perovskite Nano-Sheets
Jacob Lee and Rajesh Sardar; Indiana University Purdue University Indianapolis, United States

The discovery of atomically thin carbon sheets known as graphene in 2004 has prompted intense scientific research on synthesizing and characterizing two-dimensional (2D) nanomaterials. It has been demonstrated both experimentally and theoretically that the 2D confinement of electrons offer distinct optoelectronic properties unlike their corresponding bulk materials including band-gap tunability and improved charge transport properties. Over the last 15 years several types of 2D nanomaterials such as metal oxides, transition metal dichalcogenides, layered metal hydroxides, and MXenes have been extensively studied. More recently organic-inorganic hybrid perovskite 2D sheets have been synthesized and characterized for their use in solution-processable photovoltaic devices. Perovskites possess defect tolerant electronic properties, wide band gap control, and large absorption coefficients necessary for many applications; however, lead free compositions along with combining 2D syntheses and assemblies need further research to reduce environmental toxicity. Cs₃Bi₂X₆ (X=Cl, Br, and I) is a perovskite family material with a hexagonal crystal structure. Herein, we report the synthesis of Cs₃Bi₂X₆ nanosheets with specific halide control by a low temperature colloidal synthetic method, for the first time. UV-visible absorption spectroscopy and powdered X-ray diffraction (XRD) characterizations, along with electron microscopy (EM) analyses, shows formation of atomically-thin perovskite nanosheets. EM analyses also observed formation of stacked nanosheets as superlattice structures. Furthermore, we conducted small angle X-ray scattering techniques to provide an in-depth study of the factors such as the...
van der Waals forces induced from core stoichiometry, crystal structure, and ligand-ligand interactions between sheets impacting the self-assembly of 2D nanosheets into larger stacked superstructures. We hypothesize that these superstructures are self-assembled mainly through ligand-ligand interactions. The unique properties of the perovskite family, in combination with the well-studied benefits of 2D nanomaterials, suggest that our 2D Cs$_3$Bi$_2$X$_9$ will display well-controlled optoelectronic and charge transport properties leading to advanced solid-state device applications.

**Particulate Mass Tracking with Ruggedized Nanoparticle Tracers for Explosive Events** Lance Hubbard, Clara Reed, Nie Uhlnak, Trevor Cell, Nathaniel Smith, Ryan Sumner, Martin Liezers, Michael Foxxe and April Carman; Pacific Northwest National Laboratory, United States

Tracing the flow of particulate matter through harsh conditions (such as a chemical explosion) requires a rugged tag that can be measured by a unique, identifiable signature. Small semiconductor core-shell particles of ZnS@CdSe provide a unique, tunable photoluminescent signature that can be adjusted by the material’s composition and core/shell thickness. The particles have been ruggedized by the growth of a silica layer around the quantum dots (QDs) that acts as a sacrificial layer during finite periods of elevated temperatures and pressures. Incorporating the QDs into a matrix allows for the identification of the debris by its unique photoluminescence. The silicated QD-bound powders were suspended in a hydrated silica gel pending incorporation into temperature-resistant paints and synthetic stone. Initial explosive testing of the tags embedded in enclosures and concrete showed the deposition and movement of particles based on size. The incorporation of temperature-resistant QD-bound powders has enabled unique identifiers, which allows for the tracking of mass through explosive events and other inaccessible environments.

**SESSION S.NM07.07/S.EL06.06: Keynote Session: Light-Matter Interaction in Two-Dimensional Semiconductors**

Vinod Menon; City College and Graduate Center of CUNY, United States

Owing to their large oscillator strength and strong exciton binding energy, two-dimensional (2D) transition metal dichalcogenides (TMDs) have emerged as an attractive material platform for studying strong light-matter coupling and associated phenomena. Following up on our previous work on strong light-matter coupling in 2D TMDs [1, 2], here we will present results on enhancing the nonlinear interaction between the quasiparticles (exciton-polaritons). This is achieved using excited states of excitons (Rydberg states) which have larger Bohr radii. We will also present our recent results on controlling the valley pseudospin via the pseudomagnetic fields in optical cavities and our work on realizing an electrically pumped polariton LED [3]. Finally, we will first present our work on realizing single photon emitters (SPEs) in hexagonal boron nitride (hBN), a van der Waals material, via strain engineering [4] and coupling of these SPEs to high Q silicon nitride microresonators [5].

Non-Equilibrium Effects in Quantum Magnets  Kate Ross and Steffen Saeubert; Colorado State University, United States
The study of non-equilibrium properties of quantum phases of matter is important in the context of future quantum technologies, since all devices operate in the non-equilibrium limit. Theoretically, the transverse field Ising model (TFIM) and its disordered variants provide a tractable platform to study effects of quantum quenches (a rapid variation of a non-thermal parameter, leading to interesting transient effects), or quantum annealing (a slow variation of a non-thermal parameter, leading to efficient optimization). While there is enormous theoretical interest in these ideas, they have not yet been thoroughly tested on real Ising magnetic systems. There are well-known magnetic material realizations of the TFIM, CoNb2O6 and LiHoYF4, which display quantum critical points in accessible transverse magnetic field ranges. We have studied these materials following various protocols of time variation of the magnetic field, using ac susceptibility and neutron scattering as probes. I will discuss the non-equilibrium effects we have observed in these TFIM materials.

Effect of Proton Irradiation on the Magnetocaloric Effect and Critical Phenomena of Transition Metal Trichalcogenides  Jose A. Delgado1, Rubyann Olmos1, Luis M. Martinez1, Christian Saiz1, Lin Shao2, Yu Liu3, Cedomir Petrovic3 and Srinivasa Rao Singamaneni1; 1University of Texas at El Paso, United States; 2Texas A&M University, United States; 3Brookhaven National Laboratory, United States
Proton irradiation as a form of defect engineering is used to inhibit the crystal structure of van der Waals crystals in order to provoke a change in the magnetic properties. In this study, the magnetocaloric effect, heat capacity, and critical behavior of transition metal trichalcogenides as a function of proton irradiation were analyzed for Mn3Si2Te6, Fe2.7GeTe3, and CrSiTe3. The crystals were irradiated at fluences of 1x1015, 5x1015, 1x1016 and 1x1018 H+/cm2 with a 2 MeV beam. Following proton irradiation, the Curie temperatures (T_C) were obtained experimentally using heat capacity and magnetization as a function of temperature, and by critical exponent analysis. Critical exponents were calculated using the Kouvel-Fisher model and modified Arrott plot. In this work, the correlation between proton irradiation and the resulting critical behavior, magnetocaloric effect, and Curie temperatures will be discussed.

Local Site Magnetic Susceptibility on Quantum Materials by Polarized Neutron Diffraction  Huibo Cao; Oak Ridge National Laboratory, United States
Understanding the interactions leading to magnetic quantum phenomena in a wide range of quantum materials is extremely important for development of new quantum materials and future technologies. Although neutron scattering is a powerful tool for this purpose, it also faces a range of challenges, such as the lack of sizable high-quality crystals, limited high pressure capabilities, and the difficulty in disentangling the intrinsic quantum phenomena versus effects from defects and site-disorder. Recently we have introduced the local magnetic susceptibility methods for studying quantum materials, which can be used for small crystals and powder samples. A single crystal neutron diffractometer DEMAND at the High Flux Isotope Reactor at the Oak Ridge National Laboratory has been upgraded for studying magnetic materials under various extreme sample environment conditions. In this talk, I will introduce the local site magnetic susceptibility methods, the current capabilities at the DEMAND, and our recent studies on two-dimensional quantum materials.

5:40 AM  *SNM07.08.05
Nonequilibrium Synthesis of Mismatched 1T' Transition Metal Dichalcogenide Alloys for 2D Topological Insulators  Hui Cai, Yiling Yu, Raymond R. Unocic, Kunlun Hong, Alexander Puretzky, Wonhee Ko, Christopher Rouleau, David B. Geohegan and Kai Xiao; Oak Ridge National Laboratory, United States
Transition metal dichalcogenides (TMDC) are an emerging class of quantum materials because they are 2D topological insulators in the 1T' phase and Weyl semimetals in the Td phase. To optimize the properties of these materials, synthetic methods to tune their Fermi level and bulk gap opening are necessary. This can be realized by synthesizing alloys with a wide range of adjustable compositions. Mismatched alloys, such as MoS2_xTe_x, are alloys formed by elements far away from each other in the periodic table. Due to the large mismatch in atomic radius and electronegativity, a small addition of the alloying element can induce dramatic modifications in the electronic structure of the material. However, such immiscible alloys are hard to synthesize as bulk crystals by conventional crystal growth methods, especially in metastable phases such as the 1T'
phase. Here, we report the bottom-up synthesis of 2D MoS$_2$-Te$_x$ mismatched alloys in the 1T’ phase by chemical vapor deposition through non-equilibrium methods. We introduce K$^+$ during the synthesis to grow the 1T’ phase, followed by fast cooling to stabilize this phase to room temperature. With this approach, MoS$_{2-x}$Te$_x$ alloys can be grown on various substrates including mica, sapphire and gold. The 1T’ structure of the flakes are confirmed by Raman spectroscopy and scanning transmission electron microscopy. Our results open new opportunities in tailoring the structure and properties of quantum materials by alloying mismatched elements through non-equilibrium synthesis.

Research is sponsored by the U.S. Dept. of Energy, Office of Science, Basic Energy Sciences, Materials Science and Engineering Div. (synthesis science) and Scientific User Facilities Div. (characterization science).

Ultrafast Energy- and Momentum-Resolved Dynamics of Magnetic Correlations in the Photo-Doped Iridates

Mark P. Dean; Brookhaven National Laboratory, United States

Measuring how the magnetic correlations evolve in doped Mott insulators has greatly improved our understanding of the pseudogap, non-Fermi liquids and high-temperature superconductivity. Recently, photo-excitation has been used to induce similarly exotic states transiently. However, the lack of available probes of magnetic correlations in the time domain hinders our understanding of these photo-induced states and how they could be controlled. This talk will describe our implementation of magnetic resonant inelastic X-ray scattering at free-electron lasers to directly determine the magnetic dynamics after photo-doping the Mott insulators Sr$_2$IrO$_4$ and Sr$_3$Ir$_2$O$_7$ [1-3]. We find that the non-equilibrium states host strong 2D magnetic correlations even in cases where 3D long-range magnetic order is completely suppressed [1]. The marked difference in these 2D and 3D timescales implies that the dimensionality of magnetic correlations is vital for our understanding of ultrafast magnetic dynamics. We also uncover distinct differences in the magnetic dynamics between insulators Sr$_2$IrO$_4$ and Sr$_3$Ir$_2$O$_7$, which we attribute to a “spin-bottle-neck” effect [3].

Spin Excitations in Magnetic 2D van der Waals Materials—Nonlocal Electron Correlation Effects

Liqin Ke; Ames Laboratory, United States

The recent experimental realization of magnetic two-dimensional van der Waals (m2DvdW) materials has generated significant interest in exploiting such systems for novel 2D magnetism and for developing applications such as energy-efficient ultra-compact spin-based electronics. A better understanding of the magnetic interactions in these systems may help to accelerate the discovery of materials with higher magnetic ordering temperatures, moving these novel systems closer to practical applications. Using linear-response ab initio methods, we investigate the magnetic interactions and spin excitations in various m2DvdW systems, such as CrI$_3$, CrGeTe$_3$, VI$_3$, and Fe$_5$GeTe$_2$. Dynamical transverse spin susceptibility is calculated to directly compare with available Inelastic Neutron Scattering (INS) measurements. Accurate descriptions of electronic structure can provide reliable predictions of electronic and magnetic properties. Due to confinement, electrons in these 2D systems are likely to be strongly correlated, and electron screening anisotropic, so that their description may require advanced ab initio methods beyond density functional theory (DFT). Therefore, we also use the quasiparticle self-consistent GW (QSGW) method, a self-consistent many-body perturbation method, to describe the electronic structure and calculate magnetic properties. In contrast to DFT, the electron-electron interaction is evaluated explicitly by calculating the dynamically-screened Coulomb interaction $W$. We found that the nonlocal electron correlations, which are not included in methods such as DFT+U, have profound effects on the electronic and magnetic properties in these m2DvdW materials. A more elaborate description of electron interactions helps better describe the magnetic interactions in these 2D quantum systems. By comparing the electronic structures obtained in QSGW and DFT, we discuss the applicability and limitations of the widely-used DFT+U methods for these systems. We will also discuss the effects of spin-orbit coupling, the Dzyaloshinskii-Moriya interaction, impurities, pressure, and electric fields on the magnetic interactions and excitations in relevant systems.

Manipulating Valley-Selective Photon Dressed States in Monolayer Semiconductors
Nathaniel P. Stern; Northwestern University, United States

Control over the interactions between light and matter underlies many classical and quantum applications. In recent years, 2D layered semiconductors have gained prominence for optoelectronics because of their strong excitonic features and capacity for van der Waals assembly in layered heterostructures. Through integration with various photonics devices, the interactions between these materials and light can be tailored and new physical regimes can be achieved, highlighting the importance of understanding photonic dressed states of 2D materials. One of the unique features of monolayer materials such as transition metal dichalcogenides is the valley pseudospin addressable by circularly-polarized light. Understanding how this valley polarization can be manipulated is an exciting goal with implications for devices and quantum information science. Here, I discuss hybrid light-matter dressed states, or exciton-polaritons, in transition metal dichalcogenides embedded in dielectric microcavities. These strongly-coupled polaritons preserve the valley pseudospin known from bare monolayers [1]. Distinct behavior of valley-polarized exciton-polaritons can be accessed with microcavity engineering by tuning system parameters such as cavity decay rate and exciton-photon coupling strength. In the opposite dressed state regime of weak light-matter coupling, intense off-resonant light can be used to shift energy levels though the Stark effect [2]. Applied to valley-sensitive states, this shift can be used for coherent manipulation of valley pseudospin. I will show how this approach can be translated to valley-selective exciton-polaritons. Cavity reflectance spectra exhibit a simultaneous shift of both polariton branches when ultrafast coincident pump and probe pulses are co-circularly-polarized, and no appreciable shift when they are cross-polarized. This valley-selective polariton Stark shift combines both dressed state regimes of strong, near resonant interactions with weak, off-resonant optical interactions, providing a new tool for state control in coherent valleytronics. Exploiting photonic dressed states can be viewed as another approach in the toolbox for manipulating the optoelectronic properties of 2D materials and their heterostructures.

Computational Search for Magnetic and Non-Magnetic 2D Topological Materials Using Spin-Orbit Spillage
Kamal Choudhary; National Institute of Standards and Technology, United States

Intrinsically two-dimensional materials have a variety of properties that make them attractive for potential topological devices, but the electronic and topological properties of this class of materials remains under-explored. Using density functional theory-based spin-orbit spillage, Wannier-interpolations, and related techniques, we identify topologically non-trivial intrinsic 2D materials in several classes, include magnetic and non-magnetic materials, as well as insulators and semimetals. Using JARVIS-DFT 2D material dataset we first identify materials with high spin-orbit spillage among 683 materials resulting in 108 materials with high-spillage values. Then we use Wannier-interpolation to carry-out Z2, Chern-number, anomalous hall conductivity, Curie temperature surface and edge state calculations to identify topological insulators and semimetals such as quantum spin-hall and anomalous-hall insulators (QSHI, QAHI), magnetic and non-magnetic semimetals. For a subset of predicted QAHI materials, we run GW+SOC and GGA+U calculations. We find that as we introduce many-body effects only few materials retain non-trivial band-topology suggesting the importance of high-level DFT methods in predicating 2D topological materials. However, as an initial step, the automated spillage screening and Wannier-approach provide useful predictions for finding new topological materials.

Quantum Oscillations in Resistivity and Magnetization in Kondo Insulators
Lu Li; University of Michigan, United States

In metals, orbital motions of conduction electrons on the Fermi surface are quantized in magnetic fields, which is manifested by quantum oscillations in electrical resistivity. This Landau quantization is generally absent in insulators. Here we report a notable exception in an insulator — ytterbium dodecaboride (YbB12). The resistivity of YbB12 exhibits distinct quantum oscillations despite having a much larger magnitude than in metals. This unconventional oscillation is shown to arise from the insulating bulk, even though the temperature dependence of the oscillation amplitude follows the conventional Fermi liquid theory of metals. The large effective masses indicate the presence of a Fermi surface consisting of strongly correlated
electrons. Quantum oscillations are also observed in the magnetization of YbB₁₂. Our result reveals a mysterious dual nature of the ground state in YbB₁₂: it is both a charge insulator and a strongly correlated metal.

5:55 AM *S.NM07.09.07
Excitons in Nanophotonic Landscapes—Fluctuating, Diffusing, Annihilating Alberto G. Curto; TU/e – Eindhoven University of Technology, Netherlands

Excitons in two-dimensional semiconductors exhibit rich dynamics. Their fluorescence is sensitive to the nanoscopic environment. They are confined in the vertical direction while extending and diffusing along the atomically thin plane. Excitons can also interact with each other, notably to reduce light emission at high densities through exciton-exciton annihilation.

In this presentation, first, we will demonstrate that an atomically thin semiconductor can display substantial temporal fluctuations in fluorescence intensity influenced by its environment. We show blinking and flickering synchronized over monolayer domains tens of micrometers in size. We analyze the fluctuation statistics to draw analogies with blinking in conventional quantum dots.

Second, we will discuss strategies to increase the amount of photons emitted by a 2D semiconductor based on nanophotonic enhancement. We study how exciton diffusion impacts fluorescence enhancement using nanophotonic structures. As mobile excitons diffuse through optical hotspots, the careful balance of diffusion constants and nanophotonic geometry can lead to enhanced or suppressed fluorescence. Finally, we investigate the effect of nanophotonic enhancement on exciton-exciton annihilation.

Our results open new vistas for nanoscale photonics and optoelectronics with atomically thin semiconductors. Controlling exciton dynamics in the form of fluctuations, diffusion, or annihilation has direct implications for stable single-photon sources, molecular sensors based on excitonic fluorescence, or high-power light-emitting devices.

Pressure Induced Magnetic Properties of Crystal Cobalt-Ferrite Dawn S. Blazer1, Kinjal Gandha2, Hector Iturriaga1, Rubyann Olmos1, Denis Prodijus2, Srinivasa Rao Singamaneni1 and Cajetan Nlebedim2; 1The University of Texas at El Paso, United States; 2Ames Laboratory, United States

Hydrostatic pressure is an effective way in tuning the physical properties of materials. This study examines the impact of hydrostatic pressure on the magnetic properties of 3-d transition metal oxide; CoFe₂O₄. The high cubic magnetocrystalline anisotropy, coercivity, moderate saturation magnetization, chemical stability, wear resistance, electrical insulation, and photo magnetic properties of CoFe₂O₄ have resulted in its study for engineering applications. The ease with which cobalt ferrite can be synthesized makes it suitable for scientific investigations and also increases its potential for cost-effective engineering applications. Our results show that the coercive field is decreased from 1600 Oe to 1000 Oe upon the application of 0.2 GPa, and the saturation magnetization is decreased from 91 emu/g to 88 emu/g, measured at cryogenic temperatures (4 K). The modification in the magnetic exchange interaction upon the application of pressure is believed to alter the magnetic properties. We will present our results based on magnetic experiments collected as a function of pressure (0-1 GPa), temperature (4-400 K), and magnetic field (3T).

S.NM07.10.02
Phase Transitions in Novel Li-Containing Honeycombs, Li₈Cr₂(Te/Sb)₂O₁₂ Hector C. Mandujano1, Sandra L. Gonzalez1, Narayan Poudel2, Krzysztof Gofryk2, Stuart A. Calder3 and Harikrishnan S. Nair4; 1The University of Texas at El Paso, United States; 2Idaho National Laboratory, United States; 3Oak Ridge National Laboratory, United States

Octahedral layers of metal atom separated and charge-compensated by alkali-metal ions have the ideal architecture to be used as electrodes for Li-ion batteries, ionic conductors, and visible light photocatalysts. Li₈M₂(Te/Sb)₂O₁₂ (M = transition metal)
are relatively new members of this class. Forming honeycomb frameworks, they present interesting magnetic phenomena related to frustrated two-dimensional lattices of spins. In the present work, polycrystalline Li$_8$Cr$_2$(Te/Sb)$_2$O$_{12}$ were synthesized by standard solid-state route. Powder X ray diffraction patterns were recorded to check the phase formation and purity. $C_{2am}$ space group was confirmed using Rietveld analysis and lattice parameters are determined to be $a = 5.141\, \text{Å}$, $b = 8.884\, \text{Å}$, $c = 5.143\, \text{Å}$, $\beta = 109.5\, \text{°}$ for Li$_8$Cr$_2$Sb$_2$O$_{12}$, and $a = 5.128\, \text{Å}$, $b = 8.850\, \text{Å}$, $c = 5.151\, \text{Å}$, $\beta = 109.8\, \text{°}$ for Li$_8$Cr$_2$Te$_2$O$_{12}$, presenting diminished unit cell sizes compared to that of Li$_8$Co$_2$Te$_2$O$_{12}$ are 5.226\,Å, $b = 8.892\, \text{Å}$, $c = 5.160\, \text{Å}$, $\beta = 110.9\, \text{°}$. In the case of Li$_8$Cr$_2$Sb$_2$O$_{12}$ a magnetic phase transition is present at 7.4 K as determined from the derivative, $\text{d}C_p/\text{d}T$. A similar transition is found in Li$_8$Co$_2$Te$_2$O$_{12}$ at 9.5 K. Neutron diffraction is underway for comprehending cationic ordering, crystal, and magnetic structure of Li$_8$Cr$_2$(Te/Sb)$_2$O$_{12}$ as well as its mixed occupancy of the 4g Wyckoff position in the $C_{2am}$ space group. Our experimental results will highlight the magnetism of the honeycomb layers of Cr and the ionic diffusion of inter-layer Lithium and will be of interest to magnetism as well as battery research.

**Fluence Dependent Magnetic Properties of Proton Irradiated CrSiTe$_3$**

Hector Iturriaga$^1$, Rubyann Olmos$^1$, Dawn S. Blazer$^1$, Luis M. Martinez$^1$, Samir A. Muniz$^1$, Kinjal Gandha$^2$, Cajetan Nlebedim$^2$, Yu Liu$^3$, Cedomir Petrovic$^3$, Lin Shao$^4$, Qiang Wang$^5$ and Srinivasa Rao Singamaneni$^1$; 1The University of Texas at El Paso, United States; 2Ames Laboratory, United States; 3Brookhaven National Laboratory, United States; 4Texas A&M University, United States; 5West Virginia University, United States

Proton irradiation as a means of modifying the magnetic properties of layered van der Waals (vdW) materials has considerable, yet unexplored potential. Although vdW crystals display strong correlation and stability, their susceptibility to various kinds of stimuli promotes research into the flexible control of magnetism via proton irradiation for various applications. In this study, layered ferromagnetic vdW CrSiTe$_3$ (CST) crystals were subjected to proton irradiation at fluences ranging from $10^{16}$ to $10^{18}$ protons/cm$^2$. Low-temperature and isothermal magnetometry was conducted with a Quantum Design MPMS 3 on both pristine and irradiated samples. Direction dependent isothermal magnetization confirms the presence of magnetocrystalline anisotropy, with a stable easy axis along the in-plane direction. Furthermore, at the fluence of $5 \times 10^{16}$ protons/cm$^2$, we have observed a 35% increase in saturation magnetization from 25 emu/g to 34 emu/g at $T = 2\, \text{K}$. We will present and discuss our experimental findings on saturation magnetization, coercive field, magnetocrystalline anisotropy, and Curie temperature on proton irradiated CST.

**S.NM07.10.04**

**Pressure Dependent Magnetic Properties of CrBr$_3$ Bulk Crystals**

Rubyann Olmos$^1$, Hector Iturriaga$^1$, Kinjal Gandhi$^2$, Cajetan Nlebedim$^2$, Fazel Fallah Tafti$^3$ and Srinivasa Rao Singamaneni$^1$; 1University of Texas at El Paso, United States; 2Ames Laboratory, United States; 3Boston College, United States

The van der Waals (vdWs) class of materials offer a new approach for two-dimensional magnetism allowing spin fluctuations to be tuned upon exfoliation of layers. The magnetic properties with pressure are investigated for the highly anisotropic MX$_3$ (M = Cr, V; X = Cl, Br, I) family. A clear understanding of the bulk magnetic structure and its tunability can be used as a means towards predicting material properties upon exfoliation. As research on pressure induced magnetic properties of exfoliated CrX$_3$ is at its nascent stage, hydrostatic pressure as a probe to induce a change in magnetic properties is employed in this study of bulk CrBr$_3$. Furthermore, pressure studies on CrI$_3$, VI$_3$, and Cr$_2$Ge$_2$Te$_6$ have appeared in literature reporting that pressure can modify the spin-lattice coupling and long-range magnetic order, however, the origin of magnetic behavior and whether pressure increases or decreases the long-range magnetic ordering is under debate. This study as a whole will take a deeper look into characterizing the magnetic properties of these crystals to understand the underlying magnetic behavior. Results for CrBr$_3$ upon the application of 0.4 and 0.8 GPa show a decrease in magnetization with no significant change in Curie temperature ($T_C$) with pressures of 0.0, 0.4, 0.8 GPa with $T_C = 33, 32, 31\, \text{K}$, respectively. In the future, further insight will be collected by looking at the local electronic and magnetic structure of these materials by employing x-ray magnetic circular dichroism (XMCD) (Cr L2,3 edge) measurements upon the application of pressure (0-10 GPa). In this work we will present all comprehensive experimental findings.

**Magnetism in the Honeycomb Layers of Na$_2$Ni$_2$TeO$_6$ with Chiral Layers of Na**

Nathan C. Episcopo$^1$, Kinley Wangmo$^1$, Narayan Poudel$^1$, Krzysztof Gofryk$^2$, Po-Hao Chang$^1$, Rajendra R. Zope$^1$, Ryan Klein$^3$, Craig Brown$^4$, Thomas W. Heitmann$^5$ and Hari Nair$^1$; 1The University of Texas at El Paso, United States; 2Idaho National Laboratory, United States; 3National Renewable Energy Laboratory, United States; 4National Institute of Standards and Technology, United States; 5University of Missouri Research Reactor, United States
Low dimensional magnetic lattices offer the possibility of realizing flatbands in the magnon spectrum which can then lead to dissipation-less spin transport and associated magnon Hall effect. One could expect to find a magnon insulator, similar to a topological insulator. In the present work we present a rather less-studied honeycomb material Na$_2$Ni$_2$TeO$_6$ where our preliminary density functional theory calculations of magnetic structure shows departures from reported structures. Our samples of Na$_2$Ni$_2$TeO$_6$ confirmed hexagonal $P6_3/mcm$ space group with refined lattice parameters, $a=5.2023(1)$Å and $c=11.1552(8)$Å. The bulk magnetism for the present sample is characterized using magnetic susceptibility and specific heat, both of which confirm a phase transition at 28 K. Application of 8 T magnetic field only slightly polarizes the transition. We obtain a Curie-Weiss temperature of -9.7(2)K and effective paramagnetic moment of 2.24(4)$\mu$$_B$/Ni. This matches well with the spin-only moment of Ni$^{2+}$. Elastic and inelastic neutron scattering experiments are currently underway and reveal a rather flat spin wave excitation at 5 meV. Combining neutron diffraction with the DFT results, we would arrive at an accurate estimation of the exchange constants for Na$_2$Ni$_2$TeO$_6$.

Thermodynamically Driven Stacking of All-Inorganic Perovskite Nano-Sheets Jacob Lee and Rajesh Sardar; Indiana University Purdue University Indianapolis, United States

The discovery of atomically thin carbon sheets known as graphene in 2004 has prompted intense scientific research on synthesizing and characterizing two-dimensional (2D) nanomaterials. It has been demonstrated both experimentally and theoretically that the 2D confinement of electrons offer distinct optoelectronic properties unlike their corresponding bulk materials including band-gap tunability and improved charge transport properties. Over the last 15 years several types of 2D nanomaterials such as metal oxides, transition metal dichalcogenides, layered metal hydroxides, and MXenes have been extensively studied. More recently organic-inorganic hybrid perovskite 2D sheets have been synthesized and characterized for their use in solution-processable photovoltaic devices. Perovskites possess defect tolerant electronic properties, wide band gap control, and large absorption coefficients necessary for many applications; however, lead free compositions along with combining 2D syntheses and assemblies need further research to reduce environmental toxicity. Cs$_3$Bi$_2$X$_9$ (X=Cl, Br, and I) is a perovskite family material with a hexagonal crystal structure. Herein, we report the synthesis of Cs$_3$Bi$_2$X$_9$ nanosheets with specific halide control by a low temperature colloidal synthetic method, for the first time. UV-visible absorption spectroscopy and powdered X-ray diffraction (XRD) characterizations, along with electron microscopy (EM) analyses, shows formation of atomically-thin perovskite nanosheets. EM analyses also observed formation of stacked nanosheets as superlattice structures. Furthermore, we conducted small angle X-ray scattering techniques to provide an in-depth study of the factors such as the van der Waals forces induced from core stoichiometry, crystal structure, and ligand-ligand interactions between sheets impacting the self-assembly of 2D nanosheets into larger stacked superstructures. We hypothesize that these superstructures are self-assembled mainly through ligand-ligand interactions. The unique properties of the perovskite family, in combination with the well-studied benefits of 2D nanomaterials, suggest that our 2D Cs$_3$Bi$_2$X$_9$ will display well-controlled optoelectronic and charge transport properties leading to advanced solid-state device applications.

Particulate Mass Tracking with Ruggedized Nanoparticle Tracers for Explosive Events Lance Hubbard, Clara Reed, Nic Uhnak, Trevor Cell, Nathaniel Smith, Ryan Sumner, Martin Liezers, Michael Foxe and April Carman; Pacific Northwest National Laboratory, United States

Tracing the flow of particulate matter through harsh conditions (such as a chemical explosions) requires a rugged tag that can be measured by a unique, identifiable signature. Small semiconductor core-shell particles of ZnS@CdSe provide a unique, tunable photoluminescent signature that can be adjusted by the material’s composition and core/shell thickness. The particles have been ruggedized by the growth of a silica layer around the quantum dots (QDs) that acts as a sacrificial layer during finite periods of elevated temperatures and pressures. Incorporating the QDs into a matrix allows for the identification of the debris by its unique photoluminescence. The silicated QD-bound powders were suspended in a hydrated silica gel pending incorporation into temperature-resistant paints and synthetic stone. Initial explosive testing of the tags embedded in enclosures and concrete showed the deposition and movement of particles based on size. The incorporation of temperature-resistant QD-bound powders has enabled unique identifiers, which allows for the tracking of mass through explosive events and other inaccessible environments.

S.NM10.05.02
High Temperature Synthesis of a Crystalline MXene with Ordered Surface Terminations Jacob Pawlik and Daniel Druffel; University of North Carolina, United States
In this work, a new MXene is experimentally described which exhibits uniform functionality on MX layers (-Cl), contrary to the mixed functionality (-F, -O, -OH) of traditional MXenes. Most MXenes contain random surface terminations, arising from the vigorous etching process of the MAX phase with acids such as HF. However, the present MXene \( \text{Y}_2\text{CCl}_2 \) is synthesized by a direct high temperature method followed by liquid exfoliation, which results in highly crystalline 2D flakes. This MXene has well-defined properties due to single moiety surface terminations, allowing for construction of simple computational models. Previous research in the field highlights the difficulty of predicting properties such as band gap and surface energy due to the unpredictable arrangement of surface terminations and complexity of computational models. A crystalline MXene with ordered terminations offers an easily synthesizable target with properties that can be predictably tuned.

First, \( \text{Y}_2\text{CCl}_2 \) was directly synthesized by heating a pellet composed of \( \text{Y} \), \( \text{C} \), and \( \text{YCl}_3 \) in a sealed tantalum tube at 950°C for 5 days according to literature procedures. Next, density functional theory (DFT) calculations were performed to predict the energy required to exfoliate \( \text{Y}_2\text{CCl}_2 \) into an MXene. The binding energy of \( \text{Y}_2\text{CCl}_2 \) (0.14 J/m²) is less than half the binding energy of graphite, indicating that \( \text{Y}_2\text{CCl}_2 \) should be easier to exfoliate than graphite. A common method for exfoliating graphite is sonication in a liquid with similar surface properties, so the material was sonicated in the polar aprotic solvent propylene carbonate. The mixture quickly forms a well-dispersed solution of 2D \( \text{Y}_2\text{CCl}_2 \) flakes. Transmission electron microscopy (TEM) shows flakes with lateral sizes of 2-5 µm, and electron diffraction confirms retention of the crystalline \( \text{Y}_2\text{CCl}_2 \) structure. The optical properties were evaluated by UV-Vis spectroscopy, which reveals an absorption peak at 1.64 eV that is close to the expected band gap of 1.56 eV, calculated using the HSE06 functional. Furthermore, X-ray photoelectron spectroscopy measurements reveal unusual oxidation states associated with yttrium (2+) and carbon (2-), suggesting interesting electrical properties.

This material has several attractive features that may be utilized. \( \text{Y}_2\text{CCl}_2 \) is easily exfoliated in mild conditions, avoiding the hazards of corrosive media such as HF and HCl. Also, the material absorbs light in the visible, making \( \text{Y}_2\text{CCl}_2 \) potentially useful for light harvesting and photocatalytic applications. More broadly, \( \text{Y}_2\text{CCl}_2 \) is part of a larger class of metal carbide halide materials with the stoichiometry \( \text{M}_2\text{CX}_2 \) (\( \text{M} = \text{Y}, \text{Sc}, \text{Gd}; \text{X} = \text{F}, \text{Cl}, \text{Br}, \text{I} \)) that share similar structure and properties. Through preliminary calculations, we predict that other metal carbide halides may be exfoliable and contain similar properties to \( \text{Y}_2\text{CCl}_2 \). Overall, \( \text{Y}_2\text{CCl}_2 \) and other similar metal carbide halides offer a new class of MXenes with ordered surface terminations.

Investigating Chemical Reactivity of MXenes Using Gas Chromatography
ShuoHan Huang, Gabriel Hulliung and Vadym Mochalin; Missouri University of Science and Technology, United States

MXenes are a new family of two-dimensional (2D) materials discovered in 2011. Because of their 2D structure and many outstanding properties [1], MXenes have raised significant interest for various applications, such as batteries, optoelectronic devices [2], supercapacitors, lasers [3,4], sensors [5], etc. It was found that titanium carbide MXene flakes in aqueous solutions spontaneously transform into TiO₂ and recently, it has been demonstrated that water plays the main role in the reactions leading to this chemical transformation [6]. Thus, studying MXene reactivity is important for prolonged shelf life of MXene colloidal solutions, as well as for robust performance of MXene based devices. In this work, we demonstrate the use of gas chromatography technique to study reactivity of MXenes. Several hypotheses have been put forward to explain the degradation of MXenes in aqueous environments. However, no studies of the gaseous products of this reaction have been reported. The analysis of gases produced during MXene degradation, using gas chromatography, allows for a better understanding of the degradation process. The chemical reactivity of MXenes with different monolayer thickness was also investigated at different pH and temperatures. Our results have led to new, important conclusions about the chemical reactivity of MXenes in aqueous solutions. This knowledge will have significant impacts on the development of MXenes and other 2D materials for many applications.

Raman Spectroscopy Reveals the Effect of Synthesis Conditions on Ti3C2
Asia Sarycheva and Yury Gogotsi; Drexel University, United States

Raman spectroscopy has been one of the most helpful tools for analysis of two-dimensional (2D) materials1-2. While newly discovered materials should be probed using this technique, there have been just a few studies available for a large family of 2D transition metal carbides and nitrides known as MXenes3-5. To see which effects Raman spectroscopy can detect for MXenes we performed a systematic study of the mostly used MXene to date - Ti3C2Tx. By synthesizing material in different ways, we monitored changes in Raman spectra. we have synthesized Ti3C2 via MILD method, where HF is formed in-situ by mixing LiF and HCl, HF-HCl (mixture of two acids), and by using various concentration of HF: 5%, 10%, 20% and 30% solutions in water3. We collected Raman spectra from samples collected at different stages of MXene synthesis: from multilayer powders to delaminated flakes, in order to observe the effect of stacking. The whole spectrum of Ti3C2 is divided into 4 regions: a resonant peak, A1g out-of-plane vibrations of Ti, C and O, the surface group vibrations region and carbon vibrations region. Those regions change based on the synthesis method and flake surrounding. All those peaks are affected not only by surface functional groups5, but also by stacking of the flakes. Due to a plasmonic peak of Ti3C2Tx around 785 nm, resonant conditions6 are achieved enabling an extra peak at around 119-123 cm⁻¹ when using a red diode laser. Lastly, we showed how photoluminescence, usually considered as an unwanted background of Raman spectra, can be used to detect the early stages of MXene degradation.

S.NM10.05.14
MXene-Based Composite Functional Inks for 3D Printed Lithium-Ion Batteries Jafar Orangi and Majid Beidaghi; Auburn University, United States

In a broad range of applications, including energy storage, flexible electronics, and sensors, additive manufacturing is considered as a promising device fabrication technique due to its potential for the development of complex architectures and using a variety of materials. Extrusion-based three-dimensional (3D) printing is a low-cost and straightforward method that offers rapid and precise fabrication of “on-chip” batteries and supercapacitors with 3D architectures. In this presentation, we report on our recent research on the development of functional nanocomposite inks based on two-dimensional (2D) MXenes, with the application in lithium-ion storage. MXenes are a new class of 2D materials with high electronic conductivity and hydrophilicity and have gained interest high-performance electrode materials for electrochemical energy storage. The developed nanocomposite inks are incorporated with the MXene sheet as a conductive additive that can also provide the rheological properties required for extrusion-based 3D printing without the need for any other additive or binder. The inks were prepared by mixing lithium iron phosphate and lithium titanate nanoparticles with a highly concentrated water-based MXene ink and were directly used for printing of the cathode and the anode of a microbattery, respectively. A programmable printing machine was used in the fabrication process that follows the layer-by-layer deposition of the nanocomposite ink. The developed inks and printing methodologies facilitate the rapid fabrication of microbatteries on a variety of substrates, while the loading of active material per area of the device can be controlled by the number of deposited layers. The electrochemical test results show the excellent performance of 3D printed batteries.

Controlling Defects in 2D GaS Continuous Films and Heterostructures for High Performance Wavelength-Tunable Photodetectors Yang Lu and Jamie Warner; University of Oxford, United Kingdom

The rapid development of two-dimensional (2D) materials calls for the development of novel 2D semiconductors with large bandgap for applications in short-wavelength LEDs, type-I heterojunctions, etc. Gallium sulfide (GaS), a wide-bandgap semiconductor, fulfills these requirements but was not fully explored due to lack of controllable synthesis methods, unexplored layer-dependent properties and unanswered stability issues. Here, to answer these questions, we developed a CVD synthesis method of thickness-controlled (1–4L), uniform and continuous films of both defective GaS and defect-free GaS. A simple method for determination of thickness by Raman spectroscopy is developed. An enhanced stability of the defect-free GaS was demonstrated under laser and strong UV lights, and by controlling defects in GaS, the photoresponse range could be changed from vis-to-UV to UV-discriminating. The defect-free GaS is suitable for large-scale UV-sensitive high-performance photodetector arrays for information encoding under large vis-light noise, with short response time, excellent UV photoresponsivity and a 26-times increase of signal-to-noise ratio compared with small bandgap 2D semiconductors. By comprehensive characterizations from atomic-scale structures to large-scale device performances in 2D semiconductors, we provide insights into the role of defects, the importance of neglected material-quality control and how to enhance device performance. Finally, both layer-controlled defective and defect-free GaS prove to be promising platforms for study of novel phenomena and new applications in WS₂-GaS van der Waals heterojunctions.

Laser-Assisted Accelerated Synthesis of 2D Quantum Materials Nurul Azam¹, Zabihollah Ahmadi¹, Salah Elafandi¹, Baha Yakupoglu¹, Mengkun Tian², Abdelaziz Boulesbaa¹ and Masoud Mahjouri-Samani¹; ¹Auburn University, United States; ²Georgia Institute of Technology, United States; ³California State University Northridge, United States

The firmly defined dimensionalities of two-dimensional (2D) layered materials including transition metal dichalcogenides (TMDs) exposed numerous unusual properties that have been recently at the center of the quantum materials and information sciences research. In pursuit of the accelerated growth and discovery of 2D materials, many efforts have concentrated on developing new approaches including physical and chemical vapor deposition techniques. However, complex, uncontrolled gas-phase reactions, and flow dynamics have made the synthesis of these multi-component 2D crystals exceedingly challenging. This work demonstrates a novel laser-assisted synthesis technique (LAST), which significantly reduces the existing growth complexities and remarkably accelerates the growth of 2D materials. The uniqueness of this approach arises from the direct vaporization technique of stoichiometric powders by the laser heating process. We show that this directed laser heating permits pressure-independent decoupling of the growth and evaporation kinetics, enabling the use of stoichiometric powder as precursors for the growth of various high-quality 2D materials including MoS₂, MoSe₂, WSe₂, and WS₂.

Mr. Nurul Azam is currently a Ph.D. student in the Department of Electrical and Computer Engineering (ECE) at Auburn University (AU). His research in the Laser-Assisted Science and Engineering (LASE), Lab under the supervision of Prof. Mahjouri-Samani, focuses on investigating and developing novel approaches for the synthesis of 2D quantum materials and heterostructures.

Synthesis of Two-Dimensional, Semiconducting Quantum Materials via Chemical Vapor Deposition (CVD) Daniel S. Choi¹, Evgeniya H. Lock² and Shashi P. Karna³; ¹National Research Council, United States; ²Naval Research Laboratory, United States; ³U.S. Army Research Laboratory, United States

In the past decade, there have been unprecedented advancements in research and development of materials for quantum applications such as ultrasensitive detection, quantum information processing, energy efficient ultrafast electronics, quantum light-emission, and many more that require a fundamental understanding of never-before observed physical and chemical phenomena in known materials. Of these new generation of materials, transition metal dichalcogenides (TMDs) have become attractive candidates for more extensive investigation due to their novel and non-classical behaviors observed at nanoscale as well as potential for their incorporation into devices and applications. For instance, nanoscale TMDs such as tungsten diselenide (WSe₂), tungsten disulfide (WS₂), and molybdenum disulfide (MoS₂) have been shown to exhibit highly localized, intense, quantum emission of single photons that have not been previously observed in their bulk counterparts. While understanding fundamental mechanism and origin, as well as the physical structure of these quantum materials and their properties are crucial, parallel efforts in developing large scale, controlled synthesis of these materials is just as imperative.
Currently, much of the studies on TMD materials for quantum applications have primarily been on larger flakes and crystals, or exfoliated films, which limits scalability of the material production as well as the need for transfer of the exfoliated material onto a suitable substrate.

In this work, we present a systematic synthesis of 2-dimensional, single- to few-layers of transition metal chalcogenides thin film directly on silicon substrate via chemical vapor deposition (CVD). Our approach not only sheds light into understanding the growth mechanism of 2-dimensional TMDs, but also provides optimal growth parameter for consistent, large scale production of these materials. The results presented will provide basis for synthesis of next-generation of 2-dimensional materials as well as shed light into bottom-up building approach of van der Waals heterostructures for quantum applications.

*This work was partially supported by the Office of Naval Research through Naval Research Laboratory Base Program.

Substrate-Mediated Hyperbolic Phonon Polaritons in MoO$_3$ Jeffrey Schwartz$^{1,2}$, Son T. Le$^{2,3}$, Sergiy Krylyuk$^2$, Albert Davydov$^2$ and Andrea Centrone$^2$; $^1$University of Maryland, United States; $^2$National Institute of Standards and Technology, United States; $^3$Theiss Research, United States

Hyperbolic phonon polaritons (HPhPs) are hybrid excitations of light and coherent charge oscillations that exist in strongly optically anisotropic 2D materials (e.g., MoO$_3$). These polaritons propagate through the material’s volume with long lifetimes, enabling novel mid-infrared nanophotonic applications by compressing light to sub-diffraction dimensions. Here, the dispersion relations and HPhP lifetimes (up to $\approx 2$ ps) in single-crystal $\alpha$-MoO$_3$ are determined by Fourier analysis of real-space, nanoscale-resolution polariton images obtained with the photothermal induced resonance (PTIR) technique. Measurements of MoO$_3$ crystals deposited on periodic gratings showed longer HPhPs propagation lengths ($\approx 2 \times$) and lower optical compressions in suspended regions compared to regions in direct contact with the substrate. Additionally, PTIR data reveal polymeric contaminants, resulting from sample preparation, localized under parts of the MoO$_3$ crystals. This work enhances the ability to engineer nanophotonic devices by leveraging substrate morphology to control polariton propagation.

S.NM09.10.13
Anion Charge Density Disturbance Induces In-Plane Instabilities within 2D Lateral Heterojunction of TMD—An Atomic View Bolong Huang; The Hong Kong Polytechnic University, Hong Kong

Two-dimensional (2D) heterostructure semiconductors are emerging as the potential candidates for broad applications, in which the transition-metal dichalcogenides (TMDs) have attracted the most attention due to their abundant advantages. TMDs have attracted tremendous interest due to the advantages of low-cost, earth-abundant, non-toxic, and environmentally friendly. Owing to the atomically thin structure, unique electronic and optical properties and rich diversity in chemical compositions, they have displayed considerable potential in the applications of integrated optoelectronic devices and systems such as p–n diodes, photodetectors, transistors, nanogenerators, and sensors as well as in catalysis. However, the investigations of these TMD heterostructure semiconductors usually only limit to the synthesis approach and opt-electronic properties, lacking the in-depth guidelines from the atomic exploration. Within the lateral heterojunction, the unique ripple effect has been identified as the consequence of the important interplay between different TMDs. Herein, the anion coupling induced charge disturbance within the WSe$_2$/WS$_2$ lateral heterojunction has been identified as the origin for the ripple structure induced by in-plane interfacial instability. Different scales of the first-principle simulations all verify the similar ripple phenomenon near the interfacial region of the WSe$_2$/WS$_2$ lateral heterojunction. Beyond the simple factor of lattice misfit, we confirm that the Se-S p-p coupling effect induced the uneven charge distribution is the intrinsic reason for such a unique structural phenomenon. By the introduction of the perturbation elastic entropy concept, we successfully predict the interfacial ripple scale in the WSe$_2$/WS$_2$ lateral heterojunction systems, supporting the simulation of experimental size. This work has compensated the knowledge gap between the theoretical investigation and experimental synthesis, which is essentially beneficial for the future fabrication of 2D heterostructure semiconductors with superior performance. The fundamentally general mechanism for the experimentally observed phenomenon is of pivotal significance in the further exploration in such 2D heterojunction semiconductor materials.

S.NM09.10.14
Materials for Resonant Passage of Isotopes Aleksey M. Bubenchikov; Tomsk State University, Russian Federation

The method of mathematical modelling is a good tool for constructing new materials [1]. The present work considers the problem which concerns quantum sifting of isotopes of gas components at cryogenic temperatures. The authors also focus on the task of constructing the membrane itself. The calculations show that the
membrane should have two identical ultrathin layers. By now, graphene nitride with regular pores has been synthesized using the double epitaxy method [2]. Mono-atomic layers of porous boron nitride [3] can also serve as the working layer of the membrane. Over the last decade, a group of new graphene-like mono-element 2D materials, such as germanene [4], silken [5, 6], phosphorus [7], and stanene [8] have also been synthesized. In principle, all porous analogues of these materials are suitable for application as the working layer of the membrane. This appears to be possible since the result of resonant passage of one of the mixture components is largely determined by the distance between the plates.

The considered problem of particles passing through a composite barrier is a generalization of the well-known Landau problem of particles with a certain energy passing through a unitary barrier. When constructing an analytical solution to the generalized problem of wave dynamics, the authors proceeded from the Schrödinger integral equation. The solution was built as a result of dividing the functions containing a shift in the independent variable into a nonlinear differential operator and separated exponential functions of the parameter and the argument. Next, algebraic operations with differential operators were performed, and the resulting operator was applied to separated functions. The resulting solution for the wave function is completely determined by the spectrum of the composite barrier. Studying the asymptotic behaviour of the solution allowed for finding the zeros of the reflection coefficient. As a result, resonance modes of transmission of one of the components were found. These modes were determined by the sequence of resonant distances between the plates. Choosing the distance between the layers from this sequence it is possible to achieve a selectivity effect in which a particle with a mass of \( m \) and energy of \( E \) passes through a potential barrier consisting of two identical parts without reflection. In other words, one of the components shows complete passage, while the other component is characterized by partial passage only. This ensures operation of the membrane as a gas separator. The calculations show that, at certain temperatures, it is possible to achieve hyperselectivity of mixture separation.

Synthesis and Study of 1H Structural Phase of Liquid-Exfoliated 2D Lead Iodide Nanodisks Using ADF-STEM Sapna Sinha1, Taishan Zhu2, Arthur France-Lanord2, Yuwen Sheng1; Jeffrey C. Grossman2, Kyriakos Porfyakis1 and Jamie Warner1; 1University of Oxford, United Kingdom; 2Massachusetts Institute of Technology, United States

Synthesis and study of new two-dimensional (2D) materials nanosheets is very important for both fundamental study of physical phenomenon as well as for new applications in nanoelectronics and optoelectronics. Lead Iodide (PbI\(_2\)) has been reported to be an excellent candidate for applications in thin films, transistors and PbI\(_2\) perovskites. However, not a lot of study has been carried out on easy and facile preparation of this material to produce scalable monolayer films. Liquid phase exfoliation (LPE) is considered to be an efficient method to obtain 2-dimensional nanosheets on a large scale. Based on previous findings on screening solvents for LPE, in this study, I will present results on obtaining several hundreds of >99% monolayer (PbI\(_2\)) using CHCl\(_3\) as a solvent. We have then used atomic-resolution annular dark field scanning transmission electron microscopy (ADF-STEM) imaging to study the monolayer flakes of PbI\(_2\). Here, I will report on a new structure of PbI\(_2\) which has not been studied before. PbI\(_2\), when suspended on graphene, converts into more energetically stable H-phase crystal structure compared to T-phase structure which was found to be more stable on lacyce carbon TEM grid. I will also present results on the defects and edge structure of the monolayer PbI\(_2\) and the unusually mobile atoms on the surface. The structural change of the PbI\(_2\) depending on substrate, i.e. graphene, opens up the possibility to control and further study its properties by using other different kinds of substrates.

**Chemical Vapor Deposition Synthesis of MoS2 Crystal Assisted by HSS/H2 Precursors—A Quantum Molecular Dynamics Study** Sungwook Hong; California State University, Bakersfield, United States

Layered van der Waals Heterostructures such as MoS2 monolayers have attracted great attentions for the application in optoelectronic devices owing to their outstanding physical, chemical, and mechanical properties. Chemical vapor deposition (CVD) is commonly used for scalable growth of layered materials. During CVD synthesis, reactions of MoO3 and H2S reactants are essential reaction steps where MoO3 flakes are reduced and sulfurized, transferring to MoS2 crystals. Recent studies suggested that addition of H2 gas in this synthesis process could lead to synthesis of higher-quality MoS2 monolayers. However, effects of H2 partial pressure on synthesis of MoS2 still remain elusive. Here, we present quantum molecular dynamics (QMD) simulations for CVD synthesis of MoS2 layer using MoO3 flakes and H2S gas precursors with and without H2 gas. Our QMD simulations revealed that H2 molecules indeed act as effective reducing agents for the MoO3 flake. As such, our work provides a valuable input for the scalable growth of layered van der Waals Heterostructures.

**Imaging Spin-Filter (Au/Ir) for Momentum Microscopy** Marten Patt1, Nils Weber2, Matthias Escher2, Timna-Joshua Kuehn2, Michael Merkel2 and Brandon Giles1; 1Scienta Omicron GmbH, Germany; 2FOCUS GmbH, Germany

Momentum Microscopy is a new technique in surface science, in which the momentum distribution of photoelectrons is projected onto an image plane. This image plane can be energy-filtered by a double-hemispherical electrostatic analyzer (NanoESCA) to achieve a monochromatic momentum distribution. Scanning the energy along the valence band is then used for band structure mapping which is a key technique to understand the electronic structure of novel materials. A new innovative method is to use the monochromatic electron distribution behind the double-hemispherical analyzer to retard it to the needed scattering energy of an Au/Ir (100) single crystal. This allows for spin-polarization dependent reflection, which enables a highly efficient imaging spin-filter technique [1].

We will show recent band-structure measurements of several TMDCs acquired with the NanoESCA and discuss the latest technical improvements of momentum microscopy with respect to 2D material characterization. First results of the imaging spin-filter installed at the ELI-Alps NanoESCA are shown, demonstrating its efficiency in real-space microscopy (e.g. imaging of magnetic domains) and in spin-resolved band-structure mapping.

Strong Magnetophonon Oscillations in Monolayer Graphene—A Spectroscopic Probe of Electron-Phonon Interactions
Mark T. Greenaway1,2, P Kumaravadivel3,3, D Perello3,3, A Berdyugin4, J Birkbeck3,3, J Wengraf3,4, S Liu5, J Edgar5, A Geim3,3, L Eaves2,3 and R Krishna Kumar3; 1Loughborough University, United Kingdom; 2The University of Nottingham, United Kingdom; 3University of Manchester, United Kingdom; 4University of Lancaster, United Kingdom; 5Kansas State University, United States

For more than 50 years, magnetophonon resonance (MPR) has proved to be a powerful tool for investigating electron-phonon interactions in a wide range of elemental and compound semiconductors and heterostructures. Its experimental signature is a series of oscillations in the magnetoresistance, periodic in inverse magnetic field, given by the equation,

\[ p \omega_c = \omega_p, \]

where \( p \) is an integer, \( \omega_c \) is the Landau level splitting and \( \omega_p \) is the phonon frequency. The successful observation of MPR in graphene has proved elusive due, in part, to the relative weak interaction of the massless Dirac Fermions with the lattice phonons.

Here we report the observation of large amplitude, temperature-dependent MPR oscillations in the magnetoresistance of large area, electrostatically gated Hall bars of exfoliated monolayer graphene encapsulated by hexagonal boron nitride (hBN) [1,2]. The oscillations are observed only in devices with a width which exceeds the ballistic carrier mean free path, 5 μm. We observe two distinct series of resonant peaks arising from inelastic scattering by transverse acoustic (TA) and longitudinal acoustic (LA) phonons. The LA phonon resonant amplitude is significantly weaker than that of the TA phonons. This is due, in part, to the carrier screening of the LA phonon modes. The magnetic field values of the resonant peaks are found to shift linearly with carrier sheet density from 10^{12} to 10^{13} cm^{-2}. These experiments also allow us to measure the dispersion curves of the LA and TA phonons up to wavevectors of ~ 10^9 m^{-1}. We model the experimental data to high accuracy using the Kubo formalism. We demonstrate that the LA and TA phonon speeds and the electron-phonon coupling strengths determined from the magnetophonon resonance measurements provide an excellent fit to the measured dependence of the resistivity at zero magnetic field over a temperature range of 4-150 K. Thus, MPR provides a spectroscopic tool for studying electron-phonon interaction in two-dimensional semiconductors.

Refractive Index Control of Highly Anisotropic 2D Materials
Joshua D. Caldwell; Vanderbilt University, United States

Two-dimensional materials are inherently anisotropic – with strong bonding in-plane and weak bonding out-of-plane. Consequently, their optical properties are birefringent, particularly at frequencies of the optically active infrared phonons. At these frequencies, the strong optical anisotropy results in hyperbolicity, where the permittivity tensor along at least one axis is negative, while at least one is positive. Hexagonal boron nitride (hBN) is an exemplary material in this regard. Materials which exhibit hyperbolicity can support volume-confined polaritonic modes, which have a wavelength much shorter than that of light in free space. Such spatially compressed modes have important implications for IR technologies, as they may be utilized to create planar meta-optics that are much more compact than the current state of the art. In particular, 2D materials can be used to realize metasurfaces, capable of shaping both nearfield- and far field light waves for a broad range of applications.
Conventional metasurface designs use geometrically fixed structures, or materials with excessive propagation losses, thereby limiting their potential applications. Here demonstrate that this can be overcome through the realization of a reconfigurable hyperbolic metasurface comprising a heterostructure of isotopically enriched hexagonal boron nitride (hBN) in direct contact with the phase-change material (PCM), such as single-crystal vanadium dioxide (VO₂) or GST. Here, the metallic and dielectric domains in PCM provide spatially localized changes in the local dielectric environment that modify the polariton wavelength supported in hBN by a factor of 1.6. Using this platform, we demonstrate the first reduction to practice of in-plane HPhP refraction, and the means for launching, reflecting and transmitting of HPhPs at the PCM domain boundaries. Ultimately, this phenomenon can be used to create planar refractive optics, such as lenses or waveguides, but on length scales far below the diffraction limit. Further, my employing doped semiconductor materials with controllable plasma frequencies, such direct control of hyperbolic polaritons can also be obtained via modification of the free carrier density of the underlying semiconductor.

**Light Induced Phase Transitions in Halide Perovskites**  
Aditya D. Mohite; Rice University, United States

Organic-inorganic (hybrid) perovskite have recently emerged as a new semiconductor platform for next generation optoelectronics devices. These perovskite solids feature weak bonds between their organic and inorganic building blocks, which results in an intrinsic softness and dynamics disorder of the lattice and an acute sensitivity to external stimuli. Here, we present comprehensive in-situ studies of light induced structural dynamics of in layered two-dimensional (2D) hybrid perovskites. We correlate the changes in the structure of the 2D perovskite to modification of both the physical properties and the figures of merit in solar cells and light emitting devices. We propose a new microscopic model to explain the evolution of the structure and optoelectronic properties under external stimuli. These results demonstrate the direct correlation between structural characterization of halide perovskites under external perturbation and intrinsic physical properties.

**Wafer-Scale Epitaxy of Transition Metal Dichalcogenides by Gas Source CVD**  
Tanushree H. Choudhury, Mikhail Chubarov, Xiaotian Zhang and Joan M. Redwing; The Pennsylvania State University, United States

Novel electronic and optical properties of monolayer transition metal dichalcogenides (MX₂, M=W, Mo and X=S, Se) have garnered a lot of attention in the recent years. A major challenge to integrating these materials with existing device fabrication processes is the availability of epitaxial single-crystal monolayers over a wafer scale. Our approach focusses on synthesis of these monolayers using gas source precursors, like those used in traditional III-V semiconductor industry. These precursors are placed in temperature and pressure-controlled bubblers placed outside the chamber and can be metered independently into the growth zone with precision. Uniform epitaxial binary TMD monolayers including MoS₂, WS₂, WSe₂ and MoSe₂ have been deposited on 2” sapphire wafers in a cold-wall CVD reactor using metal hexacarbonyl and hydride chalcogen precursors. A multi-step growth process comprising of precursor modulation was developed for WSe₂ to independently control nucleation density and the lateral growth rate of monolayer domains on the sapphire substrate [1]. For the sulfides, additional temperature modulation was introduced to increase crystalline quality. Using this approach, uniform, coalesced monolayer and few-layer TMD films were obtained on 2” sapphire substrates. Deposition of these materials in the same reactor provides insight into the factors controlling their growth, which in essential for the growth of heterostructures and/or alloys. In-plane X-ray diffraction demonstrates that the films are epitaxially oriented with respect to sapphire with narrow X-ray full-width-at-half-maximum indicating minimal rotational misorientation of domains within the basal plane [2]. Transmission electron microscopy analysis of these materials revealed additional information about the coalesced film structure. For instance, ~95 \% single oriented WS₂ domains were observed when the film growth rate was modulated. For WS₂, it was also confirmed that despite translational line defects present in the film, mirror boundaries were predominantly absent. WS₂ also showed no defect related photoluminescence peak at 80 K, indicating its high quality. In this talk the factors affecting the growth of TMDs (MX₂, M=W, Mo and X=S, Se) will be presented. The role of the substrate surface in the nucleation and growth of these TMDs will be discussed. In addition, the structural and optoelectronic characteristics for these films will also be presented.

The authors acknowledge financial support of the U.S. National Science Foundation through the Penn State 2D Crystal Consortium – Materials Innovation Platform (2DCC-MIP) under NSF cooperative agreement DMR-1539916 and EFRI 2-DARE Grant EFRI-143378.

Magnetic Transition Metal Dichalcogenides  
Christopher Hinkle; University of Notre Dame, United States

The incorporation of magnetic dopants is a way to realize magnetism in semiconductors. The 2D material WSe₂ is a semiconductor with a bandgap of 1.3 eV, and Fe-doped WSe₂ is predicted to have room temperature, long-range ferromagnetism. Moreover, WSe₂ has been extensively studied for applications in electronic devices, and can be prepared by deposition methods that are compatible with semiconductor fabrication processes. 2D magnetic films are particularly intriguing in technologies that rely on exchange coupling since the efficiency of the exchange with the magnet is inversely proportional to the magnet thickness 1/tFM. Chalcogenide-based TMD magnets can also have ideal interfaces with chalcogenide-based topological insulators (like Bi₂Se₃), enabling efficient spin torque devices and potentially realizing the quantum Hall effect without an external magnetic field.

Focusing on materials growth and integration techniques that utilize non-equilibrium, kinetically restricted strategies, coupled with in-situ characterization, enables the realization of atomic configurations and materials that are challenging to make but once attained, display enhanced and unique properties. In this work, we will highlight the growth of Fe-doped WSe₂ and report on its up to room temperature ferromagnetic properties. The evolution of Fe-doped WSe₂ films under different doping levels indicates that strain from the impurity atom itself coupled with strain imparted by the substrate can drive phase separation at high Fe concentrations. We find that suppressing that film strain helps promote more Fe incorporation (and higher Curie temperatures).

Cr₂O₃ has only 0.2% lattice mismatch with WSe₂ and is a magnetoelectric that can couple with ferromagnetic films. By using seed-layer techniques, we successfully prepared layered Fe-WSe₂ on Cr₂O₃ and demonstrate magnetic coupling between the two, a potentially promising route toward realizing electric field control of 2D magnets. Magnetic measurements show a clear hysteresis loop at 100 K in a 2 Tesla cooling field, from which a large negative bias field of 600 Oe is resolved. The bias field vs temperature measurements, where a negative bias field emerges below 250 K, indicates the existence of ferromagnetic exchange coupling in this heterostructure.

This work is supported in part by NEWLIMITS, a center in nCORE, a Semiconductor Research Corporation (SRC) program sponsored by NIST through award number 70NANB17H041. This work is also supported by the National Science Foundation under awards 1917025 and 1921818.

Moiré Heterostructure Quantum Emitter Arrays  
Brian Gerardot; Heriot Watt University, United Kingdom

Van der Waals heterostructures present unique opportunities to synthesize artificial quantum materials. For example, a slight lattice mismatch or relative rotation between the constituent layers of a hetero-bilayer results in a long-range moiré superlattice which spatially modulates the electronic bandstructure. Single particle wavepackets can be trapped in the periodic potential pockets with three-fold symmetry to form an intrinsic quantum dot lattice. Here I will discuss the properties of such quantum emitter arrays. In a heterostructure of bilayer 2H-MoSe₂ and monolayer WSe₂, we observe two interlayer exciton (IX) species trapped in moiré potentials with distinct spin-layer-valley configurations. Due to the phenomenon of locked electron spin and layer pseudospin in bilayer 2H-MoSe₂, the IX species exhibit opposite valley magnetic moments. Further, we find the 2H-MoSe₂ stacking intrinsically locks the atomic registries of the spin-layer locked IX species together. I will also present photon antibunching of moiré trapped excitons to unambiguously prove their quantum nature. Finally, I will discuss the properties of the moiré quantum emitters under applied electric fields and changing chemical potential.

Quantum Devices with 2D Materials  
Klaus Ensslin; ETH Zurich, Switzerland

We demonstrate electronic constrictions on bilayer graphene that can be completely pinched off [1]. Split-gate devices in combination with a graphite backgates enable electronic tunability of the devices. The level spectrum of quantum point contacts in bilayer graphene has a peculiar magnetic field dependence quite different from what is known from semiconductors. We understand the details of this spectrum [2] based on the Berry curvature in bilayer graphene.

In few electron and hole quantum dots confined by p-n junctions [3] we investigate valley and spin splitting. Also many electron quantum dots with standard tunneling barriers as well as double and triple quantum dots [4] can be realized with an electronic quality comparable to the best dots fabricated in standard semiconductor environments. The spectrum of excited states in graphene dots is qualitatively different [5] compared to semiconductors because of the valley degree of freedom. These experiments open the door for using graphene quantum dots as spin qubits with potentially long coherence times. We also discuss the properties of MoS₂ as a host material [6,7] for quantum dot-based qubits.

Strain Engineering of the Valley Magnetization and Berry Curvature Dipole in 2D Materials Jieun Lee; Seoul National University, Korea (the Republic of)

The valley degree of freedom in two-dimensional (2D) honeycomb lattices has attracted much recent attention due to its non-trivial Berry curvature effects associated with two nonequivalent valleys. This feature gives rise to many interesting valley-dependent phenomena such as the valley optical selection rule and the valley Hall effect, each of which accessing the valley-dependent electron control using the optical and electrical means. The valley manipulation in these works, however, focus on the control of the electron occupation while the Berry curvature at the two valleys are remained constant. In this talk, we show the mechanical control of the valley degree of freedom which is enabled by the strain engineering of the Berry curvature. By fabricating flexible monolayer MoS2 devices, we reversibly control strain on monolayer MoS2 and demonstrate the generation of the current-induced valley magnetization due to the formation of the Berry curvature dipole. The measured valley magnetization is in excellent agreement with the calculated Berry curvature dipole, which depends on the magnitude and direction of strain. Our results show that the Berry curvature dipole acts as an effective magnetic field in current-carrying systems, providing a novel route to generate magnetization in 2D crystals.

IV-VI van der Waals Materials and Their Properties Jie Yao1,2; 1University of California, Berkeley, United States; 2Lawrence Berkeley National Laboratory, United States

Low-dimensional nanomaterials with properties distinctive from their bulk counterparts have been extensively investigated in recent years. Besides the widely explored graphene and transition metal chalcogenides (TMDCs), a new family of van der Waals (vdW) materials composed of group IV and VI elements, especially Ge/Sn monocalcogenides, have attracted great attention in recent years. They have shown strong in-plane anisotropy that is similar to phosphorene (black phosphorous layers), and a number of unique electrical, optical, thermal and mechanical properties. Here I would like to share some of our recent discoveries on this unique family of materials, including their valleytronic behaviors and Eshelby twist formation in crystal growth.

Unlike conventional valleytronic materials where cryogenic temperatures, strong electric or magnetic field are needed to differentiate the valleys, Tin sulfide (SnS) was expected to have non-degenerate valleys with selection rules that are fundamentally different. I will talk about our experimental demonstration of the valley effect in an ambient, and bias-free
model system of SnS and its alloys with other IV-VI materials. We elucidate the direct access and identification of different sets of valleys, based primarily on the selectivity in absorption and emission of linearly polarized light by optical reflection/transmission and photoluminescence measurements, and demonstrate strong optical dichroic anisotropy of up to 600% and nominal polarization degrees of up to 96% for the two valleys with band-gap values 1.28 and 1.48 eV, respectively; the ease of valley selection further manifested in their non-degenerate nature. In addition, the band gap values can be tuned effectively through alloying of SnS with similar materials such as SnSe. Such discovery enables a new platform for better access and control of valley polarization.

The IV-VI material family is also enabling new opportunities from twisting topology generation. Twisting of vdW layers has been shown to provide a new degree of freedom to tailor the electrical and optical properties of vdW crystals. I will talk about the first observation of Eshelby twist in Ge monochalcogenides that results in continuous twisting of multiple vdW layers. We exploit the screw dislocation driven growth of GeS nanowires, with growth direction perpendicular to the vdW layers. Results from comprehensive characterization on the helical vdW crystals agree well with Eshelby’s theory. Moreover, the planar growth of the vdW layers co-exists with the screw dislocation driven growth and leads to radial expansion of the nanowires, which results in discretized Eshelby twists resembling a helical assembly of nanofilms. We attribute the discretization to the change of twist rates of the nanowires in conjunction with a substrate pinning effect. We further show that the twisting topology can be tailored by controlling the radial size of the structure. In these helical crystals, atomically sharp interfaces with various twist angles are created, providing an intriguing tunable platform to explore various interlayer coupling effects in vdW materials.

Orbital Magnetism and Quantized Anomalous Hall Effect in Twisted Bilayer Graphene Andrea Young; University of California, Santa Barbara, United States

In moire flat band systems, interlayer moire patterns can be used to engineer isolated superlattice bands in which the Coulomb interaction is comparable to the bandwidth. As in a Landau level, this leads to electron interaction dominated physics despite the low density of electrons, enabling full density control using electrostatic gates. Unlike Landau levels, however, moire flat bands occur under time reversal symmetric conditions. I will discuss experiments that observe the spontaneous breaking of time reversal symmetry, observed as magnetic hysteresis. Remarkably, hysteresis is accompanied by a quantized anomalous Hall effect, persisting to zero magnetic field and elevated temperatures. I will discuss the origins of this effect in the spontaneous orbital polarization of the electron system into a single, topological nontrivial superlattice band, and describe magnetic imaging data that confirms the orbital character of the magnetism.

Magnetism and Topology in Graphene-Based Flat Minibands David Goldhaber-Gordon1,2; 1Stanford Univ, United States; 2SLAC National Accelerator Laboratory, United States

Until recently, flat bands were achieved as Landau levels at high magnetic field. Then, Pablo Jarillo-Herrero of MIT and coworkers demonstrated flat minibands in graphene-based superlattices, discovering correlated insulators and superconductors at different fillings. We have now discovered dramatic magnetic states in such systems. Specifically, in magic-angle twisted bilayer graphene also aligned with a hexagonal boron nitride (hBN) cladding layer, we observe a giant anomalous Hall effect and signs of chiral edge states. This all occurs at zero magnetic field, near 3 electrons per moire cell in the conduction miniband [1]. Remarkably, the magnetization of the sample can be reversed by applying a small DC current. Although the anomalous Hall resistance is not quantized, and dissipation is significant, we suggest that the system is an incipient Chern insulator, similar to an integer quantum Hall state. In a different superlattice system, ABC-trilayer graphene aligned with hBN, again near 3 electrons per moire cell a Chern insulator emerges [2]. A magnetic field of order 100 mT is needed to quantize the anomalous hall signal. This trilayer system can be tuned in-situ to display superconductivity instead of magnetism [3]. We will discuss possible magnetic states, and complementary probes to examine which state actually emerges as the ground state in each system.

Spontaneous Out-of-Equilibrium Correlated Phases in van der Waals Materials Plasmonics

Justin Song\textsuperscript{1,2}; \textsuperscript{1}Nanyang Technological University Singapore, Singapore; \textsuperscript{2}Institute of High Performance Computing, Singapore

Spontaneous symmetry breaking lies at the heart of the description of interacting phases of matter. Here we argue that a driven interacting system subject to a linearly polarized (achiral) driving field can spontaneously magnetize (acquire chirality). In particular, we find when a metal is driven close to its plasmon resonance, it hosts strong internal ac fields that enable Berryogenesis: the spontaneous generation of a self-induced Bloch band Berry flux, which supports and is sustained by a circulating plasmonic motion, even for a linear polarized driving field. This non-equilibrium phase transition occurs above a critical driving amplitude, and depending on system parameters, can enter the spontaneously magnetized state in either a discontinuous or continuous fashion. Berryogenesis relies on nontrivial interband coherences for electronic states near the Fermi energy generated by ac fields readily found in a wide variety of multiband systems. We anticipate that graphene devices, in particular, which can host high quality plasmons, provide a natural and easily available platform to achieve Berryogenesis and spontaneous non-equilibrium (plasmon-mediated) magnetization in present-day devices, e.g., those based on graphene plasmonics. If we have time, we will also discuss other manifestations of non-trivial quantum geometry in Dirac systems.

Artificial Neurons and Synapses with CVD MoS\textsubscript{2} for Neuromorphic Computing

Tania Roy; University of Central Florida, United States

The prevalent von Neumann architecture in today’s processors involves memory and processing units to reside in physically separate locations. With memory speeds lagging behind the processor speeds, latency in accessing data from memory has resulted in the “von Neumann bottleneck”. To alleviate this issue, several alternative non-von Neumann architectures have been explored. Neuromorphic computing is one such non-von Neumann approach, inspired by the human brain’s ability of cognitive recognition. The brain operates through a network of neurons that are connected to each other by synapses. In 2008, after the discovery of memristors, the fourth circuit element, researchers have explored the idea of mimicking synaptic behavior with a single memristive device. Albeit significant advances, synaptic devices using phase change materials-based memristors and metal oxide-based resistive switching devices have some limitations. These devices exhibit high programming current in the range of µA to mA. Additionally, the synaptic weight update, i.e. the increase (decrease) of the synapse’s conductance with the application of a continuous stream of identical positive (negative) input voltage pulses, is non-linear. Non-linearity in weight update increases the complexity of using these devices for real-time unsupervised learning. So, it becomes necessary to employ a materials system which exhibits low programming current as well as a linear weight update.

Recently, two-dimensional (2D) materials are being largely explored to demonstrate their viability as electronic synapses and neurons. In this talk, we shall discuss the realization of a synaptic device using graphene/MoS\textsubscript{2} heterostructures. In these devices, CVD-grown monolayer graphene acts as an electrode to CVD MoS\textsubscript{2}. These memristive devices exhibit low programming currents and a high dynamic range from 1 nA to 1 mA. In contrast with oxide-based or PCM-based synapses, these devices exhibit a gradual set and reset process when symmetric input voltage pulses are applied, resulting in a near-linear weight update. Linearity and symmetry in weight update is much desired for real-time learning applications. We shall also present the demonstration of an integrate-and-fire neuron using Ag/MoS\textsubscript{2}/Au vertical structures. These devices possess the four crucial features of neuron – all-or-nothing spiking, threshold-driven firing, post-firing refractory period and stimulus strength based frequency response. Realizing neurons and synapses using the same materials system allows the monolithic integration of the essential building blocks of neuromorphic hardware, and bears potential for a highly scalable spiking neural networks suitable for unsupervised learning applications.

Indirect Excitons

Leonid Butov; University of California, San Diego, United States

An indirect exciton (IX), also known as an interlayer exciton, is a bound pair of an electron and a hole confined in spatially separated layers. Due to their long lifetimes, IXs can cool below the temperature of quantum degeneracy. This gives an opportunity to realize and study cold excitons.

We will overview studies of Bose-Einstein condensation of IXs. We will present direct measurements of spontaneous
coherence and condensation of IXs in GaAs heterostructures. We will present phenomena observed in the IX condensate, including the exciton density wave, spin textures, Pancharatnam-Berry phase and long-range coherent spin currents, and interference dislocations.

We will present van der Waals transition-metal dichalcogenide (TMD) heterostructures where IX condensation can be realized at high temperatures. We will present IXs at room temperature and indirect charged excitons, i.e. indirect trions, in van der Waals heterostructures.

SESSION S.NM09.02: Synthesis of van der Waals Heterostructures
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
S-NM09

5:00 AM *S.NM09.02.01
Tailoring the Synthesis and Assembly of 2D Materials for Monolayer and Bilayer Heterostructures Kai Xiao1, Yu-Chuan Lin4, Yiling Yu1, Hui Cai1, Xufan Li1, Kai Wang1, Chenze Liu2, Alexander Puretzky1, Gerd Duscher2, Mina Yoon4, Eva Zarkadoula1, Christopher Rouleau* and David B. Geohegan1; 1Oak Ridge National Laboratory, United States; 2The University of Tennessee, Knoxville, United States

2D layered materials enable the construction of hybrid heterostructures with emergent electronic, optical, and quantum properties resulting from the interplay between the individual nanosheets. However, the synthesis of 2D heterostructures with
controlled twist angles and stackings is still a great challenge which currently limits their development. In this talk, I will discuss our recent work on the synthesis and assembly of 2D heterostructures through non-equilibrium synthesis and processing approaches including isoelectronic doping, atomic implantation, and van der Waals epitaxy. First, by tailoring isoelectronic doping of chalcogens and metals in 2D TMDs (e.g., MoSe2, WS2) during CVD synthesis, the uniform alloys, gradient alloys, and lateral heterostructures are controlled grown on substrates which exhibit many novel properties including tunable bandgaps, enhanced photoluminescence, modulated charge carriers, etc. Second, with well controlled kinetic energy of Se clusters impaled laser deposition (PLD) plasmas, the CVD-synthesised 2D WS2 crystals are precisely converted to monolayer Janus heterostructure and bilayer heterostructures by laser implantation. Last, I will briefly discuss the vdW epitaxial growth of GaSe/MoSe2 heterostructures and corresponding gate-tunable photovoltaic properties. The interlayer stacking, interfacial structure and optical properties are characterized by atomic-resolution STEM, Raman and PL spectroscopy. The atomistic origins of the emerging properties of vdW heterostructures, including interlayer excitons, persistent photoconductivity, and gate-tunable photovoltaic response, will be discussed. Our results demonstrate that with nonequilibrium synthesis and processing approaches, 2D heterostructures can be precisely realized for future applications in atomically thin optoelectronics and quantum information science.

Research sponsored by the U.S. Dept. of Energy, Office of Science, Basic Energy Sciences, Materials Science and Engineering Div. (synthesis science) and Scientific User Facilities Div. (characterization science). Throughout the presentation, facilities available for collaboration at the Center for Nanophase Materials Sciences (CNMS) user facility will be presented.

5:15 AM S.NM09.02.02
Epitaxial Growth of Two-Dimensional WSe2 on Highly Crystalline CVD Graphene Benjamin Huet, Xiaotian Zhang, Mikhail Chubarov, Tanushree H. Choudhury, David Snyder and Joan M. Redwing; The Pennsylvania State University, United States

Co-integrating graphene with other two-dimensional (2D) materials represents an important step toward the development of novel 2D material-based electronic and optoelectronic devices. In order to fully exploit the unique physical properties of graphene and the semiconducting transition metal dichalcogenides (TMDs) in functional applications, it is essential to control the crystallinity, the material sequence, the stacking order or twisting angle, and the interface cleanliness.

In this study, we investigate the direct growth of WSe2 by gas source chemical vapor deposition (CVD) on top of CVD grown graphene. Isolated millimeter-size graphene crystals are first produced by CVD on Cu foils and then transferred onto fused silica or sapphire which are more compatible with the gas-source CVD process. This graphene template is used as the synthesis substrate for the high temperature growth of WSe2 using tungsten hexacarbonyl (W(CO)6) and hydrogen selenide (H2Se) as precursors.

Using scanning electron microscopy (SEM) and atomic force microscopy (AFM), we compare the nucleation site density, size and shape of WSe2 crystals grown on single layer graphene, bare C-plane sapphire and bare fused silica. WSe2 crystals typically exhibit a triangular shape with a lateral size exceeding 1 micrometer.

The nucleation site density of WSe2 crystals has also been studied as a function of the number of graphene layers and their relative twisting angle. The samples have been characterized by Kelvin probe force microscopy (KPFM), transmission electron microscopy (TEM), and Raman spectroscopy in order to better understand why single-layer graphene leads to a lower WSe2 seeding density compared to twisted bi-/tri-layer graphene and an even lower density compared to AB stacked bi-/tri-layer.

WSe2 crystals grown on graphene are found to follow 2 specific orientations rotated by a 60° angle. The alignment of the zigzag edges of the triangular WSe2 crystals with the zigzag edges of the underlying hexagonal graphene domain is indicative of van der Waals epitaxy rather than remote epitaxy with the underlying substrate.

Finally, given that the graphene transfer process inherently leads to impurity intercalation, we investigate the impact of the transfer protocol and post-transfer annealing on the cleanliness of graphene/substrate and WSe2/graphene interfaces. The cleanliness of the interface is mainly studied using photoluminescence (PL) and Raman spectroscopy.

Synthesis and Properties of van der Waals Heterostacks with Controlled Angle Camilla Coletti; Istituto Italiano di Tecnologia, Italy
In this talk recent advances on the synthesis and application of large-scale highly-crystalline van der Waals heterostacks will be presented. The electronic performance of single-crystal graphene arrays obtained via patterned growth [1] will be discussed in terms of homogeneity and repeatability. Particular focus will be put in the heterostack obtained by directly synthesizing via chemical vapor deposition (CVD) graphene bilayers and few layers with controlled angle [2, 3]. Also, the synthesis of azimuthally aligned tungsten disulfide (WS2) on graphene will be presented [4, 5]. It will be shown via microstructural and electronic characterization that monolayer WS2 on graphene presents a remarkable spin-orbit splitting [5]. Nanomechanical properties such as superlubric sliding of WS2 flakes on graphene triggered by scanning probe microscopy will be discussed [6]. Furthermore, the fabrication and performance of an entirely scalable hybrid WS2/graphene photodetector will be presented [7]. Finally, the synthesis of transition metal dichalcogenide heterostructures with controlled angle via liquid phase CVD will be introduced.

Twisted Spirals of Layered Transition Metal Dichalcogenides Yuzhou Zhao, Chenyu Zhang, Paul M. Voyles and Song Jin; University of Wisconsin-Madison, United States

Twisted moiré pattern introduces new phenomena to Van der Waals layered materials by periodically changing the local registry of atoms, making it a new degree of freedom for 2D material engineering. Conventional twisted structures are fabricated by mechanically stacking layers, however, it still remains challenging to get clean interfaces. Direct vapor phase growth may yield small fractions of twisted bilayers as byproduct, there is no rational control over the twist angle. In this work, we demonstrate that continuously twisted structures beyond Eshelby twist can be realized starting with screw dislocation spirals of layered MX2 materials. Super twisted spirals of MX2 materials up to tens of microns in lateral size are grown, and the orientation of layers and moiré superlattices can be directly observed and measured using scanning transmission electron microscope. Our study provides a new strategy to the rational control of twist angle of 2D materials from direct growth, which could enable the study of twisted moiré superlattices.

Modeling the Growth of 2D Crystals—Analytical, Phase-Field and Machine Learning Methods Vivek B. Shenoy, Nathan Frey and Arkamita Bandyopadhyay; University of Pennsylvania, United States

Vertical stacking of monolayers via van der Waals (vdW) interaction opens promising routes toward engineering physical properties of two-dimensional (2D) materials and designing atomically thin devices. Increasingly, the bottleneck in this field is the controlled synthesis of these materials through methods such as chemical etching and chemical vapor deposition (CVD). In this talk, I will present insights into synthesis and growth of 2D materials developed from analytical, phase-field, and machine learning models. First, we adapt the state-of-the-art positive and unlabeled (PU) machine learning framework to predict which theoretically proposed 2D materials in the MXene family have the highest likelihood of being successfully synthesized. By considering both the MXenes and their precursors, we identify 18 MXene compounds that are highly promising candidates for synthesis. Next, we develop a general multiscale model for scalable CVD growth of layered materials and predict the necessary growth conditions for vertical (initial + subsequent layers) versus in-plane lateral (monolayer) growth. An analytic thermodynamic criterion is established for multilayer growth that depends on the sizes of both layers, the vdW interaction energies, and the edge energy of 2D layers. We connect the model to experimental controls
and find that temperature and adatom flux from vapor are the primary criteria affecting the self-assembled growth. This model agrees with experimental observations of various monolayer and bilayer transition metal dichalcogenides grown by CVD. Finally, we consider CVD synthesizable transition metal dichalcogenide heterostructures as a robust platform for engineering quantum confinement of Dirac fermions using a multiscale model for electronic properties.

SESSION S.NM09.03: Optical Phenomena in van der Waals Materials

5:00 AM *S.NM09.03.01

IV-VI van der Waals Materials and Their Properties Jie Yao1,2; 1University of California, Berkeley, United States; 2Lawrence Berkeley National Laboratory, United States

Low-dimensional nanomaterials with properties distinctive from their bulk counterparts have been extensively investigated in recent years. Besides the widely explored graphene and transition metal chalcogenides (TMDCs), a new family of van der Waals (vdW) materials composed of group IV and VI elements, especially Ge/Sn monocalcogenides, have attracted great attention in recent years. They have shown strong in-plane anisotropy that is similar to phosphorene (black phosphorous layers), and a number of unique electrical, optical, thermal and mechanical properties. Here I would like to share some of our recent discoveries on this unique family of materials, including their valleytronic behaviors and Eshelby twist formation in crystal growth.

Unlike conventional valleytronic materials where cryogenic temperatures, strong electric or magnetic field are needed to differentiate the valleys, Tin sulfide (SnS) was expected to have non-degenerate valleys with selection rules that are fundamentally different. I will talk about our experimental demonstration of the valley effect in an ambient, and bias-free model system of SnS and its alloys with other IV-VI materials. We elucidate the direct access and identification of different sets of valleys, based primarily on the selectivity in absorption and emission of linearly polarized light by optical reflection/transmission and photoluminescence measurements, and demonstrate strong optical dichroic anisotropy of up to 600% and nominal polarization degrees of up to 96% for the two valleys with band-gap values 1.28 and 1.48 eV, respectively; the ease of valley selection further manifested in their non-degenerate nature. In addition, the band gap values can be tuned effectively through alloying of SnS with similar materials such as SnSe. Such discovery enables a new platform for better access and control of valley polarization.

The IV-VI material family is also enabling new opportunities from twisting topology generation. Twisting of vdW layers has been shown to provide a new degree of freedom to tailor the electrical and optical properties of vdW crystals. I will talk about the first observation of Eshelby twist in Ge monocalcogenides that results in continuous twisting of multiple vdW layers. We exploit the screw dislocation driven growth of GeS nanowires, with growth direction perpendicular to the vdW layers. Results from comprehensive characterization on the helical vdW crystals agree well with Eshelby’s theory. Moreover, the planar growth of the vdW layers co-exists with the screw dislocation driven growth and leads to radial expansion of the nanowires, which results in discretized Eshelby twists resembling a helical assembly of nanoplates. We attribute the discretization to the change of twist rates of the nanowires in conjunction with a substrate pinning effect. We further show that the twisting topology can be tailored by controlling the radial size of the structure. In these helical crystals, atomically sharp interfaces with various twist angles are created, providing an intriguing tunable platform to explore various interlayer coupling effects in vdW materials.

Moiré Heterostructure Quantum Emitter Arrays Brian Gerardot; Heriot Watt University, United Kingdom

Van der Waals heterostructures present unique opportunities to synthesize artificial quantum materials. For example, a slight lattice mismatch or relative rotation between the constituent layers of a hetero-bilayer results in a long-range moiré superlattice which spatially modulates the electronic band-structure. Single particle wavepackets can be trapped in the periodic potential pockets with three-fold symmetry to form an intrinsic quantum dot lattice. Here I will discuss the properties of such quantum emitter arrays. In a heterostructure of bilayer 2H-MoSe2 and monolayer WSe2, we observe two interlayer exciton (IX) species trapped in moiré potentials with distinct spin-layer-valley configurations. Due to the
phenomenon of locked electron spin and layer pseudospin in bilayer 2H-MoSe2, the IX species exhibit opposite valley magnetic moments. Further, we find the 2H-MoSe2 stacking intrinsically locks the atomic registries of the spin-layer locked IX species together. I will also present photon antibunching of moiré trapped excitons to unambiguously prove their quantum nature. Finally, I will discuss the properties of the moiré quantum emitters under applied electric fields and changing chemical potential.

5:30 AM *S.NM09.03.03
Indirect Excitons Leonid Butov; University of California, San Diego, United States

An indirect exciton (IX), also known as an interlayer exciton, is a bound pair of an electron and a hole confined in spatially separated layers. Due to their long lifetimes, IXs can cool below the temperature of quantum degeneracy. This gives an opportunity to realize and study cold excitons.

We will overview studies of Bose-Einstein condensation of IXs. We will present direct measurements of spontaneous coherence and condensation of IXs in GaAs heterostructures. We will present phenomena observed in the IX condensate, including the exciton density wave, spin textures, Pancharatnam-Berry phase and long-range coherent spin currents, and interference dislocations.

We will present van der Waals transition-metal dichalcogenide (TMD) heterostructures where IX condensation can be realized at high temperatures. We will present IXs at room temperature and indirect charged excitons, i.e. indirect trions, in van der Waals heterostructures.

5:45 AM *S.NM09.03.04
Spontaneous Out-of-Equilibrium Correlated Phases in van der Waals Materials Plasmonics Justin Song; 1Nanyang Technological University Singapore, Singapore; 2Institute of High Performance Computing, Singapore

Spontaneous symmetry breaking lies at the heart of the description of interacting phases of matter. Here we argue that a driven interacting system subject to a linearly polarized (achiral) driving field can spontaneously magnetize (acquire chirality). In particular, we find when a metal is driven close to its plasmon resonance, it hosts strong internal ac fields that enable Berryogenesis: the spontaneous generation of a self-induced Bloch band Berry flux, which supports and is sustained by a circulating plasmonic motion, even for a linear polarized driving field. This non-equilibrium phase transition occurs above a critical driving amplitude, and depending on system parameters, can enter the spontaneously magnetized state in either a discontinuous or continuous fashion. Berryogenesis relies on nontrivial interband coherences for electronic states near the Fermi energy generated by ac fields readily found in a wide variety of multiband systems. We anticipate that graphene devices, in particular, which can host high quality plasmons, provide a natural and easily available platform to achieve Berryogenesis and spontaneous non-equilibrium (plasmon-mediated) magnetization in present-day devices, e.g., those based on graphene plasmonics. If we have time, we will also discuss other manifestations of non-trivial quantum geometry in Dirac systems.

6:00 AM *S.NM09.03.05
Light Induced Phase Transitions in Halide Perovskites Aditya D. Mohite; Rice University, United States

Organic-inorganic (hybrid) perovskite have recently emerged as a new semiconductor platform for next generation optoelectronics devices. These perovskite solids feature weak bonds between their organic and inorganic building blocks, which results in an intrinsic softness and dynamics disorder of the lattice and an acute sensitivity to external stimuli. Here, we present comprehensive in-situ studies of light induced structural dynamics of in layered two-dimensional (2D) hybrid perovskites. We correlate the changes in the structure of the 2D perovskite to modification of both the physical properties and the figures of merit in solar cells and light emitting devices. We propose a new microscopic model to explain the evolution of the structure and optoelectronic properties under external stimuli. These results demonstrate the direct correlation between structural characterization of halide perovskites under external perturbation and intrinsic physical properties.

6:15 AM *S.NM09.03.06
Nano-Electronic and Photonic Devices Based on 2D Materials Miriam Serena Vitiello; NEST, National Research Council CNR-NANO and Scuola Normale Superiore, Italy

Bi-dimensional nano-materials and related heterostructures are establishing themselves as intriguing material systems for the development of a new class of electronic, photonic and plasmonic devices with ad hoc-properties, that can be engineered
“from scratch”. Huge potential can be envisaged in a variety of application fields, ranging from saturable absorbers to optical modulators, from optical communication modules to spintronics, from near-field components to photodetectors. Their peculiar band-structure and electron transport characteristics, which can be easily manipulated via layer thickness control, suggest they could also form the basis for a new generation of high-performance devices operating in the Terahertz frequency range (1-10 THz) of the electromagnetic spectrum. This talk will review latest achievements in the developments of active and passive THz photonic and nano-electronic devices exploiting 2D nano-materials and combined heterostructures and will discuss future perspectives of this rapidly developing research field.

5:00 AM *S.NM09.04.01
Light-Matter Interactions of 2D Materials and Their Novel Sensing Applications Shengxi Huang; The Pennsylvania State University, United States

Emerging quantum materials, such as novel two-dimensional (2D) materials and topologically nontrivial materials, have gained increasing attention due to their unique electronic and photonic properties. The realization of the optoelectronic applications of these materials still faces several challenges. For example, it is critical to gain clear understandings of (1) the fundamental light-matter interactions, which govern many of the key material properties, and (2) the coupling with other nanostructures, which is a required structure for devices and systems. This talk introduces new discoveries and pioneering works using optical spectroscopic techniques on these critical challenges, and novel applications of 2D materials in chemical and biological sensing. The first part of this talk presents the essential material properties investigated using spectroscopy, including interlayer coupling of Moiré patterns of 2D materials, anisotropic light-matter interactions of 2D quantum materials, and quantum optical emission properties of nanoengineered 2D layers. The spectroscopic techniques, including low-frequency Raman spectroscopy and polarization-and time-resolved spectroscopy, can also be widely used in other material systems such as semiconductor superlattices. The second part of this talk focuses on the interaction of 2D materials with other nanostructures and related applications. The interactions of 2D materials and selected organic molecules revealed novel enhancement effect of Raman signals for molecules on 2D surface, which offers a new paradigm in biochemical sensing. However, there is a selection rule regarding the 2D material substrates for molecules, which is critical for the design of biochemical molecular sensing platform and has been revealed recently. Overall, the works presented in this talk are significant in fundamental nanoscience, and offer important guidelines for practical applications in optoelectronics, sensing, and quantum technologies. The methodologies used here also provide a framework for the future study of many new low-dimensional and quantum materials.

5:15 AM S.NM09.04.02
Ring-Integrated Photodetectors for Silicon Photonics Based on Photo-Thermoelectric Effect in hBN/SLG/hBN Heterostructures Jakob Muench¹, Simone Schuler¹,2, Dries Van Thourhout¹, Alfonso Ruocco¹, Kenji Watanabe², Takashi Taniguchi², Alberto Montanaro², Simone Marconi³, Vito Sorianello³, Marco Romagnoli³, Andrea C. Ferrari¹ and Thomas Mueller²; ¹Cambridge Graphene Centre, University of Cambridge, United Kingdom; ²Technische Universität Wien, Austria; ³Ghent University, Belgium; ⁴National Institute for Material Science, Japan; ⁵Consorzio Nazionale per le Telecomunicazioni, Italy

Graphene is ideally suited for next generation communication systems [1], due to its unique optoelectronic properties [2] and CMOS compatibility [1]. Here, we present a graphene-based photodetector (GPD) for telecom wavelengths, combining an on-chip Si ring-cavity with high-mobility (> 10,000 cm²/Vs) single layer graphene (SLG) encapsulated in hBN. The constructive interference inside the ring results in a ~100% absorption of the guided light. Dual-gate electrodes on the active layer generate a p-n-junction in SLG, enabling a response due to the photo-thermoelectric (PTE) effect [3]. At optical input power levels ~ 0.1mW, comparable to those required by receivers used in 100 Gbps links [1], the GPD reaches a responsivity ~ 90 V/W, one order of magnitude higher than the highest reported to date for integrated PTE based GPDs [4], an electrical 3-dB cut-off frequency ~ 11 GHz, and a noise-equivalent power ~ 40 pW/√Hz. For higher input powers (~1mW), the strong light-matter interaction inside the Si ring results in electronic temperature increases of the photo-excited carriers ~ 100 K, and the transition to the ‘strong heating’ regime, characterized by sublinear scaling between photovoltage

2020 MRS Virtual Spring/Fall Meeting, November 27-December 4, 2020, Spring Abstracts Final Program 2/3/21
Scalable MoS₂/W₅₋₂-Heterostructure Photodetectors Fabricated by a Transfer-Free Approach
Tilmar Kuemmell¹, Ulrike Hutten¹, Leon Daniel¹, Annika Grundmann², Michael Heuken²,³, Holger Kalisch², Andrei Vescan² and Gerd Bacher¹; ¹Universität Duisburg-Essen, Germany; ²RWTH Aachen University, Germany; ³Aixtron SE, Germany

2D semiconductors based on TMDCs are highly promising materials for ultrathin, flexible and large-area photodetectors due to their thickness in the nm range and their effective absorption. The high exciton binding energy in these materials leads to a fast recombination and poor charge carrier separation, which represents an inherent drawback of such devices. To overcome this challenge, 2D heterostructures have been developed, separating optically generated charge carriers and thus increasing photoresponsivity. However, up to now, such heterostructure devices have been fabricated by stacking exfoliated flakes [1] or by transferring CVD-synthesized layers on top of each other [2]. These approaches suffer from process-induced defects and contaminations, and are hardly suited for industrially relevant fabrication routes.

We realized photodetectors based on TMDC heterostructures that are directly grown by MOCVD on a sapphire substrate [3], without any change between systems and without delicate transfer steps that bear the risk of uncontrolled contamination. The 1 mm² active area of the devices consists of a MoS₂/W₅₋₂-heterobilayer, and interdigital contact patterns have been defined by electron beam lithography and metallization with Ti/Au. As a reference, devices based on MoS₂ and WS₂ monolayers, respectively, have been fabricated.

The photocurrent of the devices is analyzed under illumination with a defocussed laser (λ = 442 nm). Using either MoS₂ or WS₂ monolayers for light detection, only very low responsivities - far below 1 mA/W - are obtained. Obviously, low carrier mobilities and fast recombination rates are detrimental for the photosensitivity in monolayer devices. The situation is completely different for the directly grown MoS₂/W₅₋₂-heterostructures: A several orders of magnitude enhanced responsivity of up to 16 A/W is achieved under an illumination of 45 mW/cm², corresponding to absolute photocurrents in the mA range. We attribute the large gain not only to an effective charge carrier separation, but also to an efficient hole trapping, leading to an enhanced electron flow in the heterostructure. This interpretation is consistent with the observation of a reduced responsivity for higher excitation densities, where these trap states become saturated.

Refractive Index Control of Highly Anisotropic 2D Materials
Joshua D. Caldwell; Vanderbilt University, United States

Two-dimensional materials are inherently anisotropic – with strong bonding in-plane and weak bonding out-of-plane. Consequently, their optical properties are birefringent, particularly at frequencies of the optically active infrared phonons. At these frequencies, the strong optical anisotropy results in hyperbolicity, where the permittivity tensor along at least one axis is negative, while at least one is positive. Hexagonal boron nitride (hBN) is an exemplary material in this regard. Materials which exhibit hyperbolicity can support volume-confined polaritonic modes, which have a wavelength much shorter than that of light in free space. Such spatially compressed modes have important implications for IR technologies, as they may be utilized to create planar meta-optics that are much more compact than the current state of the art. In particular, 2D materials can be used to realize metasurfaces, capable of shaping both nearfield- and far field light waves for a broad range of applications.

Conventional metasurface designs use geometrically fixed structures, or materials with excessive propagation losses, thereby limiting their potential applications. Here demonstrate that this can be overcome through the realization of a reconfigurable hyperbolic metasurface comprising a heterostructure of isotopically enriched hexagonal boron nitride (hBN) in direct contact with the phase-change material (PCM), such as single-crystal vanadium dioxide (VO₂) or GST. Here, the metallic and
dielectric domains in PCM provide spatially localized changes in the local dielectric environment that modify the polariton wavelength supported in hBN by a factor of 1.6. Using this platform, we demonstrate the first reduction to practice of in-plane HPhP refraction, and the means for launching, reflecting and transmitting of HPhPs at the PCM domain boundaries. Ultimately, this phenomenon can be used to create planar refractive optics, such as lenses or waveguides, but on length scales far below the diffraction limit. Further, my employing doped semiconductor materials with controllable plasma frequencies, such direct control of hyperbolic polaritons can also be obtained via modification of the free carrier density of the underlying semiconductor.

Strong Correlation in Low-Dimensional Materials of TMPS3 Je-Geun Park1,2; 1Institute for Basic Science (IBS), Korea (the Republic of); 2Seoul National University, Korea (the Republic of)

One of the most pressing questions in condensed matter physics is how electron correlations play out on two-dimension. For this question, the newly emerged magnetic van der Waals material can be helpful. In particular, TMPS3 with TM=transition metal elements have attracted significant attention as it exhibits all three fundamental magnetic models of magnetism; Ising (FePS3), XY (NiPS3) and Heisenberg (MnPS3) Hamiltonian. Using these materials, we have studied some of the fundamental theorems of modern magnetism: Onsager solution for the Ising model, The Berezinskii–Kosterlitz–Thouless transition for the XY model, and Mermin-Wagner theorem for the Heisenberg model. Besides, we have also investigated how correlation physics plays a role in optical spectroscopy data. In this talk, I will demonstrate how we can use this unique magnetic property of these materials to learn of the old physics.

Understanding Local Spatially Varying Photoconductivity across Nanoscale Interfaces in Two-Dimensional MoS2/WS2 Lateral Heterostructures Sanjini Nanayakkara1, Samuel Berweger2, Hanyu Zhang1, Prasana Sahoo3, Dmitry Voronine3, Pavel Kabos2, Andrew Ferguson1, Jeffrey Blackburn1 and Elisa Miller-Link1; 1National Renewable Energy Laboratory, United States; 2National Institute of Standards and Technology, United States; 3University of South Florida, United States

Heterostructuring of 2D materials, through the formation of vertical or lateral structures, may provide access to a multitude of novel photo-physical and electronic properties than can be tailored through a wide breath of available 2D materials. In this research, we will focus on chemical vapor deposition grown lateral heterostructures of MoS2/WS2 with a goal of measuring and understanding the local carrier distribution and conductivity across the atomically precise material interfaces. We have used advanced atomic force microscopy methods, including scanning microwave microscopy to elucidate the local, spatially varying carrier distribution in 2D MoS2/WS2 under dark conditions as well as under illumination with photon energy-resolved narrowband illumination. Our results show that strong spatial variations in the photoconductive response exists, even within individual flakes that were imaged. We corroborate our analysis with spatially resolved photoluminescence mapping and discuss our results in terms of the dynamics of long-lived photo generated carriers.

Direct Visualisation of Non-Equilibrium Structural Transformations in Atomically-Thin Chalcogenides Pawan Kumar, James P. Horwath, Alexandre C. Foucher, Natalia Aacero, Eric A. Stach and Deep M. Jariwala; University of Pennsylvania, United States
Two-dimensional (2D) transition metal dichalcogenides have been the subject of sustained research interest due to their extraordinary electronic and optical properties. At the same time, they are also a very rich system from the perspective of structural phases and phase transitions. Thus far transformation from 2H semiconducting to 1T metallic phase in MoS2 has been well demonstrated. Likewise, thermally induced defect creation, etching and oxidation have also been well studied. However, one aspect of structural properties of semiconducting TMDCs that has been understudied is the structural transformation in a highly non-equilibrium or far out of equilibrium thermodynamic conditions. In this talk, we will discuss our recent progress in studying disintegration and phase evolution of atomically thin MoS2 under varying temperatures (upto 700 C) and heating rates (25 C/sec). We probe these transformations at the atomic scale using aberration corrected scanning transmission electron microscope (AC-STEM) while heating the samples in-situ. We observe strong dependence of the resulting structures and phases on the heating rates and temperatures. In particular, for fast heating rates (~25 C/sec), we observe abrupt melting of the few layer regions into high ordered and crystalline, hexagonal islands of sizes < 20 nm. Importantly we also find, lateral heterostructures of 2H and 3R phases including presence of ordered, intermediate phases and sharp boundaries. For slower heating rates (~25 C/min) ex-situ in a furnace, this transformation occurs via sulphur sublimation resulting in formation of etch pits to nanocrystalline and amorphous regions that are sub-stoichiometric. We further use Electron Energy Loss Spectroscopy (EELS) to distinguish atomic level electronic structure information. The use of non-equilibrium heating rates to achieve highly crystalline and quantum confined features from 2D atomic layers opens new avenues for fundamental materials engineering and applications in confined dimensions.

SESSION S.NM09.07: New Approaches to Synthesis of van der Waals Materials

5:00 AM *S.NM09.07.01
Magnetic Transition Metal Dichalcogenides Christopher Hinkle; University of Notre Dame, United States

The incorporation of magnetic dopants is a way to realize magnetism in semiconductors. The 2D material WSe2 is a semiconductor with a bandgap of 1.3 eV, and Fe-doped WSe2 is predicted to have room temperature, long-range ferromagnetism. Moreover, WSe2 has been extensively studied for applications in electronic devices, and can be prepared by deposition methods that are compatible with semiconductor fabrication processes. 2D magnetic films are particularly intriguing in technologies that rely on exchange coupling since the efficiency of the exchange with the magnet is inversely proportional to the magnet thickness 1/tFM. Chalcogenide-based TMD magnets can also have ideal interfaces with chalcogenide-based topological insulators (like Bi2Se3), enabling efficient spin torque devices and potentially realizing the quantum Hall effect without an external magnetic field.

Focusing on materials growth and integration techniques that utilize non-equilibrium, kinetically restricted strategies, coupled with in-situ characterization, enables the realization of atomic configurations and materials that are challenging to make but once attained, display enhanced and unique properties. In this work, we will highlight the growth of Fe-doped WSe2 and report on its up to room temperature ferromagnetic properties. The evolution of Fe-doped WSe2 films under different doping levels indicates that strain from the impurity atom itself coupled with strain imparted by the substrate can drive phase separation at high Fe concentrations. We find that suppressing that film strain helps promote more Fe incorporation (and higher Curie temperatures).

Cr2O3 has only 0.2% lattice mismatch with WSe2 and is a magnetoelectric that can couple with ferromagnetic films. By using seed-layer techniques, we successfully prepared layered Fe-WSe2 on Cr2O3 and demonstrate magnetic coupling between the two, a potentially promising route toward realizing electric field control of 2D magnets. Magnetic measurements show a clear hysteresis loop at 100 K in a 2 Tesla cooling field, from which a large negative bias field of 600 Oe is resolved. The bias field vs temperature measurements, where a negative bias field emerges below 250 K, indicates the existence of ferromagnetic exchange coupling in this heterostructure.

This work is supported in part by NEWLIMITS, a center in nCORE, a Semiconductor Research Corporation (SRC) program sponsored by NIST through award number 70NANB17H041. This work is also supported by the National Science Foundation under awards 1917025 and 1921818.

5:15 AM *S.NM09.07.04
Wafer-Scale Epitaxy of Transition Metal Dichalcogenides by Gas Source CVD Tanushree H. Choudhury, Mikhail
Novel electronic and optical properties of monolayer transition metal dichalcogenides (MX$_2$, M=W, Mo and X=S, Se) have garnered a lot of attention in the recent years. A major challenge to integrating these materials with existing device fabrication processes is the availability of epitaxial single-crystal monolayers over a wafer scale. Our approach focuses on synthesis of these monolayers using gas source precursors, like those used in traditional III-V semiconductor industry. These precursors are placed in temperature and pressure-controlled bubblers placed outside the chamber and can be metered independently into the growth zone with precision. Uniform epitaxial binary TMD monolayers including MoS$_2$, WS$_2$, WSe$_2$, and MoSe$_2$ have been deposited on 2” sapphire wafers in a cold-wall CVD reactor using metal hexacarbonyl and hydride chalcogen precursors. A multi-step growth process comprising of precursor modulation was developed for WSe$_2$ to independently control nucleation density and the lateral growth rate of monolayer domains on the sapphire substrate [1]. For the sulfides, additional temperature modulation was introduced to increase crystalline quality. Using this approach, uniform, coalesced monolayer and few-layer TMD films were obtained on 2” sapphire substrates. Deposition of these materials in the same reactor provides insight into the factors controlling their growth, which in essential for the growth of heterostructures and/or alloys. In-plane X-ray diffraction demonstrates that the films are epitaxially oriented with respect to sapphire with narrow X-ray full-width-at-half-maximum indicating minimal rotational misorientation of domains within the basal plane [2]. Transmission electron microscopy analysis of these materials revealed additional information about the coalesced film structure. For instance, ~95% single oriented WS$_2$ domains were observed when the film growth rate was modulated. For WS$_2$, it was also confirmed that despite translational line defects present in the film, mirror boundaries were predominantly absent. WS$_2$ also showed no defect related photoluminescence peak at 80 K, indicating its high quality.

In this talk the factors affecting the growth of TMDs (MX$_2$, M=W, Mo and X=S, Se) will be presented. The role of the substrate surface in the nucleation and growth of these TMDs will be discussed. In addition, the structural and optoelectronic characteristics for these films will also be presented.

The authors acknowledge financial support of the U.S. National Science Foundation through the Penn State 2D Crystal Consortium – Materials Innovation Platform (2DCC-MIP) under NSF cooperative agreement DMR-1539916 and EFRI 2-DARE Grant EFRI-1433378.

5:30 AM *S.NM09.07.05
Synthesis and Characterization of Two-Dimensional Metal Carbides Otitoaleke Akinola, Suyogya Karki, Vivian Rogers, Deji Akinwande and Jean Anne Incorvia; The University of Texas at Austin, United States

MXenes (formula MX$_n$), are a class of two-dimensional (2D) materials, which are derived from a MAX crystal structure M$_{x+y}$AX$_n$ where the M represents early transition metals (Sc, Ti, V, Cr, Zr, Nb, Mo, Hf, Ta), the X is for C and/or N, and the A elements include Al, Si, P, and others. The MAX phase is structured with the A atoms sandwiched between the M and X layers from which MXene monolayer sheets can be derived by selectively etching out the A atoms from the bulk MAX crystal. While MXenes have been extensively explored theoretically, they are just starting to be made in experiment due to the difficulty in having to chemically etch to separate the layers, compared to van der Walls [1]. Hence, it is important to make progress in the chemical exfoliation in order to study them experimentally and understand how their behavior matches theory.

Extensive work has been done predicting intrinsic 2D ferromagnetic and antiferromagnetic materials with high Curie temperature T$_C$ (or Neel temperature) [2] coupled with recent discoveries of low-dimensional materials with intrinsic long-range magnetic ordering [3]. But still few low-dimensional magnetic materials have been even synthesized. In addition to great electronic properties such as tunable bandgap with tensile strain or electric field, and mechanical properties [4], MXenes can have exciting magnetic properties [5]. For example, from theory pristine Ti$_2$C and Ti$_2$N are nearly half-metallic ferromagnets, Cr$_2$N is antiferromagnetic, and Cr$_2$C is a half-metallic ferromagnet which can undergo ferromagnetic metallic to anti-ferromagnetic insulating state transitions using appropriate surface functionalization with F, OH, H, or Cl groups [5]. These spintronic and manipulatable magnetic/electronic properties give MXenes an edge over the more popular graphene material [1].

Here we show our work on synthesizing chromium carbide (Cr$_2$C) nanosheets from the parent bulk chromium aluminum carbide (2:1:1 Cr$_2$Al$_2$C atomic %) MAX phase powder through wet etching. We show the processes that has been developed to successfully exfoliate the material to reduce it to low-dimensional flakes using HCL+LiF, and HCL+NaF chemical etching. We also show how we have been able to reduce the etch time from 96 hours to 48 hours. After the etch, the samples are dried. Using the scanning electron microscope, a clear accordion structure is seen as is expected for MXenes, showing sheets of Cr$_2$C after the Al is etched away. We find a large number of accordion structures, with sheet lengths 5-10 μm in
size, similar to mechanically exfoliated sizes of commonly studied 2D materials. We will show our results separating the accordion structures into low-dimensional flakes using mechanical exfoliation following the chemical exfoliation and will show energy-dispersive x-ray spectroscopy results showing that the Al content has been significantly reduced by our etching procedure. Lastly, we will show characterization of the structural, electronic, and magnetic properties of the Cr$_2$C flakes.

Orbital Magnetism and Quantized Anomalous Hall Effect in Twisted Bilayer Graphene Andrea Young; University of California, Santa Barbara, United States

In moire flat band systems, interlayer moire patterns can be used to engineer isolated superlattice bands in which the Coulomb interaction is comparable to the bandwidth. As in a Landau level, this leads to electron interaction dominated physics despite the low density of electrons, enabling full density control using electrostatic gates. Unlike Landau levels, however, moire flat bands occur under time reversal symmetric conditions. I will discuss experiments that observe the spontaneous breaking of time reversal symmetry, observed as magnetic hysteresis. Remarkably, hysteresis is accompanied by a quantized anomalous Hall effect, persisting to zero magnetic field and elevated temperatures. I will discuss the origins of this effect in the spontaneous orbital polarization of the electron system into a single, topological nontrivial superlattice band, and describe magnetic imaging data that confirms the orbital character of the magnetism.

Strong Magnetophonon Oscillations in Monolayer Graphene—A Spectroscopic Probe of Electron-Phonon Interactions Mark T. Greenaway$^{1,2}$, P Kumaravadivel$^{1,3}$, D Perello$^{1,3}$, A Berdyugin$^{1}$, J Birkbeck$^{3,3}$, J Wengraf$^{6,4}$, S Liu$^{5}$, J Edgar$^{5}$, A Geim$^{7,13}$, L Eaves$^{2,3}$ and R Krishna Kumar$^{3}$; $^{1}$Loughborough University, United Kingdom; $^{2}$The University of Nottingham, United Kingdom; $^{3}$University of Manchester, United Kingdom; $^{4}$University of Lancaster, United Kingdom; $^{5}$Kansas State University, United States

For more than 50 years, magnetophonon resonance (MPR) has proved to be a powerful tool for investigating electron-phonon interactions in a wide range of elemental and compound semiconductors and heterostructures. Its experimental signature is a series of oscillations in the magnetoresistance, periodic in inverse magnetic field, given by the equation, $p \omega_c = \omega_p$, where $p$ is an integer, $\omega_c$ is the Landau level splitting and $\omega_p$ is the phonon frequency. The successful observation of MPR in graphene has proved elusive due, in part, to the relative weak interaction of the massless Dirac Fermions with the lattice phonons.

Here we report the observation of large amplitude, temperature-dependent MPR oscillations in the magnetoresistance of large area, electrostatically gated Hall bars of exfoliated monolayer graphene encapsulated by hexagonal boron nitride (hBN) [1,2]. The oscillations are observed only in devices with a width which exceeds the ballistic carrier mean free path, 5 μm. We observe two distinct series of resonant peaks arising from inelastic scattering by transverse acoustic (TA) and longitudinal acoustic (LA) phonons. The LA phonon resonant amplitude is significantly weaker than that of the TA phonons. This is due, in part, to the carrier screening of the LA phonon modes. The magnetic field values of the resonant peaks are found to shift linearly with carrier sheet density from $10^{12}$ to $10^{13}$ cm$^{-2}$. These experiments also allow us to measure the dispersion curves of
the LA and TA phonons up to wavevectors of ~ 10^9 m^-1. We model the experimental data to high accuracy using the Kubo formalism. We demonstrate that the LA and TA phonon speeds and the electron-phonon coupling strengths determined from the magnetophonon resonance measurements provide an excellent fit to the measured dependence of the resistivity at zero magnetic field over a temperature range of 4-150 K. Thus, MPR provides a spectroscopic tool for studying electron-phonon interaction in two-dimensional semiconductors.

Quantum Devices with 2D Materials Klaus Ensslin; ETH Zurich, Switzerland

We demonstrate electronic constrictions on bilayer graphene that can be completely pinched off [1]. Split-gate devices in combination with a graphite backgates enable electronic tunability of the devices. The level spectrum of quantum point contacts in bilayer graphene has a peculiar magnetic field dependence quite different from what is known from semiconductors. We understand the details of this spectrum [2] based on the Berry curvature in bilayer graphene. In few electron and hole quantum dots confined by p-n junctions [3] we investigate valley and spin splitting. Also many electron quantum dots with standard tunneling barriers as well as double and triple quantum dots [4] can be realized with an electronic quality comparable to the best dots fabricated in standard semiconductor environments. The spectrum of excited states in graphene dots is qualitatively different [5] compared to semiconductors because of the valley degree of freedom. These experiments open the door for using graphene quantum dots as spin qubits with potentially long coherence times. We also discuss the properties of MoS_{2} as a host material [6,7] for quantum dot-based qubits. Work done in collaboration with A. Kurzmann, M. Eich, H. Overweg, M. Mangold, F. Herman, P. Rickhaus, R. Pisoni, Y. Lee, R. Garreis, C. Tong, K. Watanabe, T. Taniguchi, and T. Ihn

Engineering 2D Materials with a Twist Cory R. Dean; Columbia University, United States

Atomically thin crystals such as graphene, boron nitride and the transition metal dichalcogenides continue to attract enormous interest. Encompassing a wide range of properties, including single-particle, topological and correlated phenomenon, these 2D materials represent a rich class of materials in which to explore both novel physical phenomenon and new technological pursuits. By integrating these materials with one another, an exciting new opportunity has emerged in which entirely new layered heterostructures can be fabricated with emergent properties beyond those of the constituent materials. In this talk I will discuss some of our recent efforts where, by tuning the geometry of these heterostructures at the nanoscale, we are able to realize yet a new level of control over their electronic properties. In particular I will discuss the significant role played by the rotational alignment between adjacent layers and the approach we are taking towards manipulating this degree of freedom to dynamically tune device properties in ways that are not possible with conventional materials.

Thermoelectricity in Twisted Bilayer Graphene

Thermoelectricity in Twisted Bilayer Graphene

Arindam Ghosh, Phanibhusan Mahapatra, Bhaskar Ghawri, U. Chandni and Manjari Garg; Indian Institute of Science, India

Twisted bilayer graphene (TBLG) is a new and versatile platform to realize effects of strong electron-electron interaction as the mis-orientation angle (theta) between the graphene lattices profoundly affects the electronic structure of the combined system. While the layers behave independently at large theta (> 3 degree), new electronic bands emerge when theta is decreased, including nearly flat bands at the magic angle of 1.1 degree that has been shown the harbor superconductivity and magnetism. In addition of direct electrical transport, thermoelectric properties are also highly sensitive to electronic correlations, and often manifest in departure from the well-established Mott semiclassical framework. Here we present the results of measurement of thermoelectric power in TBLG over a wide range of theta. We have shown that thermoelectricity in TBL at large theta (> 2 - 3 degree) is expectedly determined by independent excitations in the two graphene layers, and can be described by the Mott relation [1,2]. At low theta (< 2 degree), however, we observed a strong departure from the semi-classical description, which is most pronounced at the half-filling of the underlying Moire lattice, and persists up to temperatures as high as 40 K [3]. In accordance with the strong enhancement in the electronic interactions at half filling, our experiments suggest the possibility of a novel interaction-driven thermoelectricity in TBLG.

Strain Engineering of the Valley Magnetization and Berry Curvature Dipole in 2D Materials

Jieun Lee; Seoul National University, Korea (the Republic of)

The valley degree of freedom in two-dimensional (2D) honeycomb lattices has attracted much recent attention due to its non-trivial Berry curvature effects associated with two nonequivalent valleys. This feature gives rise to many interesting valley-dependent phenomena such as the valley optical selection rule and the valley Hall effect, each of which accessing the valley-dependent electron control using the optical and electrical means. The valley manipulation in these works, however, focus on the control of the electron occupation while the Berry curvature at the two valleys are remained constant. In this talk, we show the mechanical control of the valley degree of freedom which is enabled by the strain engineering of the Berry curvature. By fabricating flexible monolayer MoS2 devices, we reversibly control strain on monolayer MoS2 and demonstrate the generation of the current-induced valley magnetization due to the formation of the Berry curvature dipole. The measured valley magnetization is in excellent agreement with the calculated Berry curvature dipole, which depends on the magnitude and direction of strain. Our results show that the Berry curvature dipole acts as an effective magnetic field in current-carrying systems, providing a novel route to generate magnetization in 2D crystals.

High-Speed Two-Dimensional Solid-State Non-Volatile Memory Based on Electric Double Layer Gating with a Monolayer Electrolyte

Shubham Sukumar Awate1, Jierui Liang1, Ke Xu1, Benjamin Hunt2 and Susan Fullerton1,1; 1University of Pittsburgh, United States; 2Carnegie Mellon University, United States

A high-speed, two-dimensional, solid-state, non-volatile memory has been demonstrated using electric double layer (EDL) gating of two-dimensional (2D) field effect transistors (FETs) with nanosecond scale switching speeds. The “monolayer electrolyte” FET (i.e., MEFET) consists of cobalt crown ether phthalocyanine (CoCrPc) and lithium ions deposited as a monolayer on the surface a 2D semiconductor by drop casting and annealing. CoCrPc is an electrically insulating (band gap ~ 1.34 eV) and the four crown ethers each solvate a Li+ ion. In response to an applied electric field, Li+ ions diffuse through the crown ether cavity and are positioned either near or away from the channel resulting in on and off states, respectively. We have previously shown switching behavior on 2D FETs using this material with potential application in non-volatile memory. Achieving well-ordered monolayers of CoCrPc and complete solvation of Li+ into the crown ethers are critical for device
operation because the location and orientation of the molecules governs the device mechanism. Here we will show how the quality of the drop-casted CoCrPc/LiClO₄ depends on concentration and annealing temperature. When the well-ordered electrolyte layer deposited on a WSe₂ FET is capped with h-BN, the off-state is stabilized (as confirmed by density functional theory (DFT)) and 50 nanosecond switching speeds (limit of the instrument) are demonstrated with an on-off current ratio > 10³. The device is stable for at least 1000 cycles (max. measured) after programming with 50 ns pulse and the retention of each state persists for at least 28 hours (max. measured). Top-gated MEFETs are currently being fabricated to reduce the program/erase voltages.

Cross-Plane Thermal Conductance Modulation in van der Waals Heterojunctions
Charles A. Sievers¹, Aditya Sood², Eric Pop² and Davide Donadio¹; ¹University of California, Davis, United States; ²Stanford University, United States

Van der Waals heterostructures have been shown to exhibit a multitude of quantum electronic transport phenomena, such as superconductivity and integer quantum Hall effects, which entail great promise for new nanoscale devices.¹ Alongside exceptional electronic properties, two-dimensional van der Waals materials present intriguing heat transport properties, such as ultra-high thermal conductivity.² Here, we use elastic scattering lattice dynamics³ calculations to investigate cross-plane thermal conductance across twisted and untwisted heterojunctions composed of graphene, molybdenum disulfide, and hexagonal boron nitride sheets. We found large degrees of cross-plane thermal conductance modulation through phonon filtering and localization based on heterojunction composition and twisting angle.

Novel Infrared Photodetectors Based on Layered van der Waals Heterostructures
Jinshui Miao, Fang Wang, Peng Wang and Weida Hu; Chinese Academy of Sciences, China

Infrared photodetectors based on traditional thin-film semiconductors such as InGaAs, InSb, HgCdTe, Si BIB, and QWIP as well as novel type-II superlattice exhibit highly sensitive detection capability. However, these devices always need to work at low temperature, resulting in an additional large and expensive cooling system. Recently, two dimensional (2D) materials and their van der Waals heterostructures have attracted tremendous attention owing to their optoelectronic tunability and potential optoelectronic applications. Nevertheless, as a photoconductive detector, the signal-to-noise ratio could be very low without the suppression of dark current. Meanwhile, the performance of the photodetectors, which are based on 2D materials and layered van der Waals Heterostructures, including phototransistors, photoconductors with photogating, and photodiodes, is strongly affected by surface/interface and in-plane trap states resulting in the restricted electron-hole separation efficiency and slow speed, and intrinsic ultrathin absorption thickness for 2D photodetectors suffers the low quantum efficiency. Here we report the progress on novel uncooled infrared photodetectors based on 2D materials and their van der Waals heterostructures manipulated by localized fields. We fully exploit the detection ability of 2D materials and their van der Waals heterostructures by introducing localized-field, including ferroelectric filed, vertical heterojunction field, p-n junction photovoltaic field and so forth. With a strong induced localized-field, high performance infrared photodetectors based on Graphene, TMDs, Pd (Pt) Se, Black phosphorus, Black arsenic-phosphorus etc. may lead to a disruptive revolution in prospective low dimensional electronic/optoelectronic devices. Our study opens a new avenue for the controllable fabrication of built-in localized-field in 2D devices, which is a prominent challenge in low dimensional material researches.

Mingsheng Long, Anyuan Gao, Peng Wang, Hui Xia, Claudia Ott, Chen Pan, Yajun Fu, Erfu Liu, Xiaoshuang Chen, Wei Lu, Tom Nilges, Jianbin Xu, Xiaomu Wang*, Weida Hu*, Feng Miao*, Room-temperature high detectivity mid-infrared
The prevalent von Neumann architecture in today’s processors involves memory and processing units to reside in physically separate locations. With memory speeds lagging behind the processor speeds, latency in accessing data from memory has resulted in the “von Neumann bottleneck”. To alleviate this issue, several alternative non-von Neumann architectures have been explored. Neuromorphic computing is one such non-von Neumann approach, inspired by the human brain’s ability of cognitive recognition. The brain operates through a network of neurons that are connected to each other by synapses. In 2008, after the discovery of memristors, the fourth circuit element, researchers have explored the idea of mimicking synaptic behavior with a single memristive device. Albright significant advances, synaptic devices using phase change materials-based memristors and metal oxide-based resistive switching devices have some limitations. These devices exhibit high programming current in the range of \( \mu A \) to mA. Additionally, the synaptic weight update, \textit{i.e.} the increase (decrease) of the synapse’s conductance with the application of a continuous stream of identical positive (negative) input voltage pulses, is non-linear. Non-linearity in weight update increases the complexity of using these devices for real-time unsupervised learning. So, it becomes necessary to employ a materials system which exhibits low programming current as well as a linear weight update.

Recently, two-dimensional (2D) materials are being largely explored to demonstrate their viability as electronic synapses and neurons. In this talk, we shall discuss the realization of a synaptic device using graphene/MoS\(_2\) heterostructures. These memristive devices exhibit low programming currents and a high dynamic range from 1 nA to 1 mA. In contrast with oxide-based or PCM-based synapses, these devices exhibit a gradual set and reset process when symmetric input voltage pulses are applied, resulting in a near-linear weight update. Linearity and symmetry in weight update is much desired for real-time learning applications. We shall also present the demonstration of an integrate-and-fire neuron using Ag/MoS\(_2\)/Au vertical structures. These devices possess the four crucial features of neuron – all-or-nothing spiking, threshold-driven firing, post-firing refractory period and stimulus strength based frequency response. Realizing neurons and synapses using the same materials system allows the monolithic integration of the essential building blocks of neuromorphic hardware, and bears potential for a highly scalable spiking neural networks suitable for unsupervised learning applications.

**Artificial Neurons and Synapses with CVD MoS\(_2\) for Neuromorphic Computing**  
*Tania Roy; University of Central Florida, United States*

Two-dimensional (2D) van der Waals materials and related heterostructures have shown a wide variety of novel electronic and opto-electronic properties. However, a key challenge in fully realizing their potential is a general lack of manufacturing techniques capable of producing desired heterostructures at a large scale. Here, we demonstrate a highly scalable direct-laser-writing approach to fabricating in-plane heterostructures in two-dimensional In\(_2\)Se\(_3\) layers. This approach derives from an optically activated solid-solid phase transition that leads to significant changes in local properties (semiconducting vs. metal-like), while preserving the single crystallinity of the local lattice, leading to well-defined heterointerfaces and demonstrating a scalable path to large-area device manufacturing. Carrier transport across in-plane heterojunction nanoscale devices fabricated by this technique exhibits asymmetric diode behaviors supported by the presence of interface energy barriers as revealed by Kelvin probe force microscopy. Scanning photocurrent microscopy shows short-circuit photocurrent in these devices, demonstrating their potential applications in efficient photodetection and photovoltaics. Our numerical modeling of the device characteristics reveals space-charge-limited and injection-limited conduction as the carrier transport mechanisms,

Controlling Defects in 2D GaS Continuous Films and Heterostructures for High Performance Wavelength-Tunable Photodetectors Yang Lu and Jamie Warner; University of Oxford, United Kingdom

The rapid development of two-dimensional (2D) materials calls for the development of novel 2D semiconductors with large bandgap for applications in short-wavelength LEDs, type-I heterojunctions, etc. Gallium sulfide (GaS), a wide-bandgap semiconductor, fulfills these requirements but was not fully explored due to lack of controllable synthesis methods, unexplored layer-dependent properties and unanswered stability issues. Here, to answer these questions, we developed a CVD synthesis method of thickness-controlled (1–4L), uniform and continuous films of both defective GaS and defect-free GaS. A simple method for determination of thickness by Raman spectroscopy is developed. An enhanced stability of the defect-free GaS was demonstrated under laser and strong UV lights, and by controlling defects in GaS, the photoresponse range could be changed from vis-to-UV to UV-discriminating. The defect-free GaS is suitable for large-scale UV-sensitive high-performance photodetector arrays for information encoding under large vis-light noise, with short response time, excellent UV photoresponsivity and a 26-times increase of signal-to-noise ratio compared with small bandgap 2D semiconductors. By comprehensive characterizations from atomic-scale structures to large-scale device performances in 2D semiconductors, we provide insights into the role of defects, the importance of neglected material-quality control and how to enhance device performance. Finally, both layer-controlled defective and defect-free GaS prove to be promising platforms for study of novel phenomena and new applications in WS2-GaS van der Waals heterojunctions.

S.NM09.10.02
Laser-Assisted Accelerated Synthesis of 2D Quantum Materials Nurul Azam1, Zabihollah Ahmadi1, Salah Elafandi1, Baha Yakupoglu1, Mengkun Tian2, Abdelaziz Boulesbaa3 and Masoud Mahjouri-Samani1; 1Auburn University, United States; 2Georgia Institute of Technology, United States; 3California State University Northridge, United States

The firmly defined dimensionalities of two-dimensional (2D) layered materials including transition metal dichalcogenides (TMDCs) exposed numerous unusual properties that have been recently at the center of the quantum materials and information sciences research. In pursuit of the accelerated growth and discovery of 2D materials, many efforts have concentrated on developing new approaches including physical and chemical vapor deposition techniques. However, complex, uncontrolled gas-phase reactions, and flow dynamics have made the synthesis of these multi-component 2D crystals exceedingly challenging. This work demonstrates a novel laser-assisted synthesis technique (LAST), which significantly reduces the existing growth complexities and remarkably accelerates the growth of 2D materials. The uniqueness of this approach arises from the direct vaporization technique of stoichiometric powders by the laser heating process. We show that this directed laser heating permits pressure-independent decoupling of the growth and evaporation kinetics, enabling the use of stoichiometric powder as precursors for the growth of various high-quality 2D materials including MoS2, MoSe2, WSe2, and WS2.

Mr. Nurul Azam is currently a Ph.D. student in the Department of Electrical and Computer Engineering (ECE) at Auburn University (AU). His research in the Laser-Assisted Science and Engineering (LASE), Lab under the supervision of Prof. Mahjouri-Samani, focuses on investigating and developing novel approaches for the synthesis of 2D quantum materials and heterostructures.

S.NM09.10.11
Synthesis of Two-Dimensional, Semiconducting Quantum Materials via Chemical Vapor Deposition (CVD) Daniel S. Choi1, Evgeniya H. Lock2 and Shashi P. Karna3; 1National Research Council, United States; 2Naval Research Laboratory, United States; 3Naval Research Laboratory, United States

The synthesis of two-dimensional, semiconducting quantum materials via chemical vapor deposition (CVD) is a powerful method for the controlled growth of high-quality 2D materials with a diverse range of properties. This presentation will highlight recent advancements in CVD growth techniques for the synthesis of MoS2, MoSe2, WSe2, and WS2. The CVD process involves the decomposition of gaseous precursors at high temperatures to form 2D layers. The growth process is influenced by factors such as precursor flow rates, furnace temperature, and pressure, which can be adjusted to control the thickness and uniformity of the grown layers. Effective control of these parameters is crucial for the synthesis of large-scale, high-quality 2D materials with desired properties.

In this talk, we will discuss the role of gas-phase reactions and flow dynamics in the CVD process, and how these factors impact the growth of 2D materials. We will also present results on the growth of high-quality MoS2, MoSe2, WSe2, and WS2 using a novel CVD system. The presented results demonstrate the potential of CVD as a scalable and controllable method for the synthesis of 2D materials, paving the way for the development of novel applications in electronics, optoelectronics, and catalysis.
In the past decade, there have been unprecedented advancements in research and development of materials for quantum applications such as ultrasensitive detection, quantum information processing, energy efficient ultrafast electronics, quantum light-emission, and many more that require a fundamental understanding of never-before observed physical and chemical phenomena in known materials. Of these new generation of materials, transition metal dichalcogenides (TMDs) have become attractive candidates for more extensive investigation due to their novel and non-classical behaviors observed at nanoscale as well as potential for their incorporation into devices and applications. For instance, nanoscale TMDs such as tungsten diselenide (WSe₂), tungsten disulfide (WS₂), and molybdenum disulfide (MoS₂) have been shown to exhibit highly localized, intense, quantum emission of single photons that have not been previously observed in their bulk counterparts. While understanding fundamental mechanism and origin, as well as the physical structure of these quantum materials and their properties are crucial, parallel efforts in developing large scale, controlled synthesis of these materials is just as imperative. Currently, much of the studies on TMD materials for quantum applications have primarily been on larger flakes and crystals, or exfoliated films, which limits scalability of the material production as well as the need for transfer of the exfoliated material onto a suitable substrate.

In this work, we present a systematic synthesis of 2-dimensional, single- to few-layers of transition metal chalcogenides thin film directly on silicon substrate via chemical vapor deposition (CVD). Our approach not only sheds light into understanding the growth mechanism of 2-dimensional TMDs, but also provides optimal growth parameter for consistent, large scale production of these materials. The results presented will provide basis for synthesis of next-generation of 2-dimensional materials as well as shed light into bottom-up building approach of van der Waals heterostructures for quantum applications.

**Substrate-Mediated Hyperbolic Phonon Polaritons in MoO₃** Jeffrey Schwartz¹,², Son T. Le²,³, Sergiy Krylyuk², Albert Davydov² and Andrea Centrone³; ¹University of Maryland, United States; ²National Institute of Standards and Technology, United States; ³Theiss Research, United States

Hyperbolic phonon polaritons (HPhPs) are hybrid excitations of light and coherent charge oscillations that exist in strongly optically anisotropic 2D materials (e.g., MoO₃). These polaritons propagate through the material’s volume with long lifetimes, enabling novel mid-infrared nanophotonic applications by compressing light to sub-diffraction dimensions. Here, the dispersion relations and HPhP lifetimes (up to ≈ 2 ps) in single-crystal α-MoO₃ are determined by Fourier analysis of real-space, nanoscale-resolution polariton images obtained with the photothermal induced resonance (PTIR) technique. Measurements of MoO₃ crystals deposited on periodic gratings showed longer HPhPs propagation lengths (≈ 2 ×) and lower optical compressions in suspended regions compared to regions in direct contact with the substrate. Additionally, PTIR data reveal polymeric contaminants, resulting from sample preparation, localized under parts of the MoO₃ crystals. This work enhances the ability to engineer nanophotonic devices by leveraging substrate morphology to control polariton propagation.

**S.NM09.10.13**
**Anion Charge Density Disturbance Induces In-Plane Instabilities within 2D Lateral Heterojunction of TMD—An Atomic View** Bolong Huang; The Hong Kong Polytechnic University, Hong Kong

Two-dimensional (2D) heterostructure semiconductors are emerging as the potential candidates for broad applications, in which the transition-metal dichalcogenides (TMDs) have attracted the most attention due to their abundant advantages. TMDs have attracted tremendous interest due to the advantages of low-cost, earth-abundant, non-toxic, and environmentally friendly. Owing to the atomically thin structure, unique electronic and optical properties and rich diversity in chemical compositions, they have displayed considerable potential in the applications of integrated optoelectronic devices and systems such as p–n diodes, photodetectors, transistors, nanogenerators, and sensors as well as in catalysis. However, the investigations of these TMD heterostructure semiconductors usually only limit to the synthesis approach and opt-electronic properties, lacking the in-depth guidelines from the atomic exploration. Within the lateral heterojunction, the unique ripple effect has been identified as the consequence of the important interplay between different TMDs. Herein, the anion coupling induced charge disturbance within the WSe₂/WS₂ lateral heterojunction has been identified as the origin for the ripple structure induced by in-plane interfacial instability. Different scales of the first-principle simulations all verify the similar ripple phenomenon near the interfacial region of the WSe₂/WS₂ lateral heterojunction. Beyond the simple factor of lattice misfit, we confirm that the Se-S p-p coupling effect induced the uneven charge distribution is the intrinsic reason for such a unique structural phenomenon. By the introduction of the perturbation elastic entropy concept, we successfully predict the
interfacial ripple scale in the WSe$_2$/WS$_2$ lateral heterojunction systems, supporting the simulation of experimental size. This work has compensated the knowledge gap between the theoretical investigation and experimental synthesis, which is essentially beneficial for the future fabrication of 2D heterostructure semiconductors with superior performance. The fundamentally general mechanism for the experimentally observed phenomenon is of pivotal significance in the further exploration in such 2D heterojunction semiconductor materials.

Materials for Resonant Passage of Isotopes
Aleksey M. Bubenchikov; Tomsk State University, Russian Federation

The method of mathematical modelling is a good tool for constructing new materials [1]. The present work considers the problem which concerns quantum sifting of isotopes of gas components at cryogenic temperatures. The authors also focus on the task of constructing the membrane itself. The calculations show that the membrane should have two identical ultrathin layers. By now, graphene nitride with regular pores has been synthesized using the double epitaxy method [2]. Mono-atomic layers of porous boron nitride [3] can also serve as the working layer of the membrane. Over the last decade, a group of new graphene-like mono-element 2D materials, such as germanene [4], silken [5, 6], phosphorus [7], and stanene [8] have also been synthesized. In principle, all porous analogues of these materials are suitable for application as the working layer of the membrane. This appears to be possible since the result of resonant passage of one of the mixture components is largely determined by the distance between the plates.

The considered problem of particles passing through a composite barrier is a generalization of the well-known Landau problem of particles with a certain energy passing through a unitary barrier. When constructing an analytical solution to the generalized problem of wave dynamics, the authors proceeded from the Schrödinger integral equation. The solution was built as a result of dividing the functions containing a shift in the independent variable into a nonlinear differential operator and separated exponential functions of the parameter and the argument. Next, algebraic operations with differential operators were performed, and the resulting operator was applied to separated functions. The resulting solution for the wave function is completely determined by the spectrum of the composite barrier. Studying the asymptotic behaviour of the solution allowed for finding the zeros of the reflection coefficient. As a result, resonance modes of transmission of one of the components were found. These modes were determined by the sequence of resonant distances between the plates. Choosing the distance between the layers from this sequence it is possible to achieve a selectivity effect in which a particle with a mass of $m$ and energy of $E$ passes through a potential barrier consisting of two identical parts without reflection. In other words, one of the components shows complete passage, while the other component is characterized by partial passage only. This ensures operation of the membrane as a gas separator. The calculations show that, at certain temperatures, it is possible to achieve hyperselectivity of mixture separation.

Synthesis and Study of 1H Structural Phase of Liquid-Exfoliated 2D Lead Iodide Nanodisks Using ADF-STEM
Sapna Sinha1, Taishan Zhu2, Arthur France-Lanord3, Yuwen Sheng1, Jeffrey C. Grossman3, Kyriakis Porfyrikas1 and Jamie Warner1; 1University of Oxford, United Kingdom; 2Massachusetts Institute of Technology, United States

Synthesis and study of new two-dimensional (2D) materials nanosheets is very important for both fundamental study of
physical phenomenon as well as for new applications in nanoelectronics and optoelectronics. Lead Iodide (PbI₂) has been reported to be an excellent candidate for applications in thin films, transistors and PbI₂ perovskites. However, not a lot of study has been carried out on easy and facile preparation of this material to produce scalable monolayer films. Liquid phase exfoliation (LPE) is considered to be an efficient method to obtain 2-dimensional nanosheets on a large scale. Based on previous findings on screening solvents for LPE, in this study, I will present results on obtaining several hundreds of >99% monolayer (PbI₂) using CHCl₃ as a solvent. We have then used atomic-resolution annular dark field scanning transmission electron microscopy (ADF-STEM) imaging to study the monolayer flakes of PbI₂. Here, I will report on a new structure of PbI₂ which has not been studied before. PbI₂, when suspended on graphene, converts into more energetically stable H-phase crystal structure compared to T-phase structure which was found to be more stable on lacey carbon TEM grid. I will also present results on the defects and edge structure of the monolayer PbI₂ and the unusually mobile atoms on the surface. The structural change of the PbI₂ depending on substrate, i.e. graphene, opens up the possibility to control and further study its properties by using other different kinds of substrates.

Chemical Vapor Deposition Synthesis of MoS2 Crystal Assisted by HSS/H2 Precursors—A Quantum Molecular Dynamics Study Sungwook Hong; California State University, Bakersfield, United States

Layered van der Waals Heterostructures such as MoS₂ monolayers have attracted great attentions for the application in optoelectronic devices owing to their outstanding physical, chemical, and mechanical properties. Chemical vapor deposition (CVD) is commonly used for scalable growth of layered materials. During CVD synthesis, reactions of MoO₃ and H₂S reactants are essential reaction steps where MoO₃ flakes are reduced and sulfurized, transferring to MoS₂ crystals. Recent studies suggested that addition of H₂ gas in this synthesis process could lead to synthesis of higher-quality MoS₂ monolayers. However, effects of H₂ partial pressure on synthesis of MoS₂ still remain elusive. Here, we present quantum molecular dynamics (QMD) simulations for CVD synthesis of MoS₂ layer using MoO₃ flakes and H₂S gas precursors with and without H₂ gas. Our QMD simulations revealed that H₂ molecules indeed act as effective reducing agents for the MoO₃ flake. As such, our work provides a valuable input for the scalable growth of layered van der Waals Heterostructures. This work was supported as part of the Computational Materials Sciences Program funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, under Award Number DE-SC00014607.

The Variety of Colors—Optical Properties of MXenes Kathleen A. Maleski and Yury Gogotsi; Drexel University, United States

The largest family of 2D materials, known as transition metal carbides and/or nitrides (MXenes), have a chemical formula of $M_{n+1}X_nT_x$, where $M$ represents a transition metal (Ti, Mo, Nb, V, Cr, etc.), $X$ is either carbon and/or nitrogen, and $T_x$ represents surface terminations. The diversity in composition (~30 MXenes synthesized so far), availability of solid solutions on $M$ and $X$ sites, and control of surface terminations offers a plethora of structures and chemistries to investigate.¹ The first discovered and most studied MXene, titanium carbide ($\text{Ti}_3\text{C}_2\text{T}_x$), has shown interaction with a wide range of the electromagnetic spectrum, including visible light transparency (>97% visible light transmittance per nanometer), a transverse surface plasmon in the near-infrared range (750-800 nm), and to capability to perform as an electromagnetic shield or dipole antenna in microwave or radio frequencies.² Combining the optical properties with ease in processing, high electronic conductivity and mechanical strength, MXenes have the characteristics necessary to develop as optical materials. This talk will provide insight into the optical properties and potential applications of MXenes as well as spectroscopic information which can be applied to designing photonic and optoelectronic devices, such as electron transport layers for solar cells, optical sensors, random or femtosecond lasers, electrochromic devices, photonic diodes, metamaterials, photothermal therapy.
agents, and more.

Magnetic and Electronic Characterization of 2D Cr$_2$TiC$_2$T, MXene Kanit Hantanasirisakul1, Babak Anasori2, Slavomir Nemšak3, James Hart4, Jiabin Wu4, Yizhou Yang1, Jun Zhou1, Mitra L. Taheri1, Steven J. May1 and Yury Gogotsi1; 1Drexel University, United States; 2Indiana University-Purdue University, United States; 3Lawrence Berkeley National Laboratory, United States; 4Huazhong University of Science and Technology, China

2D magnetic materials have received tremendous attention recently due to their fundamentally unique properties from their bulk counterparts and promises in data storage, sensing, and magneto-opto-electronic applications. Following the discovery of 2D ferromagnetic ordering of monolayer CrI$_3$ and ultrathin Cr$_2$Ge$_2$Te$_6$, several 2D magnetic materials including halides, chalcogenides, and sulphides, have been reported. MXenes are 2D transition metal carbides, carbonitrides, and nitrides with a general formula M$_{n-1}$X$_n$T$_x$, where M is early transition metal (such as Ti, Cr, Mn), X is C and/or N, n = 1-3, and T, represents surface terminations (such as O and F). Although there are several DFT calculations that suggest magnetic ordering in 2D MXene flakes, there is no experimental report on magnetic ordering of MXenes. In this talk, magnetic and electronic properties of Cr$_2$TiC$_2$T, a double-metal ordered transition metal carbide MXene will be presented and discussed. We used a combination of vibrating sample magnetometry (VSM) and synchrotron X-ray magnetic linear dichroism (XMLD) to obtain evidence of antiferromagnetic order below 40 K in a free-standing film and a single flake of this MXene. Moreover, the temperature-dependence of resistivity and angular-dependent magnetoresistance measurements reveal distinct changes below 40 K, suggesting a coupling between the magnetic order and electronic transport.

Distinguishing Electronic Contributions of Surface and Sub-Surface Transition Metal Atoms in Ti-Based MXenes Yizhou Yang1, Kanit Hantanasirisakul1, Nathan Frey2, Babak Anasori3,1, Robert J. Green3,5, Paul C. Rogge1, Irradwikanari Waluyo6, Adrian Hunt6, Padraic Shafer7, Elke Arenholz8,7, Vivek Shenoy2, Yury Gogotsi1 and Steven J. May1; 1Drexel University, United States; 2University of Pennsylvania, United States; 3Indiana University – Purdue University Indianapolis, United States; 4University of Saskatchewan, Canada; 5University of British Columbia, Canada; 6Brookhaven National Laboratory, United States; 7Lawrence Berkeley National Laboratory, United States; 8Cornell University, United States

MXenes are a rapidly-expanding family of 2D transition metal carbides and nitrides that have attracted attention due to their suitability for solution processing, hydrophilic surfaces, metallic conduction, and versatility in hosting a range of intercalant agents, and more. Numerous additional properties such as magnetic ordering, semiconductor band gaps, and presence of topological band features have been computationally predicted but remain largely unrealized due to the experimental difficulty in obtaining uniform surface terminations (T$_s$). To better understand the impact of surface terminations and to develop design strategies that are independent of T$_s$, a layer-resolved understanding of electronic properties is needed. In this study, we distinguished the contributions of surface and sub-surface Ti atoms to the electronic structure of four Ti-based MXenes (Ti$_2$CT$_x$, Ti$_3$C$_2$T$_x$, Cr$_2$TiC$_2$T$_x$, and Mo$_2$TiC$_2$T$_x$) using soft X-ray absorption spectroscopy, revealing minimal changes in the spectral features between the parent MAX phase and its MXene counterpart when no surface Ti atoms are present in the MXene, such as the M-site ordered Mo$_2$TiC$_2$T$_x$ and Cr$_2$TiC$_2$T$_x$. In contrast, for MXenes with surface Ti atoms, here Ti$_2$CT$_x$ and Ti$_3$C$_2$T$_x$, the Ti L-edge spectra are significantly modified compared to their parent MAX phase compounds, indicative of a decrease in the electron count per Ti atom upon conversion to MXene. First principles calculations provide similar trends in the partial density of states derived from surface and interior Ti atoms, corroborating the spectroscopic measurements. These results reveal that electronic states derived from sub-surface M-site layers are largely unperturbed by the surface termination, indicating a relatively short length scale over which the T$_s$ groups alter the nominal electron count associated with surface atoms and suggesting that desired band features should be hosted by sub-surface M-sites that are electronically more robust than their surface M-site counterparts. This work not only represents the first systematic L-edge transition metal XAS study in multi-element MXenes, but also points to the importance of deriving desired function from sub-surface M-site layers, to realize robust electronic, magnetic or topological behavior in MXenes. This work was supported by the U.S. Department of Energy (DOE), Office of Science, Office of Basic Energy Sciences, grant #DE-SC0018618.

The Interlayer Space, Cations and Water in Multilayered MXenes

Michel W. Barsoum; Drexel Univ, United States

Discovered in 2011, the 2D early transition metal carbides known as MXenes - obtained by etching the A-layers from the MAX phases - have generated substantial interest in the scientific community because of their potential in an ever-expanding host of applications. Whether during etching or use, it is critical to understand what happens in the interlayerspace. In most applications, the first step is to etch and wash MXene multilayers, MLs, until they disperse. Using primarily XRD diffraction, the relationship between etchant used and washing protocols and the swelling of the interlayer space of Ti3C2Tx MLs is elucidated. How changing the intercalant cations can change the spacing, and even the nature of Ti3C2Tx MLs from hydrophilic to hydrophobic, is discussed. How to render MXenes oxidation resistant in aqueous solutions is described. Lastly, the similarities of MXenes and clays are overviewed.

5:50 AM S.NM10.01.06

Raman Spectroscopy of Transition Metal Carbides and Nitrides (MXenes) Asia Sarycheva and Yury Gogotsi; Drexel University, United States

Raman spectroscopy is known as a fast and non-invasive tool to characterize materials, in particular their atomic bonding. In the recent years, it was widely used in the field of 2D materials, including graphene1, transition metal dichalcogenides2, boron nitride3 and others4. It has also been used to evaluate the composition and defects in the structure of those materials. Moreover, Raman spectra could be collected even from a monolayer of 2D material. This impact on the field shows that Raman spectroscopy can give a lot of information about 2D materials, therefore is an essential tool for studying the new families of 2D materials. One of those families are MXenes, 2-dimensional transition metal carbides and nitrides, discovered at Drexel University at 20115, which gained already a lot of interest in a variety of applications.

There is a limited number of Raman spectroscopy studies of MXenes studies6-10, therefore a database for quick assessment of a MXene is needed. We obtained Raman spectra and assigned peaks for M2X members of the family: Nb2C, Mo2C, V2C and Ti3C, as well as M2X3: Ti3C2, Mo2TiC2 and M2X3: Cr2TiC2 and NbC3, Mo2TiC4, covering the most widely used MXenes. We showed the difference between multilayer form (powder), delaminated form (deposited thin film or filtrated free-standing film). In the collected library of Raman spectra of MXenes we showed the change in the atomic vibrations with changing or substituting M element(s).

6:00 AM S.NM10.01.08

MXenes for Plasmonic Photodetection Jehad K. El-Demellawi; King Abdullah University of Science and Technology, Saudi Arabia

MXenes have recently shown impressive optical and plasmonic properties associated with its ultrathin atomic layer structure.[1] However, their use in photonic and plasmonic devices is still marginally explored. Herein, we have fabricated various flexible photodetectors made of different MXenes, i.e., Mo2CTx, Ti3C2Tx, Nb2CTx, T2CTx and V2CTx. The surface chemistry and the optoelectronic properties of the mechanically flexible arrays of two-terminal, parallel-type photodetectors deposited on paper substrates are thoroughly investigated. Amongst the five studied MXenes, Mo2CT have exhibited the best...
performance owing to its relative stability against oxidation, moderately high free carrier density and electrical conductivity,[2] though not as high as that of Ti3C2Tx.[1,3,4]
The Mo2CTx flexible devices have exhibited broad responsivity in the range of 400-800 nm with high responsivity (R, up to 9 A W⁻¹), detectivity (D* , ~5x10¹¹ Jones) and reliable photoswitching characteristics at a wavelength of 660 nm. It is worth mentioning that despite being the first demonstration of MXene-based photodetection, the performance of Mo2CTx thin films considering their R and D* is surpassing the majority of previously reported visible-band photodetectors based on solution-processed 2D materials. In particular, the responsivity of Mo2CTx devices were found to be ~18000 and ~1200 times higher than that of the first reported graphene[5] and MoS2[6] photodetectors, respectively. In addition to their attractive performance and solution processability, we have revealed that our MXene-based devices possess an additional set of advantages including full visible spectrum coverage, highly stable operation and mechanical flexibility. Furthermore, micro-Raman spectroscopy conducted on bare and on gold-coated Mo2CTx films allowing for surface-enhanced Raman scattering demonstrated a surface chemistry and a specific low-frequency band that we have related to the vibrational modes of the single Mo2CTx nanosheets.

The photodetection mechanism of our devices was unveiled using spatially-resolved STEM-EELS and ultrafast femtosecond transient absorption spectroscopy. We show that the photoresponse is dominated by the intrinsic plasmon-assisted hot carrier generation. The demonstrated ability of coupling with light and dephasing of surface plasmons with a short lifetime, without the need of integration with other metallic plasmonic structures, as previously demonstrated with several 2D materials,[7] have led to a photoresponse outperforming that of photoelectron-based devices. Our findings shed light on the knowledge of photocurrent generation mechanisms in MXenes, making them much more viable for many photonic and plasmonic device applications. Moreover, the specific ability to detect and excite individual surface plasmon modes, provide a viable platform for various MXene-based optoelectronic applications.

6:10 AM *S.NM10.01.09
Rational Design of 2D Magnetic Materials Vivek B. Shenoy, Nathan Frey and Arkamita Bandyopadhyay; University of Pennsylvania, United States

Recent experimental success in the realization of two-dimensional (2D) magnetism has invigorated the search for low-dimensional material systems with tunable magnetic anisotropy that exhibit intrinsic long-range ferromagnetic order. In this talk, I will present a rational design approach for studying and engineering magnetism in MXenes. I will also discuss a recently developed model for applying machine learning to accelerate MXene synthesis. Using a crystal field theory model and first-principles simulations, we demonstrate intrinsic ferromagnetism, high magnetic moments, high Curie temperatures, and intrinsic semiconducting and half-metallic transport behavior in nitride and ordered double-transition-metal MXenes. We report that modifying the surface termination and transition metal in monolayer M2NTx nitride MXenes gives rise to a rich diversity of noncollinear spin structures and finely tunable magnetic anisotropy. We predict that manipulating the strength of the spin-orbit interaction and electron localization via the chemical degrees of freedom can induce sufficient anisotropy to counteract thermal fluctuations that suppress long-range magnetic order. Further, surface engineering and applied electric fields enable robust switching and stabilization of magnetic behavior in MXenes. We extend this approach to study recently synthesized non-van der Waals 2D transition metal oxide materials, showing an observable net magnetic moment in 2D iron and chromium oxides. Our work suggests that MXenes and transition metal oxides offer a promising avenue for achieving practical solid-state devices with 2D magnetic materials.

The Role of “X” in MXenes—Titanium Carbonitride as a Model System Michael Naguib; Tulane University, United States

MXenes is a large family of two-dimensional (2D) transition metal carbidies and nitrides of composition Mn+1XnTz; M is an early transition metal (e.g. Ti, V, Nb, Mo), X is carbon or nitrogen, n =1-3 and Tz stands for mixture of surface terminations (e.g. O, OH, F). With more than two dozen of MXene reported in the recent years, MXenes has expanded significantly the chemical space of 2D materials. Most of studies on MXenes focused on the first reported MXene viz. Ti3C2Tz, much smaller
number of studies focused on other transition metals including ordered double transition metal and solid solutions at the M sites in MXenes. While nitrogen doping nanomaterials including transition metal carbides and oxides are known to be a very promising approach for altering materials properties and performance, very limited number of studies focused on carbonitride MXene. Herein, we use the titanium carbonitride as a model system to highlight the importance of studying the role of "X" in MXene. The characteristic differences between Ti$_3$C$_2$T$_z$ and Ti$_3$CNT$_z$ MXenes from both structure and surface chemistries points of views are discussed based on experimental results obtained using multiple techniques and theoretical calculations. Also, the performances of Ti$_3$CNT$_z$ as electrode materials for electrochemical energy storage electrocatalysis in addition to their performance as catalysts will be discussed and compared to that of Ti$_3$C$_2$T$_z$. 

5:15 AM S.NM10.02.03
Computational Investigation of the Structure-Property Relationships of MXenes Susan B. Sinnott; The Pennsylvania State University, United States

Material modeling methods are now widely applied to investigate and design new materials. This is especially helpful in cases where different compositions are possible and structure-property relationships need to be predicted. This presentation will discuss the application of material modeling methods to MXenes. The methods used include density functional theory calculations and atomic-scale simulations with reactive force fields.

5:25 AM *S.NM10.02.04
MXene Surface Chemistry Per O. Persson; Linköping University, Sweden

Since their discovery in 2011 [1], MXenes have outperformed existing materials for a range of applications such as energy storage [2], water filtering [3], electromagnetic shielding [4], as catalysts for H$_2$ evolution from water [5] and as astonishingly effective materials for capturing CO$_2$ [6] to name but a few examples. Their outstanding performance is accredited to a range of properties, e.g. hydrophilic and conductive, that can be attributed to a rich transition metal chemistry. Ultimately, the range of properties are dictated by the tailoring potential of the MXenes. In this respect, MXenes stand out in stark contrast to commonly employed 2-dimensional structures.

The general formula to describe MXenes, M$_{n+1}$X$_T$x, identifies that the tailoring potential in the MXene family is vast. In addition to choice of thickness (n) and X element, for instance, M can be a range of single transition metal elements, or an extensive set of combinations between multiple M elements in an ordered or disordered condition. Similarly, the range and corresponding potential mix of terminating elements or molecules is an apparent key in determining the final MXene properties. On top of this, the surfaces may be further decorated by functional elements. The present contribution primarily adopts advanced electron microscopy methods to reveal the state of the art available tailoring of the MXene structure and chemistry, owing to recent advances in tuning of surface terminations, surface decoration and corresponding properties.

5:40 AM *S.NM10.02.05
MXene Chemistry—Fundamentals and Applications Vadym Mochalin; Missouri University of Science and Technology, United States

A large family of two-dimensional transition metal carbides and nitrides (MXenes) raises interest for many applications due to their high electrical conductivity, mechanical properties [1], potentially tunable electronic structure [2], nonlinear optical properties [3], and the ability to be manufactured in the thin film state [4]. However, their chemistry that is key to development of these applications, still remains largely terra incognita [5]. In this presentation we will discuss recent progress in understanding fundamental MXene chemistry and harnessing it for development of applications.

For example, during delamination and storage in ambient air environment, spontaneous oxidation of MXene flakes leads to formation of titanium oxide, a process that can be harnessed for simple, inexpensive, and environmentally benign manufacturing MXene–titania composites for optoelectronics, sensing, and other applications [6]. We show that partially oxidized MXene thin films containing the in situ formed phase of titanium oxide have a significant photoresponse in the UV region of the spectrum. The relaxation process of photoexcited charge carriers, which takes a long time (~24 h), can be accelerated in the presence of oxygen and water vapor in the atmosphere. These properties of spontaneously formed MXene-titania thin films make them attractive materials for photoresistors with memory effect and sensitivity to the environment, as well as many other photo- and environment-sensing applications.

Other selected examples illustrating connections between understanding MXene chemistry and development of their applications will also be considered.
5:55 AM S.NM10.02.06
Scalable Synthesis of Ti3C2Tx MXene Christopher E. Shuck1, Asia Sarycheva1, Mark Anayee1, Ariana S. Levitt1, Yuanzhe Zhu1, Simge Uzun1, Vitaliy Balitskiy2, Veronika Zahorodna2, Oleksiy Gogotsi1 and Yury Gogotsi1; 1Drexel University, United States; 2Materials Research Center, Ukraine

Scaling the production of synthetic two-dimensional (2D) materials to industrial quantities has faced significant challenges due to synthesis bottlenecks whereby few have been produced in large volumes. These challenges typically stem from bottom-up approaches limiting the production to the substrate size or precursor availability for chemical synthesis and/or exfoliation. MXenes are a large family of 2D carbides and/or nitrides that have applications in electrochemical energy storage, electromagnetic interface shielding, electrocatalysis, gas sensing, electrochromic devices, and many others. In contrast to other 2D materials, MXenes are produced via a top-down synthesis approach. The selective wet etching process does not have similar synthesis constraints as some other 2D materials. The reaction occurs in the whole volume; therefore the process can be readily scaled with reactor volume. In this study, the synthesis of 2D titanium carbide MXene (Ti3C2Tx) was studied in two batch sizes, 1 and 50 g, to determine if large-volume synthesis affects the resultant structure or composition of MXene flakes. Characterization of the morphology and properties of the produced MXene using scanning electron microscopy, X-ray diffraction (XRD), dynamic light scattering (DLS), Raman spectroscopy, X-ray photoelectron spectroscopy (XPS), UV-visible spectroscopy, and conductivity measurements showed that the materials produced in both batch sizes are essentially identical. This illustrates that MXenes experience no change in structure or properties when scaling synthesis, making them viable for further scale-up and commercialization.

6:05 AM S.NM10.02.08
Composition-Dependent Oxidation Stability of 2D Transition Metal Carbides (MXenes) Mikhail Shekhirev1,2, Zein Alali1,2 and Yury Gogotsi1,2; 1Drexel University, United States; 2A.J. Drexel Nanomaterials Institute, United States

Transition metal carbides, carbonitrides and nitrides, also known as MXenes, attract significant attention due to their unique combination of properties. In addition to interest from scientific community, MXenes hold a great promise for multiple applications, such as energy storage, electromagnetic interference shielding, water purification and others. In order to transition from the lab bench to industrial scale applications, however, it becomes increasingly important to understand how stable MXenes are under different conditions and to find approaches to optimize shelf life of the material. That is why a number of recent reports focused on oxidation stability of titanium carbide (Ti3C2Tx) as the most studied member of MXene family, suggesting different strategies to inhibit its degradation. Despite the recent advances in improving of Ti3C2Tx stability, understanding degradation process for other members of MXene family remains elusive. With the wide variety of MXene compositions available (>30 reported, about 100 of possible stoichiometric compositions and infinite number of solid solutions) it is critical to investigate how MXenes other than Ti3C2Tx behave and how their chemical composition affects stability.

In this presentation we report on our studies on stability of MXenes against hydrolysis and oxidation in aqueous solutions. We evaluate different approaches suggested in literature and numerically compare their efficiency. For instance, efficiency of different additives, such as antioxidants and edge capping agents, will be discussed using Ti3C2Tx MXene as a model system, as well as other MXene compositions. Significant attention will be paid to effect of synthesis method and surface groups on MXene stability. Finally, the effect of M element in MXene will be discussed using the M2CTx MXene family (M=Ti, Nb or V) as an example.

6:15 AM *S.NM10.02.10
2D Multi-Principal Element Carbides MXenes Babak Anasori; Purdue School of Engineering, Indiana University-Purdue University, United States

2020 MRS Virtual Spring/Fall Meeting, November 27-December 4, 2020, Spring Abstracts Final Program 2/3/21
The family of two-dimensional (2D) transition metal carbides and nitrides, MXenes, is one of the largest families of 2D materials with more than thirty synthesized compositions (e.g., Ti2C, Ti3C2, Nb2C, Mo2C) and several more that are predicted to exist. MXenes with two transition metals exist in either random solid solutions or ordered forms. The latter MXenes are called ordered double-transition metals carbides, in which two transition metals form either in-plane or out-of-plane atomic ordering, such as in Mo1.33Y0.66C, Cr2TiC2, and Mo2Ti2C3. In the ordered double-transition metal carbides (MXenes), physical, electrochemical, and mechanical properties can be tuned by controlling the transition metals ordered chemistry. Here, by combining two relatively new fields of double-transition metal MXenes and high entropy alloys and ceramics, a new area in the MXenes field has emerged as multi-principal element MXenes. In these MXenes, four transition metals are combined in the form of solid-solutions in the 2D atomic planes of MXenes. In this talk, the rationale behind high entropy MXenes, their synthesis conditions, and their properties will be discussed.

6:30 AM S.NM10.02.11
Self-Assembly of Recombinant Silk Fibroin on Ti3C2 MXene Surface Michelle Krecker1, Daria Bukharina1, Christine B. Hatter2, Yury Gogotsi2 and Vladimir Tsukruk1; 1Georgia Institute of Technology, United States; 2Drexel University, United States

Here we show that MXene flakes can be uniformly coated with amorphous recombinant silk fibroin in aqueous solution under ambient conditions. X-ray photoelectron spectroscopy has revealed a reduction of TiO2 formation by half on modified flakes after 21 days in water, suggesting the silk coating provides some protection against oxidation of the MXene surface, a common issue of MXene dispersions. High resolution atomic force microscopy was used to map the morphological changes of these modified flakes over time and showed silk fibril formation on flake surfaces. This spontaneous reorganization of recombinant silk, a material that typically has difficulty reorganizing after the harsh chemical treatment used to solubilize spun fibers, suggesting some chemical reduction provided by the MXene flake.

SESSION S.NM10.03: Electrochemical Properties and Energy Storage Applications
On Demand Abstracts Available for Viewing Starting Saturday, November 21, 2020
5:00 AM *S.NM10.03.01
Dense Charge Accumulation in MXene with a Hydrate-Melt Electrolyte Masashi Okubo and Atsuo Yamada; The University of Tokyo, Japan

Renewable energy systems are in urgent demand; however, integration of renewable energy into electrical grids requires rapid load-leveling of abrupt power spikes/drops and a wide distribution of high-power energy storage devices represents the most promising solution. However, current electrochemical energy storage devices do not meet all the requirements for grid-scale use, particularly because of slow charge/discharge rates caused by limited ion transport. Supercapacitors have rapid operation owing to the formation of an electric double-layer (EDL) at the electrode surface, which contributes to a higher power density and longer cycle lifetime than achievable in conventional batteries. In particular, supercapacitors based on aqueous electrolytes are attractive because of their low cost, high ion conductivity, non-flammability, and eco-friendliness. However, the energy density of such devices is severely limited by the narrow potential window of water (1.23 V).

To overcome this obstacle, we focus on a highly-concentrated aqueous electrolyte known as a hydrate melt (Li(TFSI)0.7(BETI)0.3/2H2O, TFSI: bis(trifluoromethanesulfonyl)imide, BETI: bis(pentafluoroethanesulfonyl)imide). Owing to the unique local coordination structure of water, hydrate melts show an exceptionally wide electrochemical potential window (> 3 V) as electrolytes, which far exceeds the thermodynamic hydrogen/oxygen evolution limits of water (1.23 V). Aqueous supercapacitors based on hydrate-melt electrolytes are expected to realize much higher voltage operation and hence much higher energy densities with an appropriate choice of electrode materials.

As an electrode material that can maximize use of the wide electrochemical window provided by hydrate-melt electrolytes, we used transition-metal carbides MXene. Because MXenes are reported to provide a large specific capacitance greater than 300 F/g in conventional aqueous electrolytes, their combination with a hydrate-melt electrolyte should realize a much higher energy density.

Here, we demonstrate the high-voltage operation of an aqueous supercapacitor consisting of an MXene Ti2CTx electrode and
a hydrate melt electrolyte.

5:15 AM S.NM10.03.02
3D Printing of Additive-Free MXene Ink for Fabrication of Micro-Supercapacitors with Ultra-High Energy Densities Jafar Orangi, Fatima Hamade, Virginia A. Davis and Majid Beidaghi; Auburn University, United States

Small scale energy storage devices are expected to play a significant role in the future advances of portable electronics, wireless sensors, and multifunctional micro/nanosystems. A crucial requirement for the fabrication of energy storage devices with high energy and power densities is using electrode materials with superior electrochemical properties. Another important requirement is the assembly of the electrode materials into structures that promote high ionic and electronic conductivities. In this talk, we report a scalable printing method for fabrication of on-chip three-dimensional (3D) micro-supercapacitors based on a class of 2D transition metal carbides called MXenes as electrode materials. MXenes offer high electronic conductivity and high specific capacitance and therefore, have attracted much interest as high-performance electrode materials for supercapacitors. In our work, the fabrication of MXene electrodes and device assembly is achieved using an extrusion-based 3D printing process that uses viscoelastic water-based MXene ink. A programmable printing machine was used in the printing process which involved layer-by-layer deposition of the MXene ink to fabricate the 3D electrodes. The developed printing method allows rapid fabrication of micro-supercapacitors on a variety of substrates, while electrode height can be controlled by the number of deposited layers. All-solid-state devices printed on flexible substrates showed excellent electrochemical performances under different bending conditions and delivered extremely high areal capacitances (over 800 mF cm-2). Our study suggests that due to its high electronic conductivity and electrochemical properties, MXene is an excellent electrode material for the fabrication of 3D energy storage devices.

5:25 AM S.NM10.03.03
d-Spacing Effect on the Electrochemical Performance of MXene in Organic and Room Temperature Ionic Liquids Kun Liang1, Naresh Osti2, Eugene Mamontov2, Bishnu Thapaliya1, Sheng Dai1 and Michael Naguib1; 1Tulane University, United States; 2Oak Ridge National Laboratory, United States; 3The University of Tennessee, Knoxville, United States

MXenes exhibit excellent capacitance at high rates in aqueous electrolytes, especially in H2SO4 aqueous electrolyte, but in a narrow potential window, which limits the energy density. Moreover, oxidation of Ti3C2 under high anodic potentials in aqueous electrolytes further limits its use to cathodes of asymmetric devices. Organic electrolyte and room temperature ionic liquids (RTIL) can provide a higher potential window, leading to higher energy density and open circuit potential. While they can host other ions beyond protons, the rate capability of MXenes is not at the same level as what has been achieved in aqueous electrolytes. We hypothesis that there should be an optimum d-spacing that can allow for fast ions (beyond protons) for high power with high energy considering the larger voltage window offered by both organic and RTIL electrolytes. To test this hypothesis, we are studying the effect of interlayer spacing on the overall electrochemical performance of the electrodes to define. The specific capacitances from intercalated Ti3C2Tz for both Li+ and EMI+ were higher than those from non-intercalated Ti3C2Tz. The intercalated MXene shows a higher specific capacitance of 137 and 98 F g⁻¹ in 1-ethyl-3-methylimidazolium bis(trifluoromethanesulfonyl)imide (EMI-TFSI) and EMI-TFSI/AN electrolyte, respectively. The diffusion coefficient of EMI+ in intercalated Ti3C2Tz was higher than that from non-intercalated Ti3C2Tz, and the larger d-spacing, the higher the diffusion coefficient. Moreover, quasi-elastic neutron scattering was used to study MXene with different d-spacing, and it showed high mobile EMI+ confined in-between the layers of MXene with large d-spacing.

5:40 AM *S.NM10.03.04
Capacitive Energy Storage in MXenes—Termination Dependence and Ion Specific Intercalation Processes Paul Kent; Oak Ridge National Laboratory, United States

The capacitive properties of MXenes are high tunable based on their composition, terminal groups, electrolyte, choice of intercalated ions, and nanoscale confinement. To enhance the energy stored and power that can be delivered in these materials requires a significantly improved understanding of the MXene properties, intercalation chemistry, and determining the relevant processes. I will first describe a first-principles computational study focused on predicting the achievable capacitance in different MXenes with a simplified model aqueous electrolyte. Second, I will describe a highly integrated and high fidelity study between experimental and modeling approaches to investigate the intercalation processes for aqueous Li⁺, Na⁺, K⁺, Cs⁺, Mg²⁺ into Ti3C2 MXenes. Experiments include microcalorimetry, atomic force microscopy and cyclic voltammetry whose results are directly linked to the results of detailed first-principles modeling. Our integrated analysis allows us to understand the energy storage processes and highlights the importance of the dynamics of cations and
positionings and their role in capacitive energy storage properties. These findings will expedite the evolutions of energy related functional devices by enabling improved design of higher-performing membranes and two-dimensional materials.

This work was supported as part of the Fluid Interface Reactions, Structures and Transport (FIRST) Center, an Energy Frontier Center funded by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences.

Energy Storage Devices in Textiles by Knitting MXene Yarns Ariana S. Levitt, Genevieve Dion and Yury Gogotsi; Drexel University, United States

Textile devices integrate exciting functionalities into clothing, including the ability to sense, actuate, monitor health signals, and communicate with nearby electronics. These devices require power to function, motivating researchers to develop energy storage devices that can be seamlessly integrated into textiles. In the last ten years, several works have been published on the development of fiber- and yarn-based supercapacitors using various carbon-based active materials such as activated carbon, graphene, and intrinsically conducting polymers. These devices demonstrate high energy density below ~4 cm in length but suffer from high resistance at longer lengths leading to reduced performance. For this reason, new active materials with higher conductivity and advanced device architectures are needed to improve the capacitance and rate performance of textile supercapacitors.

We pioneer the incorporation of Ti3C2Tx, a two-dimensional carbide and member of the MXene family, into commercial natural and synthetic fibers to develop highly conductive and electrochemically active yarn electrodes. The outstanding electrical and electrochemical performance of these yarns produced by several techniques, from electrospinning to infiltration, can be attributed to the high conductivity (10,000 S cm−1 as a thin film) and high capacitance of Ti3C2Tx (1500 F cm−3) due to redox reactions of surface titanium atoms. These yarns were knitted into a new architecture of textile energy storage devices, 3D knitted supercapacitors, using industrial knitting machines. Unlike fiber- and yarn-based supercapacitors, knitted supercapacitors consist of interconnected loops of fiber/yarn electrodes, providing multiple pathways for electron transport and reducing resistance relative to a freestanding fiber/yarn. By tuning the knit structure and geometry, such as stitch density and fabric dimensionality, the spacing between electrodes reduced 4-fold, increasing the areal capacitance from 402 mF cm−2 to 707 mF cm−2 at 2 mV s−1. This is the first work to study industrially relevant knitting parameters in designing textile-based supercapacitors and their effects on electrochemical performance. The ability to rapidly fabricate meters of electrochemically active yarns and energy storing textiles enables the design and study of fully integrated textile circuits that could one day be developed into garments capable of sensing and computing.

6:05 AM S.NM10.03.08
Supercapacitor Yarns Based on Graphene-Oxide and MXene Flakes—Size Effect and More Wei Gao; North Carolina State University, United States

We will discuss our recent progress on direct fiber extrusion from graphene-oxide (GO) and MXene dispersions in water, and the corresponding fiber performance as supercapacitor electrodes in supercapacitor yarns. The flake sizes of these 2D sheets turn out to impact the resulted fiber properties and performance to a great extent. Supercapacitors are known to have superior power densities over batteries due to their surface-centered charge-discharge processes. Recently, increasing attention has been attracted to yarn-shaped supercapacitor systems, mainly due to their high flexibility and pliable nature, leading to potential applications in wearable electronics, microrobots, medical implants, and smart textiles. However, one of the major limitations that occurs when supercapacitors are made into fiber/yarn shapes, is the increased equivalent series resistance (ESR) due to the fibrous geometry adopted here. For instance, even the best supercapacitor yarns reported will exhibit a few hundred ohms of resistance at one-meter length, which is usually neglected by researchers in their publication. To directly tackle this issue, here we report our strategies of using a metallic core filament in the yarn supercapacitors developed in our lab. With detailed materials and process engineering, we can boost the power density by one order of magnitude.

6:15 AM *S.NM10.03.10
Theoretical Exploration of the Potential of MXenes as Electrode Materials in Batteries Jun Fan; City University of Hong Kong, Hong Kong

MXenes, a class of two-dimensional transition metal carbides, nitrides and carbonitrides, have been extensively studied since their discovery. Because of their superior conductivity, large specific surface area and tunable physico-chemical properties, MXenes have been demonstrated to be promising electrode materials for various batteries such as: Li ion batteries, Na ion
batteries and Lithium-sulfur batteries etc. So far, more than thirty different kinds of MXenes have been successfully synthesized in experiment and at the same time more members were predicted to exist by theoretical calculations. Since MXenes possess rich chemical compositions and their family are still growing, it is meaningful to further exploit more high-performance MXenes-based electrode materials for various batteries. In this talk, some strategies including changing the functional groups and transition metals of MXenes for designing high-capacity anode materials in Na ion batteries will be discussed. Specifically, the structural, electronic, adsorption and diffusion properties of Ti$_3$C$_2$, Ti$_3$C$_2$S$_2$ and Zr-based MXenes as anode materials for Na ion batteries by using density functional theory (DFT) calculations will be included. More importantly, a correlation between charge transfer, lattice mismatch and the capacity of MXenes were identified, which will be useful for designing other 2D anode materials for Na ion batteries [1-2]. At the meantime, the potential of a series of MXenes as anchoring materials for Lithium-sulfur batteries and structure-properties correlation will also be presented [3]. Moreover, the strain effects on electronic properties of MXenes with a focus on lithium adsorption and structural transformation will also be discussed [4].

MXenes Thin Film for Lightweight Electromagnetic Interference Shielding Chong Min Koo$^{1,2}$; 1Korea Institute of Science and Technology, Korea (the Republic of); 2Korea University, Korea (the Republic of)

MXenes, 2D transition metal carbides, has emerged as a light-weight, ultrathin electromagnetic shielding materials for mobile telecommunication devices and advanced 5G smart electronics, since it offers an attractive combination of high electronic conductivity (~5000 S/cm), low density, hydrophilicity, and processability. In this presentation, we demonstrate that MXene is an ideal candidate for light-weight shielding with minimal thickness. The MXene thin film shows the extraordinary EMI shielding behavior due to its large electrical conductivity and 2D nano structure. These unique experimental results will be understood by theoretical calculations. Additionally, this presentation demonstrates that the simple post-treatment of MXene thin film deduces an unusual strong interaction with electromagnetic wave, resulting in strong absorption-induced attenuation.

5:15 AM S.NM10.04.03
Mechanical and Electrical Properties of Ti$_3$C$_2$T, MXene Single Flakes Alexey Lipatov$^1$, Mohamed Alhabeb$^2$, Haidong Lu$^1$, Babak Anasori$^2$, Alexei Gruverman$^1$, Yury Gogotsi$^2$ and Alexander Sinitskii$^1$; 1University of Nebraska–Lincoln, United States; 2Drexel University, United States

Two-dimensional (2D) transition metal carbides and nitrides, known as MXenes, are a large class of materials that are finding numerous applications ranging from energy storage and electromagnetic interference shielding to water purification and antibacterial coatings. However, while bulk applications of MXenes are rapidly developing, their intrinsic physical property characterization through single-flake measurements remains a largely unexplored area of research. Here, we report the elastic properties of monolayers and bilayers of the most important MXene material to date, Ti$_3$C$_2$T$_x$ (T stands for surface termination) measured using nanoindentation with the tip of an atomic force microscope. The effective Young’s modulus of a
single layer of Ti$_3$C$_2$T$_x$ was found to be 0.33 ± 0.03 TPa, which is the highest among the reported values for solution-processed 2D materials, including graphene oxide. Individual Ti$_3$C$_2$T$_x$ flakes also exhibit a high conductivity of 4600±1100 S/cm and field-effect electron mobility of 2.6±0.7 cm$^2$/Vs. We found that the resistivity of individual flakes is only one order of magnitude lower than the resistivity of multilayer Ti$_3$C$_2$T$_x$ films, which indicates a surprisingly good electron transport through the surface terminations of different flakes, unlike in many other 2D materials.

5:25 AM S.NM10.04.04

Scalable, Highly Conductive and Micro-Patternable MXene Films Jason Lipton$^1$, Jason A. Röhr$^1$, Vi Dang$^1$, Adam Z. Goad$^2$, Kathleen A. Maleski$^2$, Yury Gogotsi$^2$ and André D. Taylor$^1$; $^1$New York University, United States; $^2$A.J. Drexel Nanomaterials Institute, United States

2D transition metal carbides and nitrides (MXenes) have accumulated tremendous interest recently as a result of their high conductivity, aspect ratio, and excellent figures of merit in numerous application areas. Freestanding films of MXenes are important for versatility in their incorporation into roll-to-roll production to allow for large-scale fabrication. Vacuum assisted filtration is currently the state-of-the-art for fabrication of freestanding MXene films, but this method does not project well for large-scale production due to limitations on film areas and thicknesses as well as the required use of a vacuum system. Aqueous-based solution casting onto hydrophilic substrates is a useful way to make MXene coatings but they cannot be delaminated from the substrate to yield a freestanding film. In this work, we show that it is possible to fabricate Ti$_3$C$_2$ MXene freestanding films through simple drop-casting onto hydrophobic substrates. MXene films prepared using this technique have greater alignment of MXene flakes due to repulsive interactions between the substrate and the Ti$_3$C$_2$ MXenes and allows for facile delamination of the film from the substrate. We show that freestanding drop-cast MXene films can be fabricated in large areas (125 cm$^2$) and thicknesses (23.2 µm), have high electronic conductivity and smooth surfaces as a result of improved flake alignment. Drop-cast MXene films can also be micropatterned in three dimensions simply by using commercially available microstructured plastics as substrates. The results presented here suggest a new scalable path towards creating MXene freestanding films for novel prototypes and industrialization.

5:35 AM S.NM10.04.05

MXene Family of Materials for Electromagnetic Interference Shielding Meikang Han$^1$, Christopher E. Shuck$^1$, Roman Rakhmanov$^1$, David Parchment$^1$, Babak Anasori$^2$, Chong Min Koo$^3$, Gary Friedman$^1$ and Yury Gogotsi$^1$; $^1$Drexel University, United States; $^2$Indiana University–Purdue University Indianapolis, United States; $^3$Korea Institute of Science and Technology, Korea (the Republic of)

New ultrathin and multifunctional electromagnetic interference (EMI) shielding materials are required for protecting electronics against electromagnetic pollution in the fifth-generation (5G) era. Micrometer-thin films built of 2D Ti$_3$C$_2$T$_x$ MXene nanosheets have shown extraordinary promise for EMI shielding. Yet, EMI shielding properties of other MXenes have not been explored, despite the fact that more than 30 different stoichiometric MXenes have been reported and many more are possible, including an infinite number of solid solutions. We report on a systematic study of EMI shielding properties of 16 single-metal, ordered double-metal and random solid solution MXenes. Films with thickness ranging from nanometers to micrometers were produced by spin-casting, spray-coating and vacuum filtration. EMI shielding effectiveness of the sprayed Ti$_3$C$_2$T$_x$ film with a thickness of ~40 nm reaches 21 dB (shielding >99% EM wave). Adjustable EMI shielding properties were achieved in solid solution MXenes with different ratios of elements. This work opens a pathway for designing ultrathin, flexible and multifunctional MXene films with outstanding EMI shielding performance coupled with other specific characteristics of particular MXenes.

5:45 AM S.NM10.04.07

Effect of Cation Pre-Intercalation on the Electrochemical Performance of Multilayer Ti$_3$C$_2$: MXene in Aqueous Electrolyte Kaitlyn E. Prenger$^1$, Ameer Al-Temimy$^{2,3}$, Kun Liang$^1$, Simone Raoux$^{2,4}$, Tristan Petit$^2$ and Michael Naguib$^1$; $^1$Tulane University, United States; $^2$Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Germany; $^3$Freie Universität Berlin, Germany; $^4$Humboldt-Universität zu Berlin, Germany

Electrically conductive 2D transition metal carbides and nitrides known as MXenes, discovered in 2011, have already shown an enormous potential in the field of electrochemical energy storage, due to their capabilities to host ions and protons in addition to their high electrical conductivity. MXenes are synthesized by selective etching of atomically thin metal layers from layered ceramics called MAX phases. The as synthesized MXene is in the form of multilayers held together by hydrogen and van der Waals bonds. The multilayers can be delaminated via intercalation followed by mechanical agitation to separate the layers from each other forming colloidal solution that can then be filtered forming freestanding MXene paper. While delaminated Ti$_3$C$_2$ MXene has shown high capacitance, multilayer Ti$_3$C$_2$ has shown more modest values. One
limitation for using the free-standing MXene paper is the thickness, which results in low areal capacitance.

Herein, we will present on the electrochemical performance of multilayer MXene that was pre-intercalated with metal cations (Na⁺, K⁺, Mg²⁺) in between layers of Ti₃C₂ in H₂SO₄ aqueous electrolyte. At 5 A/g a gravimetric capacitance of 325 F/g was achieved, and it was stable over thousands of cycles. This is comparable to electrochemical performance of freestanding MXene paper but much higher than what can be achieved for conventional multilayer MXene without pre-intercalation. More interestingly, an areal capacitance up to 3 F/cm² was achieved for cation pre-intercalated multilayer Ti₃C₂. This simple modification of Ti₃C₂ MXene in its multilayer form yielded an easier avenue for making Ti₃C₂ supercapacitor electrodes with high areal capacitance. X-ray absorption spectroscopy (XAS) shows that changing cations in-between the layers alters the oxidation state of the titanium atoms in Ti₃C₂ MXene, whereas dispersing MXene in an H₂SO₄ environment resulted in reducing the surface titanium atoms of MXene. These results also encourage further investigation on the effects of intercalation and other modifications to Ti₃C₂ interlayer chemistry.

5:55 AM S.NM10.04.10

Two-Dimensional MXene Ti3C2Tx Membrane-Based Osmotic Power Generator Seunghyun Hong¹, Fangwang Ming¹, Yifeng Shi¹, Renyuan Li¹, In S. Kim², Chuyang Y. Tang³, Peng Wang¹,4 and Husam N. Alshareef¹; ¹King Abdullah University of Science and Technology, Saudi Arabia; ²Gwangju Institute of Science and Technology, Korea (the Republic of); ³The University of Hong Kong, Hong Kong; ⁴The Hong Kong Polytechnic University, Hong Kong

Salinity-gradient is emerging as one of promising clean and renewable sources of energy, but its energy efficiency is severely limited by unsatisfactory performance of available semipermeable membranes [1]. Most recently, nanoconfined two-dimensional channels, as fluidic conduits for harnessing the Gibbs free energy of mixing under salinity gradient, have exhibited their superior energy conversion performance to conventional technologies [2]. Here, the lamellar Ti₃C₂Tx MXene membrane is presented as a high-performance salinity battery, directly converting the stored chemical potential energy to electricity [3]. Subnanometer 2D channels in the MXene Ti₃C₂Tx membranes enable cation-selective passage, assisted with tailored surface functional groups, under salinity gradient, and consequently produce diffusion potential. A record-high output power density of 21 W-m⁻² at room temperature with an energy conversion efficiency of up to 40.6 % is achieved by controlled surface charges at a 1000-fold salinity gradient. Furthermore, thermal control of surface charges and ionic mobility yields a power density of up to 54 W-m⁻². Our findings advance the fundamental understanding of nanoinert transport through MXene 2D channels and thus offer a new opportunity to develop MXene membranes as a promising platform for the high-performance salinity battery.

6:05 AM S.NM10.04.11

Biological Activities and In Vitro Toxicological Features of the MXenes Agnieszka M. Jastrzebska¹, Aleksandra Szuplewska¹ and Anita Roxmysłowska-Wojciechowska¹; ¹Warsaw University of Technology, Faculty of Materials Science and Engineering, Poland; ²Warsaw University of Technology, Poland

The past few years have witnessed significant development in the chemistry and potential biological applications of two-dimensional (2D) materials. Innovative 2D carbides, nitrides and carbonitrides of early transition metals, called MXenes, have been also extensively studied for several years on the applications in human health protection. The recent advances include biotechnological and biomedical applications such as anticancer treatment, photothermal therapy, drug delivery platforms, or nano-drugs without any additional modification. These can be combined with bioimaging, magnetic resonance or photoacoustic techniques. It is currently accepted that the specific functionalities of the MXenes can result in wide spectrum of bio-activities. In this context, MXenes are currently being carefully studied, with strong attention to mechanisms of action and biocompatibility features. We already know that MXenes exhibit different cellular effects which can be additionally induced by multiple external or internal factors. These effects are in turn strictly dependent on MXenes structure, chemical composition, and surface characteristics which positively support their interesting potential in nano-therapies. In fact, MXenes are promising anticancer agents, which can not only inhibit proliferation of cancer cells but also induce oxidative stress, and even influence the cell functioning and cell cycle through inducing programmed cellular death (apoptosis). On the other hand, such a wide range of bio-activities may inevitably cause unexpected toxicological effects that require a broader understanding. The obtained results clearly indicate that in this respect, the surface chemistry of MXenes has a significant impact on their biological properties. This is closely related to the synthesis methods and also oxidizing properties, leading to the occurrence of potentially toxic superficial metal oxides. In the case of MXenes, the challenge now relates not only to obtain the needed biological properties but above all, to understand and maintain (stabilize) them in the
desired environment. The presented studies will shed some light on the issues raised above and also outline new directions in toxicology of the MXene phases. They are focused on elucidating antiproliferative, pro-oxidative, and pro-apoptotic mechanisms of action. The specific features of MXenes such as a high degree of morphological anisotropy, specific chemical functionalities, surface oxides, and unique surface charges undoubtedly define their biological properties.

6:15 AM S.NM10.04.12
Photosensitizer and Anticancer Drug-Loaded 2D Nanosheet—Preparation, Stability and Anticancer Property
Gang Liu1,2 and Naoki Komatsu3; 1Wuhan Institute of Technology, China; 2Kyoto Univ, Japan

Cancer phototherapy (PT) including photodynamic therapy (PDT) and photothermal therapy (PTT) has attracted extensive interest due to its non-invasive and region-specific nature. In order to enhance the efficacy, we have fabricated various nanocomposites consisting of a photosensitizer (chlorin e6 (Ce6), pheophorbide a (Pa) or bacteriopheophorbide a (bPa)) for PDT and a two-dimensional nanosheet (graphene or MoS2) for PTT by a one-pot protocol through liquid phase exfoliation. In addition, an anticancer drug (doxorubicin (DOX) or irinotecan (Ir)) was loaded on the nanosheet in the same way. All the nanocomposites were stably dispersed in water except for MoS2-Ir. Among the nanocomposites, MoS2-Ce6 killed cancer cells more than ten times more effective than Ce6 loaded other nanomaterials [1].

6:25 AM S.NM10.04.13
2D MXene Heterostructures as Electrodes for High-Rate Supercapacitors
Armin VahidMohammadi1,2, Wentao Liang3, Mehrnaz Mojtabavi3, Meni Wanunu3 and Majid Beidaghi1; 1Auburn University, United States; 2University of Connecticut, United States; 3Northeastern University, United States

Two-dimensional (2D) transition metal carbides (called MXenes) are among the most promising candidates for supercapacitor electrodes because of their ability to intercalate a variety of cations and high rate pseudocapacitive properties in acidic and neutral electrolytes. However, the research on 2D MXenes is just at its early stages, and out of ~30 MXene compositions that are experimentally made, only Ti3C2Tx MXene has been extensively studied. A few reports have also shown the promise of other MXenes, such as 2D V2CTx, in aqueous supercapacitors. Recently, we have shown high rate pseudocapacitance and exceptional (electro)chemical stability of cation-pillared delaminated V2CTx in neutral aqueous electrolytes as well as highly acidic electrolytes with capacitances as high as ~1300 F cm-3 (obtained in 3M H2SO4).[2] Despite these promising properties, the peak capacitance of Ti3C2Tx and V2CTx in 3M H2SO4 can only be achieved in certain potentials (~ -0.3 V vs. Ag/AgCl for Ti3C2Tx and ~ 0V vs. Ag/AgCl for V2CTx). In addition, the cycle life of V2CTx electrodes in the highly acidic sulfuric acid electrolyte is not on par with the Ti3C2Tx. Also, similar to the other 2D materials, the self-restacking of MXenes and their lower capacitances compared to other pseudocapacitive materials have hindered their further development. Controlled pillaring of 2D materials into multilayers and vertical stacking of different 2D layers into heterostructures have shown to be effective methods to avoid their self-restacking and overcome drawbacks of individual 2D materials.[1] Such pillared 2D multilayers or superlattice heterostructures built by sequential stacking of multiple 2D layers can display new and improved electrochemical responses and offer the combination of their building blocks’ best properties. In this talk, we argue that combining different delaminated MXenes into stacked heterostructures can result in new electrode structures that have superior properties in supercapacitors. We demonstrated this by fabricating all MXene heterostructures from delaminated Ti3C2Tx and V2CTx, which showed new features in their cyclic voltammetry profiles and could deliver the highest volumetric capacitance of ~1470 F cm-3 in 3M H2SO4 electrolyte. This study paves the way for the preparation of high-performance hetero-layered MXene structures for electrochemical energy storage applications and beyond.

Achieving Superlubricity with 2D Transition Metal Carbides (MXenes) and MXene/Graphene Coatings
Shuohan Huang1, Kalyan Mutyala2, Anirudha Sumant2 and Vadym Mochalin1; 1Missouri University of Science and Technology, United States; 2Argonne National Laboratory, United States

Two-dimensional (2D) materials have demonstrated unique friction and wear properties compared with their bulk (3D) counterparts. Some of the well-known 2D materials such as graphene, MoS2 and h-BN have shown outstanding tribological...
properties as additives to solvents, nanofillers in composite materials, and solid lubricants. A relatively new, large and quickly growing family of two-dimensional (2D) early transition metal carbides and nitrides (MXenes) [1] possess a unique combination of high electrical conductivity and hydrophilicity [2], which offers great potential in different applications such as energy generation [3] and storage, sensors [4], composites, and biomedical applications. There is an increased interest to mechanical properties of MXenes [5]. However, their tribological behavior has not been sufficiently studied yet. Here we investigate the tribological properties of Ti3C2 MXene with different flake sizes deposited on SiO2 coted Si substrates subjected to wear by sliding against a diamond-like carbon (DLC) coated steel-ball using a ball-on-disc type tribometer operating in dry nitrogen and in ambient air environments. We have observed that the friction is reduced to superlubric regime in dry nitrogen environment. Moreover, a combination of MXene and graphene has also been studied and the results show that with the addition of graphene, the abrasion was further reduced while the superlubricity behavior was maintained. This work opens new opportunities for exploring the potential of MXenes and MXene/graphene coatings as novel solid lubricants for various applications.

High Temperature Synthesis of a Crystalline MXene with Ordered Surface Terminations Jacob Pawlik and Daniel Druffel; University of North Carolina, United States

In this work, a new MXene is experimentally described which exhibits uniform functionality on MX layers (-Cl), contrary to the mixed functionality (-F, -O, -OH) of traditional MXenes. Most MXenes contain random surface terminations, arising from the vigorous etching process of the MAX phase with acids such as HF. However, the present MXene Y2CCl2 is synthesized by a direct high temperature method followed by liquid exfoliation, which results in highly crystalline 2D flakes. This MXene has well-defined properties due to single moiety surface terminations, allowing for construction of simple computational models. Previous research in the field highlights the difficulty of predicting properties such as band gap and surface energy due to the unpredictable arrangement of surface terminations and complexity of computational models. A crystalline MXene with ordered terminations offers an easily synthesizable target with properties that can be predictably tuned.

First, Y2CCl2 was directly synthesized by heating a pellet composed of Y, C, and YCl3 in a sealed tantalum tube at 950°C for 5 days according to literature procedures. Next, density functional theory (DFT) calculations were performed to predict the energy required to exfoliate Y2CCl2 into an MXene. The binding energy of Y2CCl2 (0.14 J/m²) is less than half the binding energy of graphite, indicating that Y2CCl2 should be easier to exfoliate than graphite. A common method for exfoliating graphite is sonication in a liquid with similar surface properties, so the material was sonicated in the polar aprotic solvent propylene carbonate. The mixture quickly forms a well-dispersed solution of 2D Y2CCl2 flakes. Transmission electron microscopy (TEM) shows flakes with lateral sizes of 2-5 µm, and electron diffraction confirms retention of the crystalline Y2CCl2 structure. The optical properties were evaluated by UV-Vis spectroscopy, which reveals an absorption peak at 1.64
eV that is close to the expected band gap of 1.56 eV, calculated using the HSE06 functional. Furthermore, X-ray photoelectron spectroscopy measurements reveal unusual oxidation states associated with yttrium (2+) and carbon (2-), suggesting interesting electrical properties.

This material has several attractive features that may be utilized. Y₂CCl₂ is easily exfoliated in mild conditions, avoiding the hazards of corrosive media such as HF and HCl. Also, the material absorbs light in the visible, making Y₂CCl₂ potentially useful for light harvesting and photocatalytic applications. More broadly, Y₂CCl₂ is part of a larger class of metal carbide halide materials with the stoichiometry M₂CX₂ (M = Y, Sc, Gd; X = F, Cl, Br, I) that share similar structure and properties. Through preliminary calculations, we predict that other metal carbide halides may be exfoliable and contain similar properties to Y₂CCl₂. Overall, Y₂CCl₂ and other similar metal carbide halides offer a new class of MXenes with ordered surface terminations.

S.NM10.05.04
Investigating Chemical Reactivity of MXenes Using Gas Chromatography Shuohan Huang, Gabriel Hulliung and Vadym Mochalin; Missouri University of Science and Technology, United States

MXenes are a new family of two-dimensional (2D) materials discovered in 2011. Because of their 2D structure and many outstanding properties [1], MXenes have raised significant interest for various applications, such as batteries, optoelectronic devices [2], supercapacitors, lasers [3,4], sensors [5], etc. It was found that titanium carbide MXene flakes in aqueous solutions spontaneously transform into TiO₂ and recently, it has been demonstrated that water plays the main role in the reactions leading to this chemical transformation [6]. Thus, studying MXene reactivity is important for prolonged shelf life of MXene colloidal solutions, as well as for robust performance of MXene based devices. In this work, we demonstrate the use of gas chromatography technique to study reactivity of MXenes. Several hypotheses have been put forward to explain the degradation of MXenes in aqueous environments. However, no studies of the gaseous products of this reaction have been reported. The analysis of gases produced during MXene degradation, using gas chromatography, allows for a better understanding of the degradation process. The chemical reactivity of MXenes with different monolayer thickness was also investigated at different pH and temperatures. Our results have led to new, important conclusions about the chemical reactivity of MXenes in aqueous solutions. This knowledge will have significant impacts on the development of MXenes and other 2D materials for many applications.

Raman Spectroscopy Reveals the Effect of Synthesis Conditions on Ti₃C₂: Asia Sarycheva and Yury Gogotsi; Drexel University, United States

Raman spectroscopy has been one of the most helpful tools for analysis of two-dimensional (2D) materials1-2. While newly discovered materials should be probed using this technique, there have been just a few studies available for a large family of 2D transition metal carbides and nitrides known as MXenes3-5. To see which effects Raman spectroscopy can detect for MXenes we performed a systematic study of the mostly used MXene to date - Ti₃C₂Tx. By synthesizing material in different ways, we monitored changes in Raman spectra. We have synthesized Ti₃C₂ via MILMD method, where HF is formed in-situ by mixing LiF and HCl, HF-HCl (mixture of two acids), and by using various concentration of HF: 5%, 10%, 20% and 30% solutions in water3. We collected Raman spectra from samples collected at different stages of MXene synthesis: from multilayer powders to delaminated flakes, in order to observe the effect of stacking. The whole spectrum of Ti₃C₂ is divided into 4 regions: a resonant peak, A₁₈ out-of-plane vibrations of Ti, C and O, the surface group vibrations region and carbon
vibrations region. Those regions change based on the synthesis method and flake surrounding. All those peaks are affected not only by surface functional groups, but also by stacking of the flakes. Due to a plasmonic peak of Ti₃C₂Tₓ around 785 nm, resonant conditions are achieved enabling an extra peak at around 119-123 cm⁻¹ when using a red diode laser. Lastly, we showed how photoluminescence, usually considered as an unwanted background of Raman spectra, can be used to detect the early stages of MXene degradation.

**MXene-Based Composite Functional Inks for 3D Printed Lithium-Ion Batteries**  
Jafar Orangi and Majid Beidaghi; Auburn University, United States

In a broad range of applications, including energy storage, flexible electronics, and sensors, additive manufacturing is considered as a promising device fabrication technique due to its potential for the development of complex architectures and using a variety of materials. Extrusion-based three-dimensional (3D) printing is a low-cost and straightforward method that offers rapid and precise fabrication of “on-chip” batteries and supercapacitors with 3D architectures. In this presentation, we report on our recent research on the development of functional nanocomposite inks based on two-dimensional (2D) MXenes, with the application in lithium-ion storage. MXenes are a new class of 2D materials with high electronic conductivity and hydrophilicity and have gained interest as high-performance electrode materials for electrochemical energy storage. The developed nanocomposite inks are incorporated with the MXene sheet as a conductive additive that can also provide the rheological properties required for extrusion-based 3D printing without the need for any other additive or binder. The inks were prepared by mixing lithium iron phosphate and lithium titanate nanoparticles with a highly concentrated water-based MXene ink and were directly used for printing of the cathode and the anode of a microbattery, respectively. A programmable printing machine was used in the fabrication process that follows the layer-by-layer deposition of the nanocomposite ink. The developed inks and printing methodologies facilitate the rapid fabrication of microbatteries on a variety of substrates, while the loading of active material per area of the device can be controlled by the number of deposited layers. The electrochemical test results show the excellent performance of 3D printed batteries.

Characterization of Novel Topological Phases in Ferroelectric Materials

Javier Junquera1, Fernando Gómez-Ortiz1, Pablo García-Fernández1, Nauro A. Pererira Gonçalves2,3, and Jorge Íñiguez2,3; 1Universidad de Cantabria, Spain; 2Luxembourg Institute of Science and Technology (LIST), Luxembourg; 3University of Luxembourg, Luxembourg

Complex topological configurations are a fertile area to explore novel emergent phenomena and exotic phases in Condensed-Matter Physics. The discovery of magnetic skyrmions one decade ago [1] have triggered a flurry of research on these particle-like nanometer-sized topologically protected spin textures, mostly motivated by their potential use in spintronic devices such as race track memories [2]. Since then, researchers have long wondered whether ferroelectrics may present topological textures akin to magnetic skyrmions and chiral bubbles. In this quest, the side by side advances in experimental growth and characterization techniques, and the development of new modelling tools are of paramount importance. In this respect, the emerging field of second-principles simulations [3-4], where an effective model is constructed by a judicious choice of the essential physics, and the parameters of the model are extracted by fitting to Density Functional Theory, are proving increasingly valuable in the study of large systems, overlapping in size with those that can be currently grown by atomic layer deposition methods. As a result of this continuous feedback between theory and experiment, the recent discovery of polarization vortices [5] and their associated complex-phase coexistence and response under applied fields in superlattices of (PbTiO3)n/(SrTiO3)n [6] suggests the presence of a complex, multi-dimensional system capable of emergent physical responses, such as a chirality [7]. In this talk, I shall describe the latest developments to create, tune, and characterize topological textures in ferroelectrics [8,9]. Polar structures with a well-defined topological charge and chirality will be presented. The stabilization of such non-uniform polarization topology results in highly enhanced susceptibilities, and also provides a pathway for engineering novel functionalities previously inaccessible, such as regions with negative capacitance [10].

Photoinduced Topotactic Reduction of Colloidal Iron Oxide Nanocrystals

Hankyool Jung and Alina Schimpf; University of California, San Diego, United States

Photoinduced topotactic reduction of colloidal iron oxide nanocrystals

Magnetite (Fe3O4) and maghemite (γ-Fe2O3) nanocrystals have been extensively studied due to their superparamagnetic behavior that potentiates their application in magnetic storage devices, catalysis, and medical diagnosis and treatment. As the ratio of Fe3+/Fe2+ determines the phase and magnetic properties of iron oxide nanocrystals, controlling the oxidation state of Fe is critical for such applications. Oxidation of Fe3O4 to γ-Fe2O3 has been thoroughly studied and is known to occur slowly in air or more rapidly with heat or additional oxidants. Reduction of γ-Fe2O3 to Fe3O4, however, is less well understood. We report reduction of colloidal γ-Fe2O3 nanocrystals by UV irradiation in the presence of a sacrificial reductant. Specifically, anaerobic irradiation in the presence of ethanol reduces Fe3+ to Fe2+, yielding a topotactic reduction of γ-Fe2O3 to Fe3O4. The properties of the nanocrystals upon photoreduction are monitored by UV/visible/near-IR electronic absorption spectroscopy, superconducting quantum interference device magnetometry and powder X-ray diffraction. Factors influencing the photoreduction, such as the type of hole quencher and nanocrystal size will be discussed. Our findings demonstrate a new
route to control the oxidation states of iron species in iron oxides.

In Situ Growth of Strained Nd2Ir2O7 Films and Emerging Topological Properties Due to Hidden Magnetic Multipoles Tae Won Noh; Seoul National University, Korea (the Republic of)

Controlling topological properties by varying external parameters is the quintessential step for developing next-generation devices with topological materials. Correlated topological phases (CTPs) can be induced by the interplay of electron correlation and spin-orbit coupling. They are the promising candidates whose band topology can be engineered by breaking the intricate balance between different energy scales. Pyrochlore iridate films belong to a family of cubic 5d transition metal oxides. They are representative systems where various CTPs can be studied by manipulating magnetism with lattice strain. However, their in-situ epitaxial growth has been known to be notoriously difficult. We recently succeeded in developing a new technique to grow in-situ fully strained Nd2Ir2O7 thin films. A fully strained film with antiferromagnetism shows an anomalous Hall conductivity which is an order of magnitude larger than that in the bulk or the relaxed film. Moreover, we observed the large spontaneous Hall conductivity which comes from the strain-induced magnetic T1-octupole. Our work demonstrates that topological properties can be engineered by manipulating magnetism with strain in oxide heterostructures.

Spin Chirality Fluctuation in Two-Dimensional Ferromagnets with Perpendicular Anisotropy Weida Wu; Rutgers University New Brunswick, United States

Non-coplanar spin textures with scalar spin chirality can generate an effective magnetic field that deflects the motion of charge carriers, resulting in a topological Hall effect (THE) [1–3]. However, spin chirality fluctuations in two-dimensional ferromagnets with perpendicular magnetic anisotropy have not been considered so far. In this talk, I will present evidence of spin chirality fluctuations by probing the THE above the Curie temperature in two very different ferromagnetic ultra-thin films, SrRuO3 and V-doped Sb2Te3 [4]. The temperature, magnetic field, thickness and carrier-type dependence of the THE signal, along with Monte Carlo simulations, suggest that spin chirality fluctuations are a common phenomenon in two-dimensional ferromagnets with perpendicular magnetic anisotropy. Our results open a path for exploring spin chirality with topological Hall transport in two-dimensional magnets and beyond [5–8].

Topological Defects and Domain Walls in Chiral Magnets Dennis Meier; Norwegian University of Science and Technology, Norway
Domain walls naturally arise whenever a symmetry is spontaneously broken. They interconnect regions with different realizations of the broken symmetry, promoting structure formation from cosmological length scales to the atomic level. In my talk, I will present topological 1D spin textures and domain walls with intriguing physical properties, which emerge in spin-spiral multiferroics and chiral magnets and which hold great promise for nanoelectronics and spintronics applications. In particular, I will discuss that a wide variety of new domain walls occurs in the presence of spatially modulated domain states. In contrast to domain walls in conventional ferroics, such domain walls exhibit a well-defined inner structure, which—analogous to cholesteric liquid crystals—consists of topological disclination and dislocation defects. Similar to the magnetic skyrmions, the domain walls can carry a finite topological charge, permitting an efficient coupling to spin currents and contributions to a topological Hall effect. Our studies establish domain walls in chiral magnets as functional nano-objects with non-trivial topology, opening the door to innovative device concepts in information and communication nanotechnology.

Experimental Realization of Intrinsic Strain-Induced Ferroelectricity in SrMnO3 Films via Selective Oxygen Annealing
Hyunji An1, Jeong-Kyu Kim1, Sangmo Kim2, Jiwoong Yang1, Hojoong Choi1, Chung Wung Bark3, Bong-Joong Kim1, Kyung-Tae Ko1,4 and Sanghan Lee1; 1Gwangju Institute of Science and Technology (GIST), Korea (the Republic of); 2POSTECH, Korea (the Republic of); 3Gachon University, Korea (the Republic of); 4Korea Basic Science Institute, Korea (the Republic of)

SrMnO3 (SMO) has recently aroused enormous interest because theoretical studies predicted the paraelectric-antiferromagnetic system in its bulk state can be transformed into a new multiferroic system via strain-engineering. However, experimental verification is still inadequate due to high-leakage current density (180 A/cm²) and surface cracks, which are derived from oxygen deficiency of strained SMO thin films. Hence, we devised a selective oxygen annealing (SOA) method effectively filling the oxygen vacancies while protecting the surface of the SMO. By applying this method, clean surface and insulating behavior (current density: 3.8 × 10⁻⁶ A/cm² and dielectric loss <0.1) are successfully achieved in a 1.7% tensile-strained SMO thin film. This SOA method not only allows direct investigation of the intrinsic multiferroicity of strained SMO but also device application without leakage issues. Based on the obtained insulating behaviors, the SMO thin film shows the room-temperature ferroelectric polarization loop (Pₑ: 1 μC/cm²) and the dielectric constant (εₑ: 138.1). Moreover, a significant reduction of the dielectric constant from 138.1 to 6.7 is observed by systematically releasing the epitaxial strain. These findings can be important experimental evidence of phase transition from paraelectric to ferroelectric phase via strain-engineering as theoretically predicted. Furthermore, since SMO can be optionally a low-k or high-k material, it can be applied to a wide range of capacitors or memory devices. We also believe that our SOA method will be an important key to open the next-step of multiferroic SMO by enabling us to directly investigate its intrinsic characteristics.

Tunable Resistivity Exponents in the Metallic Phase of Epitaxial Nickelates
Beatriz Noheda1,1, Qikai Guo1, Saeedeh Farokhipoor1, Cesar Magen2 and Francisco Rivadulla3; 1University of Groningen, Netherlands; 2Universidad de Zaragoza, Spain; 3Universidade de Santiago de Compostela, Spain

The tunable resistivity of materials undergoing a metal-insulator transitions (MIT) holds great promise for resistive switching applications, such as adaptable electronics and cognitive computing. However, a complete understanding of the metallic
phase in these strongly correlated electron systems is still one of the central open problems in condensed matter physics. Here we will present a detailed analysis of the electrical resistivity exponent of thin films of NdNiO$_3$ as a function of epitaxial strain. Strain-free thin-films show a linear dependence of the resistivity versus temperature, consistent with a classical Fermi gas ruled by electron-phonon interactions. In addition, the apparent temperature exponent, n, can be tuned with the epitaxial strain between $n=1$ and $n=3$. We discuss the critical role played by quenched random disorder in the value of n. Our work shows that the assignment of Fermi/Non-Fermi liquid behaviour based on experimentally obtained resistivity exponents requires an in-depth analysis of the degree of disorder in the material.

This work is being considered for publication as Qikai Guo, Saeedeh Farokhipoor, Cesar Magen, Francisco Rivadulla and Beatriz Noheda, “Tunable resistivity exponents in the metallic phase of epitaxial nickelates” and it can be found at https://nature-research-under-consideration.nature.com/users/37265-nature-communications/posts/53928-tunable-resistivity-exponents-in-the-metallic-phase-of-epitaxial-nickelates, and at https://arxiv.org/abs/1909.06236

Majorana Zero Mode for Topological Quantum Computing Jinfeng Jia; Shanghai Jiao Tong University, China

Majorana zero mode (MZM) can be used in fault-tolerant quantum computation relying on their non-Abelian braiding statistics, therefore, lots of efforts have been made to find them. Signatures of the MZMs have been reported as zero energy modes in various systems. As predicted, MZM in the vortex of topological superconductor appears as a zero energy mode with a cone like spatial distribution. Also, MZM can induce spin selective Andreev reflection (SSAR), a novel magnetic property which can be used to detect the MZMs. Here, I will show you that the Bi$_2$Te$_3$/NbSe$_2$ hetero-structure is an artificial topological superconductor and all the three features are observed for the MZMs inside the vortices on the Bi$_2$Te$_3$/NbSe$_2$. Especially, by using spin-polarized scanning tunneling microscopy/spectroscopy (STM/STS), we observed the spin dependent tunneling effect, which is a direct evidence for the SSAR from MZMs, and fully supported by theoretical analyses. More importantly, all evidences are self-consistent. Our work provides definitive evidences of MFs and will stimulate the MZMs research on their novel physical properties, hence a step towards their statistics and application in quantum computing. Finally, the possible application in topological quantum computing is discussed.

Temperature Promoted Topological Order in PbO$_2$: Bartomeu Monserrat, Bo Peng, Ivona Bravić and Judith L. MacManus-Driscoll; University of Cambridge, United Kingdom

Topological materials host exotic properties such as dissipationless spin and charge currents or Majorana fermions that could find numerous technological applications, for example in low-power electronics and spintronics or in quantum computers. However, most topological properties are currently restricted to extremely low temperatures, precluding applications.

In this talk, we will describe our first principles quantum mechanical calculations to understand the microscopic origin of the interplay between temperature and topological order in materials. Our work reveals that this interplay is dominated by a combination of thermal expansion and electron-phonon coupling, and that increasing temperature should destroy topological order in most materials, in agreement with all available experimental reports. Interestingly, our results also suggest avenues for designing materials with the opposite behaviour, and we present a polymorph of PbO$_2$ as the first example of a material in which increasing temperature promotes rather than destroys topological order.
Topological Quantum Phenomena in Correlated Oxide Heterostructures

Ho Nyung Lee; Oak Ridge National Laboratory, United States

Many physical phenomena in condensed matter arise from strong correlation and spin-orbit coupling (SOC), and their proper control is important for creating novel quantum materials (QMs), such as Mott insulators, quantum spin liquids, topological insulators, Weyl semimetals, etc. to name a few. As the importance of quantum information science emerges, there is an increased attention to QMs to address the need for new materials for addressing challenges in quantum computing and sensing. Among many classes of QMs, complex oxides offer a rich playground to exploit both correlations of Coulombic interactions between electrons often found in 3$d$ transition metal oxides (TMOs) and SOC from heavy metal based 5$d$ TMOs, such as SrIrO$_3$ and Na$_2$IrO$_3$, leading to many intriguing physical properties. Hybrid materials with a proper balancing of the correlation and SOC offer unique opportunities to discover new properties, and heterostructuring or combining dissimilar materials is a great approach to harnessing the complex interplay between quantum wavefunctions and various control parameters, such as proximity, dimensionality, topology, and symmetry. In this talk, I will review recent progresses in topological quantum materials and present our recent work on topological Hall effect from chiral magnetism and its control via interfacial symmetry control. Furthermore, an effort to combine topology and correlation to develop correlated topological materials and an approach to develop novel Berry phase engineered heterostructures will be presented.

This work was supported by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, Materials Sciences and Engineering Division.

LaTiO$_3$/SrTiO$_3$ Interfaces—From Giant Rashba Spin Splitting to Edge State Conduction

Michael Veit$^1$, Xin Yu Zheng$^1$, Remi Arras$^2$, Brad Ramshaw$^3$, Mun Chan$^4$, Di Yi$^1$, Rossitza Pentcheva$^3$ and Yuri Suzuki$^1$; $^1$Stanford University, United States; $^2$University of Toulouse, France; $^3$Cornell University, United States; $^4$Los Alamos National Laboratory, United States; $^5$University of Duisberg-Essen, Germany

The Mott insulator/band insulator interface of LaTiO$_3$/SrTiO$_3$ was first shown to exhibit metallicity due to electronic reconstruction by Ohtomo and Hwang in 2002. This work led to significant research activity exploring emergent metallicity at complex oxide interfaces – most notably at the LaAlO$_3$/SrTiO$_3$ interface. However there has been comparably less study of the LaTiO$_3$/SrTiO$_3$ interface versus the LaAlO$_3$/SrTiO$_3$ interface. We have recently found that the metallic behavior at the LaTiO$_3$/SrTiO$_3$ interface is accompanied by giant Rashba spin-orbit coupling. Evidence for this giant Rashba spin splitting is manifest in two sets of Shubnikov-de Haas oscillations associated with an inner and outer Fermi surface, Berry phase of $\pi$, substantial anisotropic magnetoresistance and a weak anti-localization correction to the magnetoconductivity. Together these results indicate a giant Rashba coupling which is an order of magnitude larger than other complex oxide interfaces such as LaAlO$_3$/SrTiO$_3$. By gating the samples with an electric field, we observe (i) quantized resistance peaks which are independent of sample dimensions in a conventional 6-terminal Hall bar geometry, (ii) a strong negative magnetoconductance near the quantized peaks in resistance, and (iii) nonlocal transport in a 4-terminal geometry. All of these observations are consistent with edge state conduction and the quantum spin Hall effect.

$^1$This work was funded by the Vannevar Bush Fellowship of the Department of Defense under Contract No. N00014-15-1-0045.
SrTiO$_3$/FeSe Superlattice for Robust Interface Enhanced Superconductivity

Kamron L. Kopecky, Sumner B. Harris and Renato P. Camata; The University of Alabama at Birmingham, United States

The unconventional, iron-based superconductor FeSe has a low $T_c$ in bulk form at 8 K but sees a massive enhancement up to as high as $\sim10^9$ K when monolayers are interfaced with the complex oxide SrTiO$_3$. The origin of this $T_c$ enhancement is due to both electron transfer from SrTiO$_3$ to FeSe as well as interfacial electron-phonon interactions. Since FeSe monolayers are highly unstable in air, protective layers must be grown on top to enable ex-situ study or application. These capping layers limit the $T_c$ enhancement to $\sim30$ K. In order to preserve the high $T_c$ as well as environmentally stabilize the FeSe layers, we have explored the growth of novel SrTiO$_3$/FeSe superlattice heterostructures by pulsed laser deposition (PLD). Starting with TiO$_2$ terminated SrTiO$_3$ single crystals as the growth substrate, alternating FeSe and SrTiO$_3$ layers are grown in a reducing, high vacuum environment. Typically, SrTiO$_3$ growth takes place in an oxygen background, but here we have achieved low to zero defect SrTiO$_3$ layers by controlling the kinetic energy of the laser-generated plasma plume by monitoring the plasma properties in-situ with planar and cylindrical Langmuir probes. The kinetic energy cut-off for both the SrTiO$_3$ and FeSe plume is kept below $\sim30$ eV by balancing the laser energy and spot size on the ablation targets. Adjusting the kinetic energy allows control over the oxygen defects, which dope electrons into the FeSe, while the superlattice structure enables double-sided interfacial electron-phonon interactions between SrTiO$_3$ and FeSe. We report on both in-situ and separate, extensive plasma measurements during PLD conditions used for superlattice growth. The plasma density can be fine-tuned over orders of magnitude between $1\times10^{18}$-$1\times10^{20}$ m$^{-3}$ by changing the spot size on the target while utilizing the same laser fluence, which changes the growth rate. The kinetic energy distribution of the plasma plume constituents is also highly tunable below the plasma absorption threshold. Ions and neutrals can be easily generated with kinetic energies as high as 150 eV if large laser spot sizes greater than $\sim6$ mm$^2$ are used. However, it is by decreasing the spot size down to 3.5 mm$^2$ or less, and thereby reducing the high-energy tail of the kinetic energy distribution, that layers with significantly fewer defects are produced. We also report on x-ray diffraction and x-ray photoelectron characterization of the superlattices.

10:15 AM INTRODUCTION AND ANNOUNCEMENTS

10:17 AM *S.NM12.05.03
Magnetic Weyl Semimetals Claudia Felser and Jacob Gayles; Max Planck Institute, Germany

Topology a mathematical concept became recently a hot topic in condensed matter physics and materials science. One important criteria for the identification of the topological material is in the language of chemistry the inert pair effect of the s-electrons in heavy elements and the symmetry of the crystal structure [1]. Beside of Weyl and Dirac new fermions can be identified compounds via linear and quadratic 3-, 6- and 8-band crossings stabilized by space group symmetries [2]. In magnetic materials the Berry curvature and the classical AHE helps to identify interesting candidates. Magnetic Heusler compounds were already identified as Weyl semimetals such as Co$_2$YZ [3-6] (Y=Ti, Mn; Z=Ge, Sn, Ga, Al), in Mn$_3$Z [7-9] (Z=Ge, Sn). Co$_3$Sn$_2$S$_2$ is a 2D Weyl semimetal with edge states [8-10].

10:47 AM *S.NM12.07.02
Controlling Quantum Materials by Nonlinear Phononics Michael Först; Max Planck Institute for the Structure and Dynamics of Matter, Germany

Irradiation with light is able to dynamically push quantum materials away from equilibrium, driving them into states with transiently perturbed magnetic and electronic properties. This field has become a rich playground for fundamental research but may also be relevant for technical applications that require ultrafast switching capabilities.

In this talk, I will focus on our use of intense terahertz and mid-infrared light fields to control quantum solids by resonant excitation of crystal lattice vibrations. This approach has been demonstrated to switch between different phases and reveal hidden states not accessible at equilibrium. Examples are the control of insulator-metal transitions[1][2][3][4], magnetism[4][5] and ferroelectricity[6][7], as well as the enhancement of superconducting coherence[8].

Anharmonicities in the crystal lattice dynamics, like rectification[9][10], parametric amplification[11] and harmonic generation[12] of optical phonons, are an important ingredient of the microscopic physics underlying these phenomena. I will present the fundamentals of these nonlinear physics and discuss how they connect to the manipulation of the magnetic and electronic phases.

Optical Signatures of a 3D Electronic Liquid Crystal in Cd$_2$Re$_2$O$_7$  

David Hsieh; California Institute of Technology, United States

In the presence of strong interactions, the fluid of mobile electrons in a metal can spontaneously break the point group symmetries of its underlying host lattice, forming an electronic analogue of a classical liquid crystal. The experimental discovery of 2D electronic liquid crystals (ELCs) was first made nearly 20 years ago in semiconductor heterostructures and has since been reported in several other systems including the copper- and iron-based high-temperature superconductors. However whether or not a 3D version of an ELC can exist has remained unclear. In this talk, I will present signatures of a 3D ELC in the strongly spin-orbit coupled metallic pyrochore Cd$_2$Re$_2$O$_7$ detected using ultrafast coherent phonon spectroscopy and a recently developed spatially-resolved nonlinear optical polarimetry technique. I will discuss implications for the possible topological superconducting phase that has been reported to emerge in Cd$_2$Re$_2$O$_7$ under pressure.

Machine Learning Data from Quantum Materials  

Eun-Ah Kim; Cornell University, United States

Decades of efforts in improving computing power and experimental instrumentation were driven by our desire to better understand the complex problem of quantum emergence. However, increasing volume and variety of data made available to us today present new challenges. I will discuss how these challenges can be embraced and turned into opportunities by employing machine learning. It is important to note that the scientific questions in the field of electronic quantum matter require fundamentally new approaches to data science for two reasons: (1) quantum mechanical imaging of electronic behavior is probabilistic, (2) inference from data should be subject to fundamental laws governing microscopic interactions. Hence machine learning quantum emergence requires collective wisdom of data science and condensed matter physics. I will review rapidly developing efforts by the community in using machine learning to solve problems and gain new insight. I will then present my group’s results on the machine-learning-based analysis of complex experimental data on quantum matter.

Probing Order and Disorder in Quantum Materials Using Scanning Transmission Electron Microscopy  

Lena F. Kourkoutis$^{1,2}$; $^1$Cornell University, United States; $^2$Kavli Institute at Cornell, United States

Coupling between charge, spin, lattice, or orbital degrees of freedom gives rise to remarkable phenomena such as colossal magnetoresistance, metal–insulator transitions and superconductivity. Many aspects of these competing interactions, however, remain elusive. Traditional bulk measurements of phases transitions, which average the material’s response over large length scales, can inferred the presences of spatial inhomogeneity. Understanding their character, however, requires local probes. Direct, real-space measurements of the onset of emerging order are key to understanding the diverse properties of complex electronic materials.

Today, atomic-resolution imaging is routinely achieved by aberration-corrected scanning transmission electron microscopy
(STEM). Coupled with spectroscopy STEM provides direct information about the local structure and chemistry of thin films and heterostructures. In this talk, I will first discuss our results on two classes of superconducting materials, the layered perovskite ruthenates and the recently reported infinite-layer nickelates [1], with particular focus on the microscopic structure, strain and the role of defects in these thin film superconductors. Going beyond room temperature STEM, cryogenic sample cooling promises direct access to low temperature phases. While limitations in hardware currently hamper STEM measurements of ruthenates and nickelates in their superconducting states, high-precision cryogenic STEM near liquid nitrogen temperature has been demonstrated [2, 3]. These new capabilities have paved a path to visualize subtle lattice and electronic orders in emergent low temperature phases as I will show in the second part of the talk. Focus will be on the lattice behavior of charge-ordered manganites, where direct imaging can discriminate between multiple structure models, and mapping over larger length scales shows phase coexistence and nanoscale inhomogeneities.

[4] Research performed in collaboration with Ismail El Baggari, Berit H. Goodge, David J. Baek, Michael J. Zachman and the groups of Harold Y. Hwang (Stanford), Darrell G. Schlom (Cornell), Kyle M. Shen (Cornell) and Beth Nowadnick (New Jersey Institute of Technology). This work was supported by the DoD, AFOSR (FA 9550-16-1-0305), NSF (DMR-1539918, DMR-1429155, DMR-1719875), and the Packard Foundation.

**Quantum Transport Properties of Cadmium Arsenide Films Grown by Molecular Beam Epitaxy** Susanne Stemmer, David Kealhofer, Luca Galletti, Timo Schumann, Manik Goyal and Honggyu Kim; University of California, Santa Barbara, United States

Interfaces and heterostructures with topological semimetals offer new opportunities to control and manipulate their unique electronic states and a wealth of associated phenomena, for example, via electric field effect, strain, or symmetry breaking. In this presentation, we will discuss recent progress in heterostructures of a prototype three-dimensional Dirac semimetal, cadmium arsenide (Cd₃As₂), which are grown by molecular beam epitaxy. We show that high-mobility, epitaxial Cd₃As₂ films can be grown in different crystallographic orientations. The easy cleavage plane of single crystals, the tetragonal (112) plane, is also the most common growth surface. In this orientation, the bulk Dirac nodes project on two points in the surface Brillouin zone. The (001) plane differs from the (112) plane and indeed all others in that the two bulk nodes project onto one point, rather than two, of the surface Brillouin zone. Here, we discuss the nature of quantum oscillations and of the quantum Hall effect of thin Cd₃As₂ films grown in both orientations. The quantum Hall effect of (112) films is characterized by a degeneracy factor of two that is lifted in fields above approximately 10 T. Gated magnetotransport and quantum capacitance revealed ambipolar quantum transport, a zero-energy Landau level, and linear dispersion in the 2D states giving rise to the quantum Hall effect. The important feature is that (112) surfaces host double Fermi arcs, which can give rise to two Fermi pockets near the center of the surface Brillouin zone and thus an even integer Hall effect until their degeneracy is lifted by the magnetic field. A single (112) surface can give rise to an integer quantum Hall effect and explain the observed characteristics. By contrast, the states of (001) films are non-degenerate and integer filling factors are due to crossing Landau levels. We will discuss other remarkable phenomena in the quantum Hall effect of (001) films. We will also discuss pathway towards realizing novel topological systems.

6:45 PM *S.NM12.09.02*
**Topological f-Electron Materials** Filip Ronning; Los Alamos National Laboratory, United States

f-electrons possess both strong electronic correlations and strong spin orbit coupling. This combination suggests that f-electron materials are ideal for discovering new topologically non-trivial phases, which arise as a consequence of strong electronic correlations. Broadly speaking, we adopt four approaches to discover new topological states of matter. First, we explore correlation driven narrow gap materials such as SmB₆. Second, in systems such as Eu₅In₅Sb₁₀, we exploit the fact that rare-earth magnetism is strongly localized, resulting in only minor perturbations to the non-interacting electronic structure. Third, we attempt to exploit (non-symmorphic) crystal symmetries for generating protected nodal crossings. Finally, we examine metallic systems such as U₃Ru₄Al₁₂ where broken time reversal symmetry can yield a finite and tunable Berry phase contribution to transverse transport measurements. This talk will review our strategies, efforts, lessons learned, and unexpected discoveries in searching for such new states of matter.
5:00 AM  S.NM12.01.01
Topologically Nontrivial Interband Plasmon in Type-II Weyl Semimetal MoTe2: Xun Jia¹², Xuetao Zhu² and Jiandong Guo²; ¹Argonne National Laboratory, United States; ²Institute of Physics, Chinese Academy of Sciences, China

In many realistic topological materials, more than one kind of fermions contribute to the electronic bands crossing the Fermi level, leading to various novel phenomena that cannot be well understood by single kind of particle picture. Here, using momentum-resolved inelastic electron scattering, we investigate the plasmons in type-II Weyl Semimetal MoTe2, in which both Weyl fermions and trivial nonrelativistic fermions contribute to the Fermi surface in the Td phase at low temperature. We observe one plasmon mode in the 1T' phase at high temperature and two plasmon modes in the topological Td phase at low temperature. Combining with first-principles calculations, we show that the plasmon modes in the Td phase, dominated by the interband transitions between the topologically nontrivial bands for Weyl fermions and the trivial bands for nonrelativistic electrons, are attributed to band splitting due to inversion symmetry breaking and the spin-orbit coupling.

5:10 AM  *S.NM12.01.02
Quantum Designer Materials and Devices by Single-Atom Manipulation Roland M. Wiesendanger; University of Hamburg, Germany

The ability to construct nano-scale systems with atomic-level precision by using STM-based single-atom manipulation techniques has led to numerous outstanding examples of Quantum Designer Physics. In particular the combination of single-atom manipulation with spin-sensitive imaging and spectroscopy [1] based on the spin-polarized STM technique [2] offers an exciting approach towards the design of specific properties of 1D spin chains [3,4] as well as 2D arrangements of tailored nanomagnets [5]. Investigating such artificially built spin arrays on superconductor surfaces has recently led to the observation of Majorana zero-energy modes in atomically well-defined magnet-superconductor hybrid systems [6] allowing for a detailed comparison with theoretical predictions. Moreover, prototypes for all-spin atomic-scale spin logic devices could be demonstrated by a bottom-up fabrication technique [7]. Another exciting research direction is the tailoring of the spin dynamics of artificially built atomic arrangements on surfaces, such as few-atom clusters [8,9] or 2D spin arrays [10]. Making use of time- and spin-resolved STM techniques [11] the spin dynamics can be tuned by the choice of the substrate, the chemical identity and number of the adatoms as well as their geometric arrangement. Interestingly, the symmetry of the adatom arrangements can have a decisive influence on the spin dynamics. This can be explained by the effect of anisotropic indirect exchange interactions which can lead to a destabilization of the spin system for atomic arrangements exhibiting a lower symmetry [10].

SESSION S.NM12.02: Theory of Quantum Matter

5:00 AM *S.NM12.02.01
The Chiral Qubit—Quantum Computing with Chiral Anomaly Qiăng Li; Brookhaven National Laboratory, United States

The quantum chiral anomaly enables a nearly non-dissipative current in the presence of chirality imbalance. We propose to utilize the chiral anomaly for the designs of qubits potentially capable of operating at THz frequency and at room temperature with a coherence time to gate time ratio of about $10^4$. The proposed “Chiral Qubit” is a micron-scale ring made of a Weyl or Dirac semimetal, with the $|0\rangle$ and $|1\rangle$ states corresponding to the symmetric and antisymmetric superpositions of chiral currents circulating along the ring clockwise and counter-clockwise. A fractional magnetic flux through the ring induces a quantum superposition of the $|0\rangle$ and $|1\rangle$ quantum states. The entanglement of qubits can be implemented through the near-field THz frequency electromagnetic fields (EMF). We show that the Hamiltonian of the chiral qubit is similar to that of the superconducting qubit. This means that quantum gates can be implemented in a traditional way, and the algorithms developed for superconducting quantum processors will apply. Light-driven (THz) ultrafast topology switching, demonstrated experimentally in Dirac/Weyl semimetal recently, will be discussed, together with its implications on THz topological quantum gate applications.

The author is grateful for collaborations with Dmitri Kharzeev and Jigang Wang. This work is supported by the US Department of Energy, Office of Basic Energy Science, Materials Sciences and Engineering Division, under contract #DE-SC0012704.

Machine Learning Data from Quantum Materials Fun-Ah Kim; Cornell University, United States

Decades of efforts in improving computing power and experimental instrumentation were driven by our desire to better understand the complex problem of quantum emergence. However, increasing volume and variety of data made available to us today present new challenges. I will discuss how these challenges can be embraced and turned into opportunities by employing machine learning. It is important to note that the scientific questions in the field of electronic quantum matter require fundamentally new approaches to data science for two reasons: (1) quantum mechanical imaging of electronic behavior is probabilistic, (2) inference from data should be subject to fundamental laws governing microscopic interactions. Hence machine learning quantum emergence requires collective wisdom of data science and condensed matter physics. I will review rapidly developing efforts by the community in using machine learning to solve problems and gain new insight. I will then present my group’s results on the machine-learning-based analysis of complex experimental data on quantum matter.

5:30 AM *S.NM12.02.03
Two-Dimensional Topological Quantum Materials with Room Temperature Stabilities—Engineered by Low-Dimensional Heterogeneities Mina Yoon; Oak Ridge National Laboratory, United States

Our understanding of two-dimensional (2D) materials has developed rapidly with the recent development of theoretical and computational capabilities, as well as the development of experimental synthesis and characterization tools. Now it has become feasible to perform atomic-level manipulations of 2D materials, such as introducing atomic defects and dopants, and engineering boundaries by applying strains and interfaces by growing them on different substrates. The rich parameter space of 2D materials makes them appealing candidates for new types of flexible electronic devices, such as topological electronics, that are stable at room temperature and operate at ambient conditions. Theoretical/computational modeling is desirable to guide experimental efforts in exploring the vast parameter space of 2D material and to identify desirable parameter space. On the other hand, modeling 2D materials in realistic experimental conditions is challenging; not only do these materials contain many atoms (exceeding thousands of atoms) but also the materials’ parameter space is highly complex. Using a prototypical topological 2D system as an example—
e.g., graphene, stanene, and 2D metal-organic frameworks—schemes combining various levels of theoretical/computational approaches were developed, including a tight-binding approach, high-throughput density functional theory calculations, data analytics, and large-scale ab initio dynamics using supercomputer capabilities at the Department of Energy’s Oak Ridge National Laboratory. The developed schemes are targeted to enhance theoretical predictability for topological materials while significantly narrowing the gap with the experimental effort toward robust topological materials.

Is Cd$_3$As$_2$ a Dirac or a Weyl Semimetal?—Symmetry Determination by Convergent Beam Electron Diffraction
Honggyu Kim$^1$, Manik Goyal$^2$, Salva S. Rezaie$^2$, Timo Schumann$^2$, Tyler Pardue$^2$, Jian-Min Zuo$^3$ and Susanne Stemmer$^2$; $^1$University of Florida, United States; $^2$University of California, Santa Barbara, United States; $^3$University of Illinois at Urbana-Champaign, United States

Cadmium arsenide (Cd$_3$As$_2$) has been identified to belong to the family of three-dimensional topological semimetal, featuring topologically stable band crossing ("nodes") in the bulk and unconventional surface states. Crystal structures reported for Cd$_3$As$_2$ differ, however, in a crucial aspect, namely the presence or absence of an inversion center, which determines whether Cd$_3$As$_2$ is Dirac or Weyl semimetals. Both types of semimetals exhibit band crossings in the bulk with linear energy dispersion in momentum space that are protected by the presence of certain crystal symmetries. While Dirac semimetals possess both time reversal and inversion symmetry, one of these (or both) is absent in Weyl semimetals. This difference defines their unique electronic structures and has profound effects on their properties. Here, we report on the determination of point group of Cd$_3$As$_2$ thin films grown by molecular beam epitaxy (MBE) using convergent beam electron diffraction (CBED). Using CBED patterns recorded from multiple zone axes and Bloch wave simulation, we demonstrate that Cd$_3$As$_2$ is a tetragonal structure with $4/mmm$ point group, possessing an inversion center and four-fold symmetry, indicative of Dirac semimetals. Lastly, we present that high-angle annular dark-field (HAADF) imaging recorded in scanning transmission electron microscopy (STEM) can be used to directly visualize the Cd vacancy ordering which further confirms our conclusion. The findings in this study offer new opportunities to unveil the symmetry-property relationship in a wide range of topological materials.

Probing Order and Disorder in Quantum Materials Using Scanning Transmission Electron Microscopy
Lena F. Kourkoutis$^{1,2}$; $^1$Cornell University, United States; $^2$Kavli Institute at Cornell, United States

Coupling between charge, spin, lattice, or orbital degrees of freedom gives rise to remarkable phenomena such as colossal magnetoresistance, metal–insulator transitions and superconductivity. Many aspects of these competing interactions, however, remain elusive. Traditional bulk measurements of phases transitions, which average the material’s response over large length scales, can inferred the presences of spatial inhomogeneity. Understanding their character, however, requires local probes. Direct, real-space measurements of the onset of emerging order are key to understanding the diverse properties of complex electronic materials.

Today, atomic-resolution imaging is routinely achieved by aberration-corrected scanning transmission electron microscopy (STEM). Coupled with spectroscopy STEM provides direct information about the local structure and chemistry of thin films and heterostructures. In this talk, I will first discuss our results on two classes of superconducting materials, the layered perovskite ruthenates and the recently reported infinite-layer nickelates [1], with particular focus on the microscopic structure, strain and the role of defects in these thin film superconductors. Going beyond room temperature STEM, cryogenic sample cooling promises direct access to low temperature phases. While limitations in hardware currently hamper STEM measurements of ruthenates and nickelates in their superconducting states, high-precision cryogenic STEM near liquid nitrogen temperature has been demonstrated [2, 3]. These new capabilities have paved a path to visualize subtle lattice and electronic orders in emergent low temperature phases as I will show in the second part of the talk. Focus will be on the lattice behavior of charge-ordered manganites, where direct imaging can discriminate between multiple structure models, and
mapping over larger length scales shows phase coexistence and nanoscale inhomogeneities.

[4] Research performed in collaboration with Ismail El Baggari, Berit H. Goodge, David J. Baek, Michael J. Zachman and the groups of Harold Y. Hwang (Stanford), Darrell G. Schlom (Cornell), Kyle M. Shen (Cornell) and Beth Nowadnick (New Jersey Institute of Technology). **Quantum Transport Properties of Cadmium Arsenide Films Grown by Molecular Beam Epitaxy** Susanne Stemmer, David Kealhofer, Luca Galletti, Timo Schumann, Manik Goyal and Honggyu Kim; University of California, Santa Barbara, United States

Interfaces and heterostructures with topological semimetals offer new opportunities to control and manipulate their unique electronic states and a wealth of associated phenomena, for example, via electric field effect, strain, or symmetry breaking. In this presentation, we will discuss recent progress in heterostructures of a prototype three-dimensional Dirac semimetal, cadmium arsenide (Cd₃As₂), which are grown by molecular beam epitaxy. We show that high-mobility, epitaxial Cd₃As₂ films can be grown in different crystallographic orientations. The easy cleavage plane of single crystals, the tetragonal (112) plane, is also the most common growth surface. In this orientation, the bulk Dirac nodes project on two points in the surface Brillouin zone. The (001) plane differs from the (112) plane and indeed all others in that the two bulk nodes project onto one point, rather than two, of the surface Brillouin zone. Here, we discuss the nature of quantum oscillations and of the quantum Hall effect of thin Cd₃As₂ films grown in both orientations. The quantum Hall effect of (112) films is characterized by a degeneracy factor of two that is lifted in fields above approximately 10 T. Gated magnetotransport and quantum capacitance revealed ambipolar quantum transport, a zero-energy Landau level, and linear dispersion in the 2D states giving rise to the quantum Hall effect. The important feature is that (112) surfaces host double Fermi arcs, which can give rise to two Fermi pockets near the center of the surface Brillouin zone and thus an even integer Hall effect until their degeneracy is lifted by the magnetic field. A single (112) surface can give rise to an integer quantum Hall effect and explain the observed characteristics. By contrast, the states of (001) films are non-degenerate and integer filling factors are due to crossing Landau levels. We will discuss other remarkable phenomena in the quantum Hall effect of (001) films. We will also discuss pathway towards realizing novel topological systems.

**Optical Signatures of a 3D Electronic Liquid Crystal in Cd₂Re₂O₇** David Hsieh; California Institute of Technology, United States

In the presence of strong interactions, the fluid of mobile electrons in a metal can spontaneously break the point group symmetries of its underlying host lattice, forming an electronic analogue of a classical liquid crystal. The experimental discovery of 2D electronic liquid crystals (ELCs) was first made nearly 20 years ago in semiconductor heterostructures and has since been reported in several other systems including the copper- and iron-based high-temperature superconductors. However whether or not a 3D version of an ELC can exist has remained unclear. In this talk, I will present signatures of a 3D ELC in the strongly spin-orbit coupled metallic pyrochore Cd₂Re₂O₇ detected using ultrafast coherent phonon spectroscopy and a recently developed spatially-resolved nonlinear optical polarimetry technique. I will discuss implications for the possible topological superconducting phase that has been reported to emerge in Cd₂Re₂O₇ under pressure.

5:15 AM *S.NM12.04.02*
**Inelastic X-Ray Scattering on Tungsten Carbide** Qingan Cai; University of California, Riverside, United States
Tungsten carbide (WC) is widely used in industrial field due to its excellent performance in hardness, roughness and high melting temperature. Bulk modulus measuring the resistant to compression is related to phonon dynamics as well. In recent work, phonon transport properties of topological metals WC and WN are investigated, the thermal conductivity of WC is found to be two orders of magnitude higher than that of WN because the large acoustic-optical gap prohibits the acoustic+acoustic®optical scattering[1]. A first-principles study on phonon related properties of tungsten carbide has been published and the calculated phonon dispersion of WC can be referred, but experimental investigations still need to be conducted. In our work phonon dispersion relation of tungsten carbide in high symmetry directions has been measured by inelastic X-ray scattering. Super resolution is applied to extract phonon lifetime. Ab initio phonon calculation based on Density Function Theory is compared to the experimental results with excellent agreements. Furthermore, inelastic scattering intensity has been simulated at various q points. Our dispersion results are essential for understanding the thermal conductivity and chiral phonons in tungsten carbide.

Polarized photons can excite the chiral phonons at Brillouin-zone corners in honeycomb lattices with threefold rotational broken inversion symmetry in monolayer tungsten disulfide. Tungsten carbide with space group P-6m2 (No.187) is a good candidate for experiments for underlying chiral phonons. We generate circular polarized X-ray to detect the phonon intensity change at zone boundary (K) in tungsten carbide. Present scattering theory could not be applied in our experiment results.

5:00 AM S.NM12.05.01
Magnetic Weyl Semimetal Properties Controlled by Non-Magnetic Doping Dimuthu Obeysekera1,2, Virginia Carnevali1, Andrew Supka1, Keith M. Taddei3, Clarina dela Cruz2, Marco Fornari1 and Junjie Yang1,2; 1Central Michigan University, United States; 2New Jersey Institute of Technology, United States; 3Oak Ridge National Laboratory, United States

New mechanisms that result in controllable ferromagnetism (FM) in a Weyl semimetal are of utmost importance for the advancement of the science of topological materials. Here, we report the FM behavior induced by non-magnetic doping and the emergence of magnetic Weyl states in SrMn1-xZnxSb2. Building on a synergy between experimental data and first principles calculations we will show that mixing non-magnetic SrZnSb2 with antiferro-magnetic (AFM) SrMnSb2 leads to FM SrMnSb2 and SrZn0.25Mn0.75Sb2 with strong spin-orbit coupling. From the computed band structures and fermi surface, we deduce semimetal, small-gap insulator and Weyl semimetal character for SrZnSb2, SrMnSb2 and SrZn0.25Mn0.75Sb2 respectively.

Samples of SrMn1-xZnxSb2 (x = 0.065 and 0.262) were synthetized and characterized. Non-trivial de-Haas van Alphen and Shubnikov – de Haas oscillations were measured, supporting the theoretical finding of Weyl semimetal nature for SrMn1-xZnxSb2. Our results show that non-magnetic doping is an important parameter that could be used to discover new magnetic topological Weyl semimetals.

5:10 AM *S.NM12.05.03
Magnetic Weyl Semimetals Claudia Felser and Jacob Gayles; Max Planck Institute, Germany

Topology a mathematical concept became recently a hot topic in condensed matter physics and materials science. One important criteria for the identification of the topological material is in the language of chemistry the inert pair effect of the s-electrons in heavy elements and the symmetry of the crystal structure [1]. Beside of Weyl and Dirac new fermions can be identified compounds via linear and quadratic 3-, 6- and 8- band crossings stabilized by space group symmetries [2]. In magnetic materials the Berry curvature and the classical AHE helps to identify interesting candidates. Magnetic Heusler compounds were already identified as Weyl semimetals such as Co2YZ [3-6] (Y=Ti, Mn; Z=Ge, Sn, Ga, Al), in Mn3Z [7-9] (Z=Ge, Sn). Co3Sn2S2 is a 2D Weyl semimetal with edge states [8-10].

Topological Quantum Phenomena in Correlated Oxide Heterostructures Ho Nyung Lee; Oak Ridge National Laboratory, United States

Many physical phenomena in condensed matter arise from strong correlation and spin-orbit coupling (SOC), and their proper control is important for creating novel quantum materials (QMs), such as Mott insulators, quantum spin liquids, topological insulators, Weyl semimetals, etc. to name a few. As the importance of quantum information science emerges, there is an increased attention to QMs to address the need for new materials for addressing challenges in quantum computing and sensing. Among many classes of QMs, complex oxides offer a rich playground to exploit both correlations of Coulombic interactions between electrons often found in 3d transition metal oxides (TMOs) and SOC from heavy metal based 5d TMOs, such as SrIrO$_3$ and Na$_2$IrO$_3$, leading to many intriguing physical properties. Hybrid materials with a proper balancing of the correlation and SOC offer unique opportunities to discover new properties, and heterostructuring or combining dissimilar materials is a great approach to harnessing the complex interplay between quantum wavefunctions and various control parameters, such as proximity, dimensionality, topology, and symmetry. In this talk, I will review recent progresses in topological quantum materials and present our recent work on topological Hall effect from chiral magnetism and its control via interfacial symmetry control. Furthermore, an effort to combine topology and correlation to develop correlated topological materials and an approach to develop novel Berry phase engineered heterostructures will be presented.

Exploring Non-Equilibrium Phases with Ultrafast X-Rays John Freeland; Argonne National Laboratory, United States

With the explosion of recent work exploring the out of equilibrium energy landscape of quantum materials, a need has developed to expand the set of available tools to be able to follow these dynamic pathways in as much details as possible. A key aspect of this mode of exploration is the ability to follow these trajectories to map the energy landscape to understand how the phases evolve and ideally seek out new states. However, this requires the ability to extract as much detail about the how the crystalline, electronic and magnetic properties change on ultrafast timescales. Here I will talk about how time-resolved X-ray probes at synchrotrons and free electron lasers can allow one to separate explore these degrees of freedom.
Such direct information about the evolution of lattice, electronic, and magnetic order can then be merged with theoretical studies to build a clear model to describe the ultrafast evolution of the system. To illustrate the possibilities, I will present examples ranging from decoupling order parameters in Nickelates and optical creation of hidden structural phases in Titanate superlattices[1]. This work will highlight what is possible with today's X-ray sources and potential experiments we can consider in the very near future.

The work at Argonne is supported by the U.S. Department of Energy, Office of Science, under Contract No. DE-AC02-06CH11357. The development of the materials and ultrafast experiments is supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences under Award Number DE-SC-0012375.

5:15 AM *S.NM12.07.02
Controlling Quantum Materials by Nonlinear Phononics Michael Först; Max Planck Institute for the Structure and Dynamics of Matter, Germany

Irradiation with light is able to dynamically push quantum materials away from equilibrium, driving them into states with transiently perturbed magnetic and electronic properties. This field has become a rich playground for fundamental research but may also be relevant for technical applications that require ultrafast switching capabilities. In this talk, I will focus on our use of intense terahertz and mid-infrared light fields to control quantum solids by resonant excitation of crystal lattice vibrations. This approach has been demonstrated to switch between different phases and reveal hidden states not accessible at equilibrium. Examples are the control of insulator-metal transitions[1][3][5], magnetism[4][5] and ferroelectricity[6][7], as well as the enhancement of superconducting coherence[8]. Anharmonicities in the crystal lattice dynamics, like rectification[9][10], parametric amplification[11] and harmonic generation[12] of optical phonons, are an important ingredient of the microscopic physics underlying these phenomena. I will present the fundamentals of these nonlinear physics and discuss how they connect to the manipulation of the magnetic and electronic phases.

Imaging Spin-Filter (Au/Ir) for Momentum Microscopy Marten Patt1, Nils Weber2, Matthias Escher2, Timna-Joshua Kuehn2, Michael Merkel2 and Brandon Giles1; 1Scienta Omicron GmbH, Germany; 2FOCUS GmbH, Germany
Momentum Microscopy is a new technique in surface science, in which the momentum distribution of photoelectrons is projected onto an image plane. This image plane can be energy-filtered by a double-hemispherical electrostatic analyzer (NanoESCA) to achieve a monochromatic momentum distribution. Scanning the energy along the valence band is then used for band structure mapping which is a key technique to understand the electronic structure of novel materials.

A new innovative method is to use the monochromatic electron distribution behind the double-hemispherical analyzer to retard it to the needed scattering energy of an Au/Ir (100) single crystal. This allows for spin-polarization dependent reflection, which enables a highly efficient imaging spin-filter technique [1].

We will show recent band-structure measurements of several TMDCs acquired with the NanoESCA and discuss the latest technical improvements of momentum microscopy with respect to 2D material characterization. First results of the imaging spin-filter installed at the ELI-Alps NanoESCA are shown, demonstrating its efficiency in real-space microscopy (e.g. imaging of magnetic domains) and in spin-resolved band-structure mapping.

Topological semimetals such as Weyl and Dirac systems are three-dimensional phases of matter characterized by topology and symmetry protected gapless electronic excitations. These three-dimensional analogs of graphene have generated a lot of interest recently given that their quasiparticles display properties akin to those of relativistic and chiral fermions in particle physics. Their unconventional electronic structures are predicted to lead to protected surface states and to unconventional responses to applied electric and magnetic fields. In the past few years, we have studied a few of these compounds [1-11] under high magnetic fields, with the goal of i) extracting their electronic structure at the Fermi level in order to ii) compare it with theoretical predictions, and of iii) exposing their transport properties which are expected to be unconventional due to their “topological” character. Here, after a brief introduction, we will focus on the magnetoresistivity and the Hall-effect of the type-I Weyl semimetal TaAs in an attempt to address the strong controversy surrounding its anomalous transport properties in relation to its bulk topological character. For fields and currents along the basal plane, we observe a very pronounced planar Hall effect (PHE) upon field rotation with respect to the crystallographic axes at temperatures as high as $T = 100$ K [10]. Parametric plots of the PHE signal as a function of the longitudinal magnetoresistivity (LMR), collected at $T = 10$ K, lead to concentric traces as reported for Na$_3$Bi and GdBiPt suggesting that both the negative LMR and the PHE observed in TaAs are intrinsically associated to the axial anomaly among its Weyl nodes. For fields nearly along the $a$ axis we also observe hysteresis as one surpasses the quantum limit, where the magnetic torque indicates a change in regime as the field increases, i.e., from paramagnetism and diamagnetism due to Weyl fermions above and below the Weyl node(s), respectively, to a paramagnetic one associated with the field-independent $n = 0$ Landau level. Hysteresis coupled to the overall behavior of the torque would be consistent with a topological phase transition associated with the suppression of the Weyl dispersion at the quantum limit. This transition leads to the suppression of the negative LMR confirming that it is associated to the Weyl dispersion [10]. Finally, for fields along the $c$ axis the Hall effect reveals two successive changes in slope, or two successive decrements in carrier mobility, one at the quantum limit and a second one at the critical field where a phase transition toward an insulating state was recently reported. This suggests the possibility of two successive phase transitions as a function of the field with the higher-field one involving solely the $n = 0$ Landau level. For both field orientations we observe Shubnikov–de Haas like oscillations beyond the quantum limit therefore involving quasiparticles at fractional filling factors.

Topological f-Electron Materials Filip Ronning; Los Alamos National Laboratory, United States

f-electrons possess both strong electronic correlations and strong spin orbit coupling. This combination suggests that f-electron materials are ideal for discovering new topologically non-trivial phases, which arise as a consequence of strong electronic correlations. Broadly speaking, we adopt four approaches to discover new topological states of matter. First, we explore correlation driven narrow gap materials such as SmB$_6$. Second, in systems such as Eu$_3$In$_2$Sb$_6$ we exploit the fact that
rare-earth magnetism is strongly localized, resulting in only minor perturbations to the non-interacting electronic structure. Third, we attempt to exploit (non-symmorphic) crystal symmetries for generating protected nodal crossings. Finally, we examine metallic systems such as U₃Ru₄Al₁₂ where broken time reversal symmetry can yield a finite and tunable Berry phase contribution to transverse transport measurements. This talk will review our strategies, efforts, lessons learned, and unexpected discoveries in searching for such new states of matter.

Exotic Topological and Other Complex Phases of Quantum Matter—Progress toward First-Principles Modeling of Strongly Correlated Materials Arun Bansil; Northeastern University, United States

Predictive capabilities of the widely used band theory paradigm, despite its spectacular successes, have been limited to weakly correlated materials.[1-3] I will discuss how advanced density functionals are enabling new insights into the electronic structure, phase diagrams and magnetism of a wide variety of materials that have been considered to be so strongly correlated as to lie outside the scope of first-principles treatment. A spectacular example is that of the cuprate high-Tc superconductors in which the density functional theory fails to correctly predict the half-filled parent compounds to be insulators. In sharp contrast, however, the recently constructed SCAN functional [4] not only reproduces the insulating character and magnetism of the half-filled cuprates, but also captures the transition to the metallic state with doping without invoking any free parameters such as the Hubbard U. [5,6] I will also discuss with examples drawn from our recent work on the opportunities for a new generation of predictive modeling of correlated topological and non-topological phases of quantum matter more generally. Work supported by the U.S. Department of Energy.

5:15 AM S.NM12.10.04
Chiral Anomaly in Dirac Semimetal PtSe₂ for Field-Modulated Electronics with Integrated Sensing and Logic Functions Jiewei Chen; HKPU, Hong Kong

Efficient electric transport is one of the key topics in modern electronics. Generally, electrons scattering is unavoidable for ordinary current flowing through the materials. Different from this, chiral anomaly current in Dirac semimetals is the charge pumping process with inhibited electrons scattering. Here, we investigate the application of chiral anomaly current for field-effect efficient electronics with integrated sensing and logic functions. The type-II Dirac is theoretically predicted through first-principle calculations in Dirac semimetal PtSe₂ and experimentally investigated by magnetotransport behaviors. Angle-dependent longitudinal negative magnetoresistance (MR) is observed in prepared devices and when electric field is parallel to the magnetic field, there is the maximum magnetic conductance value proportional to B². Besides sensitive to the angles and magnetic field strength, chiral anomaly current can be well field-modulated by ion liquid. Moreover, AND-OR logic operation and three-inputs coincidence detection are demonstrated by using chiral anomaly properties. Our results provide new sights on achieving field-modulated electronics with integrated sensing and logic functions based on the chiral anomaly current with inhibited electrons scattering.

Epitaxial Growth of Topological Insulators on Compliant BaF2/Si Substrates Karen Long1, Patrick Taylor2 and Jiwei Lu3; 1Naval Surface Warfare Center, United States; 2U.S. Army Research Laboratory, United States; 3University of Virginia, United States

The rapid evolution of topological matter has led to strong interest in electronic and spintronic devices that can leverage the unique and attractive physics of the topological surface states. One path to integrate both topological-based devices with classical electronics (CMOS) would be to grow the materials on silicon. Because topological properties can be affected by strain and because the mismatch in thermal expansion coefficients between silicon and bismuth telluride is approximately a factor of 10, techniques to mitigate strain are of interest. In this report, we investigated the use of a unique strain-compliant barium-fluoride-based buffer layer to mitigate the effects of thermal expansion strain between Bi2Te3 and Si. Under our previous research we have shown that BaF2 can be latticed matched to Si by first growing a compliant BaSi2 layer. These thin films have been grown in our MBE (molecular beam epitaxy) system of various thicknesses and partial coverage. With partial coverage, the result is (111) BaF2triangles. We observe that growing Bi2Te3 on BaF2 reduces twinning because of the excellent lattice matching. Ionic substrates such as BaF2 have been shown to n dope graphene and their strong bonds can influence several monolayers, thus the nature of the substrate can be used to control the properties of the topological insulator. Recently, we have grown Bi2Te3 on BaF2/Ba-Si/Si with good results. Growing on a substrate with partial coverage showed good Bi2Te3 domain alignment with the BaF2 domain. The BaF2 triangles effectively create a nanostructure surface where the topological insulator is exposed to different surface energies. Hall probe results have shown that the Bi2Te3 grown on BaF2/Si is n type with good mobility. Excellent crystal structure was confirmed by XRD (x-ray diffraction). Here we report our results of growing Bi2Te3 on BaF2/Si and Bi2Se3 on SrF2/Si of various thickness and partial coverage as well as discuss potential applications for DoD.

5:10 AM S.NM12.11.02
Epitaxial Growth and Tuning of the Chiral Anomaly in MBE-Grown Gd0.95La0.05PtSb Thin Films and Membranes Dongxue Du1, Laxman R. Thoutam2, Chenyu Zhang1, Sebastian Manzo1, Vivek Saraswat1, Patrick J. Strohbeen1, Konrad Genser2, Paul Voyles1, Michael S. Arnold1, Bharat Jalan3, Karin M. Rabe2 and Jason K. Kawasaki1; 1University of Wisconsin-Madison, United States; 2Rutgers, The State University of New Jersey, United States; 3University of Minnesota, United States

Weyl semimetals (WSM) are topologically non-trivial materials hosting massless chiral fermions. However, to date nearly all measurements of Weyl semimetals have been conducted on bulk crystals, which have limited ability to tune via external parameters such as electrostatic gating or strain. Here, we report the first epitaxial growth of the Weyl semimetal candidate Gd0.95La0.05PtSb, using molecular beam epitaxy. We grow these materials in two forms: (1) epitaxial Gd0.95La0.05PtSb films on Al2O3 (0001) substrates, and (2) semi-freestanding membranes grown on graphene-terminated Al2O3, using the so-called "remote epitaxy."

For x<0.95 the Gd0.95La0.05PtSb films adopt a hexagonal stuffed wurtzite structure (LiGaGe-type, P6_3 mc), while the x=1 end member GdPtSb has cubic half Heusler structure. Angular dependent magnetotransport measurements of GdPtSb reveal a negative magnetoresistance that is highly dependent on angle, consistent with the chiral anomaly. More detailed measurements as functions of Gd/La doping (magnetic moment and cubic/hexagonal structural transition) and electrostatic gating will also be discussed.

We also demonstrate the epitaxial growth of LaPtSb on graphene-terminated Al2O3 (0001). Despite the presence of monolayer graphene, the LaPtSb film adopts epitaxial registry with the underlying Al2O3 substrate, as confirmed by X-ray diffraction and transmission electron microscopy measurements. Due to the weak coupling between film and substrate across the graphene barrier, the LaPtSb film can be mechanically exfoliated using tape, to yield a free-standing membrane. Using in-situ photoemission, electron diffraction, and scanning probe microscopy, we will comment on the atomic scale mechanisms for growth. We will also discuss how the magnetic and transport properties Gd0.95La0.05PtSb membranes can be actively tuned via strain.

**History of BioMEMS and Fabrication Processes** Dorian Liepmann; University of California, Berkeley, United States

The tutorial sessions will introduce an overview of the history of BioMEMS materials and fabrication processes. Then the fundamentals of microfluidics will be presented focused on the designing microfluidic systems. This will include application of scaling analyses. The effects of two-phases, e.g. molecules and particles, on the dynamics of the system will be discussed along with the appropriate non-dimensional numbers needed to predict the overall behavior of the flow. A similar discussion of the effects and uses of increasing the size of the flow channels in 3-D printed devices will be given. After the microfluidic section, the tutorial will switch focus to measurement techniques that can be used in bioMEMS devices including optimization of the signal to noise for accurate measurements. Lastly, current systems and applications will be presented and discussed.

**Nanotechnology for Microfluidics and Advanced Sensors** D. Sakthi Kumar; Toyo University, Japan

Microfluidic devices are getting lot of attractions to use as an intermediate step between in vitro and in vivo conditions since it can mimic and simulate the in vivo conditions. Currently, work is progressing to construct microfluidic devices, having many organs, implanted using multiple cell lines, in other way to develop “Human on a Chip”, which may be able to obtain the physiology of an individual human being as such, will enable to work towards personalized precision medicine and can be used for many advanced rug related experiments. Based on this concept, the area of microfluidics is rapidly evolving into a sophisticated technology that may cater the futuristic need for the point-of-care (POC) devices and human-on-chip (HOC) systems with integrated sensors for autonomous and specific applications in biomedical, chemical, food or environmental research. Futuristic application of HOC system, can be visualized to integrate it to Artificial Intelligence (AI) so that it can provide the information about the potential threat for the health conditions in very early stage itself that can transform the medical field and can be the next development in the medical field sought for.

Re-engineering RNA Molecules into Therapeutic Agents—The Expanding Universe of Nucleic Acid Modifications Martin Egli; Vanderbilt University, United States

First-generation nucleic acid analogs such as 2¢-deoxy-2¢-fluoro-RNA (2¢-F RNA), 2¢-O-methyl RNA (2¢-OME RNA), and the phosphorothioates (PS-DNA/RNA) have remained staples of oligonucleotide modification strategies in the discovery and optimization of potential RNAi therapeutics.1,2 The first FDA-approved siRNA drug, patisiran (Onpattro) contains eleven 2¢-OME ribonucleotides in the sense and antisense strands formulated in a lipid nanoparticle (LNP) delivery system.3 Despite their overall appeal in terms of enhanced nuclease resistance, increased pairing stability (2¢-F/OME RNAs) and safety, newer analogs are needed to further improve the therapeutic potential of unformulated siRNAs like GalNAc conjugates. The search for oligonucleotides with therapeutic efficacy has given rise to an expanding universe of analogs, including the second-generation 2¢-O-(2-methoxyethyl)-RNA (MOE-RNA)4 and the third-generation bicyclic nucleic acids (BNAs or LNAs).5 The key enzyme in RNA interference (RNAi) is Argonaute 2 (Ago2), a dynamic multi-domain enzyme that binds multiple regions of the guide (antisense) and passenger (sense) siRNAs. Considering the complexity of protein-RNA interactions in RNA interference, it is imperative to expand the process of discovery and optimization of modified siRNAs to new analogs.6 We have explored the potential benefits for efficacy of incorporating into siRNAs sugar modifications like N-methylacetamide (NMA), 5¢-E-vinylphosphonate (5¢-E-VP) and, more recently, xeno-nucleic acid (XNA)7 residues such as glycol nucleic acid (GNA),8 altritol nucleic acid (ANA),9 and threofuranosyl nucleic acid (TNA).10 The talk will summarize siRNA modification strategies with an emphasis on regiospecific interactions between oligonucleotide and Ago2 and how structural insights based on crystallographic data for modified RNAs alone and in complex with Ago2 from molecular modeling studies can guide the choice of chemical modification at a given position of siRNA for optimizing its therapeutic efficacy.

5:45 PM *S.SM01.04.02
Delivery of RNAi Therapeutics—Tackling a Billion Years of Evolutionary Defenses with New Chemistry Steven F. Dowdy and Ian Huggins; University of California, San Diego, United States

Cancer is a complex genetic moving target that requires a therapeutic modality capable of selectively targeting all driver oncogenes combined with the inherent ability to undergo pharmaco-evolution to target new mutations at pace with the cancer cell mutation rate. siRNA RNA-interference (RNAi) therapeutics fulfill these criteria and have great potential to treat cancer and other human diseases. However, due to their 14 kDa size and 40 negative anionic charges, siRNAs have no bioavailability to overcome a billion years of evolutionary defenses to prevent RNAs from crossing the endosomal lipid bilayer to enter the cytoplasm. Consequently, developing anti-cancer RNAi therapies requires targeted delivery to malignant cells and paradigm-shifting technology to enhance endosomal escape into the cytoplasm, the critical rate-limiting delivery step. Our research is focused on solving these problems by synthesis of bioreversible charge neutral RNAi prodrugs,
called short interfering Ribonucleic Neutrals (siRNNs), and synthesis of novel hydrophilic-masked, hydrophobic endosomal escape domains (EEDs). For targeting domains, we have focused on conjugating antibodies to siRNN RNAi triggers to generate Antibody-RNAi Conjugates (ARCs).

6:15 PM *S.SM01.04.04
A Traceless Linker for Aliphatic Amines that Rapidly and Quantitatively Fragments after Reduction
Niren Murthy1,2; 1University of California, Berkeley, United States; 2Innovative Genomics Institute, United States

Reduction sensitive linkers have the potential to transform the field of drug delivery due to their ease of use and selective cleavage in intracellular environments. However, despite their compelling attributes, using reduction sensitive linkers for biomolecule conjugation reactions is still challenging because linkers have not been developed that can efficiently modify aliphatic amines and release them rapidly and completely after reduction. Developing reduction sensitive self-immolative linkers for aliphatic amines has been challenging due to their poor leaving group ability and high pKa values. Here we present a traceless linker (TRAILER), which can for the first time modify aliphatic amines and release them rapidly and quantitatively after disulfide reduction. We show here that TRAILER can reversibly modify the lysine residues on the Cas9 protein, with the cell penetrating peptide Arg10, and was able to generate a self delivering Cas9 RNP that could edit cells without transfection reagents. TRAILER has numerous applications in biotechnology given the ubiquitous presence of aliphatic amines on small molecule and protein therapeutics.

6:45 PM S.SM01.04.06
Escaping from microRNA Biogenesis—A Crucial Factor for Designing Functional Antisense microRNAs for Therapy
Ramasamy Paulmurugan1 and Venkatesan Renugopalakrishnan2,3; 1Stanford University School of Medicine, United States; 2Harvard Medical School, United States; 3Northeastern University, United States

Non-coding ribonucleic acids (ncRNAs) are a diverse group of RNA molecules that are not translated into proteins following transcription. Mainly, microRNAs and long non-coding RNAs (lncRNAs) are predominant in this group. Aberrant expression of these ncRNAs has been observed in various pathological conditions including cancer. Especially, aberrant expression of microRNAs and the associated pathology has been extensively studied in cancer. Hence, targeting microRNAs has been considered a new generation of molecularly targeted therapy for various diseases. While downregulation of cellular microRNAs can be supplemented by delivering microRNA mimics, functional knock down of microRNAs that are overexpressed in diseases is a challenging task. The secondary structure of microRNAs determines how to functionally inhibit the translation of target mRNAs. MicroRNAs with even a few base homologies to the target can functionally regulate mRNA degradation/translation. The secondary structure of microRNA is crucial for recognizing target mRNA for functional effect. Since the double stranded RNA is an important intermediate in the biogenesis process of matured microRNA, delivering antisense microRNA for functional knock down of endogenous microRNAs needs a careful design. Especially challenging is their site-targeted delivery. We study antisense microRNAs with various structural determinants (mere homology, end loops, base pair modifications, artificial linkage, etc.) by molecular dynamics of the duplex formation at 1 micro second and beyond, for the evaluation of the therapeutic effect of microRNAs in various cancer models (GBM: antisense miR-21 and antisense miR-100; Breast cancer antisense miR-21 and antisense miR-10b; Hepatocellular carcinoma: antisense miR-21, antisense miR-10b and antisense miR-100). In this presentation, we summarize how structural modification in antisense microRNAs can be used for potential applications in cancer therapy, either microRNA targeting as a monotherapy, or for improving clinical chemotherapy.

Role of Protein Corona on Oligonucleotide Delivery and Transfection with Lipid Nanoparticles Mansoor Amiji; Northeastern University, United States

Upon systemic administration of nanoparticles used in drug and gene delivery, they acquire a “biological identity” upon adsorption of plasma proteins. The protein corona layer has significant implication in the biodistribution, target specific localization, and toxicity of nanoparticle-based delivery systems. Additionally, specific enrichment of proteins may allow for an endogenous and more efficient approach for targeted delivery.

Using a wide ranging of lipid nanoparticle (LNP) formulation where individual lipid composition was varied, we have shown specific protein enrichment pattern and differential biodistribution and tumor-specific delivery of small interfering RNA (siRNA). For instance, DOTAP functionalized LNPs showed vitronectin enrichment and enhanced \textit{in vivo} tumor delivery of the nanoparticles to αvβ3 expressed tumors and endothelial cells as compared to αvβ3 negative tumors.

9:40 AM *S.SM01.09.01
Intracellular Delivery of mRNA; Exploration of Delivery Materials for Next Generation Therapeutics David Ulkoski; AstraZeneca PLC, United Kingdom

Current advances in RNA-based technologies such as therapeutic gene editing, mRNA therapeutics, and vaccines have produced strong interest and attention in safe and effective nonviral vectors for nucleic acid delivery. Nevertheless, the comprehensive application of nucleic acid therapeutics is still limited by the need for better delivery systems. Thus, the analysis of these delivery materials can be advanced to offer sharper insights into SAR learnings and provide a clearer picture of their therapeutic potential. Lipid- and polymer-based materials can be regarded as the most prominent partners for nucleic acid delivery, providing \textit{in vivo} transfection. Over the past few decades, a variety of cationic lipids and polymers have been synthesized, evaluated and applied as successful delivery vehicles for nucleic acids. Here, I will discuss some of the challenges for clinical translation of mRNA-based therapeutics and give examples of the biomaterials and delivery strategies we are investigating for the application of mRNA delivery.

SESSION S.SM01.10: Live Keynote III: CRISPR Based Technologies

CRISPR-Powered Transistors—Harnessing Biology as Technology Kiana Aran; Keck Graduate Institute, United States

We have recently developed a CRISPR powered, electronic biosensor termed, CRISPR Chip, capable of detecting the binding interactions between nuclease deactivated CRISPR with its target DNA sequence. CRISPR-Chip is a graphene field effect transistor (gFET) where the surface of the graphene is functionalized with nuclease deactivated CRISPR RNA-guided ribonucleoproteins (dRNPs). dRNPs within the CRISPR-Chip construct interact with their target sequence by scanning the genomic sample until they find and bind to their target. The selective hybridization of the target DNA to the dRNP complex modulates the graphene’s conductivity and results in a detectable change in electrical signal output which can be measured with a simple handheld reader. CRISPR-Chip was able to detect dRNP binding to two commonly deleted exon target sequences within the human dystrophin gene, without amplification. CRISPR-chip is the first example of CRISPR-powered electronic transistors that harnesses the search function of CRISPR/Cas9 and the ultra-sensitivity of graphene-based nanoelectronics to enable a complete label-free and amplification-free DNA biosensor.

5:00 AM *S.SM01.01.02 Nonenzymatic Biosensor Based Lab-on-a-Chip Device for Multi Organ Functional Analysis Satheesh Babu; Amrita Vishwa Vidyapeetham, India

A lab-on-a-chip diagnostic device for the point of care testing of non-communicable diseases has been developed considering the requirements of low cost, ease of use and diagnosis at every door-step. The device is capable of monitoring diabetes, chronic kidney and liver disorders, gout and oxidative stress-related diseases through simultaneous measurement of glucose, creatinine, bilirubin, uric acid and ascorbic acid from a single drop of body fluid. This device eliminates geographic, economic and rural barriers in healthcare and will revamp healthcare by providing access to affordable technology for better management of major non-communicable diseases.

The device consists of three parts, nanomaterial-based electrochemical sensors, a microfluidic chip and an electronic meter with read-out.

A disposable non-enzymatic, electrochemical creatinine sensor was developed using copper nanoparticles modified screen-printed carbon electrodes. The detection was based on the formation of soluble copper–creatinine complex at the applied potential. The sensor exhibited excellent response towards creatinine in the range of 6.25–378.5 μM at the physiological pH making it highly suitable for real sample analysis.

Non-enzymatic, electrochemical detection of bilirubin was carried out on disposable screen-printed carbon electrodes. The sensor exhibited excellent catalytic response towards bilirubin in the range of 5–600 μM at pH 8.5 making it highly suitable for real sample analysis. The sensor was successfully used to analyze albumin-bilirubin complex formation. The effect of ibuprofen on the unbinding of bilirubin-albumin complex was also demonstrated with the sensor.

Non-enzymatic, electrochemical detection of glucose was carried out on Pt-CuO-rGO modified SPE. The sensor exhibited excellent catalytic response towards glucose in the range of up to 27 mM in alkaline pH. A disposable non-enzymatic electrochemical sensor for AA was fabricated using copper hydroxide nanorods. The sensor works at very low potential with excellent linearity (0.0125–10 mM), sensitivity (268 μA/mM/cm²) and selectivity. The electrochemical detection of UA was carried out on activated SPCE in 0.1 M PBS. The sensor showed good linear response for UA in the range 100–1000 μM. A comparison of blood serum analysis results with those obtained from conventional clinical methods was highly correlative which further reiterates the potential of the developed sensors for POCT application.

Non-enzymatic electrochemical sensors were integrated into the microfluidic chip and tested with the indigenously developed programmable electronic meter. The device provides the preprogrammed potentials to the sensor electrodes which resulted in the oxidation of respective analyte on the working electrode. The voltage proportional to the reaction current was fed to the microcontroller from each analog front end. With the help of the calibration equation programmed into the microcontroller, the obtained voltage is converted into the corresponding analyte concentration and the results were displayed on the graphical LCD screen.

The developed LOC device is completely portable, handheld and can provide test results typically within a few minutes. The device is very simple to use and can be operated even by an individual with minimal technical training. Thus, the device will play a positive role in the prevention and management of non-communicable diseases namely diabetes, chronic kidney and liver disorders, gout and oxidative stress-related diseases, ensure better quality of life and also reduce the economic and social burden.
5:15 AM *S.SM01.01.04
Resonance Frequency Modulation for Rapid Point-of-Care Ebola Glycoprotein Diagnosis with a Graphene-Based Field-Effect Bio-Transistor Junhong Chen1,2; 1The University of Chicago, United States; 2Argonne National Laboratory, United States

Recent outbreaks of the Ebola virus infection in several countries demand a rapid point-of-care (POC) detection strategy. This talk reports on an innovative pathway founded on electronic resonance frequency modulation to detect Ebola glycoprotein (GP), based on carrier injection-trapping-release-transfer mechanism and standard antibody-antigen interaction principle within a dielectric-gated reduced graphene oxide (rGO) field-effect transistor (GFET). The sensitivity of the current Ebola detection can be significantly enhanced by monitoring the device’s electronic resonance frequency, such as inflection frequency (fi), where phase angle reaches maximum (θmax). In addition to excellent selectivity, a sensitivity of ∼36-160 % and ∼17-40 % for 0.001-3.401 mg/L Ebola GP can be achieved at high and low inflection resonance frequencies, respectively, which are several orders of magnitude higher than the sensitivity from other electronic parameters (e.g., resistance-based sensitivity). Using equivalent circuit modelling on contributions of channel and contact, analytical equations for resonance shift have been generalized. When matching with the incoming ac measurement signal, electronic resonance from the phase angle spectrum is evolved from various relaxation processes (e.g., trap and release of injected charge at surface trap sites of channel-gate oxide and channel-source/drain interface) that are associated with a characteristic emission frequency. Using charge relaxation dynamics, a high-performance bio-FET sensing platform for healthcare and bio-electronic applications is realized through resonance shifting.

5:30 AM *S.SM01.01.05
Nanostructured Metal Oxides-Based Biosensors for Oral Cancer Detection Bansi D. Malhotra; Delhi Technological University, India

Oral cancer (OC) is currently one of the most wide-spread cancers and it is known to occur more often in men than women.[1] If not detected early, this cancer can be life threatening. Smoking, alcohol consumption, diet (red and processed meat, fried foods, chewing tobacco, human papillomavirus, and exposure to certain chemicals (e.g. sulfuric acid, asbestos, and formaldehyde) are some of the common reasons behind the onset of OC. Many techniques such as laser capture microdissection, visualization adjuncts, cytopathology, and biopsy can be for detection and monitoring of OC. These methods are time-consuming, expensive, labour intensive and invasive. Biosensors are, however, user-friendly, reliable and offer increased assay speed, high sensitivity and require low sample volumes.

Nanostructured metal oxides have recently aroused much interest as immobilizing matrices for development of biosensors since these materials provide desired orientation, better conformation and high biological activity resulting in enhanced sensing characteristics for oral cancer detection.[2–5] In this context, nanostructured oxides of metals such as zirconium, yttrium and hafnium have been found to show interesting functional, bio-compatible, non-toxic and catalytic properties for oral cancer detection. These materials have been predicted to yield enhanced electron-transfer kinetics and strong adsorption capability and provide suitable microenvironments for the immobilization of oral cancer biomarkers e.g interleukin-8 (IL-8), interleukin-6 (IL-6), vascular endothelial growth factor (VEGF) and cytokeratin fragment-21-1(Cyfra-21-1) resulting in enhanced electron transfer and improved characteristics for OC detection. Among the various biomarkers, CYFRA-21-1 is a water-soluble proteinaceous biomarker and is a fragment of 40 kD of cytokeratin 19.[1] The cut-off concentration of CYFRA-21-1 in saliva for normal persons is 3.8 ng mL−1 and patients have been found to have CYFRA-21-1 concentration as high as 17.46 ng mL−1 in saliva. I will focus on the results of some the recent experiments obtained in our laboratories on nanostructured metal oxides based biosensors for non-invasive oral cancer detection.[3-5]

4. Effect of Brownian motion on reduced agglomeration of nanostructured metal oxide towards development of efficient...
Graphene has numerous applications in biomedicine as its unique physicochemical properties could be tuned to functionalize proteins, enzymes and other macromolecules for biosensor applications, or can be used as a therapeutic delivery vehicle for drug and nucleic acids delivery that can improve human life. Miniaturization of devices comes with a prerequisite need for precision control and selective placement of nanomaterials, which is still a challenge in most biosensing applications. In this study, we explore the potential of a graphene-based Field Effect Transistor (G-FET) device for glucose sensing. Specifically, we aim to selectively and precisely place monolayer of graphene on Si/SiO2 substrates through the Langmuir-Blodgett technique (self-assembly process) and electrodes are fabricated on top of the graphene. Subsequently, the microchannels were integrated with the device and were functionalized with linker molecules and further immobilized with enzymes, which can catalyze glucose metabolism by direct electronic transport. Our study will highlight the potential use of graphene-based nanomaterials as a platform for developing devices that can be used for electrochemical biosensing, optical biosensing as well as the creation of graphene-metal nanoparticle hybrids for enhanced performance.

We report results of the studies relating to the synthesis of biphasic (monoclinic and tetragonal) nanodot zirconia (zero dimension with size < 4 nm) that has been utilized for the fabrication of electrochemical biosensing platform for the detection of CYFRA-21-1 biomarker; secreted in saliva samples of oral cancer patients. In the synthesis of nanodot zirconia, hydrothermal process was used at 180 °C for 24 h. The 3-aminopropyl triethoxy silane (APTES) functionalized nanodot zirconia (APTES/ndZrO2) was electrophoretically deposited onto prehydrolyzed indium tin oxide (ITO) coated glass electrode at the potential of 14V for 120s. The monoclonal anti-CYFRA-21-1 (50 µg mL-1) was drop-cast onto the obtained uniform thin film of APTES/ndZrO2/ITO via EDC-NHS coupling. The non-specific binding sites were blocked using bovine serum albumin (BSA, 1 mg dL-1). The X-ray diffraction (XRD), high resolution transmission electron microscopy (HR-TEM) and Fourier transforms infrared spectroscopy (FT-IR), were used for characterization of nanomaterials. The electrochemical characterization and sensing response studies; cyclic voltammetry (CV) and differential pulse voltammetry (DPV) techniques were used. The fabricated biosensing platform (BSA/anti-CYFRA-21-1/APTES/ndZrO2/ITO) exhibited electrochemical response in the range of 2-20 ng mL-1, sensitivity of 3.2 µA mL ng-1cm-2 and lower detection limit of 1.96 ng mL-1. The results obtained through the enzyme linked immunosorbert assay technique (ELISA) in saliva samples of oral cancer patients.

Drop-on-Demand Inkjet Bioprinting for Tissue Engineering Sungjune Jung; Pohang University of Science and Technology, Korea (the Republic of)

Inkjet printing technology encompasses the generation, control and deposition of 1-100 picolitre liquid drops. Besides graphic printing applications, new opportunities for inkjet printing are starting to be exploited commercially in the manufacture of high value, high precision products. The applications include the fabrication of 3D biological tissues and organs for regenerative medicine as well as flexible electronics such as biosensors, solar cells, and light emitting diodes. This talk present inkjet-based cell printing technology and its applications to regenerative medicine and tissue engineering. I will show how living cells are ejected from micron-sized nozzle with single-cell level accuracy and how multiple types of cells can be patterned into 2D and 3D biological structures with high-resolution. Then, our recent studies on the applications of 3D inkjet bioprinting, including high-throughput screening for personalized medicine, 3D alveolar barrier models, engineered skin substitutes will be presented. We believe that drop-on-demand, cell-accuracy inkjet printing is a versatile tool to fabricate complex tissues for drug discovery, disease model, and toxicity.

5:00 AM S.SM01.02.02
In Vitro Modeling of Non-Alcoholic Fatty Liver Disease by Integrated Gut-Liver on a Chip Jiandong Yang1, Yoshikazu Hirai1, Ken-ichiro Kamei1, Marika Trumm2,1, Toshiyuki Tsuchiya1 and Osamu Tabata1,1; 1Kyoto University, Japan; 2Heidelberg University, Germany

Non-alcoholic fatty liver disease (NAFLD) is one of the most common chronic liver diseases, leading to cirrhosis, liver cancer and cardiovascular diseases, and is the important stage to cure the diseases without liver transplantation [1]. Until now, any effective drugs/treatments have been established due to the improper in vitro cell-based assays and animal models, misleading the results to study the disease mechanisms. A gut-liver axis (GLA) might play a critical role in NAFLD by disrupting intestinal barriers towards liver damages and fibrosis, and could be a good candidate model to study NAFLD in vitro. However, the conventional cell-culture settings did not allow recapitulating inter-tissues interactions like GLA. On the other hand, the recent Organs-on-a-Chip technology may offer recapitulating such interactions by utilizing microengineering/fluidic technology [2]. Here we report a gut-liver on a chip (iGL Chip) enabling the precise closed-loop medium circulation to represent GLA as an in vitro NAFLD model. We demonstrated to culture gut and liver cell lines (CaCO2 and HepG2 cells, respectively) under the medium recirculation, perturb with free fatty acids (FFAs) for cells to initiate NAFLD process, and monitor cellular responses in a chip.

The microfluidic device in iGL Chip composed with three polydimethylsiloxane (PDMS) layers, i.e., from top to bottom, perfusion, thin membrane, and control layers. To incorporate precise pressure-driven micro valves and pneumatic pumps utilizing thin elastic membrane, the part of a perfusion channel of the pneumatic pump has semicircular shape for the complete seal by deformed membrane. The designed device was fabricated by the combination of the simulation based-grayscale lithography and the softlithography process [3].

It is well-known that PDMS has the critical issue of an absorption of small hydrophobic molecules, and might cause FFA absorption. To reduce the absorption and improve cell growth on PDMS, PDMS surface was treated with n-dodecyl-D-maltoside (DDM) amphiphilic molecule, followed by Matrigel extracellular matrices mixture. The DDM coating reduced the background of adipocRed lipid fluorescent staining about 20% compared to bare PDMS. Next HepG2 cells and CaCO2 cells were separately introduced into their corresponding cell-culture chambers with 1.0×10^6 cells/ml. The circulation flow (15 nL/min) was actuated by the micropump after 12 hours of cell attachment. For 5-7 days of cell culture, both cells reached to the full confluence in the cell culture chamber area. The effect of coating method on cell attachment and viability were tested by the Calcein-AM living-cell staining. The cell viability of DDM/Matrigel coating was similar with those of only Matrigel
coating. The DDM/Matrigel coating could improve cell culture condition with the reduction of molecules absorption.

Next, co-culture of HepG2 and CaCO2 cells in a iGL Chip was demonstrated to investigate the effects of medium recirculation flow. Although HepG2 cells showed comparable cell viability among tested conditions, CaCO2 cells under flow conditions had higher cell viability than that of static conditions. Finally, to observe the cellular response after FFAs treatments, HepG2 and CaCO2 cells were treated with FFAs-contained medium (oleic acid : palmitic acid = 2:1) and kept under recirculation flow for 24 hours to investigate whether NAFLD-like cellular phenotypes. The intercellular lipid in HepG2 cells was increased with the increase of FFA concentrations, resulting the reduction of cell viability, on the other hands, CaCO2 cells did not change their viability after FFAs treatments. These results suggest the iGL Chip represented the initial state of NAFLD and has potential for disease modelling towards drug developments for NAFLD.

5:10 AM *SSM01.02.03
Defective Organ-on-a-Chip Strategy Xiuli Zhang¹, Jiu Deng², Yong Luo² and Bingcheng Lin³; ¹Soochow University, China; ²School of Chemical Engineering, Dalian University of Technology, China; ³Dalian Institute of Chemical Physics, Chinese Academy of Sciences, China

Defective models, such as gene-knockout cell model, gene-knockout mouse model, or immune-system-inhibited nude mouse model, have played critical roles in biological studies. We extrapolated this kind of idea into the field of organ-on-a-chip research, and proposed a defective organ-on-a-chip strategy, which we believe would find wide applications in the field of pharmaceutical and biomedical researches. To demonstrate this strategy, we developed an immuno-liver-chip featuring T cells, and realized preclinical drug-hepatotoxicity-typing by exploiting defective liver chips. In detail, we removed T cells, Kupffer cells, Stellate cells, and the artificial bile duct from the immuno-liver-chip, respectively, thus deriving four distinct defective liver chips. We then measured the hepatotoxicity of a same drug with these immuno-liver-chip series. By analysis of the difference between the measured hepatotoxicity, we can identify the role of different types of hepatic cells in the drug hepatotoxic process and therefore deduced the mechanism of the drug hepatotoxicity. As a demonstration, we used defective liver chip strategy to successfully discriminate the hepatotoxicity mechanism of four classical drugs, Abacavir, Ethynyl estradiol, Paracetamol, and Sulfamethoxazole.

5:25 AM SSM01.02.04
A Human Kidney on a Chip Microphysiological System Jonathan Himmelfarb and Edward Kelly; University of Washington, United States

Chronic kidney disease is a public health problem affecting 850 million people worldwide, 37 million people in the US adult population, and is the 9th leading cause of death according to the Centers for Disease Control and Prevention. Until recently there has been a lack of human in vitro models that recapitulate critical aspects of kidney physiology, mimic the unique complexities of specific nephron segments, model disease heterogeneity or assess reparative mechanisms in response to injury. The lack of in vitro models, coupled with numerous challenges in available animal models for modeling most human kidney diseases, has hindered the development of safe and effective therapies. This is in part because microfluidic flow is so essential to kidney structure and cellular function. In response to this critical unmet need, we and others have developed three-dimensional flow directed “kidney-on-a-chip” microphysiological systems (MPS) populated with a variety of human kidney cells, with functional characterization of key component structures of the proximal tubule, the peritubular microvascular network, and more recently the glomerular filtration barrier. Use of our kidney-on-a-chip MPS platform has been accompanied by the development of multiple reproducible data readouts, including immunocytochemistry, advanced microscopy, deployment of protein and microRNA biomarkers and mRNA gene expression data. The kidney MPS is characterized by precise control of cellular composition, extracellular matrix, vascular and tubular geometry and flow. Our integrated approach for in vitro disease modeling includes differentiating human kidney cells and organoids from diseased patient-derived inducible pluripotent stem cells (iPSC), CRISPR gene editing, single cell transcriptional profiling and engineering living human kidney vascular networks. We have demonstrated success in delineating novel molecular drivers of several disease processes and drug induced nephrotoxicity. Our in vitro on chip models recapitulate critical aspects of kidney physiology, assess the mechanisms and response to injury, have established translatable biomarkers and target engagement readouts, and test reparative mechanisms, all of which can substantially enhance therapeutic discovery and evaluation for a variety of kidney diseases.

**Human Organs Chips For Drug Discovery and Personalized Medicine** Rachelle Prantil-Baun and Donald Ingber

The human ‘Organ-on-a-Chip’ (Organ Chip) microfluidic culture technology was originally developed as a tool to provide better predictive models for drug efficacy and toxicity. We have developed 2-channel Organ Chip devices that recapitulate tissue-tissue interfaces, vascular perfusion and organ-level functionality seen in vivo by incorporating multiple cell types, mechanical cues (e.g., breathing or peristalsis-like motions), and fluid flow, as well as immune cells. Using this approach, we have created Organ Chip models of over 10 different human organs, as well as rat and dog Liver Chips. We have also developed a robotic Interrogator instrument that can link up to 10 different Organ Chips to form a ‘Human Body-On-Chips’ platform, which we have used in combination with computational modeling to carry out predicted in vitro-to-in vivo extrapolation (IVIVE) of human drug pharmacokinetic and pharmacodynamics (PK/PD) parameters in vitro. Using these approaches to carry out human experimentation in vivo, we have not only addressed key challenges relating to drug PK/PD, toxicity, and efficacy, we also have gained new insights into human physiology and disease mechanisms, and have been able to model various diseases and rare gene disorders using patient-derived cells. Thus, Organ Chips offer a powerful new approach to confront challenges relating to mechanistic pathophysiology as well as drug development and personalized medicine.

**5:50 AM *S.SM01.02.06*

**Engineering of Microfluidic Tumor On-Chip Models to Study Cancer Metastasis** Mehdi Nikkhah

Cancer is currently the second leading cause of death in the United States, claiming the lives of over half of a million Americans annually. Poor patient prognosis and treatment outcomes are in large part due to the biological complexities of this devastating disease. Improved treatment and early diagnosis have yielded a steady decrease of cancer-related mortalities, but metastatic cancers are still deadly due to a lack of effective targeted treatment options. Upon tumor formation at the primary sites, metastasis progresses through a stepwise cascade of events, in which the key initial steps include stromal desmoplasia/fibrosis, immune response, tumor invasion and cancer cell escape into the vasculature (i.e. intravasation). Tumor cells adopt an aggressive phenotype through continuous interactions with their surrounding microenvironment (TME) and the multitude of physiochemical signaling cues that emerge from their surrounding extracellular matrix (ECM) and resident stromal cells. To that end, the complexities of the native TME and the limitations of conventional in vitro platforms and in vivo tumor models pose a non-trivial challenge in identifying the key molecular and cellular signaling cues involved in the dynamic tumor-stroma crosstalk as potential therapeutic targets. In the past few years, microengineering technologies have been widely utilized in various scientific disciplines, from physics and chemistry to biology. These technologies have proved immensely beneficial for the fields of experimental biology and medicine through development of miniaturized biomimetic living tissue systems for cellular- and molecular-based studies. In addition, these technologies have gained significant attention in their ability to precisely control cell-microenvironment interactions to better understand the mechanisms of human disease progression, particularly cancer. In this seminar, I will present the multidisciplinary research focus of our laboratory at ASU on the integration of microscale technologies, advanced biomaterials and biology to develop the next generation ex vivo on-chip tumor microenvironment models to study cancer progression at the earliest stages of the metastatic cascade. I will specifically discuss our recent efforts and findings on engineering of organotypic breast and brain tumor microenvironment models to dissect the role of stromal cells (e.g. cancer associated fibroblasts) on tumor cell invasion, intravasation and vascular homing.

**6:05 AM *S.SM01.02.07*

**Micro/Nano-Engineering Approach for Developing Advanced Microphysiological Systems** Ken-ichiro Kamei

Impediments to drug discovery include increasing costs (over 10 billion USD per drug), long period of development (more than 10 years), insufficient drug efficacy, and serious side effects. These issues can largely be attributed to the current improper approach to pre-clinical testing that involves the use of experimental animals, often yielding misleading results because of variation in responses due to species difference. In addition, the use of experimental animals has become restricted in many countries due to ethical issues. Therefore, drug development by pharmaceutical companies is a high-risk endeavor and new approaches for drug discovery are urgently required.
The microphysiological system (MPS, which is also termed organs/body-on-a-chip) has considerable potential for use in drug development and toxicological testing. MPSs aim to recapitulate in vivo physiological and pathological conditions in a chip without the use of actual organs, similar to an in vitro human model. Compared with conventional animal models, MPSs are advantageous for predicting drug efficacy and toxicity in humans, obtaining more quantitative results, shortening experimentation time, improving the reproducibility and cost-effectiveness, and reducing the use of animals. The MPS platform could become an alternative to animal testing.

However, the current MPS platforms have several issues that need to be resolved. Most MPS platforms still possess a one-way flow stream or a few branches on a chip, so they cannot completely represent the inter-tissue interaction that occurs through the blood circulation system. Some studies have utilized external rotary peristaltic pumps for cell-culture medium circulation, but they require a large amount of medium, and drugs, metabolites, and products secreted from cells could be diluted and lost as a result of this process. Notably, most of the previously developed MPS platforms can only examine a set of samples on the chip, and do not have the capability to compare samples next to each other within a device. Furthermore, it is still challenging to directly integrate micropumps into a device, because the existing fabrication methods are not simple and reliable. Therefore, it is important to develop new microfabrication technologies capable of integrating pumps into a device to minimize medium volume and sample loss.

Moreover, it is also important to integrate an in situ sensor to monitor cell or tissue behavior after administering the treatments on a chip. Majority of the current cell monitoring methods used in the MPS platform are based on microscopic imaging with cell staining. However, this approach often requires cell-labeling materials that could perturb cells, influencing the drug treatment or killing the cells. Additionally, this approach only permits end-point experiments and there is loss of information over time. Accordingly, it is necessary to integrate in situ and non-invasive cell monitoring systems to obtain “living cell” information.

In the present study, we introduce an interdisciplinary approach comprising aspects of stem cell biology, material science, and micro/nano-engineering that is designed to solve the aforementioned issues. We present some applications, such as in vitro recapitulation of anti-cancer drugs on the heart as well as in vitro modeling of non-alcoholic fatty liver diseases. We envision that this technological development will allow a precise recapitulation of human physiology and pathology, which will enhance our understanding of the mechanisms underlying various diseases for which effective treatments remain elusive, and will help identify new therapeutic drugs.

6:20 AM S.SM01.02.08
Construction And Application of a Multi-Organ Microfluidic Chip Mimicking the In Vivo Pathological Process of Lung Cancer Brain Metastasis Qi Wang; Dalian Medical University, China

Brain metastasis (BM) is a leading cause of mortality in patients with non-small cell lung cancer (NSCLC). However, the molecular mechanisms underlying BM of NSCLC remain largely unknown because of the lack of models to accurately investigate such a dynamic and complex process. Here we developed a multi-organ microfluidic chip as a new methodological platform to study BM. The chip consisted of two bionic organ units – an upstream “lung” and a downstream “brain” characterized by a functional “blood-brain barrier (BBB)” structure, allowing real-time visual monitoring of the entire BM process, from the growth of primary tumor to its breaking through the BBB, and finally reaching the brain parenchyma. The chip was then applied for the BM research where we first demonstrated that the protein expression of Aldo-keto reductase family 1 B10 (AKR1B10), which was identified by proteomics profiling, was significantly elevated in lung cancer BM. Silencing AKR1B10 in brain metastatic tumor cells suppressed their extravasation through the BBB in the in vitro Transwell model, in our ex vivo microfluidic chip, as well as the in vivo model of brain metastasis in nude mice. With the combined application of our new model and traditional research platform, it was suggested that our multi-organ microfluidic chip is a practical alternative to study BM pathogenesis, and AKR1B10 is a diagnostic biomarker and a prospective therapeutic target for NSCLC BM.

6:30 AM *S.SM01.02.12
3D Printed Device Mimicking Hepatic Lobule-Like Flow Conditions for Toxicity Testing Anil Kumar P R, Shiny Velayudhan, Roopesh R. Pai and Vinod Kumar V; Sree Chitra Tirunal Institute for Medical Sciences and Technology, India

Hepatic tissue is a complex organ with very specific fluid flow characteristics. The adverse effects of chemicals and drugs are studied in vitro by conventional two dimensional monolayer cultures. 2D cultures results in loss of cell viability and decreased liver-specific functionality. In vitro models such as spheroid culture, sandwich culture and 3D printed tissues have been proposed to overcome these limitations. When culture systems are upgraded from 2D to three dimension (3D), the microenvironment also needs to be upgraded. We propose a 3D Printed hepatic lobule-Like bioreactor for in vitro Hepatotoxicity testing. The multi chamber in the perfusion device can hold functional hepatocytes and is nourished by flow conditions. Various flow conditions were simulated in silico to understand the fluid flow inside the device. Bifabricated
tissues, either cell encapsulated or 3D bioprinted, placed inside the device receives fluid flow similar to liver lobule and are functional. The device can perform like a miniaturized disposable bioreactor for hepatotoxicity testing.

6:45 AM S.SM01.02.14
Fabrication of a Physiologically Relevant and Novel Lung-on-a-Chip Device for the Study of Human Pulmonary Disease and Drug Toxicity  
David J. Blake, Marcus A. Williams and Jeff Jessing; Fort Lewis College, United States

In the scope of biomedical research, many advances have been made in the field of pulmonology with the use of multiple animal models and traditional cell culture experimentation. While these methods are useful when studying single cellular pathways or overarching biological processes, they often falter when studying the meticulous nature of human disease. In this work, we propose the development of a novel Lung-on-a-Chip device that would more accurately mimic the physiological boundaries of human alveoli than animal models or traditional in vitro studies. Utilizing multiple microfabrication techniques, we are developing a microfluidic device with an ultra-thin (25 μm) biodegradable porous silicon membrane. Current data suggests that human pulmonary epithelial and endothelial cells are viable and prolific on the proposed microfabricated silicon membrane in extended studies (14 days). Due to the biodegradability of the fabricated novel silicon membranes, it has been observed in long term studies that cells can remodel and degrade the porous silicon membrane. This degradation allows for physiological cellular contact between membranes mimicking a true blood gas exchange interface as observed in vivo. To further validate this model’s ability to recapitulate human physiology, we have begun to co-culture with immunological cell types and are monitoring for response to bacterial and tumor antigens. Preliminary data suggests that immunological cells are able to remodel the porous silicon membrane substrate and migrate across cellular boundaries in response to environmental cues as seen in vivo. Broadly, we believe that this model may be used to further characterize and study human pulmonary disease and drug toxicity.

6:55 AM *S.SM01.02.16
Innovative Organ-on-a-Chip (OOC) Platform Combined 3D Bioprinting Technology for Highly Reliable Human Tissue Mimicry  
Yimin Guan; Shanghai Industrial Technology Research Institute, China

Organ-on-a-chip (OOC) technology progresses rapidly and has attracted tremendous interest in research due to its capabilities of emulating in-vivo microenvironment and tissue structure. It has great potentials for pharmaceutical research development and precision medicine. Microfluidic technology and precision 3D cell printing are the two key enablers to make OOC. However, current OOC has some drawbacks including low throughput, inconsistency, high-cost, unmanufacturable. These issues has prevent wide use of OOC technology in industry scale. In this work, we demonstrate an approach to standardize Organ-on-a-chip (OOC) fabrication and testing process. In this process, A inkjet printing system with special designed MEMS printhead has be built and employed to printing multiple types of cells and structural bio materials in a precise and repeatable way. In addition, a special designed trans well structure and removable wells are used to hold OCC with multiple replicas. This standardized OOC process is able to provide a standardized and reliable method for 3D multi-type cell co-culture with a integrated perfusion system which can adjust flow rate to provide stable shear-force microenvironment for better simulating human-like in vivo system including hepatic sinusoids, blood-brain-barriers (BBB), intestinal villi.

7:10 AM S.SM01.02.17
A Novel Micro-injection Droplet Microfluidic System for Studying Locomotive Behavior Responses to Cu²⁺ induced Neurotoxin in Individual C.elegans  
Zongzheng Chen¹, Xiuli Zhang², Yong Luo¹ and Bingcheng Lin³; ¹First Affiliated Hospital of Shenzhen University, China; ²Soochow University, China; ³Dalian University of Technology, China; ⁴Chinese Academy of Sciences, China

Analysis of C.elegans by droplet microfluidics has been widely used in study of locomotive behavior responses to neurotoxicity due to the capacity of high-throughput manipulating single cells. However, it has been difficult to manipulate droplets flexibly and actively on account of the limitation the dimension of individual C. elegans droplets. In this study, a novel MiDMS (Micro-injection Droplet Microfluidic System) was proposed, which consist of three parts: single C. elegans droplet generator, droplets drug micro-injection channels and drug-incubation observation array. Individual C.elegans droplets were produced initiatively by regulating the flow rates between oil and water phase as well as the concentration of C.elegans in suspension. Then, the drug solution was precisely injecting into each C.elegans droplet, which by electricity induced surface tension of droplet changing. In addition, the effect of neurotoxic Cu²⁺ on locomotive behavior of C. elegans was evaluated at single cell resolution. The results showed that the neurotoxicity induced behavioral disorder of the C. elegans was more obvious with the increase of Cu²⁺ concentration treatment time, and these dose-effect and time-effect relationship in MiDMS were similar as in petri dish. It will be providing a powerful platform for the study of
the response of *C. elegans* to quantitative drug at single cell resolution.

SESSION S.SM01.03: 2D Nanomaterials Platform

S-SM01

5:00 AM S.SM01.03.01

Low-Dimensional Nano-Carbons—Form Doped Graphene to 3D Hybrids and Biological Applications Mauricio Terrones; The Pennsylvania State University, United States

We will discuss the synthesis of carbon nanotubes and nanotube networks using different dopants during chemical vapor deposition. In particular, the effects of sulfur, boron and nitrogen will be discussed. It will be demonstrated that it is indeed possible to assemble/grow carbon nanotube networks if a careful control of dopants is achieved during chemical vapor deposition (CVD) growth. High-resolution electron energy loss spectroscopy (HR-EELS) studies on these nanotube materials will be presented, and the locations of boron, sulfur and nitrogen within nanotubes will also be shown. First principles theoretical calculations on nanotubes containing pentagon, hexagons and heptagons in the presence of these dopants will be discussed. We will also discuss the cytotoxicity and applications as molecular sensors and virus traps of these doped nanocarbons. This talk will also discuss the synthesis of large-area, high-quality monolayers of nitrogen-, silicon- and boron-doped graphene sheets on Cu foils using ambient-pressure chemical vapor deposition (AP-CVD). Scanning tunneling microscopy (STM) and spectroscopy (STS) reveal that the defects in the doped graphene samples arrange in different geometrical configurations exhibiting different electronic and magnetic properties. Interestingly, these doped layers could be used as efficient molecular sensors in conjunction with Raman spectroscopy. In addition, the synthesis of hybrid carbon materials consisting of interconnected graphene layers (graphene foams) by solvothermal routes will be discussed. These foams are highly conducting, very robust and can operate at temperatures ranging from 77K to 1173K.

Engineering Conductive and Adhesive Cardiopatches for Cardiac Tissue Regeneration Brian Walker, Roberto Portillo Lara, and Nasim Annabi; **1**University of California, Los Angeles, United States; **2**Tecnologico de Monterrey, Mexico; **3**Brigham and Women's Hospital, United States; **4**California NanoSystems Institute, United States

Heart failure following myocardial infarction (MI) is the number one cause of death in the United States, and western world due to the myocardium’s inability to regenerate to a significant degree once fully matured, leaving behind a fibrous scar tissue that is unable to contract or propagate electrical impulses. Cardiac tissue engineering (TE) is a field of biomedical engineering that aims to develop materials for the treatment of patients suffering from heart failure after MI. Development of these materials may involve electrospinning, a technique utilized for engineering fibrous scaffolds for tissue engineering applications. Here, we introduce electrospun cardiopatches based on gelatin methacryloyl (GelMA), due to its tunable mechanical properties, favorable biodegradation, and the presence of cell binding sites, which promote adequate cell adhesion and proliferation. Further, we introduce electrical conductivity properties to the engineered fibrous GelMA scaffold through the incorporation of a choline-based bio-ionic liquid (Bio-IL) within the fabricated GelMA electrospun sheet, and photocrosslink the constructs in the presence of UV light.

Here, we performed mechanical characterization on these cardiopatches, which showed that the electrospun GelMA/Bio-IL scaffolds had a tunable elastic modulus based on GelMA and Bio-IL concentrations. The elastic modulus was shown to increase concomitantly with an increase in the concentration of Bio-IL incorporated onto fibrous GelMA mats. The Bio-IL incorporated GelMA fibers exhibited tunable electrical conductivity that increased consistently by increasing the concentration of Bio-IL. In addition, *ex vivo* experiments using excised rat abdominal tissues placed on electroconductive...
cardiopatches showed that the excitation threshold of these tissues decreased with and increasing concentration of Bio-IL. This test demonstrated the ability for fibrous scaffolds to propagate an electrical impulse and excite peripheral tissues. These electroconductive cardiopatches could be readily attached to the epicardial surface of the heart via photocrosslinking, which eliminates the need for sutures that could lead to further tissue trauma. *In vitro* cell studies performed by seeding cardiomyocytes and cardiac fibroblasts on the surface of our GelMA/Bio-IL cardiopatches demonstrated the scaffolds ability to support cell adhesion, and proliferation. Further, cells seeded on conductive cardiopatches exhibited a markedly improved contractile profile when compared with non-conductive patches due to the overexpression of the gap junction protein connexin 43 (Cxn43). Lastly, we were able to demonstrate the cardioprotective efficacy of these cardiopatches using a rat MI model where these electroconductive scaffolds were placed on the surface of the heart following permanent ligation of the left anterior descending coronary artery. Our histological assessment was indicative of comparatively lower thinning of the ventricular wall 3 weeks after induction of the experimental MI.

The results presented here demonstrate a new method to fabricate a highly conductive fibrous GelMA/Bio-IL cardiopatch with tunable mechanical and conductivity properties through incorporation of Bio-IL into a fibrous scaffold. Cardiopatches were also highly adhesive to wet tissue and was shown to be biocompatible in vitro using cardiomyocytes and cardiac fibroblast cells. Conductive cardiopatches were able to support the overexpression of Cxn43, necessary for cell-cell interaction. This conductive GelMA/Bio-IL cardiopatch has the potential to be implanted onto damaged site in the heart to provide mechanical stabilization to the injured myocardium and to restore electromechanical coupling at the site of MI.

5:20 AM S.SM01.03.05
**Ion-Selective Graphene-Hexagonal Boron Nitride Heterostructures for Biosensing** Adarsh D. Radadia and Nowzesh Hasan; Louisiana Tech University, United States

An intrinsic ion sensitivity exceeding the Nernst-Boltzmann limit and an sp²-hybridized carbon structure make graphene a promising channel material for realizing ion-sensitive field-effect transistors with a stable solid-liquid interface under biased conditions in buffered salt solutions. We will present on the performance of graphene field-effect transistors coated with ion-selective membranes as a tool to selectively detect changes in concentrations of Ca²⁺, K⁺, and Na⁺ in individual salt solutions as well as in buffered Locke’s solution. Both, the shift in the Dirac point and transconductance could be measured as a function of ion concentration with repeatability exceeding 99.5%, and reproducibility exceeding 98% over 60 days. However, an enhancement in selectivity, by about an order magnitude or more, was observed using transconductance as the indicator when compared to Dirac voltage, which is the only factor reported to date. Fabricating a hexagonal boron nitride multilayer between graphene and oxide substrate further increased the ion sensitivity and selectivity of transconductance. These findings incite investigating ion sensitivity of transconductance in alternative architectures as well as urge the exploration of graphene transistor arrays for biomedical applications.

5:30 AM *S.SM01.03.06
**Self-Renewing Neural Circuits in a Millimeter-Sized Invertebrate** Jacob T. Robinson; Rice University, United States

Nervous systems are remarkable for supporting stable animal behavior despite dramatic changes to neurons’ number and connectivity, yet many questions remain. For example, how do new neurons differentiate from stem cells and integrate into existing circuits? Small invertebrate model organisms offer several advantages for studying this type of neural plasticity. Unlike organoids or cultured cells, the properties of the neural circuit in an animal can be directly related to behavior; however, most invertebrates show modest regeneration or lack well-developed transgenic techniques. Here we show that *Hydra vulgaris*, a millimeter-sized transparent cnidarian, with 12 neural subtypes shows simple sensory-motor transformations that are maintained despite dramatic changes to the numbers of neurons. The small size and deformable body make allow us to study neural activity in microfluidic platforms that permit chemical, electrical, and optical interrogation. By studying this type of self-renewal in a simple and tractable model organism we can discover fundamental principles that enable neural circuits to self-assemble and reorganize to maintain stable sensory-motor responses.

5:45 AM *S.SM01.03.07
**2D Nanomaterials** Pulickel Ajayan and Anand Puthirath; Rice University, United States

There has been significant advances in the synthesis and characterization of graphene and related two-dimensional atomic layers. For many applications, including biological, these materials need to be modified to introduce specificity, functionality and flexibility. The talk will focus on the generation of two-materials and approaches for their chemical and electronic modification. Various low dimensional structures that can result from 2D layers, such as quantum dots, ribbons and heterostructures, will be described showing how chemical and dimensional modifications can change their intrinsic
properties. Interface engineering of these structures within matrices or as multilayers will be considered as opportunities to
design and create new material interface systems. The talk will also address the usefulness of 2D materials in applications
such as sensors, coatings and biological interfaces.

Re-engineering RNA Molecules into Therapeutic Agents—The Expanding Universe of Nucleic Acid
Modifications Martin Egli; Vanderbilt University, United States

First-generation nucleic acid analogs such as 2′-deoxy-2′-fluoro-RNA (2′-F RNA), 2′-O-methyl RNA (2′-OMe RNA), and
the phosphorothioates (PS-DNA/RNA) have remained staples of oligonucleotide modification strategies in the discovery and
optimization of potential RNAi therapeutics.1,2 The first FDA-approved siRNA drug, patisiran (Onpattro) contains eleven 2′-OMe
ribonucleotides in the sense and antisense strands formulated in a lipid nanoparticle (LNP) delivery system.3 Despite
their overall appeal in terms of enhanced nuclease resistance, increased pairing stability (2′-F/OMe RNAs) and safety, newer
analogs are needed to further improve the therapeutic potential of unformulated siRNAs like GalNAc conjugates. The search
for oligonucleotides with therapeutic efficacy has given rise to an expanding universe of analogs, including the second-
generation 2′-O-(2-methoxyethyl)-RNA (MOE-RNA)4 and the third-generation bicyclic nucleic acids (BNAs or LNAs).5 The
key enzyme in RNA interference (RNAi) is Argonaute 2 (Ago2), a dynamic multi-domain enzyme that binds multiple
regions of the guide (antisense) and passenger (sense) siRNAs. Considering the complexity of protein-RNA interactions in
RNA interference, it is imperative to expand the process of discovery and optimization of modified siRNAs to new
analogs.6 We have explored the potential benefits for efficacy of incorporating into siRNAs sugar modifications like N-
methylacetamide (NMA), 5′-E-vinylphosphonate (5′-E-VP) and, more recently, xeno-nucleic acid (XNA)7 residues such as
glycol nucleic acid (GNA),8 altritol nucleic acid (ANA),9 and theofuranosyl nucleic acid (TNA).10 The talk will summarize
siRNA modification strategies with an emphasis on regiospecific interactions between oligonucleotide and Ago2 and how
structural insights based on crystallographic data for modified RNAs alone and in complex with Ago2 from molecular
modeling studies can guide the choice of chemical modification at a given position of siRNA for optimizing its therapeutic
efficacy.

535-539.

8. Schlegel, M. K.; Foster, D. J.; Kel’ in, A. V.; Zlatev, I.; Bisbe, A.; Jayaraman, M.; Lackey, J. G.; Rajeev, K. G.; Charisse,
Cancer is a complex genetic moving target that requires a therapeutic modality capable of selectively targeting all driver oncogenes combined with the inherent ability to undergo pharmaco-evolution to target new mutations at pace with the cancer cell mutation rate. siRNA RNA-interference (RNAi) therapeutics fulfill these criteria and have great potential to treat cancer and other human diseases. However, due to their 14 kDa size and 40 negative anionic charges, siRNAs have no bioavailability to overcome a billion years of evolutionary defenses to prevent RNAs from crossing the endosomal lipid bilayer to enter the cytoplasm. Consequently, developing anti-cancer RNAi therapeutics requires targeted delivery to malignant cells and paradigm-shifting technology to enhance endosomal escape into the cytoplasm, the critical rate-limiting delivery step. Our research is focused on solving these problems by synthesis of bioreversible charge neutral RNAi produgs, called short interfering RiboNucleic Neutrals (siRNNs), and synthesis of novel hydrophilic-masked, hydrophobic endosomal escape domains (EEDs). For targeting domains, we have focused on conjugating antibodies to siRNN RNAi triggers to generate Antibody-RNAi Conjugates (ARCs).

A Traceless Linker for Aliphatic Amines that Rapidly and Quantitatively Fragments after Reduction

Reduction sensitive linkers have the potential to transform the field of drug delivery due to their ease of use and selective cleavage in intracellular environments. However, despite their compelling attributes, using reduction sensitive linkers for biomolecule conjugation reactions is still challenging because linkers have not been developed that can efficiently modify aliphatic amines and release them rapidly and completely after reduction. Developing reduction sensitive self-immolative linkers for aliphatic amines has been challenging due to their poor leaving group ability and high pKa values. Here we present a traceless linker (TRAILER), which can for the first time modify aliphatic amines and release them rapidly and quantitatively after disulfide reduction. We show here that TRAILER can reversibly modify the lysine residues on the Cas9 protein, with the cell penetrating peptide Arg10, and was able to generate a self delivering Cas9 RNP that could edit cells without transfection reagents. TRAILER has numerous applications in biotechnology given the ubiquitous presence of aliphatic amines on small molecule and protein therapeutics.

Boosting Intracellular Delivery of Messenger RNA

Non-coding ribonucleic acids (ncRNAs) are a diverse group of RNA molecules that are not translated into proteins following transcription. Mainly, microRNAs and long non-coding RNAs (lncRNAs) are predominant in this group. Aberrant expression of these ncRNAs has been observed in various pathological conditions including cancer. Especially, aberrant expression of microRNAs and the associated pathology has been extensively studied in cancer. Hence, targeting microRNAs has been considered a new generation of molecularly targeted therapy for various diseases. While downregulation of cellular microRNAs can be supplemented by delivering microRNA mimics, functional knock down of microRNAs that are overexpressed in diseases is a challenging task. The secondary structure of microRNAs determines how to functionally inhibit the translation of target mRNAs. MicroRNAs with even a few base homologies to the target can functionally regulate mRNA degradation/translation. The secondary structure of microRNA is crucial for recognizing target mRNA for functional effect. Since the double stranded RNA is an important intermediate in the biogenesis process of matured microRNA, delivering antisense microRNA for functional knock down of endogenous microRNAs needs a careful design. Especially challenging is their site-targeted delivery. We study antisense microRNAs with various structural determinants (mere homology, end loops, base pair modifications, artificial linkage, etc.) by molecular dynamics of the duplex formation at 1 micro second and beyond, for the evaluation of the therapeutic effect of microRNAs in various cancer models (GBM: antisense miR-21 and antisense miR-100; Breast cancer antisense miR-21 and antisense miR-10b; Hepatocellular carcinoma: antisense miR-21, antisense miR-10b and antisense miR-100). In this presentation, we summarize how structural modification in antisense microRNAs can be used for potential applications in cancer therapy, either microRNA targeting as
a monotherapy, or for improving clinical chemotherapy.

6:40 AM *S.SM01.04.08
CRISPR-Powered Transistors—Harnessing Biology as Technology Kiana Aran; Keck Graduate Institute, United States

We have recently developed a CRISPR powered, electronic biosensor termed, CRISPR Chip, capable of detecting the binding interactions between nuclease deactivated CRISPR with its target DNA sequence. CRISPR-Chip is a graphene field effect transistor (gFET) where the surface of the graphene is functionalized with nuclease deactivated CRISPR RNA-guided ribonucleoproteins (dRNPs). dRNPs within the CRISPR-Chip construct interact with their target sequence by scanning the genomic sample until they find and bind to their target. The selective hybridization of the target DNA to the dRNA complex modulates the graphene’s conductivity and results in a detectable change in electrical signal output which can be measured with a simple handheld reader. CRISPR-Chip was able to detect dRNA binding to two commonly deleted exon target sequences within the human dystrophin gene, without amplification. CRISPR-chip is the first example of CRISPR-powered electronic transistors that harnesses the search function of CRISPR/Cas9 and the ultra-sensitivity of graphene-based nanoelectronics to enable a complete label-free and amplification-free DNA biosensor.

6:55 AM S.SM01.04.09
Sense Anti-Sense MicroRNA Duplex—A Label Free Raman Study as an Approach for Functional Evaluation of Anti-Sense miRNA for Cancer Therapy Preetham Ravi¹, Surya P. Singh², Jeon Woong Kang³, Ramachandra R.Dasari⁴, Peter So⁵, Dinesh R. Katti¹, Kalpana Katti¹, Dorian Liepmann⁵, Jairam Eswara⁶, Venkatesan Renugopalakrishnan⁷ and Ramasamy Paulmurugan⁸; ¹NDSU, United States; ²Stanford University, United States; ³Massachusetts Institute of Technology, United States; ⁴University of California, Berkeley, United States; ⁵St. Elizabeth Medical Center, United States; ⁶Harvard Medical School, United States

MicroRNAs are emerging as a novel diagnostic and therapeutic targets of human pathologies. Since the expression levels of various microRNAs are dysregulated in different cellular diseases, including cancer, understanding structural dependency of microRNAs for their biological functions is essential for designing synthetic oligos with various base and linkage modifications to develop high-sensitive diagnostic devices, and to use them in therapeutic applications. Here we use a label-free Raman spectroscopy to understand the structural difference of a selective microRNA, the microRNA-21, by hybridizing it with complementary RNA, DNA, and DNA with multiple base mutations for analysis. To verify the spectral changes induced by hybridization, the spectral profiles obtained from single-stranded microRNA-21 mimic, and RNA and DNA oligos complementary to microRNA-21 were compared with microRNA-21 in the form of hybrid and mixed with complementary oligos in solutions. The spectral changes were also analyzed for the concentration of complementary DNA with single, double and triple base mutations to understand Raman specific detection signal that can specifically distinguish different structural variants within a mixture. The analysis of the results identified prominent spectral features around 930 cm⁻¹, 1017 cm⁻¹ and 1068 cm⁻¹ for C=C and C=O stretching of the ribose ring. Similarly, the broad spectral features including a sharp band and a shoulder in the area of 1350-1380 cm⁻¹ were attributed to be adenine (C8–H and C2–H out of plane bending) and guanine (C8–H bending and C8–N stretching) bases. A band at 1418 cm⁻¹ was assigned to be N=C–H bending modes from adenine, guanine and cytosine bases of RNA sequence. While analyzing the intramolecular structure in RNA, we also analyzed the DNA spectrum of Raman bands at 841 cm⁻¹, 874 cm⁻¹ and 930 cm⁻¹ which were identified to be C2'-endo (B-DNA) conformation of DNA. In addition, we identified that the Raman band around 785 cm⁻¹ to be the phosphodiester bond of the backbone linking 5’ phosphate of nucleic acid with 3’ OH of the other nucleotide. This study successfully utilized label-free Raman spectroscopy to differentiate structural features such as intramolecular (ssRNA and ssDNA) and intramolecular (RNA-RNA and RNA-DNA hybrid) interaction which can be utilized for developing biosensors to quantify microRNAs in clinical samples and to design therapeutic microRNAs with strong functionality for the treatment of cellular diseases.

7:10 AM *S.SM01.04.14
Role of Protein Corona on Oligonucleotide Delivery and Transfection with Lipid Nanoparticles Mansoor Amiji; Northeastern University, United States

Upon systemic administration of nanoparticles used in drug and gene delivery, they acquire a “biological identity” upon adsorption of plasma proteins. The protein corona layer has significant implication in the biodistribution, target specific localization, and toxicity of nanoparticle-based delivery systems. Additionally, specific enrichment of proteins may allow for an endogenous and more efficient approach for targeted delivery. Using a wide ranging of lipid nanoparticle (LNP) formulation where individual lipid composition was varied, we have shown...
specific protein enrichment pattern and differential biodistribution and tumor-specific delivery of small interfering RNA (siRNA). For instance, DOTAP functionalized LNPs showed vitronectin enrichment and enhanced \textit{in vivo} tumor delivery of the nanoparticles to $\alpha\beta^3$ expressed tumors and endothelial cells as compared to $\alpha\beta^3$ negative tumors.

\textbf{7:25 AM *S.SM01.04.13}
\textbf{Intracellular Delivery of mRNA; Exploration of Delivery Materials for Next Generation Therapeutics} David Ulkoski; AstraZeneca PLC, United Kingdom

Current advances in RNA-based technologies such as therapeutic gene editing, mRNA therapeutics, and vaccines have produced strong interest and attention in safe and effective nonviral vectors for nucleic acid delivery. Nevertheless, the comprehensive application of nucleic acid therapeutics is still limited by the need for better delivery systems. Thus, the analysis of these delivery materials can be advanced to offer sharper insights into SAR learnings and provide a clearer picture of their therapeutic potential. Lipid- and polymer-based materials can be regarded as the most prominent partners for nucleic acid delivery, providing \textit{in vivo} transfection. Over the past few decades, a variety of cationic lipids and polymers have been synthesized, evaluated and applied as successful delivery vehicles for nucleic acids. Here, I will discuss some of the challenges for clinical translation of mRNA-based therapeutics and give examples of the biomaterials and delivery strategies we are investigating for the application of mRNA delivery.

\textbf{Mechanobiological Markers for Cancer Metastasis} Dinesh R. Katti$^{1,2}$, MD S. Molla$^1$, Sumanta Kar$^{1,2}$ and Kalpana Katti$^{1,2}$; 1North Dakota State University, United States; 2NDSU, United States

According to the World Health Organization, 9.6 million people worldwide died from cancer in 2018 (an estimated 1 in 6 global deaths) with a total economic impact of $1.16 trillion per year. Deaths due to prostate and breast cancer are often the result of metastasis to bone. Currently, there are no viable markers for metastasis. We report the development of novel \textit{in vitro} models of breast cancer and prostate cancer metastasis through bone tissue engineering approaches. The tissue engineered scaffold uses amino acid modified nanoclay to develop polymeric nanocomposites. This scaffold uses biomimetic mineralization of hydroxyapatite inside nanoclays galleries, mimicking remodeling human, characterized by low Ca/P stoichiometry, a niche to which cancer cells migrate. Seeding the tissue engineered bone scaffolds with prostate and breast cancer cell lines, after bone formation, led to the creation of tumoroids of cancer. Bone metastasis is characterized by unique and complex biochemical, morphological, and genetic changes. The overall nanomechanical response of cancer tumors is representative of the complex changes at progression of metastasis. Here we report static and dynamic evaluation of nanomechanical properties of cancer cells during disease progression at the metastatic site. We report a significant softening of cancer cells as disease progression occurs at metastasis. We also examine the cytoskeletal changes that result in the observed mechanical behavior and its evolution at metastasis. The significant reduction in elastic modulus of cancer cells was attributed to reorganization of cytoskeletal elements. We report here the use of mechanics as a potential new marker for cancer metastasis progression.

2020 MRS Virtual Spring/Fall Meeting, November 27-December 4, 2020, Spring Abstracts Final Program 2/3/21
Abstract:
Currently much attention has been devoted to the image quality emerging from any of the imaging modalities such as MRI, PET, SPECT, Optical Imaging, etc. There are two major approaches to achieve the high-resolution images from the existing imaging modalities such as i) by tuning the hardware parameters like magnetic field strength, signal-to-noise ratio, matrix size, field of view, etc., and/or ii) by using smart or responsive probe as an imaging agent for the in-vivo imaging of biochemical or physiological abnormalities as the origin of the diseases. It is well-known that much of in-vivo experiments were unsuccessful after the successful standardization of in-vitro experiments due to the competitive in-vivo targets and/or administration of non-specific imaging agents. Therefore, molecular imaging probe allows earlier with more personalized diagnosis and also facilitates to understand their molecular factors underlying pathological process using the smart behavior of imaging agents. Smart or responsive probe often provides well-resolution images from MRI detectable responses depending on the specific parameter such as pH, the concentration of ions or metabolites, temperature, enzyme sensitive, etc., at the molecular or cellular level. The multimeric paramagnetic chelates have proven with promising results in diagnosis, risk stratification, localization and staging of clinically significant prostate cancer. Herein we report the development of sugar capped biphenolic systems as enzyme sensitive smart probes and its Gd(III) chelates for high-resolution MRI applications. The sugar capped dopamine intermediate is synthesized by the glycosylation of protected dopamine using acetobromogalactose. The as-prepared intermediate is reacted with DOTA-Monoamide moiety for the paramagnetic metal ions chelation. Upon the removal of protecting groups, the high polar compound was purified by flash chromatography followed by the complexation with lanthanides. Upon the cleavage of the sugar moieties by the enzyme β-galactosidase, the relaxation is significantly enhanced due to the formation of macromolecular adducts with the metal centers during the self-assembly process. The aggregation of Gd(III) based imaging agents provides the high-resolution MR Images at the conventional MRI (1.5 Tesla).

Reference
surface loaded with therapeutic miRNAs as a platform. This nanoformulation allows for monitoring the delivery by multimodality imaging. We used the microRNA delivery to presensitize GBM cells to the systemically delivered chemotherapy drug temozolomide (TMZ). We studied this approach in vivo by multimodality molecular and anatomic imaging to monitor, 1) nanoparticle delivery, 2) trafficking, and 3) treatment effects. For efficient loading of microRNAs, we used GIONs coated with b-cyclodextrin-chitosan (CD-CS) hybrid polymer. We used PEG-T7 peptide conjugated using CD-adamantane host-guest chemistry as a targeting agent. The resultant polyGIONs showed efficient miRNA loading, enhanced serum stability, and functional release in cells. For in vivo intranasal delivery, we used orthotopic human xenograft mice model. Intranasal delivery resulted efficient accumulation of miRNAs in mice GMB. We used optical fluorescence, MRI, CT and Photoacoustic imaging to demonstrate in vivo delivery and therapeutic efficiency in mice. We used optical bioluminescence imaging to measure therapeutic response of tumor to microRNA and TMZ combination therapy. Overall, predelivery of microRNAs sensitize GBM to TMZ and significantly increased survival rate of mice, compared to the other control groups. Once translated clinically, this novel theranostic nanoformulation and its associated intranasal delivery strategy will have a strong prospective to potentiate the effect of TMZ treatment in GBM patients.

Emerging Clinical Applications of Cutting Edge MRI Mukesh Harisinghani; Massachusetts General Hospital, United States

MRI is currently used as a modality to detect, characterize, and monitor disease entities. Despite its inherent high soft tissue resolution and lack of ionizing radiation, the modality can be further enhanced to function as a biomarker for specific disease processes. This invited talk will highlight key advances that can further the use of MRI in the era of precision medicine and allow it to function as a useful biomarker, eventually to a single molecule resolution.

Osteogenesis Pathways and Dysregulation at Bone Site in Breast Cancer Bone Metastasis Kalpana Katti1,2, Sumanta Kar1,3 and Dinesh R. Katti1,2; 1North Dakota State University, United States; 2NDSU, United States

Breast cancer, in the late stages, disseminates to the bones, resulting in bone metastasis. Currently, there is no cure available for bone metastasis as the underlying mechanism of the processes that occur at the cellular level is poorly understood due to the failure of animal models and the scarcity of human metastasized samples as most patients with advanced stages of cancer are already in palliative care. Therefore, it is imperative to develop translational disease models to find a cure for cancer by elucidating disease mechanisms at the cellular and molecular level. In recent years, three-dimensional (3D) culture models have attracted substantial attention due to their ability to recapitulate in vivo characteristics, leading to altered gene expression, cytokine secretion, and improved drug response. In the present study, we have developed a 3D in vitro model of breast cancer bone metastasis mimicking later stages of breast cancer pathogenesis to the bones, using osteogenically differentiated human mesenchymal stem cells (MSCs) and human breast cancer cells (MDA-MB-231 & MCF-7) on nanoclay-based scaffolds. These two cell lines represent to highly and less metastatic breast cancer. Here we specifically describe the nature of bone regulation at metastatic site due to these two cell lines. Specifically, we have evaluated the effects of breast cancer cells secreted factors on bone formation in terms of the Wnt/β-catenin signaling pathway. We noticed that stimulation of Wnt/β-catenin signaling in sequential cultures of MSCs with MCF-7 by endothelin-1 (ET-1) led to the increased bone formation while inhibition of Wnt/β-catenin signaling by dickkopf homolog 1 (Dkk-1) exhibited reduced bone formation, thus mimicking mixed bone lesions observed in human breast cancer patients. We also evaluated drug-resistance of our 3D culture model using anti-cancer drug paclitaxel and found tumor-microenvironment released cytokine Interleukin-6 (IL-6) may be involved in conferring drug resistance via STAT3 pathway. Taken together, these critical findings not only further our understanding of breast cancer-induced bone metastasis but also have broader implications in patient-specific therapies in particular those that address skeletal complication due to metastasis.

Spectral Changes in Primary and Secondary Bone Metastasis Site Prostate Cancer Tissues Evaluated by Raman Mapping Jairam Eswara1, Sumanta Kar2,3, Kalpana Katti2,3, Jeon Woong Kang4, Ramachandra R. Dasari5, Peter So4, Ramasamy Paulmurugan6, Dorian Liepmann6, Venkatesan Renugopalakrishnan7,8 and Dinesh R. Katti2,3; 1St. Elizabeth’s Medical Center, United States; 2North Dakota State University, United States; 3Center for Engineered cancer Testbeds, United States; 4MIT, United States; 5Stanford University, United States; 6University of California, Berkeley, United States; 7Northeastern University, United States; 8Harvard University, United States

Prostate cancer in its late stage is likely to metastasize to bone. A reliable marker for bone metastasis does not exist. This study evaluates the use of Raman mapping to evaluate subcellular changes and responses as a marker for bone metastasis. We
have obtained patient tissues from prostate cancer at primary and secondary (bone sites). Raman spectra and Raman maps were obtained for these tissues. A complete and comprehensive study that involved comparison of the spectral maps from the human tissues was compared with data obtained from tumors grown using MDA PCa 2b prostate cell line grown on tissue engineered bone mimetic scaffolds. Our results indicate distinct differences and changes between the prostate cancer samples obtained at primary and secondary sites. Raman spectroscopic features in the lipid, protein, DNA regions of bone metastatic prostate cancer tissues represent very valuable diagnostic information since these experiments can be conducted in a clinical regime with minimal patient discomfort through use of fiber optics. We also used a variety of novel spectral and statistical methods such as PCA to classify the event of bone metastasis. Overall, we demonstrate the potential for use of Raman Mapping combined with powerful data analysis technologies for next generation metastasis diagnosis and prediction.

Fauzi8, Andirvo Rusydi10, Dorian Liepmann9, Piran R. Kidambi10, Narayan Tharangattu11, Subbiah Alwarappan12 and Venkatesan Renugopalakrishnan13,14; 1University of Ottawa, Canada; 2CNRS, France; 3University of Pennsylvania, United States; 4University of Baroda, India; 5Nirma University, India; 6Rice University, United States; 7Stanford University School of Medicine, United States; 8National University of Singapore, Singapore; 9University of California Berkeley, United States; 10Vanderbilt University, United States; 11Tata Institute of Fundamental Research, India; 12CSIR-Central Electrochemical Research Institute, India; 13Boston Children’s Hospital, Harvard Medical School, Boston, United States; 14Northeastern University, United States

Two-dimensional materials, such as graphene and monolayer hexagonal Boron doped Graphene, are attractive for demonstrating fundamental physics in materials and potential applications in next-generation electronics. Atomic sheets containing hybridized bonds involving elements B and C over wide compositional ranges could result in new materials with properties complementary to those of graphene and Boron doped Graphene, enabling a rich variety of electronic structures with tunable properties and applications. Here we report the synthesis and characterization using spectroscopic techniques of large-area atomic layers of Boron doped Graphene material, consisting of hybridized, randomly distributed domains of B and C phases with compositions ranging from pure BNNTs to pure graphene. Our experimental and theoretical studies (based on Density Functional Theory and Continuum calculations) reveal that their structural features and bandgap are distinct from those of graphene and doped graphene. Boron -11 magic-angle spinning NMR experiments confirm the presence of boron in the sample, and the small quadrupolar broadening coupled with the center-of-gravity shift of -4.4 ppm is suggestive of a four-coordinate boron site. Similarly, the two-dimensional 11B MQMAS NMR spectrum presents a broad signal centered at -4.4 ppm (Figure 1b). Slight spectral broadenings are consistent with a small distribution of local chemical environments, such as differences in the identity of geometry about the boron nearest neighbors in boron-doped graphene. This new form of hybrid Boron doped graphene material enables the development of bandgap-engineered applications in bioelectronics and biosensors and properties that are distinct from those of graphene and h-BN.

The structural and electronic properties of Fluorographene (FG) ultra-thin films directly grown on flexible and non-flexible
insulating silicate substrates have been characterized. FG has been identified as an in-plane heterostructure consisting of sp$^2$ and sp$^3$ hybridized carbon domains. $^{19}$F NMR shows a uniform distribution of fluorine throughout the plane in thin-film FG, unlike in other chemically derived FG variants, indicating the presence of sp$^3$ carbon along with the sp$^2$ hybridized domains. It is found that dangling bonds (sp$^3$ carbons without fluorine) cause paramagnetic behavior leading to sidebands in the NMR Spectra. The fluorine doping and band-structure of FG are further confirmed by spectroscopic ellipsometry studies, showing a band-gap of 1.2 eV, consistent with ab-initio SCAN-META GGA Functional based Density Functional Theory (DFT) calculations for 7% Fluorination of the Graphene honeycomb structure. This semiconducting FG layer has been identified as an ambipolar material from gate-controlled transport measurements. The transport properties of FG resemble those of reduced graphene oxide, another functionalized graphene derivative, with an Arrhenius type temperature dependence of resistance at high temperatures. This study unravels new avenues in atomic layer-based electronic circuitries and biosensors, where FG can be used as an active layer or dielectric support by tuning its fluorine content to the requisite level.

Well-Free Cell Agglomeration and Spheroid Forming Using Guided Surface Acoustic Waves through a Couplant

Layer Jiyang Mei$^1$, Aditya Vasan$^1$, Uri Magaram$^{2,3}$, Kenjiro Takemura$^4$, Srekanth Chalasani$^2$ and James Friend$^1$; $^1$University of California, San Diego, United States; $^2$Salk Institute for Biological Studies, United States; $^3$University of California San Diego, United States; $^4$Keio University, Japan

Cell agglomeration has been useful and crucial for tissue engineering, cell culturing and drug testing, such as for cancer drug development. And a 3D structured spheroid is superior to 2D cell cultures for many aspects: greater stability, longer lifespan, more detailed cell-cell interactions, more accurate cell polarization depiction and so on. However, most of the methods require specific and complex experimental setups and the resulting agglomerates are generally slow or of poor quality. We propose a microfluidic device using surface acoustic waves (SAWs), a contact-free means, in the application of cell engineering. It is composed of a piezoelectric substrate, 127.86° Y-rotated X-propagating lithium niobate, and a focused interdigital transducer to generate focused surface waves with resonant frequency at 100 MHz. A conducting metal guiding layer is deposited on top of the substrate to overcome the beam steering and lateral diffraction problems due to the anisotropy nature of the piezoelectric material, further trapping the wave to a small region of a few wavelengths (~10$^3$ μm). The SAWs generated travel into a thin layer of liquid and diffract at the Rayleigh angle so that the acoustic radiation is coupled and propagates into the superstrate, which can be a bio-friendly container culturing cells. The localized acoustic streaming induced from the radiation carries and accumulates the cells to the center of the recirculation. By slightly tuning up the power, the stronger recirculation is able to levitate the periphery of the cell cluster and fold the structure to a three-dimensional configuration, and thus a spheroid can be formed. Our data shows the agglomerations can be created in less than 5 min, and the separation between the living human embryonic kidney cell agglomeration islands is as small as $\Delta x = 720$ μm. With the help of waveguides, the efficiency can be further improved by establishing multiple spheroid formations simultaneously in one well-free container. Therefore, this device is proven to be an effective, reliable and easy-to-handle approach for 3D cell manipulation and spheroid construction, rendering potentials in cell engineering.

8:00 AM *
An Overview of Materials and Design Principles for Skin-Integrated, Stretchable Electronic and Microfluidic Devices in Medicine and Sports John A. Rogers; Northwestern University, United States

Biological systems are mechanically soft, with complex, time-dependent 3D curvilinear shapes; modern electronic and microfluidic technologies are rigid, with simple, static 2D layouts. Eliminating this profound mismatch in physical properties will create vast opportunities in man-made systems that can intimately integrate with the human body, for diagnostic, therapeutic or surgical function with important, unique capabilities in fitness/wellness, sports performance and clinical healthcare. Over the last decade, a convergence of new concepts in materials science, mechanical engineering, electrical engineering and advanced manufacturing has led to the emergence of diverse, novel classes of ‘biocompatible’ electronic and microfluidic systems with skin-like physical properties. This talk describes the key ideas and presents some of the most recent device examples, including wireless, battery-free electronic ‘tattoos’ with applications in continuous monitoring of vital signs in neonatal and pediatric intensive care; and microfluidic/electronic platforms that can capture, manipulate and perform biomarker analysis on microliter volumes of sweat, with applications in sports and fitness.

9:30 AM BREAK

9:45 AM *
Flexible, Stretchable Bio-Inspired Artificial Nervous Systems Tae-Woo Lee; Seoul National University, Korea (the Republic of)
Living organisms have evolved to efficiently developing their functions and structures. For adopting their superior characteristics in many latest technologies, bio-inspired electronics have been extensively developed. Particularly, artificial nervous systems are one of bio-inspired electronics to replicate the functions and operating principles of biological nervous systems. Here, bio-inspired artificial nervous systems were demonstrated by using flexible and stretchable organic electronics. For the artificial mechanoreceptor nervous systems, pressure sensors (artificial mechanoreceptors), organic ring oscillators (artificial nerve fibers), and synaptic transistors (artificial synapses) were integrated like biological counterparts. The applicability for neural prostheses of this artificial sensory nerve was verified by connecting the artificial sensory nerve to the biological motor nerves in a detached inset leg and successfully actuating the biological motor nerves depending on external pressure information. Besides, an organic nanowire-based artificial sensorimotor nervous system was developed by employing a self-powered photodetector (an artificial light-sensory organ), a stretchable artificial synapse, and a polymer actuator (an artificial muscle). The voltage pulses of a self-powered photodetector triggered by optical signals drove the stretchable synaptic transistor, and synaptic outputs were used for actuation of an artificial muscle fiber in the same way that a biological muscle fiber contracts. Lastly, an organic artificial synapse was integrated with a triboelectric sensor for demonstrating an artificial auditory system. The morphology of organic semiconductors of the artificial synapses was modulated to emulate the facilitation recover time of biological synapses. Our bio-inspired artificial nervous systems based on flexible and stretchable organic electronics would be a platform for developing bio-inspired soft electronics, neuro-inspired robots, and electronic prostheses.

11:15 AM BREAK

11:30 AM *
Self-Powered Flexible Electronics Beyond Thermal Limits Keon Jae Lee; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

This seminar introduces three recent progresses of self-powered flexible electronic systems beyond thermal limits. The first part will introduce self-powered systems for IoT sensors and flexible energy source. Flexible nanogenerator converts external bio-mechanical movement into electrical energy for self-powered IoT and biomedical devices such as pacemaker and transportation. In addition, flexible piezoelectric materials detect the minute vibration of membrane or human skin that expands the application of self-powered acoustic sensor and healthcare monitor. The second part will introduce laser material interaction for flexible applications. Laser technology of ultra-short pulse duration becomes important for future flexible electronics since high temperature process can be adopted on plastic substrates, which is essential for high performance electronics. Exciting results of flexible laser material interaction will be explored from both material and device perspectives including nanomaterial synthesis, inorganic laser liftoff and plasmonic material reaction. The third part will discuss flexible large scale integration (f-LSI) for flexible CPU and high density memory. Flexible LSI is an essential part of future electronics for data processing, storage, and radio frequency (RF) communication. To fabricate f-LSI, we integrated 0.18 CMOS process of single crystal silicon nano-transistors with flexible electronics. Simultaneous roll transfer and interconnection of flexible NAND Flash memory was achieved using anisotropic conductive film (ACF). Finally, we introduce the highly efficient and long-term stable flexible vertical micro LED (f-VLED) for full color displays, wearable and biomedical applications. Using optogenetic mouse models, f-VLED stimulated motor neurons deep below layer III from the brain surface and induced mouse behavior changes. These f-VLED can be also used as tools of skin research and phototherapy.

SESSION S.SM03.01: Flexible, Stretchable Electronics, Optoelectronics and Sensor Devices with Human-Machine Integration
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
S-SM03

5:00 AM *S.SM03.01.01
Skin-Inspired Electronic Components and Systems Zhenan Bao; Stanford University, United States

In this talk, I will present our recent work on developing basic materials and devices necessary for integrated electronic systems, such as transistors, diodes, sensors and displays.
Devices interfaced with the spinal cord are critically important for investigations and treatment of spinal cord injury (SCI) as well as diseases such as spinal muscular atrophy and amyotrophic lateral sclerosis. Traditional intraspinal probes, which are capable of recording and stimulating spinal cord neurons have been used to study and develop prostheses for the spinal cord. However, these rigid intraspinal devices generally cause immune responses that lead to glial scar formation and neuronal cell depletion at the tissue/probe interface, thus making chronic applications difficult. Here we report a minimally-invasive and chronically-stable intraspinal cord interface based on tissue-like mesh electronics. Mesh probes containing recording and stimulation electrodes are injected into the mouse spinal cord spanning both the dorsal and ventral regions without removal of vertebrae. Implanted probes do not adversely affect motor behavior and show a similar recovery times as mice undergoing sham surgery but without implants. Significantly, histology analyses show that mesh probes form a seamless interface with surrounding spinal cord tissue and do not elicit glial scar formation or neuronal cell depletion near the probe surface. The seamless mesh implants yield stable in vivo chronic electrophysiology recordings of spinal cord neurons for at least 6 weeks, and have been used to measure neural spike correlations between the motor cortex and spinal cord using optogenetic methods for well-defined stimulation in the motor cortex. Notably, implanted mesh probes have been used to evoke stable movement of mouse limbs via electrical stimulation of spinal cord motor neurons. This ultra-flexible, tissue-like spinal cord interface provides advantages complementary to other spinal cord implants that can enable opportunities for in vivo studies and therapies relevant to SCI and spinal cord diseases.

Enhanced Acoustic Sensitivity of Piezoelectric Sensors with Ultrathin Porous Substrates Md Osman Goni Nayeem1, Sunghoon Lee1, Tomoyuki Yokota1 and Takao Someya1,2; 1The University of Tokyo, Japan; 2Center for Emergent Matter Science (CEMS), RIKEN, Japan

Wearable acoustic sensors have become an important and efficient platform for human-machine interactions (HMI) and body acoustics monitoring. To enable next generation applications, such sensors should be flexible, ultrathin, self-powered and highly sensitive. In contrast to conventional microphone technologies, piezoelectric acoustic sensors have greater flexibility and sensitivity1,2. In the past, the effect of Young’s modulus and thickness of substrates on piezoelectric performance has been investigated3. However, the sensitivity of such flexible piezoelectric sensors is still limited to meet the next generation voice-activated human machine interactions or wearable body acoustics monitoring.

Here, we have developed an ultrathin piezoelectric acoustic sensor with 1.5 µm thick parylene substrates having multiple millimeter sized square holes. The holes on the substrates were created by using green laser. The sensor fabrication was done by sandwiching polyvinylidene fluoride (PVDF) nanofiber between two Au-coated substrates. The overall device is ~8 µm thick and can generate a peak voltage of ~1.2 V when a sound wave of 110 dB at 250 Hz is applied. The sensitivity of our sensor is ~1770 mV/Pa which is ~9 times higher compared to the sensors having similar thickness of substrates without holes. To show the practical applicability as voice sensors, human voice uttering the words were measured and compared with the sensor having planar 1.5 µm thick parylene substrates.

Bioderived and Degradable Gels with Extreme Mechanics for Soft Devices Martin Kaltenbrunner; Johannes Kepler University, Austria

Nature inspires a wide range of bio-mimetic systems ranging from soft robotic actuators to perceptive electronic skins that enhance and support our life. The growing demand on assistive, medical and bioelectronic technologies however raises concerns on the ecological footprint of this emerging platforms, as they are often designed for a defined, limited operational lifetime. Introducing a key feature essential to nature - biodegradability - will enable soft electronic and robotic devices that reduce (electronic) waste and are paramount for a sustainable future.
We here introduce materials and methods such as tough yet biodegradable biogels for soft systems that facilitate a broad range of applications, from transient wearable electronics to metabolizable soft robots. These embodiments are highly stretchable, are able to heal and are resistant to dehydration. Our forms of soft electronics and robots are built from resilient biogels with tunable, extreme mechanical properties that uniquely combine performance and durability with degradability. They are engineered for long-term operation in ambient conditions without fatigue, but fully degrade after use through biological triggers. Electronic skins that measure pressure, strain, temperature and humidity serve as human-friendly on-skin interfaces or equip robotic systems with sensory feedback. Such advances in the synthesis of biodegradable, mechanically tough and stable gels that do not compromise in performance when compared to their non-degradable counterparts may bring bionic soft systems a step closer to nature and enable human-friendly technologies with reduced ecological footprint.

5:50 AM S.SM03.01.06
Investigating the Role of Extracellular Vesicles in Cancer Metastasis Using Bioelectronic Technologies Walther Traberg-Christensen¹, Anna-Maria Pappa¹, Malak R. Kawan², Sahika Inal², Susan Daniel³ and Roisin Owens³; ¹University of Cambridge, United Kingdom; ²King Abdullah University of Science and Technology (KAUST), Saudi Arabia; ³Cornell University, United States

Extracellular vesicles (EVs) (30-1000nm) have garnered much attention lately due to their role in cancer metastasis. EVs act as mediators in cell-cell communication and have the ability to transfer genetic information between donor and recipient cells. Tumor cell-derived EVs (TDEs) have recently been reported to play an active role in tumorigenesis and metastasis owing to their ability to transmit oncogenes. One hypothesis is that TDEs contribute to metastasis by inducing the epithelial-to-mesenchymal transition (EMT), characterized by the loss of barrier function in barrier tissue-forming cells.

This study aims to elucidate the mechanisms of TDE egress and uptake by investigating the process by which TDEs “infect” normal cells inducing EMT prior to metastasis. Current strategies for investigating the spatial and temporal aspects of EV uptake, often optical, lack the ability to obtain quantitative data in real time. We have shown that organic electronic devices (OEDs) based on the conducting polymer poly(3,4-ethylenedioxythiophene): poly(styrenesulfonate) (PEDOT:PSS) can be interfaced with biological systems of varying complexity allowing for quantitative real-time monitoring of biological interactions. The optical transparency of our PEDOT:PSS-based OEDs provides the unique advantage of dual transduction increasing the credibility of our platform and enriching the biological information obtained. Moreover, their compatibility with microfabrication methods allows for high throughput studies.

We have shown that transistor-based OEDs are highly sensitive to the integrity and interactions with barrier tissue-forming cells. As proof-of-principle, we show the chemically-induced disruption of these tissue barriers, and their subsequent recovery, in Madin-Darby Canine Kidney (MDCK) epithelial cells grown on our OEDs. In ongoing studies, monolayers of MCF-10A human mammary epithelial cells will be exposed to TDEs extracted from the human breast cancer cell line MDA-MB-231 to electrically monitor the phenotypic changes elicited by TDEs. This data will be further substantiated by monitoring the expression of immunofluorescently labelled barrier-forming tight junction proteins at set intervals. These combinatorial optical and electrical measurements of TDE interactions with cell monolayers provide invaluable information for developing strategies for inhibiting TDE interactions by e.g. blocking specific surface markers, thereby preventing TDE-induced EMT.

6:00 AM S.SM03.01.07
Facilitating Hair Growth via Flexible Vertical RED µLEDs Jae Hee Lee; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

A lot of people around the world have suffered from alopecia, which can lead to aesthetic issues, low self-esteem, and social anxiety. Therapeutic technology including thermal, electrical, pharmacological, and photo stimulation have been suggested to treat hair loss. Among them, laser stimulation to hair is a strong treatment, activating the proliferation of hair follicles without side effects. Particularly, periodically irradiating red light with a wavelength of 650nm in the hairless area can help efficient stimulation of hair follicles under the skin, because this light can penetrate deeper into the skin tissue than blue and green light with short wavelengths. However, this laser stimulation treatment has difficulty in high power consumption, large size, and spatiotemporal restriction. Recently, flexible micro-light-emitting diodes (µLEDs) have been a great attention for future biomedical devices, such as biosensors, pulse oximetry (SpO2) sensors, and optogenetic stimulators due to its high performance and outstanding stability. However, flexible µLEDs still have significant drawbacks in application to wearable phototherapeutic devices, such as high heat, low optical efficiency, and high energy consumption. Herein, we report high-performance 30 × 30 AlGaInP fVLEDs fabricated with transfer-free monolithic method for a wearable phototherapeutic
device. Ultrathin flexible μLEDs were fabricated by vertically interconnecting top and bottom electrodes. The red f-VLED arrays were conformally attached on a human wrist with high irradiance of ∼30 mW mm−2 and low forward voltage of ∼2.8 V. The red light with 650 nm wavelength deeply penetrate the skin and stimulate the hair follicles, which is located 2 mm under the skin. The thermal stability of the monolithic f-VLED was theoretically investigated by using finite element method (FEM) simulation and experimentally optimized by operating f-VLEDs on the skin. Mechanical stability of monolithic f-VLEDs was confirmed by harsh periodic bending/unbending motions, which is necessary for skin-attachable phototherapeutic devices. Finally, photostimulation in hairless region was performed to promote hair growth in a living depilated mouse via f-VLED array with thermal stability. Hair regrowth in the mice via f-VLED was verified by analyzing immunofluorescent and histological effects.

6:10 AM S.SM03.01.09
Near-Infrared Light Emitting Contact Lens for the Treatment of Diabetic Retinopathy Geon-Hui Lee and Sei Kwang Hahn; Pohang University of Science and Technology, Korea (the Republic of)

Recently, photobiomodulation using near-infrared (NIR) light has been widely investigated for non-invasive healthcare applications including skin and hair therapy, and ocular therapy for diabetic retinopathy, methanol toxicity, and light damaged retina [1-3]. NIR light activates the photoreceptor of mitochondria and increases the therapeutic effect by accelerating the production of growth factors and the cell proliferation. Here, we successfully developed a NIR light emitting contact lens for the treatment of diabetic retinopathy possibly with greatly improved patient compliance. A NIR light emitting diode (LED) connected with an application specific integrated-circuit (ASIC) chip and a wireless power and communication system was fabricated on a PET film, which was embedded by photo-crosslinking in a silicone hydrogel contact lens. The LED contact lens could be on-off controlled wirelessly even in the presence of water without any significant deformation. The retinal vascular hyper-permeability induced by diabetic retinopathy in rabbits was reduced to the statistically significant level by simply wearing the NIR light emitting contact lens. Histological analysis also confirmed the safety and feasibility of LED contact lenses for treating diabetic retinopathy. This platform technology for LED contact lens might be harnessed for various applications to photomedicines, and augmented and virtual reality display applications.

6:20 AM *S.SM03.01.10
Point-of-Use Flexible Sensors for Assessment of Motor Disorders and Wound Healing Pathways Moran Amit, Udit Parekh, Kaiping Wang, Brian Eliceiri, Harinath Garudadri and Tse Nga Ng; University of California, San Diego, United States

Rapid, on-site assessment is highly desirable in the medical diagnosis and treatment. To achieve this goal, our research aims to develop low-cost, flexible, large-area sensor devices for different health applications. In this presentation, we discuss case studies using flexible sensors for two different applications:

1) Motor skills characterization. There is no objective metric for evaluating motor skill training progress, and current assessments rely on qualitative surveys. We have fabricated an instrumented glove with pressure and motion sensors for motor characterization. This glove is useful for characterizing motor skills of people suffering from spasticity, a neuromuscular disorder that causes muscle stiffness/resistance and jerky movement. Analyses of force versus velocity show movement-dependent muscle resistance in a patient with spasticity. Through the flexible sensor systems, the shift from subjective scores to objective measurement will promote better diagnosis and dramatically improve the accuracy in tracking patient response to therapy.

2) Wound healing characterization. Wound healing is a complex process involving diverse changes in multiple cell types where the application of electric fields has been shown to accelerate wound closure. We show on an in vivo electrical stimulation model in which flexible electrodes were applied to an animal model for monitoring inflammation in a wound. The wound site was subjected to electric fields using flexible electrode arrays, and immune cells were then harvested for flow cytometry analysis to study molecular mechanisms, to identify a signaling pathway that is activated during the healing process.

6:35 AM S.SM03.01.12
Flexible, Bi-modal Sensor Array for Pressure and Temperature Sensing by Combinational Design of Thermochromic
Composite Elastomer and Transparent Ionic Hydrogel

Thanh-Giang La$^{1,2}$, Hemant Charaya$^3$, Hyun-Joong Chung$^1$ and Lawrence H. Le$^{1,1}$; $^1$University of Alberta, Canada; $^2$VinUniversity, Viet Nam; $^3$Log 9 Materials, India

Flexible sensor arrays have been developed for a broad spectrum of electronic skin (e-skin) applications such as human-machine interfaces, functional prostheses, and health monitoring devices. In many applications, high sensitivity of pressure and temperature are necessary for e-skins. Such multi-functionality, especially bio-modal sensing, of e-skins often requires complex fabrication and integration processes. We present a simple and effective design strategy of a bimodal e-skin sensor array that is capable of visual indication of temperature sensing by changing color in a range of 26 – 40 °C, as well as an ability to sense finger tap as a pressure sensor. We fabricated a 4 × 4 flexible array of soft, small-diameter capacitive bimodal sensors. The sensors consisted of a dielectric layer of elastomer composite containing thermochromic liquid crystal (TLC), which were sandwiched by transparent electrodes made of ion conductive, compliant, and adhesive polyampholyte (PAm) hydrogels. They were able to sense gentle touching of ~20 kPa and to perform reliably over a thousand repeated cycles of pressing up to 300 kPa. As functioning bimodally, these sensors also changed color in response to temperature, where the quantification of the temperature was achieved from calibration of hue-temperature curves of the elastomer composite at the precision of 0.1 °C. The e-skin array has demonstrated a promising potential for applications in medical devices and biorobots due to its biocompatibility and stretchability.

6:45 AM *S.SM03.01.13
A Bioelectronic In Vitro Model of the Microbiome-Gut-Brain Axis
Roisin Owens; University of Cambridge, United Kingdom

In vitro models of biological systems are essential for our understanding of biological systems. In many cases where animal models have failed to translate to useful data for human diseases, physiologically relevant in vitro models can bridge the gap. This is particularly true for modelling the effect of microbiome interactions on the gut-brain axis. An in vitro model of the gut-brain axis provides the opportunity to deepen our understanding at a molecular level, of the intriguing findings emerging from studies on germ-free mice and clinical studies on humans, about the interplay between the microbiome, the gut and the brain. However, many difficulties exist in interfacing complex, 3D models with sensing technology adapted for monitoring function of cells within these models. The introduction of polymeric electroactive materials into the heart of the tissues being modeled, simultaneously provides the opportunity to host the tissues in question, and monitor their growth and differentiation. In this presentation I will discuss our recent progress in developing 3D sponge-like electrodes that host a multi-cellular models with continuous monitoring and show how we are getting towards our goal of a complete platform to model microbiome-gut-brain interactions.

7:00 AM S.SM03.01.15
Soft Wireless Device Sensing Mechanoacoustic Signals of Multiple Physiological Processes and Body Motions at the Suprasternal Notch
KunHyuck Lee, Xiaoyue Ni, Jongyoon Lee and John A. Rogers; Northwestern University, United States

The human body consists of complex and dynamic systems that network throughout the body. The neck is an essential crossroads of several critical systems under soft tissue in a spatially confined area. These unique characteristics of the neck allow access to a rich set of mechanical and acoustic signals of key dynamic systems – all observable at a single location. In our recent work, we demonstrate the application of a novel wireless flexible sensor that can capture these mechano-acoustic signals effectively. The sensor design combines low modulus, elastic mechanics with mechanically isolated islands of conventional rigid electronic components along with added reinforcements. Together, the sensor can conform to intricate and irregular mounting surfaces and maintain contact during the natural motion of the neck without causing skin irritation and mechanical failure of the internal electronics.
Electronic devices are typically manufactured in planar layouts but many emerging applications, from optoelectronics to wearables, require three-dimensional curvy structures. The fabrication of such structures has been proved challenging due, in particular, to the lack of an effective manufacturing technology. This presentation will show our development of conformal additive stamp (CAS) printing technology and its employment to reliably manufacture 3D curvy electronics. CAS printing employs a pneumatically inflated elastomeric balloon as a conformal stamping medium to pick up pre-fabricated electronic devices and print them onto curvy surfaces. To illustrate the capabilities of the approach, we will demonstrate various devices with curvy shapes: silicon pellets, photodetector arrays, electrically small antennas, hemispherical solar cells, and smart contact lenses. We also show that CAS printing can be used to print onto arbitrary 3D surfaces.

5:10 AM S.SM03.02.02
Ultra-Fast R2R Manufacturing Process for Highly-Sensitive Flexible Devices

Ying Zhong¹, Long Wang², Rui Kou² and Zijian Weng³; ¹University of South Florida, United States; ²University of California, San Diego, United States

Flexible skin-like sensors are the essential component for future human health monitoring and therapeutic treatment. However, the price of flexible devices is still too high for wide applications. The development of ultra-fast and low-cost roll-to-roll (R2R) printing technology of flexible devices is critical for the actual application of flexible devices. In current printing technologies, organic additives are often mixed into the functional components to offer the flexibility of the printed flexible sensors. However, the time-consuming drying process of those additives is the major hinder for the low cost and fast R2R printing of flexible sensors.

We present a new ultra-fast R2R printing technology by taking advantage of the "induction induced absorption" behavior of dry powders in strong electric field. Dry graphene, CNT, silver nanowire, and many kinds of functional powders can be printed. The printing speed can reach as high as 50 cm²/s. The specially printed and naturally formed 3D structure offered high flexibility and sensitivity, allowing our skin-like sensors able to obtain extremely high sensitivity. Different kinds of materials can be integrated into one device. Different kinds of substrates with various surface condition can also be printed, including flat surface and complex 3D structures (e.g. textiles). The printing parameters were studied and optimized, the printing mechanism was simulated, and the printed devices were tested. Those devices are capable of detecting strain, stress, temperature, and even the frequency of sound. This technology opens a new door for fast and low-cost high-performance flexible sensor processing.

5:20 AM S.SM03.02.03
Monolithic Flexible Vertical-Structured GaN Based MicroLEDs for Biomedical Stimulator

Sang Hyun Park¹, Han Eol Lee², Jung Ho Shin¹, Jung Hwan Park¹, Jae Hee Lee¹ and Keon Jae Lee¹; ¹Korea Advanced Institute of Science and Technology, Korea (the Republic of); ²Massachusetts Institute of Technology, United States

With the upcoming of internet of things (IoT) era, visual IoT platforms for hyperconnected visual communication attract a lot of attention and flexible inorganic based micro light emitting diode (micro LED) is one of the most promising candidates for visual communication applications. Inorganic micro LEDs have been considered as a strong candidates to replace the conventional light sources such as organic light emitting diodes (OLEDs), liquid crystal displays (LCDs) for display applications, because of their great electrical/optical properties, long lifetime, fast response time and high stability in severe environments. Despite of several previous researches about the micro LEDs, flexible vertical structured GaN micro LEDs (f-VLEDs) on plastic substrates have not yet been demonstrated due to the difficulty of vertical electrical interconnection with high power efficiency and thermal stability.

Herein, we demonstrated a high-performance flexible 30 x 30 GaN f-VLEDs array through a simple monolithic process. Inorganic-based laser lift-off (ILLO) process separated GaN LED chips from the sapphire substrates which is the mother substrate of GaN epilayer. The separated micro LED chips were electrically isolated by biocompatible polymer layers and electrically interconnected vertically via silver nanowires (AgNWs). These Flexible and transparent GaN VLEDs devices were conformally attached to a human fingernail emitting bright blue light with high optical power of 30 mWmm⁻². The lifetime of f-VLEDs was investigated experimentally via high accelerated stress test (HAST) and measured theoretically via finite element method (FEM) simulation. In addition, periodic bending test was employed to verify excellent mechanical stability of f-VLEDs. The wireless power supply system successfully transmitted electrical power to the f-VLEDs on human skin. Finally, the monolithic GaN f-VLEDs successfully inserted into a living mouse brain and emitted bright blue light without severe histological damage in mouse brain.
Materials Approaches Towards Biointegrated Polymer Electronics  
Jonathan Rivnay$^{1,2}$, 1Northwestern University, United States; 2Simpson Querrey Institute, United States

Direct measurement and stimulation of ionic, biomolecular, cellular, and tissue-scale activity is a staple of bioelectronic diagnosis and/or therapy. Such bi-directional interfacing can be enhanced by a unique set of properties imparted by organic electronic materials. These materials, based on conjugated polymers, can be adapted for use in biological settings and show significant molecular-level interaction with their local environment, readily swell, and provide soft, seamless mechanical matching with tissue. At the same time, their swelling and mixed conduction allow for enhanced ionic-electronic coupling for transduction of biosignals. Such properties stress the importance of bulk transport processes and serve to enable new capabilities in bioelectronics, including new device concepts and form factors. I will demonstrate how such materials properties relax design constraints, allowing for flexible amplification systems for electrophysiological recordings. I will also discuss the unique form factors as applied to electroactive scaffolds and bioactive composites to module tissue state and/or cell fate. New materials design will continue to fill critical need gaps for challenging problems in bio-electronic interfacing.

An Ambient-Stable and Stretchable Ionic Skin with Multimodal Sensation  
Binbin Ying$^{1,2}$, Jianyu Li$^2$ and Xinyu Liu$^1$; 1University of Toronto, Canada; 2McGill University, Canada

Skin is the largest organ of the human body, serving as physical and hygroscopic barriers to protect the inner body and control transdermal water exchange and also containing signal sensors to perceive various environmental stimuli such as pressure, deformation, and temperature. These functions are linked with salient features of the skin: highly deformable polymer networks to resist physical damages; hygroscopic compositions to retain water; a variety of sensory neurons powered by biological sources to transduce stimuli into controlled ion movements and propagation of action potentials. To recapitulate these features for wearable electronics and healthcare applications, significant efforts have been made on engineering electronic counterparts of the human skin (i.e., electronic skin), leading to various design strategies involving electronic components, elastomeric substances or a combination of thereof. Despite their remarkable functionalities and applications that have been demonstrated, existing electronic skins differ from the native skin in terms of charge carriers (electrons versus ions in native skin), the content and permeability of water, resulting in limited biocompatibility and suboptimal human-machine interfaces especially for the long-term usage.

While the gap between real and electronic skins persists, recent progress of iontronics highlights the use of hydrated and ionic materials like hydrogels for making ionic devices (i.e., pressure sensors and touchpad) capable of transducing mechanical stimuli into electrical signals such as of capacitance or resistance. The existing ionic devices usually convert the applied touch, pressure, deformation or temperature into a change in their resistance or capacitance, the electrical readout of which requires continuous power supply. Although stretchable batteries can be integrated with those ionic devices, the requirement of external or on-chip power supplies still, to some extent, compromises long-term usage. Further development is needed toward a multifunctional self-powered ionic device. First, the devices should equip with self-generated power to mitigate the need of external power supply for long-term usage. Second, they need to enable the sensing of more than one stimulus like the human skin. In addition, the devices must be physically stable (i.e., mitigating water loss) during usage and biocompatible when interfacing with the human body.

Herein, a novel artificial ionic skin (Alskin) has been demonstrated to recapitulate the salient features of the human skin. Alskin exhibits excellent skin-like mechanical deformability and ambient stability. It can sustain more than 400% strains without rupture and maintain its function after storage and 800 cycles of deformation. Different from the previous ionic devices consisting of homogenous hydrogels and/or elastomer, our design utilizes a heterogenous hydrogel of bilayer structure, which can realize controlled ion movements responsive to the mechanical deformation and humidity. This design resembles the conventional electronic diodes structurally and the sensory neurons in human skin in terms of stimuli sensing function. The Alskin converts both mechanical stimuli and humidity into four types of electrical signals: resistance, capacitance, open circuit voltage (OCV) and short circuit current (SCC), among which the latter two signals are self-generated without external power supply. Its multimodal sensation maintains in a wide range of relative humidity (13%−85%). It has been demonstrated for wearable strain-humidity sensing, human-machine interaction and walking energy.
harvesting. These features of our AI skins can potentially blur the boundary between humans and devices, and promise broad applications ranging from wearable and implantable devices, soft robotics to wound dressing capable of monitoring the local body motion and moisture of the wound bed.

A Tailored, Conformable Suit for Large-Scale Spatiotemporal Physiological Sensing In Vivo Canan Dagdeviren; Massachusetts Institute of Technology, United States

The rapid advancement of electronic devices and fabrication technologies has further promoted the field of wearables and smart textiles. However, most of the current efforts in textile electronics focus on a single modality and cover a small area. In this work, we introduce a new platform of modular, conformable (i.e., flexible and stretchable) distributed sensor networks that can be embedded into digitally-knit textiles. This platform can be customized for various forms, sizes and functions using standard, accessible and low-cost manufacturing techniques. Here, we have developed a tailored, electronic textile conformable suit (E-TeCS) to perform large-scale, multi-modal physiological (temperature, heart rate, and respiration) sensing in vivo. The modular approach results in a conformable suit integrated with a large assortment of conformable electronic components for large-scale physiological sensing. The E-TeCS can detect skin temperature with an accuracy of 0.1 °C and a precision of 0.01 °C, as well as heart-rate and respiration with a precision of 0.0012 m/s² through mechano-acoustic inertial sensing. The knit textile electronics can be stretched up to 30 % under 1000 cycles of stretching without significant degradation in mechanical and electrical performance.

5:40 AM *S.SM03.03.05
Transfer Printing of Flexible, Stretchable Materials for Sticker-Like Electronics in Bio-Integrated Applications Chi Hwan Lee; Purdue Univ, United States

Advanced materials engineering and processing technologies provide means to realize a range of thin, flexible and stretchable biosensors for human body-integrated healthcare systems, opening up a new prospect in wearable technology. The mechanical flexibility and stretchability allow the devices to intimately integrate with biological systems such as the skins and organs at their length scale. The embedded semiconducting nanomaterials provide the functionalities that can monitor the clinically useful bio-signals with sufficient spatial and temporal controls. This presentation will introduce a novel technology so called as sticker-like electronics (or sticktronics) in which integrated functional circuits are defined on a temporary sticker that can be attached to anywhere of interests including the skin and organs for their wearable and implantable biomedical applications. Mechanically soft, compliant skin sensor patches and tissue-injectable silicon nano-needles will be discussed to show the representative applications in wearable healthcare monitoring and intratissue drug delivery. The novel design concepts by combining highly networked nanomaterials or nature-inspired layouts offer a route to enhance important mechanical properties, allowing for reliable contact to the skin and tissues even under dynamic motions. These strategies also provide long-term longevity of such devices against potential fracture and delamination by improving the overall crack resistance, contact adhesion, and normal/shear strength. Discussions about the results of detailed experimental and theoretical studies will be followed to reveal the essential attributes of the materials, mechanics, fabrication processes, and system configurations. Pilot demonstrations on patients with swallowing disorders for their efficient rehabilitation will demonstrate an example utility of the devices in current clinical settings.

5:55 AM S.SM03.03.06
Stretchable Epidermal Electronics on Skin Sweat Monitoring Zhibo Chen and Jie Hu; Hong Kong University of Science and Technology, Hong Kong

Clinical prevalence of electrolyte imbalances is frequently seen in kids, beginner athletes, elderly and critically ill patients, and occur in the progression of diseases such as severe cardiovascular events like myocardial infarction, acute or chronic renal failures, etc. Sweat, due to the ease of non-invasive collection and the on-demand of convenient generation, shows great promise for wearable sensing, which is ideal for real-time continuous indicating body’s deeper biomolecular state and personal health condition. Recent advances in soft bioelectronics, especially epidermal sweat sensors, serve as the foundations for novel epidermal-based healthcare systems that overcome critical limitations of conventional personalized healthcare monitoring. However, a bottleneck of advanced sweat sensing is achieving accurate and stable measurement performance, comfortability, and high-throughput fabrication of sweat sensor components, including soft integration, epidermal packaging, and data analysis. Some reports have shown the possible methods of disposable sweat sensor components for fitness application, which still stands in an early research exploration with poor epidermal compatibility and low-efficiency sensing performance.
In this work, we introduce a hybrid stretchable epidermal sweat sensor, comprised of a miniaturized thermistor, signal processor and analog front-end, etc. for integrating into a soft system in package patch module. The sensor allows sweat sensing by using a group of gold-based fine bus electrode with a micro-chamber for real-time measurement of sweat electrolyte parameters. Analytical and experimental study optimized the system to establish a trade-off between the comfort of the user, the capacity for long-term use, and the reliable epidermis sensing data. The hybrid stretchable circuit technology, which is interconnected by a meander shaped conductive line, allows a good compromise between rigid chip components and bio-compatible elastomer packaging. The electrode pattern demonstrates the minimum bio-electricity interference by body organs and fluid. The soft mechanics of the sweat sensor patch allow multi-day wear in the presence of outdoor activity.

This work overcomes current engineering challenges in fabricating a bio-stretchable soft electronics system comprising multiple functional electronic components. As such, by using the existing micro-electrical fabrication process, the design of the sensor is enabling a low-cost technology in soft electronics manufacture. Overall, by enabling a comprehensive sweat analysis, the presented sensor is a promising monitor for advancing sweat testing in the point-of-care medical and fitness applications.

6:05 AM S.SM03.03.07
Self-Healing Dielectric Supramolecular Elastomer through Multiple Hydrogen Bonds  
Matthew Tan, Gurunathan Thangavel and Pooi See Lee; Nanyang Technological University, Singapore

The application of self-healing materials to flexible and stretchable devices that can conform to biological components and deform with soft bodies in a mechanical invisible manner have been emerging. This is driven by the need to prolong their lifetime through spontaneous recovery upon physical damages. Despite these astounding abilities, these materials are often soft and lack intrinsic toughness, attributed to the high mobility of polymer chains to form entanglements and reassociations across the damaged region for self-healing purposes. Consequently, these materials usually fail at high tensile stresses (>1 MPa) making it susceptible to damages upon high loads. In this work, we address this dichotomy of achieving high self-healing efficiency and toughness simultaneously by introducing multiple hydrogen bonds into thermoplastic polyurethane to increase its intrinsic toughness, absorbing energy without fractures. With the introduction of multiple strong, reversible and complementary non-covalent hydrogen bonds, self-healing is achieved as these dynamic bonds are able to reassociate after breaking effectively. We further found that introducing particular solvents during the healing process, leads to a drastic improvement to the healing efficiency. This can be attributed to the solvent’s role as a plasticizer and a de-crosslinking agent that allows greater chain mobility. The healed polymer displayed exceptional mechanical properties of elongation at break of 1800%, a tensile strength of 5.30 MPa and toughness of 37.8 MJ m⁻³ within 12 hours. Proving to be one of the first healed polymers that realized both high tensile strengths and elongations concurrently. Furthermore, these hydrogen bond moieties are polar in nature, contributing to the high dielectric permittivity of the film. As such, when applied as a dielectric elastomer actuation (DEA) layer, the DEAs delivers higher actuator performance and achieves significant recovery of its actuator performance in terms of area strains after self-healing.

Metal Oxide-Polymer Semiconductor Blends for Flexible TFTs—Influence of the Polymer Structure and Amine Nitrogen Content  
Antonio Facchetti¹,²; ¹Northwestern University, United States; ²Flexterra Inc., United States

In this presentation we report the correlation between polymer structure and charge transport in solution-processed indium oxide (In₂O₃):polymer blend films by using several polymers having different amine nitrogen atom content (N%). These amine containing polymers control the electron mobilities of the semiconducting oxide films by tuning the carrier/trap concentrations via a combination of electron transfer/doping and charge trap/scattering center formation, effects which depend on the polymer species and loading contents in the metal oxide matrix. All polymer addition enables the formation of more ductile semiconductor metal oxide films, as measured in a flexible thin-film transistor architecture. However, while
PVP addition reduces the field-effect mobility vs. the pristine (no polymer added) In$_2$O$_3$ matrix, for all other N-containing polymers there is always a certain polymer weight addition to the In2O3 precursor formulation which increases the mobility of the In2O3 matrix. Equally interesting, increasing N% in the polymer from 0% in polyvinyl phenol (PVP) to 34% in polyethyleneimine (PEI), the electron doping capacity gradually increases, enabling to increase the polymer content in the formulation at which the mobility is maximized from 0 wt.% to 1.0 wt.%, thus further enhancing blend ductability. Note, the positive effect of the N-containing polymer remains effective even with a polymer (PVP-NH$_2$) having a N% as low as 3.9%, Finally, we discovered correlations between the electron donating capacity of the polymer, charge transport, polymer chemical structure and thermal stability, as well as elemental composition in the final In$_2$O$_3$-polymer blend film.

5:10 AM *S.SM03.04.02
Freestanding Functional Structures by Aerosol-Jet Printing for Stretchable Electronics and Sensing Applications Sohini Kar-Narayan; University of Cambridge, United Kingdom

Modern electronics is rapidly evolving away from rigid devices to soft, flexible and stretchable devices. This evolution is being driven largely by the growing demand for wearable and human health monitoring applications, which require the development of conformal electronics with added functionality. Much of the effort in this area has relied on printing or transferring structures onto elastomeric substrates. However, the processing involved can often be cumbersome, and the structures themselves tend to suffer from poor fatigue characteristics. Here, I will describe a customised aerosol-jet printing (AJP) process to fabricate fully freestanding stretchable multi-layered devices. The AJP technique has distinct advantages in terms of fast-prototyping, wide ink compatibility with minimum printed feature size down to 10 µm. This versatile method facilitates the incorporation of multiple materials for added functionality that can serve a variety of applications. The ability to print multiple layers of different materials means that multiple conductive wires could be stacked up into one freestanding wire, separated by a dielectric polymer to prevent shorting. This feature makes single-wire circuitry possible by reducing the level of design complexity for practical stretching applications. For example, such freestanding structures can be used as stretchable interconnects, strain and humidity sensors, or even for printed thermoelectric energy harvesters. Desired structures consisting comprising both conductive and functional layers can be printed layer by layer on a substrate with a sacrificial film, that is subsequently dissolved to release the printed structures, thus yielding freestanding self-supported stretchable interconnects and/or functional devices. Devices made from this approach showed good electrical stability and stretchability, and are thus well-suited for applications in flexible/stretchable electronics, such as in conformal tactile, strain and humidity sensing applications, as well as in energy harvesting.

Recent Progress on Compliant Electronic and Electromechanically Responsive Materials and Device Explorations Qibing Pei; University of California, Los Angeles, United States

The emergence of devices that combine rubbery elasticity with electronic, optoelectronic, and mechanically transductive properties offers exciting new opportunities for applications, but brings significant materials challenges. This presentation will describe our latest results in the materials efforts in developing highly compliant conductors, semiconductors, and dielectric polymers, as well as in the demonstration of integrated functional devices. Specific examples include a touch responsive sensors, a bistable electroactive polymer for tactile display, dielectric elastomer actuators, and compliant electrode for neural detection and stimulation.

Wearable Electronics Using 1D-2D Hybrid Nanomaterials Jang-ung Park$^{1,2}$; $^{1}$Yonsei University, Korea (the Republic of); $^{2}$Institute for Basic Science (IBS), Korea (the Republic of)

Research on wearable electronics with flexible and stretchable forms has been grown remarkably by adopting the advent of various nanomaterials and their hybrid. This talk presents multifunctional wearable electronic devices for humans based on RLC circuits, where R (resistance) responds to molecular binding of biomarkers in the body fluid while L (inductive) and C (capacitance) change in accordance with structural changes of capacitance materials induced by varying pressure. These devices are based on diverse nanomaterials and their hybrid structures in order to exhibit high transparency and superb mechanical stretchability, with wireless sensing capability. Furthermore, in-vivo tests demonstrate their reliable operations.

5:55 AM S.SM03.04.07
Point-of-Care Soft Contact Lens System for Monitoring and Treatment of Dry Eye Syndrome Jiuk Jang$^{1,2}$, Joohee Kim$^{1,2}$ and Jang-Ung Park$^{1,2}$; $^{1}$Yonsei University, Korea (the Republic of); $^{2}$Institute for Basic Science (IBS), Korea (the Republic of)
Contact lenses, which make continuous contact with the ocular surface and tear fluids, have been utilized recently as a wearable platform for the healthcare device. However, most of the sensors used in contact lenses have been fabricated on lens-shaped plastic substrates with low oxygen permeability using opaque electronic materials, which means that the safety of the devices is not guaranteed. To solve difficulties associated with wearable healthcare devices, the substrate materials of a wearable platform in the entire system must be convenient and harmless for people to wear, and the individual components that make up the system, such as sensors and interconnects, should be stretchable and transparent.

Here, we fabricated a graphene field-effect transistor (FET)-based biosensor on a soft contact lens and skin-attachable thermal therapeutic device using stretchable and transparent electrodes for monitoring and therapy of dry eye syndrome (DES). The smart contact lens that makes up this system is the first point-of-care device to quantitatively diagnosis MMP-9, which is a biomarker for DES. By incorporating both diagnostic and therapeutic devices and the wireless communications into an integrated system, real-time biomarker monitoring signals from the biosensors are transmitted to the smartphone, and the hyperthermia command is issued to the therapeutic device simultaneously. Furthermore, in-vivo and in-vitro test using a live rabbit exhibited the reliable operation of the system. This integrated system can provide ultimate solutions for personal health management when it is combined with advanced technologies such as artificial intelligence and virtual reality.

Skin-Mountable Submental Sensor Patch for Remote Management of Patients with Oropharyngeal Swallowing Disorders Min Ku Kim, Cagla Kantarcigil, Georgia Malandraki and Chi Hwan Lee; Purdue University, United States

Every year approximately 9.44 million of adults, and more than 500,000 children, are diagnosed with swallowing disorders (a.k.a. oropharyngeal dysphagia) in the US. Swallowing is a fundamental human need and an act of pleasure; yet, oropharyngeal dysphagia is a common symptom in many diseases (e.g., head and neck cancer, stroke, dementia, Parkinson’s disease, cerebral palsy). Without proper treatment, dysphagia can lead to devastating consequences such as malnutrition, dehydration, respiratory compromise (due to aspiration of food/liquid into the lungs), or even death. Successful rehabilitation of oropharyngeal dysphagia requires frequent performances of head/neck exercises that primarily rely on expensive biofeedback equipment (e.g., oral manometers, electromyographic devices, and endoscopy), often only available in large medical centers. Such conditions require patients to make frequent visits to the clinic for a treatment session, which is often not feasible or economically viable for many patients. This directly affects treatment compliance and outcomes which highlights the need to develop a portable and inexpensive remote monitoring system for the rehabilitation and the tele-rehabilitation of dysphagia. Alternative strategies involve the use of portable monitoring devices to obtain biofeedback signals during swallow exercises in a form that allows real-time data collection or cloud storage for post-data processing. However, much of currently available systems suffer from rigid or semi-flexible platforms that are not well suited to dynamically interface with the curvilinear surface of the submental area (under the chin), particularly within the context of head/neck movement, thereby often resulting in poor data acquisition and discomfort to patients. This talk will outline materials and optimal mechanical design for a non-invasive, skin-mountable sensor patch that can fit conformably on the surface of the submental area and can be attached and detached multiple times without causing skin irritation. The sensor patch can remotely provide high-fidelity recording of surface electromyography signals from the submental muscles, as well as, mechanical strain waveforms from thyroid notch movement during a swallow. The sensor patch has been successfully demonstrated on a patient with Parkinson’s disease suffering from dysphagia and on a healthy control subject to show the feasibility and effectiveness of this system for the remote monitoring of patients with swallowing disorders.

5:10 AM *S.SM03.05.04
Organic Mixed Ion-Electron Conductors for Bioelectronics Magnus Berggren; Linkoping University, Sweden

Organic mixed ion-electron conductors (MIEC), included in electrodes and devices, are now being heavily explored as the signal translation interface at the biology-technology interface, targeting biology, medicine and a vast array of internet-of-things applications. Commonly, the MIECs are based on polymers including conjugated conducting pathways for electronic charges and ion transport-promoting side-groups or polyelectrolytes. These MIECs operate as polarizable electrodes and the
coupled charge depletion-ion exchange defines the mode of operation for many bioelectronic devices. The fundamentals of MIECs are reported along with a few targeted device concepts targeting both electrode, sensor and actuator concepts for various applications.

5:25 AM S.SM03.05.05
Distortion-Free Direct-Patterning of Graphene on a Soft Contact Lens Using Self-Aligning Nanojet (SA-N) Dongwoon Shin, Abiral Regmi, Jonghyun Kim, Noori Na and Jiyoung Chang; University of Utah, United States

Recently, smart contact lens technology has been rapidly growing as a multi-purpose wearable device such as shielding electromagnetic waves, sensing glucose, display, and protecting eye dehydration in addition to its original vision-aid ability. Among many candidate materials for electrodes, graphene, a two-dimensional honeycomb lattice structure of the carbon atoms, has garnered much attention due to the excellent mechanical flexibility and electrical conductivity. Above all, it has superior optical transmittance, proving itself as an excellent alternative for the metal electrodes for a vision device such as a contact lens.

In order to adapt graphene as electrodes for soft smart contact lenses, one of the issues to address is developing a method for the scale-up, cost-effective, and precise graphene patterning on a surface of contact lens. Up to date, the graphene is mostly pre-patterned on a 2D substrate and then transferred onto a target 3D substrate, and such sequence inevitably causes not only distortion of the pattern but also low-yield production. In order to eliminate the distortion of the pattern and increase the yield of the production, transferring the bulk sheet of graphene on the surface of the contact lenses, followed by patterning the graphene directly on the 3D surface would be one of the ideal methods. However, to the best of our knowledge, there has been no report on a direct, nanoscale, and cost-effective patterning method of graphene on 3D surfaces.

Herein in this work, we present Self-Aligning Nanojet (SA-N) as a distortion-free and cost-effective direct-patterning-method of graphene on a soft smart contact lens. The SA-N is enabled at the lowest regime of flow rate in near-field electrospinning, which based upon surface current-induced electrostatic force without relying on hydrodynamic force. Therefore, kinematics of the SA-N is dominated by the electric force, by which the direction of the jet always self-aligns normal to the surface of the substrate rather than being pulled down by the gravity. As a result, by controlling the stage to follow the profile of the 3D surface, the precise patterning of nanofiber on multi-dimensional surfaces, such as the surface of the contact lens, is realized by the SA-N. Using the SA-N, nanofiber can be precisely patterned on top of pre-transferred-graphene as a bulk sheet on the surface of the contact lens. The patterned nanofiber serves as a masking layer during the plasma etching process, providing distortion-free patterned graphene that is ready to be used as electrodes. The proposed process is also much cost-effective compared to the typical graphene patterning method, such as photolithography or e-beam lithography.

In the presentation, we will present a study of the governing mechanism of the SA-N and show a demonstration of the direct writing of functional nanofiber on a 3D surface of the soft contact lens. Moreover, mechanical and electrical characterization of the precisely patterned nanoscale graphene will be analyzed. We believe that the SA-N can provide a promising fabrication-strategy for a wide range of functional materials, including nanoparticles and polymers, for the smart contact lens as well as other 3D structures.

5:35 AM S.SM03.05.07
Poisson Effect in Structured Dielectrics and Impacts on Sensitivity of Capacitive Sensors Mirza S. Sarwar, Kieran Morton, Tan N. Nguyen, Bertille Dupont and John Madden; University of British Columbia, Canada

Flexible and stretchable sensors with abilities to detect a light touch, pressure and even shear have been investigated. Most of these sensors are either resistive or capacitive in nature. In case of capacitive sensors, the sensitivity primarily depends on the ease of deformation of the dielectric. To enhance sensitivity to the applied force, a lot of implementations have air cavities in the dielectric material in order to obtain a lower effective Young’s modulus. This, in turn brings about a greater change in capacitance for a given applied pressure. The greater the fraction of air in the total volume of the dielectric, the softer it is. However, the architecture of the dielectric can cause this to differ due to the Poisson effect. Upon applying a force along the perpendicular direction of a unit elemental structure in the dielectric, the structure expands in the longitudinal axis.

Depending on the architecture, this effect can lead to a change in the effective Young’s modulus. In addition to the Young’s modulus, the deformation of the dielectric can also couple the electric fields differently and can even be designed to enhance the coupling. Under these circumstances, the capacitance increase due to an applied pressure will not only be due to the decrease in dielectric thickness but also due to the change in the effective dielectric constant.

Typically, the Young’s modulus of a patterned dielectric with air cavities is expected to decrease with a reduction in the volumetric ratio of solid dielectric material to air cavities. In this work, we investigated capacitive pressure sensors with various dielectric architectures keeping the ratio of solid dielectric to air cavities volume constant and therefore an expected
similar Young’s modulus magnitude. However, within these architectures, we have demonstrated that it is possible to engineer the Young’s modulus to vary by over 50% and the capacitive sensitivity to vary by over 100%. This research therefore paves the path to designing sensors to suit very specific applications, including being able to have a higher elastic modulus and yet bring about a larger change in capacitance with the same pressure applied. We have also demonstrated the ability to engineer a non-linear Young’s Modulus - sought after by artificial skin researchers in robotics and prosthetics, since human skin has a non-linear elastic response. This work discusses the critical parameters that are to be focused on when designing the dielectric for a capacitive sensor and aims to aid in the development of custom design that fulfils desired specifications.

Graphene Oxide Liquid Crystal towards Functional Hybrid Carbon Assembled Nanostructures Sang Ouk Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Graphene Oxide Liquid Crystal (GOLC) is a newly emerging graphene based material, which exhibits nematic type colloidal discotic liquid crystallinity with the orientational ordering of graphene oxide flakes in good solvents, including water. Since our first discovery of GOLC in aqueous dispersion, this interesting mesophase has been utilized over world-wide for many different application fields, such as liquid crystalline graphene fiber spinning, highly ordered graphene membrane/film production, prototype liquid crystal display and so on. Interestingly, GOLC also allow us a valuable opportunity for the highly ordered molecular scale assembly of functional nanoscale structures. This presentation will introduce our current status of GOLC research particularly focusing on the nanoscale assembly of functional nanostructures. Besides, relevant research works associated to the nanoscale assembly and chemical modification of various nanoscale graphene based materials will be presented particularly aiming at energy and catalytic applications

Wearable Gas Sensors with Wireless Communication and RF Energy Harvesting Capabilities Huanyu (Larry) Cheng; The Pennsylvania State University, United States

Recent advances in electronics enable powerful biomedical devices that have significantly reduced therapeutic risks by monitoring vital signals and providing means of treatment. Small-footprint deformable gas sensors that can be deployed on the skin surface to detect and distinguish multiple compounds in real-time are integral to accurate monitoring of health conditions. Low-dimensional nanomaterials or mixed metal oxides are state-of-the-art gas sensing materials that change their resistance upon binding of various important gases that require monitoring. However, it is challenging to integrate within a microscale footprint the numerous nanomaterials required to deconvolute signals from complex gaseous mixtures, as is necessary for deployment. The core innovation will be our ability to use laser writing to synthesize and pattern numerous low-dimensional nanomaterials and mixed metal oxides directly on laser-induced graphene gas sensing platform in order to facilitate the deconvolution of complex gas responses in mixtures. When combined with the stretchable antennas for wireless communication and rectennas for ambient RF energy harvesting, wearable gas sensors for health monitoring or toxic gas detection open new opportunities in epidermal electronic devices to enhance the operator and mitigate exposure.

5:30 AM S.SM03.06.03
3D Printing Flexible, Stimuli-Responsive and Shape Memory Polymers Rigoberto C. Advincula; Case Western Reserve University, United States

The use of 3D printing to create devices from elastomeric and polymeric materials has appended the design functionality for new materials including uses in biomedical devices enabling rapid development. While 3D printed polymers can be further classified into thermoplastics, thermosets, and elastomers based on their thermo-mechanical properties. The processability and functionality of flexible elastomers make it a challenge to employ 3D printing methods for additive manufacturing. The transition to a final phase or cross-linked structure results in new properties in combination with the processing method. This is more evident with the choices of 3D printing methodologies (FDM, SLA, SLS, VSP) which can make use of blended or
formulated compositions. We have demonstrated the 3D printing of biomedical grade thermoplastic polyurethanes (TPU), silicones, and rubberized epoxies. However, 4D printing allows the design of new materials and applications based on integrating the chemistry of conversion with the printing mode. In this talk, we demonstrate the fabrication of concept objects and elastomeric actuators based on the use of biomedical grade melts and extruded viscous solutions of nanocomposite elastomers as elastomeric actuating materials and shape memory materials.

5:40 AM *S.SM03.06.04
3D Stretchable Piezoelectric Materials Seunghum Hong; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Recently, the wearable devices combined with the internet of things (IoT) have become a vital part of our daily life. The trend of the wearable electronics is moving from small electronics to directly embedded ones. In this respect, fiber and fabric-based electronics have many advantages such as high wearability, ventilation through pores, and high durability by weave structures.

Smart fibers and fabrics, which can generate electricity from human motions and monitor the motions of human body, can act as wearable energy harvesters and sensors. As such, they will be used as important components of IoT (Internet of Things) technology. Here, we present a smart fiber and an e-textile with piezoelectric poly[(vinylidenefluoride-co-trifluoroethylene) [P(VDF-TrFE)] for wearable energy harvester applications. We used dip coating and hot pressing to deposit P(VDF-TrFE) on fibers and fabrics. We found that our prototypes had high flexibility and high interfacial adhesion strengths between P(VDF-TrFE) and electrodes, indicative of high stability. We demonstrated that our prototypes could generate piezoelectric output voltage and current from human mechanical energies with low frequencies. We envision that our fiber and fabric-based piezoelectric devices are promising as energy harvesters for supplying energy source to low power wearable devices.

5:55 AM S.SM03.06.06
Highly-Sensitive Flexible Piezoelectric Acoustic Sensors for Speaker Recognition Young Hoon Jung, Jae Hyun Han and Keon Jae Lee; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Herein, we demonstrate a new concept of flexible piezoelectric acoustic sensors (f-PAS) using mechanical sequential multi-resonance in membrane. The flexible piezoelectric film of f-PAS fabricated by sol-gel method and inorganic laser lift-off (LLO) exhibits high sensitivity to nanometer scale vibration and multiple frequency resonances in human voice frequency range. The self-powered f-PAS mimicked the mechanism of basilar membrane in the human cochlear that has multiple response to different frequencies depending on the width of membrane. The f-PAS exhibits maximum -42dB of relative sensitivity, which is four to eight times higher than the conventional condenser sensor without any amplification circuit. The f-PAS acquired abundant voice information from the multi-channel electrodes and read the frequency domain characteristics. The standard records dataset (TIDIGITs) were utilized to excite the piezoelectric membrane of the f-PAS, which converts the original analog speech sound to the electrical signal. The voltage-time data was subsequently analyzed by a Fast Fourier Transform (FFT) and a Short-Time Fourier Transform (STFT) to convert to the frequency component. The machine learning algorithm was designed by using the most highest and second highest sensitivity data among multi-channel outputs, exhibiting outstanding speaker recognition rate of 97.5% with error rate reduction of 75%, compared to the reference condense-type MEMS microphone.

Biomimetic Porous Architectures for Flexible Piezoelectric Composite Devices Chang Kyu Jeong; Jeonbuk National University , Korea (the Republic of)

Elastic composite-based piezoelectric energy harvesting technology is highly desired to enable a wide range of device applications, including self-powered wearable electronics, robotic skins, and biomedical devices. Recently developed piezoelectric composites are based on inorganic piezoelectric fillers and polymeric soft matrix to take the advantages of both components. However, there are still limitations such as the weak stress transfer to piezoelectric elements and the poor
dispersion of fillers in matrix. In this talk, a highly-enhanced piezocomposite energy harvesters (PCEH) is representatively developed using a three-dimensional (3D) interconnected electroceramic skeleton by mimicking and reproducing the sea porifera architecture (although the speaker will introduce other research examples and achievements). This new mechanically reinforced PCEH is demonstrated to resolve the problems of previous reported conventional piezocomposites, and in turn induces stronger piezoelectric energy harvesting responses. The generated voltage, current density and instantaneous power density of the biomimetic PCEH device reach up to few tens times higher power output than that of conventional randomly-dispersed particle-based PCEH. This work broadens the further developments of high-output elastic piezocomposite energy harvesting and sensor application with biomimetic architecture.

5:15 AM S.SM03.07.02
Inkjet-Printed Soft Resistive Pressure Sensor Patch for Wearable Electronics Applications
Li-Wei Lo¹,², Hongyang Shi², Haochuan Wan¹, Zhihao Xu¹, Xiaobo Tan² and Chuan Wang¹,¹;¹Washington University in St. Louis, United States;²Michigan State University, United States

Soft pressure sensors may find a wide range of applications in soft robotics, biomedical devices, and smart wearables. In this paper, an inkjet-printed resistive pressure sensor that offers high sensitivity and can be fabricated using a very simple process is reported. The device is composed of a conductive silver nanoparticle (AgNP) layer directly printed onto a polydimethylsiloxane substrate and encapsulated by a VHB tape. The pressure is measured through change in electrical resistance caused by pressure-induced strain in the printed AgNP thin film. The influence of substrate stiffness and thickness on the sensitivity and achieved sensors with an optimized configuration that exhibit highly repeatable response with a sensitivity of up to 0.48 kPa⁻¹ is systematically studied. It is further demonstrated that such a printed soft sensor patch is capable of measuring arterial pulse waveforms or detecting acoustic vibrations under various sound pressure levels. With its simple and low-cost fabrication process and high sensitivity, the inkjet-printed resistive pressure sensor is promising for future biomedical and smart wearable device applications.

5:25 AM S.SM03.07.04
Dynamic Protein Hydrogels with Reversibly Tunable Stiffness Regulate Human Lung Fibroblasts Spreading
Reversibly Linglan Fu, Amanda Haage, Na Kong, Guy Tanentzapf and Hongbin Li; University of British Columbia, Canada

Protein-based hydrogels can be utilized for extracellular matrices (ECM) by providing biocompatible and dynamic local microenvironment. Through cell-ECM interactions, these external mechanical signals are transduced to the cell’s interior, triggering biochemical signaling cascades that determine a wide variety of cellular behaviors, ranging from cell adhesion, cell spreading to cell differentiation. However, only a limited number of such hydrogels have been engineered allowing for investigating cell response to the change of hydrogel stiffness. Moreover, the stiffness of these hydrogels can only be switched uni-directionally and irreversibly. Here we report an entirely protein-based hydrogel that allows for a cyclic, reversible modulation of hydrogel mechanics in a relatively large range of Young’s modulus, and used it to investigate the cell spreading behaviors of human lung fibroblasts (HLF) in response to the cyclic change of the hydrogel Young’s modulus. This protein-based dynamic hydrogel as an ECM, was fabricated by using mutually exclusive protein (MEP, GL5CC/I27) as building blocks. MEP is a specially designed, redox-responsive protein folding switch. In the oxidized state, the host domain GL5CC is folded; in the reduced state, the GL5CC unfolds and the effective chain length of the MEP changes from 2.6 to 26 nm, leading to a change in the polymer chain length between two crosslinking points. Building upon this approach, we engineered the dynamic protein hydrogel based on TNfn3-GB1-resilin-(GB1-GL5CC/I27-resilin). TNfn3 contains a RGD motif for cell adhesion and resilin provides covalent crosslinking residues. We found that this dynamic hydrogel could be reversibly tuned between a stiff and soft state via a redox reaction. Moreover, this protein hydrogel supports cell adhesion and proliferation. In response to a cyclic change of the hydrogel’s Young’s modulus between ~6 kPa and 20 kPa, HLF dynamically change their morphology in a fully reversible fashion, demonstrating the great potential utility of such dynamic protein hydrogels in mechanochemical studies.
The recently developed laser induced graphene (LIG) process allows scribing electrically conductive circuits directly on a polyimide film. Its versatility is enabling a variety of designs, suitable for a broad range of electro-mechanical applications [1]. Silicone rubber layers incorporating LIG patterns were proposed to produce strain responsive devices such as strain gauges [2]. Nevertheless, the sensors had an overall thickness in the mm range, which makes challenging their use for thin, wearable, biointegrated devices. Here conformability plays a main role in determining a seamless interface with skin [4]. In this work we report the results on new LIG-based composites with low thickness and enhanced conformability to skin. The fabricated materials were used to develop various stretchable electrical devices.

Various silicone as well as polyurethane (PU) materials were investigated as the elastic carriers for LIG patterns. The latter were produced either in the form of a porous flat structure or as bundles of graphene fibers, by fine tuning of laser rastering parameters. The research included thin films with/without acrylic adhesives of various compositions and types of finish (including spin coating, blown film extrusion, etc.). The influence of laser rastering direction on the final functional properties of the composites was also investigated. One of the main challenges addressed in this work was an optimization of the transfer process of an electrically integer LIG circuit onto the investigated film. That was done in order to preserve low sheet resistance (100-1000 Ω/sq) and to achieve replicability among specimens. Developing a proper electrical connection suitable for flexible applications was another part of the work. A comprehensive electro-mechanical testing of composites has been carried out.

PDMS-based LIG devices have shown fully recoverable linear elastic behaviour and linear electrical resistance response up to 25% strain, as well as maximum stretchability up to 70%. These results allowed us to develop highly responsive thin strain sensors. A thin and soft (~30 μm, E ~ 15 MPa) wearable respiratory sensor based on biofriendly and medically approved flexible PU film served as another example for the proposed future applications.

The spectrum of patterned LIG applications can be further enhanced by designing compact energy efficient power storage devices such as microsupercapacitors (MSCs) [5] which could be suitable for sports and medical applications, among others. To this aim we worked on creating thin flat electrodes with high surface area for electrochemical applications. These could be integrated into the last generation of bio- and environmentally friendly electrochemical micro supercapacitors (MSCs), based on a low-cost and skin-friendly aqueous electrolyte. Since the surface area of the electrode material plays a crucial role in the charge storage processes, LIG material in form of a scribed powder was investigated by means of BET technique in order to confirm its remarkably high surface area of ~400 m²/g. Thin and soft LIG electrodes integrating electrical contacts were tested for MSC application. The obtained results of electrochemical measurements (cyclic voltammetry, galvanostatic charge/discharge curves) have shown high potential for further applications of the developed devices in the form of miniaturized power suppliers.

Polymer ionic liquids (PILs) are promising candidates for soft electronics. They are amorphous polymers and with ionic functionalities on the backbone that are paired with a counterion that leads to a low glass transition temperature ($T_g$). Here, we present our work to design redox-active polymers that allow charge transport while maintaining the behavior of PILs. Developing soft redox polymers is challenging because of their relatively high $T_g$. There have been efforts to decrease $T_g$ of redox-active polymers by increasing the length of the aliphatic chains in between tethered charge-conducting groups on the side chains and the backbone. However, this structure can harm charge transport properties because of the spatial separation of the redox active groups. In this work, we have synthesized the PIL with redox-active phenothiazine-bis(trifluoromethanesulfonyl)imide (TFSI) ionic liquid side chains placed very close to the backbone. By placing the side chains closer to each other, enhanced charge transport was successfully demonstrated upon oxidation and with increasing amounts of the TFSI anion. At the same time, the $T_g$ was significantly lowered by addition of a short ethylene glycol units on
In this presentation, we will demonstrate that both enhanced electrical and mechanical properties could be attained with our novel polymeric design for future applications.

S.SM03.08.09
In Situ Phase Transition of Peptide Side Chains Regulates Thermo-Responsive Properties of Protein-Based Hydrogels Tianyu Duan, Akash Panjabi and Hongbin Li; University of British Columbia, Canada

Protein-based hydrogels have emerged as promising biomedical materials thanks to the precisely controllable structures, mono-dispersion and biocompatibility of genetically engineered proteins. However, many protein-based hydrogels lack the ability to controllably change their biological, physical or mechanical properties in response to temperature variations, which limits their practical applications in clinical injection, pain relief, hyperthermia treatment, and drug delivery. Here we report a method to fabricate protein-based hydrogels with regulable thermo-responsive properties. By fusing an elastin-like polypeptide chain (Vn) to an elastomeric poly-(GB1-resilin) protein (YR), we synthesized a series of block co-polymers, Vn-YRs. With Vn blocks that exhibit a lower critical solution temperature (LCST) behavior, Vn-YRs become di-block amphiphiles and form micelles above the transition temperature (Tt) of Vn blocks in aqueous media. When Tyr-rich YR-blocks are cross-linked into a hydrogel network through a photo-induced di-Tyr reaction, the non-Tyr-containing Vn blocks are dispositioned into the side chains with one end attached to the network. These Vn side chains do not pronouncely alter the mechanical properties of YR-based hydrogel networks at temperature below their Tt. By contrast, above Tt, Vn side chains undergo phase transitions within the hydrogel networks, similar to their micellization in solution. Such temperature-triggered in situ phase transition of the Vn side chains is reversible and bestows reversible modulus reinforcement and deswelling to the hydrogel materials. Furthermore, the amplitude of such property changes can be tuned by factors including side chain length and composition. The results demonstrate that in situ phase behaviors of side chains can regulate thermo-responsiveness of protein-based hydrogels. We anticipate that this reported method can be applied to various biomedical applications, as well as inspire the potential development of other stimuli-responsive hydrogels.

S.SM03.08.11
High-Performance, Low Haze Silver Grid Embedded Flexible Transparent Electrode Ziyu Zhou and Paul Leu; University of Pittsburgh, United States

The higher demanding for the clarity and flexibility limit the current-leading materials such as indium tin oxide (ITO) further development in optoelectronics. Polymer substrate embedded with metal mesh has recently drawn increased attention for various flexible and transparent display devices because of their high electrical conductivity, optical transparency and robustness. However, for some commercial ITO/PET substrates applied in devices are still not satisfied the performance requirement. Our study has investigated a low-temperature, particle-free silver ink formed multi-layer micro/nano structured transparent conductor to achieve a higher light management with a lower loss of electrical properties. Ag microgrid embedded into a nanostructured polyethylene terephthalate (PET) substrate shows a high transparency, low haze as well as a low sheet resistance. An anti-reflection nanostructured fabrication is also applied to the back side of PET to further suppress the reflection, thus mostly enhanced transparency. This work focused on minimizing the optical transmittance loss and shadowing losses: (i) Small size feature for linewidth to 3 um; (ii) improve the T-Rs trade-off, making T > 90% with a Rs less than 4 ohm/sq; (iii) reducing the cost-effectiveness of fabrication method. Mechanical reliability is also demonstrated by bending and folding test comparing to ITO/PET. The sheet resistance only increased 5% under 500 bending cycles and still effectively conductive after 10-times completely folding. The mechanism of highly flexible even foldable properties resulting from lowering stress within metal grid is also discussed.

S.SM03.08.14
Exfoliated Black Phosphorus as an Active Material for High Energy Nanogenerator Application Sachin K. Singh1, Subas Muduli1, Dipti Dhakras1, Richa Pandey2, Rohit Babar1, Ankur Singh1, Dinesh Kabra2, Mukul Kabir1, Ramamooorthy Boomishankar1 and Sathishchandra Ogale1; 1Indian Institute of Science Education Research, India; 2Indian Institute of Technology Bombay, India

2D materials are at the focus of scientific attention in recent years in view of their several unique and interesting physical properties. The initial research on 2D materials was centred on their novel synthesis and property characterizations, and now the applications of these materials are being sought in different fields. Since clean and renewable energy research has acquired immense prominence lately, applications of 2D materials for energy harvesting are being keenly pursued at this time; mechanical energy harvesting being currently a rapidly developing field with several opportunities to harvest different forms of mechanical energy such as flexing, vibration, friction etc. using device systems known as nanogenerators (NGs) and
triboelectric nanogenerators (TENGs) which are based on different principles. While some very interesting research using 2D materials has already appeared in the literature, many innovative design possibilities are still open for evaluations on the use of these materials for enhanced mechanical energy harvesting performance.\(^1,2\)

Thus, in this work, we have explored the high mechanical energy harvesting possibility of the uniquely puckered structured elastically and electronically interesting 2D material, namely black phosphorous (BP). Nanogenerator device was fabricated by homogenously and densely embedding BP Nanosheets in Polydimethylsiloxiane (PDMS) matrix forming a composite film at different concentrations. The BP-PDMS based Nanogenerator displays an exceptionally high voltage output of maximum peak-to-peak voltage output of the order of ±350 V (maximum current density of 12.8 mA m\(^{-2}\) under an applied impact force of 40 N, at a frequency of 20 to 25 Hz. In terms of output power performance, the NG exhibits a power density of 1400 mW m\(^{-2}\) and a volume power density of 2 kW\(\text{m}^{-3}\), with active material (BP) contribution of 0.35 W g\(^{-1}\). By using Piezoresponse force microscopy (PFM), we have calculated the piezoelectric coefficient value \((d_{33})\) which is 20 pm/V. DFT calculations suggest the presence of strain-induced polarization \(\text{via} \) deformation-induced redistribution of intra-layer electron charge density. Demonstration of three real life applications namely wheel motion, tap water flow, and bending/flexing movements demonstrate that BP-PDMS NG is indeed a high powering capability device.\(^3\)

Adaptable Ionic Liquid-Containing Supramolecular Hydrogel with Multiple Sensations for Intelligent Robot at Subzero Temperatures
Bo Li\(^1,2\) and Ning Ma\(^1\); \(^1\)Harbin Engineering University, China; \(^2\)Tufts University, United States

There is a challenge to prepare the hydrogel that hold a high stretchability and conductivity in below zero temperature. In this work, we demonstrate a supramolecular ionic liquid hydrogel, wherein quadruple hydrogen bonding ureidopyrimidinone (UPy) units cross-linked polyethylene glycol (PEG) polyurethane was employed as networks with aqueous solution of imidazolium ionic liquid as free phase. Owing to the hydrophilic PEG segments, the hydrophobic UPy moieties, and the green molten imidazolium ionic liquid, this hydrogel exhibited high water content (~600%), swelling ratios (~400%), elongation (~750%), low resistivity (~0.51 k\(\Omega\) cm), excellent transparency (~98%), especially, the most striking characteristic could be maintain outstanding mechanical and thermal sensitivity at -20°C. The supramolecular ionic liquid hydrogel was utilized to fabricate E-skin for intelligent robot to realize pressure feedback and thermal recognition. This line of research not only demonstrates the anti-freezing stimuli-responsive hydrogel are a promising candidate for E-skins used in harsh condition, but also enrich the design of supramolecular polymers-based hydrogel sensors for future artificial intelligence applications. (This paper is funded by the International Exchange Program of Harbin Engineering University for Innovation-oriented Talents Cultivation.)

S.SM03.08.18
Self-Healing, High-Elongation Polysiloxanes with Soft-Tissue Compatibility
Barry Arkles, Allison Phillips, Santy Sulaiman and Jonathan Goff; Gelest Inc., United States

Ultra-high elongation siloxane nanocomposites that rely on mechanically interlocked polymer chains that result from high degrees of entanglement and knot formation. In a first step, living anionic ring opening polymerization techniques are employed in the synthesis, yielding monodisperse heterobifunctional polydimethylsiloxanes with a hydrido-, omega vinyl-functionalit.. Composites are formed in a second step in which a step-growth polymerization is conducted in the presence of surface modified silica nanoparticles yielding a regularly ethylene interrupted polydimethylsiloxane structure. High elongations, as great as 6000%, and self-healing properties appear to be dependent on the degree of polymerization of the linear step-growth polymers. The polymer chemistry, physical properties and practical examples of high-elongation and self-healing behavior will be presented.

S.SM03.08.19
Soft, Smart Contact Lenses for Human Disease Monitoring Using Mobiles through NFC Communications
Funkyung Cha, Joohee Kim, Minjae Ku and Jang-Ung Park; Yonsei University, Korea (the Republic of)
In order to monitor a person’s health condition and diagnose disease, it is important to continuously monitor the vital physical signals or metabolites in body fluids. Especially, eyes provide various physiological signals, thus being a promising site for non-invasive wearable sensing. Therefore, the contact lens provides a unique wearable sensing platform for monitoring various signals from the wearer’s eye. However, in the conventional smart contact lenses, the components were opaque, rigid, and brittle, so they could obstruct the wearer’s vision and damage the eyes. Moreover, to supply power and receive signals from the smart contact lens, a bulky and expensive external equipment was needed, which might restrict the wearer’s movements.

In this talk, we fabricated a transparent and stretchable soft, smart contact lens for quantitative monitoring using a smartphone. One of the diseases that can be diagnosed through eyes is glaucoma, and the only known controllable risk factor of glaucoma is intraocular pressure (IOP). For monitoring the IOP, this smart lens is composed of a strain sensor, a strain-concentrating layer, a transparent and stretchable antenna, and an integrated circuit chip, and each component is electrically connected with three-dimensional structures of stretchable metals. This smart lens can operate without battery through NFC communications with a mobile phone. The in-vivo test using live rabbits and the human pilot experiment demonstrated the real-time monitoring of IOP using the fabricated smart contact lens without blocking the wearer’s view. Another biomarker that can be detected from the eye is glucose concentration, which is a crucial factor to the diabetics. The correlation between blood glucose and tear glucose concentration was investigated by using a smart contact lens integrated with the electrochemical glucose sensor.

S.SM03.08.20
Blood-Vessel Mimicking Sensors for Deformation-, Pressure- and Chemical-Detections Weihehong Xu, Dharmeeedar Ravichandran, Sayli Jambhulkar and Dr. Kenan Song; Arizona State University, United States

Polymer nanocomposite-based piezoresistive sensors have broad applications in physiology monitoring, soft robotics, and human-machine interfaces. In this work, we developed a bio-inspired, blood-vessel-like thermoplastic polyurethane (TPU), graphene nanoplatelets (GnPs), multi-walled carbon nanotubes (MWCNTs) based fibers capable of detecting strains, high pressures, gas/liquid flow, and chemicals. Two-dimensional GnPs contributed to the formation of pores and the one-dimensional MWCNTs contributed to the electrical sensitivities of the compressible piezoresistive middle-layer, which was sandwiched by inner and outer TPU support layers. Continues fibers were manufactured via dry-jet wet spinning with a 3D laser sintered triaxial spinneret. Due to the pores generated during solvent exchange and each layer’s unique thermal stability, a hollow core is observed after undergoing hot isostatic pressing (HIP). Performances of the hollow-core multi-phase sensor were tested for gas/liquid flows at varied pressure and geometry orientations. The smallest detectable pressure is observed at ~ 200 mmHg, similar to pressures in the human arteries. A mapping of the pressure distribution in various geometries is constructed using multiple sensors and the results were confirmed by mechanical analysis. The sensor also shows a linear piezoresistive response for strain smaller than 80%, and is stable for over 1000 cycles at 10% strain. The pores of the piezoresistive-layer also enhance the sensitivity towards different types of solvents and gas vapors as they were guided through the sensor. Mechanical and thermal properties of the sensors were characterized using dynamic mechanical analyzer (DMA), differential scanning calorimetry (DSC) and thermogravimetric analyzer (TGA), demonstrating improvements of mechanical durability and thermal stability during the sensing cycles. This blood vessel-based design showed a high potential to be used in fluid pressure monitoring, 3D organ prototyping, and medical/biological educations.

S.SM03.08.26
High-Resolution, Flexible Retinal Prosthesis Based on Three-Dimensional Soft Stimulation Electrodes Hyo-beom Kim, Jiuk Jang and Jang-Ung Park; Yonsei University, Korea (the Republic of)

Loss of sight is one of the most severe problems that degrade the quality of human life, rather than any other disorders. Various methods for restoring the vision have been studied. Among them, electronic prosthetic devices for the visually-impaired person allows the individual to recognize the phase and movement of an object. It is based on the principle of converting an external light signal into an electric signal that is transmitted to the human optic nerve, which allows a person to perceive the electric signal as light. This retinal prosthesis has undergone considerable development over the last few decades; however, there are several challenges to be solved. First, the resolution is too low to visualize the information from the outside to the human eye. This problem is mainly originated from the high impedance of the electrodes. Second, the mechanical modulus of the material within the device is a mismatch to the modulus of the retina tissues, followed by severe inflammation and permanent damage to the retina. Finally, since this device is planned to be implanted on the human eye, the reliable operation is important.

Here, we presented the high-resolution, flexible retinal prosthesis based on three-dimensional (3D) soft stimulation electrodes for blind people. The high-resolution phototransistor array with a stimulation electrode allows the patient to perceive the image clearly. 3D structure of the electrode reduces the impedance of each pixel so that the single-pixel can be integrated in
high density without any electrical breakdown. Since we formed 3D electrodes using soft, self-healable materials, this stimulation electrode hardly damages the retina surface and easily restore their electrical characteristics under various mechanical deformations, suggesting the reliable operation of the implanted retinal prosthesis. Furthermore, in-vitro and in-vivo animal experiments using mouse and rabbit provided enough biocompatibility for the human trial. This high-resolution, flexible retinal prosthetic device provides a substantial chance to step-up for next-generation implantable electronic devices.

S.SM03.08.27

Modulation of Mesenchymal Stem Cell Migration Using Programmable Polymer Sheet Actuators Zijun Deng¹,², Weiwei Wang¹, Xun Xu¹, Nan Ma¹,² and Andreas Lendlein¹,²,³; ¹Institute of Biomaterial Science and Berlin-Brandenburg Centre for Regenerative Therapies, Helmholtz-Zentrum Geesthacht, Germany; ²Institute of Chemistry and Biochemistry, Free University of Berlin, Germany; ³Institute of Chemistry, University of Potsdam, Germany

The therapeutic potential of mesenchymal stem cells (MSCs) in regenerative medicine is governed by multiple factors. Recruitment of MSCs to the damaged tissue, where they differentiate into the local components and release the bioactive substances, is a crucial step to initiate and support tissue regeneration. Stimulating MSC migration with pure physical cues presents attractiveness. In this study, MSC migration responding to thermal and mechanical stimuli was investigated using programmable shape-memory polymer actuator (SMPA) sheets. Changing the temperature repetitively between 10 and 37 °C, the SMPA sheets are capable of reversibly changing between two different pre-defined shapes like an artificial muscle. After the attachment of MSCs on the SMPA sheets, cell movement was recorded using a time-lapse microscope. Compared to non-actuating control sheets, the MSCs cultured on the programmed actuating sheets presented a higher migration velocity (0.45 ± 0.17 vs. 0.58 ± 0.17 µm/min). SMPA sheets can be applied as a platform to study the combinatorial and synergetic effects of thermal and mechanical stimuli as well as their interplay, which helps to understand the orchestration of microenvironmental complexity for regulating stem cell migration. The use of physical cues to increase the homing capacity of MSCs presents a promising approach to improve their therapeutic potential in regenerative medicine.

Multifunctional Strain Sensor Based on Graphene-Hydrogel Yuting Cai¹,²; ¹The Hong Kong University of Science and Technology, Hong Kong; ²Southern University of Science and Technology, China

With the growing market for wearable and implantable electronics, strain sensors with exceptional performance in sensitivity, stretchability, biocompatibility, and tough adhesion between human/ machine interfaces have become essential. Herein, a novel graphene-ions based strain sensor, whose structure contains a carefully selected graphene foam (GF) and polyacrylamide/calcium-alginate (PAM/CA) double network hydrogel coupled with chitosan, can meet the all above requirements to the maximum extent. Taking the advantage of the excellent electrical properties of graphene and super mechanical properties of double network hydrogel, this strain sensor can measure an exceptionally wide range of strain up to 500%, which allows us to monitor and distinguish almost all human body motions, with a gauge factor of ~1800, which is up to 3 orders of magnitude larger than the 0.1–10 value reported previously. The device also shows high stability and excellent durability for 1000 cycles. Most importantly, the chitosan-bridge and skin-like elastic modulus of 8–90 kPa achieve conformal adhesion between the skin and sensor, with the adhesion energy of ~200 Jm⁻². Moreover, this structured sensor is highly biocompatible and can be implanted in vivo, and has further potential in clinical applications.

S.SM03.08.29

Reversible Shape-Memory Actuation of Individual Micro/Nanofibers Yue Liu¹, Oliver Gould¹, Karl Kratz¹ and Andreas Lendlein¹,²; ¹Helmholtz Zentrum Geesthacht, Germany; ²University of Potsdam, Germany

Advances in the fabrication and characterization of polymeric nanomaterials has greatly advanced the miniaturization of soft actuators, creating materials capable of replicating the functional physical behavior previously limited to the macroscale. Techniques such as emulsion polymerization and electrospinning have enabled the realization of nano and microscale objects whose shape change can be controlled by ensemble programming methods to realize one-way shape-memory. Previously,
we reported that a universal atomic force microscopy (AFM) test platform enables the implementation and quantification of a thermomechanically induced one-way shape memory effect for individual polymeric micro- and nanosystems. Here, we demonstrate how a reversible shape-memory polymer actuation can be generated in a single micro/nano object, where the shape change during actuation of an individual fiber can be dictated by programming using AFM. In this work, electrospinning was used to prepare poly(ε-caprolactone) micro/nano fibers, which were fixed and crosslinked on a structured silicon wafer. Using AFM, the programming as well as the observation of recovery and reversible displacement of the fiber were performed by vertical three point bending. A plateau tip was utilized to improve the stability of the fiber contact and working distance, enabling larger deformations and greater rbSMPA performance. Programming strains of 39 ± 1% or 46 ± 1% were realized for fibers with diameters of 1 ± 0.2 µm and 300 ± 50 nm, which were deformed at 80 °C and fixed at 10 °C. Values for the reversible elongation of εrev = 3.4 ± 0.1% and 10.5 ± 0.1% were obtained for a single micro and nanofiber in cyclic testing between the temperatures 10 and 60 °C. The reversible actuation of the nanofiber was successfully characterized for 10 cycles. An actuation induced pulling force of 0.2 ± 0.01 nN and pushing force of 0.5 ± 0.1 nN were measured on the tip. The demonstration and characterization of individual shape-memory nano and microfibers represents an important step in the creation of miniaturized robotic devices capable of performing complex physical functions at the length scale of cells and proteins.

Ultra-Thin Organic Photovoltaics and Sensors for Wearable Sensors Kenjiro Fukuda1, Tomoyuki Yokota2, Zhi Jiang1, Sunghoon Lee1, Wenchao Huang2, Hyunjae Lee1 and Takao Someya1,2; 1RIKEN, Japan; 2The University of Tokyo, Japan

One of an important target application of biointegrated electronics is wearable sensors that enable accurate and continuous detection of physiological signals. These devices require conformable and biocompatible sensors and power source to continuously supply electricity to health-monitoring systems. In this talk, we will report on recent progresses of ultraflexible organic photovoltaic cells as power sources and wearable sensors. First, the progresses of power conversion efficiency (PCE) and mechanical/long-term stability of ultraflexible organic photovoltaics have been achieved using new material and process engineering. The certified PCE of 12.3% for the ultra-flexible organic photovoltaic cell has been achieved with novel ternary blend active layer [1]. Second, long-term continuous monitoring using organic electrochemical transistors with nonvolatile gel electrolyte has been achieved with a high mechanical stability and high signal-to-noise ratio (24dB) [2]. Then, the integration of the ultra-flexible organic photovoltaic cells as power sources with OECT-based sensors has been demonstrated [3].

Fish-Eye-Inspired Wide Field-of-View Camera Dae-Hyeong Kim1,2; 1Institute for Basic Science, Korea (the Republic of); 2Seoul National University, Korea (the Republic of)

Although recent efforts in device designs and fabrication strategies have resulted in meaningful progresses to the goal of novel high-performance imaging devices, significant challenges still exist in developing a miniaturized and lightweight camera that enables the wide field-of-view (FoV) imaging. This is mainly due to bulky and heavy multiple lenses employed in the conventional wide angle camera. In this work, inspired by structural and functional features of the aquatic vision, we have developed a novel wide FoV camera by integrating a tailored monocentric lens and a hemispherical silicon nanorod photodetector array. This bioinspired camera offers the wide FoV, a miniaturized module size, minimal optical aberrations, the deep depth-of-field, and the enhanced light sensitivity in one simple integrated device. Theoretical analyses in conjunction with imaging demonstrations have corroborated the validity of the proposed concept. The fish-eye-inspired camera is expected to provide new opportunities for the advanced mobile electronics.

9:00 AM *S.SM04.03.01
Bioelectronics with Nanocarbons Tzahi Cohen-Karni; Carnegie Mellon University, United States

We focus on developing a new class of nanoscale materials and novel strategies for the investigation of biological entities at multiple length scales, from the molecular level to complex cellular networks. Our highly flexible bottom-up nanomaterials synthesis capabilities allow us to form unique hybrid-nanomaterials. Recently, we have demonstrated highly controlled synthesis of 3D out-of-plane single- to few-layer fuzzy graphene (3DFG) on a Si nanowire (SiNW) mesh template. By varying graphene growth conditions, we control the size, density, and electrical properties of the NW templated 3DFG (NT-3DFG). This flexible synthesis inspires formation of complex hybrid-nanomaterials with tailored optical and electrical properties to be used in future applications such as biosensing, and bioelectronics. For example, we have developed a unique bioelectrical platform based on 3DFG and have demonstrated, for the first time, recording of the electrical activity of excitable cells using ultra microelectrodes ranging from 10µm down to 2µm, without the need of any surface coatings. Currently, we target the limits of cell-device interfaces using out-of-plane grown 3DFG, aiming at electrical recordings with subcellular spatial resolution (<5µm) and μsec temporal resolution. In summary, the exceptional synthetic control and flexible assembly of nanomaterials provide powerful tools for fundamental studies and applications in life science and open up the potential to seamlessly merge either nanomaterials-based platforms or unique nanosensor geometries and topologies with cells, fusing nonliving and living systems together.

9:15 AM *S.SM04.03.02
Soft Tissue-Like Rubbery Electronics and Integrated Systems Cunjiang Yu; University of Houston, United States

While human organs and tissues are mostly soft; conventional electronics are hard. Seamlessly merging electronics with human is of imminent importance in addressing grand societal challenges in health and joy of living. However, the main challenge lies in the huge mechanical mismatch between the current form of rigid electronics and the soft curvy nature of biology. Here, I will present a new form of electronics, namely “rubbery electronics and bioelectronics”, with skin-like softness and stretchability, which is constructed all based upon elastic rubbery electronic materials. These rubbery electronic
materials are structured in the format of composites, which can be scalably manufactured from common and commercial available materials without dedicated and complicated synthesis. Specifically, we build nanofibril organic semiconductor and metallic nanowires percolated in the elastomeric polymer matrix in a composite format for the rubbery semiconductors and conductors, respectively. Employing these rubbery electronic materials, we have achieved fully rubber format devices, including transistors and sensors, logic gates, active matrices, elastic sensory skin systems, and biointegrated devices, etc. I will showcase a few examples including artificial skins, biomedical implants, and wearable applications.

9:30 AM *S.SM04.03.03
Wireless Modular E-Tattoos Chargeable On-the-Go Nanshu Lu; University of Texas at Austin, United States

Soft, noninvasive and multifunctional epidermal electronics (a.k.a. electronic tattoos or e-tattoos) have demonstrated many exciting applications in mobile health, athletic training, human-machine interface (HMI) and so on. However, e-tattoos are only practically useful when they are low cost and wireless. Previously, our group has invented a dry and digital manufacturing approach named the “cut-and-paste” method for the rapid prototyping of e-tattoo sensors using a paper/vinyl cutter plotter [1]. This method has been demonstrated to work for thin film metals [1, 2], various polymer sheets [1, 3], ceramics [4], as well as 2D materials such as graphene [5, 6]. The cut-and-pasted e-tattoos are low cost and can be used to measure a variety of physiological signals such as electrocardiogram (ECG), seismocardiogram (SCG), electrooculogram (EOG), skin hydration, skin temperature, respiratory rate and so on [1-3, 5, 6]. To make the e-tattoos go wireless, we now report the “cut-solder-paste” process to incorporate integrated circuits (ICs) for signal readout and processing, near field communication (NFC) [7], as well as Bluetooth transmission [8]. To overcome the limited patterning resolution of the cutter plotter and to recycle the tattoo layers with ICs, we propose a modular concept in which the wireless charging layer (NFC layer), the wireless communication layer (Bluetooth layer), the readout circuit layer, and the sensor/electrode layer are fabricated individually and stacked up at the final step of fabrication. The thickness of a fully assembled multilayer e-tattoo (excluding IC chips) is less than 300 um and the overall stretchability is still beyond 20%. In addition to already mentioned capabilities, such e-tattoos can also wirelessly track motion, mechano-acoustic heart signals, and oxygen saturation (SpO2) [3, 7, 8]. The NFC-enabled e-tattoos can be wirelessly charged so no battery is needed but the sampling rate is limited to 25 Hz and the wireless communication distance is limited to 5 cm. The Bluetooth-enabled e-tattoos require on-tattoo batteries but the sampling rate can be up to 4 kHz and the wireless communication range can be up to 10 m. Combining the NFC layer and the Bluetooth layer in one e-tattoo, we demonstrate that such wireless e-tattoo can also be wirelessly charged on-the-go via stretchable fabric feeding coils [8], enabling long-term, ambulatory and continuous sensing. Moreover, we propose that different layers can be disassembled and reassembled multiple times. After disassembly, the electrode layer should be disposed but the other layers can be reassembled into new e-tattoos. The low-cost, rapid prototyping method together with the wireless and reconfigurable capabilities represent exciting advancement towards practically useful wireless e-tattoos.

9:45 AM *S.SM04.03.06
Memory and Learning in Biomolecular Soft Matter for Low-Power, Brain-Like Computing Joseph S. Najem; The Pennsylvania State University, United States

The brain carries out complex cognitive and computing tasks by optimizing energy efficiency, information processing, communication, and learning in massively parallel, dense networks of highly interconnected neurons. To cope with its
everchanging surroundings, the brain is able to grow neurons, synapses, and connections—owing to its plastic nature. At the molecular and cellular levels, synaptic plasticity and neuronal excitation are the main mechanisms underlying these processes. Therefore, the ability of next-generation computing devices, robots, and machines to autonomously sense, process, learn, and act in complex and dynamic environments while consuming very little power will require approaches to computing and sensing that are inherently brain-like. Reproducing these features using traditional electronic circuit elements is virtually impossible, requiring the design and fabrication of new hardware elements that can adapt to incoming signals and remember processed information. These elements should be scalable, biomimetic, and preferably ionic to achieve energy consumption levels approaching those in the brain. While a major effort is being invested in developing inorganic materials that could emulate synaptic and neural functionalities, I believe that an overlooked, yet high-reward, pathway to success is through the development of biomolecular materials with the composition, structure, and switching mechanisms of actual biological synapses and neurons. Here, I describe two-terminal, biomolecular memcapacitors and memristors, consisting of highly insulating 5 nm-thick lipid bilayers assembled between two water droplets in oil. These devices exhibit memcapacitance that is nonlinearly dependent on the applied voltage as well as hysteresis in the charge due to voltage-driven, reversible changes in the area and thickness of the bilayer membrane. This is the first demonstration of a memcapacitor in which capacitive memory results from geometrical changes in a lipid bilayer membrane. We also show that the incorporation of voltage-activated alamethicin and monazomycin peptides in these devices results in variable ionic conductance across the membrane and memristive behavior. We discuss how these devices exhibit learning through synaptic plasticity, and how to implement them in online learning applications. These results serve as a foundation for a new class of low-cost, low-power, soft mem-elements based on lipid interfaces and other biomolecules for applications in neuromorphic computing which could have major implications on the robotics and computing fields.

Three-Dimensional Curvy Electronics Created Using Conformal Additive Stamp (CAS) Printing Cunjiang Yu; University of Houston, United States

Electronic devices are typically manufactured in planar layouts but many emerging applications, from optoelectronics to wearables, require three-dimensional curvy structures. The fabrication of such structures has though proved challenging due, in particular, to the lack of an effective manufacturing technology. This presentation will show our development of conformal additive stamp (CAS) printing technology and its employment to reliably manufacture 3D curvy electronics. CAS printing employs a pneumatically inflated elastomeric balloon as a conformal stamping medium to pick up pre-fabricated electronic devices and print them onto curvy surfaces. To illustrate the capabilities of the approach, we will demonstrate various devices with curvy shapes: silicon pellets, photodetector arrays, electrically small antennas, hemispherical solar cells, and smart contact lenses. We also show that CAS printing can be used to print onto arbitrary 3D surfaces.

7:30 PM S.SM04.05.03
From Functional Nanomeshes to Advanced Soft Microsystems Hui Fang; Northeastern University, United States

New form of materials can often enable new device and system applications. In this talk, I will highlight our group's recent work under this motivation in two synergistic areas. Firstly, by stacking individual layers of polymer, metal, and low-impedance coating reliably in a same nanomeshed pattern, the final multilayer multifunctional nanomeshes achieved system-level performance from all individual layers, in addition to nanomesh advantages. Compelling demonstrations from this multifunctional nanomesh approach include high-performance transparent and flexible neuroelectrode arrays, which has been recently validated in vivo. The second part of my talk will introduce our recent concept on semiconductor nanomeshes. By making a silicon film into homogeneous nanomeshes, we achieve high mobility semiconductor that is intrinsically stretchable to conventional microelectronic layouts. Together, our work demonstrates that nanomeshing is a unique way of transforming microelectronics for emerging applications.

7:45 PM S.SM04.05.07
Insertion Mechanics of Microscale Devices into the Brain Nicholas Melosh and Abdul Obaid; Stanford University, United States

Microscale electrodes, on the order of 10-100 µm, are rapidly becoming critical tools for neuroscience and brain-machine interfaces (BMIs) for their high channel counts and spatial resolution, yet the mechanical details of how probes at this scale insert into brain tissue are largely unknown. Here, we discuss quantitative measurements of the force and compression mechanics together with real-time microscopy for insertion of a systematic series of microelectrode probes as a function of diameter (7.5–100 µm and rectangular Neuropixels) and tip geometry (flat, angled, and electrochemically sharpened), within phantoms, ex vivo and in vivo. Results from each model system elucidated the role of tip geometry, surface forces, and mechanical scaling with diameter. Surprisingly, real-time microscopy revealed that at small enough length scales (<25 µm), blood vessel rupture and bleeding during implantation could be entirely avoided. This appears to occur via vessel displacement, avoiding capture on the probe surface which led to elongation and tearing for larger probes. We propose a new, three-zone model to account for the probe size dependence of bleeding, giving a new conceptual framework for how blood vessels fail and provide guidance for probe design.

8:00 PM *S.SM04.06.03
Rehealable, Recyclable and Reconfigurable Electronics Based on Dynamic Covalent Thermoset Jianliang Xiao; University of Colorado, United States

Dynamic covalent thermosets show superior properties, including self-healability, recyclability, malleability/reprocessability, thanks to the molecular level bond exchange reactions. These properties promise bright future of dynamic covalent thermosets in broad applications. We here report our work on dynamic covalent thermoset-based electronic systems that are rehealable, recyclable and reconfigurable. A flexible multifunctional electronic device that integrates electrocardiograph (ECG), temperature, motion, and acoustic sensing capabilities was demonstrated. It was exhibited that the rehealed and recycled devices showed electronic performance comparable to the original ones. Bond exchange reactions in the polymer network effectively relaxes stresses induced by mechanical deformation, which made it possible to reconfigure the flexible device into different configurations that are suited for different applications. Such rehealable, recyclable and reconfigurable electronics provides an approach to address sustainability and environment issues associated with mass production of electronics. It can find broad applications in prosthetics, health care, and human-computer interface and other areas that are hard to be addressed by conventional approaches.

8:15 PM *S.SM04.06.04
3D Printing Electronics Directly on the Body Michael C. McAlpine; University of Minnesota, United States

The ability to directly print biomedical devices on the body could benefit patient monitoring, wound treatment, and even allow for the possibility of human augmentation. In reality, this concept requires the 3D printer to adapt to the various translations, rotations, and deformations of the biological surface. Conventional 3D printing technologies typically rely on open-loop, calibrate-then-print operation procedures. An alternative approach is adaptive 3D printing, which is a closed-loop method that combines real-time feedback control and direct ink writing of functional materials in order to fabricate devices on moving freeform surfaces. Here we demonstrate that the changes of states in the 3D printing workspace in terms of the geometries and motions of target surfaces can be perceived by an integrated robotic system aided by computer vision. This allow us to directly 3D print a wireless antenna based on a novel silver ink a free-moving human hand, to power a skin-mounted LED. Using this same approach, cell-laden hydrogels were also printed on live mice, creating a model for future studies of wound-healing diseases. Moreover, we developed an in situ 3D printing system that estimates the motion and deformation of the target surface to adapt the toolpath in real time. With this printing system, a hydrogel-based sensor was printed on a porcine lung under respiration-induced deformation. The sensor was compliant to the tissue surface and provided continuous spatial mapping of deformation via electrical impedance tomography. This adaptive 3D printing approach may enhance robot-assisted medical treatments with additive manufacturing capabilities, enabling advanced medical treatments, and autonomous and direct printing of wearable electronics and biological materials on and inside the human body.

8:30 PM *S.SM04.06.07
Exploring Bioelectric Dynamics at the Soft-Hard Interfaces Bozhi Tian; University of Chicago, United States

Although there are numerous studies on either hard or soft materials, our understanding of the fundamentals at hard/soft interfaces has been limited. As different types of energy (such as electrostatic, mechanical, thermal, and chemical energies) display diverse scaling behaviors and can converge, an appropriate selection of the length scale is critical for promoting new
scientific discoveries across these interfaces. Our group integrates material science with biophysics to study several hard/soft interfaces. We synthesize new materials and probe interfacial dynamics, with particular focus at the sub-micrometer and sub-cellular length scales. In this talk, I will focus on the interfaces that enabled non-genetic, freestanding, and semiconductor-based bioelectric modulation. I will also discuss some recent work that exploits the dynamic behaviors of granular materials in polymeric matrices toward bioelectric and robotic applications. I will end the talk by proposing several new scientific and engineering approaches to improving our fundamental understanding of the (bio)chemical processes at soft/hard interfaces and to exploring new applications of these interfacial (bio)chemical processes.

1:30 PM *S.SM04.07.02
Liquid Metal Embedded Polymers for Soft-Matter Electronics, Actuation and Energy Harvesting Carmel Majidi; Carnegie Mellon University, United States

Soft polymers that are embedded with nano- and microscale droplets of liquid metal (LM) can be tailored to exhibit a broad range of electrical, thermal, mechanical, and dynamic shape morphing properties. In contrast to lithographically-fabricated soft microfluidic architectures, these LM-embedded soft polymer (LMSP) composites are statistically homogenous and exhibit effective medium properties at the mesoscale. Depending on the choice of polymer matrix, LMSPs can be engineered to achieve a wide variety of properties – from thermally conductive rubber for heat management and thermoelectric energy harvesting in wearable electronics to shape memory materials that dynamically respond to electrical stimulation. Eutectic Ga-In (EGaIn) and Ga-In-Sn (Galinstan) alloys are used as the liquid metal due to their high electrical conductivity, low viscosity, non-toxicity, and the self-passivating formation of an oxide skin (Ga2O3) that enables emulsification and wetting to non-metallic materials. Because they are liquid-phase at room temperature, these alloys have virtually no influence on the mechanics of the surrounding elastomer medium. This allows the resulting composite to exhibit a unique and extraordinary combination of features not seen in other heterogeneous material systems. In this talk, I will review recent experimental and theoretical studies of this unique class of soft material architectures, with specific emphasis on LM-filled liquid crystal elastomers and soft polymers for stretchable electronics and energy harvesting. I’ll also highlight several applications in which LMSPs can have a potentially transformative impact, especially in the domains of wearable computing, physical human-machine interaction, and bioinspired soft robotics.

1:45 PM *S.SM04.06.08
Self-Powered Wearable and Implantable Electrical Stimulation Devices for Therapeutics Xudong Wang; University of Wisconsin–Madison, United States

Electrical stimulation (ES) is a widely used therapeutic treatment strategy. It showed significantly positive results in treating a variety of diseases, biological disorders, and neurological problems. Today, the emergence of wearable devices is rapidly reshaping the development of medical devices, pushing them from conventional bulky and rigid silicon electronics to flexible and primarily polymer-based systems. Among many types of functions, nanogenerators are developed as a unique device for converting biomechanical energy into electrical pulses. In addition to applying it directly as a power source, this pulsed electricity can be applied directly as a ES signal for therapeutic treatment. In our recent research, we successfully implemented such an electromechanical system for skin wound healing and vagus nerve stimulation for obesity control. An electrical stimulation bandage was developed by integrating a flexible nanogenerator and a pair of dressing electrodes on a flexible substrate. Rat studies demonstrated rapid closure of a full-thickness rectangular skin wound within 3 days as compared to 12 days of usual contraction-based healing processes in rodents. From in vitro studies, the accelerated skin wound healing was attributed to the electric field-facilitated fibroblast migration, proliferation and transdifferentiation. In another work, an implanted vagus nerve stimulation system was developed. The device comprises a flexible and biocompatible nanogenerator that is attached on the surface of stomach. It generates biphasic electric pulses in responsive to the peristalsis of stomach. The electric signals generated by this device stimulates the vagal afferent fibers to reduce food intake and achieve weight control. This strategy is successfully demonstrated on rat models. Within 100 days, the average body weight is controlled at 350 g, 38% less than the control groups. Both results bring a new concept in electrical
therapeutic technology that is battery-free, self-activated and directly responsive to body activities.

**Assembly of Nanoelectronics Via Tissue Development**  
*Jia Liu; Harvard University, United States*

Tissue-wide electrophysiology with single-cell and single-spike spatiotemporal resolution is critical for biological studies and biomedical applications. In this talk, I will discuss the creation of cyborg organisms: the three-dimensional (3D) assembly of soft, stretchable mesh nanoelectronics across the entire living organism by the cell-cell attraction forces from 2D-to-3D tissue reconfiguration during organogenesis. We demonstrate that stretchable mesh nanoelectronics can migrate with and grow into the initial 2D cell layers to form the 3D organ with minimal impact on tissue growth and differentiation. The intimate contact between the dispersed nanoelectronics and cells enables us to chronically and systematically observe the evolution, propagation and synchronization of the bursting dynamics in different organisms through their entire organogenesis and maturation. I will also discuss the potential applications of these cyborg organisms in biology and biomedicine.

**Bio-Derived, Green Electronics Made from Microbially Produced Protein Nanowires**  
*Jun Yao; University of Massachusetts Amherst, United States*

Protein nanowires harvested from microbes are a revolutionary green electronic material. They have unique properties for novel electronic devices with improved performance, for a broad range of applications from energy harvesting to neuromorphic computing and sensing. (1) Thin-film protein nanowire devices were shown to continuously harvest electricity from ambient humidity (*Nature* 578, 550-554 (2020)), enabled by the unique structural (e.g., nanopores at wire-wire interface) and chemical (e.g., a high density of hydroscopic groups) properties. This leads to a continuous energy harvesting mechanism from the ubiquitous and enormous ambient humidity, and hence a promising strategy to powering self-sustained systems. (2) The protein nanowires are cleverly designed and recruited by the microbe to facilitate charge exchange with environments (e.g., through redox metallization). Thus, protein nanowires can be assembled into bio-dielectrics to construct memristor devices, in which the protein nanowires catalytically reduce the energy barrier involved in memristive switching and enable ultralow operational voltage in the biological regime of <100 mV (*Nature Commun.* 11, 1861 (2020)). Neuromorphic components (e.g., artificial neuron, synapse) made from the protein nanowire memristors take a further step in bio-emulation from functional emulation to parameter matching, creating opportunities for future ultralow-power electronics and bioelectronic interfaces. (3) Protein nanowires have ultra-small diameters (3 nm) and an ultra-high density of surface functional groups (e.g., 10 per nm) that are advantageous for sensing applications. Electronic sensors made from protein nanowires were shown to have enhanced selectivity and sensitivity (*Nano Res.* 13, 1479-1484 (2020)) for ammonia detection compared to inorganic nanowire devices. These studies, combined with the advantages of renewability, biocompatibility, and eco-friendliness in protein nanowires, have provided the starting point for future green electronics based on synthetic protein nanowires.

**Polymerized Liquid Metal Networks for Stretchable Electronics**  
*Carl Thrasher, Zachary Farrell, Nicholas J. Morris, Michelle C. Yuen and Chris Tabor; Air Force Research Laboratory, United States*

Room-temperature liquid metals, such as nontoxic gallium alloys, show enormous promise to revolutionize stretchable electronics for next-generation soft robotic, e-skin, and wearable technologies. Core–shell particles of liquid metal with various surface-bound ligands can be synthesized and polymerized together to create cross-linked particle networks comprising >99.9% liquid metal by weight. When stretched, particles within these polymerized liquid metal networks (Poly-LMNs) rupture and release their liquid metal payload, resulting in a rapid transformation from insulating to conducting behavior. These networks autonomously form hierarchical structures that mitigate the deleterious effects of strain on electronic performance and give rise to emergent properties. Notable characteristics include nearly constant resistances over large strains, electronic strain memory, and increasing volumetric conductivity with strain to over 20 000 S cm-1 at >700% elongation. Furthermore, these Poly-LMNs exhibit exceptional performance as stretchable heaters, retaining 96% of their areal power across relevant physiological strains. Remarkable electromechanical properties, responsive behaviors, and facile processing make Poly-LMNs ideal for stretchable power delivery, sensing, and circuitry.

2:45 PM  S.SM04.07.05  
**Advanced Multimodal Optoelectronic Systems for Bio-Interfacing**  
*Luyao Lu; The George Washington University,*
Recent advances in new materials, electronics, and assembly techniques have allowed optoelectronic systems to interface with biology and contribute significantly to the progress in basic biological research as well as clinical medicine. In this talk, I will introduce a novel class of flexible, multimodal optoelectronic systems that combines high-performance nanoscale electrodes with microscale optical components for simultaneous electrophysiological recording under optogenetic modulation. We envision this unique technology will open up new windows to understanding important biological processes by enabling mapping the dynamics of perturbed cell populations and correlating cellular responses to behavior.

**Improved Capacitive Pressure Sensor Design Methodology Using Pyramidal Microstructures for Specialized Monitoring of Biosignals**

Sara Ruth, Helen Tran, Levent Beker, Vivian R. Feig, Naoji Matsuhiisa and Zhenan Bao; Stanford University, United States

There is an increasing demand for specialized pressure sensors in various biomedical applications, especially health monitoring. For example, cardiovascular monitoring, which has implications in early diagnosis of heart failure.[1] To date, there have been numerous reports on pressure sensor designs in order to meet the demands of specialized pressure sensors. However, in order to address the growing demand for tailored pressure sensors for such a diverse range of applications, it is important to understand how different sensor parameters impact performance. By quantifying these relationships, we aim to determine design parameters that will enable researchers to predict a priori the specific design needed to achieve the targeted performance. Previously, capacitive pressure sensors have been shown to have wide versatility in use, with a high degree of potential tuning possible through manipulating the geometry or material selection of the dielectric layer. One effective approach first reported by our group to tune the performance of capacitive pressure sensors is microstructuring the dielectric layer, which improves its compressibility and, consequently, its sensitivity.[2,3] As researchers seek to incorporate novel materials into sensors, there is also a need to understand how various intrinsic material properties, such as compressive modulus, impact sensor performance. Compressive modulus is qualitatively known to affect the sensitivity of the pressure sensor.[4] Quantifying the relationships between intrinsic material properties, dielectric geometry, and sensor performance will enable a design of pressure sensors and selection of materials to meet requirements for specific applications. Presented here is an improved fabrication method to achieve simple, tunable, consistent, and reproducible pressure sensors by using a pyramid microstructured dielectric layer along with an added lamination layer to improve consistency and reproducibility. The as-produced sensor performance matches predicted trends of parameters that can be explicitly controlled. Further, we develop a simple computational model using intrinsic properties of the elastic dielectric layer and experimentally confirmed its efficacy. We then use our model to predict other properties and a wider range within the tested properties to better understand the effect of material property and microstructure geometry on the sensor performance. This would allow us to anticipate trends and sensor performance. Finally, we demonstrate that we can more directly design sensors for a specific application, such as wrist pulse sensing, using our model and fabrication method.

5:10 AM S.SM04.01.05

**Cable Bacteria as Living (Semi)Conductors with Record Intrinsic Electrical Properties—A New Paradigm for Bioelectronics?**

Robin Bonné, Raghavendran Thiruvallur Eachembadi, Rob Cornelissen, Roland Valcke, Bart Cleuren and Jean V. Manca; Universiteit Hasselt, Belgium
In nature, fibre-like organisms such as Geobacter sulfurreducens [1], Shewanella oneidensis [2] and Cable Bacteria [3] demonstrate surprising electrical transport properties and could be considered as ‘living electrical (nano)wires’. Cable bacteria, a group of recently discovered filamentous, electroactive, multicellular bacteria, have developed a unique energy metabolism and parallel fibre structures demonstrating electron transport for conduction lengths up to 1 cm and with fibre conductivities exceeding 10 S/cm [4]. Conduction measurements carried out in high vacuum excluded the possibility of ionic conduction, but the fundamental charge transport mechanisms remain unknown. The observed electron transport in cable bacteria over distances in the order of centimeters is unprecedented in the biological world.

Cable bacteria as ‘champion living electrical wires’ are of fundamental interest to better understand the underlying biological processes, but are also potentially interesting as alternative organic electronic materials for the emerging field of bioelectronics as e.g. biocompatible electrical connections and circuits, conductive composite materials, (nano-) sensors, transistors,... In order to investigate the intrinsic electrical properties and underlying transport mechanisms, our approach is to study them with a range of solid state electrical characterisation techniques and prototype electrical circuits/devices [4,5]. These activities revealed an unique electrical network architecture [5] and intrinsic electrical properties very similar to for instance organic semiconductors, situating them in the context of electrical functional materials between semiconductors and conductors [4].

While for various so-called biological semiconducting materials (e.g. peptides, DNA,..) the studied semiconducting properties do not have a direct functionality as electron transporting channel in the occurring life processes, for cable bacteria they are expected to be of key importance. The exceptional intrinsic (semi)conducting electrical properties and extracellular electron transport behaviour of cable bacteria highlighted in this work are therefore worthwhile to be further studied in a cross-disciplinary manner at the nexus of (micro-)biology, (materials) physics and electronics and to be further explored in a variety of bioelectronic devices/circuits.

Highly Sensitive Electro-Chemical Sensor Based on Biomimetic Porous Structured Oxide Semiconductor for Detecting Nitric Oxide | J. Sak Lee, Hyung Tae Kim, Dong Hyun Choi, Sujin Jung and Hyun Jae Kim; Yonsei University, Korea (the Republic of)

In recent years, as the number of patients with Alzheimer’s disease increases due to the advent of early-onset dementia, the social severity of Alzheimer’s disease is on the rise. Accordingly, there are increasing demands for various dementia diagnosis methods because Alzheimer's disease can be prevented from disease development by early detecting and treatment. Among these methods, biosensors are emerging as applications that enable point-of-care testing with low cost and fast response time. The interest in these technologies has mainly focused on field-effect transistor-based biosensor (bio-FET), where the conventional gate and gate insulator are replaced by a reference electrode and the electrolyte, respectively. In addition, the bio-FET uses receptors such as enzyme and aptamer on the sensing surface for detecting targeted bio-molecules. From then on, a lot of researches on the improvement of performance for bio-FET have been reported. However, the bio-FET suffered from low sensitivity and chemical instability. Therefore, oxide semiconductors have been attracted for leading candidates for bio-FET with high chemical stability compared to one- and two- dimensional (1D and 2D) materials. Also, oxide semiconductors based bio-FETs have been attracted much attention for high sensitivity due to low off current characteristics. The low off current (< 10⁻¹² A) of oxide FETs guarantee high signal-to-noise ratio in biosensor
because they have large changes before and after sensing. In this study, we suggest a facile approach to fabricate highly sensitive and durable biosensors based on a bio-mimetic structure (i.e. spongia officialis) of the oxygen plasma-treated porous indium–gallium–zinc oxide (IGZO):polytetrafluoroethylene (PTFE), which is PIP, thin–film layer. The PIP layer could be easily deposited by co-sputtering process and oxygen-plasm etching. Through this fabrication process, we were able to discuss two effects of the technique on the PIP film: 1) It is possible to drastically higher the surface area of the PIP layer utilizing the oxygen-plasma because the PTFE was selectively etched by oxygen-plasma process, which results in a porous of the PIP surface. 2) Improvement of hydrophilicity through the oxygen-plasma process of the PIP layer with free radical species formed by chemical etching. Due to the two effects mentioned above, the PIP layer could more easily be functionalized for surface silanization compared to conventional IGZO layer. In conclusion, to test the IGZO with the PIP layer for bio-FET, we investigated molecular detection of the pH and the neurotransmitter nitric oxide, which is known to induce in dementia, using an aptamer. As a result, the pH sensor with ultra-high sensitivity (1 pH⁻¹) as well as a small limit of detection (0.001 pH) was demonstrated. Furthermore, specific detection of nitric oxide also was demonstrated, and an extremely low limit of detection (< 10fM) was achieved in 0.1× phosphate-buffered saline solution.

5:10 AM S.SM04.02.02
Chemical to Electrical Transduction Using Floating Gate Organic Electrochemical Transistors Siew Ting Melissa Tan, Alexander Giovannitti and Alberto Salleo; Stanford University, United States

Organic Electrochemical Transistors (OECTs) have been investigated as biosensors and logic circuitry due to their biocompatibility and large transconductance [1]. Minute perturbations in gate potentials enable significant changes in channel conductance, allowing OECTs to transduce weak potential changes in biological systems into large current modulations. They can additionally be used in sensing of metabolites enabled by enzymatic reactions [2]. While simple in design, the operation of OECTs still requires independent power and synchronized control of the gate and source-drain voltages, hindering the simplification of supporting control circuits. Furthermore, performing a chemical reaction within the electrolyte of the OECT can be challenging due to effects arising from electrochemical side reactions with both the gate and channel materials.

We demonstrate the development of an OECT that transduces a chemical signal (e.g. oxidation reaction) into an electrical signal (e.g. change of the conductivity of the channel material). To achieve this, the chemical reaction is isolated on a floating-gate, which acts as the chemical-to-electrical transducer for the electrochemical redox-reaction in the OECT. This approach eliminates the need for controlling the gate potential externally, simplifying device operation. We utilize a redox-active polymer on the floating-gate that is sensitive to hydrogen peroxide, intentionally produced by Oxidase enzymatic reactions, to generate a concomitant potential change on the gate of the OECT that modulates the conductivity of the channel material. Investigating different redox-active polymers, we elucidate several design criteria for the floating-gate and OECT channel to optimize the current modulation and amplification of these chemically gated OECTs. Adopting this approach, we achieve large changes in OECT source-drain current of up to three orders of magnitude and demonstrate its versatility by detecting a diverse range of biomolecules spanning glucose to lactate or alcohol. This approach can be further generalized to other Oxidase enzymatic reactions that produce hydrogen peroxide. By harvesting the chemical potential energy of abundantly available biomolecules, the control circuitry and operation of next generation OECT biosensors can be simplified by solely supplying a single source of power.

5:20 AM *S.SM04.02.03
Ultra-Thin Organic Photovoltaics and Sensors for Wearable Sensors Kenjiro Fukuda1, Tomoyuki Yokota2, Zhi Jiang1, Sunghoon Lee1, Wenchao Huang2, Hyunjae Lee1 and Takao Someya1; 1RIKEN, Japan; 2The University of Tokyo, Japan

One of an important target application of biointegrated electronics is wearable sensors that enable accurate and continuous detection of physiological signals. These devices require conformable and biocompatible sensors and power source to continuously supply electricity to health-monitoring systems. In this talk, we will report on recent progresses of ultraflexible organic photovoltaic cells as power sources and wearable sensors. First, the progresses of power conversion efficiency (PCE) and mechanical/long-term stability of ultraflexible organic photovoltaics have been achieved using new material and process engineering. The certified PCE of 12.3% for the ultra-flexible organic photovoltaic cell has been achieved with novel ternary blend active layer [1]. Second, long-term continuous monitoring using organic electrochemical transistors with nonvolatile...
A gel electrolyte has been achieved with a high mechanical stability and high signal-to-noise ratio (24dB) [2]. Then, the integration of the ultra-flexible organic photovoltaic cells as power sources with OECT-based sensors has been demonstrated [3].

Bio-Derived, Green Electronics Made from Microbially Produced Protein Nanowires Jun Yao; University of Massachusetts Amherst, United States

Protein nanowires harvested from microbes are a revolutionary green electronic material. They have unique properties for novel electronic devices with improved performance, for a broad range of applications from energy harvesting to neuromorphic computing and sensing. (1) Thin-film protein nanowire devices were shown to continuously harvest electricity from ambient humidity (Nature 578, 550-554 (2020)), enabled by the unique structural (e.g., nanopores at wire-wire interface) and chemical (e.g., a high density of hydroscopic groups) properties. This leads to a continuous energy harvesting mechanism from the ubiquitous and enormous ambient humidity, and hence a promising strategy to powering self-sustained systems. (2) The protein nanowires are cleverly designed and recruited by the microbe to facilitate charge exchange with environments (e.g., through redox metallization). Thus, protein nanowires can be assembled into bio-dielectrics to construct memristor devices, in which the protein nanowires catalytically reduce the energy barrier involved in memristive switching and enable ultralow operational voltage in the biological regime of <100 mV (Nature Commun. 11, 1861 (2020)). Neuromorphic components (e.g., artificial neuron, synapse) made from the protein nanowire memristors take a further step in bio-emulation from functional emulation to parameter matching, creating opportunities for future ultralow-power electronics and bioelectronic interfaces. (3) Protein nanowires have ultra-small diameters (3 nm) and an ultra-high density of surface functional groups (e.g., 10 per nm) that are advantageous for sensing applications. Electronic sensors made from protein nanowires were shown to have enhanced selectivity and sensitivity (Nano Res. 13, 1479-1484 (2020)) for ammonia detection compared to inorganic nanowire devices. These studies, combined with the advantages of renewability, biocompatibility, and eco-friendliness in protein nanowires, have provided the starting point for future green electronics based on synthetic protein nanowires.

5:45 AM S.SM04.02.05
Macroporous and Conductive Hydrogels for Stimulated Delivery of Biomolecules Teuku Fawzul Akbar1,2, Christoph Tondera1,2, Jana Sievers2, Jens Friedrichs2, Petra Welzel2, Carsten Werner2 and Ivan Minev3; 1Technische Universität Dresden, Germany; 2Leibniz Institute of Polymer Research Dresden (IPF), Germany; 3University of Sheffield, United Kingdom

Current neural electrodes which usually employ metallic materials are known to trigger foreign body reaction which leads to material degradation and decline of electrical performance over long time period. Hydrogels as a novel class of materials for neural electrodes come up as a promising alternative because they can be designed to mimic some of the properties of soft tissues. Electrical functionality could be added to the hydrogels by formation of conductive polymers on the hydrogel struts. Porosity of the hydrogels could be used as reservoir of drugs where the release kinetics are controlled by the interactions between drug molecules and hydrogel building blocks.

Here we present electrically conductive hydrogels based on chemically crosslinked 4-arm star-shaped poly(ethylene glycol) (starPEG) and heparin. The conductive polymer poly(3,4-ethylenedioxythiophene) (PEDOT) is incorporated in the hydrogel using interfacial polymerization method. Negatively charged heparin increases electrical conductivity of the hydrogel more than 3 orders of magnitude from 6.75x10⁻³ S/m for bulk hydrogels without heparin to 58.5 S/m for hydrogels containing both heparin and PEDOT. The increase in conductivity is due to the ability of heparin to dope the conductive polymer. Macropores are formed by maintaining the polymerization reaction at -15°C as a result of ice crystals formation which act as porogens. Typical pore sizes are 670.6 μm². The conductivity of macroporous hydrogels is measured to be 8.5 S/m. The macroporous hydrogels achieve superior toughness in comparison to bulk hydrogels as observed from compression test. The compression modulus of the conductive porous hydrogels is less than 10 kPa which demonstrates potential applications for interfacing with soft tissue.

Furthermore, we investigate the capability of the composite hydrogels to bind Nerve Growth Factor β (NGF-β) as heparin is known to bind with various types of growth factors. In our ongoing work we are investigating if conductivity in the hydrogel can be used to release the growth factor from the hydrogel in a controlled manner. Optimized condition of uptake and release
of NGF-β can then be employed to observe morphological change of PC12 cells.

In conclusion, we will discuss a system which may allow interfacing with electroactive tissue by adopting controlled electrical and biochemical cues.

5:55 AM *S.SM04.02.07
Fish-Eye-Inspired Wide Field-of-View Camera Dae-Hyeong Kim\textsuperscript{1,2}; \textsuperscript{1}Institute for Basic Science, Korea (the Republic of); \textsuperscript{2}Seoul National University, Korea (the Republic of)

Although recent efforts in device designs and fabrication strategies have resulted in meaningful progresses to the goal of novel high-performance imaging devices, significant challenges still exist in developing a miniaturized and lightweight camera that enables the wide field-of-view (FoV) imaging. This is mainly due to bulky and heavy multiple lenses employed in the conventional wide angle camera. In this work, inspired by structural and functional features of the aquatic vision, we have developed a novel wide FoV camera by integrating a tailored monocentric lens and a hemispherical silicon nanorod photodetector array. This bioinspired camera offers the wide FoV, a miniaturized module size, minimal optical aberrations, the deep depth-of-field, and the enhanced light sensitivity in one simple integrated device. Theoretical analyses in conjunction with imaging demonstrations have corroborated the validity of the proposed concept. The fish-eye-inspired camera is expected to provide new opportunities for the advanced mobile electronics.

SESSION S.SM04.03: Fundamental Materials and Devices for Biointegrated and Bioinspired Electronics
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020

5:00 AM *S.SM04.03.01
Bioelectronics with Nanocarbons Tzahi Cohen-Karni; Carnegie Mellon University, United States

We focus on developing a new class of nanoscale materials and novel strategies for the investigation of biological entities at multiple length scales, from the molecular level to complex cellular networks. Our highly flexible bottom-up nanomaterials synthesis capabilities allow us to form unique hybrid-nanomaterials. Recently, we have demonstrated highly controlled synthesis of 3D out-of-plane single- to few-layer fuzzy graphene (3DFG) on a Si nanowire (SiNW) mesh template. By varying graphene growth conditions, we control the size, density, and electrical properties of the NW templated 3DFG (NT-3DFG). This flexible synthesis inspires formation of complex hybrid-nanomaterials with tailored optical and electrical properties to be used in future applications such as biosensing, and bioelectronics. For example, we have developed a unique bioelectrical platform based on 3DFG and have demonstrated, for the first time, recording of the electrical activity of excitable cells using ultra microelectrodes ranging from 10µm down to 2µm, without the need of any surface coatings. Currently, we target the limits of cell-device interfaces using out-of-plane grown 3DFG, aiming at electrical recordings with subcellular spatial resolution (<5µm) and μsec temporal resolution. In summary, the exceptional synthetic control and flexible assembly of nanomaterials provide powerful tools for fundamental studies and applications in life science and open up the potential to seamlessly merge either nanomaterials-based platforms or unique nanosensor geometries and topologies with cells, fusing nonliving and living systems together.

5:15 AM *S.SM04.03.02
Soft Tissue-Like Rubbery Electronics and Integrated Systems Cunjiang Yu; University of Houston, United States

While human organs and tissues are mostly soft; conventional electronics are hard. Seamlessly merging electronics with human is of imminent importance in addressing grand societal challenges in health and joy of living. However, the main challenge lies in the huge mechanical mismatch between the current form of rigid electronics and the soft curvy nature of biology. Here, I will present a new form of electronics, namely “rubbery electronics and bioelectronics”, with skin-like softness and stretchability, which is constructed all based upon elastic rubbery electronic materials. These rubbery electronic materials are structured in the format of composites, which can be scalably manufactured from common and commercial available materials without dedicated and complicated synthesis. Specifically, we build nanofibril organic semiconductor and metallic nanowires percolated in the elastomeric polymer matrix in a composite format for the rubbery semiconductors and conductors, respectively. Employing these rubbery electronic materials, we have achieved fully rubber format devices,
including transistors and sensors, logic gates, active matrices, elastic sensory skin systems, and biointegrated devices, etc. I will showcase a few examples including artificial skins, biomedical implants, and wearable applications.

5:30 AM  *S.SM04.03.03*  
**Wireless Modular E-Tattoos Chargeable On-the-Go**  
Nanshu Lu; University of Texas at Austin, United States

Soft, noninvasive and multifunctional epidermal electronics (a.k.a. electronic tattoos or e-tattoos) have demonstrated many exciting applications in mobile health, athletic training, human-machine interface (HMI) and so on. However, e-tattoos are only practically useful when they are low cost and wireless. Previously, our group has invented a dry and digital manufacturing approach named the “cut-and-paste” method for the rapid prototyping of e-tattoo sensors using a paper/vinyl cutter plotter [1]. This method has been demonstrated to work for thin film metals [1, 2], various polymer sheets [1, 3], ceramics [4], as well as 2D materials such as graphene [5, 6]. The cut-and-pasted e-tattoos are low cost and can be used to measure a variety of physiological signals such as electrocardiogram (ECG), seismocardiogram (SCG), electrooculogram (EOG), skin hydration, skin temperature, respiratory rate and so on [1-3, 5, 6]. To make the e-tattoos go wireless, we now report the “cut-solder-paste” process to incorporate integrated circuits (ICs) for signal readout and processing, near field communication (NFC) [7], as well as Bluetooth transmission [8]. To overcome the limited patterning resolution of the cutter plotter and to recycle the tattoo layers with ICs, we propose a modular concept in which the wireless charging layer (NFC layer), the wireless communication layer (Bluetooth layer), the readout circuit layer, and the sensor/electrode layer are fabricated individually and stacked up at the final step of fabrication. The thickness of a fully assembled multilayer e-tattoo (excluding IC chips) is less than 300 μm and the overall stretchability is still beyond 20%. In addition to already mentioned capabilities, such e-tattoos can also wireless track motion, mechano-acoustic heart signals, and oxygen saturation (SpO2) [3, 7, 8]. The NFC-enabled e-tattoos can be wirelessly charged so no battery is needed but the sampling rate is limited to 25 Hz and the wireless communication distance is limited to 5 cm. The Bluetooth-enabled e-tattoos require on-tattoo batteries but the sampling rate can be up to 4 kHz and the wireless communication range can be up to 10 m. Combining the NFC layer and the Bluetooth layer in one e-tattoo, we demonstrate that such wireless e-tattoo can also be wirelessly charged on-the-go via stretchable fabric feeding coils [8], enabling long-term, ambulatory and continuous sensing. Moreover, we propose that different layers can be disassembled and reassembled multiple times. After disassembly, the electrode layer should be disposed but the other layers can be reassembled into new e-tattoos. The low-cost, rapid prototyping method together with the wireless and reconfigurable capabilities represent exciting advancement towards practically useful wireless e-tattoos.

5:45 AM  *S.SM04.03.04*  
**A Biohybrid Synapse with Neurotransmitter-Mediated Plasticity**  
Scott T. Keene¹, Claudia Lubrano²,¹, Setareh Kazemzadeh³, Armantha Melianas¹, Yaakov Tuchman¹, Giuseppina Polino²,³, Lucio Ciná⁴, Alberto Salleo¹, Yoeri van de Burg⁵, and Francesca Santoro⁴; ¹Stanford University, United States; ²Istituto Italiano di Tecnologia, Italy; ³Università degli Studi di Roma Tor Vergata, Italy; ⁴Cicci Research, Italy

Brain-inspired computing paradigms have led to substantial advances in automation of visual and linguistic tasks by emulating the distributed information processing of biological systems. The similarity between artificial neural networks (ANNs) and biological systems has inspired ANN implementation in biomedical interfaces including prosthetics and brain-
machine interfaces. While promising, these implementations rely on software to run ANN algorithms. Ultimately, it is desirable to build hardware ANNs that can directly interface with living tissue which adapt based on biofeedback. The first essential step towards biologically integrated neuromorphic systems is to achieve synaptic conditioning based on biochemical signaling activity.

Direct communication between artificial and biological neurons is of particular interest because of the vast utility that can be achieved by interacting with the nervous system. In this work, we bridge the gap between artificial and biological neurons by directly coupling an organic neuromorphic device with dopaminergic neuron-like cells to constitute a biohybrid synapse with neurotransmitter mediated plasticity. Voltage pulses at the pre-synaptic electrode drive the oxidation of the excitatory neurotransmitter dopamine, leading to both a short-term potentiation of the channel from ionic drift as well as a long-term potentiation due to the redox reaction with dopamine at the interface.

We elucidate the working principle of the biohybrid synapse by characterizing the electrochemical response of the organic neuromorphic device to dopamine signaling both in solution and in vitro. Furthermore, we use focused-ion beam and scanning electron microscopy to visualize the interface between the living cells and organic postsynaptic electrode. We utilize microfluidic flow across the channel to mimic the dopamine recycling machinery of biological synapses to demonstrate both long-term conditioning and recovery of the synaptic weight. Finally, we report direct translation of dopamine secreted by PC12 neuron-like cells to long-term modulation of the biohybrid synapse memory state, paving the way towards combining neuromorphic systems with biological neural networks.

5:55 AM *S.SM04.03.05
Assembly of Nanoelectronics Via Tissue Development Jia Liu; Harvard University, United States

Tissue-wide electrophysiology with single-cell and single-spike spatiotemporal resolution is critical for biological studies and biomedical applications. In this talk, I will discuss the creation of cyborg organisms: the three-dimensional (3D) assembly of soft, stretchable mesh nanoelectronics across the entire living organism by the cell-cell attraction forces from 2D-to-3D tissue reconfiguration during organogenesis. We demonstrate that stretchable mesh nanoelectronics can migrate with and grow into the initial 2D cell layers to form the 3D organ with minimal impact on tissue growth and differentiation. The intimate contact between the dispersed nanoelectronics and cells enables us to chronically and systematically observe the evolution, propagation and synchronization of the bursting dynamics in different organisms through their entire organogenesis and maturation. I will also discuss the potential applications of these cyborg organisms in biology and biomedicine.

6:10 AM *S.SM04.03.06
Memory and Learning in Biomolecular Soft Matter for Low-Power, Brain-Like Computing Joseph S. Najem; The Pennsylvania State University, United States

The brain carries out complex cognitive and computing tasks by optimizing energy efficiency, information processing, communication, and learning in massively parallel, dense networks of highly interconnected neurons. To cope with its everchanging surroundings, the brain is able to grow neurons, synapses, and connections—owing to its plastic nature. At the molecular and cellular levels, synaptic plasticity and neuronal excitation are the main mechanisms underlying these processes. Therefore, the ability of next-generation computing devices, robots, and machines to autonomously sense, process, learn, and act in complex and dynamic environments while consuming very little power will require approaches to computing and sensing that are inherently brain-like. Reproducing these features using traditional electronic circuit elements is virtually impossible, requiring the design and fabrication of new hardware elements that can adapt to incoming signals and remember processed information. These elements should be scalable, biomimetic, and preferably ionic to achieve energy consumption levels approaching those in the brain. While a major effort is being invested in developing inorganic materials that could emulate synaptic and neural functionalities, I believe that an overlooked, yet high-reward, pathway to success is through the development of biomolecular materials with the composition, structure, and switching mechanisms of actual biological synapses and neurons. Here, I describe two-terminal, biomolecular memcapacitors and memristors, consisting of highly insulating 5 nm-thick lipid bilayers assembled between two water droplets in oil. These devices exhibit memcapacitance that is nonlinearly dependent on the applied voltage as well as hysteresis in the charge due to voltage-driven, reversible changes in the area and thickness of the bilayer membrane. This is the first demonstration of a memcapacitor in which capacitive memory results from geometrical changes in a lipid bilayer membrane. We also show that the incorporation of voltage-activated alamethicin and monazomycin peptides in these devices results in variable ionic conductance across the membrane and memristive behavior. We discuss how these devices exhibit learning through synaptic plasticity, and how to implement them in online learning applications. These results serve as a foundation for a new class of low-cost, low-power, soft mem-elements based on lipid interfaces and other biomolecules for applications in neuromorphic computing which could have
Harnessing the diversity of sensing platforms for applications in complex biological and chemical environments has been a challenge in the field of biosensing for many years. Electrochemical, optical, and magnetic techniques have been proposed, most with limitations ranging from biocompatibility, sensitivity, and signal transduction through opaque media, to longevity under non-laboratory conditions. Through advances in core/shell nanobiotechnology, we have developed an implantable diagnostic device for the measurement of biomarkers using a magnetic particle assay. This assay behaves as a platform technology tunable for biochemical monitoring in health, manufacturing, security, agriculture, and veterinary care. Our current applications focus on medical diagnostics in subclinical, chronic, and transient cardiac and cancer disease models with low sampled concentrations or temporary spikes in biomarker presence frequently missed by serial sampling. In situ diagnostics offer continuous sentineling of critical biomarkers, providing a deeper understanding of the local biology in heterogeneous systems. This monitoring provides valuable timescale data to clinicians giving them insight into their patients’ lab results for early intervention and data collection throughout treatment. Nanoparticle science, NMR technology, and modern biomaterials are combined in a multidisciplinary approach in this study to improve the diagnostic paradigm in addressing biochemical sensing.

Layered core/shell particles have been designed to detect the presence of specific molecules. Magnetic contrast is made possible by careful selection of the core material while biological functionality is provided by tunable surface ligands (antibodies, complementary DNA, aptamers, etc.) for specific affinity toward multivalent targets. Reversible (current concentration), irreversible (dosimetric, cumulative exposure), and switch (on/off) systems have been tuned by varying the affinity properties of the functionalization layers. We have shown proof-of-concept of a system composed of nanostructured materials easily implantable in vivo for both local and systemic chemical monitoring. Colloidal suspensions are kept at a constant particle concentration within a depot, protected from their environment by a semi-permeable membrane. Target diffusion across the membrane induces a switch from a dispersed to an assembled state with a corresponding change in magnetic properties allowing for robust contrast. Devices are deployed within the subcutaneous space or locally at the site of disease and immediately begin tracking their milieu. Magnetic relaxation measurements taken by Magnetic Resonance Imaging (MRI) and single-sided NMR systems are compared to demonstrate the feasibility of implementation in clinic-based and point-of-care, resource-limited settings.

Depot usable lifetime and nanostructure degradation are key parameters in multi-month applications. Recent work in tuning surface chemistry and bioconjugation strategies has enhanced the performance of the switch-based system by an order of magnitude over prior studies, increasing the expected lifetime to over 29 weeks in elevated temperature experiments. Progress in biomaterial capsule development has also shown promise in the deployment of a controlled degradation system with the added benefit of minimally invasive implantation compared to previous surgical placement methods. Overall this implant has the potential to broaden diagnostics in personalized medicine by addressing the hurdles of longevity and robust sensor signal stability in complex environments.

5:00 AM S.SM04.04.01
Elucidating and Replicating Topography-Based Chemical Crypsis in the Puff Adder and Related South African Snake Species Via Micron Scale 3D Printing and Multidimensional Fourier Analysis Rachel Miller1, Stephen Lee2 and Robert Shepherd1; 1Cornell University, United States; 2U.S. Army Research Laboratory, United States

Humans have been studying and mimicking animals’ visual crypsis using wearable camouflage since the 18th century. Yet, only recently we have documented and attempted to understand the origins of chemical crypsis, the ability to become
imperceptible to olfaction. Specifically this work aims to elucidate the mechanism of chemical crypsis in the first vertebrate shown to exhibit this trait, a snake known as the puff adder (Bitis arietans). Extensive behavioral and ecological studies show that puff adders are well evolved to be chemically imperceptible to predators, prey, and even potential mates without the capability to modulate pheromone molecular weight, produce odorant counteractants, or eliminate skin odorant sources such as bacteria. Therefore we turned to the skin surface structure, the major feature distinguishing the puff adder from its non-cryptic brethren such as the night adder (Causus rhombeatus). The skin’s micron-scale, high aspect ratio, curved features known as ‘fingers’ create an array of wells for odorants to pool, significantly reducing odorant volatility and therefore rendering the puff adder imperceptible to smell. To study and quantify this phenomena independent of snakeskin material, snakeskin surface biomes, and environmental contaminants, we employ various imaging and 3D printing processes to create a variety of detailed and accurate scaled models of both the puff adder skin and night adder skins. Nano-focused computed tomography (nano-CT) is used to create three-dimensional renderings of skins. To maximize accuracy of replicas, nano-CT image segmentation is informed by focused ion beam (FIB) and scanning electron microscopy (SEM) images. These digitally rendered surfaces are printed in urethane methacrylate or other acrylic using 3D printing. 90:1 models are printed using projection stereolithography (SLA) for millimeter resolution while 1:1 models require the use of two photon polymerization for micron scale feature resolution. 2D Fourier transforms of 2D slices examined along the third axis in real space in addition to 3D Fourier transform are used to pinpoint key frequencies present in cryptic versus non cryptic snakes. This analysis is used as a means to quantify periodicity and investigate the degree of quasi-ordered orientation as a predictor for surface thermodynamic phenomena. Physical experiments on printed models and topographical analysis of digital renderings are used together to analyze the effects of structure periodicity and surface-area-to-volume ratio on adhesion, wetting, and evaporation.

5:10 AM S.SM04.04.02
Dry Sensor with Strong Self-Adhesion to Hairy Skin for Contact Mode Bio-Signal Recording Abhijith Balamuraleekrishna Shyam, Anan Zhang, Alexandra Cunningham, Marianna Kontopoulou, Aris Docoslis and Shideh K. Ameri; Queen’s University, Canada

One in four people are affected globally by mental and neurological disorders during their lives. There is a stigma towards mental disorders and therefore, most of such issues remain undetected. Electroencephalography (EEG) is noninvasive recording of brain signals. Numerous studies suggest the correlation between electroencephalography (EEG) signals, and mental state. Conventional EEG systems are bulky and stationary which make them unstable for continuous ambulatory measurements. Further, accurate EEG measurements, used for diagnosis, requires medical experts and is done in medical centers, which makes it time consuming and costly. In order to overcome these challenges and make the mental health monitoring accessible and low cost, wearable sensors are highly desirable. Here, we report a novel long-term wearable, dry, miniaturized self-adhesive sensor (DSAS). It can firmly adhere to hairy scalp without the use of any adhesive, gel or mechanical support and be used for high quality EEG recording with low motion artifacts. DSAS is a reusable and soft sensor that can be simply attached and detached. It consists of the arrays of low-density tulip-like microstructures made of PDMS-conductive-filler composite (graphene and carbon nanotube) that deploy between the hairs and stick to the scalp. Each tulip-like microstructure consists of a long stem (400-450 µm) and a micro-suction cup head (200-300 µm diameter). DSAS adhere to any surface including hairy skin by accumulative work of adhesion force, generated by forming negative pressure in each micro-structure. Negative pressure is generated when microstructures in DSAS are pressed against a surface and the air is pushed out of micro-suction heads. DSAS is made by a novel scalable fabrication process and comprehensive theoretical studies were performed for the optimization of the fabrication process. Our results suggest that each tulip-like microstructure produces 12 mN adhesion force. The cups’ shell wall in the tulip-like microstructure head is 15 µm thick and ultra-soft which allows forming conformal contact to the rough surfaces such as skin and prevents leaking the air into the interface between sensor and surface after attaching it to skin. An array of just 100 per cm² microstructures in DSAS can hold 120 gm of weight for extended amount of time and maintains the adhesive properties up to 15 attach-detach cycles.

5:20 AM S.SM04.04.04
Epidermal Antenna-based Sensor for Pervasive Healthcare Zhibo Chen and Jie Hu; Hong Kong University of Science and Technology, Hong Kong

While individual epidermal sensors present a good compromise between comfortability, affordability, and functionality, the assembly of soft electronics adds a performance sacrifice and a cost overhead to the sensor system manufacturing process – especially when interfacing these with wireless communication and data processing. The more functionalities, the more rigid components involved. Therefore, it is a big challenge to compromise between soft individual components and rigid integrated circuits. Even though some reports have shown promising fundamental soft electronics solutions, such as transistor and diode, etc., the epidermal sensor system is still trapped in an early-stage analog level due to the sophisticated Von Neumann
hardware architecture.

A novel far-field wireless epidermal pressure sensor system is presented here. The sensor which changes in the antenna electrical parameter is mapped to the changes in the properties of the electromagnetic wave propagation. This mechanical – electrical conversion manifests itself as a controlled sensing method from the signal response of the antenna device. Signal processing is demodulated from the reader side, making the epidermal pressure sensor a passive parasitic component in the antenna. This allows the sensor to directly leverage and benefit from concurrent advancements in wearable antenna research and conductive elastomer development while seamlessly extending to the pervasive low-cost wireless sensing applications.

Besides, an example of this approach will be presented in detail, including the design of the PDMS-based on-body sensor antenna and the signal response of Sub 1 GHz microstructure-based epidermal pressure sensor, etc. All key processing parts share the same on-body packaging, therefore enabling a chip-scale technology that can be designed in different elastic packaging forms. This unique sensor concept can lead to new applications and lead the pervasive epidermal healthcare sensing to a new level.

Unusually Conductive Organic-Inorganic Hybrid Nanostructures Derived from Bio-Inspired Mineralization of a Peptide/Pi-Electron Assembly Taein D. Lee, Sayak S. Panda, John D. Tovar and Howard E. Katz; Johns Hopkins University, United States

Highly efficient charge-transport phenomena in biological systems ignited researchers’ interest to investigate the conductivity of biologically relevant macromolecules processed from aqueous solution. Self-assemblying peptides and proteins are of particular interest due to their ease of synthesis and tunable side chains. Polypeptides have been designed and synthesized for self-assembly and charge delocalization of organic pi-electron systems. Of these, peptide-π conjugated materials form robust 1D nanostructures with tunable electronic and photonic properties while retaining significant conductivity and mobility. Electronic and photonic properties of π-conjugated oligopeptides can be tuned by incorporation of electron withdrawing and electron accepting chromophores in the peptide chains. Oligothiophenes are also one of the standard organic semiconductor subunits investigated for semiconducting properties of π-conjugated peptides. However, peptide-based charge transporting materials still suffer from relatively low conductivities due to the large insulating peptidic regions, posing a challenge for characterization of electrical transport pathways in biologically relevant materials.

Here, we investigated 1D nanostructures and electrical properties of a peptide-π-peptide oligopeptide self-assembly composed of peptides, HCl, and KOH in aqueous solution. Using supramolecular systems, oligomers with central chromophore groups with non-polar amino acid side chains plus one glutamic acid were self-assembled into macrostructures via pH triggering. In order to decouple the amino acid side chains from the chromophores, 3- carbon spacers were added in between them on both sides. Using KOH to dissolve the oligomers and subsequently exposing them to HCl vapor triggered self-assembly via pH change leading to protonation of glutamic acid, as well as biomineralization of KCl, presumably initiating at the glutamic acid. Together, the self-assembly achieved by formation of β-sheets, π-orbital overlaps and biomineralization formed highly interconnected dendritic structure given conditions with well-balanced kinetic and thermodynamic contributions. The solution conditions with HCl exposure enabled biomineralization of KCl nanocrystals templated by the glutamic acid in the underlying oligopeptides prior to self-assembly, resulting in a synergy of self-assembled peptides and biomineralized KCl to form supramolecular structures.

Electrical measurements indicated that these interconnected dendritic structures were highly conductive systems with conductivities comparable to that of a metal at around 1800 S/cm for samples with robust dendritic pathways. About 50 mA current was measured for 0.5 V at drain. Varying the gate V, however, had no effect on the current levels indicating a conductive material instead of a semiconducting material. Various experiments showed the conductivity of these systems were derived from proton doping of chromophores in strong acid environment in addition to closely fixated chromophores from the biomineralized KCl leading to easily transferred π-electrons along the interconnected dendritic pathways. Shelf-life tests showed that the conductive pathways degraded about 90% after 6 weeks; the KCl crystals formed around the self-
assembled structures further functioned as a protective layer to dedoping of protons as well as preventing disintegration of the closely packed chromophores. Our findings suggest that in supramolecular systems, biomineralization triggered with appropriate amino acids combined with self-assembly can be used as a template to grow highly conductive dendritic macrostructures as well as control nanowire growth in specific directions.

5:10 AM S.SM04.05.03
From Functional Nanomeshes to Advanced Soft Microsystems Hui Fang; Northeastern University, United States

New form of materials can often enable new device and system applications. In this talk, I will highlight our group's recent work under this motivation in two synergistic areas. Firstly, by stacking individual layers of polymer, metal, and low-impedance coating reliably in a same nanomeshed pattern, the final multilayer multifunctional nanomeshes achieved system-level performance from all individual layers, in addition to nanomesh advantages. Compelling demonstrations from this multifunctional nanomesh approach include high-performance transparent and flexible neuroelectrode arrays, which has been recently validated in vivo. The second part of my talk will introduce our recent concept on semiconductor nanomeshes. By making a silicon film into homogeneous nanomeshes, we achieve high mobility semiconductor that is intrinsically stretchable to conventional microelectronic layouts. Together, our work demonstrates that nanomeshing is a unique way of transforming microelectronics for emerging applications.

5:25 AM S.SM04.05.04
Flexible Carbon Nanotube Synaptic Transistor for Neurological Electronic Skin Applications Haochuan Wan, Li-Wei Lo and Chuan Wang; Washington University in St. Louis, United States

There is an increasing interest in the development of memristive or artificial synaptic devices that emulate the neuronal activities for neuromorphic computing applications. While there have already been many reports on artificial synaptic transistors implemented on rigid substrates, the use of flexible devices could potentially enable an even broader range of applications. In this talk, we report high performance synaptic thin-film transistors (TFTs) built on ultrathin flexible substrate using high carrier mobility semiconducting carbon nanotubes (CNTs). The synaptic characteristics, including spike amplitude-dependent plasticity, long-term/short-term plasticity (LTP/STP), spike-number dependent plasticity (SNDP), spike-timing dependent plasticity (STDP) have all been systematically characterized on the flexible synaptic CNT TFT. Moreover, we have demonstrated an individual pixel circuit that may be used to construct a flexible neurological electronic skin in the future. The circuit comprises a flexible ferroelectret nanogenerator (FENG) serving as the sensory mechanoreceptor that generates action potentials to be processed by the artificial synapse. In such a system, the flexible FENG sensor converts the tactile input (the magnitude and frequency of force) into presynaptic action potential pulses, which are then passed to the gate of the synaptic transistor to induce change in its drain current (post-synaptic current), mimicking the modulation of synaptic weight in biological synapses. The single pixel circuit closely emulates the behavior of actual human skin and it allows for instantaneous detection of force stimuli and offers biological synapse-like behavior to relay the stimuli signal to the next stage. It could be further integrated into an array to achieve a neurological electronic skin with synaptic behavior and memory capabilities, which could potentially be used to interface with skeletal muscle fibers for applications in neuroprosthetic devices.

5:35 AM S.SM04.05.05
Selective Eradication of Bacteria by a Flexible Bacterial-Imprinted Electronic Chip Liwei Hui, Parmila Kafley and Haitao Liu; University of Pittsburgh, United States

Pathogen invasion not only release toxins to attack mammalian cells, but also colonize and disturb the balance of healthy microbiome. Therefore, it is desirable to develop antibacterial methods that target specific bacteria. Here we show a strategy to selectively immobilize bacteria on surface to allow its eradication by electricity. We designed a flexible PDMS chip that has been imprinted with bacteria and with integrated electrodes. The chip could selectively capture the target bacteria to the surface by shape complementarity. Upon applying a low voltage, we observed a fast killing of bacteria in real time. The work suggests a new approach to design intelligent antimicrobial devices that are suitable for use on microbiota sites.

5:45 AM S.SM04.05.06
MXene Ink-Infused Bioelectronic Interfaces Enabled by Rapid Laser Machining Nicolette Driscoll1,1,2, Nicholas Apollo1,1,2, Brian Erickson1, Brendan B. Murphy1,1,2, John Medaglia1 and Flavia Vitale4,1,2; 1University of Pennsylvania, United States; 2Corporal Michael J. Crescenz VA Medical Center , United States; 4Drexel University, United States

2020 MRS Virtual Spring/Fall Meeting, November 27-December 4, 2020, Spring Abstracts Final Program 2/3/21
In recent years, there has been tremendous interest in developing new technologies enabling the seamless integration of electronics with soft biological tissues. This has required significant innovation in materials and fabrication strategies to develop bioelectronic interfaces which are soft, biocompatible, and highly conformable to the tissue of interest. Many of the most successful technological advances in this realm so far have leveraged traditional metal and silicon materials along with thin-film microfabrication strategies to create highly flexible and conformable bioelectronic interfaces. While these thin-film technologies have been shown to achieve exquisite tissue conformability, one of their primary limitations to achieving clinical translation and widespread use is the high cost and low scalability of the materials and fabrication methods. Here, we present a novel process for rapid, low-cost, and highly scalable manufacturing of flexible bioelectronic interfaces by leveraging the electronic, physical, and chemical properties of Ti\textsubscript{3}C\textsubscript{2} MXene. In this process, a laser-patterned cellulose-polyester blend substrate is infused with a water-based ink of Ti\textsubscript{3}C\textsubscript{2} MXene to generate a bulk conductive composite which is subsequently encapsulated in thin layers of flexible silicone elastomer. This method is highly customizable, and allows manufacturing of electrode arrays of different scales and geometries for recording a wide range of bioelectronic signals, including scalp electroencephalography (EEG), electromyography (EMG), electrocardiography (EKG), and electrocorticography (ECoG). We have thoroughly characterized the electrochemical and mechanical properties of the MXene-textile electrodes at varying diameters, and validated their impedance and recording properties \textit{in vivo} in a range of biosensing and stimulation applications. Enabled by the high conductivity and capacitance of Ti\textsubscript{3}C\textsubscript{2} MXene, as well as the high effective surface area of the porous MXene interface, these electrodes show remarkably low electrochemical impedance both in saline (1 kHz $|Z|$ 205.6 ± 11.1 $\Omega$, 3mm MXene vs. 287.3 ± 7.8 $\Omega$, 2.3mm Pt) and on human skin (1 kHz $|Z|$ 6.2 ± 4.1 k$\Omega$, 3mm MXene vs. 3.62 ± 0.6 k$\Omega$, 1cm gelled commercial electrodes, Natus Inc.). Particularly interesting for epidermal sensing applications, our mm-scale dry MXene electrodes achieve comparable electrode-skin interface impedance and recorded signal quality compared to cm-scale gelled electrodes, which enables recording with higher spatial resolution as well as improving subject comfort and long-term recording capabilities by avoiding the need to use conductive gels. We demonstrated this advantage through EEG recording on a healthy human subject, where our mm-scale electrodes produced signals which were indistinguishable in signal-to-noise ratio, spectral content, or magnitude from a standard cm-scale gelled Ag/AgCl EEG electrode placed next to the MXene array. The MXene electrodes also exhibit extremely high cathodal charge storage capacities (901.5 ± 38.4 mC cm\textsuperscript{-2}, 500µm MXene vs. 105.2 mC cm\textsuperscript{-2}, 200µm PEDOT:PSS on Pt) and charge injection capacities (2.4 ± 0.5 mC cm\textsuperscript{-2}, 500µm MXene vs. 1.4 mC cm\textsuperscript{-2}, 200µm PEDOT:PSS on Pt), which make them a promising candidate for delivering electrical stimulation. Finally, we have demonstrated the compatibility of the MXene electrodes with both MRI and CT imaging, due to the low magnetic susceptibility and low density of the electrode materials. The work presented here is a platform technology, enabling rapid and low-cost manufacturing of bioelectronic interfaces by leveraging the unique properties and solution-processability of Ti\textsubscript{3}C\textsubscript{2} MXene.

**5:55 AM SSM04.05.07** Microscale Devices into the Brain Nicholas Melosh and Abdul Obaid; Stanford University, United States

Microscale electrodes, on the order of 10-100 µm, are rapidly becoming critical tools for neuroscience and brain-machine interfaces (BMIs) for their high channel counts and spatial resolution, yet the mechanical details of how probes at this scale insert into brain tissue are largely unknown. Here, we discuss quantitative measurements of the force and compression mechanisms together with real-time microscopy for insertion of a systematic series of microelectrode probes as a function of diameter (7.5–100 µm and rectangular Neuropixels) and tip geometry (flat, angled, and electrochemically sharpened), within phantoms, \textit{ex vivo} and \textit{in vivo}. Results from each model system elucidated the role of tip geometry, surface forces, and mechanical scaling with diameter. Surprisingly, real-time microscopy revealed that at small enough lengthscales (<25 µm), blood vessel rupture and bleeding during implantation could be entirely avoided. This appears to occur via vessel displacement, avoiding capture on the probe surface which led to elongation and tearing for larger probes. We propose a new, three-zone model to account for the probe size dependence of bleeding, giving a new conceptual framework for how blood vessels fail and provide guidance for probe design.

**6:10 AM SSM04.05.08** Biodegradable, Wireless Electroceutical for Accelerated Regenerative Medicine Jio Kim, Sung-Geun Choi and Seung-Kyun Kang; Seoul National University, Korea (the Republic of)

Biodegradable systems are critically important in regenerative medicine since complete systems must be replaced by new tissues and organs. Biodegradable or transient electronics provide the electrical functionalities for typical biodegradable...
regenerative materials that are generally used in tissue engineering like scaffolds and metal joints. The wireless electrical stimulator made of completely biodegradable materials proposed here can accelerate the regeneration of injured nerve and dissolve away. Passive electrode and capacitors were constructed using biodegradable metal Mg and dielectric SiO2 on a flexible PLGA substrate. Doped Si nanomembranes were used as diodes to rectify the stimulating pulse into monophasic form. Animal demonstrations showed the functional recovery of transected peripheral nerves by monitoring the EMG, muscle mass and force for up to three months.

PVDF-TrFE/PDMS Composite with Inkjet Printed PEDOT:PSS Electrodes for Flexible Sensing Andrew Closson, Lin Dong, Haley C. Richards and John X. Zhang; Thayer School of Engineering, United States

The development of soft and highly flexible electronics enables seamless interfaces with biology, with applications ranging from implantable medical devices to wearable sensors for health monitoring. Piezoelectric polymers have demonstrated superior performance compared to standard ceramic piezoelectric materials however, these polymer-based devices still require metallic electrodes, patterned through photolithography techniques which are time and resource intensive. Here we aim to fill this gap with inkjet printing, an iterative, low-cost, and scalable fabrication method for patterning polymer electrodes. Specifically, we developed an inkjet printing process, with over 500cm² printable area and linewidth resolution of 100 µm, able to print a patterned 5 cm² polymer electrode layer in minutes. The polymer electrodes showed a layer dependent conductivity with a high conductivity of 5.4*10⁻¹ S/cm at 10 layers. Utilizing this technology, we developed a flexible piezoelectric PVDF-TrFE nanofiber/PDMS composite, with inkjet-printed patterning of a conductive PEDOT:PSS electrodes on either side of the piezoelectric material. Further, we are able to create a flexible sensor array. For a single 1 cm² element, voltage peak-peak output was measured over a range of forces giving a sensitivity of 258 mV/N, which outperforms many PVDF based force sensors in the literature. The 2x2 piezoelectric array is able to detect localized force, with a 12.5x greater output on the pressed element versus the output from adjacent untouched elements, even though they share the same substrate. This result is significantly higher than that seen in Piezoelectric-OSFET arrays for tactile sensing in the literature. For wearable health monitoring applications, we have shown the ability to detect a resting heart rate of 55 bpm from the carotid artery. This study develops a promising scalable method for high-throughput fabrication of polymer-based piezoelectric sensors on a laboratory scale that can be selectively patterned with inkjet technology.

5:10 AM S.SM04.06.02
Rapid Prototyping of Microfluidic Devices With Versatile Geometries and Functionalizations by Aerosol-jet Printing Nordin Catic and Sohini Kar-Narayan; University of Cambridge, United Kingdom

Microfluidic devices can be used as powerful analytical tools for biology, ranging from drug discovery to medical diagnostics, requiring only small sample volumes for testing. Such devices enable the scaling down of reaction volumes so that a small amount of material is required and the time for testing is reduced. The ability to perform a suite of diagnostic tests on a single device, with minimal reagents, is a major goal of ‘lab-on-a-chip’ research. For more than 20 years, microfluidic technology has promised to deliver such devices and thereby revolutionize biological and chemical research. However, the impact of this technology has yet to be fully realized, with plenty of room for innovation[1]. Currently, the microfluidic channels in most devices play a passive role and are simply used to direct flow. The ability to “functionalize” the channels would impart greater use of these channels, by incorporating functional materials directly within the channels that can partake in, guide or facilitate the reactions taking place. Integrating functional materials could also serve to introduce new sensing functionalities within the channels themselves. At the same time, rapid prototyping of microfluidic devices is beneficial in a research environment, yet the high cost, slow turnaround and wasteful nature of the current techniques severely impede the development process. Finally, the lack of portability of the associated detection mechanisms, such as the complex optical microscopes typically employed, makes the ‘lab-on-a-chip’ aspect a moot point. The requirement of complex microscopes and equipment to drive and detect changes within microfluidic channels limits the range of applications of such devices.
Here, we demonstrate for the first time, the use of Aerosol Jet Printing (AJP) to produce bespoke molds for microfluidic devices, as well as functionalized microfluidic channels. We show that such an advanced microscale additive manufacturing method can be used to rapidly design cost-efficient and customized microfluidic devices, and add “functional” coatings while simultaneously embedding sensors and active elements on the same platform for electrical detection. Such functionalized microfluidic biosensors could become a transformative tool in biological and bio-medical research, with potential impact in areas such as drug screening, point-of-care diagnostics, and pharmacology. By using an AJP, these sensors can be localized to specific parts of the microfluidic device for constant monitoring and feedback using integrated electrical detection methods, without the need for complex equipment.

5:20 AM *S.SM04.06.03*  
Rehealable, Recyclable and Reconfigurable Electronics Based on Dynamic Covalent Thermoset Jianliang Xiao; University of Colorado, United States

Dynamic covalent thermosets show superior properties, including self-healability, recyclability, malleability/reprocessability, thanks to the molecular level bond exchange reactions. These properties promise bright future of dynamic covalent thermosets in broad applications. We here report our work on dynamic covalent thermoset-based electronic systems that are rehealable, recyclable and reconfigurable. A flexible multifunctional electronic device that integrates electrocardiograph (ECG), temperature, motion, and acoustic sensing capabilities was demonstrated. It was exhibited that the rehealed and recycled devices showed electronic performance comparable to the original ones. Bond exchange reactions in the polymer network effectively relaxes stresses induced by mechanical deformation, which made it possible to reconfigure the flexible device into different configurations that are suited for different applications. Such rehealable, recyclable and reconfigurable electronics provides an approach to address sustainability and environment issues associated with mass production of electronics. It can find broad applications in prosthetics, health care, and human-computer interface and other areas that are hard to be addressed by conventional approaches.

5:35 AM *S.SM04.06.04*  
3D Printing Electronics Directly on the Body Michael C. McAlpine; University of Minnesota, United States

The ability to directly print biomedical devices on the body could benefit patient monitoring, wound treatment, and even allow for the possibility of human augmentation. In reality, this concept requires the 3D printer to adapt to the various translations, rotations, and deformations of the biological surface. Conventional 3D printing technologies typically rely on open-loop, calibrate-then-print operation procedures. An alternative approach is adaptive 3D printing, which is a closed-loop method that combines real-time feedback control and direct ink writing of functional materials in order to fabricate devices on moving freeform surfaces. Here we demonstrate that the changes of states in the 3D printing workspace in terms of the geometries and motions of target surfaces can be perceived by an integrated robotic system aided by computer vision. This allow us to directly 3D print a wireless antenna based on a novel silver ink a free-moving human hand, to power a skin-mounted LED. Using this same approach, cell-laden hydrogels were also printed on live mice, creating a model for future studies of wound-healing diseases. Moreover, we developed an *in situ* 3D printing system that estimates the motion and deformation of the target surface to adapt the toolpath in real time. With this printing system, a hydrogel-based sensor was printed on a porcine lung under respiration-induced deformation. The sensor was compliant to the tissue surface and provided continuous spatial mapping of deformation via electrical impedance tomography. This adaptive 3D printing approach may enhance robot-assisted medical treatments with additive manufacturing capabilities, enabling advanced medical treatments, and autonomous and direct printing of wearable electronics and biological materials on and inside the human body.

5:50 AM *S.SM04.06.05*  
Flexible Self−Powered Systems Based on Functional Polymers Ruiyuan Liu1, Zhong Lin Wang2 and Takao Someya1,3; 1Center for Emergent Matter Science (CEMS), RIKEN, Japan; 2Georgia Institute of Technology, United States; 3The University of Tokyo, Japan

Growing demand in advanced portable and wearable electronics raises requirements for the composed materials to be stretchable, conducting or even healable, for which functional polymers are ideal choices. Flexible devices (triboelectric nanogenerators and solar cells) using organic materials for effectively energy harvesting will be firstly presented (1-3). An integration with flexible energy storage components is followed to enable a self−powered system which can simultaneously harvest solar/mechanical energy and store electricity (2-4). These work pave a new direction for functional polymers in the
field of energy harvesting, storage and mechanosensing for potential applications in areas such as soft robotics, biomedical
deVICES, and wearable electronics.

6:00 AM *S.SM04.06.07
Exploring Bioelectric Dynamics at the Soft-Hard Interfaces Bozhi Tian; University of Chicago, United States

Although there are numerous studies on either hard or soft materials, our understanding of the fundamentals at hard/soft
interfaces has been limited. As different types of energy (such as electrostatic, mechanical, thermal, and chemical energies)
display diverse scaling behaviors and can converge, an appropriate selection of the length scale is critical for promoting new
scientific discoveries across these interfaces. Our group integrates material science with biophysics to study several hard/soft
interfaces. We synthesize new materials and probe interfacial dynamics, with particular focus at the sub-micrometer and sub-
cellular length scales. In this talk, I will focus on the interfaces that enabled non-genetic, freestanding, and semiconductor-
based bioelectric modulation. I will also discuss some recent work that exploits the dynamic behaviors of granular materials
in polymeric matrices toward bioelectronic and robotic applications. I will end the talk by proposing several new scientific
and engineering approaches to improving our fundamental understanding of the (bio)chemical processes at soft/hard
interfaces and to exploring new applications of these interfacial (bio)chemical processes.

6:15 AM *S.SM04.06.08
Self-Powered Wearable and Implantable Electrical Stimulation Devices for Therapeutics Xudong Wang; University of Wisconsin--Madison, United States

Electrical stimulation (ES) is a widely used therapeutic treatment strategy. It showed significantly positive results in treating
a variety of diseases, biological disorders, and neurological problems. Today, the emergence of wearable devices is rapidly
reshaping the development of medical devices, pushing them from conventional bulky and rigid silicon electronics to flexible
and primarily polymer-based systems. Among many types of functions, nanogenerators are developed as a unique device for
converting biomechanical energy into electrical pulses. In addition to applying it directly as a power source, this pulsed
electricity can be applied directly as a ES signal for therapeutic treatment. In our recent research, we successfully
implemented such an electromechanical system for skin wound healing and vagus nerve stimulation for obesity control. An
electrical stimulation bandage was developed by integrating a flexible nanogenerator and a pair of dressing electrodes on a
flexible substrate. Rat studies demonstrated rapid closure of a full-thickness rectangular skin wound within 3 days as
compared to 12 days of usual contraction-based healing processes in rodents. From in vitro studies, the accelerated skin
wound healing was attributed to the electric field-facilitated fibroblast migration, proliferation and transdifferentiation. In
another work, an implanted vagus nerve stimulation system was developed. The device comprises a flexible and
biocompatible nanogenerator that is attached on the surface of stomach. It generates biphasic electric pulses in responsive to
the peristalsis of stomach. The electric signals generated by this device stimulates the vagal afferent fibers to reduce food
intake and achieve weight control. This strategy is successfully demonstrated on rat models. Within 100 days, the average
body weight is controlled at 350 g, 38% less than the control groups. Both results bring a new concept in electrical
therapeutic technology that is battery-free, self-activated and directly responsive to body activities.

Polymerized Liquid Metal Networks for Stretchable Electronics Carl Thrasher, Zachary Farrell, Nicholas J. Morris,
Room-temperature liquid metals, such as nontoxic gallium alloys, show enormous promise to revolutionize stretchable electronics for next-generation soft robotic, e-skin, and wearable technologies. Core–shell particles of liquid metal with various surface-bound ligands can be synthesized and polymerized together to create cross-linked particle networks comprising >99.9% liquid metal by weight. When stretched, particles within these polymerized liquid metal networks (Poly-LMNs) rupture and release their liquid metal payload, resulting in a rapid transformation from insulating to conducting behavior. These networks autonomously form hierarchical structures that mitigate the deleterious effects of strain on electronic performance and give rise to emergent properties. Notable characteristics include nearly constant resistances over large strains, electronic strain memory, and increasing volumetric conductivity with strain to over 20 000 S cm-1 at >700% elongation. Furthermore, these Poly-LMNs exhibit exceptional performance as stretchable heaters, retaining 96% of their areal power across relevant physiological strains. Remarkable electromechanical properties, responsive behaviors, and facile processing make Poly-LMNs ideal for stretchable power delivery, sensing, and circuitry.

5:10 AM *S.SM04.07.02
Liquid Metal Embedded Polymers for Soft-Matter Electronics, Actuation and Energy Harvesting Carmel Majidi; Carnegie Mellon University, United States

Soft polymers that are embedded with nano- and microscale droplets of liquid metal (LM) can be tailored to exhibit a broad range of electrical, thermal, mechanical, and dynamic shape morphing properties. In contrast to lithographically-fabricated soft microfluidic architectures, these LM-embedded soft polymer (LMSP) composites are statistically homogenous and exhibit effective medium properties at the mesoscale. Depending on the choice of polymer matrix, LMSPs can be engineered to achieve a wide variety of properties – from thermally conductive rubber for heat management and thermoelectric energy harvesting in wearable electronics to shape memory materials that dynamically respond to electrical stimulation. Eutectic Ga-In (EGaIn) and Ga-In-Sn (Galinstan) alloys are used as the liquid metal due to their high electrical conductivity, low viscosity, non-toxicity, and the self-passivating formation of an oxide skin (Ga2O3) that enables emulsification and wetting to non-metallic materials. Because they are liquid-phase at room temperature, these alloys have virtually no influence on the mechanics of the surrounding elastomer medium. This allows the resulting composite to exhibit a unique and extraordinary combination of features not seen in other heterogeneous material systems. In this talk, I will review recent experimental and theoretical studies of this unique class of soft material architectures, with specific emphasis on LM-filled liquid crystal elastomers and soft polymers for stretchable electronics and energy harvesting. I’ll also highlight several applications in which LMSPs can have a potentially transformative impact, especially in the domains of wearable computing, physical human-machine interaction, and bioinspired soft robotics.

5:25 AM S.SM04.07.03
Spray-coated Graphene Oxide-Vitamin C Mixtures for the Safe and Efficient Production of Reduced Graphene Oxide Biomolecular Sensors Brendan B. Murphy1,2; Nicholas Apollo1,1, Nicolette Driscoll1,1,2, Tessa Posey3, Nancy Rodriguez-Perez2, Quincy Hendricks1 and Flavia Vitale1,1,2; 1University of Pennsylvania, United States; 2Corporal Michael J. Crescenz Veterans Affairs Medical Center, United States; 3University of South Carolina, United States; 4Arizona State University, United States

Conductive carbon-based nanomaterials, such as graphene, carbon nanotubes (CNTs), and reduced graphene oxide (rGO), are flexible, corrosion-resistant, and exhibit high electrochemical capacitance, which are ideal properties for probing excitable neural tissue. The realization of a high-fidelity, multi-modal electrochemical biosensor, which is capable of simultaneously monitoring the electrical and chemical signaling between neurons in a single platform, has been a focus of much research over the past 15 years. To enable such a technology, rGO has been extensively explored, because it can be handled using scalable, solutions-processing techniques starting from aqueous dispersions of its precursor structure, graphene oxide (GO). The oxygen moieties of dried GO films must be reduced in order to restore the film conductivity and a number of methods have been developed to achieve this goal, both in bulk and on an individual film basis. Exposure to hydrazine in vapor form, as well as high temperature annealing, typically at temperatures exceeding 1000 °C, are two of the most common methods to form rGO dried films. However, these methods pose toxicity and safety concerns, and are not compatible with flexible polymeric substrates that typically compose many bioelectronic devices. To address these issues, we have developed a novel, safe, low-temperature, and scalable method of direct GO film reduction using L-ascorbic acid, or Vitamin C, as the reducing agent. Room temperature aqueous mixtures of GO and Vitamin C were loaded into a spray-coating apparatus and deposited onto pre-heated substrates. The influence of Vitamin C concentration and substrate heating time on film conductivity were studied. Using 50 mM Vitamin C and a holding time of 15 minutes at 150 °C, we achieved our lowest sheet resistance value of 354.70 ± 20.52 kΩ sq⁻¹. On average, rGO films were 2.20 ± 0.19 nm in thickness, and thus had conductivities as high as...
Using a rapid prototyping method, 3 mm diameter disc-shaped electrodes were made on glass substrates encapsulated in polyimide (PI). These PI electrodes allowed for direct comparison with size-matched glassy carbon (GC) and gold (Au) working electrodes \textit{in vitro}. Electrochemical capacitances as high as 3.05 mF cm\(^{-2}\) were achieved by spray-coating GO-Vitamin C onto thin film Au, which is an order of magnitude greater than the capacitances of either bare GC (0.29 mF cm\(^{-2}\)) or bare Au (0.11 mF cm\(^{-2}\)). Electrochemical impedance was also observed to decrease as the volume of spray-coated rGO increased, particularly in the frequency range from 0.1–100 Hz. The 10 Hz impedance of rGO electrodes was as low as 0.23 ± 0.15 kΩ, for example, compared to bare Au, which had impedance of 2.78 kΩ at the same frequency. At 1 kHz, the impedances of rGO/Au and Au were 0.13 ± 0.06 kΩ and 0.15 kΩ, respectively. To demonstrate the feasibility of using GO-Vitamin mixtures to realize high-fidelity electrochemical biosensors, the electrocatalytic activity of a handful of biologically relevant molecules was studied, including the direct voltammetric detection of dopamine, ascorbic acid, uric acid, and serotonin. Our novel approach to the production of rGO electrodes offers a safer alternative to chemical reduction using hydrazine or other strong acids, as well as a scalable method which is fully compatible with the soft, polymeric substrates used in state-of-the-art bioelectronic interfaces. Thus, this method enables the development of highly sensitive, biocompatible, and flexible conductive films for applications in fields of biosensors and bioelectronics.

5:35 AM *S.SM04.07.04
Flexible microLED for Bio-Integrated Electronics Keon Jae Lee; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

With the emergence of the internet of things (IoT) era, visual IoT platforms have attracted significant interest, which can offer sensing, collecting, and processing of optical information in hyperconnected society. Flexible displays are a potential candidate for bilateral visual communication, as they can be easily affixed anywhere, such as on the surfaces of human skin, clothes, automobiles and buildings. III-V Inorganic LEDs have superior characteristics, such as long-term stability, high efficiency, and strong brightness compared to OLED. However, due to the brittle property of inorganic materials, III-V LED limits its applications for the flexible electronics. This seminar introduces the flexible vertical GaAs/GaN microLED on plastic substrates using anisotropic conductive film (ACF), resulting high optical power density. The superb properties of the flexible inorganic LED enable the dramatic extension of flexible displays toward not only wearable devices of light source but also full color flexible microLED displays for consumer TV.

MicroLED stimulation of specific neural populations of the brain is one of the facile and reliable methods used in neuroscience for deduction of functional movement, complex behavior and even long-range connectivity. Recent advanced biomedical tools now employ flexible optoelectronic devices combined with optogenetic mouse models to activate small functional regions using blue-light driven channelrhodopsin. Here we introduce flexible vertical light-emitting diodes (VLEDs) for 2D perturbation of specific functional areas of mouse cortex, capable of stimulating motor neurons deep below layer III from the brain surface. Selective operation of pulsed red light from f-VLEDs induces mouse body movements and synchronized electromyogram (EMG) signals. These results show that the III-V based flexible LED can be used as the future flexible implantable biomedical applications such as skin research and phototherapeutic tool.

Recent advances in new materials, electronics, and assembly techniques have allowed optoelectronic systems to interface with biology and contribute significantly to the progress in basic biological research as well as clinical medicine. In this talk, I will introduce a novel class of flexible, multimodal optoelectronic systems that combines high-performance nanoscale electrodes with microscale optical components for simultaneous electrophysiological recording under optogenetic modulation. We envision this unique technology will open up new windows to understanding important biological processes by enabling mapping the dynamics of perturbed cell populations and correlating cellular responses to behavior.

Capillary-Assisted Electrochemical Delamination for Wafer-Scale Fabrication of Ultrathin Flexible Electronics and Degradable Electronics

Youfan Hu, Heng Zhang and Li Xiang; Peking University, China

Constructing electronic systems on ultrathin polymer films is superior to render the system more flexible, conformable, and imperceptible. These characteristics are particularly beneficial for epidermal and implantable electronics. Generally, the system is processed with rigid supporting substrates during fabrication, followed by delamination and transfer to the targeted working areas. The challenge associated with an efficient and innocuous delamination operation is one of the major hurdles toward high-performance ultrathin flexible electronics at large scale. Here, a facile, rapid, damage-free approach is reported for detachment of wafer-scale ultrathin electronic foils from Si wafers by capillary-assisted electrochemical delamination (CAED) with a 100% success rate. Anodic etching and capillary action drive an electrolyte solution to penetrate and split the polymer/Si interface, leading to complete peel-off of the electronic foil. Such a process incurs neither mechanical damage nor chemical contamination; therefore, the delaminated electronic systems remain intact. Via this approach, carbon nanotube (CNT)-based CMOS technology has been realized on a 2.5 μm-thick plastic foil with high performance. The performances of both the p- and n-type CNT thin film transistors (TFTs) are excellent and symmetric on plastic foil with a low operation voltage of 2 V: width-normalized transconductances (gm/W) as high as 4.69 μS/μm and 5.45 μS/μm, width-normalized on-state currents reaching 5.85 μA/μm and 6.05 μA/μm, and mobilities up to 80.26 cm²V⁻¹s⁻¹ and 97.09 cm²V⁻¹s⁻¹, respectively, together with a current on/off ratio of approximately 10⁵. Based on CAED, we also developed a wafer-scale manufacturing process for degradable electronic platforms with an average yield of the transferred TFTs up to 96.6%. Great uniformity was achieved in the transferred TFTs and ICs on each chip and among different chips. Finally, real-time sunlight exposure and temperature monitoring and degradation of the system under artificial rain were successfully demonstrated in a simulated ecosystem outdoors with distributed sensor nodes consisting of TFTs, UV and temperature sensors.

Scanning Nanowire Probe Interferometer for Scalable Humidity Mapping

Namho Kim¹, Junho Lee¹, Moon-Jung Yong¹, Un Yang¹, Ji Tae Kim², Jonghwan Kim¹-¹, Byung Mook Weon¹, Chong Cook Kim¹ and Jung Ho Je¹; ¹Pohang University of Science and Technology, Korea (the Republic of); ²The University of Hong Kong, Hong Kong; ³Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of)

Quantifying humidity has long been an unavoidable task in science, industry, and society. Recent developments of
nanoscience and technology that deal with ultrasmall droplets have aroused interest in microscopic moisture. Utilization of nanomaterials has been emerging as a promising strategy to miniaturize hygrometers for high-sensitive, ultrasmall-area sensing. However, a lack of high-precision, on-demand position control of sensing nanomaterials makes it difficult to explore spatial distribution of humidity at the micro- and nanoscale. Here, we develop a scanning probe hygrometry (SPH) that enables not only micro/nano-resolution but also scalable spatial mapping of humidity distribution. The SPH is realized with an unprecedented scanning nanowire probe interferometer (NPI) that is produced by direct 3D nanoprinting of a moisture-sensitive polymer on a tapered optical fiber. We observe the interferometric response of the NPI probe in ultrasmall-areas quantitatively depends on humidity, arising from its refractive index change and volumetric swelling. By scanning the NPI probe and reading out the interferometric signals, we demonstrate not only multiscale spatial mapping of humidity distribution with versatile scanning steps from ~ 10² nm to a few mm, but also local humidity in very small spaces. We expect our NPI to provide a new nanoscale metrology that could answer fundamental questions about evaporation-related science and engineering.

5:10 AM S.SM04.08.07
Non-Invasive Neuromodulation Using Ultrasound Aditya Vasan and James Friend; University of California, San Diego, United States

The discovery of light sensitive proteins led to the development of optogenetics and allowed the precise manipulation of neuronal and non-neuronal cells[1, 2]. This technique uses particular wavelengths of light to precisely manipulate cells that have been engineered to express this class of proteins. It has enabled the study of information processing in the brain and recent studies are looking into clinical translational applications of the technique[3]. Despite the advantages offered by optogenetics, it has the drawback of being invasive as light does not penetrate skin past a few millimeters. It is not possible to target deep tissue within the body using this technique and this limits the application in the context of diseases such as Parkinson's[5] or heart malfunction[4]. We are developing devices that can non-invasively manipulate cells using low-intensity ultrasound, in a technique termed "sonogenetics". This technique uses a combination of engineering cells to be more sensitive to a mechanical stimulus as well as developing ultrasound transducers capable of stimulating these cells. We demonstrate the development of miniature transducers made from non-hysteretic single crystal lithium niobate to be used for affecting behavior of freely moving, awake mice. In addition, we offer mathematical insights to the mechanism of action of ultrasound on neurons. Our analysis of membrane deflection enables us to predict cellular activity based on the applied ultrasound stimulus. By extension, we use this analytical framework to inform the development of transducers and stimulation parameters for achieving non-invasive stimulation of cells.

Chemical vapor deposited (CVD) graphene is considered a promising material for biomedical applications, namely in vitro and in vivo sensors. When the graphene sensor surface comes in contact with an analyte solution, electrochemical effects caused by a liquid aqueous environment start to take place and interfere with the material stability and detection of an analyte. Here we report our observations about two instances of such reactions. In the first system, fracturing of the graphene layer during anodization is recorded using a Quartz Crystal Microbalance (QCM) method combined with a 3-electrode electrochemical configuration. Positive biasing in a region of potentials that enable an oxygen oxidation reaction caused a layer fracturing and loss of the graphene film integrity. In the second system, origins of gate/leakage currents on an electrolyte-gated Graphene Field Effect Transistors (GFETs) are investigated. A potential-dependent reaction of oxygen is found to be responsible for these currents. Moreover, a surface activation towards this process is observed. As revealed by a complementary method, cyclic voltammetry with a redox probe Fe(MeOH)2+, more defects appear on the graphene transistor surface when extensive leakage currents are present during the GFET operation mode.

Impact of Gate Structure on Printed Electronic Biosensors for Detection in Whole Blood Nicholas Williams, Joseph B. Andrews, Faris Albarghouthi, Steven G. Noyce, James L. Doherty, Shiheng Lu, Daniel Y. Joh, Ashutosh Chilkoti and Aaron D. Franklin; Duke University, United States

As more hospitals close in rural America, healthcare in these areas has been pushed towards community- and home-care situations. To support this shifting market, new point-of-care (POC) diagnostic techniques are needed to fill the void left by the healthcare industry. Thin-film transistor (TFT) -based electronic biosensors are ideally suited for POC applications due to their ability for miniaturization, low operating voltage, and high sensitivity. Yet, one significant hurdle in developing TFT biosensors is that the Debye length in complex fluids, such as serum or whole blood, is sufficiently small that electrical interactions between the analyte and the TFT are completely screened, rendering the device insensitive to changes in analyte concentration. Combining the TFT design with a non-fouling polymer brush layer, poly(oligo(ethylene glycol) methyl ether methacrylate) (POEGMA), has the potential to both extend the Debye length to support the measurement of analyte binding events and minimize nonspecific binding that could prove detrimental to the small electrical perturbations related to sensing low concentration analytes. In this work, we demonstrate the impact of the field-effect gating structure on the operation of a printed carbon nanotube (CNT) -TFT biosensing platform, harnessing the high sensitivity of the CNT thin film and the Debye length extension (in addition to non-fouling properties) of the POEGMA layer. As a demonstration, we print down capture and detection antibodies for the protein leptin on the POEGMA-coated CNT-TFT and measure leptin concentration in both phosphate buffered saline (PBS) and whole human blood. We demonstrate that, unlike optical techniques, no cumbersome wash procedure is required to enable concentration-dependent measurements. Furthermore, a comparison is made between substrate-gated and solution-gated approaches with the CNT-TFT, revealing the role of solution charge and leakage currents in the successful operation of these biosensors. Also explored is the impact of the solution gate stack for the CNT-TFT, where inclusion of a passivating buffer layer of Al2O3 over the entire device structure enhances yield without significantly compromising sensitivity and the addition of a secondary passivation from SU8 directly over the contacts increases measurement stability over longer duration tests. These results mark key progress towards realizing a printed CNT-TFT biosensing platform that can open the way for low-cost, biomedical sensors – a paradigm shift for POC electronic diagnostic systems.

S.SM04.09.06
Proton Conductivity Properties of Electrospun Chitosan Nanofibers Woo-Kyung Lee1, Jeremy J. Pietron2, David Kidwell1, Jeremy Robinson1, Christopher McGann1 and Shawn Mulvaney1; 1Naval Research Lab, United States; 2Lawrence Livermore National Laboratory, United States

A major challenge of the 21st century will be to establish meaningful two-way communication between biology and electronics. The study of protonics, devices that mimic electronics but pass protons instead of electrons, seeks to bridge this gap. Protonic conductive materials (PCMs) are essential elements of these devices and we have demonstrated significant improvement in conductivity for chitosan PCMs when deposited as electrospun nanofibers. The observed improvements stem from both enhanced molecular alignment and from chemical doping due to the electrospinning carrier fluid, trifluoroacetic acid (TFA). We deposited electrospun chitosan nanofibers over palladium protodes and then used the helium ion microscope to isolate single nanofibers for detailed study. We observed that single chitosan nanofibers are strongly doped by TFA with x-ray photoelectron spectroscopy demonstrating extensively protonated nitrogen functionality. With the isolated, single chitosan nanofibers we observed that water uptake, fiber/electrode contact area, and doping concentration are critical parameters of protonic device performance and lead to increased conductivity (i.e. low resistivity). The average resistivity of...
single chitosan nanofibers is $6.2 \times 10^4 \, \Omega \cdot \text{cm}$, approximately two orders of magnitude lower than the resistivity of cast chitosan PCMs (cast from acetic acid solutions not TFA). We have observed excellent agreement between theoretical models and experiment results that explore each of the contributions to the improved conductivity. Finally, the fabrication and measurement of ionic field-effect transistor of single chitosan fiber using conductive atomic force microscope will be discussed.\(^1\)

S.SM04.09.07

Mimicking Signal Transmission in Single Neuron by Organic Electrochemical Transistors Kwok Ki Chik and Paddy K. L. Chan; The University of Hong Kong, Hong Kong

Neuromorphic organic electrochemical transistors (OECTs) have been reported to demonstrate different synaptic plasticity features including short and long-term plasticity (STP & LTP) and spike-timing-dependent plasticity (STDP), which allows us to mimic synaptic transmission thus construct the neuromorphic circuits. Apart from the inherent advantages of neuromorphic circuits like low-power operations (~nW-pW) and learning capability, the operating mechanism of OECT has a high resemblance with the actual neurons: the movement of ions, which allows OECT to be a competent candidate for developing neuromorphic device. However, in order to build a comprehensive neuromorphic device, not only the synaptic transmissions, but also the signal propagations within single neuron should also be taken into consideration. In this study, a device mimicking signal transmission in single neuron based on a linear organic electrochemical transistors array featuring the regeneration of action potential at Nodes of Ranvier has been constructed. By utilizing the organic electrochemical transistors based on conducting polymer poly(3,4-ethylenedioxythiophene) doped with poly(styrene sulfonate) (PEDOT:PSS), together with UV-cured poly(2-hydroxyethyl methacrylate) (PHEMA) hydrogel and PVC based ion-selective membrane (ISM), we attempt to fabricate a neuromorphic transistors device in mimicking the propagation of neuronal signals from dendrites to axon. The regeneration of action potentials at the Nodes of Ranvier is achieved by using the ion-sensing capability of OECT and the ion-selectivity of the ISM. In our devices, voltage as low as 0.2 V is enough for the operation, comparable with the ~0.1V of an actual action potential. This device can be incorporated with existing neuromorphic circuits and possibly bridges the future human–machine interfaces between biomimicking organic electronics and authentic neuronal systems.

S.SM04.09.09

Needle-Shaped Micro-Electrodes for Tissue Structural Differentiation by Bioimpedance Spectroscopy Timothy K. Leung and Paddy K. L. Chan; The University of Hong Kong, Hong Kong

Biopsy is a well-known minimal invasive technique to extract tissues from patients through a needle followed by performing histology to view cellular structures under the microscope. Biopsy studies of cancerous tissue is very common in surgical practice. To identify the cancer tissue, pathologists will usually examine the tissue features such as cell pattern, cytological atypia, mitotic activity, size and shape of cell nuclear. These structural features are highly correlated to the conductivity of the tissues which are composed of tightly packed cells. The cell walls are made of lipid which is a good insulator. When a D.C. current passes through the tissue, the cell wall stores the charges and prevent the current from passing through the cell. However, at high frequency, current can pass through the cell wall because the cell wall behaves as a capacitor. This difference of frequency response is often a characteristic for different tissue with different fluid composition. Currently, biopsy is still at the level for qualitative analysis and the measurements take a relatively long time around 20 minutes. There is a strong demand to develop a fast, localized biopsy tools which can provide quantitative characterizations of the tissue structures. In the current work, we will demonstrate a micro-scaled impedance sensing device developed on the tip of a glass capillary tube of 1mm diameter. Even the size of the electrodes is limited, we employed the organic semiconductor material, PEDOT:PSS (poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate)), to reduce interface impedance of microelectrodes. By adding this PEDOT:PSS layer on the bare gold electrode, the interface becomes highly capacitive and possess a lower impedance. It is important to point that many of the reported impedance measurement tools uses electrode with large surface area and therefore very inefficient in performing localized measurement. As the proposed needle diameter is only 1mm, the reduction of the electrode surface area will suffer from the effect of mass diffusion and data in the low frequency spectrum will be masked. Our approach to modify the impedance allows us to reveal the impedance response of tissues at low frequency range for more precise equivalent circuit model fitting.
Investigation of Structure and Composition of Laser Induced Graphene from Polymer Precursors for Bioelectronics Applications

Hana Hampel¹, Maria Jernej¹, Alexander Dallinger¹, Harald Schröttner², and Francesco Greco¹; ¹Graz University of Technology, Austria; ²Graz Centre for Electron Microscopy, Austria

Laser Induced Graphene (LIG) was first described in 2014 and ever since it has been a far-reaching field of research. Research has focused on fundamental understanding of LIG structure and properties, as well as on technological applications in flexible/stretchable electronics, energy, among others[1-2]. LIG is a porous and conductive carbon material produced by laser-induced pyrolysis of various polymer precursors, including biologically derived ones (e.g. wood, paper, silk)[3]. An infrared laser, as typically used in commercial CO2 laser cutter for manufacturing, is used for this purpose. This process allows for fast scribing of circuits onto insulating substrates in ambient condition.

We investigated the LIG formation process on polyimide to get a better understanding of the boundary conditions for the formation of LIG and the tuning of its morphology and properties (especially conductivity). LIG conductors are prepared by varying the various process parameters affecting laser fluence (i.e. energy per scribed area).

In this way, either a flat porous LIG or a dense forest of long (100-200 µm) carbon fibres bundles (with single fibres having a diameter of around 50-100 nm) can be obtained.

Composition, morphology and structure are characterized by optical, scanning and transmission electron microscopy, EDX, and correlative Raman-SEM spectroscopy. A variation of graphene content along the fibre growth direction was found.

Variations in structure and morphology were correlated with conductivity.

Due to the huge potential of LIG in stretchable and wearable bioelectronics, latest developments of this research include investigation of biologically derived precursors.

Fabrication and Integration of a Novel Coupled Lead Free Perovskite Oxide and Halide Active Multi-Morph—Towards Development of a Flexible Wearable and Continuous Non-Invasive Glucose Monitoring System

Jodi Bishop¹, Faheem Shaikh¹, Noah Haworth¹, Riley Wells¹, Soumyasanta Laha¹, Saquib Ahmed² and Sankha Banerjee¹; ¹California State University, Fresno, United States; ²Buffalo State College, United States

A novel device architecture using a coupled media of an electro-active perovskite oxide (PO) and lead free photo active perovskite halide (PH) layer will be used to enhance signal strength through increased electron mobility, and the photoactive nature of the multimorph. Although, the optical and PA approaches have been studied individually in the past, there were no efforts to integrate the two approaches using perovskite layers and a flexible substrate to improve the wearable form factor, reliability and accuracy of the measurements. So far, all these studies conducted with PA system for non-invasive glucose monitoring used class-IV lasers and non-continuous and mostly in-vitro. This unique approach will integrate electro-active PO, and photoactive PH layers for signal conversion from acoustic and photoluminescence to electrical signals respectively.

The following work involves the development of an integrated PO (BaTiO3-PMMA-Graphene) - PH (Tin Iodide active layer) multimorph with a P3HT hole transport layer as the coupled media and development of the device architecture for the wearable device.

S.SM04.09.13
Stretchable Wideband Dipole Antennas and Rectennas for Wireless Communication and RF Energy Harvesting

Jia Zhu¹ and Chaoyun Song²; ¹The Pennsylvania State University, United States; ²University of Liverpool, United Kingdom

Bio-integrated electronic devices can pliably conform on the textured skin surface to continuously monitor the physiologically relevant parameters or biomarkers, with a huge impact on human health from preventative monitoring and early diagnostic confirmation to non-invasive and convenient therapeutic options. The ultimate application of this class of emerging electronics hinges on the indispensable modules of stretchable wireless transmission and power supplies. While near field communication (NFC) allows for wireless powering and communication with a working distance of ~ 3 cm, radio frequency (RF) antennas enable wireless transmission of data and energy in the far-field. Compared to the approaches that exploit stretchable conducting materials such as liquid metal or elastomers with conductive fillers, designing conventional metals in a serpentine or meshed geometry is still of high interest because of their high radiation efficiency. Although this structural design concept has resulted in various stretchable dipole and patch antennas, the narrow bandwidth still limits their applications in wireless communication and energy harvesting because of the frequency detuning from mechanical
While the efforts on wideband antennas could possibly overcome this challenge, the deformation-dependent radiation properties are yet to fully investigated. Here we demonstrate a stretchable wideband dipole antenna that consists of serpentine units for both main and parasitic arms created by exploiting the laser-induced graphene (LIG) pattern and maskless metal coating. Additionally, combining stretchable dipole antenna with a high-efficiency impedance matching network and rectifying circuit leads to a stretchable rectifying antenna (i.e., stretchable rectenna) that can continuously harvest electromagnetic radiation energies from various widely available RF sources (e.g., WI-FI, 4G, and upcoming 5G). As an added component into the clean energy portfolio for future energy supply, the ambient RF energy-harvesting solution could also contribute to integrated energy systems and enable self-powered systems and remote monitoring of the environment.

Characterization of Glassy Carbon and Graphene Based Metamaterial as Electrocorticography Electrodes
Transferred on Flexible Substrate

Graphene is the gold-standard for electrical conductivity along with its high mechanical strength and excellent thermal conductivity. On the other hand, GC has exceptional chemical inertness, good electrical properties, high electrochemically stability (gold-standard for electrochemistry), purely capacitive charge injection, and fast surface electrokinetics coupled with lithography patterning ability. Therefore, to leverage the unique strength of these ‘gold-standard’ materials in electrode technology, we introduce a new material system that brings the best qualities of these materials in a single format joined through strong covalent bonds. In this preliminary study, we investigate fabrication methodology, transfer on flexible substrate, bonding between the two allotropes of carbon through FTIR (Fourier transform Infrared) spectroscopy, surface morphology through SEM (Scanning electron microscopy) and topography by AFM (atomic force microscopy), and application of metamaterial based microelectrodes for neural signal recording i.e. electrocorticography (ECoG).

Lactic Acid Neurotransmitter Detection using Functionalized Glassy Carbon Microelectrodes

Neurotransmitters are often referred to as the body’s chemical messengers. They are the molecules used by the nervous system to transmit messages between neurons. Dopamine and serotonin are electroactive neurotransmitters and can be detected though conventional neural probes. However, lactic acid is a non-electroactive molecule that cannot be detected by these conventional probes. Lactic acid can be found in the brain as a byproduct of energy production and a buildup of lactic acid leads to lactic acidosis. Lactic acidosis can hamper normal mitochondrial functions and has been linked to seizures and can be caused by ischemia or hypoxia. To detect lactic acid our group at SDSU are functionalizing glassy carbon electrodes by immobilizing an enzyme to catalyze lactic acid into a molecule that is electroactive. By immobilizing lactate oxidase into a chitosan matrix, we aim to cause a reaction that will create hydrogen peroxide which is an electroactive molecule with a redox potential of 1.2. In addition to functionalizing glassy carbon with lactate oxidase, we aim to immobilize lactate dehydrogenase which will catalyze lactic acid into NADH and pyruvate and compare both enzyme detection efficacies. We will use electrochemical methods such as fast scan cyclic voltammetry (FSCV), FTIR, and potentiostat reading to characterize, understand the chemical reactions occurring, and qualify these functionalized glassy carbon electrodes. Preliminary characterization results show a slight increase in impedance values once the immobilization matrix has been applied, but despite the increase in impedance the limit of detection has not decreased. Preliminary looks at FTIR data show an increase in functional groups for chitosan on glassy carbon compared to bare glassy carbon showing the chance of adherence.

New Platform for Detecting Non-Electroactive Neurotransmitters – Case of Glutamate

Glassy Carbon (GC) microelectrodes have shown to be a promising material in Neuroscience, specifically electrochemistry with a capability of detecting electroactive and non-electroactive species such as Glutamate. Here we demonstrate immobilization of glutamate oxidase on a probe with a four-electrode array and subsequently using fast scan cyclic voltammetry (FSCV) where we pass a current through each microelectrode to detect the presence of neurotransmitters. Electroactive species such as Dopamine and Serotonin oxidize when they come in contact with the electroactive surface. The detection of neurotransmitters will happen at specific voltages in-vitro. Here, we focus on some recent strategies for Glutamate probes immobilization on the surface of electrochemical transducer such as adsorption,
covalent bonding and Glutaraldehyde and GluOx interaction on the electrode surface for specific interaction with its complementary Glutamate target. Using Glutaraldehyde, BSA and Glutamate oxidase we were able to detect as an electrochemical reduction of O2 to H2O2. The immobilization matrix of GluOx on the GC electrode acts as a barrier that allows the electrode to give supporting electrons.

By functionalizing bare glassy carbon electrodes we have shown detection of Glutamate, non-electrode molecule. Through the chemical reaction with an enzyme happening at the surface of the electrode and cyclic voltammetry we were able to show the chemical reduction of non-electroactive of molecules.

Absorption of the Solar Radiation with Arrays of Subwavelength Nonimaging Light Concentrators Ashish Prajapati; Ben Gurion University of the Negev, Israel

Light trapping and the broadband absorption of the solar radiation is of interest to various solar energy harvesting applications. In the current work, we report a new paradigm for light trapping, that is light trapping based on arrays of subwavelength nonimaging light concentrators (NLCs). We numerically show that silicon NLC arrays provide >75% broadband absorption enhancement of the solar radiation compared with that of optimized nanopillar arrays. The paper focuses on free-floating arrays of subwavelength compound parabolic concentrators (henceforth CPC arrays) as a case study. The calculations reveal that CPC arrays function as anti-transmission layers as only few photons transverse the CPC arrays which is in contrast to nanopillar arrays that function as anti-reflection layers. We show that the absorption enhancement in CPC arrays is due to efficient occupation of Mie modes which is motivated by the unique CPC geometry, and we demonstrate light trapping at the Yablonovitch limit. Finally, we examine the performance of a photovoltaic cell based on CPC arrays with respect to base doping levels and surface recombination. We show that the short-circuit current density of the CPC-based cell is >75% higher than the short-circuit current density of a photovoltaic cell based on optimized nanopillar arrays. We believe that light trapping based on NLC arrays pave the way to various applications such as ultra-thin photovoltaic cells.

Damage of CVD Graphene Layers in Contact with Electrolyte Solutions by Dissolved Oxygen Anastasia Svetlova1,2, Guillermo Beltramo1, Dirk Mayer1, Andreas Offenhäusser1 and Dmitry Kireev3; 1Forschungszentrum Jülich GmbH, Germany; 2RWTH Aachen University, Germany; 3The University of Texas at Austin, United States

Chemical vapor deposited (CVD) graphene is considered a promising material for biomedical applications, namely in vitro and in vivo sensors. When the graphene sensor surface comes in contact with an analyte solution, electrochemical effects caused by a liquid aqueous environment start to take place and interfere with the material stability and detection of an analyte. Here we report our observations about two instances of such reactions. In the first system, fracturing of the graphene layer during anodization is recorded using a Quartz Crystal Microbalance (QCM) method combined with a 3-electrode electrochemical configuration. Positive biasing in a region of potentials that enable an oxygen oxidation reaction caused a layer fracturing and loss of the graphene film integrity. In the second system, origins of gate/leakage currents on an electrolyte-gated Graphene Field Effect Transistors (GFETs) are investigated. A potential-dependent reaction of oxygen is found to be responsible for these currents. Moreover, a surface activation towards this process is observed. As revealed by a complementary method, cyclic voltammetry with a redox probe Fe(III(MeOH)), more defects appear on the graphene transistor surface when extensive leakage currents are present during the GFET operation mode.

S.SM04.09.05
Impact of Gate Structure on Printed Electronic Biosensors for Detection in Whole Blood Nicholas Williams, Joseph B. Andrews, Faris Albarghouthi, Steven G. Noyce, James L. Doherty, Shiheng Lu, Daniel Y. Joh, Ashutosh Chilkoti and Aaron D. Franklin; Duke University, United States
As more hospitals close in rural America, healthcare in these areas has been pushed towards community- and home-care situations. To support this shifting market, new point-of-care (POC) diagnostic techniques are needed to fill the void left by the healthcare industry. Thin-film transistor (TFT)-based electronic biosensors are ideally suited for POC applications due to their ability for miniaturization, low operating voltage, and high sensitivity. Yet, one significant hurdle in developing TFT biosensors is that the Debye length in complex fluids, such as serum or whole blood, is sufficiently small that electrical interactions between the analyte and the TFT are completely screened, rendering the device insensitive to changes in analyte concentration. Combining the TFT design with a non-fouling polymer brush layer, poly(oligo(ethylene glycol) methyl ether methacrylate) (POEGMA), has the potential to both extend the Debye length to support the measurement of analyte binding events and minimize nonspecific binding that could prove detrimental to the small electrical perturbations related to sensing low concentration analytes. In this work, we demonstrate the impact of the field-effect gating structure on the operation of a printed carbon nanotube (CNT)-TFT biosensing platform, harnessing the high sensitivity of the CNT thin film and the Debye length extension (in addition to non-fouling properties) of the POEGMA layer. As a demonstration, we print down capture and detection antibodies for the protein leptin on the POEGMA-coated CNT-TFT and measure leptin concentration in both phosphate buffered saline (PBS) and whole human blood. We demonstrate that, unlike optical techniques, no cumbersome wash procedure is required to enable concentration-dependent measurements. Furthermore, a comparison is made between substrate-gated and solution-gated approaches with the CNT-TFT, revealing the role of solution charge and leakage currents in the successful operation of these biosensors. Also explored is the impact of the solution gate stack for the CNT-TFT, where inclusion of a passivating buffer layer of Al2O3 over the entire device structure enhances yield without significantly compromising sensitivity and the addition of a secondary passivation from SU8 directly over the contacts increases measurement stability over longer duration tests. These results mark key progress towards realizing a printed CNT-TFT biosensing platform that can open the way for low-cost, biomedical sensors – a paradigm shift for POC electronic diagnostic systems.

Proton Conductivity Properties of Electrospun Chitosan Nanofibers
Woo-Kyung Lee, Jeremy J. Pietron, David Kidwell, Jeremy Robinson, Christopher McGann and Shawn Mulvaney; 1Naval Research Lab, United States; 2Lawrence Livermore National Laboratory, United States

A major challenge of the 21st century will be to establish meaningful two-way communication between biology and electronics. The study of protonics, devices that mimic electronics but pass protons instead of electrons, seeks to bridge this gap. Protonic conductive materials (PCMs) are essential elements of these devices and we have demonstrated significant improvement in conductivity for chitosan PCMs when deposited as electrospun nanofibers. The observed improvements stem from both enhanced molecular alignment and from chemical doping due to the electrospinning carrier fluid, trifluoroacetic acid (TFA). We deposited electrospun chitosan nanofibers over palladium protodes and then used the helium ion microscope to isolate single nanofibers for detailed study. We observed that single chitosan nanofibers are strongly doped by TFA with x-ray photoelectron spectroscopy demonstrating extensively protonated nitrogen functionality. With the isolated, single chitosan nanofibers we observed that water uptake, fiber/electrode contact area, and doping concentration are critical parameters of protonic device performance and lead to increased conductivity (i.e. low resistivity). The average resistivity of single chitosan nanofibers is 6.2×10⁴ Ω⋅cm, approximately two orders of magnitude lower than the resistivity of cast chitosan PCMs (cast from acetic acid solutions not TFA). We have observed excellent agreement between theoretical models and experiment results that explore each of the contributions to the improved conductivity. Finally, the fabrication and measurement of ionic field-effect transistor of single chitosan fiber using conductive atomic force microscope will be discussed.¹

S.SM04.09.07
Mimicking Signal Transmission in Single Neuron by Organic Electrochemical Transistors
Kwok Ki Chik and Paddy K. L. Chan, The University of Hong Kong, Hong Kong

Neuromorphic organic electrochemical transistors (OECTs) have been reported to demonstrate different synaptic plasticity features including short and long-term plasticity (STP & LTP) and spike-timing-dependent plasticity (STDP), which allows us to mimic synaptic transmission thus construct the neuromorphic circuits. Apart from the inherent advantages of neuromorphic circuits like low-power operations (~nW-pW) and learning capability, the operating mechanism of OECT has a high resemblance with the actual neurons: the movement of ions, which allows OECT to be a competent candidate for
developing neuromorphic device. However, in order to build a comprehensive neuromorphic device, not only the synaptic transmissions, but also the signal propagations within single neuron should also be taken into consideration. In this study, a device mimicking signal transmission in single neuron based on a linear organic electrochemical transistors array featuring the regeneration of action potential at Nodes of Ranvier has been constructed. By utilizing the organic electrochemical transistors based on conducting polymer poly(3,4-ethylenedioxythiophene) doped with poly(styrene sulfonate) (PEDOT:PSS), together with UV-cured poly(2-hydroxyethyl methacrylate) (PHEMA) hydrogel and PVC based ion-selective membrane (ISM), we attempt to fabricate a neuromorphic transistors device in mimicking the propagation of neuronal signals from dendrites to axon. The regeneration of action potentials at the Nodes of Ranvier is achieved by using the ion-sensing capability of OECT and the ion-selectivity of the ISM. In our devices, voltage as low as 0.2 V is enough for the operation, comparable with the ~0.1V of an actual action potential. This device can be incorporated with existing neuromorphic circuits and possibly bridges the future human–machine interfaces between biomimicking organic electronics and authentic neuronal systems.

S.SM04.09.09
Needle-Shaped Micro-Electrodes for Tissue Structural Differentiation by Bioimpedance Spectroscopy Timothy K. Leung and Paddy K. L. Chan; The University of Hong Kong, Hong Kong

Biopsy is a well-known minimal invasive technique to extract tissues from patients through a needle followed by performing histology to view cellular structures under the microscope. Biopsy studies of cancerous tissue is very common in surgical practice. To identify the cancer tissue, pathologists will usually examine the tissue features such as cell pattern, cytological atypia, mitotic activity, size and shape of cell nuclear. These structural features are highly correlated to the conductivity of the tissues which are composed of tightly packed cells. The cell walls are made of lipid which is a good insulator. When a D.C. current passes through the tissue, the cell wall stores the charges and prevent the current from passing through the cell. However, at high frequency, current can pass through the cell wall because the cell wall behaves as a capacitor. This difference of frequency response is often a characteristic for different tissue with different fluid composition. Currently, biopsy is still at the level for qualitative analysis and the measurements take a relatively long time around 20 minutes. There is a strong demand to develop a fast, localized biopsy tools which can provide quantitative characterizations of the tissue structures. In the current work, we will demonstrate a micro-scaled impedance sensing device developed on the tip of a glass capillary tube of 1mm diameter. Even the size of the electrodes is limited, we employed the organic semiconductor material, PEDOT:PSS (poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate)), to reduce interface impedance of microelectrodes. By adding this PEDOT:PSS layer on the bare gold electrode, the interface becomes highly capacitive and possess a lower impedance. It is important to point that many of the reported impedance measurement tools uses electrode with large surface area and therefore very inefficient in performing localized measurement. As the proposed needle diameter is only 1mm, the reduction of the electrode surface area will suffer from the effect of mass diffusion and data in the low frequency spectrum will be masked. Our approach to modify the impedance allows us to reveal the impedance response of tissues at low frequency range for more precise equivalent circuit model fitting.

Investigation of Structure and Composition of Laser Induced Graphene from Polymer Precursors for Bioelectronics Applications Hana Hampel1, Maria Jernej1, Alexander Dallinger1, Harald Fitzek2, Hartmuth Schröttner2,1 and Francesco Greco1; 1Graz University of Technology, Austria; 2Graz Centre for Electron Microscopy, Austria

Laser Induced Graphene (LIG) was first described in 2014 and ever since it has been a far-reaching field of research. Research has focused on fundamental understanding of LIG structure and properties, as well as on technological applications in flexible/stretchable electronics, energy, among others[1,2]. LIG is a porous and conductive carbon material produced by laser-induced pyrolysis of various polymer precursors, including biologically derived ones (e.g. wood, paper, silk)[3]. An infrared laser, as typically used in commercial CO2 laser cutter for manufacturing, is used for this purpose. This process allows for fast scribing of circuits onto insulating substrates in ambient condition.

We investigated the LIG formation process on polyimide to get a better understanding of the boundary conditions for the formation of LIG and the tuning of its morphology and properties (especially conductivity). LIG conductors are prepared by varying the various process parameters affecting laser fluence (i.e. energy per scribed area).

In this way, either a flat porous LIG or a dense forest of long (100-200 μm) carbon fibres bundles (with single fibres having a diameter of around 50-100 nm) can be obtained.

Composition, morphology and structure are characterized by optical, scanning and transmission electron microscopy, EDX, and correlative Raman-SEM spectroscopy. A variation of graphene content along the fibre growth direction was found. Variations in structure and morphology were correlated with conductivity.

Due to the huge potential of LIG in stretchable and wearable bioelectronics, latest developments of this research include
investigation of biologically derived precursors.

Fabrication and Integration of a Novel Coupled Lead Free Perovskite Oxide and Halide Active Multi-Morph—Towards Development of a Flexible Wearable and Continuous Non-Invasive Glucose Monitoring System Jodi Bishop¹, Faheem Shaikh¹, Noah Haworth¹, Riley Wells¹, Soumyasanta Laha¹, Saquib Ahmed² and Sankha Banerjee¹; ¹California State University, Fresno, United States; ²Buffalo State College, United States

A novel device architecture using a coupled media of an electro-active perovskite oxide (PO) and lead free photo active perovskite halide (PH) layer will be used to enhance signal strength through increased electron mobility, and the photoactive nature of the multimorph. Although, the optical and PA approaches have been studied individually in the past, there were no efforts to integrate the two approaches using perovskite layers and a flexible substrate to improve the wearable form factor, reliability and accuracy of the measurements. So far, all these studies conducted with PA system for non-invasive glucose monitoring used class-IV lasers and non-continuous and mostly in-vitro. This unique approach will integrate electro-active PO, and photoactive PH layers for signal conversion from acoustic and photoluminescence to electrical signals respectively. The following work involves the development of an integrated PO (BaTiO3-PMMA-Graphene) - PH (Tin iodide active layer) multimorph with a P3HT hole transport layer as the coupled media and development of the device architecture for the wearable device.

Stretchable Wideband Dipole Antennas and Rectennas for Wireless Communication and RF Energy Harvesting Jia Zhu¹ and Chaoyun Song²; ¹The Pennsylvania State University, United States; ²University of Liverpool, United Kingdom

Bio-integrated electronic devices can pliably conform on the textured skin surface to continuously monitor the physiologically relevant parameters or biomarkers, with a huge impact on human health from preventative monitoring and early diagnostic confirmation to non-invasive and convenient therapeutic options. The ultimate application of this class of emerging electronics hinges on the indispensable modules of stretchable wireless transmission and power supplies. While near field communication (NFC) allows for wireless powering and communication with a working distance of ~3 cm, radio frequency (RF) antennas enable wireless transmission of data and energy in the far-field. Compared to the approaches that exploit stretchable conducting materials such as liquid metal or elastomers with conductive fillers, designing conventional metals in a serpentine or meshed geometry is still of high interest because of their high radiation efficiency. Although this structural design concept has resulted in various stretchable dipole and patch antennas, the narrow bandwidth still limits their applications in wireless communication and energy harvesting because of the frequency detuning from mechanical deformations. While the efforts on wideband antennas could possibly overcome this challenge, the deformation-dependent radiation properties are yet to fully investigated. Here we demonstrate a stretchable wideband dipole antenna that consists of serpentine units for both main and parasitic arms created by exploiting the laser-induced graphene (LIG) pattern and maskless metal coating. Additionally, combining stretchable dipole antenna with a high-efficiency impedance matching network and rectifying circuit leads to a stretchable rectifying antenna (i.e., stretchable rectenna) that can continuously harvest electromagnetic radiation energies from various widely available RF sources (e.g., WI-FI, 4G, and upcoming 5G). As an added component into the clean energy portfolio for future energy supply, the ambient RF energy-harvesting solution could also contribute to integrated energy systems and enable self-powered systems and remote monitoring of the environment.

Characterization of Glassy Carbon and Graphene Based Metamaterial as Electrocorticography Electrodes Transferred on Flexible Substrate Surabhi Nimbalkar and Sammuel Kassegne; San Diego State University, United States

Graphene is the gold-standard for electrical conductivity along with its high mechanical strength and excellent thermal conductivity. On the other hand, GC has exceptional chemical inertness, good electrical properties, high electrochemically stability (gold-standard for electrochemistry), purely capacitive charge injection, and fast surface electrokinetics coupled with lithography patternability. Therefore, to leverage the unique strength of these ‘gold-standard’ materials in electrode technology, we introduce a new material system that brings the best qualities of these materials in a single format joined through strong covalent bonds. In this preliminary study, we investigate fabrication methodology, transfer on flexible
substrate, bonding between the two allotropes of carbon through FTIR (Fourier transform Infrared) spectroscopy, surface morphology through SEM (Scanning electron microscopy) and topography by AFM (atomic force microscopy), and application of metamaterial based microelectrodes for neural signal recording i.e. electrocorticography (ECoG).

**Lactic Acid Neurotransmitter Detection using Functionalized Glassy Carbon Microelectrodes**

Amish Rohatgi and Sammuel Kassegne; San Diego State University, United States

Neurotransmitters are often referred to as the body’s chemical messengers. They are the molecules used by the nervous system to transmit messages between neurons. Dopamine and serotonin are electroactive neurotransmitters and can be detected through conventional neural probes. However, lactic acid is a non-electroactive molecule that cannot be detected by conventional probes. Lactic acid can be found in the brain as a byproduct of energy production and a buildup of lactic acid leads to lactic acidosis. Lactic acidosis can hamper normal mitochondrial functions and has been linked to seizures and can be caused by ischemia or hypoxia. To detect lactic acid our group at SDSU are functionalizing glassy carbon electrodes by immobilizing an enzyme to catalyze lactic acid into a molecule that is electroactive. By immobilizing lactate oxidase into a chitosan matrix, we aim to cause a reaction that will create hydrogen peroxide which is an electroactive molecule with a redox potential of 1.2. In addition to functionalizing glassy carbon with lactate oxidase, we aim to immobilize lactate dehydrogenase which will catalyze lactic acid into NADH and pyruvate and compare both enzyme detection efficacies. We will use electrochemical methods such as fast scan cyclic voltammetry (FSCV), FTIR, and potentiostat reading to characterize, understand the chemical reactions occurring, and qualify these functionalized glassy carbon electrodes. Preliminary characterization results show a slight increase in impedance values once the immobilization matrix has been applied, but despite the increase in impedance the limit of detection has not decreased. Preliminary looks at FTIR data show an increase in functional groups for chitosan on glassy carbon compared to bare glassy carbon showing the chance of adherence.

Optimizing Bicontinuous Structure of Bijels-Derived Polymer-Hydrogel Hybrids for the Controlled Release of Different Cells Haoran Sun and Min Wang; University of Hong Kong, Hong Kong

Controlled cell release is an important strategy in tissue engineering which deliver live cells to the repair sites in human bodies with well-designed cell density and distribution that mimic targeted tissues and facilitate tissue regeneration. Bicontinuous interfacially jammed emulsion gels ("bijels") are a new class of materials consisting of two interpenetrating continuous liquid phases. Bijels can be used as templates for fabricating bijels-derived bicontinuous structures having interconnected channels. These channels ("pores") in bicontinuous structures can provide desired space for cell encapsulation, proliferation and migration in tissue engineering while enabling the transport of nutrients and bioactive molecules. However, pore sizes of bijels-derived bicontinuous structures are normally small. To realize their potential in tissue engineering, bijels-derived bicontinuous structures with larger pore sizes need to be made for cell encapsulation and delivery. Our research has developed new methods for fabricating bijels and bijels-derived structures. In this investigation, bijels-derived polymer-hydrogel hybrids with normal pore size (~30 μm) and large pore size (~60 μm) were produced, and human dermal fibroblasts (HDFs) and osteoblast precursor cell line (MC3T3 cells) were encapsulated in respective hybrid. The cells were encapsulated in the crosslinked alginate hydrogel (with different crosslinking degrees) of polymer-hydrogel hybrids. The hybrids were then cultured for different periods to study controlled cell release. SEM examinations showed successful fabrication of cell-encapsulated polymer-hydrogel bicontinuous structures and the degradation of alginate hydrogel during culture. The cell release process was studied using confocal microscopy and SEM. Live/Dead assay and MTT assay were also used in the studies. It was observed that live cells were locked in hybrid structures at the beginning and were gradually released since Day 1 during culture. Both HDFs and MC3T3 cells exhibited good cell viability and proliferation after their release and were able to migrate from the channels of hybrid structures to the surface of hybrids and to the outer culture plate. The two types of cells displayed different release behaviors. In the bijels-derived hybrids with small pore size (~30 μm), HDFs were released significantly slower than MC3T3 cells. The major release period of encapsulated HDFs was 24 h later than the major release period of encapsulated MC3T3 cells. For the bijels-derived hybrids with large pore size (~60 μm), the release rates of HDFs and MC3T3 cells were similar. A possible explanation for the differences is that the sizes of cells and pores in hybrids could affect cell release. HDFs have a larger cell size (~50 μm) than MC3T3 cells (20-30 μm), which may have caused slower release of HDFs in bijels-derived hybrids with small pore size. This investigation has demonstrated that bijel-derived bicontinuous hybrid structures are a good vehicle for cell delivery in tissue engineering. By controlling the pore size of hybrid structures, the release of different types of cells could be controlled. The released live cells could proliferate well and migrate in and outside the hybrid structures.

Poplar Reinforced Biocomposites Via Cellulose Nanofibril Modification Xianhui Zhao, Kai Li, Daniel Rasmussen, Halil Tekinalp, Erin Webb and Soydan Ozcan; Oak Ridge National Laboratory, United States

A common material used for large-scale 3D printing is a composite consisting of acrylonitrile butadiene styrene (ABS) polymer compounded with carbon fiber (CF/ABS). However, the high cost of CF/ABS indicates a market for 3D printing with biodegradable materials. Natural lignocellulosic fibers have the advantages of biodegradability, abundance, low density, low cost, and easy availability. In the present study, poplar fibers (Populus spp.) were modified using cellulose nanofibril (CNF) slurry (~ 3 wt% solid). The modified CNF/poplar fibers were used to reinforce ABS. The biocomposites obtained were characterized using techniques including tensile testing, differential scanning calorimetry (DSC), dynamic mechanical analysis (DMA), rheometer, thermogravimetric analysis (TGA), and scanning electron microscope (SEM). The tensile strength and Young’s modulus of neat ABS were 36 MPa and 1,901 MPa, respectively. After the addition of CNF/poplar fibers into ABS, the tensile strength and Young’s modulus of the biocomposites increased by 19% and 143%, respectively. The physical treatment of doping CNF solution on poplar fibers was found to be an effective technique to improve the thermomechanical properties of biocomposites.

Blow-Spun Hybrid PEO-PCL Scaffolds with Improved Mechanical and Biological Properties Meichen Liu and David...
Tissue-engineered scaffolds play an important role in the repair or regeneration of tissues and organs. Scaffolds provide strength, stability, and support for cell and tissue development and growth. Common scaffold materials are natural and synthetic polymers, however, each one has its own limitations and different disadvantages. Interestingly, in order to promote the mechanical properties and increase the bioactivity, the composite systems composed of various sources or types of polymers can retain the advantages of each material. Furthermore, composite polymer systems have the ability to allow stem cell adhesion and differentiation and to carry drug molecules and special biological molecules, like growth factor and enzyme. Research on composite scaffolds is focused on identifying composites with enhanced mechanical properties, sustained drug-releasing capabilities and the ability to support tissue development and growth.

In this study, we produced and characterized a novel nanocomposite polymer scaffold composed of polyethylene oxide (PEO), polycaprolactone (PCL) and halloysite clay nanotubes (HNTs). PGS, a polymer with repeating -O-CH2-CH2- units, and PCL, a hydrophobic aliphatic polyester with exceptional biodegradable and biocompatible properties, were used in combination with HNTs to form nanocomposite polymer scaffolds. The nanocomposite polymer scaffold thin films were prepared by solution blow coating, which is an easy and convenient way to make fibers and films. We characterized the structural, morphological, thermal and functional properties of these novel nanocomposite polymer (PEO-PCL-HNT) scaffolds. The nanocomposite polymer scaffolds should be biocompatible and resorbable, maintain long-term cellular viability and functionality, have the ability to induce cellular differentiation leading to complex tissue formation, have the improved mechanical properties to support cell growth and have sustained-release capabilities.

S.SM06.08.08
Polysaccharide-Based Hybrid Hydrogels as Tissue Engineering Scaffolds and/or Drug Delivery System Jinku Kim and Byungduk Kim; Hongik University, Korea (the Republic of)

Introduction: Hydrogels have potential in many biomedical applications such as tissue engineering and drug delivery system. Among those, Polysaccharide-based hydrogels such as hyaluronic acid (HA) have been extensively studied for tissue engineering applications, for example cartilage tissue engineering, partly because they are involved in cellular processes such as proliferation, morphogenesis, and wound repair. A number of polysaccharide-based hydrogels were designed, synthesized by free radical polymerization and their properties were analyzed in vitro and in vivo. In this study, we hypothesized that the properties of polysaccharide-based hydrogels can be controlled and enhanced by combining with small molecules (e.g., proteins) or large molecules (e.g., PEG-based hydrogels). To test this hypothesis, novel biodegradable polysaccharide-based hydrogels were developed by combining polysaccharides (e.g., hyaluronic acid or HA) with PEG based macromers such as PEG sebacic acid diacylates (PEGSDA) via free radical polymerization under mild conditions. Their physicochemical properties (e.g., swelling ratios) as well as biological properties were evaluated

Materials & Methods: Polysaccharide-based hydrogels were synthesized by free radical polymerization under mild conditions and their properties were controlled by incorporation of proteins (e.g., collagen or growth factors) or synthetic polymers such as polyethylene glycol (PEG). Physicochemical properties and in vitro and in vivo biological properties were investigated using mesenchymal stem cells (MSCs) and rat mandibular defect models.

Results: The chitosan-based hydrogels conjugated with collagen and/or growth factors were well synthesized under mild conditions. Growth factors were delivered from the hydrogel systems in a controlled manner. The encapsulated MSCs showed their potential of condrogenic differentiation in vitro. The physically crosslinked chitosan-based hydrogels revealed their capability of bone regeneration on the critical-sized defects (CSD) in rat mandibular in addition, the physicochemical properties of hyaluronic acid-based polysaccharide hydrogels can be controlled by combining them with PEG-based hydrogels.

Conclusion: Polysaccharide-based hydrogels with well controlled their properties can be synthesized by incorporations of additives such as growth factors or synthetic hydrogels. These hybrid polysaccharide-based hydrogels can be useful as tissue engineering scaffolds and drug delivery systems to repair or regenerate the defects in organs or tissues, caused by injuries or diseases.

Acknowledgement: This study is supported by the National Research Foundation of Korea (NRF) Grants (NRF-2016R1D1A3B01008280).

A Screen-Printable Ph Sensor for Smart Textiles

Recently, wearable sensors attract tremendous interest as real-time monitoring of physiological activities or environmental conditions becomes more important for many smart devices. Screen printing of sensing materials directly on fabric could not only enhance portability but also improve productivity by enabling a roll-to-roll process. Here, we present a solid-state pH sensor formed by a reliable screen printing technique. The pH sensor consists of two patterned electrodes. One is made of polyaniline(PANI)-carbon nanotube(CNT)-agarose composite. PANI, CNT, and agarose are a pH-sensing material, a conducting filler, and a binder and matrix material, respectively. For preliminary test, the composite in a paste state is deposited by doctor blade method with thickness of 150 um. The film shows negative dependence on pH condition: e.g. higher potential at lower pH. The other electrode is a “reference” electrode, made of Ag/AgCl thin film with ion-selective solid membrane. The resulting electrode shows similar current-voltage curves with commercial Ag/AgCl reference electrode. Finally, the compositions of PANI film as well as the conditions for screen printing such as mesh thickness, printing temperature & speed, etc. are optimized, to establish the continuous, roll-to-roll process of a pH-sensor patterned directly on fabric by the screen printing.

Synthesis and Characterization of a New Antibacterial N-halamine Coating Based on Polydopamine. Nadia Nazi;
Sorbonne Université, France

In the presence of moisture, surfaces are an ideal support for the development of biofilms containing bacteria that can be pathogenic. This poses a real public health, economic or even environmental problems in view of the use of biocides to eradicate this phenomenon. Due to the rise of multi-drug resistant microorganism, the investigation of new antibacterial coating is extremely requested.

The goal of this study is the development of a new regenerative antimicrobial coating based on polydopamine, containing haloamine (or N-halamine) functions (>N-Cl or/and >N-Br) that have oxidative properties due to the oxidation state +I of Cl or Br. Thus, the antimicrobial activity of N-halamines is attributable to halogen exchange reactions between N-halamines and microorganisms, leading to death of the microorganisms. N-halamines are broad-spectrum biocidal groups due to their mode of action, i.e. oxidation, bacteria should not develop resistance, unlike after repeated use of antibiotics.

The protection of surfaces with N-halamine compounds requires the immobilization of amine, amide or imine functions that will be transformed into haloamine either during synthesis or by post-treatment in the presence of NaOCl or NaOBr. The originality of this antibacterial coating is its regenerative proprieties. In fact, N-halamines, after contact with bacteria, can be regenerated by simple immersion of the coating in a diluted bleach recharge.

The purpose of this study was to investigate the synthesis and the antibacterial properties of a new N-halamine coating based on polydopamine (PDA). First the formation of the PDA coating by oxidative polymerization of dopamine in aqueous solution was studied and characterized. The thickness of the deposited layer reached a constant value around 50 nm after 24h of functionalization. Then this film was chlorinated by contact with a NaOCl solution in order to form on and into the coating chloramine functions. An amount of 10^16 at/cm² of chlorine was successfully grafted into the surface. Finally, the antibacterial properties of the modified PDA coating were evaluated by testing its properties toward Escherichia coli. Bacterial viability in contact with the PDA-Cl film evaluated by epifluorescence microscopy revealed promising results.

References
Stimuli-responsive materials, or smart materials, has been intensively studied for decades and numerous interesting materials have been developed. Among them, materials with controllable mechanical properties have found use in a wide variety of applications including aerospace, civil applications, and implantable medical devices. However, synthetic hydrogels are the most heavily investigated. Considering its sustainability, a biodegradable polylactic acid (PLA) based free-stand film with controllable mechanical properties was developed. It was found that through chain end modification with anthracene (AN), PLA experiences a 10-fold increase in toughness with no change in tensile strength. Interestingly, after 365 nm UV light irradiation, AN modified PLA became brittle and tensile strength increased by 20%. π-π* stacking of AN groups was proposed to be the mechanism behind the toughening, and light induced dimerization of two AN group resulted in the brittleness. Based on the light reversible dimerization nature of the AN group, light with different wavelengths (365 nm and 254 nm) can be used to control the mechanical properties of newly developed PLA+AN materials in solid state.

NIR Triggered Upconversion Nanocomposites for Synergistic Photodynamic and Photothermal Therapy Lei Ma and Xiujun J. Li; The University of Texas at El Paso, United States

Development of near-infrared (NIR) laser triggered photo cancer therapy is highly desirable but still a big challenge. Herein, NaYF₄:Yb/Er Upconversion Nanoparticles (UCNPs) was rationally synthesized through a novel low-temperature hydrothermal method, exhibiting photoluminescence emissions at the wavelength of 538, 653 and 839 nm, under 980 nm laser radiation. The UCNPs were firstly surface-modified with silanization of tetraethyl orthosilicate (TEOS) and aminopropyltrimethoxysilane (APTMS) for water solubility improvement and amine terminals decoration. Subsequently, via a carbodiimide coupling reaction, UCNPs were grafted with benzoyloxy pyrrolidine based C₆₀ derivatives, as photosensitizers. Finally, gold nanorods (AuNRs) with localized surface plasmon resonance (LSPR) at 980 nm were synthesized, carboxylic polyethylene glycol (PEG) functionalized and covalently conjugated around the UCNPs-C₆₀ nanocomposite to obtain a multifunctional nanoplatform for photothermal therapy (PTT) and photodynamic therapy (PDT). Notably, under NIR laser irradiation, singlet oxygen was effectively generated from an upconverting photodynamic combination of UCNPs and C₆₀, while localized hyperthermia was simultaneously induced by LSPR activity of AuNRs. The therapeutic efficacy was validated in vitro on breast cancer cell lines MCF-7 and MDA-MB-231 by various microscopic and biochemical studies under a significantly mild NIR irradiation and low dosage of the nanoplatforms. Furthermore, according to cell viability comparative analysis, such nanocomposite presents a remarkable synergistic therapeutic effect by the combination of PTT and PDT. Overall, this work provides an innovative strategy for the design and understanding of clinical phototherapeutics.

Synthesis and Surface Modification Effect of BaTiO₃ Nanoparticles by Sodium Oleate and Chitosan on Their Piezoresponse Force Microscopy (PFM) Luis M. Angelats Silva¹, Jose Roldan Lopez¹, Nikita A. Emelianov², Henry León-León¹ and Rudy Céspedes-Vásquez¹; ¹Universidad Privada Antenor Orrego, Peru; ²Kursk State University, Russian Federation; ³Universidad Nacional de Trujillo, Peru

Spherical titanium barium nanoparticles with an average size about 100 nm in the tetragonal crystal phase were obtained by peroxide synthesis and then with formation of OH groups on its surface by hydrogen peroxide. To prevent their agglomeration and reduce the toxic effect, the surface of nanoparticles was chemically modified with sodium oleate and chitosan. Influence of surface modification by these compounds on piezoresponse force microscopy and their structure were investigated.

Laser-Induced Strong Marangoni Effect in Deformation and Manipulation of Ferrofluid Feng Lin¹, Talari Talari Vishal², Junyi Zhao³, John Schaibley⁴, Dong Liu⁴, Zhiming M. Wang¹ and Jiming Bao²; ¹University of Electronic Science and Technology of China, China; ²University of Houston, United States; ³Washington University in St. Louis, United States; ⁴University of Arizona, United States

Optical manipulation of fluid or droplet has long been investigated for applications in microfluidics. The light-induced thermocapillary effect is one of the strategies in optical control of liquid. We demonstrate the laser-induced deformation of ferrofluid surfaces with ultra-violet to infra-red lasers. The surface deformation reaches the bottom and breaks the liquid, achieving the highest liquid deformation thickness for over 1000 μm. The deformation process and rupture are related to strong Marangoni effect, high laser absorption and low viscosity of ferrofluid. As applications of the laser-controlled ferrofluid, we show that a ferrofluid droplet in the capillary can be easily moved horizontally and vertically by the
illumination of a laser beam. We also demonstrate that letters and patterns can be written on the black surface of ferrofluid thin film with a laser beam even with a common laser pointer. Laser manipulation of ferrofluid also makes it a controlling vehicle for varieties of liquid or droplets.

**Preparation and Characterization of Nitroxide-Based Magnetic Nanoemulsions Directed toward MRI-Visible Targeted Delivery System**

Kota Nagura and Naoki Komatsu; Kyoto Univ, Japan

We have prepared various all-organic magnetic soft materials containing a cyclic nitroxide radical moiety as a spin source [1]. In this talk, we report the preparation of all-organic magnetic nanoemulsions composed of the non-ionic surfactant and the hydrophobic nitroxide radical compound [2]. The properties of the nanoemulsions have been investigated by small angle neutron scattering (SANS) and dynamic light scattering (DLS) analyses, EPR spectroscopy, and MRI method. The nanoemulsions showed high colloidal stability, high reduction resistance to ascorbic acid, low cytotoxicity and an enough contrast enhancement in the proton longitudinal relaxation time (T1)-weighted MR images in (-)-PBS in vitro and in vivo. Furthermore, an additional hydrophobic anticancer drug such as Taxol® was simultaneously encapsulated inside the nanoemulsions. We expect that the drug-loaded nanoemulsions can be used as a biocompatible magnetic drug carrier for MRI-visible targeted delivery system.

**One-Pot Synthesis of Highly Water-Soluble Iron Oxide Nanoparticles with Functional Groups in Polyols for T1-Weighted MRI**

Pohlee Cheah, Paul Brown and Yongfeng Zhao; Jackson State University, United States

The direct synthesis of water soluble iron oxide nanoparticles with both controlled size and functional groups on the surface has gained intensive interests. In this study, ultrasmall iron oxide nanoparticles (IONPs) with different functional groups were successfully synthesized via one-pot synthesis. The IONPs are prepared by first thermal decomposition of iron acetylacetonate Fe(acac)3 precursor in diethylene glycol (DEG), followed by mixing the surface ligands at the end of the reaction. This facile synthesis method enabled binding of different surface materials such as dopamine hydrochloride (Dopa), polyethylene glycol with thiol end group (thiol-PEG), and polyacrylic acid (PAA) onto the IONPs. The size growth of IONPs can be well controlled as evidenced by transmission electron microscopy (TEM) studies. The high water stability of nanoparticles was correlated with the change of hydrodynamic size and zeta potential. While TEM results showed no significant change in the nanoparticles core size before and after surface modification, hydrodynamic size slightly increases due to the presence of ligands molecules on the surface. The attachment of surface ligands was studied by FTIR and TGA. FTIR results indicated the corresponding functional group for each surface ligands as a result of surface modification. In addition, we confirmed the introduce of functional groups by bioconjugation of fluorescence dyes on to the surface. The magnetic resonance phantom study show that the resulted nanoparticles can be used for T1-weighted MRI imaging. The effect of surface ligands on the relaxivities of IONPs were also studied.

**Activation of Electrocured Bioadhesives Using DC and AC for Electroceutical Therapies**

Manisha Singh and Terry W. Steele; Nanyang Technological University, Singapore

Stimuli sensitive adhesives can be cured with temperature, UVA, and voltage. However, heat and light cured adhesives are limited to heat-sensitive and transparent substrates. Electrochemically mediated adhesive curing (i.e. electrocuring) can be utilized on a wide range of substrates including heat- sensitive and opaque surfaces. When an applied voltage potential is raised above a certain threshold, voltage activation initiates the diazirine groups to crosslink neighboring surfaces. Under the influence of direct current (1-3 mA), electrocuring progresses from the cathode to the anode but the maximum migration of the electrocuring is limited to 60-70% of the surface area. The application of alternating current (AC) is hypothesized to improve the electrocuring progression resulting in 100% surface activation, with a subsequent improvement in material properties. Structure-activity relationships of DC vs. AC currents are evaluated for the migration rate, shear modulus, gelation time, and adhesion strength of Voltaglue. Complete progression is achieved under AC stimulation and the maximum bioadhesion strength achieved for AC is 33 % higher than that for DC stimulation.

Optical Control of Nerves Using Organic Electrolytic Photocapacitors (OEPCs) Marie Jakešová¹, Malin Silverå-Ejneby¹, Ludovicigo Migliaccio¹, Oliya Abdullaeva¹, Maciej Gryszel¹, Vedran Derek¹ and Eric D. Glowacki¹,²; ¹Linkoping University, Sweden; ²Warsaw University of Technology, Poland

A great demand exists for nongenetic optical neuromodulation technologies. We report on our developments of ultrathin organic optoelectronic devices for neurostimulation. All of these devices rely on far red/near infrared irradiation in the tissue transparency window to actuate nanoscale organic semiconductor components. Our flagship technology is the organic electrolytic photocapacitor (OEPC) – a device that mimics biphasic current-pulse neurostimulation and thus transduces an optical signal into directly-evoked action potentials in neurons. These devices are not only wireless, but also 100-1000 times thinner than most existing technologies. Making implants with as small as possible mechanical footprint improves the efficacy of bioelectronic medical treatments by minimizing the risk for inflammation and making surgical implantation less invasive. We will present our results on pushing the limits of efficiency and stability, with benchmarking of performance using in vitro and ex vivo models, and cover our developments of peripheral nerve stimulation implants.

1:00 PM *S.SM06.05.02
Multi-Modal Sensors and Actuators for Biointerfacing Ivan Minev; University of Sheffield, United Kingdom

Interfaces that link biological systems with machines are increasingly evolving beyond the electrical domain. Multi-modal bioelectronics aims to add chemical, optical, thermal or mechanical functionality to the capabilities of classical electrode arrays. When such systems are used in physical contact with tissues or cells, the need for overall mechanical compliance is crucial for their biointegration. This raises a question: how do we build multi-modal arrays of sensors and actuators with tissue-like softness? In this talk I will present our efforts to adapt direct ink writing (multi-material 3D printing) for the purpose of fabricating elastic systems of electrodes, optrodes, thermotrodes, and chemotrodes. A palette of silicones, composites and hydrogels are used as inks, where each of the inks enables one interfacing modality. As an example of *in vitro* application, I will present multi-modal pacing and monitoring of stem cell derived cardiomyocytes. *In vivo*, I will present printed neuro-muscular implants tailored to specific anatomical niches and animal models. These developments are expected to contribute to the development of personalized platforms for bioelectronic medicine.
Neural prostheses are devices integrated with the neural tissue for diagnostic or therapeutic purposes, such as restoring impaired or lost functions. Despite a large variety of devices exists, a shared future is the presence of cables connecting the electrode-tissue interface to implantable electronic circuits for signal management. The presence of wires and connectors is a significant disadvantage for neural prostheses; in fact, they are weak points often leading to failure, they exert mechanical forces and tractions on the implant and the tissue, and they are often transcranial or transcutaneous connections that might lead to post-surgical complications, such as infection. Also, the use of implantable electronic units is another disadvantage. Several aspects limit their operation, such as power consumption, excessive heat generation, and high risk of failure in a wet environment due to leakage.

In neural prostheses, wireless electrodes are desirable. Retinal prostheses are a particular category of neural prostheses, in which wireless neuronal stimulation was achieved thanks to photovoltaic technology, that also avoids the need for active implantable electronic units. In the case of retinal stimulation, photovoltaic technology is intuitive since the retina is made to absorb light entering from the pupil naturally. Although photovoltaic retinal prostheses do not work with ambient and natural light, electrical stimulation is triggered by artificial light projected into the pupil and absorbed by semiconductor elements embedded into the stimulating pixels. This solution allows retinal prostheses to avoid a transscleral flat cable which limits the maximum number of stimulating pixels on the device and induce post-operative complications such as eye inflammation or leakage through the incision.

In the first part of this talk, the development and validation in-vitro and in-vivo of a wide-field, photovoltaic, and injectable retinal prosthesis will be reported. POLYRETINA is a wide-field epiretinal prosthesis which contains 10,499 photovoltaic electrodes (diameter of 80 µm and pitch of 120 µm) distributed with a pixel density of 80.33 pixels mm-2. The pixels cover an active area of 12.9 mm in diameter; thus, the prosthesis covers a visual angle of 46.3 °. Each pixel is composed by a conductive polymer (PEDOT:PSS) a bulk heterojunction (P3HT:PCBM) and a metallic cathode (Ti). The results obtained both in-vitro with retinal explants and in-vivo with large animal models will be reported.

In the second part of the talk, a novel visual prosthesis based on intra-neural stimulation of the optic nerve will be described. OpticSELINE is an intraneural 3D electrode array capable of selectively activating the optic nerve fibres to induce artificial vision. This technology is essential to overcome the exclusion criteria of retinal implants. The results from our in-vivo preclinical trial in large animals will be presented.

In conclusion, the use of photovoltaic technology to design novel neuroprostheses will be highlighted.

5:13 PM S.SM06.01.04

**Design and Patterning of Conductive PEDOT:PSS Hydrogels with Tissue-Like Mechanical Properties for Long-Term Bio-Electronic Interfacing**

Vivian R. Feig¹, Helen Tran¹, Minah Lee² and Zhenan Bao¹, ¹Stanford University, United States; ²Korea Institute of Science and Technology (KIST), Korea (the Republic of)

Bioelectronics are poised to revolutionize health care, providing exciting opportunities for therapeutics, health monitoring, prosthetics, and human augmentation. Yet, there remain significant barriers to long-term implantation of these technologies within the body. This is due in large part to inflammatory responses resulting from the severe mismatch in mechanical properties between conventional device components, which are rigid (E~GPa) and non-deformable, and biological tissues, which are significantly more soft (E~ kPa) and dynamic. With their high water content (70-99 wt%), hydrogels are capable of achieving tissue-level elastic moduli, though existing strategies to render hydrogels electrically conductive involve incorporating stiff, conductive additives into inert and stretchable hydrogels, necessitating a tradeoff between electrical and mechanical properties. Here, we present a new materials design strategy for conductive hydrogels that overcomes this tradeoff by decoupling mechanical from electrical properties through the use of two distinct, interpenetrating polymer networks. We first leverage the gel-forming capabilities of the conducting polymer poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) to form a macroscopically connected conductive network at
remarking remarkably low polymer concentrations (~1 wt%). The highly dilute yet interconnected conductive network enables us to orthogonally tune elastic modulus using a second, interpenetrating polymer network. Our unique design enables an unprecedented combination of mechanical tunability over 3 biologically-relevant orders of magnitude (8 kPa – 374 kPa), stretchability (up to 400%), elasticity, and electrical conductivity up to 23 S/m. To enable their integration into devices, we further introduce a novel method for patterning these materials with high resolution onto surfaces of planar and even curved objects. We overcome limitations precluding the use of conventional molding or lithographic methods by using a sacrificial metal pattern that can be oxidized in the presence of a PEDOT:PSS electrolyte to locally induce gelation only at the pattern interface. This materials design strategy and its corresponding new patterning method represent a significant step towards the development of next-generation bioelectronics that can seamlessly interface with biological targets over extended timescales.

5:21 PM S.SM06.02.03
Super-Soft Solvent-Free Bottlebrush Elastomers for Touch Sensing Veronica G. Reynolds1,1, Sanjoy Mukherjee1,1, Renxuan Xie1,1, Adam E. Levi1,1, Amalie Atassi2, Takumi Uchiyama3, Hengbin Wang4, Michael L. Chabinyc1,1 and Christopher M. Bates4,1,1; 1University of California, Santa Barbara, United States; 2University of Florida, United States; 3Tokyo Institute of Technology, Japan

Pressure sensors with high sensitivity have uses ranging from pulse monitoring and plantar pressure measurement (10–100 kPa) to in vivo intraocular and intracranial pressure measurement (1–10 kPa). The sensitivity of capacitive pressure sensors is primarily determined by the modulus of a dielectric layer that reversibly deforms to produce an electrical signal. Crosslinked polymers provide a means to achieve good dielectric properties with low modulus relative to inorganic materials. Unfortunately, the mechanical properties of conventional linear polymer networks are constrained such that a lower limit on softness translates to poor capacitive pressure sensor performance. Here, we overcome this limitation by leveraging the intrinsic “super-soft” characteristic of bottlebrush polymers, which can be crosslinked to form solvent-free networks with moduli in a range matching that of biological tissues (1–100 kPa). A simple light-induced crosslinking strategy is introduced to facilitate device fabrication. Parallel plate capacitive pressure sensors constructed with these bottlebrush polymer networks exhibit up to a 53× increase in sensitivity compared to commonly used elastomers, e.g., PDMS (Sylgard 184). The sensors show pressure resolution on the order of 0.1 kPa, capable of differentiating subtle forces in the light touch regime. Transparent and flexible sensors fabricated using indium-tin-oxide (ITO)-coated poly(ethylene terephthalate) (PET) electrodes are shown to be functional in a bent configuration. This combination of contemporary synthetic chemistry and application-driven materials design accentuates the opportunities available at the intersection of science and engineering to advance soft, flexible, and biocompatible devices.

5:29 PM *S.SM06.02.02
Iontronics for Human-Machine Interactions Pooi See Lee; Nanyang Technological University, Singapore

Gel based iontronics are attractive for epidermal electronics due to their compatible and tunable mechanical properties. Many receptive interface for birectional human-machine interactions require tactile sensors that are intrinsically soft, skin conforable and dynamically deformable. While addressable touch input can be realized using capacitive, resistive, piezoelectric or triboelectric signals, the output signal often requires integrated lighting for visual detection or optoelectronic signal feedback on a transparent interface. In addressing these needs, ionic conductors provide the advantages of optically transparent, skin compliant, ease of processibility and added novel functionality in the presence of ions and electrons transport.

We have demonstrated the use of conductive hydrogel composites as versatile strain sensors for monitoring of human motion. In addition, hydrogel ionic conductor was shown to be effective current collector by harnessing the electrical double layer for triboelectric nanogenerators, allowing them to be mounted onto skin or machine. On the other hand, we have formulated inkjet printable ionic gels with precise control of the rheological characteristics of gels. As a result, transparent deformable touch panels have been realized using the microscale patterning of ionic gel. The transparent touch interface is capable of remarkable signal fidelity under dynamic human-machine interactive conditions. We have further prepared thermally stable gels with self-healing ability and found applications in dielectric actuators, potentially used in biostimulation applications.

5:37 PM *S.SM06.02.04
Direct Writing of 3D Conducting Polymer Microarrays for Biological Sensing and Cell Stimulation Jadranka Travas-Sejdic1,2, Peikai Zhang1, Jeremy Crook1 and Eva Tomaskovic-Crook1; 1Polymer Electronics Research Centre, University of Auckland, New Zealand; 2MacDiarmid Institute for Advanced Materials and Nanotechnology, New Zealand; 3University of Wollongong, Australia
Conducting polymers (CPs) have been widely used as electroactive biointerfaces in applications such as DNA sensors, in electrically-stimulated tissue engineering and more recently in stretchable and conformable organic bioelectronics. However, the majority of these applications are based on the electropolymerized or solution deposited 2D films of CPs, and as such cannot fully probe the actual 3D cell environment within tissues and organs. Our approach to address that is based on a precise fabrication of individually addressable, high aspect ratio, 3D CP-pillar microelectrode arrays by means of ‘micro-extrusion printing’ using our in-house constructed system. The ‘printing’ principle is simple ‘extrusion’ of CP ‘ink’ from a micro-pipette into ‘pillars’, accompanied by evaporation of solvent (water) during the process. CP pillars of different aspect ratios (from 2 to 7000) were successfully fabricated, with excellent stability, mechanical properties and electrochemical properties.

Such 3D CP-pillar microelectrode arrays could be employed in variety of applications, from biological sensing to recording and electrically stimulating cells and tissues, with the design of the arrays being easily adjustable to a particular application. Our demonstrated examples include: exosome capture, sensing and release - where the CP pillars can be easily functionalized for capture/release of exosomes; and 3D electrical stimulation of human neural stem cells into a high-density of mature neurons and functional neural networks.

Overall, the 3D CP microelectrodes provide promising versatile substrates for a variety of bioelectronics applications, including where spatiotemporal control of individually electrically addressable microelectrodes is desired.

5:45 PM *S.SM06.03.03
Conformable Organic Photonic Systems Tomoyuki Yokota and Takao Someya; The University of Tokyo, Japan

In this talk, I will introduce our recent activity of conformable organic photonic systems. We have developed ultra-flexible and lightweight highly efficient, ultra-flexible, air-stable, three-color, organic light-emitting diodes (OLEDs). The total thickness of the devices, including the substrate and encapsulation layer, is only three micrometers, which is one order of magnitude thinner than the epidermal layer of the human skin. Due to the very thin substrate and neutral position, our device shows the highly flexibility and conformability. The OLEDs are directly laminated on the surface of skin and are used as indicators/displays. Furthermore, we have developed ultra-flexible organic imager which consists with a monolithically processed rectifying pixel and an organic photo diode. Our organic imager has pixel pitches as small as 50 µm, with resolutions of up to 262 ppi. Using our ultra-flexible organic imager, we succeed to measure the spatial photoplethysmography (PPG) mapping.

5:59 PM *S.SM06.02.05
Remote, Non-Genetic Modulation Cellular Activity Using Hybrid-Nanomaterials Tzahi Cohen-Karmi; Carnegie Mellon University, United States

Electrical stimulation of tissue and ultimately individual cells has not only played an essential role in our understanding of the structure and function of excitable tissue but continues to serve as the basis for a variety of therapeutic interventions for the treatment of disorders ranging from cardiac arrhythmias to Parkinson’s disease. Advances in technology have attempted to overcome barriers associated with the spatial resolution (i.e., who and where to stimulate) and the invasiveness of the process. Optogenetics has revolutionized the way we can record and affect the electrophysiology of cells and tissue, using light as the input/output (I/O) interface. Though optogenetics has developed at a great pace and is making profound scientific contributions, the core of the technique requires genetic modifications of the cells or organism. This presents challenges both in terms of achieving targeted gene expression and the potential deleterious consequences of the expression of foreign proteins, which have implications on clinical translation to humans and regulatory approval. We report our developed breakthrough hybrid-nanomaterial synthesis process to enable minimally invasive, remote and non-genetic light-induced control of targeted cell activity with high spatial-temporal resolution. We combine one-dimensional (1D) nanowires (NWs) and two-dimensional (2D) graphene flakes grown out-of-plane with tailor-made physical properties for highly controlled photostimulation. Photostimulation using NW templated 3D fuzzy graphene (NT-3DFG) is flexible due to its broadband absorption and does not generate cellular stress. Our light-based platform adds a powerful toolset to the basic scientists studying cell signaling within and between tissues. Last, this platform can be adapted to address challenges in tissue...
engineering, i.e. the much-needed non-genetic stimulation control of engineered tissues. By controlled delivery of the NT-3DFG we will be able to locally and selectively control cellular activity with high spatial and temporal resolution of 3D tissues.

6:07 PM S.SM06.03.09
Transparent Flexible Polymer Actuator with Enhanced Output Force Enabled by Conductive Nanowires Interlayer
Tony Fook1,2, Jin Han Jeon2 and Pooi See Lee1; 1Nanyang Technological University, Singapore; 2Robert Bosch (SEA) Pte Ltd, Singapore

As the role of flexible soft materials become more crucial for applications such as flexible displays in foldable mobile phones, compliant sensors and actuators in wearables, etc., new functional soft materials are needed to fill the roles previously fulfilled by rigid and bulky conventional materials. The field of haptic technology has recently seen emerging needs for integration into soft, flexible and even transparent interfaces. Since several decades ago, haptic feedback in electronic devices such as mobile phones, gaming controllers, are provided by bulky mechanical motors that vibrate the entire device upon application of an electric signal to give a tactile sensation to the users. In recent years, piezoceramics such as lead zirconate titanate are seen as a popular alternative due to its high performance and small form factor. However, their high stiffness, density and opacity prove to be a large obstacle in applications where flexibility, weight and transparency are crucial. In such applications, electroactive polymers (EAPs) serve as an excellent solution and have been a rapidly growing focus of research due to the wide range of potential applications such as energy harvesters, sensors and actuators, artificial muscles, etc. In reported methods to enhance the dielectric and electromechanical properties of EAPs, there is a compromise in at least one of these factors: electrical breakdown strength, transparency and flexibility.

In this work, we present an approach to enhance the output force of polymer actuators by increasing the dielectric permittivity and polarizability of the EAP, poly (vinylidene fluoride-trifluoroethylene-chlorotrifluoroethylene) (P(VDF-TrFE-CTFE)), by incorporation of a conductive nanowire interlayer into the polymer matrix. The interlayer is formed by a network of highly conductive silver nanowires with high aspect ratio and enhances the dielectric permittivity and polarizability of the EAP over a broad range of frequencies including ultra low frequencies (e.g. 0.1 Hz) and the range of 200 to 300 Hz at which the mechanoreceptors in the human fingertips are most sensitive to. Through experiments and finite element modelling, the enhancement of dielectric properties were found to originate from charge accumulation at the nanowire/polymer interface and resulted in an output force double that of a neat EAP actuator. The higher output force can be used to improve tactile feedback perception of a human user and allows a 40% reduction in the actuator excitation voltage compared to that of a neat EAP actuator. Even with enhanced dielectric properties and output force, the composite actuator retains its transparency and flexibility without severe compromise in the electrical breakdown strength. The excellent transparency and flexibility of the modified EAP are promising for a wider range of possible applications such as direct and localized haptic feedback on flexible electronic displays, touch screens, etc.

7:30 PM *S.SM06.04.01
Robotic Fabrics as Thin, Wearable, Fiber-Based Machines Rebecca Kramer-Bottiglio; Yale University, United States

Robot function is largely determined by the structural platform upon which it is built. The field of soft robotics aims to expand the design space by introducing unconventional robotic materials and methods to the engineering toolkit. In this talk, it is proposed that this increasing repertoire of robotic platforms be extended to include fabrics, which are known for their extreme deformability, versatility, and customizability. Possible fiber-based forms to achieve actuation, sensing, and stiffness control will be presented, including: (1) shape memory alloy ribbon as a thin-body actuator, which is effective at pure-bending motion, in contrast with typical fiber actuators that rely on axial contraction alone; (2) An in-fabric sensor that changes in resistance as the fabric weave is stretched and the gaps present between fibers are enlarged; and (3) A stiffness-
changing fiber based on a glass-transition polymer epoxy with low-melting-point metallic alloy inclusions that is capable of a stiffness change of two orders of magnitude using Joule heating. By designing actuators, sensors, and structural components that conform to a fiber-based geometry, we show that simple fabrics can be functionalized to create damage-responsive tournquets, self-deploying structures, and morphing airfoils.

8:00 PM *S.SM06.05.04
Brain Machine Interfaces Using Flex to Chip Bonding Eric Zhao, Marc Ferro, Tyler Chen, Pingyu Wang and Nicholas Melosh; Stanford University, United States

Enabled by new materials and device designs, a new generation of brain interface technologies is replacing bulkier, non-compliant systems with the aim of seamless electronic-biological interfaces with lower tissue damage, reduced immunogenicity, high-density, tunable spatial distribution, and long-term stability. Recent successful examples leveraging mechanically compliant materials have demonstrated major breakthrough in brain research using ultra-flexible systems for ECoGs recordings, and for depth electrodes.

However, connectorization of these ultra-flexible electrodes to traditional electronics remains a significant challenge. Current connectors, such as zero-insertion force (ZIF) devices, are limited to 64 or 128 channels at most. While these may then be stacked together this approach does not scale, limiting the maximum number of channels feasible.

Here, we demonstrate an easy to use, massively scalable connector technology. Rather than using traditional amplifier electronics, we couple thousands of flexible electrodes directly to a CMOS pixel array, such as typically found in a camera or OLED display. These devices have millions of available pixels, and by taking advantage of the small, flexible nature of the electrodes we are able to attach thousands of electrodes in seconds. These form robust Ohmic contact that can be extensively cycled. We demonstrate the simplicity of the process, and show how it can be used to perform massively parallel neural recordings.

8:30 PM *S.SM06.06.05
Organic Mixed Conductors—Fundamental Properties and Applications Alberto Salleo; Stanford University, United States

Organic mixed ionic/electronic conductors have elicited much interest lately as the enablers of a “new wave” of organic electronic devices in the biomedical space. In this talk I will start by exploring how the microstructure of the polymer interacts with the electrolyte and the effect of the electrolyte on the characteristics of electrochemical transistors. I will then show some applications of these materials in the sensor space ranging from flexible sensors to quantify electrolytes in sweat to biomimetic sensors to determine antibiotic activity of small molecules and detect the presence of pathogens. Finally I will show how devices based on these materials can be modulated by neuron-like cells where neurotransmitters elicit both short and long term potentiation in the device demonstrating a first building block of a new type of brain-machine interface.

Bioadhesives for Clinical Applications and Biointegrated Devices Hyunwoo Yuk and Xuanhe Zhao; Massachusetts Institute of Technology, United States

Rapid and robust adhesion of wet tissues has critical importance for clinical applications such as wound closure and tissue repair as well as biointegrated devices for their stable yet functional operations and communications with the target tissues. For example, traumatic injuries and failure of prompt wound closure and hemostasis cause over 2 million deaths annually in the world; and the development of a broad range of biointegrated devices for therapeutic and diagnostic applications is one of the fastest growing fields in recent decades. However, conventional approaches such as sutures and staples have face numerous challenges including complications and problems caused by their non-continuous, tissue-damaging, and highly
technical nature. While tissue adhesives and glues have been investigated as promising alternatives for sutures and staples, practical utility and impact of existing tissue adhesives and glues have been greatly dampened by several limitations including 1) incompatibility to wet tissues, 2) incompatibility to body fluids such as blood and mucus, 3) slow adhesion formation, 4) weak and brittle adhesion, and 5) inability to allow bioelectronic communication between tissue and adhered device. In this talk, we will introduce a set of novel bioinspired mechanisms and tissue adhesives capable of instant, strong, and conductive adhesion formation on various tissues covered by blood or mucus to address all abovementioned challenges. We will demonstrate a broad range of potential applications of these novel tissue adhesives and their implications in clinical, biomedical, and bioelectronic applications.

5:10 AM S.SM06.01.04
Design and Patterning of Conductive PEDOT:PSS Hydrogels with Tissue-Like Mechanical Properties for Long-Term Bio-Electronic Interfacing Vivian R. Feig1, Helen Tran1, Minah Lee2 and Zhenan Bao1; 1Stanford University, United States; 2Korea Institute of Science and Technology (KIST), Korea (the Republic of)

Bioelectronics are poised to revolutionize health care, providing exciting opportunities for therapeutics, health monitoring, prosthetics, and human augmentation. Yet, there remain significant barriers to long-term implantation of these technologies within the body. This is due in large part to inflammatory responses resulting from the severe mismatch in mechanical properties between conventional device components, which are rigid (E~GPa) and non-deformable, and biological tissues, which are significantly more soft (E~kPa) and dynamic. With their high water content (70-99 wt%), hydrogels are capable of achieving tissue-level elastic moduli, though existing strategies to render hydrogels electrically conductive involve incorporating stiff, conductive additives into inert and stretchable hydrogels, necessitating a tradeoff between electrical and mechanical properties. Here, we present a new materials design strategy for conductive hydrogels that overcomes this tradeoff by decoupling mechanical from electrical properties through the use of two distinct, interpenetrating polymer networks. We first leverage the gel-forming capabilities of the conducting polymer poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) to form a macroscopically connected conductive network at remarkably low polymer concentrations (~1 wt%). The highly dilute yet interconnected conductive network enables us to orthogonally tune elastic modulus using a second, interpenetrating polymer network. Our unique design enables an unprecedented combination of mechanical tunability over 3 biologically-relevant orders of magnitude (8 kPa – 374 kPa), stretchability (up to 400%), elasticity, and electrical conductivity up to 23 S/m. To enable their integration into devices, we further introduce a novel method for patterning these materials with high resolution onto surfaces of planar and even curved objects. We overcome limitations precluding the use of conventional molding or lithographic methods by using a sacrificial metal pattern that can be oxidized in the presence of a PEDOT:PSS electrolyte to locally induce gelation only at the pattern interface. This materials design strategy and its corresponding new patterning method represent a significant step towards the development of next-generation bioelectronics that can seamlessly interface with biological targets over extended timescales.

5:20 AM S.SM06.01.05
Skin-Inspired Soft Electronic Materials and Devices for Biointerfacing Zhenan Bao; Stanford University, United States

In this talk, I will present our recent work on engineering soft electronic materials and their applications in biointerfacing
relation allows not only to fully describe their optical appearance, but it enables to gather insights on the mechanisms used for communication and their biological function. Further, the ability to genetically modify them allowed us to modify their colouration and control their optical appearance on-demand, enabling us to use such colonies as novel photonic living materials.

5:10 AM *S.SM06.02.02
Iontronics for Human-Machine Interactions  
Pool See Lee; Nanyang Technological University, Singapore

Gel based iontronics are attractive for epidermal electronics due to their compatible and tunable mechanical properties. Many receptive interface for bidirectional human-machine interactions require tactile sensors that are intrinsically soft, skin conformable and dynamically deformable. While addressable touch input can be realized using capacitive, resistive, piezoelectric or triboelectric signals, the output signal often requires integrated lighting for visual detection or optoelectronic signal feedback on a transparent interface. In addressing these needs, ionic conductors provide the advantages of optically transparent, skin compliant, ease of processibility and added novel functionality in the presence of ions and electrons transport.

We have demonstrated the use of conductive hydrogel composites as versatile strain sensors for monitoring of human motion. In addition, hydrogel ionic conductor was shown to be effective current collector by harnessing the electrical double layer for triboelectric nanogenerators, allowing them to be mounted onto skin or machine. On the other hand, we have formulated inkjet printable ionic gels with precise control of the rheological characteristics of gels. As a result, transparent deformable touch panels have been realized using the microscale patterning of ionic gel. The transparent touch interface is capable of remarkable signal fidelity under dynamic human-machine interactive conditions. We have further prepared thermally stable gels with self-healing ability and found applications in dielectric actuators, potentially used in biostimulation applications.

5:25 AM S.SM06.02.03
Super-Soft Solvent-Free Bottlebrush Elastomers for Touch Sensing  
Veronica G. Reynolds1,1, Sanjoy Mukherjee1,1, Renxuan Xie1,1, Adam E. Levi1,1, Amalie Atassi1, Takumi Uchiyama3, Hengbin Wang1, Michael L. Chabinyc1,1 and Christopher M. Bates1,1,1; 1University of California, Santa Barbara, United States; 2University of Florida, United States; 3Tokyo Institute of Technology, Japan

Pressure sensors with high sensitivity have uses ranging from pulse monitoring and plantar pressure measurement (10–100 kPa) to in vivo intraocular and intracranial pressure measurement (1–10 kPa). The sensitivity of capacitive pressure sensors is primarily determined by the modulus of a dielectric layer that reversibly deforms to produce an electrical signal. Crosslinked polymers provide a means to achieve good dielectric properties with low modulus relative to inorganic materials. Unfortunately, the mechanical properties of conventional linear polymer networks are constrained such that a lower limit on softness translates to poor capacitive pressure sensor performance. Here, we overcome this limitation by leveraging the intrinsic “super-soft” characteristic of bottlebrush polymers, which can be crosslinked to form solvent-free networks with moduli in a range matching that of biological tissues (1–100 kPa). A simple light-induced crosslinking strategy is introduced to facilitate device fabrication. Parallel plate capacitive pressure sensors constructed with these bottlebrush polymer networks exhibit up to a 53× increase in sensitivity compared to commonly used elastomers, e.g., PDMS (Sylgard 184). The sensors show pressure resolution on the order of 0.1 kPa, capable of differentiating subtle forces in the light touch regime. Transparent and flexible sensors fabricated using indium-tin-oxide (ITO)-coated poly(ethylene terephthalate) (PET) electrodes are shown to be functional in a bent configuration. This combination of contemporary synthetic chemistry and application-driven materials design accentuates the opportunities available at the intersection of science and engineering to advance soft, flexible, and biocompatible devices.

5:35 AM *S.SM06.02.04
Direct Writing of 3D Conducting Polymer Microarrays for Biological Sensing and Cell Stimulation  
Jadranka Travas-Sejdic1,2, Peikai Zhang1, Jeremy Crook1 and Eva Tomaskovic-Crook1; 1Polymer Electronics Research Centre, University of Auckland, New Zealand; 2MacDiarmid Institute for Advanced Materials and Nanotechnology, New Zealand; 3University of Wollongong, Australia

Conducting polymers (CPs) have been widely used as electroactive biointerfaces in applications such as DNA sensors, in electrically-stimulated tissue engineering and more recently in stretchable and conformable organic bioelectronics. However, the majority of these applications are based on the electopolymerized or solution deposited 2D films of CPs, and as such cannot fully probe the actual 3D cell environment within tissues and organs. Our approach to address that is based on a precise fabrication of individually addressable, high aspect ratio, 3D CP-pillar microelectrode arrays by means of ‘micro-
extrusion printing’ using our in-house constructed system. The ‘printing’ principle is simple ‘extrusion’ of CP ‘ink’ from a micro-pipette into ‘pillars’, accompanied by evaporation of solvent (water) during the process. CP pillars of different aspect ratios (from 2 to 7000) were successfully fabricated, with excellent stability, mechanical properties and electrochemical properties [1].

Such 3D CP-pillar microelectrode arrays could be employed in variety of applications, from biological sensing to recording and electrically stimulating cells and tissues, with the design of the arrays being easily adjustable to a particular application. Our demonstrated examples include: exosome capture, sensing and release - where the CP pillars can be easily functionalized for capturer/release of exosomes; and 3D electrical stimulation of human neural stem cells into a high-density of mature neurons and functional neural networks [2].

Overall, the 3D CP microelectrodes provide promising versatile substrates for a variety of bioelectronics applications, including where spatiotemporal control of individually electrically addressable microelectrodes is desired.

5:50 AM  S.SM06.02.05
Remote, Non-Genetic Modulation Cellular Activity Using Hybrid-Nanomaterials  Tzahi Cohen-Karni; Carnegie Mellon University, United States

Electrical stimulation of tissue and ultimately individual cells has not only played an essential role in our understanding of the structure and function of excitable tissue but continues to serve as the basis for a variety of therapeutic interventions for the treatment of disorders ranging from cardiac arrhythmias to Parkinson’s disease. Advances in technology have attempted to overcome barriers associated with the spatial resolution (i.e., who and where to stimulate) and the invasiveness of the process. Optogenetics has revolutionized the way we can record and affect the electrophysiology of cells and tissue, using light as the input/output (I/O) interface. Though optogenetics has developed at a great pace and is making profound scientific contributions, the core of the technique requires genetic modifications of the cells or organism. This presents challenges both in terms of achieving targeted gene expression and the potential deleterious consequences of the expression of foreign proteins, which have implications on clinical translation to humans and regulatory approval. We report our developed breakthrough hybrid-nanomaterial synthesis process to enable minimally invasive, remote and non-genetic light-induced control of targeted cell activity with high spatial-temporal resolution. We combine one-dimensional (1D) nanowires (NWs) and two-dimensional (2D) graphene flakes grown out-of-plane with tailor-made physical properties for highly controlled photostimulation. Photostimulation using NW templated 3D fuzzy graphene (NT-3DFG) is flexible due to its broadband absorption and does not generate cellular stress. Our light-based platform adds a powerful toolset to the basic scientists studying cell signaling within and between tissues. Last, this platform can be adapted to address challenges in tissue engineering, i.e. the much-needed non-genetic stimulation control of engineered tissues. By controlled delivery of the NT-3DFG we will be able to locally and selectively control cellular activity with high spatial and temporal resolution of 3D tissues.

6:05 AM  S.SM06.02.06
Studying Human Cell Membrane Function Using Bioelectronic Technologies  Anna-Maria Pappa1, Walther Traberg-Christensen1, Han-Yuan Liu2, Susan Daniel2, Alberto Salleo3, Quentin Tribuce4 and Roisin Owens4; 1University of Cambridge, United Kingdom; 2Cornell University, United States; 3Stanford University, United States

Despite their significance in the aetiology of many diseases, cellular membranes are still an underexplored target for studying the mechanisms of diseases or drug therapies. Supported lipid bilayers (SLB), are a preferred model membrane system for cell membrane studies, including ion channel recording and pharmaceutical screening. However, to date, cell-free commercially available technologies for plasma membrane studies have been limited to synthetic membranes that lack the inherent complexity found in the membrane of the cell.

Here, we use vesicles derived from live cells to create cell-free native membrane models on top of active bio-transducers. These vesicles fuse on top of the desired substrates forming an SLB. In this work we use human embryonic kidney 293 cells (HEK) and a hydrated polymer-based transducer, based on poly(3,4-ethylenedioxythiophene): poly(styrenesulphonate) (PEDOT: PSS), instead of inorganic solid supports. This provides a fluid environment close to the physiologically relevant one, thus facilitating mobility of the transmembrane proteins (TMPs), which is a prerequisite for protein membrane studies.
Moreover, the optical transparency of PEDOT:PSS ensures compatibility with standard optical methods allowing us to confirm the presence and correct orientation of TMPs as well as the mobility (fluidity) of the bilayer using fluorescent microscopy techniques, such as fluorescence recovery after photobleaching (FRAP) and total internal reflection fluorescence (TIRF). These features enhance the native structural and functional properties of the membrane and ensure the usefulness of our platform as a physiologically relevant and predictive mimic of membrane molecular interactions.

In this study we carry out electrical characterization of membrane properties and interactions using both PEDOT:PSS-based electrodes and transistors (the Organic Electrochemical Transistor). This is based on measuring the ionic flux through the membrane via electrical impedance spectroscopy and transistor-characteristics. In this way, we can monitor biological interactions quantitatively and in real time, revealing useful information regarding the dynamics of membrane fusion. This allows for sensitive detection of minute changes of membrane properties, e.g. receptor binding events, changes in membrane potential and ion channel activity. As an example, we can observe differences in the electrical properties between the native membrane derived from HEK cells and a native membrane derived from HEK cells overexpressing the potassium ion channel TREK-1. Our device allows us to measure the chemically-induced gating of TREK-1 ion channels with the ability to distinguish between general ion channel activity and that of TREK-1, specifically. Overall, our results highlight the suitability of this platform for drug screening against ion channel targets paving the way for a scalable and cost-efficient alternative method to using whole cells e.g. patch clamp assays.

6:15 AM *S.SM06.02.07
Graphene-Based Sensing of Oxygen Permeation through Pulmonary Membranes Cecilia Leal; University of Illinois at Urbana-Champaign, United States

Lipid-protein complexes are the basis of pulmonary surfactants covering the respiratory surface and mediating gas exchange in lungs. Cardiolipin is a mitochondrial lipid overexpressed in mammalian lungs infected by bacterial pneumonia. In addition, increased oxygen supply (hyperoxia) is a pathological factor also critical in bacterial pneumonia. In this work we present the fabrication of a micrometer-size graphene-based sensor to measure oxygen permeation through pulmonary membranes. Combining oxygen sensing, X-ray scattering, and Atomic Force Microscopy, we discovered that mammalian pulmonary membranes suffer a structural transformation induced by cardiolipin. We observe that cardiolipin promotes the formation of periodic protein–free inter–membrane contacts with rhombohedral symmetry. Membrane contacts, or stalks, promote a significant increase in oxygen gas permeation which may bear significance for alveoli gas exchange imbalance in pneumonia.

Conformable Organic Photonic Systems Tomoyuki Yokota and Takao Someya; The University of Tokyo, Japan

In this talk, I will introduce our recent activity of conformable organic photonic systems. We have developed ultra-flexible and lightweight highly efficient, ultra-flexible, air-stable, three-color, organic light-emitting diodes (OLEDs). The total thickness of the devices, including the substrate and encapsulation layer, is only three micrometers, which is one order of magnitude thinner than the epidermal layer of the human skin. Due to the very thin substrate and neutral position, our device shows the highly flexibility and conformability. The OLEDs are directly laminated on the surface of skin and are used as indicators/displays. Furthermore, we have developed ultra-flexible organic imager which consists with a monolithically processed rectifying pixel and an organic photo diode. Our organic imager has pixel pitches as small as 50 µm, with resolutions of up to 262 ppi. Using our ultra-flexible organic imager, we succeed to measure the spatial photoplethysmography (PPG) mapping.

Efficient Ultra-Flexible Photo-Charging Systems for Simultaneous Solar Energy Conversion and Storage Ruiyuan Liu¹, Masahito Takakuwa¹, Kenjiro Fukuda² and Takao Someya¹;¹ Center for Emergent Matter Science (CEMS), RIKEN, Japan; ²The University of Tokyo, Japan
Integration of high performance ultra-flexible energy harvesters with energy storage units not only provides an efficient, stable self-powered source, but also realizes a volume miniaturization with reduced thickness and wiring requirements, which is an unprecedented demand for biomedical devices and wearable electronics. The main challenge for an efficient flexible self-powered system lies in the management between the stable operation with mechanical flexibility and long-term electrical performance, the proposed research task will focus on materials design, interface engineering, device configuration and reliable packaging technologies mainly based on organic components to tackle with the latent issues. Here we report flexible integrated photo-charging devices subsequently constructed based on ultra-thin efficient organic photovoltaics and supercapacitors via advanced design and power management, achieving high overall energy conversion and storage efficiency as well as maintaining superior system operation stability and mechanical flexibility for multifunctional wearable electronics.

5:25 AM S.SM06.03.05
A High-k, Stretchable and Self-Healing Dielectric for Electroluminescent Devices Yu Jun Tan1,1, Hareesh Godaba1, Ge Chen1, Siew Ting Melissa Tan1,2, Guan Xiang Wan1, Guojingxian Li1, Pui Mun Lee1, Yongqing Cai1, Si Li1, Robert Shepherd4, John Ho1 and Benjamin C. Tee1,1; 1National University of Singapore, Singapore; 2Stanford University, United States; 3University of Macau, China; 4Cornell University, United States

Stretchable and conformable optoelectronic devices enable exciting applications in wearable electronics displays, human-machine interfaces as well as emerging soft robotics. We have developed a low-field emission electroluminescent device using a solvent processable self-healing dielectric material that exhibits high relative dielectric permittivity. Our device can be assembled facilely, which can then be stretched to 800% strain. The device also exhibits opto-healing from punctures or bifurcations. We achieved very low turn-on threshold voltages as low as 23 V, and can achieve an unprecedented electroluminescent brightness of >1000 cd m^{-2}. We further demonstrate the use of our device in soft robotics applications. Our soft, repeatable autonomous self-healing electroluminescent devices will enable applications in electronic skins and stretchable display interfaces that are easily reconfigurable, and robust to mechanical damage.

5:35 AM S.SM06.03.09
Transparent Flexible Polymer Actuator with Enhanced Output Force Enabled by Conductive Nanowires Interlayer Tony Fook1,2, Jin Han Jeon2 and Pooi See Lee1; 1Nanyang Technological University, Singapore; 2Robert Bosch (SEA) Pte Ltd, Singapore

As the role of flexible soft materials become more crucial for applications such as flexible displays in foldable mobile phones, compliant sensors and actuators in wearables, etc., new functional soft materials are needed to fill the roles previously fulfilled by rigid and bulky conventional materials. The field of haptic technology has recently seen emerging needs for integration into soft, flexible and even transparent interfaces. Since several decades ago, haptic feedback in electronic devices such as mobile phones, gaming controllers, are provided by bulky mechanical motors that vibrate the entire device upon application of an electric signal to give a tactile sensation to the users. In recent years, piezoceramics such as lead zirconate titanate are seen as a popular alternative due to its high performance and small form factor. However, their high stiffness, density and opacity prove to be a large obstacle in applications where flexibility, weight and transparency are crucial. In such applications, electroactive polymers (EAPs) serve as an excellent solution and have been a rapidly growing focus of research due to the wide range of potential applications such as energy harvesters, sensors and actuators, artificial muscles, etc. In reported methods to enhance the dielectric and electromechanical properties of EAPs, there is a compromise in at least one of these factors: electrical breakdown strength, transparency and flexibility.

In this work, we present an approach to enhance the output force of polymer actuators by increasing the dielectric permittivity and polarizability of the EAP, poly (vinylidene fluoride-trifluoroethylene-chlorotrifluoroethylene) (P(VDF-TrFE-CTFE)), by incorporation of a conductive nanowire interlayer into the polymer matrix. The interlayer is formed by a network of highly conductive silver nanowires with high aspect ratio and enhances the dielectric permittivity and polarizability of the EAP over a broad range of frequencies including ultra low frequencies (e.g. 0.1 Hz) and the range of 200 to 300 Hz at which the mechanoreceptors in the human fingertips are most sensitive to. Through experiments and finite element modelling, the enhancement of dielectric properties were found to originate from charge accumulation at the nanowire/polymer interface and resulted in an output force double that of a neat EAP actuator. The higher output force can be
used to improve tactile feedback perception of a human user and allows a 40% reduction in the actuator excitation voltage compared to that of a neat EAP actuator. Even with enhanced dielectric properties and output force, the composite actuator retains its transparency and flexibility without severe compromise in the electrical breakdown strength. The excellent transparency and flexibility of the modified EAP are promising for a wider range of possible applications such as direct and localized haptic feedback on flexible electronic displays, touch screens, etc.

Robotic Fabrics as Thin, Wearable, Fiber-Based Machines Rebecca Kramer-Bottiglio; Yale University, United States

Robot function is largely determined by the structural platform upon which it is built. The field of soft robotics aims to expand the design space by introducing unconventional robotic materials and methods to the engineering toolkit. In this talk, it is proposed that this increasing repertoire of robotic platforms be extended to include fabrics, which are known for their extreme deformability, versatility, and customizability. Possible fiber-based forms to achieve actuation, sensing, and stiffness control will be presented, including: (1) shape memory alloy ribbon as a thin-body actuator, which is effective at pure-bending motion, in contrast with typical fiber actuators that rely on axial contraction alone; (2) An in-fabric sensor that changes in resistance as the fabric weave is stretched and the gaps present between fibers are enlarged; and (3) A stiffness-changing fiber based on a glass-transition polymer epoxy with low-melting-point metallic alloy inclusions that is capable of a stiffness change of two orders of magnitude using Joule heating. By designing actuators, sensors, and structural components that conform to a fiber-based geometry, we show that simple fabrics can be functionalized to create damage-responsive tourniquets, self-deploying structures, and morphing airfoils.

5:15 AM S.SM06.04.05
A Tuneable Method of Nanostructuring Polymers as Surfaces for Tissue Growth Thomas Chalklen, Michael Smith, Matthew Sims and Sohini Kar-Narayan; University of Cambridge, United Kingdom

The biological world relies on a variety of stimuli: chemical, electrical and also mechanical. For the fields of regenerative medicine and tissue engineering, understanding these cues is an important pathway for directing tissue behaviour.

Currently however, our understanding of the effect of mechanical stimulation on cell behaviour is poor, but it is becoming clear that these cues play an important role in regulating phenotype, recently being used to direct stem cell differentiation, for example [1]. A major issue for this field remains that the stiffness of biological tissue is many orders of magnitude lower than that of bulk materials such as polymers or ceramics. Work is being done to address this stiffness imbalance, the majority through the use of hydrogels [2], but this approach has some drawbacks, as the stiffness of a hydrogel is directly correlated to its chemistry, so in order to change the stiffness we require a change in chemistry. In addition, hydrogels fail to provide routes to actively direct cell behaviour whilst in culture.

In this work we utilise template wetting to create a tuneable, low stiffness surface through the use of nanostructuring to alter the effective surface stiffness of a widely used piezoelectric bio-polymer, poly-l-lactic acid [3]. By altering the length of the resulting nanotubes, we have successfully shown a strong preference by induced Pluripotent Stem Cells (iPSCs) for higher aspect ratio, softer, surfaces, and furthermore demonstrated the long term viability of this surface for cell growth. It is concluded that this nanostructuring presents a viable, controllable route to providing appropriate mechanical stimuli. Moreover, by exploiting the piezoelectric properties of the polymer there is the opportunity for active mechanical stimulation in culture. The implementation of this mechanical control opens up new avenues for detection, characterisation and stimulation of cell mechanobiology, paving the way towards an externally addressable lab-on-a-chip device.

SESSION S.SM06.05: Bioelectronics for Tissue- and Neural-Interfacing

S-STM06

5:00 AM *S.SM06.05.02
Multi-Modal Sensors and Actuators for Biointerfacing Ivan Minev; University of Sheffield, United Kingdom

Interfaces that link biological systems with machines are increasingly evolving beyond the electrical domain. Multi-modal bioelectronics aims to add chemical, optical, thermal or mechanical functionality to the capabilities of classical electrode arrays. When such systems are used in physical contact with tissues or cells, the need for overall mechanical compliance is crucial for their biointegration. This raises a question: how do we build multi-modal arrays of sensors and actuators with tissue-like softness?

In this talk I will present our efforts to adapt direct ink writing (multi-material 3D printing) for the purpose of fabricating elastic systems of electrodes, optrodes, thermotrodes, and chemotrodes. A palette of silicones, composites and hydrogels are used as inks, where each of the inks enables one interfacing modality. As an example of in vitro application, I will present multi-modal pacing and monitoring of stem cell derived cardiomyocytes. In vivo, I will present printed neuro-muscular implants tailored to specific anatomical niches and animal models. These developments are expected to contribute to the development of personalized platforms for bioelectronic medicine.

5:15 AM *S.SM06.05.04
Brain Machine Interfaces Using Flex to Chip Bonding Eric Zhao, Marc Ferro, Tyler Chen, Pingyu Wang and Nicholas Melosh; Stanford University, United States

Enabled by new materials and device designs, a new generation of brain interface technologies is replacing bulkier, non-compliant systems with the aim of seamless electronic-biological interfaces with lower tissue damage, reduced immunogenicity, high-density, tunable spatial distribution, and long-term stability. Recent successful examples leveraging mechanically compliant materials have demonstrated major breakthrough in brain research using ultra-flexible systems for ECoGs recordings, and for depth electrodes.

However, connectorization of these ultra-flexible electrodes to traditional electronics remains a significant challenge. Current connectors, such as zero-insertion force (ZIF) devices, are limited to 64 or 128 channels at most. While these may then be stacked together this approach does not scale, limiting the maximum number of channels feasible.

Here, we demonstrate an easy to use, massively scalable connector technology. Rather than using traditional amplifier electronics, we couple thousands of flexible electrodes directly to a CMOS pixel array, such as typically found in a camera or OLED display. These devices have millions of available pixels, and by taking advantage of the small, flexible nature of the electrodes we are able to attach thousands of electrodes in seconds. These form robust Ohmic contact that can be extensively cycled. We demonstrate the simplicity of the process, and show how it can be used to perform massively parallel neural recordings.

5:30 AM S.SM06.05.05
Sono-Optogenetics: A Circulation Delivered Rechargeable Light Source for Minimally Invasive Optogenetics Xiang Wu, Xingjun Zhu, Paul Chong, Junlang Liu, Louis Andre, Kyrstyn Ong, Kenneth Brinson Jr., Ali I. Mahdi, Jiachen Li, Lief E. Fenno, Huiliang(Evan) Wang and Guosong Hong; Stanford University, United States

Understanding the complex neural circuitry and its correlation to specific behaviors requires spatially and temporally precise
modulation of neuron subtypes in certain brain regions. For decades, neural stimulation has predominantly been achieved by traditional electrical stimulation electrodes. More recently, optogenetics, which utilizes visible light to achieve neural modulation by genetically expressing microbial opsins in mammalian cells, has gained great popularity due to its rapid and precise control of neural activities and its capability of dissecting neural circuitry by selectively modulating specific neuron subtypes. However, owing to the limited tissue penetration of visible light, invasive craniotomy and intracranial implantation of tethered optical fibers are usually required for in vivo optogenetic modulation. Here, we report a new method termed ‘sono-optogenetics’, which provides minimally invasive optogenetic neuromodulation in the brain without any scalp incision, craniotomy or brain implant. Sono-optogenetics delivers nanoscopic light sources—mechanoluminescent nanoparticles—via the endogenous blood circulation, and provides millisecond-timescale switching of 470 nm light emission for optogenetic neuromodulation via brain-penetrant focused ultrasound. Furthermore, the mechanoluminescent particles could be recharged by 400-nm photoexcitation light in superficial blood vessels during circulation, enabling repetitive through-scalp optogenetic stimulation. Unlike the conventional ‘outside-in’ approaches of optogenetics with fiber implantation, our method, which combines minimal-invasive ultrasound excitation and intravenous delivery of mechanoluminescent nanoparticles, provides an ‘inside-out’ approach to deliver nanoscopic light emitters via the intrinsic circulatory system and switch them on and off at any time and location of interest in the brain. We envisage that sono-optogenetics provides a unique tool of rapid screening of different target regions in the brain for optogenetic neural modulation, owing to the ease of changing the location of ultrasound focus in the brain by eliminating fiber optic implantation. Furthermore, sono-optogenetics can be used in other regions of the central and peripheral nervous systems, as well as in other organs such as the heart and lungs, which are usually refractory to fiber implantation due to structural and functional constraints, for precise modulation with optogenetic control of cell activity. In addition, reduction of the footprint and the weight of the ultrasound transducer, as well as the use of ultraflexible neural probes with neural-tissue-like mechanical compliance, may enable sono-optogenetic stimulation of deep-brain regions with simultaneous electrophysiology in a behavioral setting. We anticipate that this approach could also be extended to applications in much deeper brain regions in larger animals owing to the penetration depth of ultrasound reaching several centimeters. The manuscript based on this work “Sono-optogenetics: a circulation delivered rechargeable light source for minimally invasive optogenetics. 5:40 AM S.SM06.05.07
Tissue Adhesive Nanofiber Membranes for pH-Responsive Delivery of Oral Therapeutics Sunil Kumar Boda and Conrado Aparicio; University of Minnesota Twin Cities, United States

INTRODUCTION
Tissue adhesive nanofiber membranes present a synchronous capability of oral tissue regeneration and bio-sensing. Natural polymers such as chitosan, pectin and their combinations have been previously characterized for mucoadhesion ex vivo [1]. On a similar note, the mucoadhesion of gecko-inspired synthetic elastomer nanopatterns was enhanced via surface coating with oxidized sugar/ polysaccharide [2]. Taking cue from the aforementioned studies, electrospun nanofiber membranes of chitosan were modified by surface coating with oxidized pectin for oral tissue adhesion. Such tissue adhesive nanofiber membranes are employed for pH-responsive delivery of oral therapeutics.

EXPERIMENTAL METHODS
Chitosan nanofiber membranes were fabricated by electrospinning a 5 wt% of chitosan dissolved in trifluoroacetic acid-dichloromethane (TFA: DCM = 70:30 v/v) solvent system. The nanofiber membranes were spin coated with 0.05 and 0.5 wt% of periodate oxidized pectin. A texture analyzer (TA-XT-plus, Stable Micro Systems) was used for recording the adhesion properties of the nanofiber membranes ex vivo to porcine oesophagus and hydroxyapatite discs representing the mucosal and enamel surfaces, respectively. The nanofiber membranes loaded with oral antibiotics/ antimicrobial peptides were evaluated for pH-responsive release in 0.1 M acetate buffers of pH = 4.5, 5.5 and 6.5 and their consequent antimicrobial activity assessed against oral pathogens (Streptococci). The cytocompatibility of similar membranes was examined using human gingival fibroblasts.

RESULTS AND DISCUSSION
The 0.05 wt% oxidized pectin coating on chitosan nanofiber membranes elicited maximum detachment force and work of adhesion to porcine oesophagus suggesting enhanced muco-adhesion resulting from the synergistic interaction of the nanofiber topography and surface aldehydes from oxidized pectin with the mucosal proteins. A higher 0.5 wt% oxidized pectin coating only enhanced the detachment force, but reduced the work of adhesion to mucosal mimic. Overall, our ex vivo mucoadhesion results are in agreement with an earlier report of oxidized dextran coating mediated improvement of...
mucoadhesion of elastomeric nanopatterns [2]. On the contrary, the uncoated chitosan nanofiber membrane exhibited the strongest adhesion to hydroxyapatite discs. The greater abundance of cationic amines (-NH$_3^+$) in pure chitosan promoted adhesion to negatively charged phosphates (-PO$_4^{3-}$) on hydroxyapatite surfaces. The in vitro cytocompatibility of the membranes was illustrated by co-culture with human gingval fibroblasts for 24 h. Lastly, the pH-responsive delivery of oral therapeutics was demonstrated via the antibacterial activity of antibiotic/antimicrobial peptide loaded membranes against Streptococcus gordonii, a primary colonizer of oral prosthesis.

CONCLUSIONS
A synergistic combination of surface topography and surface chemistry can promote the tissue adhesion properties of nanofiber membranes to hard, soft or hard-soft tissue interfaces. The pH-responsive adhesive nanofiber membranes can be utilized for pH-induced delivery of oral therapeutics.

Morphing Electronics for Growing Tissue Yuxin Liu, Jinxing Li, Shang Song, Paul George and Zhenan Bao; Stanford University, United States

Bioelectronics for modulating nervous system, such as the vagus nerve stimulator, demonstrate great promise in treating various neurological diseases. However, their fixed sizes and shapes cannot accommodate the rapid tissue growth and negatively influence normal developmental functions. For infants, children and adolescents, once the implanted devices are ‘outgrown’, additional surgeries are usually needed for device removal, followed by replacement. These tedious processes inevitably lead to repeated intervention and elevated complication rates. Although stretchable electronics with high elasticity is ideal for repeated motion and volumetric expansion of organs, they still cannot adapt to developmental tissue growth, which should not be restricted by any strain. Here, we address this limitation with Morphing Electronics (termed MorphE) which are designed and fabricated to suitably adapt to in vivo nerve tissue growth with zero strain. This is achieved by viscoplastic electronic materials (VEMs) that eliminate the stress and tissue constraint on growing tissue. In addition, water-insensitive self-healing property of the multilayered MorphE consisting of viscoplastic electrodes and a strain sensor allows fora reconfigurable platform for individualized implantation procedures. Animal study demonstrated that the soft and self-adapting MorphE showed no damage to the rat nerve after grown 2.4 times its initial diameter. This stable neural interface allowed chronic electrical stimulation and monitoring without disruption of functional behavior in developing rats. Our MorphE creates a new avenue for adaptive pediatric electronics medicine.

Wireless Photovoltaic Neuroprostheses for Artificial Vision Diego Ghezzi; École polytechnique fédérale de Lausanne, Switzerland

Neural prostheses are devices integrated with the neural tissue for diagnostic or therapeutic purposes, such as restoring impaired or lost functions. Despite a large variety of devices exists, a shared future is the presence of cables connecting the electrode-tissue interface to implantable electronic circuits for signal management. The presence of wires and connectors is a significant disadvantage for neural prostheses; in fact, they are weak points often leading to failure, they exert mechanical
forces and tractions on the implant and the tissue, and they are often trancranial or transcutaneous connections that might lead to post-surgical complications, such as infection. Also, the use of implantable electronic units is another disadvantage. Several aspects limit their operation, such as power consumption, excessive heat generation, and high risk of failure in a wet environment due to leakage.

In neural prostheses, wireless electrodes are desirable. Retinal prostheses are a particular category of neural prostheses, in which wireless neuronal stimulation was achieved thanks to photovoltaic technology, that also avoids the need for active implantable electronic units. In the case of retinal stimulation, photovoltaic technology is intuitive since the retina is made to absorb light entering from the pupil naturally. Although photovoltaic retinal prostheses do not work with ambient and natural light, electrical stimulation is triggered by artificial light projected into the pupil and absorbed by semiconductor elements embedded into the stimulating pixels. This solution allows retinal prostheses to avoid a transscleral flat cable which limits the maximum number of stimulating pixels on the device and induce post-operative complications such as eye inflammation or leakage through the incision.

In the first part of this talk, the development and validation in-vitro and in-vivo of a wide-field, photovoltaic, and injectable retinal prosthesis will be reported. POLYRETINA is a wide-field epiretinal prosthesis which contains 10,499 photovoltaic electrodes (diameter of 80 µm and pitch of 120 µm) distributed with a pixel density of 80.33 pixels mm-2. The pixels cover an active area of 12.9 mm in diameter; thus, the prosthesis covers a visual angle of 46.3 °. Each pixel is composed by a conductive polymer (PEDOT:PSS) a bulk heterojunction (P3HT:PCBM) and a metallic cathode (Ti). The results obtained electrodes (diameter of 80 µm and pitch of 120 µm) distributed with a pixel density of 80.33 pixels mm-2. The pixels cover an active area of 12.9 mm in diameter; thus, the prosthesis covers a visual angle of 46.3 °. Each pixel is composed by a conductive polymer (PEDOT:PSS) a bulk heterojunction (P3HT:PCBM) and a metallic cathode (Ti). The results obtained both in-vitro with retinal explants and in-vivo with large animal models will be reported.

In the second part of the talk, a novel visual prosthesis based on intra-neural stimulation of the optic nerve will be described. OpticSELINE is an intraneural 3D electrode array capable of selectively activating the optic nerve fibres to induce artificial vision. This technology is essential to overcome the exclusion criteria of retinal implants. The results from our in-vivo preclinical trial in large animals will be presented.

In conclusion, the use of photovoltaic technology to design novel neuroprostheses will be highlighted.

5:15 AM S.SM06.06.02
Active Shape Memory Polymer-Based Electrode Array for Minimally Invasive Electrocorticography Anastasiia Kravtcova1, Antoniya Toncheva2,3, Jean-Marie Raquez2, Pierre Lambert4 and Quan Zhou1; 1Aalto University, Finland; 2University of Mons, Belgium; 3Bulgarian Academy of Sciences, Bulgaria; 4Free University of Brussels, Belgium

Electrocorticography (ECoG) is considered a gold standard for assessing neuronal activity in patients with epilepsy prior to surgical resection of epileptogenic zone [1]. During the procedure, ECoG electrode array is places on the surface of the brain between cerebral cortex and the skull bone. Although electrodes do not penetrate the brain tissue, implantation is still invasive and requires large craniotomy, which is traumatic and uncomfortable for the patient and expensive for the healthcare system. Herein, we demonstrate a novel approach to fabricate active and biocompatible shape memory polymer-based ECoG electrode array that can be implanted into tight subdural space through the small skull opening and unfold there triggered by the body temperature. The device fabrication includes 4 steps process: (i) synthesis of biocompatible poly(ε-caprolactone) (PCL) shape memory polymer and films production [2,3], (ii) gold pattern deposition on the films surface, (iii) insulation and (iv) laser micromachining to achieve the final material design. The developed electrode array demonstrates excellent shape memory properties by unfolding from 3 mm diameter tube into 40 x 40 mm flat sheet. Mechanical properties of the device are in line with the materials used in commercial and research ECoG electrode arrays. Moreover, due to small film thickness (200 µm) and low polymer matrix stiffness at body temperature, the electrode array has a potential to conform curvy brain surface improving measurement quality. Finally, gold patterns retain their conductivity after deformation and shape recovery proving the developed ECoG electrode array has a promising potential of being employed in the minimally invasive implantation application.

Shape Morphable Hydrogel/Elastomer Bilayer for Implanted Flexible Electronics Muru Zhou, DoHyun Kang, Yi Zhu, Evgueni Filipov, Jinsang Kim and James Weiland; University of Michigan, Ann Arbor, United States

Hydrogel/elastomer bilayers have a tunable shape morphing ability, excellent flexibility and good biocompatibility. Thus,
they have been studied intensively for various applications such as wearable electronics, micro-actuators, and micro-robots. However, there are few studies of implanted electronics using a hydrogel/elastomer bilayer. Here, we fabricated a bilayer system with polydimethylsiloxane (PDMS)/polyacrylamide (PAAm). While PDMS works as the passive layer defining the motion of hydrogel, the PAAm active layer can respond to water and change the shape of the bilayer by swelling and deswelling[1].

To fabricate the bilayer, benzophenone was used to bond the wet PAAm hydrogel and PDMS with good reliability[2]. The bilayer remained integral after 72 hours in water. To demonstrate the shape morphing ability, the bilayer was rolled up into a tube and then expanded into a curved film due to swelling in water. For implantation, the shape morphing ability will create a compact structure to minimize the incision during surgery. After implantation, the device will unfurl to increase the size of the neural interface. Furthermore, the permanent 3D shape of the bilayer is tunable. Initial results showed that varying the concentrations of crosslinkers of the PAAm hydrogel allowed different curvatures to be achieved. A 25 mm long bilayer strip (thickness of PAAm: 200 μm, thickness of PDMS: 840 μm), with high monomer concentration (33.4 wt. %) and low crosslinker density (0.5 wt.%), demonstrated a curvature of 0.230 mm⁻¹. Another strip with the same dimension and a higher crosslinker density (1.3 wt.%) demonstrated a smaller curvature of 0.110 mm⁻¹. In addition to the properties of the PAAm hydrogel, the curvature also depends on the thickness ratio between the hydrogel and the elastomer layer. A bilayer bending beam model developed by Timoshenko was used to predict the curvature with different thicknesses[3]. By using the expansion ratio and elastic modulus previously reported[4][1], the result of the model showed that 1000 μm thick PDMS with 175 μm thick PAAm could achieve a bending degree of 180°. The results from the model can guide the designing of the thicknesses of the two layers.

The shape morphable bilayer will serve as a substrate for a retinal stimulating array that maximizes the size of the implanted electronics while minimizing the surgical trauma.

Optical Control of Nerves Using Organic Electrolytic Photocapacitors (OEPCs) Marie Jakešová¹, Malin Silverå-Ejneby¹, Ludovico Migliaccio¹, Oliya Abdullaeva¹, Maciej Gryszel¹ and Eric D. Glowacki¹,²; ¹Linkoping University, Sweden; ²Warsaw University of Technology, Poland

A great demand exists for nongenetic optical neuromodulation technologies. We report on our developments of ultrathin organic optoelectronic devices for neurostimulation. All of these devices rely on far red/near infrared irradiation in the tissue transparency window to actuate nanoscale organic semiconductor components. Our flagship technology is the organic electrolytic photocapacitor (OEPC) – a device that mimics biphasic current-pulse neurostimulation and thus transduces an optical signal into directly-evoked action potentials in neurons. These devices are not only wireless, but also 100-1000 times thinner than most existing technologies. Making implants with as small as possible mechanical footprint improves the efficacy of bioelectronic medical treatments by minimizing the risk for inflammation and making surgical implantation less invasive. We will present our results on pushing the limits of efficiency and stability, with benchmarking of performance using in vitro and ex vivo models, and cover our developments of peripheral nerve stimulation implants.

5:50 AM *S.SM06.06.05
Organic Mixed Conductors—Fundamental Properties and Applications Alberto Salleo; Stanford University, United States

Organic mixed ionic/electronic conductors have elicited much interest lately as the enablers of a “new wave” of organic electronic devices in the biomedical space. In this talk I will start by exploring how the microstructure of the polymer interacts with the electrolyte and the effect of the electrolyte on the characteristics of electrochemical transistors. I will then show some applications of these materials in the sensor space ranging from flexible sensors to quantify electrolytes in sweat to biomimetic sensors to determine antibiotic activity of small molecules and detect the presence of pathogens. Finally I will show how devices based on these materials can be modulated by neuron-like cells where neurotransmitters elicit both short
and long term potentiation in the device demonstrating a first building block of a new type of brain-machine interface.

6:05 AM S.SM06.06.07
A Wearable Organic Electrochemical Transistor Patch for Multiplexed Sensing of Calcium and Ammonium Ions from Human Perspiration Scott T. Keene1, Daragh Fogarty1,2, Ross Cooke1,2, Carlos Casadevall1,3, Alberto Salleo1 and Onur Parlak1,4; 1Stanford University, United States; 2Trinity College Dublin, Ireland; 3University of Florida, United States; 4Karolinska Institutet, Sweden

Wearable health monitoring has garnered considerable interest from the health care industry as an evolutionary alternative to standard practices with the ability to provide rapid, off-site diagnosis and patient-monitoring. In particular, sweat-based wearable biosensors offer a non-invasive route to continuously monitor a variety of biomarkers for a range of physiological conditions. Both the accessibility and wealth information of sweat make it an ideal target for non-invasive devices that can aid in early diagnosis of disease or to monitor athletic performance.

Here, we demonstrate the integration of ammonium (NH4+) and calcium (Ca2+) ion-selective membranes with a poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) organic electrochemical transistor (OECT) for multiplexed sensing of NH4+ and Ca2+ in sweat with high sensitivity and selectivity. The presented wearable sweat sensor is designed by combining a flexible and stretchable styrene-ethylene-butene-styrene substrate with a laser-patterned microcapillary channel array for direct sweat acquisition and delivery to the ion-selective OECT. The resulting dermal sensor exhibits a wide working range between 0.01 mM to 100 mM, well within the physiological levels of NH4+ and Ca2+ in sweat. The integrated devices are successfully implemented with both ex-situ measurements and on human subjects with real-time analysis using a wearable sensor assembly.

5:00 AM S.SM06.07.01
Self-Induced Hollow Chemiresistor Fiber With High Volatile Organic Compounds Sensitivity, Selectivity and Piezoresistivity Weiheng Xu, Dharmeevar Ravichandran, Sayli Jambhulkar, Rahul Franklin and Kenan Song; Arizona State University, United States

The detection and monitoring of volatile organic compounds (VOCs) are vital to numerous applications, such as long-term exposure to health issues, environmental protection, and chemical process control. Many previous attempts have successfully demonstrated portable chemiresistive devices on either conductive nanoparticle polymer composites or metal oxide semiconductor-based thin films. Nevertheless, composite sensors suffer from low sensitivity while thin-film sensors have limited flexibility. In this work, a carbon nanotubes (CNTs) and graphene nanoplatelets (GnP)s filled thermoplastic polyurethane (TPU) fiber sensor is investigated with engineered micro-scale multiple layers. Through controlling the solvent exchange process, a self-induced hollow core with high porosity is formed and is utilized to transport vapor flow with high VOCs/CNTs/GNPs interactions. The sensitivity is greatly enhanced, up to 60 ppm for xylene, comparing to traditional polymer composite sensors, usually over 1000 ppm. Additionally, the highly flexible polymer matrix, similar to traditional piezoresistor, enables the detection of different deformations, such as vibration at 0.3% strain, under different VOCs concentrations with distinct signal patterns. The unique multi-layer structure also provides pressure sensing application as low as 6.89 kPa (1 psi) with high reversibility. This work provides new insights on the design and fabrication of complex polymer composite structures that enable more sensitive chemiresistors with piezoresistivity behavior.

Balancing Local, Regional and Global Interactions to Direct Assembly of Engineered, Patchy Protein Particles James J. De Yoreo1,2, Shuai Zhang3,1, Robert Alberstein4, Harley Pyles2,3, Jiajun Chen4,3, Faik A. Tezcan2,3 and David Baker2,3; 1Pacific Northwest National Laboratory, United States; 2University of Washington, United States; 3University of California, San Diego, United States

Self-assembly of nanocrystals to form superlattices and mesocrystals is typically thought of in terms of colloidal forces and
liquid crystal ordering. Considerations of shape and solvent entropy dominate the controls on organization while atomic-scale details are of lesser importance due to the fairly homogeneous nature of the building blocks. Proteins offer unique advantages over inorganic particles as nanoscale building blocks, including monodisperse structures and patchy interactions that are both atomically precise and tuneable. For this reason, ordered assemblies of protein building blocks exhibit a wide range of structural motifs including 1D nanofibers and tubes, 2D lattices and 3D capsids and frameworks. Protein-based systems have the further advantage that they are readily assembled in interrogated in mild aqueous conditions, making them amenable to molecular resolution imaging techniques that provide a unique window into the assembly process. Here we report on two systems of engineered proteins. The first consists of a highly patchy 4-fold symmetric protein building block (L-rhamnulose-1-phosphate aldolase; RhuA), whose self-assembly is driven at the shortest length scale by disulphide bonds designed into four corners of the protein. By introducing a charged, atomically patterned substrate and varying charge states via solution ionic strength, we achieve simultaneous control of four different classes of interactions (covalent bonding, electrostatic surface templating, dipole-dipole interactions and desolvation-induced complexation) to yield four distinct, precisely patterned 2D crystals. The second system consists of a de novo designed rod-shaped helical repeat whose length can be set arbitrarily in units of one repeat. These MicaN proteins are designed to interact in an epixial manner with the K⁺-sublattice of mica. Variation of the design created an end-to-end hydrophobic interactions that were either dimeric at both ends or trimeric interface at one end and dimeric at the other. As with RhuA, we show that the interplay of the specific intermolecular interactions, regional electrostatic interactions and global colloidal forces lead to a variety of distinct ordered phases. In all cases, in situ AFM reveals the development of order and its relationship to protein design and surface and solution interactions. The results provide a mechanistic picture of assembly by patchy protein building blocks that links pathways and outcomes to the influence of interactions over many length scales.

5:25 AM S.SM06.07.03
Robot-Assisted Synthesis of Alternating and Random Multiblock Copolymers Based on Oligo(ε-caprolactone)/Oligotetrahydrofuran and Their Phase Morphology Marc Behl1, Maria Balk1,2 and Andreas Lendlein1,2; 1Helmholtz-Zentrum Geesthacht, Germany; 2University of Potsdam, Germany

The design of polymeric materials like multiblock copolymers (MBCs) is guided by the requirements of specific applications but demands an understanding of structure-function relationships. MBC materials provide a complex hierarchical structure. The chemical nature, the number length of integrated building blocks, as well as their sequence structure (e.g. alternating or random) impact the phase morphology. This organisation level largely influences the macroscopic mechanical properties such as deformability and the modulus. We hypothesized that a strictly alternating sequence should favour crystallization and in this way the elastic properties. Well-defined multiblock copolymers (MBCs) composed of two different hydrophobic, semi-crystalline blocks providing domains with well-separated melting temperatures (Tm;s) were thought to differ e.g. in the elongation at break just controlled by the polymer architecture of the MBC designed as strictly alternating (MBCsalt) or random (MBCsran). Accordingly, two different types of MBCs (MBCalt and MBCsran) were synthesized from the same type of precursor building blocks and compared. Three different series of MBCsalt or MBCsran were created by means of high-throughput synthesis by coupling oligo(ε-caprolactone) (OCL) of different molecular weights (2, 4, and 8 kDa) with oligotetrahydrofuran (OTHF, 2.9 kDa) via Steglich esterification whereby the blocks were designed either as macrodiol or as macrodicarboxylic acid. The maximum of weight average molecular weight (Mw) of MBCsalt of the three different series were 70,000 g mol⁻¹, 160,000 g mol⁻¹, and 190,000 g mol⁻¹ and increased with increase of the chain length of the OCL block. This increase in the maximum Mw was also observed for the series of MBCsran, where maximum Mw of 100,000 g mol⁻¹, 130,000 g mol⁻¹, and 160,000 g mol⁻¹ were obtained.

While the average phase size between the domains of the amorphous phase increased from 100 nm to 600 nm for MBCsran when the Mw increased the strictly alternating structure limited the demixing between OCL and OTHF blocks resulting in an almost constant average phase size between the amorphous phase domains with raising Mw. Comparing MBCsran a more pronounced amorphous phase separation was observed with increasing OCL block length size and was attributed to higher phase separation tendency of a mixed OCL and OTHF mixed amorphous phase. The increase in Mw of MBCs resulted in a reduced degree of crystallinity as detected by transmission electron microscopy and x-ray scattering experiments attributed a decreased phase separation tendency. When the chain length of OCL building blocks was increased, the tendency for phase separation was facilitated, which was attributed to the decrease in chain mobility within the MBCs. For MBCalt compared to MBCsran the crystallinity was lower and decrease in crystallinity with raising Mw was lower, which both was attributed to the confined crystallization in MBCalt. For all MBCs a decrease of both Tm;s associated to the melting of the OCL and OTHF domains was observed when the molecular weight increased. Tm (OTHF) of MBCs was always higher than Tm (OTHF) of MBCalt which was attributed to a confined crystalline lamella growth of OTHF incorporated in alternating copolymers. In addition, the complex modulus of MBCsalt was almost half as high when compared to MBCsran.

2020 MRS Virtual Spring/Fall Meeting, November 27-December 4, 2020, Spring Abstracts Final Program 2/3/21
In this way this study demonstrates the pronounced role of the block length and sequence structure in MBCs and enables a quantitative elucidation of the structure-function relationship when two semi-crystalline block segments are utilized for the design of block copolymers.

5:35 AM S.SM06.07.05
Optoelectronic Nature of Ampicillin to Enhance the Performance of Organic Light-Emitting Diodes Hassan Hafeez, Justin Jesuraj Periyanayagam, Dong Hyun Kim and Seung Yoon Ryu; Korea University, Korea (the Republic of)

With the exponential increase in the demand for flat-panel displays, portable electronics, and biomedical devices, considerable attention has been directed towards the fabrication of highly efficient organic light-emitting diodes (OLEDs). Several techniques and methods were presented but the single-unit phosphorescent OLEDs have demonstrated a maximum external quantum efficiency (EQE) limit of 25% without additional out-coupling aid. In order to overcome this efficiency barrier, new exotic materials are to be investigated with exceptional properties like an interfacial dipole, exciton generation, and charge balance.

Herein, we present the robust contribution of a widely used antibiotic; ampicillin in optoelectronics.\(^1\) The optimum fusion of ampicillin with Poly(3,4-ethylenedioxythiophene): poly(styrenesulfonate) (PEDOT: PSS) considerably improved the device efficiency of a single-unit green phosphorescent OLED. The charge distribution over ampicillin’s structure due to the presence of primary, secondary and tertiary amine along with the lactam ring was found to be the key parameter. The concentration-dependent analysis of the mixture (ampicillin-PEDOT:PSS) revealed that the addition of 25% ampicillin in PEDOT:PSS provided a horizontal interfacial dipole. The dipole suppressed the hole injection by lowering the work function of the anode and improved the charge balance. Moreover, the parallel arrangement of molecules facilitated the generation of J-aggregations which contributed extra excitons to the device. Consequently, the values of current efficiency (120 cd/A), EQE (35%) and power efficiency (70 lm/W) boosted by J-aggregated excitons were demonstrated, which to our knowledge are the highest reported efficiencies.\(^1\) The EQEs were analyzed using integrating sphere and variable-angle measurements, which demonstrated a Lambertian emission trend. The devices with penicillin-PEDOT:PSS were also fabricated for cross-evaluation, where the only difference in penicillin structure as compared to ampicillin is the absence of primary amine. The resulting EQE of the penicillin devices was found to be ~11% lesser than that of the ampicillin devices. This indicated that the specific molecular structure and interfacial dipole generated by ampicillin was the crucial aspect to obtain higher efficiency (EQE ~35.1%). Further, the concentration (25, 40, and 75%) and time (2 days, 1 month, and 2 years) dependent interactions of ampicillin with PEDOT:PSS, and their role in device performance was systematically investigated by analyzing the physical, chemical, electrical, and optical properties of the layers.\(^1\)

The investigation of dynamic properties using antibiotic materials such as ampicillin opens new horizons for the technical advancements in the field of optoelectronics. The work presented here provides a facile, cost-effective and nature-friendly method to enhance the efficiency of the OLED devices and has high potential to be applied in photovoltaic and biomedical devices.

5:45 AM S.SM06.07.06
Eco-Friendly Flexible Nanogenerator Based on Biowaste Squid-Pens-Extracted b-Phase Dominant Chitin Nanofiber/Polyvinylidene Fluoride Nanocomposites Pin-Yi Her\(^1\) and Jyh-Ming Wu\(^1,2\); \(^1\)National Tsing Hua University, Taiwan; \(^2\)University of California, Los Angeles, United States

Chitin nanofiber (ChNF) is one of a promising eco-friendly material because it is non-toxic, biocompatible, robust, and sustainable. It is also the most abundant marine polysaccharide. The b-ChNF is known to show piezoelectric properties due to its intrinsic molecular polarization arising from the non-centrosymmetric crystal structure. This work, we demonstrate a b-phase dominant ChNF/poly(vinylidene fluoride) (PVDF)-based flexible piezoelectric nanogenerators (PENGs) that exhibit superior electrical output. The PVDF is incorporated with ChNF to significantly enhance its piezoelectric properties. This is primarily because of the electrostatic interaction between the α-ChNF and the CH₂/CF₂ dipoles, the crystallinity of the b-
ChNF and b-PVDF are increased. The ChNF/PVDF film is characterized by scanning electron microscopy (SEM), polarizing optical microscope (POM), and peak force TUNA (PF-TUNA), x-ray diffraction (XRD), Fourier-transform infrared spectroscopy (FTIR), and Raman spectroscopy to investigate the optical and piezoelectric properties of the ChNF/PVDF film. The ChNF/PVDF film exhibits superior remnant polarization ~10.8 μC/cm².

5:55 AM S.SM06.07.08
High-Resolution 3D Printing of Soft Electrode Arrays for Electrophysiological Signals Yohan Cho1,2, Young-Geun Park1,2 and Jang-Ung Park1,2; 1Yonsei University, Korea (the Republic of); 2Yonsei-IBS Institute, Korea (the Republic of)

Electrophysiological signals of the body provide critical information to assess the functionalities of organs or to diagnose diseases. In order to detect minute biological signals effectively, three-dimensional (3D) electrodes are required to minimize the tissue-electrode impedance and to form conformal interfaces with tissues. However, conventional approaches to form 3D-structured electrodes are based on photolithographic patterning and etching, and these processes result in the low variety of 3D structures limited to certain crystallographic planes of materials. Also, the poor selectivity of materials and their high stiffness easily damage tissues and obstruct the effective signal recording.

Herein, the 3D electrode arrays composed of tissue-compatible soft metals have been formed by high-resolution direct printing. Various form factors of 3D electrodes with different heights (20 to 100 μm), diameters (5 to 30 μm) and the tip morphologies (sharpness) are printed and studied in terms of the tissue-electrode interfaces. While conventional materials for 3D microelectrode arrays have compatibility problems such as inflammation or the detachment of tissues because of a modulus mismatch, our 3D electrodes based on soft metals have Young’s modulus at least five orders of magnitude lower than that of platinum and silicon which are conventional materials for bioelectrodes. When human dermal fibroblasts are directly seeded to test the viability of the soft 3D electrodes, over 80% of cells were viable after 7 days with adhesion to the surfaces of electrodes. The improvement of signal transfer, including the signal-to-noise ratio of biopotentials and the persistency of signals at the tissue-electrode interface, can be found by an in-vitro recording of neurons directly cultured on the 3D soft electrode arrays with a comparison to the platinum-based two-dimensional electrode arrays.

6:05 AM S.SM06.07.09
Designing Nanostructured Interfaces—Focus on Shape Changes and Clustering of Nanogels Chandan K. Choudhury, Vaibhav Palkar and Olga Kuksenok; Clemson University, United States

Understanding and controlling dynamics of gels at fluid-fluid interfaces is critical for a plethora of bioinspired and biointerfaces since hydrogels can be biocompatible, compliant, and responsive to a number of orthogonal stimuli. Herein, we use Dissipative Particle Dynamics simulations to focus on the shape changes of a nanogel as it adsorbs from the aqueous phase onto the interface between two immiscible fluids effectively acting as compatibilizer. Upon adsorption at the interface, the hydrogel spreads over the interface adopting various shapes depending on its size and crosslink density. We characterize these shapes by the shape anisotropy and an effective extent of spreading. We highlight the differences between these characteristics for cubic and spherical nanogels and show that the choice of the cubic shape over the spherical one results in a wider range of topographies that could be dynamically prescribed onto the soft interface due to the gels’ adsorption. Further, we focus on the interactions between multiple gels placed at the fluid-fluid interface. We show that controlling the shapes and clustering of the gels at the interfaces via variations in solvent quality results in tailoring dynamics and topography of soft nanostructured interfaces. Hence our findings provide insights into design of nanostructured bioinspired and biointerfaces with topographies controlled externally or by the properties of the surrounding bioenvironment.

6:15 AM S.SM06.07.10
High-Performance Biocompatible MRI Contrast Agents—Exploiting Inter-Particle Interactions with Permanent and Dynamic Nanoparticle Arrays Aaron King1, Caroline Bray2, Stephen C. Hall1, Lara K. Bogart1, Sebastien Perrier1 and Gemma-Louise Davies1; 1University College London, United Kingdom; 2CSIRO, Australia; 3University of Warwick, United Kingdom

Magnetic resonance imaging (MRI) is a powerful non-invasive imaging technique, the effectiveness of which can be improved through the introduction of contrast agents (CAs). Magnetic iron oxide nanoparticles have demonstrated excellent potential in biomedicine and have been used as clinical MRI contrast agents (e.g. Feridex, Resovist), though their popularity has plummeted recently due to their low efficacy. There is therefore a real need for new contrast agents with excellent MRI contrast capabilities and good biocompatibility.

The importance of the strong interactions between neighbouring magnetic nanoparticles has been well documented when producing high performance MRI contrast agents. These interactions, and thus the anisotropy, can be increased in a number
of different ways. One such method, is via the utilisation of biopolymers, such as DNA and heparin, as templating stabilisers. However, the inherently high polydispersity of such biopolymers, means that a lack of precise control over these vital interparticle interactions. To remedy this we have exploited synthetic analogues of the naturally occurring anticoagulant heparin, to be used as a templating stabiliser in the production of iron oxide-based MRI contrast agents. This new family of negative contrast agents demonstrates excellent MRI contrast capabilities ($r_2$ values reaching 434.2 mM$^{-1}$s$^{-1}$ at 25 °C and 23 MHz, several times higher than similar commercial analogues). Such behaviour results from additional control over the polymers molecular weight and thus number of sulfonate seeding sites. This affords the opportunity to finely tune interactions between neighbouring particles and therefore the MRI properties of said contrast agents. Variable field relaxometry provided unexpected but important insights into the dynamic environment of the hydrated materials, providing reasoning for their exceptional MRI behavior. Thanks to the polymer’s templating backbone and flexible conformation in aqueous suspensions, nanocomposites appear to behave as “multi-core” clustered species, enhancing interparticle interactions whilst retaining necessary water diffusion.

The vital importance of anisotropy and the interactions between superparamagnetic nanoparticles on resulting MR contrast has been further investigated through the production of permanent 1-dimensional magnetic nanostructures. Building on the templating effects of sulfonated polyelectrolytes we discuss a novel magnetically driven one-pot synthetic strategy to produce 1-D contrast agents which boast excellent MRI capabilities.

Optimizing Bicontinuous Structure of Bijels-Derived Polymer-Hydrogel Hybrids for the Controlled Release of Different Cells Haoran Sun and Min Wang; University of Hong Kong, Hong Kong

Controlled cell release is an important strategy in tissue engineering which deliver live cells to the repair sites in human bodies with well-designed cell density and distribution that mimic targeted tissues and facilitate tissue regeneration. Bicontinuous interfacially jammed emulsion gels (“bijels”) are a new class of materials consisting of two interpenetrating continuous liquid phases. Bijels can be used as templates for fabricating bijels-derived bicontinuous structures having interconnected channels. These channels (“pores”) in bicontinuous structures can provide desired space for cell encapsulation, proliferation and migration in tissue engineering while enabling the transport of nutrients and bioactive molecules. However, pore sizes of bijels-derived bicontinuous structures are normally small. To realize their potential in tissue engineering, bijels-derived bicontinuous structures with larger pore sizes need to be made for cell encapsulation and delivery. Our research has developed new methods for fabricating bijels and bijels-derived structures. In this investigation, bijels-derived polymer-hydrogel hybrids with normal pore size (~30 μm) and large pore size (~60 μm) were produced, and human dermal fibroblasts (HDFs) and osteoblast precursor cell line (MC3T3 cells) were encapsulated in respective hybrid. The cells were encapsulated in the crosslinked alginate hydrogel (with different crosslinking degrees) of polymer-hydrogel hybrids. The hybrids were then cultured for different periods to study controlled cell release. SEM examinations showed successful fabrication of cell-encapsulated polymer-hydrogel bicontinuous structures and the degradation of alginate hydrogel during culture. The cell release process was studied using confocal microscopy and SEM. Live/Dead assay and MTT assay were also used in the studies. It was observed that live cells were locked in hybrid structures at the beginning and were gradually released since Day 1 during culture. Both HDFs and MC3T3 cells exhibited good cell viability and proliferation after their release and were able to migrate from the channels of hybrid structures to the surface of hybrids and to the outer culture plate. The two types of cells displayed different release behaviors. In the bijels-derived hybrids with small pore size (~30 μm), HDFs were released significantly slower than MC3T3 cells. The major release period of encapsulated
HDFs was 24 h later than the major release period of encapsulated MC3T3 cells. For the bijels-derived hybrids with large pore size (~60 μm), the release rates of HDFs and MC3T3 cells were similar. A possible explanation for the differences is that the sizes of cells and pores in hybrids could affect cell release. HDFs have a larger cell size (~50 μm) than MC3T3 cells (20-30 μm), which may have caused slower release of HDFs in bijels-derived hybrids with small pore size. This investigation has demonstrated that bijel-derived bicontinuous hybrid structures are a good vehicle for cell delivery in tissue engineering. By controlling the pore size of hybrid structures, the release of different types of cells could be controlled. The released live cells could proliferate well and migrate in and outside the hybrid structures.

**Poplar Reinforced Biocomposites Via Cellulose Nanofibril Modification** Xianhui Zhao, Kai Li, Daniel Rasmussen, Halil Tekinalp, Erin Webb and Soydan Ozcan; Oak Ridge National Laboratory, United States

A common material used for large-scale 3D printing is a composite consisting of acrylonitrile butadiene styrene (ABS) polymer compounded with carbon fiber (CF/ABS). However, the high cost of CF/ABS indicates a market for 3D printing with bioderived materials. Natural lignocellulosic fibers have the advantages of biodegradability, abundance, low density, low cost, and easy availability. In the present study, poplar fibers (*Populus* spp.) were modified using cellulose nanofibril (CNF) slurry (~ 3 wt% solid). The modified CNF/poplar fibers were used to reinforce ABS. The biocomposites obtained were characterized using techniques including tensile testing, differential scanning calorimetry (DSC), dynamic mechanical analysis (DMA), rheometer, thermogravimetric analysis (TGA), and scanning electron microscope (SEM). The tensile strength and Young’s modulus of neat ABS were 36 MPa and 1,901 MPa, respectively. After the addition of CNF/poplar fibers into ABS, the tensile strength and Young’s modulus of the biocomposites increased by 19% and 143%, respectively. The physical treatment of doping CNF solution on poplar fibers was found to be an effective technique to improve the thermomechanical properties of biocomposites.

S.SM06.08.06
**Blow-Spun Hybrid PEO-PCL Scaffolds with Improved Mechanical and Biological Properties** Meichen Liu and David Mills; Louisiana Tech University, United States

Tissue-engineered scaffolds play an important role in the repair or regeneration of tissues and organs. Scaffolds provide strength, stability, and support for cell and tissue development and growth. Common scaffold materials are natural and synthetic polymers, however, each one has its own limitations and different disadvantages. Interestingly, in order to promote the mechanical properties and increase the bioactivity, the composite systems composed of various sources or types of polymers can retain the advantages of each material. Furthermore, composite polymer systems have the ability to allow stem cell adhesion and differentiation and to carry drug molecules and special biological molecules, like growth factor and enzyme. Research on composite scaffolds is focused on identifying composites with enhanced mechanical properties, sustained drug-releasing capabilities and the ability to support tissue development and growth.

In this study, we produced and characterized a novel nanocomposite polymer scaffold composed of poly-ethylene oxide (PEO), polycaprolactone (PCL) and halloysite clay nanotubes (HNTs). PGS, a polymer with repeating -O-CH₂-CH₂- units, and PCL, a hydrophobic aliphatic polyester with exceptional biodegradable and biocompatible properties, were used in combination with HNTs to form nanocomposite polymer scaffolds. The nanocomposite polymer scaffold thin films were prepared by solution blow spraying, which is an easy and convenient way to make fibers and films. We characterized the structural, morphological, thermal and functional properties of these novel nanocomposite polymer (PEO-PCL-HNT) scaffolds. The nanocomposite polymer scaffolds should be biocompatible and resorbable, maintain long-term cellular viability and functionality, have the ability to induce cellular differentiation leading to complex tissue formation, have the improved mechanical properties to support cell growth and have sustained-release capabilities.

**Polysaccharide-Based Hybrid Hydrogels as Tissue Engineering Scaffolds and/or Drug Delivery System** Jinku Kim and Byungduk Kim; Hongik University, Korea (the Republic of)

**Introduction:** Hydrogels have potential in many biomedical applications such as tissue engineering and drug delivery system.² Among those, Polysaccharide-based hydrogels such as hyaluronic acid (HA) have been extensively studied for tissue engineering applications, for example cartilage tissue engineering, partly because they are involved in cellular processes such as proliferation, morphogenesis, and wound repair. A number of polysaccharide-based hydrogels were designed, synthesized by free radical polymerization and their properties were analyzed in vitro and in vivo. In this study, we hypothesized that the properties of polysaccharide-based hydrogels can be controlled and enhanced by combining with small
molecules (e.g., proteins) or large molecules (e.g., PEG-based hydrogels). To test this hypothesis, novel biodegradable polysaccharide-based hydrogels were developed by combining polysaccharides (e.g., hyaluronic acid or HA) with PEG based macromers such as PEG sebacic acid diacylates (PEGSDA) via free radical polymerization under mild conditions. Their physicochemical properties (e.g., swelling ratios) as well as biological properties were evaluated.

**Materials & Methods:** Polysaccharide-based hydrogels were synthesized by free radical polymerization under mild conditions and their properties were controlled by incorporation of proteins (e.g., collagen or growth factors) or synthetic polymers such as polyethylene glycol (PEG). Physicochemical properties and *in vitro* and *in vivo* biological properties were investigated using mesenchymal stem cells (MSCs) and rat mandibular defect models.

**Results:** The chitosan-based hydrogels conjugated with collagen and/or growth factors were well synthesized under mild conditions. Growth factors were delivered from the hydrogel systems in a controlled manner. The encapsulated MSCs showed their potential of condrogenic differentiation in vitro. The physically crosslinked chitosan-based hydrogels revealed their capability of bone regeneration on the critical-sized defects (CSD) in rat mandibular. In addition, the physicochemical properties of hyaluronic acid-based polysaccharide hydrogels can be controlled by combining them with PEG-based hydrogels.

**Conclusion:** Polysaccharide-based hydrogels with well controlled their properties can be synthesized by incorporations of additives such as growth factors or synthetic hydrogels. These hybrid polysaccharide-based hydrogels can be useful as tissue engineering scaffolds and drug delivery systems to repair or regenerate the defects in organs or tissues, caused by injuries or diseases.

A Screen-Printable pH Sensor for Smart Textiles  
Sooyoung Kim¹, Jongwon Lee¹, Minyoung Choi¹, Ju-Hee So² and Hyung-Jun Koo³; ¹Seoul National University of Science and Technology, Korea (the Republic of); ²Korea Institute of Industrial Technology, Korea (the Republic of)

Recently, wearable sensors attract tremendous interest as real-time monitoring of physiological activities or environmental conditions becomes more important for many smart devices. Screen printing of sensing materials directly on fabric could not only enhance portability but also improve productivity by enabling a roll-to-roll process. Here, we present a solid-state pH sensor formed by a reliable screen printing technique. The pH sensor consists of two patterned electrodes. One is made of polyaniline(PANI)-carbon nanotube(CNT)-agarose composite. PANI, CNT, and agarose are a pH-sensing material, a conducting filler, and a binder and matrix material, respectively. For preliminary test, the composite in a paste state is deposited by doctor blade method with thickness of 150 μm. The film shows negative dependence on pH condition: e.g. higher potential at lower pH. The other electrode is a “reference” electrode, made of Ag/AgCl thin film with ion-selective solid membrane. The resulting electrode shows similar current-voltage curves with commercial Ag/AgCl reference electrode. Finally, the compositions of PANI film as well as the conditions for screen printing such as mesh thickness, printing temperature & speed, etc. are optimized, to establish the continuous, roll-to-roll process of a pH-sensor patterned directly on fabric by the screen printing.

Synthesis and Characterization of a New Antibacterial N-halamine Coating Based on Polydopamine.  
Nadia Nazi; Sorbonne Université, France

In the presence of moisture, surfaces are an ideal support for the development of biofilms containing bacteria that can be pathogenic. This poses a real public health, economic or even environmental problems in view of the use of biocides to eradicate this phenomenon. Due to the rise of multi-drug resistant microorganism, the investigation of new antibacterial coating is extremely requested.

The goal of this study is the development of a new regenerative antimicrobial coating based on polydopamine, containing haloamine (or N-halamine) functions (>N-Cl or/and >N-Br) that have oxidative properties due to the oxidation state +1 of Cl or Br. Thus, the antimicrobial activity of N-halamines is attributable to halogen exchange reactions between N-halamines and microorganisms, leading to death of the microorganisms. N-halamines are broad-spectrum biocidal groups due to their mode of action, i.e. oxidation, bacteria should not develop resistance, unlike
The protection of surfaces with N-halamine compounds requires the immobilization of amine, amide or imine functions that will be transformed into haloamine either during synthesis or by post-treatment in the presence of NaOCl or NaOBr. The originality of this antibacterial coating is its regenerative properties. In fact, N-halamines, after contact with bacteria, can be regenerated by simple immersion of the coating in a diluted bleach recharge.

The purpose of this study was to investigate the synthesis and the antibacterial properties of a new N-halamine coating based on polydopamine (PDA). First, the formation of the PDA coating by oxidative polymerization of dopamine in aqueous solution was studied and characterized. The thickness of the deposited layer reached a constant value around 50 nm after 24 h of functionalization. Then this film was chlorinated by contact with a NaOCl solution in order to form on and into the coating chloramine functions. An amount of 10^16 at/cm^2 of chlorine was successfully grafted into the surface. Finally, the antibacterial properties of the modified PDA coating were evaluated by testing its properties toward Escherichia coli. Bacterial viability in contact with the PDA-C1 film evaluated by epifluorescence microscopy revealed promising results.

Poly(lactic acid) with On-Demand Mechanical Properties Kai Li1, Denver Mcgrady1,2, Darby Ker1, Xianhui Zhao1, Reagan Newman1,2, Matthew Rowe3, Halil Tekinalp1 and Soydan Ozcan1,3; 1Oak Ridge National Laboratory, United States; 2Pellissippi State Community College, United States; 3University of Tennessee, United States

Stimuli-responsive materials, or smart materials, has been intensively studied for decades and numerous interesting materials have been developed. Among them, materials with controllable mechanical properties have found use in a wide variety of applications including aerospace, civil applications, and implantable medical devices. However, synthetic hydrogels are the most heavily investigated. Considering its sustainability, a biodegradable polyactic acid (PLA) based free-standing film with controllable mechanical properties was developed. It was found that through chain end modification with anthracene (AN), PLA experiences a 10-fold increase in toughness with no change in tensile strength. Interestingly, after 365 nm UV light irradiation, AN modified PLA became brittle and tensile strength increased by 20%. π-π* stacking of AN groups was

NIR Triggered Upconversion Nanocomposites for Synergistic Photodynamic and Photothermal Therapy Lei Ma and Xiujun J. Li; The University of Texas at El Paso, United States

Development of near-infrared (NIR) laser triggered photo cancer therapy is highly desirable but still a big challenge. Herein, NaYF4:Yb/Er Upconversion Nanoparticles (UCNPs) was rationally synthesized through a novel low-temperature hydrothermal method, exhibiting photoluminescence emissions at the wavelength of 538, 653 and 839 nm, under 980 nm laser radiation. The UCNPs were firstly surface-modified with silanization of tetraethyl orthosilicate (TEOS) and aminopropyltrimethoxysilane (APTMS) for water solubility improvement and amine terminals decoration. Subsequently, via a carbodiimide coupling reaction, UCNPs were grafted with benzoxoxy pyrrolidine based C60 derivatives, as photosensitizers. Finally, gold nanorods (AuNRs) with localized surface plasmon resonance (LSPR) at 980 nm were synthesized, carboxy polyethylene glycol (PEG) functionalized and covalently conjugated around the UCNPs-C60 nanocomposite to obtain a multifunctional nanoplatform for photothermal therapy (PTT) and photodynamic therapy (PDT). Notably, under NIR laser irradiation, singlet oxygen was effectively generated from an upconverting photodynamic combination of UCNPs and C60, while localized hyperthermia was simultaneously induced by LSPR activity of AuNRs. The therapeutic efficacy was validated in vitro on breast cancer cell lines MCF-7 and MDA-MB-231 by various microscopic and biochemical studies under a significantly mild NIR irradiation and low dosage of the nanoplatforms. Furthermore, according to cell viability comparative analysis, such nanocomposite presents a remarkable synergistic therapeutic effect by the combination of PTT and PDT. Overall, this work provides an innovative strategy for the design and understanding of clinical
Synthesis and Surface Modification Effect of BaTiO$_3$ Nanoparticles by Sodium Oleate and Chitosan on Their Piezoresponse Force Microscopy (PFM)  
Luis M. Angelats Silva$^1$, Jose Roldan Lopez$^1$, Nikita A. Emelianov$^2$, Henry León-León$^1$ and Rudy Céspedes-Vásquez$^3$; $^1$Universidad Privada Antenor Orrego, Peru; $^2$Kursk State University, Russian Federation; $^3$Universidad Nacional de Trujillo, Peru

Spherical titanium barium nanoparticles with an average size about 100 nm in the tetragonal crystal phase were obtained by peroxide synthesis and then with formation of OH groups on its surface by hydrogen peroxide. To prevent their agglomeration and reduce the toxic effect, the surface of nanoparticles was chemically modified with sodium oleate and chitosan. Influence of surface modification by these compounds on piezoresponse force microscopy and their structure were investigated.

Laser-Induced Strong Marangoni Effect in Deformation and Manipulation of Ferrofluid  
Feng Lin$^1$, Talari Talari Vishal$^2$, Junyi Zhao$^3$, John Schaibley$^4$, Dong Liu$^2$, Zhiming M. Wang$^1$ and Jiming Bao$^2$; $^1$University of Electronic Science and Technology of China, China; $^2$University of Houston, United States; $^3$Washington University in St. Louis, United States; $^4$University of Arizona, United States

Optical manipulation of fluid or droplet has long been investigated for applications in microfluidics. The light-induced thermocapillary effect is one of the strategies in optical control of liquid. We demonstrate the laser-induced deformation of ferrofluid surfaces with ultra-violet to infra-red lasers. The surface deformation reaches the bottom and breaks the liquid, achieving the highest liquid deformation thickness for over 1000 μm. The deformation process and rupture are related to strong Marangoni effect, high laser absorption and low viscosity of ferrofluid. As applications of the laser-controlled ferrofluid, we show that a ferrofluid droplet in the capillary can be easily moved horizontally and vertically by the illumination of a laser beam. We also demonstrate that letters and patterns can be written on the black surface of ferrofluid thin film with a laser beam even with a common laser pointer. Laser manipulation of ferrofluid also makes it a controlling vehicle for varieties of liquid or droplets.

Preparation and Characterization of Nitroxide-Based Magnetic Nanoemulsions Directed toward MRI-Visible Targeted Delivery System  
Kota Nagura and Naoki Komatsu; Kyoto Univ, Japan

We have prepared various all-organic magnetic soft materials containing a cyclic nitroxide radical moiety as a spin source [1]. In this talk, we report the preparation of all-organic magnetic nanoemulsions composed of the non-ionic surfactant and the hydrophobic nitroxide radical compound [2]. The properties of the nanoemulsions have been investigated by small angle neutron scattering (SANS) and dynamic light scattering (DLS) analyses, EPR spectroscopy, and MRI method. The nanoemulsions showed high colloidal stability, high reduction resistance to ascorbic acid, low cytotoxicity and an enough contrast enhancement in the proton longitudinal relaxation time (T1)-weighted MR images in (-)-PBS in vitro and in vivo. Furthermore, an additional hydrophobic anticancer drug such as Taxol® was simultaneously encapsulated inside the nanoemulsions. We expect that the drug-loaded nanoemulsions can be used as a biocompatible magnetic drug carrier for MRI-visible targeted delivery system.

One-Pot Synthesis of Highly Water-Soluble Iron Oxide Nanoparticles with Functional Groups in Polyols for T1-Weighted MRI  
Pohlee Cheah, Paul Brown and Yongfeng Zhao; Jackson State University, United States

The direct synthesis of water soluble iron oxide nanoparticles with both controlled size and functional groups on the surface has gained intensive interests. In this study, ultrasmall iron oxide nanoparticles (IONPs) with different functional groups were successfully synthesized via one-pot synthesis. The IONPs are prepared by first thermal decomposition of iron acetylacetonate Fe(acac)$_3$ precursor in diethylene glycol (DEG), followed by mixing the surface ligands at the end of the reaction. This facile synthesis method enabled binding of different surface materials such as dopamine hydrochloride (Dopa),
polyethylene glycol with thiol end group (thiol-PEG), and polyacrylic acid (PAA) onto the IONPs. The size growth of IONPs
can be well controlled as evidenced by transmission electron microscopy (TEM) studies. The high water stability of
nanoparticles was correlated with the change of hydrodynamic size and zeta potential. While TEM results showed no
significant change in the nanoparticles core size before and after surface modification, hydrodynamic size slightly increases
due to the presence of ligands molecules on the surface. The attachment of surface ligands was studied by FTIR and TGA.
FTIR results indicated the corresponding functional group for each surface ligands as a result of surface modification. In
addition, we confirmed the introduce of functional groups by bioconjugation of fluorescence dyes on to the surface. The
magnetic resonance phantom study show that the resulted nanoparticles can be used for T1-weighted MRI imaging. The
effect of surface ligands on the relaxivities of IONPs were also studied.

Activation of Electro cured Bioadhesives Using DC and AC for Electroceutical Therapies Manisha Singh and Terry W.
Steele; Nanyang Technological University, Singapore

Stimuli sensitive adhesives can be cured with temperature, UVA, and voltage. However, heat and light cured adhesives are
limited to heat-sensitive and transparent substrates. Electrochemically mediated adhesive curing (i.e. electrocuring) can be
utilized on a wide range of substrates including heat- sensitive and opaque surfaces. When an applied voltage potential is
raised above a certain threshold, voltage activation initiates the diazirine groups to crosslink neighboring surfaces. Under the
influence of direct current (1-3 mA), electrocuring progresses from the cathode to the anode but the maximum migration of
the electrocuring is limited to 60-70% of the surface area. The application of alternating current (AC) is hypothesized to
improve the electrocuring progression resulting in 100% surface activation, with a subsequent improvement in material
properties. Structure-activity relationships of DC vs. AC currents are evaluated for the migration rate, shear modulus,
gelation time, and adhesion strength of Voltaglue. Complete progression is achieved under AC stimulation and the maximum
bioadhesion strength achieved for AC is 33 % higher than that for DC stimulation.

Switchable Protein Interfaces for Controlled Assembly of Biomaterials Dominic J. Glover; University of New South
Wales Sydney, Australia

The fabrication of nanoscale devices requires architectural templates on which to align functional molecules in complex arrangements. Nature has met this challenge of nanofabrication by exploiting the remarkable ability of proteins to self-assemble into ordered and intricate nanostructures. Protein assemblies in nature can also serve as inspiration to build novel material templates with defined size and symmetry. Furthermore, control over assembly and disassembly processes of protein nanostructures will enable dynamic protein devices to be created that can sense and respond to specific input signals. This presentation will highlight recent engineering of modular protein subunits whose assembly and disassembly can be controlled to create novel biomaterials, including electrically conductive protein nanowires.

The central protein building block in our approach is gamma-prefoldin (gPFD), a filamentous protein chaperone from a hyperthermophilic archaeon. The protein-protein interfaces of gPFD were redesigned with helical sequences to create unique subunits that assemble into filaments through orthogonal dimeric coiled coils. Subsequently, these multicomponent filaments could be used to position and align functional enzymes. To gain switch-like control over the assembly process, post-translational modification systems were exploited to regulate the binding kinetics of coiled coils. By placing protein kinase recognition motifs in the interface of synthetic coiled coils of varied sequences, we could in vitro phosphorylate the coiled coils and thereby modulate electrostatic interactions. These engineerable protein interfaces are now being applied to control the assembly and disassembly of protein nanostructures. In one example, we aligned cytochrome c proteins on gPFD filaments to create metalloprotein nanowires. Electrochemical transport measurements indicated the nanowires could conduct current between electrodes at the redox potential of the cytochromes, and subsequently be used to interface with enzymes. The ability to control protein interactions will allow the design of smart protein devices capable of sensing inputs such as enzymatic activity, for applications in the disassembly of nanocages for drug delivery and new types of biosensors.

5:15 AM S.SM07.01.02
Biotemplated Carbon Nanofibers for Chemical and Biological Defense Krystina L. Hess1, Jifa Qi2,3, Michael Kim1, Greg Peterson1, Angela Belcher2,3, and Jared DeCoste1; 1U.S. Army Combat Capabilities Development Command Chemical Biological Center, United States; 2Koch Institute for Integrative Cancer Research, United States; 3Massachusetts Institute of Technology, United States

The nanomaterials field is rapidly evolving as scientists and engineers attempt to solve increasingly complex problems. Researchers are focused on the synthesis of new materials, assembly into higher order structures, improving consistency of materials properties, and synthesis at large scales. One area of increasing interest for creating new materials is biotemplating, an approach that uses a biological molecules, such as DNA or viruses, as scaffolds for deposition of materials of interest. This strategy has several notable advantages, including the exploitation of unique morphologies, the possibility of genetic engineering, and rapid and sustainable production at large scales. The M13 bacteriophage, in particular, is an attractive template for synthesizing nanomaterials and facilitating self-assembly.

Bacteriophages, or phages, are viruses that infect bacteria and replicate by coopting the cellular machinery. The phage genome can be genetically engineered to induce the display of specific surface proteins that may promote binding of a wide variety of molecules. This programmable functionalization makes phages an attractive template for nanotechnology applications ranging from batteries to vaccine carriers. The M13 filamentous phage is of particular interest due to its nanofiber-like shape and the high copy number (~2,700) of the pVIII major coat protein present along the 900 nm length, presenting many locations for material interactions. This particular phage is well studied and characterized, and can be easily manipulated on the genomic level due to its simplicity.

We have designed a novel, biorenewable, bacteriophage-templated, carbon-based material with a very high surface area (up to 2000 m²g⁻¹) and tunable porosity. The M13 filamentous phage was first used to create a resin-like material by adding resorcinol and formaldehyde. The incorporation of benzoxazine chemistry into this process results in the formation of uniform resorcinol-formaldehyde (RF) nanofibers and allows for the incorporation of heteroatoms and functional groups that can promote material binding. RF resins can serve as precursors for mesoporous carbon aerogels with controllable porosity and particle size. Carbon materials have been explored for many applications, including filtration of small molecules and gas storage, due to their high surface area and microporous structures. To create a material with these features, resin-coated phage were burned at a high temperature, resulting in "carbonized" nanofibers, termed BioCNFs. The desirable structure and surface area of the BioCNFs were confirmed by transmission electron microscopy and nitrogen isotherms, respectively. The material properties of BioCNFs could be tailored to specific applications by adjusting the precursor composition and carbonization temperature. Micro-breakthrough testing of BioCNFs revealed a high adsorption capacity for and neutralization activity against a range of chemical warfare agents (CWAs) and toxic industrial chemicals (TICs). Remarkably, this
performance either met or exceeded that of current state-of-the-art materials such as activated carbon and metal organic frameworks. This capability can be harnessed for military or industrial applications in part due to the ability of BioCNFs to be integrated into a variety of materials ranging from decontamination wipes to gas masks.

Biosynthesis is on track to revolutionize the way new materials are developed. The biotemplating method is gaining traction because a biological material can be manipulated to promote certain properties and binding capabilities. BioCNFs, created from the biotemplating of phage, can be grown in a biorenewable manner and can be easily engineered to address emerging chemical and biological threats. Future studies with this material will focus on further optimization for chemical filtration and development of gas storage capabilities.

5:25 AM *S.SM07.01.03
Bioinspired Synthesis of Hybrid Materials through Peptoid-Based Approaches Chun-Long Chen; Pacific Northwest National Laboratory, United States

In nature, biominerals (e.g. bones and teeth) are outstanding examples of hierarchically-structured hybrid materials whose formation and functions are controlled over multiple length scales by high information content biomacromolecules. Inspired by these feats of nature, many biomimetic approaches have been developed for the preparation of nanostructured hybrid materials. These approaches are attractive because they generate complex, functional nanomaterials under mild aqueous synthetic conditions. Despite the advances in developing bioinspired materials synthesis approaches, the rules of designing sequence-defined molecules that lead to the predictable synthesis of hybrid materials are unknown.

One of the most advanced classes of sequence-defined protein-mimetics are peptoids. They offer unique opportunities for producing complex architectures with tunable functions based solely on sidechain chemistry. In this presentation, two peptoid-based approaches for controlled synthesis of hierarchically-structured hybrid materials will be discussed. The first involves the design and synthesis of surfactant-like amphiphilic peptoids for controlling formation and morphogenesis of inorganic nanomaterials. The second approach exploits self-assembling peptoids for controlled synthesis of hierarchically structured hybrid materials. A combination of in situ imaging and molecular simulations were used to elucidate the principles underlying peptoid-controlled synthesis of hybrid materials with the ultimate goal of enabling predictive materials synthesis across scales.

Directed Discovery of Short Peptide Modules for Assembly, Recognition and Reporting Rein Ulijn; CUNY Advanced Science Research Center, United States

We are interested in how functionality emerges from sequence in ensembles of very short peptides, and subsequently how these functions can be incorporated into functional materials. Instead of using sequences known in biological systems, we use unbiased computational and experimental approaches to search and map the peptide sequence space, which has provided new families of functional short peptides. The talk will focus on our latest results in three areas. First, we will demonstrate how to program molecular order and disorder in tripeptides, and how the conformations adopted by these peptides can be exploited to regulate assembly properties, and give rise to tunable emission in the visible range. Second, we will demonstrate how dynamic exchange of peptide sequences can form adaptive libraries that provide insights into peptide sequences that can complex ligands. Finally, we discuss peptide-based melanin mimics with tunable chromophoric properties that are achieved through oxidative incorporation of amino acids.

**Bioinspired Humidity Driven Peptide Materials** Roxana Piotrowska1,1, Travis Hesketh2, Xi Chen1,3 and Rein Ulijn1,1; 1City University of New York, United States; 2University of Strathclyde, United Kingdom; 3The City College of New York, United States

While natural functional materials offer exceptional mechanical properties and reversibly respond to various stimuli, engineering their analogs with tunable properties remains challenging mainly due to complexity. Here we take advantage of bottom-up assembly to develop tunable peptide based materials that reversibly change their structure in response to applied stimulus. To do so we propose the use of simple tripeptide crystals as biocompatible, cheap and tunable materials which have significant responses to changes in relative humidity (RH). We selected tri-peptide sequences that contain hydrophobic - YF dyad, and charged amino acid. Using RH controlled Atomic Force Microscopy (AFM), Fourier-Transform Infrared Spectroscopy (FTIR), Powder X-ray Diffraction (PXRD) and Molecular Dynamics Simulations (MD) we observed that these supramolecular tri-peptide assemblies form three-dimensional, porous crystal networks that undergo reversible shape change in response to applied RH.

We demonstrated sequence-dependent performance allowing for tuning such properties as stiffness (0.5-2GPa), strain (3-25%), energy density (10-100kJ/m³) or pore size. The modulation of peptide-sequence dependent properties help us identify key parameters that contribute to functionality during transition processes, such as dual network domains, the importance of structured water and strengthening of hydrogen bonds, hierarchical order, order/disorder domains and intrinsic porosity. Due to their intrinsic order, short-peptide crystals are an excellent platform to investigate the fundamental understanding of the relationship between function and structure. We believe that these findings open up a magnitude of possibilities for programing simple, bioinspired peptide materials.

6:00 AM S.SM07.01.07
**Bioinspired Manufacturing of Molecular Composites for Critical Technologies** Melik C. Demirel, Sezin Sayin and Oguzhan Colak; The Pennsylvania State University, United States

Recent advances in nanotechnology of two-dimensional (2D) layered materials combined with parallel improvements in biotechnology and synthetic biology demonstrated that more complex composites materials with properties engineered precisely to optimize performance could be achieved. We propose to create functional programmable materials with user defined physical properties from composites of 2D-layered materials and polymeric proteins [1]. Our approach is based on an ultra-fast microscopy technique to screen molecular morphology of polymeric proteins [2]. These proteins have several advantages as programmable materials [3]: (i) their chain length, sequence, and stereochemistry can be easily controlled, (ii) their molecular structure and morphology is well-defined, (iii) they provide a variety of functional chemistries for conjugation to 2D materials, and (iv) they can be designed to exhibit a variety of physical properties. The variability of the amino-acid sequences in the polymeric proteins, which will dictate the degree of crystallinity and alignment of the protein layers, are used to control the interactions at the 2D material/protein interface, ultimately dictating the functional physical properties (e.g., electrical resistivity and thermal conductivity) of novel materials and devices. 6:10 AM *S.SM07.01.10
**Bioengineering and Processing of Spider Silk Proteins for Technical and Biomedical Applications** Thomas Scheibel; University of Bayreuth, Germany

Proteins reflect one fascinating class of natural polymers with huge potential for technical as well as biomedical applications. One well-known example is spider silk, a protein fiber with excellent mechanical properties such as strength and toughness. We have developed biotechnological methods using bacteria as production hosts which produce structural proteins mimicking the natural ones. Besides the recombinant protein fabrication, we analyzed the natural assembly processes and we have developed spinning techniques to produce protein threads closely resembling natural silk fibers. In addition to fibers, we employ silk proteins in other application forms such as hydrogels, particles or films with tailored properties, which can be employed especially for biomaterials applications.

Our bio-inspired approach serves as a basis for new materials in a variety of technical as well as biomedical applications.

Spider silk fibers show excellent mechanical properties such as a combination of strength and elasticity yielding a so far
unreached fiber toughness. Such fibers can be used e.g. in various textile applications. In biomedical applications the performance of materials largely depend on their surfaces and is further strictly related to the materials biocompatibility. Often the appearance of unwanted side effects hampers the applicability of biomaterials including foreign body responses and inflammation, and interaction of cells with a material’s surface, for example cell adhesion. In case of implants or catheters cell adhesion plays a crucial role for the overall function of the to-be-used material. To change the properties of in-use polymers and to adopt their biocompatibility, we established coatings based on engineered spider silk proteins. All kinds of polymers (polyurethane, polytetrafluoroethylene, silicone) have so far be stably coated with recombinant spider silk proteins, which can themselves be functionalized. Several parameters of the silk proteins can be easily adopted to the intended application, including the surface net charge, hydrophilicity etc. Several cell types, including HaCaT keratinocytes (epidermal cells), B50 neuronal cells, C2C12 myoblasts (muscle cells) and BALB/3T3 fibroblasts (connective tissue), exhibit low or no adhesion on the silk-coated materials. In an vivo study in Sprague-Dawley rats, silk coatings diminished the risk of side effects of silicone breast implants such as fibrosis.

Drug delivery systems allow tissue / cell specific targeting of drugs in order to reduce total drug amounts administered to an organism and potential side effects upon systemic drug delivery. Spider silk proteins represent a new class of (bio)polymers that can be used as drug depots or drug delivery systems. A recombinant polyanionic spider silk protein, which can be processed into different morphologies such as particles, films, or hydrogels, has been shown to fulfil most criteria necessary for its use as biomaterial. Further, such particles have been shown to be well-suited as drug carriers for polycationic or neutral drugs, but cellular uptake of such particles is low.

Spider silk hydrogels can also be employed as new bioinks for biofabrication. Their elastic behavior dominate over the viscous behavior over the whole angular frequency range with a low viscosity flow behavior and good form stability. No structural changes occur during the printing process, and the hydrogels solidify immediately after printing by robotic dispensing. Due to the form stability it was possible to directly print multiple layers on top of each other without structural collapse. Cell-loaded spider silk constructs can be easily printed without the need of additional cross-linkers or thickeners for mechanical stabilization. Encapsulated cells show good viability in such spider silk hydrogels.

Degradable Hydrogels for Ocean Sensing Jennifer M. Boothby and Zhiyong Xia; Johns Hopkins University Applied Physics Lab, United States

Traditionally, ocean salinity and temperature are measured using Conductivity, Temperature and Depth (CTD) sensors. CTDs are relatively large, rigid devices that are negatively buoyant. These CTDs are expensive and prone to marine biofouling (esp. for the conductivity probes), which greatly reduces the durability of these systems. Velellas are a subclass of jellyfish that live on the ocean surface. Velellas are often also called sailors-by-the-wind since their biological sails mimic conventional boat sails. Inspired by the Velellas, we proposed to develop a unique Velella Sensor system based on biodegradable hydrogels that can measure ocean surface temperature, salinity and indirectly, the winds at the ocean surface via Global Positioning System (GPS)-tracking.

Here, we report a cost effective approach for making the biodegradable hydrogels for this application. Our approach uses click-chemistry to tailor the molecular structure of polyethylene glycol (PEG) hydrogel networks in order to control the mechanical properties and degradation time. Oligomer chains were built by base catalyzed thiol-Michael addition reactions between acrylates and thiols, where the end groups are controlled by the molar ratios between the reactants. The molecular weight of oligomer chains of varying monomer ratios and monomer weights is measured by dynamic light scattering, and the ester group content is measured by Fourier Transform Infrared Spectroscopy. The oligomer chains were crosslinked by radical polymerization, yielding either thiol-ene networks from thiol-capped chains or acrylate-capped chains. Tensile tests were used to determine the effect of varying these chemistries on mechanical properties, and degradation tests were carried out in both deionized water and artificial seawater. The method of crosslinking affects the degradation profile of the networks though the oligomer compositions are nearly identical. Importantly, the size and composition of the degradation products are characterized by dynamic light scattering and nuclear magnetic resonance to confirm sufficient degradation occurs and safe byproducts are released. Effects of molecular weight between crosslinks on the lower critical solution temperature of the hydrogels and the impacts on degradation were also addressed. Further research will include deployment of these hydrogels in ocean environments to determine the susceptibility to biofouling and the actual ocean lifetime.

6:35 AM S.SM07.01.16
Automating Micro-Rheology Using Differential Dynamic Microscopy, Robotic Liquid Handling and Machine
**Learning** Rhett L. Martineau¹, Jeremy Kemball¹, Kristofer G. Reyes², Matthew E. Helgeson³ and Maneesh K. Gupta⁴; ¹UES, Inc/Air Force Research Laboratory, United States; ²University at Buffalo, The State University of New York, United States; ³University of California, Santa Barbara, United States; ⁴Air Force Research Laboratory, United States

Differential dynamic microscopy (DDM) is a micro-rheology technique that enables parameter-free estimation of the mean-squared displacement of tracer particles embedded in a test medium. The mean-squared displacement of tracer particles is a bridge to important rheological information including the complex shear modulus and thus DDM provides an avenue to truly automated and potentially high-throughput micro-rheology.

In this presentation, we discuss an automated pipeline based on DDM which incorporates robotic liquid handling and machine learning. We present the utility of the pipeline in two case studies. First, we show how a complex, multi-parameter gel point formulation space of silk hydrogels can be objectively navigated and characterized. Second, we present results of high-throughput viscosity measurement of pre-polymers and polymer melts in non-aqueous solvents. We discuss challenges to automation including the mitigation of bulk drift in samples prepared using liquid handling robots, quality control in the face of numerous automation failure modes, and issues encountered in generalizing hardware and analysis over broad time scales and sample chemistries.

**Accelerating Antibody Discovery with Cell-Free Systems** Andrew Hunt and Michael Jewett; Northwestern University, United States

The COVID-19 pandemic has highlighted the need for rapid, high-throughput, and robust therapeutic antibody screening platforms. Advances in both synthetic selections and antibody repertoire mining have enabled the rapid identification of hundreds of candidate binders in a single experiment. However, the expression and evaluation of these candidate antibodies still remains a major bottleneck in the discovery pipeline due to labor intensive steps and process throughput mismatches. In this work, we present a newly developed workflow that leverages cell-free protein synthesis (CFPS) and an Echo® 525 acoustic liquid handler to enable the expression and evaluation of hundreds of antibodies in a single experiment. Our workflow consists of a cell-free DNA assembly step to generate antibody expression templates, a modified E. coli CFPS system to express antibodies, and the AlphaLISA protein-protein interaction assay to evaluate binding. Each step of this workflow can be carried out entirely within 384-well plates without ever going into cells, making it highly suitable for automation. The resulting platform is capable of evaluating more than an order of magnitude more antibody candidates in less than half the time when compared to state-of-the-art antibody discovery pipelines. To validate the platform, we expressed 13 different human antibodies, 12 of which neutralize the SARS-CoV-2 virus. We evaluated these antibodies by mapping their target epitopes and evaluating their ability to compete with ACE2, the SARS-CoV-2 target human receptor. Our results are largely consistent with published literature on these antibodies, indicating our workflow is suitable for identifying therapeutic candidates. We expect that these advancements will accelerate antibody discovery and development not only for viral diseases like COVID-19, but for the entire antibody industry.

7:00 AM S.SM07.01.20

**Cell-Free Synthetic Biology Chassis for Nanocatalytic Photon-to-Hydrogen Conversion** Elena A. Rozhkova¹, Peng Wang², Valentyn Novosad¹ and Richard D. Schaller¹,³; ¹Argonne National Laboratory, United States; ²Shandong University, China; ³Northwestern University, United States

We demonstrated synthetic use of biology cell-free expression chassis for the design and assembly of an entirely man-made energy transformation nano-bio hybrid assembly. Similarly to a natural light-driven proton pump bR from H. salinarium, the pump bRsyn in artificial purple nano-membranes was integrated with TiO2 semiconductor nanoparticles, yielding a catalytic assembly for photon-to-hydrogen conversion. The system produces H2 at a turnover rate of 240μmol of H2 (μmol protein)−1 h−1 under green and 17.74 mmol of H2 (μmol protein)−1 h−1 under white light at ambient conditions, in water at neutral pH with methanol as a sacrificial electron donor. While the cell-free expression technique has been successfully developed as a handy approach for rapid high fidelity production of membrane proteins for fundamental structure–functional studies, cell-free methodology can become a useful flexible platform for on-demand expression of natural and designed light-responsive membrane architectures with precisely controllable structure, nanoscale dimensions, and photochemical properties. Such biological building blocks can be consequently integrated with semiconductor nanoparticles via systemic manipulation at the nanoparticle–bio interface toward directed evolution of energy nanomaterials and nanosystems.

ACS Nano 11, 6739−6745 (2019)
Living Materials with Programmable Functionalities Grown from Engineered Microbial Co-Cultures

Tzu-Chieh Tang1,1, Charlie Gilbert2,2, Wolfgang Ott2,2, Brandon Dorr1,1, William Shaw2,2, Timothy K. Lu1,1,1 and Tom Ellis2,2; 1Massachusetts Institute of Technology, United States; 2Imperial College London, United Kingdom

Genetic engineering enables new engineered living materials (ELMs) that harness the remarkable properties of nature to sense and respond to their environment. Bacterial cellulose (BC) is a natural biological material with impressive physical properties, high natural yield and low cost of production that is an attractive substrate for ELMs. Here, inspired by the ‘symbiotic culture of bacteria and yeast’ (SCOBY) used to make fermented kombucha tea, we describe a variety of novel BC-based ELMs containing yeast cells programmed to perform chosen functions. This is achieved via a synthetic SCOBY (Syn-SCOBY) approach that uses a stable co-culture of the model yeast *Saccharomyces cerevisiae* with BC-producing bacteria *Komagataeibacter rhaeticus*. We show that co-cultured yeast can be engineered to secrete enzymes into BC, generating autonomously grown catalytic materials and enabling DNA-encoded modification of BC bulk material properties. We further developed a method for incorporating *S. cerevisiae* within the growing cellulose matrix, creating living materials that can sense chemical and optical inputs. This enabled the growth of living sensor materials that can detect and respond to environmental pollutants, as well as living films that grow images based on projected patterns. Starting with only engineered cells and simple culture media, this novel and robust Syn-SCOBY system empowers the sustainable production of BC-based ELMs with genetically programmable properties under mild conditions.

Photosynthetic Bacterial Reaction Center for Electrode Biointerfaces

Gianluca M. Farinola1, Roberta Ragni1, Francesco Milano2, Danilo Vona1, Gabriella Buscemi1,2 and Massimo Trotta2; 1University degli Studi-Bari Aldo Moro, Italy; 2National Research Council, Italy

Photoenzymes are the specialized component in photosynthetic organisms able to perform light transduction into charge separated states. As natural photoconverters that harvest light by photoactive antennas, generating electron-hole pairs and tunnelling electrons in precise biochemical pathways, they can be exploited for biodiodes scaffolds [1-2]. In this frame, the engineering of bioelectronic frameworks have the upmarket asset to be considerate as an eco-friendly and scalability technology, using one of the greenest energy source available to us, sunlight, to gain other forms of useful energy. Therefore, the possibility of taking advantage of this unmatched photoconversion efficiency to create functional nanomaterials and bio-hybrid devices is very attractive[3].

The implementation of these unique biological systems into nanostructures or anchoring on devices electrode surfaces require the development of suitable chemical manipulation, because an efficient interfacing with electrodes for electronic applications still represents an issue. To overcome this problem, which limits the performance and applicability of photoenzymes-based technology, several attempts have been undertaken, focusing on the deployment of soft organic materials that can boost the bio-electrode interface. With this aim photoenzymes have been embedded in liposomes [4], giant vesicles [5] and polymersomes [6]. Moving forward, soft material with conductive and tunable features have been tested [7-8] to improve the energy extraction by photosynthetic proteins and the communication between the biological and electronic components in hybrid devices, that will be addressed in this presentation.

7:30 AM S.SM07.01.23
Interfacing Photosynthetic Bacteria with Soft Materials  Danilo Vona¹, Gabriella Buscemi¹², Mariangela Cantore², Marco Lo Presti¹, Roberta Ragni¹, Francesco Milano², Gianluca M. Farinola¹ and Massimo Trotta²; ¹Università degli Studi di Bari Aldo Moro, Italy; ²Consiglio Nazionale delle Ricerche, Italy

Photosynthesis is the most important metabolic process taking place on Earth. It converts solar energy in many other forms of energy that are used to fuel virtually all other forms of life on our planet. Two forms of photosynthesis are known: oxygenic, developed more recently on Earth and widespread on the entire globe, and anoxygenic, very ancient and limited to small ecological niches. Notwithstanding what would resemble a drawback for its exploitation, anoxygenic bacteria are sturdy, very adaptable and thrive in environmental conditions that would not be accessible to other photosynthetic organisms [1,3]. Anoxygenic photosynthetic bacteria have often been used in combination with several soft materials, including biocompatible polymers[4] and conductive hydrogels[5], for various applications in the field of energy conversion [6]. The most recent results relative to the intimate interface between the whole photosynthetic bacteria, in particular the species Rhodobacter sphaeroides, its mutant strains, or portion of the bacteria will be addressed in this presentation.

7:40 AM S.SM07.01.24
Engineering Interfaces of Nanomaterials with Living Bacteria  Hong Dong, Deborah A. Sarkes, Jessica L. Terrell, Justin P. Jahnke, Meagan C. Small, Margaret M. Hurley and Dimitra N. Stratis-Cullum; CCDC Army Research Laboratory, United States

The ability to control the interactions between bacteria and materials is fundamental for creating living hybrid systems as well as pathogen anti-adhesion. Herein we discuss our work in tuning the abio-bio interfaces for binding nanomaterials to living bacteria either through genetic engineering or through material functionalization. In the first study, living bacteria/nanoparticle hybrids were prepared by genetically controlling binding peptide displayed on bacterial surfaces. Escherichia coli (E. coli) was engineered with inducible gene circuits to control display of peptides on bacteria with desired sequences. Driven by metal-peptide affinity, nanoparticles such as gold or magnetic nanoparticles could self-assemble onto the bacteria with programmed peptides. Peptide-mediated binding of gold nanoparticles to E. coli showed enhanced microbial fuel cell power generation. In the second study, cellulose nanofibrils, a biocompatible and easily modified nanomaterial platform, were chemically functionalized with mannose derivative to be used as a new tool in the control of bacterial pathogenesis. The functionalized nanofibrils were able to regulate fimbriated E. coli association due to strong affinity between mannose grafted on nanofibrils and FimH receptor on E. coli. These bioactive nanofibrils demonstrated the capability of capturing fimbriated E. coli as well as significant inhibition of E. coli adherence to mannosylated surfaces.

7:50 AM S.SM07.01.26
Chemical Mechanical Nano-Structuring Implementation on Titanium Based Implants to Control Biocompatibility  G. Bahar Basim, Kimberly Beers and Debashish Sur; University of Florida, United States

Nano-scale modification of macro-scale 3-dimensional implantable devices is gaining more attention as the cell attachment/detachment mechanisms at the bio-interfaces are profoundly affected by the nanoscale interfacial interactions [1]. Titanium-based biomaterials are widely used for dental prostheses, orthopedic devices, and cardiac pacemakers. Titanium and its alloys are most favored for hard tissue replacement due to their excellent mechanical properties and surface characteristics promoting biocompatibility due to the spontaneous formation of a thick oxide layer in the presence of an oxidizer. This study focuses on the development of a three-dimensional chemical mechanical nano-structuring (CMNS)
In an alkaline media (pH = 10), the swelling ratio was ~35 independent of (AATris) and the non-glucose-sensitive crosslinker methylenebisacrylamide (BIS) was created. In this primary network stimulation by a porous cryogel structure and by implementing temporary netpoints which are cleavable by glucose.

form the semi-IPN. The boronic ester bonds, which can be reversibly formed between the PBA groups on linear chains and linear copolymer poly(AAm-co-AAPBA) from AAm and the triol groups provided by AATris act as the reversible crosslinks to fix the temporary shape.

We hypothesized that glucose-sensitive shape-memory hydrogels can be created by minimizing the volume change upon order to create a bio-induced shape-memory effect.

Physical signals have been used to control the degree of swelling or to induce a shape-change in hydrogels. Taking in view potential future application of soft materials in life sciences more specific responsivities to biological signals are desirable. Chemical and physical sensors for glucose have been explored extensively motivated by device developments for diabetes treatment [4]. Here we aim at integrating glucose sensitive chemical moieties into hydrophilic polymer networks in order to create a bio-induced shape-memory effect.

We hypothesized that glucose-sensitive shape-memory hydrogels can be created by minimizing the volume change upon stimulation by a porous cryogel structure and by implementing temporary netpoints which are cleavable by glucose.

Our concept for the glucose sensitive bases on a semi-interpenetrating network (semi-IPN) architecture. A primary copolymer network poly(AAm-co-AATris-co-BIS) from acrylamide (AAM) and N-[Tris(hydroxymethyl)]methylacrylamide (AATris) and the non-glucose-sensitive crosslinker methylenebisacrylamide (BIS) was created. In this primary network linear copolymer poly(AAm-co-AAPBA) from AAM and m-acrylamido phenylboronic acid (AAPBA) was immobilized to form the semi-IPN. The boronic ester bonds, which can be reversibly formed between the PBA groups on linear chains and the triol groups provided by AATris act as the reversible crosslinks to fix the temporary shape.

In an alkaline media (pH = 10), the swelling ratio was ~35 independent of $C_{glu}$ varied between 0 and 300 mg dL$^{-1}$. In rheological measurements it could be shown that G’ decreases remarkably from approximately 3800 Pa to approximately 2200 Pa when $C_{glu}$ was raised from 0 to 90 mg dL$^{-1}$. In bending experiments shape fixity ($R_f$) and shape recovery ($R_r$) was determined. After 5 programming/recovery cycles a $R_f \approx 80\%$ and a $R_r \approx 100\%$ could be measured. $R_f$ was a function of $C_{glu}$ in the range from 0 to 300 mg dL$^{-1}$ which accords with the fluctuation range of $C_{glu}$ in human blood, and in this way, the SMC could be used to determine $C_{glu}$.

The presented hydrogels could play a role in future Diabetes treatment options that are able to determine the blood glucose level and release insulin according to the detected glucose level automatically and in this way provide painless treatment for diabetes without insulin injection.

In Operando Analysis of Peptide-Based Biorecognition Elements for Volatile Organic Compounds in Breath

Daniel Sim\textsuperscript{1,2}, Rachel M. Krabacher\textsuperscript{1}, Jorge L. Chávez\textsuperscript{1}, Jennifer A. Martin\textsuperscript{1}, Ahmad Islam\textsuperscript{1}, Zhifeng Kuang\textsuperscript{1}, Benji Maruyama\textsuperscript{1}, Rajesh R. Naik\textsuperscript{1} and Steve S. Kim\textsuperscript{1}; \textsuperscript{1}Air Force Research Laboratory, United States; \textsuperscript{2}The National Academies of Sciences, Engineering, and Medicine, United States

Air Force requires wearable sensors to enhance performance and protect warfighters in operational environments. Volatile organic compounds (VOCs) found in exhaled breath are key biomarkers for estimating human physical/physiological statuses. Biorecognition elements (BREs) are biological materials specifically binding to the biomarker of interest. Short peptides (normally composed of 5-15 amino acid residuals) are promising BREs for the selective detection of VOCs. They provide chemical stability, straightforward design and engineering capability, and controlled affinity to a target. Carbon nanotube (CNT) field-effect transistors (FETs) have been generally accepted as a suitable platform for sensor miniaturization and wearable applications. Previous CNT FETs for VOC detection have measured explosives or food quality-related molecules. Selective detection of VOCs in breath, meanwhile, still remains a technical challenge since many VOCs share similar chemical characteristics such as polarity and partition coefficient. To facilitate discovery of peptides selective towards target VOCs, it is important to investigate a wide range of molecular properties relating to the peptides and VOCs. Here, we present an \textit{in-operando} approach to investigate peptides’ affinity towards VOCs of interest (isopropyl alcohol, acetone, isoprene, and toluene) on a CNT FET platform. CNTs were functionalized by a number of peptides, and binding events between peptide and VOC have been directly observed by measuring changes in the electrical properties of the CNT FET. We tested three groups of peptides (14 total) that were obtained from phage display and/or \textit{in-silico} modeling. The results showed not only decisive discrimination of the four different breath-related VOCs, but also possible binding affinity of amino acids towards target VOCs. The proposed BRE investigations have potential for selective breath monitoring sensors facilitating real-time human performance assessments.

8:20 AM *S.SM07.01.30

Peptides as Modulators of Materials Properties

Carole C. Perry; Nottingham Trent University, United Kingdom

The synthesis of materials with complex structures and well-defined properties is a central focus of the ‘Directed assembly of extended structures with targeted properties’ grand challenge, given their importance to economic growth and role in addressing key societal challenges. In materials produced by nature, i.e. biominerals; proteins, lipids and carbohydrates act as agents to control both the formation and the physicochemical properties of the composite materials that result. Taking inspiration from nature we extend the ideas of molecular recognition, adsorption/desorption to the formation of some commercially relevant materials. Using examples of MOFS (Metal-organic framework materials) and composites of ZnO and gold we showcase how peptides can be used to tailor the structures formed.

8:35 AM S.SM07.01.33

Production and Application of a Cephalopod-Derived Protein-Based Material

Atrouli Chatterjee, Aleeza Farrukh and Alon Gorodetsky; University of California, Irvine, United States

Cephalopods possess adaptive camouflage and signaling capabilities that are unrivaled among both artificial and natural systems. Such capabilities are enabled by the cephalopods’ unique skin morphology, wherein transparent dermal layers contain neurally-triggered, pigment-based color-changing organs called chromatophores; narrow-band reflective cells that act like Bragg stacks called iridocytes; and broadband reflective cells that act like diffuse reflectors called leucocytes. The optical functionalities of these organs and cells critically rely upon subcellular ultrastructures from unusual proteins known as reflectins. We have used these architectures and proteins as sources of inspiration to develop conductive materials for applications in biocompatible devices with a unique combination of electrical and optical capabilities. More recently, we have demonstrated the production of reflectin-based architectures for interfacing with various biological systems. In particular, we have discovered that reflectins can be used as a platform for controlling biological processes, such as cellular adhesion and differentiation. Altogether, our findings will facilitate the further development of cephalopod-based bio-electronic technologies that can control cell fate.

8:45 AM S.SM07.01.34

Biomateriomics at the Nexus of Sound and Matter—Design, Synthesis and Manufacturing of Biomaterials

Markus J. Buehler; Massachusetts Institute of Technology, United States

What if we could design materials that integrate powerful concepts of living organisms - self-organization, the ability to self-heal, tunability, and an amazing flexibility to create astounding material properties from abundant and inexpensive raw
materials? This talk will present a review of bottom-up analysis and design of materials for various purposes - as structural materials such as bone in our body or for lightweight composites. These new materials are designed from the bottom up and through a close coupling of experiment and powerful computation as we assemble structures, atom by atom. We review case studies of joint experimental-computational work of biomimetic materials design, manufacturing and testing for the development of strong, tough and smart mutable materials for applications as protective coatings, cables and structural materials.

Modeling matter as resonating systems, this talk will then discuss the interface of material and sound, and present how we can transcend scales in space and time to make the invisible accessible to our senses and to manipulate matter from different vantage points, using innovative agents such as AI interacting with human creativity. The impact of this work is the design and making of new materials, art and music, and a deep mathematical understanding of the functional underpinnings of disparate manifestations of hierarchical systems. Building on these concepts, using AI, we explore a new interface of human expression with learned behavior to better understand the physiology and disease etiology due to the misfolding of proteins, explore it as the basis to generative algorithms, and present musical compositions based on the natural soundings of amino acids and proteins.

Using sets of harmonic oscillations as a unifying description, model of disparate hierarchical systems are developed, and then used to illustrate competing concepts of order and disorder and how they are the basis to create functional cross-scale relationships. The insights from this theory explain practically relevant issues such as the strength of silk or the emergence of disease, and the creation of new art. The translation from various hierarchical systems into one another presents a paradigm to understand the emergence of properties in materials, language, visual art, music, and similar systems.

8:55 AM S.SM07.01.35
Biopolymer Nanocomposite Materials from Plant Cells Eleftheria Roumeli1,2, Luca Bonanomi2, Rodinde C. Hendrickx3 and Chiara Daraio2; 1University of Washington, United States; 2California Institute of Technology, United States

Over the past years, significant efforts have been made towards manufacturing innovative sustainable materials. One of the most promising avenues is utilizing the remarkable efficiency and diversity of natural synthesis processes. In this direction, we present here a fabrication platform based on plant cells dehydration, which delivers bulk, biopolymer nanocomposite materials. Plant cells naturally synthesize intricate and hierarchical biopolymer composite structures that comprise their cell walls. Here we demonstrate a modified compression molding method that allows the preservation of cell walls upon dehydration. The final product is a bulk, hierarchical, lamellated biopolymer nanocomposite that is entirely biodegradable. We report the mechanical properties of the pure biopolymer composite, which are superior to other biological matrix materials, such as mycelium or yeast-based composites. Additionally, we demonstrate that filler additives can be incorporated in the fabrication process in order to introduce new properties or tune the native properties of the nanocomposite.

9:05 AM *S.SM07.01.38
Programming Nanoscale Architectures and Lattices Oleg Gang1,2; 1Columbia University, United States; 2Brookhaven National Laboratory, United States

The ability to organize nano-components into the desired architectures with targeted properties is one of the major objectives of nanotechnology. Our efforts are focused on establishing a broadly applicable DNA-based platform for programmable assembly of nano-components into desired and structurally defined organizations. We explore the use of DNA-encoded nano-components and designed DNA constructs to guide self-assembly process towards the desired lattices and arbitrary designed architectures. Through the development of effective assembly strategies, revealing the principles governing these DNA-programmable systems and understanding the role of geometry, interactions and pathways, we develop methods for creation of well-defined three-dimensional lattices, two-dimensional arrays and finite-sized cluster architectures from the inorganic and biomolecular nano-components. Our resent advances in ability to form the desired inorganic, organic and hybrid nanoscale architectures and their applications for nano-optics and biomaterials will be discussed.
Biomineralization Strategies for Synthesizing Defective Metal Oxide Based Nano-Catalysts

Junjie Jiang, Nicholas Bedford, Jason Scott and Rahman Daiyan; University of New South Wales, Australia

Biological systems have provided us much inspiration to design and engineering new materials. For example, nature has utilized biomolecules for the synthesis of complex inorganic structure in a process collective termed biomineralization. In-vitro biomineralization methods are capable of synthesizing nanoscale materials, for instance, SiO2, TiO2 and etc. with high surface area and disordered structure occurring under mild reaction conditions. Based on these unique material characteristics, in-vitro biomineralization has great potential for a variety of functional applications, particularly in catalysis wherein access to disordered surface structures is beneficial. As such, in-vitro biomineralization can bring an innovative strategy for synthesizing nanoscale metal oxides which can serve as catalysts and catalyst support materials.

In this work, a biomimetic analogue, protamine, is used to enable a cost-effective, larger scale metal oxide catalyst synthesis approach. The protamine based biomineralization technique was adopted to synthesize a range of mixed metal oxide nanoparticles for a series of reactions. This technique brings many advantageous features for catalytic materials such as nanoscale, high specific surface area, low preparation cost, and stable thermal properties. For example, biomineralized SiO2-TiO2 composite metal oxides were implemented for the CO2 hydrogenation reaction. The modularity of the synthetic techniques enabled surface area increase and additional defect engineering strategies, that lead to the inducing of extra defects on the material which served as active sites to further enhance the catalytic performance. In addition, we have created Zn-Sn mixed metal oxides for catalysts in the electrochemical CO2 reduction reaction. All materials were thoroughly characterized using a suite of synchrotron characterization methods to establish structure/function relationships. Through these techniques, we have discovered that most materials are largely disordered and change in local structure depending on the synthetic conditions applied. Through these efforts, we have demonstrated a new material manufacturing strategy based on in-vitro biomineralization for nanoscale metal oxide catalysts.

Enhanced Cellulose Nanocrystal Composite Films with Tunable Iridescence Driven by Intercalation of Wood-Derived Amorphous Polymers

Katarina Adstedt1, Kellina Pierce1, Elizabeth Popenov1, Rui Xiong1, Ren Geryak1, Vladyslav Cherpak2, Dhriti Nepal3, Tim Bunning3 and Vladimir Tsukruk1; 1Georgia Institute of Technology, United States; 2University of Colorado Boulder, United States; 3Air Force Research Laboratory, United States

The mechanical performance of cellulose nanocrystal (CNC) is typically enhanced through crosslinking, the addition of strong filler materials or mixing with soft matrices. However, these modifications that can lead to higher mechanical strength tend to disrupt the original helical organization of the chiral phases and destroy the corresponding vivid iridescence. Herein, we demonstrate a unique case of enhanced and tunable structural colors combined with much improved strength of CNC composite materials through the addition of amorphous wood-derived polymers of similar chemical composition. Adding these polysaccharides, pullulan, dextran, and xylan, promotes seamless integration into the original helicoidal organization with full chain intercalation, even at very high loading, a unique behavior for composites from components with different structural organization, amorphous and chiral nematic in our case. CNC-polymer composites demonstrate enhanced mechanical performance, nearly a two-fold increase in toughness. A systematic red-shift in selective light reflection is observed for all polymer composites due to the gradual increase in pitch length because of the intercalation of natural polymer backbones into helicoidal organization without disturbing long-range ordering. The utilization of wood-derived amorphous polymers with similar composition, hydrogen bonding capabilities, and mechanical properties, instead of foreign synthetic components provides a sustainable method of significant mechanical enhancement of chiral composite films without disrupting the original helicoidal organization and vivid iridescence with controlled color appearance.

Developing Non-Iridescent Structural Colors on Flexible Substrates with High Bending Resistance

Mario A. Echeverri1, Anvay Patil1, Ming Xiao1,2, Weiyao Li1, Matthew D. Shawkey3 and Ali Dhinojwala1; 1University of Akron, United States; 2Harvard University, United States; 3University of Ghent, Belgium

Nanostructured materials producing structural colors have a great potential in replacing toxic metals or organic pigments.
Electrophoretic deposition (EPD) is a promising method for producing these materials quickly on a large scale. However, the colors reported so far lack brightness, saturation, and mechanical stability. Herein we use EPD assembly to co-deposit silica (SiO$_2$) nanoparticles with precursors of synthetic melanin, polydopamine (PDA), to produce mechanically robust, wide-angle structurally colored coatings. We use spectrophotometry to show that PDA precursors enhance saturation of structural colors and nanoscratch testing to demonstrate that they increase the mechanical stability of the EPD coatings. Stabilization by PDA precursors allows us to coat flexible substrates that can sustain bending stresses, opening an avenue for electro-printing on flexible materials.

Synthetic Biology—New Capabilities for Army Materials Applications Joshua A. Orlicki and Justin P. Jahnke; Army Research Laboratory, United States

The emerging field of synthetic biology provides opportunity and new capabilities for the precision synthesis, assembly, and function of materials. Currently, there are significant challenges for the integration of bio-derived and bio-based technologies in the defense-oriented materials space. Army platforms must reliably operate over wide temperature ranges (e.g. -40 to 75 deg C), extremes in humidity, exhibit durability to be fielded for long periods of time (e.g. 5+ years) and endure strain rate deformations from low strain, high frequency vibration to high strain impact events. We are making initial forays into the synthesis and assembly of materials, and are developing protocols to probe performance metrics, production repeatability, and aging. Materials under evaluation include bio-derived organics and bio-templated inorganics, and integration into materials systems has been undertaken using both traditional processes and bio-synthetic processes. This poster will give an overview of current projects employing the tools of Synthetic Biology and highlight the key performance targets of these materials.

S.SM07.02.14

Anisotropic Hydrogels Templated by Chromonic Liquid Crystals for Biomedical Applications Suitu Wang$^1$, Jennifer M. Boothby$^2$, Daniel Maruri$^1$, Victor D. Varner$^1$ and Taylor H. Ware$^1$; $^1$University of Texas at Dallas, United States; $^2$Johns Hopkins University Applied Physics Laboratory, United States

Approaches to control the microstructure of hydrogels are critical for the control of cell-material interactions. Herein, we report a versatile approach for the synthesis of anisotropic polyacrylamide hydrogels by lyotropic chromonic liquid crystal (LCLC) templating. Specifically, polyacrylamide hydrogels with aligned porosity can be obtained by polymerizing the network in the presence of an aligned chromonic phase. By varying crosslink density, the resulting hydrogels have tunable pore size and distinct mechanical anisotropy. For example, the elastic moduli measured parallel and perpendicular to the LCLC order are 124.6 kPa ± 7.9 kPa and 17.4 kPa ± 1.1 kPa and the hydrogels have a 4-fold larger swelling normal to the LCLC director than along the LCLC director. This anisotropy can be patterned by using surface anchoring to locally control the nematic director, which in turn patterns the polymer network. The director can be patterned both within the plane and through the thickness of the hydrogels. Fibroblasts cultured on the resulting hydrogels align along the pore walls, which in turn provides a powerful approach to control cell orientation. This new strategy to make anisotropic hydrogels can have potential applications for patternable tissue scaffolds, soft robotics, or microfluidic devices.

3D-Printed Shape-Morphing Living Composites Laura K. Rivera-Tarazona, Tarjani Shukla, Zachary T. Campbell and Taylor H. Ware; The University of Texas at Dallas, United States

Shape-transformation is a prevalent function observed in living systems, from the blooming of flowers to muscle actuation. While current shape changing synthetic materials are capable of sensing non-specific stimuli such as pH, light, temperature or ultrasound, new materials are needed that detect specific biochemical cues and respond mechanically in a programmed manner. Materials that respond to such subtle cues could enable biosensors or drug-delivery devices. Recently, we demonstrated that synthetic materials can be designed to host genetically engineered yeast cells capable of responding to very specific and pre-determined stimuli (e.g. biogenic amines). Specifically, we presented a new method to create programmable shape-morphing composites using polyacrylamide hydrogels embed with *Saccharomyces cerevisiae*. Cellular proliferation within these composites can be spatio-temporally controlled to generate large volume expansions of up to 600% of the composite. Here, we report the design of living composites with shear-thinning properties based on cellulose nanocrystals (CNC) and acrylamide monomers using direct-write printing. CNC concentrations at 11 wt% and 22 wt% enabled active (yeast-embedding) and passive (cell-free) bioinks respectively to be printed. By developing a hydrogel-based printable
bioink, engineered yeast strains can be patterned into three-dimensional (3D) structures with defined geometry, organization and porosity. Using this control, we spatially pattern cellular proliferation within a monolith to induce complex shape transformations and demonstrate specificity to single amino acids. Finally, we will discuss the 3D printing of a living composite capsule for in vitro biomolecular detection and subsequent drug delivery in a model of the gastrointestinal tract. In this device, genetically-engineered probiotic yeast only proliferate in the presence of a particular biomolecule, such as heme, which leads to expansion of one portion of the capsule. This expansion ruptures the device and releases a hydrophobic compound to the surrounding environment. Our study may enable new opportunities to develop drug-delivery devices for the diagnosis and treatment of gastrointestinal disorders.

S.SM07.02.17
Dynamic Structural Color by Self-Assembling Cellulophaga Lytica
Claretta J. Sullivan¹, Chia-Suei Hung¹, Kennedy Brown¹, Lewis Shabshelowitz²,³, Vincent Chen¹, Pamela Lloyd¹, Maneesh K. Gupta¹, Milana Vasudev²,³, Abby Juhl¹, Wendy Goodson¹ and Patrick Dennis¹; ¹Air Force Research Laboratory, United States; ²University of Massachusetts Dartmouth, United States

Under laboratory conditions, the micron-scale dimensions and gliding motility of some prokaryotes, including Cellulophaga lytica, facilitate the self-assembly of discrete cells into iridescent biofilms. This is in sharp contrast to structural coloration in eukaryotic systems (e.g. lepidoptera, coleoptera), where multiple cell types, complex architectures and fixed structures are frequently involved. We propose using biofilms of C. lytica as a platform for material synthesis since properties derived from their exquisite ordering can be tuned using ‘simpler’ bacterial genetics. Importantly, the sequence of C. lytica strain 7489 is known, making it amenable to future synthetic biology approaches for tailoring. Though facile growth of its biofilms is possible, we report nuances of growth conditions which impact iridescence. Toward a fundamental understanding of the strategies employed in self-assembly, the current study also examines community organization and cellular morphology. Specifically, iridescent and non-iridescent regions of the biofilms are probed using complementary imaging techniques including confocal, electron and atomic force microscopes. These multi-scaled microscopies have provided surprising insights into the biofilm structure. Specifically, we report that differences in morphology and packing correspond to changes in the wavelength of reflected light. To facilitate these studies, sample preparation strategies which allow cells to be imaged in context were developed. In addition to establishing the structure-property relationship derived from the biofilm’s organization, our findings suggest that novel mechanisms may be involved in assembly and that a comprehensive investigation to identify cellular components contributing to assembly is indeed warranted.

Bioinspired Photonic Crystal Enhancement of Raman Signatures for the Early Detection of Cancer
Milana C. Vasudev, Prathyushkrishna Macha and Matthew Moore; University of Massachusetts Dartmouth, United States

Over the past few decades, cancer and other fatal diseases have become more prevalent affecting large populations around the world. Earlier detection could improve prognosis for the patient. A possible solution includes using photonic crystal-based sensors to detect biomarkers in exosomes shed by cancerous cells. Photonic crystals have become increasingly important for biosensor applications due to the need for a label-free alternative to detect biomarkers. Surface enhanced Raman scattering (SERS) using gold nanoparticles is a sensitive analytical technique, which has been exploited in chemical, molecular and environmental monitoring. In this study, a photonic crystal SERS substrate was designed and synthesized for the early detection of changes which occur in the exosomes shed by the cancerous cells. Optical signal amplification due to gold nanoparticles and photonic components, leads to the enhanced interactions between the analyte and the sensor. Electromagnetic enhancement using photonic crystal substrate can greatly enhance the SERS detection when compared to traditional methods. The two-dimensional photonic structural organization in the comb structures of the ctenophore species, Mnemiopsis Leidyi and Beroe Cucumis was used as the inspiration to design the photonic crystal substrate used in this study. The structural organization of the cilia in the comb rows consists of arrays of hexagonally packed cilia with a central microtubule pair. Transmission electron microscopy was used to study the arrangements of the comb structures. Reverse engineering of these submicron structures aids in designing a novel photonic template. The design of the comb structures was recreated using AutoCAD and Raith software. Photonic nanostructures were synthesized using the direct-write e-beam lithography technique. The structures were characterized with scanning electron microscope (SEM), and reflectance measurements. Gold nanoparticles will be used to in conjugation with the photonic crystal structure and Raman signatures measured, both with and without gold molecules. Finally, these gold nanoparticle coated photonic templates were utilized as a SERS active surface for exosomal detection. Some advantages of utilizing photonic crystals include point of care diagnostics and their response to a multitude of external stimuli including light.

Functionalization of Iron Carbide@Iron Oxide Nanoparticles through Conjugated Oleic Acid with L-Asparagine and L-Arginine

Anya I. Arguelles, Paul Zavala-Rivera, Aaron Rosas Durazo, Armandp Lucero-Acuña, Patricia Guerrero-Germán and Armando Tejeda; Universidad de Sonora, Mexico

The delivery of nanoparticles, as vectors in biological environments, depends on the interaction and stability in the environment where it is delivered. The functional groups are given by surfactants that gives stability to the particles, avoiding the aggregation between themselves aside from chemical associations not only with the environment but also with other molecules depending on the surface charge. Recent studies have shown that the use of carbodiimides has been helpful in achieving changes in the behavior in nanoparticle solution, from organic to aqueous phase [1-3].

There is an extensively research field on surfactants, called "green surfactants", based on the integration of amino acid and proteins, due to the functional groups that compose them, such as carboxyl and amino groups, that can be chemically adhered to the surface through a possible nucleophilic substitution achieving amphiphilic conformations in the form of micelles or enanimers and dependent on the change of pH for the deliberation of the vehicle in the biological system [4–8].

This research aims iron carbide@iron oxide nanoparticles (ICIONPs) from organic nature[9], coated of amino acids through the conjugation of oleic acid with L-Arginine and L-Asparagine performing by N,N′-dicyclohexylcarbodiimide (DCC) with N-Hydryxsuccinimide (NHS) as a coupling reagents, forming behavioral structures, known as polypeptides, with an organic center and aqueous surface arrangement for encapsulation of nanoparticles as possible interaction with other biological molecules and their application in bioseparation processes.

SYMPOSIUM S.SM07

Citrus limon as Reducing Agent for the Synthesis of Gold Nanoparticles by Multiwave Ultrasonic Technique

Juan Carlos Martinez, Julio Cesar Ramos Dominguez, Cesar Fernando Lopez Sanchez and Raul Carrera Cerritos; Instituto Politécnico Nacional, Mexico

Nanotechnology has studied applications in biomedical areas, for which several nanomaterials have been synthesized that present limitations such as toxicity and instability in organisms, so green methodologies have been developed that help reduce this problem. In this work we report the green synthesis of AuNPs using as a reducing agent lemon extract (Citrus limon), and the multiwave ultrasonic technique as an excitation element. As the precursor reagent, trihydrated chlorouric acid (HAuCl4.3H2O, Sigma Aldrich SKU 520918) was used, and as a reducing agent the lemon juice extract. The reaction was carried out in an ultrasonic bath at a frequency of 40kHz, at 55 °C for one hour (Branson 2800 series). The final solution obtained showed a purple coloration, and was characterized by UV-VIS spectrophotometry and transmission electron microscopy (JEOL JEM 1010). Absorbance peak resonant at 530 nm was observed and particle diameters between 12 and 16 nm were obtained. The reported results could be of interest to carry out fusion of nanometric inorganic materials by the ultrasonic technique, and by controlling the temperature and frequency, metal structures with different morphology and properties could be generated.

SYMPOSIUM S.SM08
Imparting Hydrophilicity and Water Absorbability of Polycaprolactone Nanofibrous Membrane by Incorporating Alginate-Chitosan Particles

Joshua Kae B. Macugay and Leslie Joy L. Diaz; Department of Mining, Metallurgical and Materials Engineering, University of the Philippines Diliman, Philippines

Polycaprolactone (PCL) have been used in medical applications due to its inertness, biocompatibility, biosorbability and biodegradability. However, its hydrophobic nature and absence of fluid absorption capacity limits its potential in such applications. This can be improved by incorporating particles that will facilitate interaction with water or body fluids. In this study, alginate-chitosan PECs are synthesized and incorporated in PCL nanofibrous membrane. Given this structure, alginate nanoparticles were synthesized to allow incorporation into the membrane. Varying mass ratio of alginate to calcium ions were investigated in the pre-gel formation which was controlled through viscosity measurements. Viscosity decreased significantly from 1.873 to 1.515 cPs indicated the formation of the alginate particles as a consequence to the rearrangement of the long alginate polymer chains into discrete coiled structure. Meanwhile, varying mass ratio of alginate to chitosan was investigated in the polyelectrolyte complexation to facilitate the formation of a stable suspension thereby suggesting formation of alginate-chitosan nanoparticles. A minimum particle size of 1.924 microns is measured for stable solutions. The alginate-chitosan was incorporated into the PCL nanofiber membrane to impart hydrophilicity and water absorbability. Infrared spectroscopy done on the nanofiber membrane confirmed the presence of both PCL and alginate in the final structure. Further, contact angle measurements showed a significant decrease from 82.56 to 73.58° which suggests the improvement of hydrophilicity of the membrane. Water absorption capacity of the membrane increased to 7.82%. Varying the amount of alginate-chitosan particles would allow improvement and control of the nanofiber membrane’s hydrophilicity and water absorption capacity. This material has potential use in wound dressing devices, extracellular membranes, as well as filter membranes in medical devices.

Antibacterial Activity and Controlled Delivery of Amoxicillin from Polyacrylamide/Starch Hydrogels

Ana Valeria Torres Fiqueroa, Cinthia Jhovanna Pérez Martínez, Teresa Del Castillo, Enrique Bolado Martínez and María Alba Guadalupe Corella Madueño; Universidad de Sonora, Mexico

Hydrogels are water-compatible polymer networks which can increase their volume without losing their shape. The applications for this type of materials depend on their maximum swelling grade and mechanical properties, which are closely related with the cross-linking porosity and the density of the network. Their flexibility degree is very similar to that of natural
tissues, so the hydrogels are considered a very important group in the pharmaceutical industry for biomedical applications, particularly, as controlled drug delivery systems. The advantages of these systems include the possibility of drug delivery at specific sites, the continuity of the treatment during the night, the stability of the drug, its optimal absorption by the tissues, as well as the reduction of side effects. In this study, we report the evaluation of hydrogels of polyacrylamide (PAAm)/starch, synthesized in different molar ratios (100/0, 90/10, 80/20, 70/30, 60/40, 50/50), as a potential platform for the controlled release of amoxicillin. The swelling capacity of the hydrogels and the effect of the molar ratio between both polymers on the antibiotic release kinetics under normal physiological conditions of temperature and pH were evaluated in vitro. Finally, bacterial growth inhibition assays in ATCC strains were carried out to analyze the clinical potential of materials. The results have demonstrated the potential of polymeric hydrogels as controlled release systems of amoxicillin.

S.SM08.05.06
Characterization of a Novel Se-bioactive Glass for a Chemotherapeutic Bone Cement Rebecca Potts, Kapil Raghruman and Aisling Coughlan; University of Toledo, United States

Selenium (Se) ion release from a bone cement is hypothesized to provide chemotherapeutic effects and to be beneficial in the prevention of recurrence of osteosarcoma in the setting of tumor resection surgery. Se containing compounds have been shown to act as redox modulators with higher selectivity and sensitivity in malignant cells. A four glass series, SiO2-Na2O-CaO-SrO-SeO2, was investigated substituting varying levels of CaO for SeO2. The glass series was synthesized using the air-quench method. This method was repeated twice for each glass in the series in order to ensure homogeneity of the material. This study focuses on the characterization of the bioactive glass and its ability to release beneficial ions in an aqueous environment. Structural and thermal properties were evaluated for the glass series using differential thermal analysis (DTA) along with magic angle spinning nuclear magnetic resonance (MAS-NMR) to confirm network connectivity (NC) calculations. X-ray diffraction (XRD) was used to confirm the presence of an amorphous structure in the series. Inductively coupled plasma mass spectroscopy (ICP-MS) was performed in order to quantify the ion release from the glass in an aqueous environment at physiological temperature for all elements present in the glass. Antibacterial efficacy tests were completed along with cytocompatibility studies via MTT assay of the material plated conditioned media with MC3T3 cells. The glass composition was determined to have bioactive properties, detectable and predictable Se ion release, antibacterial abilities, and also promoted growth of pre-osteoblast cells. Future directions include assessing the ability of the selenium based bioglass to stop or reverse growth of osteosarcoma cells.

S.SM08.05.07
Multifunctional Peptide-Conjugated Non-Viral Gene Vector for Dental Pulp Regeneration Qian Li and Xiaohua Liu; Texas A&M University, United States

Dental pulp, a highly vascularized tissue situated in an inextensible environment surrounded by rigid dentinal walls, receives blood supply solely from a small apical foramen (diameter < 1 mm) of the tooth root canal. Therefore, regeneration of pulp in the full-length tooth root has long been a challenge. In this study, we aimed to develop angiogenic human dental pulp stem cells (hDPSCs) for pulp regeneration in a full-length tooth root. Specifically, we developed a multifunctional peptide-conjugated non-viral gene vector to enhance the expression of vascular endothelial growth factor (VEGF) in hDPSCs, and evaluated the efficiency and bioactivity of the angiogenic transfected hDPSCs in vitro and in a full-length human tooth root model in vivo.

Multifunctional peptide C-Rg-G-NLS-W was conjugated to polylysine (PLL) using click chemistry method. The multifunctional peptide-modified PLL encapsulated pVEGF plasmid using electrostatic interaction and formed polymer/gene complexes. Next, hDPSCs were transfected using the gene complexes. Cellular uptake and transfection efficiency were examined using flow cytometry. PCR was used to evaluate VEGF gene expression of the transfected cells at mRNA level. Furthermore, the effects of transfected DPSCs on the cytotoxicity and endothelial vascular-like tube formation were performed by MTT assay and Matrigel assay in vitro. Transfected DPSCs were injected in human tooth roots sectioned into 11 mm segments and implanted in nude mice. The constructs were retrieved after 4 weeks and examined for regeneration of pulp-like tissue and vascularization by histology. The MTT result showed that at higher DNA concentration, the cell viability of peptide-modified complexes group was higher than PLL/pVEGF complexes group. The cellular uptake and transfection efficiency of peptide-modified gene complexes was higher than control group. PCR analysis indicated that the mRNA expression after transfected with peptide-modified gene complexes was enhanced. Furthermore, the gene transfection enhanced endothelial cell migration and vascular-like tube formation.

The peptide-conjugated polylysine is an effective non-viral vector for gene delivery and enhanced endothelial cell migration and vascular-like tube formation.

Core-Polyethylene-glycol-Lipid Shell Nanoparticles (CPLS NPs) with Tunable Morphology and Surface Charge for Potential Therapeutic Delivery
David T. Loe¹, Zhiqiang Shen¹, Martin Kröger², Ying Li¹ and Jessica Rouge¹; ¹University of Connecticut, United States; ²ETH Zürich, Switzerland

Due to their biocompatibility and large payload capacity, liposomes are the premier delivery vehicle for hydrophilic therapeutics. However, traditional procedures produce liposomes without size uniformity and stable nanoscale structures, both of which determine efficacy of delivery. We have found that templating the growth of liposomes promotes uniform size and increases the structural stability, as predicted by simulations in Dissipative Particle Dynamics (DPD). We refer to our construct as a Core–Polyethylene-glycol–Lipid Shell nanoparticle (CPLS NP), synthesized through a bottom up approach utilizing an inorganic nanoparticle as a platform from which to scaffold the liposome. Using colloidal Au NPs as the core of the CPLS, a PEG molecule, functionalized with a thiol functional group, self-assembles into a layer on the surface of the Au NP. The PEG molecule is also functionalized with a lipid moiety. Through a second self-assembly, free lipids adsorb on to the templated lipid at the NP surface. The morphology of the lipid shell is determined by the morphology of the core, a phenomenon caused by the template-scaffold. The surface charge can be tuned by incorporating various ionic lipids, a property of traditional liposomes that is retained in the CPLS. The surface charge of the lipid shell can direct cellular uptake of the CPLS NPs. The CPLS NP retains the attractive features of the liposome, an aqueous lumen and direct fusion to a membrane, while also having a predictable volume and morphology with increased stability, important features for drug delivery applications.

S.SM08.05.09
Metal-organic Framework Preserves Biorecognition of Antibodies on Nanoscale Surfaces Validated by Single Molecule Force Spectroscopy
Lin Kang¹,², Steve Smith¹,² and Congzhou Wang¹,²; ¹South Dakota School of Mines and Technology, United States; ²South Dakota School of Mines & Technology, United States

Antibody biorecognition forms the basis for numerous biomedical applications such as diagnostic assays, targeted drug delivery and targeted cancer imaging. However, antibodies, especially after being conjugated to surfaces or nanostructures, suffer from stability issues when stored under non-refrigerated conditions. Therefore, enhancing the stability of antibodies on surfaces and nanostructures under ambient and elevated temperatures is of paramount importance for many nanobiotechnology applications. In this study, we introduce a simple and facile approach based on a metal-organic framework (MOF) coating to preserve the biorecognition capability of antibodies immobilized to nanoscale surfaces after exposure to elevated temperatures for a prolonged period. By using atomic force microscopy (AFM)-based force spectroscopy, we demonstrate that the MOF coating is able to preserve the binding force and binding frequency of the anti-CD-146 antibody attached to an AFM tip to CD-146 antigen on the surface of melanoma cells at the single molecule level. We also demonstrate that the MOF coating outperforms another commonly used sucrose coating in terms of maintaining binding force and binding frequency of the antibody to antigen. Herein, the AFM tip functionalized with antibodies provides a nanoscale testbed (analogous to an antibody-conjugated nanostructure) to assess antibody biorecognition at the single molecule level and preservation efficacy under antibody denaturing conditions. This MOF coating approach should be applicable to the preservation of antibody-conjugated nanostructures aiming for targeted drug delivery, targeted cancer imaging, nanobiosensors, and a wide range of applications relying on surface-bound antibodies. The improved stability and elimination of refrigeration requirements will facilitate wide applications of antibody-enabled nanobiotechnology in resource-limited environments and populations.

S.SM08.05.13
Porous Silicon Nanoneedles—An Emerging Nanofabricated Tool for Enhanced Transdermal Drug Delivery
Nazia Tabassum¹,², Maria Alba¹,³, Tony Yan¹,³ and Nico Voelcker¹,³,⁴; ¹Monash University, Melbourne, Australia, Australia; ²University of central Punjab, Pakistan; ³Commonwealth Scientific and Industrial Research Organisation (CSIRO), Australia; ⁴Melbourne Centre for Nanofabrication, Australia

The transdermal route is attractive for minimal invasive administration of small and large molecular bioactives. Among the transdermal techniques (e.g. iontophoresis, electroporation, jet injectors, ultrasound, ablation, powder injection), micro/nanoneedles are particularly promising because of their straightforward, cost-effective and safe administration. However, precise control over the degradation rate of micro/nanoneedles within the skin remains a great challenge. Here, we introduce porous silicon nanoneedles (pSiNNs) for pain-free transdermal drug delivery of biomolecules with controlled degradation rate.
In this work, 40-50 µm pSiNNs were fabricated via deep reactive ion etching with a tip diameter below 1 µm and a diameter of about 8-10 µm. Then, a porous surface was obtained by electrochemical anodisation. It was found that nanoneedle biodegradability and mechanical strength could be tuned by changing the thickness of the porous layer. pSiNNs with a 4.0 µm porous layer can degrade much quicker than 1.6 µm porous layer. In addition, small as well as macromolecular drug molecules could be uniformly loaded into the porous layer of the pSiNN arrays with high drug loading capacity. *Ex vivo* pig and mouse skin penetration experiment demonstrated that pSiNN can significant increase the transdermal delivery efficacy compared to topical application.

In summary, we have fabricated 40-50 µm pSiNNs with tunable porosity, biodegradability and mechanical strength for transdermal delivery. This platform is able to deliver various biotherapeutics (small molecules to large molecules) through the skin and thereby contributes to innovations in pharmaceutical sciences.

**Nanoparticles to Cancer Cells Through Peptide Ligand-Mediated Endocytosis—Cancer Cell Receptor-Targeting Versus Cancer Cell Penetrating Peptides**

Eunji Jo and Jeewon Lee; Korea University, Korea (the Republic of)

The performances of endocytosis mediated cell uptake of two different types of functional peptides, cell receptor-targeting peptide (CRTP) and cell penetrating peptide (CPP), were analyzed and compared with a common carrier of functional peptides-heavy chain of human ferritin (huHF) nanoparticle. 24 copies of a CPP(TAT peptide from transduction domain of human immunodeficiency virus) and/or a CRTP (functional peptide with specific and strong affinity with either human integrin(αvβ3) or epidermal growth factor receptor I(EGFR)) were genetically presented and exposed on the surface of each huHF nanoparticle. We confirmed both *in vitro* and *in vivo* tumor-targeting and endocytosis performance of CRTP-presenting huHF nanoparticles and systematically analyzed the cell targeting, endocytosis, and intracellular localization of recombinant huHF nanoparticles labeled with the in the fluorescent dye (Cy5.5) *in vitro* cultures of cancer and normal cells. In particular, it is notable that CRTPs led to a uniformly diffused localization of the huHF nanoparticles in cancer cell cytosol, while CPP-mediated endocytosis made the huHF nanoparticles remain in a narrow confined cell endosomal region. These novel and remarkable findings provide highly useful informations to many researchers both in industry and in academia are interested in developing delivery systems/carriers of anticancer drugs.

**Rescuing Cells from Oxidative Stress Using Surface Functionalized Carbon Quantum Dots**

Jyoti Ahlawat, Sreeprasad T. Sreenivasan and Mahesh Narayan; University of Texas at El Paso, United States

Carbon Quantum Dots (CQDs) has demonstrated high potency to mitigate neuronal oxidative stress and related pathologies, including Alzheimer's disease (AD). However, the application of CQDs is limited due to their inability to cross the Blood Brain Barrier (BBB) without disrupting the structural integrity of tight junctions. Here, we introduce surface modified CQD nanoencased in β-lactoglobulin for easy passage across the BBB and displaying both prophylactic and therapeutic efficacy. The diverse ligand binding ability of β-lactoglobulin was leveraged to encapsulate and transport the surface functionalized CQDs, β-lactoglobulin owing to its biocompatibility was chosen to improve bioavailability of the encapsulated core. Due to the evidences of the role played by Amyloid-β to initiate AD, the study employs Amyloid-β as the model causative species and SH-SY5Y neuroblastoma cell line as the model cell line. Our study illustrates neuroprotective efficacy of the surface functionalized CQDs.

**S.SM08.05.25**

**Light Triggered Switchable Nanosystems for Remotely Targeted Drug Delivery**

Jun Chen; Institute of High Energy Physics, Chinese Academy of Sciences, China

Light triggered switchable nanosystems have recently gained increasing attention as a promising approach of remotely controlled drug delivery. We used the strategy of remotely controlled delivery technology that may overcome the pathophysiological barriers existing in targeted drug delivery. Unlike pathophysiology actived drug targeting strategies, light triggered switchable nanosystems are minimally influenced by the heterogeneity of cells, tissue types, and/or microenvironments. Instead, they are triggered by light (i.e., near-infrared) stimuli, which are absorbed by photoresponsive molecules or nanotransducer. The sequential conversion of light to heat or reactive oxygen species can activate the property change of nanoparticles in a spatio-temporally controlled manner. This talk will present several recent studies of light triggered switchable systems to overcome the pathophysiology barriers and future directions in the application of light-switchable systems for remotely targeted drug delivery.

**S.SM08.05.26**
Service textiles are high-touch surfaces in the healthcare environment and they play an important role in the acquisition and transmission of pathogenic microorganisms, including multi-drug resistant organisms that can survive for weeks on fabrics. Contaminated service textiles have caused infections, which not only affects the safety and health of healthcare personnel and/or patient, but also is incompatible with good hygiene and cross-infection control practices and inconsistent with the expectations of modern healthcare. Here, we use a versatile dip-pad-cure approach to graft/coat polymethacrylamide (PMAA) onto the surfaces of representative service textiles including polyester, cotton, and polyester/cotton blend. Upon treatment with commercial bleach, the amide groups on PMAA were transformed into stable acyclic N-halamines, providing the resultant fabrics with potent, durable (against wash/wear), and rechargeable biocidal activities against *E. coli* (gram-negative bacteria), *S. aureus* (gram-positive bacteria), and *C. albicans* (fungi). The antimicrobial potency of the fabrics could be readily controlled by adjusting the treatment conditions, and the N-halamine contents could be easily determined via a simple chlorine strip test. Further, the comfort performances and the mechanical properties of the antimicrobial fabrics were not adversely affected by the grafting and chlorination treatments. These functions make the N-halamine based antimicrobial fabrics as attractive candidates of service textiles for various healthcare applications.

**S.SM08.05.28**  
**Charge Transformable Polymer-Coated Boron Carbon Oxy-Nitride as Novel Theranostic Agent**  
Chen-Wei Chiang, Yun Chen Chien, Chih Yi Wang, Wei-Hui Yu, Liang Cheng Chien, Chou Chio Lao, Chi-Shiun Chiang and Pei Yuin Keng; National Tsing Hua University, Taiwan

Herein, we will present the first charge transformable theranostic boron-based nanoparticles for Boron Neutron Capture Therapy (BNCT) and optical imaging. BNCT is an emerging targeted cancer therapy modality that can deliver an immense dose gradient within cellular spatial specificity between tumor and healthy cells. Individually, boron-10 isotope and epithermal neutron flux is not harmful to the body. When combined, boron-10 undergoes a nuclear fission reaction, producing two highly energetic particles in MeV. The alpha-4 and lithium-7 particles deposit all its energy within 5-9 µm in diameter, which corresponds to the size of a single cell. These particles, produced during BNCT treatment, have characteristic of high linear energy transfer (LET) radiation, which induced complex DNA double-strand breaks (DSB). BNCT has showed promising results in clinical trials of patient with recurrent head and neck cancers and enjoyed a good quality of life after receiving two sessions of BNCT treatment. To advance BNCT as one of the cancer treatment modalities, a new and more specific boron drug is needed with superior efficacy compared to currently available boron drug. Specifically, our group is developing the preparation of boron carbon oxynitride (BCNO) nanostructures as a novel theranostic agent, which relies on the inherent luminescence properties of BCNO and the high loading of $^{10}$B within a single nanoparticle for maximizing the efficacy of BNCT treatment. A successful BNCT treatment relies on the delivering a high payload of boron-10 isotopes with high specificity. According to a recent review article on nanoparticle drug delivery, less than 1% of the injected dose of nanoparticle drug reached to the tumor site in small animal studies. This is due to our biological complexity, which demands nanoparticles of different sizes and charges during drug delivery. For examples, for tumor accumulation via EPR effect, the optimal size of the nanoparticles should be between 30-150 nm and possessed a neutral surface charge. Upon accumulation within the tumor microenvironment, a nanoparticle with positive surface charge is known to be effective for cell internalization. Herein, we aim to tackle the latter problem related to the particle surface charge. Positively charge nanoparticles and macromolecules is known to be toxic to cells by forming holes on the cell membrane during internalization and thus resulted in diffusion of cytosolic proteins out of the cells. While this effect is desirable at the cancer cells, the toxic nature of the nanoparticles needs to be first protected with a stealthy polymer ligand until the nanoparticles is delivered to the cancer site. As the first proof of concept, we have successfully synthesized and functionalized BCNO nanostructures with a positively charge polymer followed by a stealthy layer of polyethylene glycol for enhanced tumor accumulation. At the tumor microenvironment, the chemically engineered polymer coating with an acid sensitive bond will break, thus releasing the toxic, and positive charge nanoparticles for effective cell penetration. Previously, our group has successfully showed the functionalization of 5 nm BCNO nanoparticles with polyethyleneimine (PEI) and confirmed the functionality via FTIR and zeta potential measurement. The bare BCNO nanoparticles in water possessed negative charge while the BCNO@PEI possessed a positive charge in water. Herein, we will present the preparation of the block copolymers with an acid reactive linker, nanoparticle functionalization and finally shows the particle charge transformation. In vitro cell toxicity and cell membrane penetration of a series of polymer-coated BCNO nanostructures will also be presented at this meeting.

**S.SM08.05.32**
Developing a Novel Co3O4@CNDs Hybrid Functional Nanoparticle for Bioimaging Applications

Anitha Jayapalan, Durga Manjari Arvapalli, Alex Sheardy and Jianjun Wei; University of North Carolina at Greensboro, United States

The fluorescent hybrid nanomaterial systems with inexpensive, transition metal oxide (TMO), such as cobalt oxide and carbon nanomaterials, has gained impressive attention in cellular imaging and viability studies. Surface functionalizing the TMOs with the carbon nanodots (CNDs) leads to synergistic, tunable photoelectronic properties in a hybrid nanoparticle for increasing their photoluminescence intensity, thereby making it a potential bioimaging agent for the cancer cells. By incorporating the cobalt oxide (Co3O4) nanoparticles with CNDs, we hypothesize that the surface defect states are altered in a nitrogen-rich carbon nanodots matrix, thereby increasing the surface as well as photoelectronic properties of the hybrid nanoparticles due to the synergistic interfacial properties between the Co3O4 and CNDs. Hence, the aim of this research was to synthesize a spherical hybrid with Co3O4 nanoparticles on CNDs, which could serve as an efficient bioimaging agent in the cancer cells. A simple, modified microwave technique was carried out for the synthesis of the hybrid nanoparticles. The characterization studies such as UV-Visible, Photoluminescence, Raman, and X-ray photoelectron spectroscopies, X-ray Diffraction, and Transmission electron microscopic techniques were performed for the hybrid nanoparticles. The absorbance and the photoluminescent intensity were observed to be higher for the hybrid nanoparticles than the CNDs due to the incorporation of Co3O4 nanoparticles, which may cause structural as well as tunable electronic properties in the hybrid nanomaterial. Cellular uptake and viability studies were performed using A549 and normal human cell line, EA. Hy926. The hybrid nanoparticles were efficiently uptaken by the cancer cells, and a decrease in the cell viability was observed, compared to the human epithelial cells. Overall, the synthesized hybrid nanoparticles can be used as a potential theranostic agent for cancer therapy.

S.SM08.05.35
Chitosan-Lactic Acid Films as Low-Cost Bovine Milk Whey Protein Carriers for Enhanced Skin Wound Healing
Gerardo Cedillo-Servin1, Ma. Concepcion Peña-Juarez2 and Ricardo Vera-Graziano3; 1Instituto de Investigaciones en Materiales, Universidad Nacional Autonoma de Mexico, Mexico; 2Facultad de Estudios Superiores Cuautitlan, Mexico

In chronic and burn wounds, novel low-cost therapeutic devices and agents are still sought after in order to actively stimulate skin regeneration at the structural, vascular, and immune levels. Recently, bovine milk extracts have been described to have regenerative capabilities comparable to phenytoin in skin-wound in vivo models [1], thus drawing interest in exploiting this potential. Chitosan films are useful in skin regeneration due to their highly adhesive and antimicrobial properties [2], though their use as protein delivery agents needs to be further explored. Additionally, when supplied cutaneously, lactic acid has been found to promote angiogenesis, collagen deposition, and growth factor production, resulting in accelerated skin regeneration for in vivo models [3]. Here we report the isolation and loading of bovine milk whey proteins onto chitosan-lactic acid films, as well as the evaluation of their chemical, thermal, and mechanical properties and release profiles. The incorporation of chitosan (CS), lactic acid (LA), and milk whey proteins (MWP) is expected to yield low-cost, scalable cutaneous delivery biomaterials with antimicrobial, angiogenic, and immunomodulating capabilities as a result of their respective individual properties.

Milk whey was isolated from commercial pasteurized bovine milk by pH adjustments, centrifugation, and salting out. The protein precipitates were quantified with a Bradford colorimetric assay and analyzed via SDS-PAGE. This analysis revealed that the isolated proteins did not degrade as a result of the process, thus validating the whey isolation protocol as reliable. Gel permeation and cationic exchange chromatographies were performed to confirm the identities of the protein components in the isolated milk whey. The deacetylation degree of the chitosan samples was determined by nuclear magnetic resonance. Dialyzed, freeze-dried milk whey protein isolate was loaded onto chitosan films prepared from chitosan-lactic acid solutions. The resulting CS-LA-MWP films were analyzed using texturometry, FTIR, TGA, and DSC to evaluate film adhesion strength on human skin, elastic modulus, and elongation to break; the incorporation of all components; and the degradation and glass transition temperatures. Protein release kinetics were determined by UV-vis spectroscopy. Antibacterial activity in vitro and water vapor permeability were also determined for CS-LA-MWP films.

Overall, the protein isolation and film preparation processes reported in this work yielded CS-LA-MWP films that were found to be highly elastic and adhesive, while inhibiting bacterial proliferation and releasing their protein load with an appropriate release profile for skin delivery applications. The regenerative potential of these films will be evaluated shortly in murine skin-wound models.

In Vitro Antitumoral Activity of the Black-Tailed Rattlesnake (Crotalus molossus molossus) Venom Encapsulated in Chitosan-Alginate Nanoparticles Jorge Jimenez-Canale, Jose A. Sarabia-Sainz, Daniel Fernández-Quiroz, Alexel J. Burgara-Estrella, Hector M. Sarabia-Sainz and Erika Silva-Campa; Univ de Sonora, Mexico

Nanomedicine has led to the development of new materials able to improve the pharmaceutical effect of bioactive components, broadening the options of treatment for several diseases like cancer. Chitosan (Cs) and Alginate (ALG) have been firmly established in recent years as biocompatible, biodegradable, mucoadhesive and low-toxic polymers able to form complexes with bioactive agents, making them promising drug delivery vehicles. Some snake venom toxins such as A2 phospholipases (PLA2s), serine proteinases (SVSPs) and metalloproteinases (SVMPs) have been reported to present antitumoral activity in different tumor cell-lines, making them a promising option to be used as cancer pharmaceuticals. We identified the major proteins of a black-tailed rattlesnake (Crotalus molossus molossus) venom through MALDI-QTOF analysis. Additionally, the venom against red blood cells and T-47D breast carcinoma cells was evaluated. Afterwards, the snake's venom was loaded into Cs-ALG nanoparticles through the ionotropic gelation process with tripolyphosphate (TPP), obtaining particles of 504.7 ± 22 nm and a Zeta potential of +41 ± 1.6 mV. The Cs-Venom-ALG complex was able to deliver the venom into the breast carcinoma cells through endocytosis, inhibiting their viability and inducing morphological changes in the T-47D cells. Thus, we suggest the potential use of C. m. molossus venom toxins entrapped within polymer nanoparticles for the future development and research of cancer pharmaceuticals.

Nature-Inspired Nanocomposites Endow Epigenetic Mediated Neurotherapeutic Potential of Neuroprotective Agents in PD Prevention Mohammed N. Sardoiwala, Subhasree R. Choudhury and Surajit Karmakar; Institute of Nanoscience and Technology, India

Posttranslational modification and agglomeration of α -Synuclein (α -Syn), mitochondrial dysfunction, oxidative stress and loss of dopaminergic neurons are hallmark of Parkinson’s disease (PD). The α-synucleinopathy is attributed to phosphorylation and aggregation of α-Syn. A strategy to degrade or reduce phosphorylated protein paves the way to develop PD therapy. Hence, nanoformulations of emerging neuroprotective agents, metformin and FTY720 have been evaluated in in vitro and ex vivo experimental PD models. Nature inspired bio-compatible polydopamine nanocarrier for metformin delivery and chitosan nanocarrier for FTY720 has been employed to enhance delivery, brain targeting and bio-availability of drugs. Nanomaterials have shown effective neuroprotection with controlled drug release to improve absorption and bio-availability of drugs. The neuroprotective potential was arbitrated by downregulation of phospho-serine 129 (pSer129) α -Syn, with reduction in oxidative stress, prevention of apoptosis and anti-inflammatory activities. The neuroprotective mechanism uncovered novel physical interaction of protein phosphatase PP2A- polycomb protein EzH2 and EzH2- pSer129 α-Syn to mediate ubiquitination and degradation of agglomerated pSer129 α-Syn. In summary, this study divulges the enhanced neuroprotective role of Met loaded PDANPs and FTY720 nanocomposites by reversing the neurochemical deficits by confirming an epigenetic mediated nanotherapeutic approach for the PD prevention.

High Density Lipoprotein Biomimetic Nanoparticles for Drug and Vaccine Delivery Anna Schwendeman; University of Michigan, United States

High density lipoprotein (HDL) is a nanoparticle (~8-10 nm) composed of a lipid membrane bilayer wrapped around by a
“belt” of amphipathic helices of Apolipoprotein A-I (ApoA-I). HDL travels in directly interacts with macrophages in arterial plaques to efflux excess cholesterol and subsequently deliver it to the liver by a process of reverse cholesterol transport (RCT). Our research focus is on design of synthetic high density lipoprotein (HDL) nanoparticles for treatment of cardiovascular disease. We discover novel ApoA-I mimetic peptides, explore biophysics of peptide-lipid interactions and optimize HDL compositions for interaction with specific cellular receptors, transporters and enzymes involved in RCT. We examine sHDL biodistribution, pharmacokinetics and pharmacodynamic properties. We take advantage of small size and clinical safety of sHDL to use it platform for drugs and vaccines delivery. This talk will cover the use of sHDL nanoparticles to deliver liver X receptor agonist to atheroma to reduce inflammation and atherosclerosis. This strategy utilizes pharmacological ability of sHDL to serve as an acceptor of cholesterol effluxed from atheroma. The use of sHDL nanoparticles for personalized vaccine and chemo-immuno therapy delivery results in development lasting protective immunity against tumor reoccurrence in animal models of colon cancer, glioblastoma and melanoma.

Reactive Oxygen Species Delivery by Nanoformulation Xiaoyuan (Shawn) Chen; National Institutes of Health, United States

The reactive oxygen species (ROS)-mediated mechanism is the major cause underlying the efficacy of photodynamic therapy (PDT). The PDT procedure is based on the cascade of synergistic effects between light, a photosensitizer (PS) and oxygen, which greatly favors the spatiotemporal control of the treatment. This procedure has also evoked several unresolved challenges at different levels including (i) the limited penetration depth of light, which restricts traditional PDT to superficial tumors; (ii) oxygen reliance does not allow PDT treatment of hypoxic tumors; (iii) light can complicate the phototherapeutic outcomes because of the concurrent heat generation; (iv) specific delivery of PSs to sub-cellular organelles for exerting effective toxicity remains an issue; and (v) side effects from undesirable white-light activation and self-catalyzation of traditional PSs. In this talk, the current status and the possible opportunities of nanomedicine for ROS generation for cancer therapy will be discussed in detail.

5:15 AM S.SM08.02.11
Efficient Delivery of Nerve Growth Factors to the Central Nervous System for Neural Regeneration Duo Xu and Yunfeng Lu; University of California, Los Angeles, United States

The central nervous system (CNS) plays a central role in the control of sensory and motor functions, and the disruption of its barriers can result in severe and debilitating neurological disorders. Neurotrophins are promising therapeutic agents for neural regeneration in the damaged CNS. However, their penetration across the blood-brain barrier remains a formidable challenge, representing a bottleneck for brain and spinal cord therapy. We have developed a nanocapsule-based delivery system that enables intravenously injected nerve growth factor (NGF) to enter the CNS in healthy mice and nonhuman primate. In pathological conditions, the delivery of NGF enables neural regeneration, tissue remodeling, and functional recovery in mice with spinal cord injury. This technology can be utilized to deliver other neurotrophins and growth factors to the CNS, opening a new avenue for tissue engineering and the treatment of CNS disorders and neurodegenerative diseases.

5:25 AM S.SM08.02.12
Fabrication of Non-Spherical and Multiphasic Particles with Independent Control of Particle Size, Shape and Chemistry Catherine Snyder, Sai P. Kobaku, Geeta Mehta and Anish Tuteja; University of Michigan, United States

Introduction: Cancer is the second leading cause of death in the world and current treatment methods have low 5-year survival rates. One potential solution to improving treatment methods is targeted nanoparticle drug delivery. Nanoparticles can be engineered to increase the efficacy of chemotherapeutic drugs through increased targeting and dose delivery. Despite proven benefits of nanoparticle drug delivery, it comes with its own challenges, the largest of which is overcoming the physiological barriers between the nanoparticle injection site and the tumor in the body. In order to better understand the pharmacokinetics of nanoparticles in vivo, nanoparticle characteristics need to be varied in a systematic study to identify ideal
formulations. This systematic study would need to test nanoparticles of different sizes, shapes, and chemistries with multiple phases, and these properties would need to be independently varied. Current fabrication methods are unable to make monodisperse, multiphasic or non-spherical particles and spherical particles, and to independently alter each parameter.

**Objective:** To address the need of a nanoparticle fabrication method which can modulate particle properties in a systematic and independent manner, we have developed a novel polymeric particle synthesis technique, called Wettability Engendered Templated Self-assembly (WETS) and have demonstrated the ability to control size, shape and composition independently.

**Methods and Results:** The WETS methodology uses surfaces with patterned wettability to self-assemble discrete, monodisperse polymer particles in an array after dip-coating in a polymer solution. These particles can have dimensions ranging from 25 nm to 150 µm, and can have a variety of non-spherical, planar geometries such as disks, squares, triangles and hexagons. Size and shape are independently controlled through the patterned wettability surface and the dip-coating parameters. Additional dip-coating layers of other polymers on top of previously deposited polymer layers allows for the fabrication of multiphasic particles with each phase able to independently encapsulate a different therapeutic or diagnostic agent. As each phase is added to the particle individually, the size and composition of the phases can be independently altered. Single and multiphasic spherical particles are formed from the reconfiguration of non-spherical particles in a predictable manner. Multiphasic spherical particles can be tuned to create Janus or core-shell morphologies based on reconfiguration parameters. These results show the ability to synthesize varied particles with a single method which is required to make direct comparisons between particle characteristics in order to develop improvements in cancer therapies.

**Conclusion:** With the novel WETS fabrication method, we have demonstrated the ability to have systematic and independent control over the size, shape and composition of polymeric particles in a predictable manner. This method will allow for a systematic study of nanoparticle pharmacokinetics *in vivo* in order to identify ideal nanoparticle formulations for cancer therapies. Continued work is focused on the scale up of WETS in order to undertake *in vitro* and *in vivo* studies in the future.

**All-Atom Simulation Method for Dipolar Assembly and Alignment of Single Domain Magnetic Nanoparticles**

Akhlak-ul Mahmood and Yaroslava G. Yingling; North Carolina State University, United States

Magnetic nanoparticles under the influence of the external magnetic field have been widely studied for the past few decades due to their potential applications in bio and nanotechnology. However, the interplay of dipolar and Zeeman interactions during the assembly process is a major question that remained to be answered. Current modeling and simulation techniques are primarily limited to coarse-grained methods, which lack proper resolution for understanding these processes at the atomic level. In this work, we developed a novel method to study the dipolar and Zeeman interactions within stable single domain (SSD) magnetic nanoparticles using atomistic molecular dynamics simulation. The primary advantage of this technique is the atomistic resolution that permits the study of magnetic nanoparticles’ alignment and their explicit interactions with the surrounding environment. Our methodology permits the investigation of the formation of chain and ring shapes of 3.2 nm and 8.2 nm cubic and spherical Magnetite (Fe3O4) nanoparticles functionalized with Oleic Acid under the influence of an external magnetic field and detailed investigation of the role of solvent properties on shape formation. This developed method can be used as a plugin with the LAMMPS molecular dynamics software to study the behavior of small magnetic nanoparticles to gain insights into the physics and chemistry of different magnetic assembly processes.

5:45 AM S.SM08.02.18

**Gold-Implanted Plasmonic Quartz Plate as a Launch Pad for Laser-Driven Photoacoustic Microfluidic Pumps**

Feng Lin1, Talari Talari Vishal2, Junyi Zhao3, John Schaibley4, Dong Liu2, Zhiming M. Wang1 and Jiming Bao2; 1University of Electronic Science and Technology of China, China; 2University of Houston, United States; 3Washington University in St. Louis, United States; 4University of Arizona, United States

Enabled initially by the development of microelectromechanical systems, current microfluidic pumps still require advanced microfabrication techniques to create a variety of fluid-driving mechanisms. Here we report a generation of micropumps that involve no moving parts and microstructures. This micropump is based on a principle of photoacoustic laser streaming and is simply made of an Au-implanted plasmonic quartz plate. Under a pulsed laser excitation, any point on the plate can generate a directional long-lasting ultrasound wave which drives the fluid via acoustic streaming. Manipulating and programming laser beams can easily create a single pump, a moving pump, and multiple pumps. The underlying pumping mechanism of photoacoustic streaming is verified by high-speed imaging of the fluid motion after a single laser pulse. As many light-absorbing materials have been identified for efficient photoacoustic generation, photoacoustic micropumps can have diversity in their implementation. These laser-driven fabrication-free micropumps open up a generation of pumping technology and
opportunities for easy integration and versatile microfluidic applications

Supramolecular Hydrogels for Drug Delivery and Thermal Stabilization of Biologics Mark W. Tibbitt; ETH Zürich, Switzerland

In this talk, we will present our recent work on the synthesis and engineering of supramolecular hydrogels for controlled drug delivery and thermal stabilization of encapsulated biologics. Polymer–nanoparticle (PNP) hydrogels have been produced from drug-loaded nanoparticles (NPs) and cross-linking polymers. These transient physical assemblies are formed through supramolecular interactions between the NPs and the polymers and exhibit shear-thinning and self-healing behavior suitable for injection or extrusion. In our lab, we are applying PNP hydrogels for local injection of therapeutics and as immune-modulatory biomaterials. In addition, we have developed the platform as a universal rheological carrier for biomaterials additive manufacturing. Uniquely, the nano-carrier can accommodate a range of secondary polymers for post-print stabilization and functionality. We are exploiting these printable PNP gels to assemble additively manufactured drug delivery systems for dual release of both hydrophilic and hydrophobic molecules. We also employ dynamic covalent chemistry to design moldable polymeric hydrogels. Here, we have fabricated ideal reversible networks and investigated how the molecular characteristics of the dynamic covalent cross-links impact the emergent material properties. We have leveraged this understanding to design biomaterials that can encapsulate, thermally stabilize, and release temperature-sensitive biologics. We are exploiting these materials to mitigate the global reliance on the cold chain in the distribution of value-added biologics and biotherapeutics, including vaccines. In total, this talk will illustrate how molecular design of hydrogels can enable emerging applications in drug delivery from injectable biomaterials, additive manufacturing controlled release systems, and materials for the thermal stabilization of biologics.

6:10 AM S.SM08.02.20
Polyglycerol-Grafted Nanoparticles Improve Stealth Effect by Resisting Protein Corona Formation—A Comparison Study to PEG Yajuan Zou and Naoki Komatsu; Kyoto University, Japan

In biological fluids, proteins are adsorbed onto the surface of nanoparticles (NPs) to form a coating known as protein corona. Most of the corona proteins act as opsonin which activates the macrophage from immune system to uptake NPs, leading to the rapid removal of NPs [1]. This restricts the development of nanomedicine. Although conjugation with linear polyethylene glycol (PEG) is the standard approach to reduce protein attachment and to avoid non-specific uptake, it cannot fully prevent the opsonization. On the other hand, we have demonstrated polyglycerol (PG) as a promising alternative to PEG, because PG enhanced the aqueous dispersibility and gave stealth effect to NPs [2]. In order to understand the role of PG, we compare protein affinity and stealth effect of PG and PEG grafted nanodiamond (ND-PG and ND-PEG, respectively) with different density in this paper. Protein analyses by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) indicated that PG was much more resistant than PEG to adsorption of the opsonin proteins such as IgG and complement protein. In particular, there was almost no protein on the dense PG layer. In vitro stealth effect was revealed by TEM; almost no ND-PG was observed in the TEM images of U937 macrophage, while there was ND-PEG in the macrophage. This indicates that PG has much better stealth effect than PEG. In vivo stealth effects including blood circulation and biodistribution will be reported in due course.

Theranostic Microcapsules for Image-Guided and Ultrasound-Enabled Drug Delivery Eugenia Kharlampieva; University of Alabama, United States

The ability to track drug carriers in their administered environment in real time and to release the drug in a controlled, minimally invasive manner are hallmarks of an advanced drug delivery system. This presentation focuses on ultrasound-sensitive multilayer capsules as efficient contrast-enhanced imaging agents utilizing ultrasound, magnetic resonance imaging
Owing to the active contrast, long circulation, customizable size, shape, composition, and precise delivery of high payload that can influence immune responses for prolong circulation in the blood. The ability of this material to conjugate concentrations, these materials present a powerful and safe platform for imaging-guided precision drug delivery.

Metallic nanomaterials in polymers have been used in a variety of biomedical applications including drug delivery, enhanced antibacterial activity, and tumor ablation. The plasmonic response of metallic nanomaterials involves electrons that oscillate at resonance with incident light. The plasmon resonance frequency at the particles’ surface is dependent on factors such as nanoparticle (NP) size, shape, composition, state of aggregation, and environment. In the case of polymers impregnated with metallic nanomaterials, non-propagating surface plasmon modes within the electromagnetic spectrum enable the conversion of optical energy to thermal energy with a coincident temperature change within the polymer. In previous work, investigators have used polymer capsules containing metallic nanomaterials in the shell to melt the shell and release encapsulated drugs in the presence of light. Such capsules are functionalized to target cancer tissues and, once at the correct locale, are activated by light to treat tumors or other cancerous matter. For this work, we will focus on topical, electrospun fiber drug delivery systems that can be stored and activated in the presence of light to release treatments such as antibiotics or coagulants when needed.

In our previous work, colloidal gold NPs (GNPs, max. absorption λ = 522 nm) were incorporated into polymer films and electrospun into fibers to utilize the NP plasmonic response for localized heating of the polymer. Mathematical modeling was used to describe the GNP distribution and heat/melt profile surrounding each GNP under illumination in the polymer, demonstrating that a bulk temperature change of only 0.2 °C results in a 20-nm-diameter melted polymer sphere around the GNP. Such results provided us with a mathematical guide to predict the GNP size that would result in a desired melt thickness. In our previous work, it was shown that by reducing the radius of polymer material around the GNP though the use of nanoscale-diameter electrospun fibers in place of an infinite thin film (centimeter scale) heating of the bulk material increased by 72 %. This result is attributed to the reduction of polymer material surrounding each GNP. Bulk heating of polymer blend films containing GNPs were mapped using a forward-looking infrared (FLIR) camera system with light-emitting diodes (LEDs). Change in temperature observed in the thin films was related to photothermal energy conversion efficiency of the thin films through heat transfer calculations. Significantly, the GNP-doped film photothermal conversion efficiency increased by 1.8 times (75.7 % increase) under 530-nm LED illumination. Based on the mathematical model developed, the enhanced heating observed, and the enhanced efficiencies of the materials explored thus far, future objectives include developing these materials further for light activated drug delivery systems. Future work will include developing the mathematical model for silver nanoplates (SNPs), which demonstrated a stronger...
absorption response and are more economical than gold. SNPs used will be doped into polymer thin films and electrospun into fibers, and bulk heating will be monitored on the FLIR system. Heating in the thin films versus nanoscale-diameter fibers will be compared, and efficiencies of the materials will be calculated. In addition, ideal photothermal heating will be studied through altered nanomaterial concentrations in the polymers. The relationship between photothermal heating and SNP concentration will elucidate any plasmonic coupling and guide material optimization schemes.

5:35 AM S.SM08.03.07
Polymer Nanosheets: Multi-Scale Drug Controlled Release Systems and Production Rigoberto C. Advincula; Case Western Reserve University, United States

Layered polymer systems than can be fabricated using roll-to-roll methods have been demonstrated using film extrusion methods. Together with lithography, they enable the fabrication of capsules and colloidal particles that have controlled kinetics for release of agents both pre-loaded and post-loaded. In this talk, we demonstrate the scalability of drug release using a hierarchical configuration of layers that can be fabricate layer-by-layer as applied to patches, capsules, and nanosheets. The methods make use of solution methods as well as polymer multilayer extrusion methods more popularly known as the CLIPS process. The solution methods take advantage of the physisorption of polyelectrolytes to form suspendable ultrathin nanosheets. It is possible to achieve a production scale of roll-to-roll films using the CLIPS process. The controlled release of model drugs is demonstrated under buffer conditions including the demonstration on the preparation of patches and nanosheets.

5:45 AM *S.SM08.03.08
Minimally Invasive In Vivo Brain Modulation with Neuron-Type Specificity Guosong Hong; Stanford University, United States

Understanding the complex neural circuity and its correlation to specific behaviors requires spatially and temporally precise modulation of neuron subtypes in certain brain regions. One major challenge of existing neural modulation techniques is the tradeoff between invasiveness and depth: invasive implants of electrodes and optical fibers are usually required for electrical and optogenetic modulation of neural activity in deep brain, while non-invasive brain stimulation methods lack penetration depth and neuron-type specificity of brain modulation. The invasive brain implant and head tethering result in acute tissue damage and chronic gliosis at the neural interface, leading to degradation of recording and stimulation capabilities over time. In this talk, I will present the latest advances of minimally invasive approaches for in vivo neuron-type specific brain modulation from my lab at Stanford University. First, I will describe a new approach termed ‘sono-optogenetics’, which uses a circulation delivered rechargeable light source for non-invasive optogenetics in deep brain regions through the intact scalp and skull. In this approach, we address the challenge of limited tissue penetration of visible photons via the intravenous delivery of mechanoluminescent nanoparticles, which can act as local light sources in the brain when triggered by brain-penetrant focused ultrasound (FUS). After delivery, these particles can be recharged by 400-nm photoexcitation light in superficial blood vessels during circulation, and turned on by FUS to emit 470-nm light repetitively in the intact brain for optogenetic stimulation. Second, I will describe a type of new deep-brain stimulating devices termed ‘injectable photovoltaics’ for a wireless, gliosis-free neural stimulation interface. Micron-sized, ultraflexible and wirelessly powered microdevices can be delivered into the brain via syringe injection so as to disturb the brain as little as possible when deployed. These injectable devices are fabricated with photovoltaic polymers, turning brain-penetrating near-infrared light into electrical impulses for deep-brain neural stimulation. These two brain-modulation approaches have the potential of generating transformative results for both neuroscience research and neurological applications, not only expanding the toolbox of neuromodulation techniques, but also offering strategies for clinical translation of therapeutic neural implants.

New Delivery Vehicles for Gene Editing Enzymes Niren Murthy1,2; 1University of California, Berkeley, United States; 2Innovative Genomics Institute, United States
Cas9 based therapeutics have the potential to revolutionize the treatment of genetic diseases. However, safe and effective methods for delivering the Cas9-guide RNA complex (Cas9 RNP) need to be developed before the clinical potential of Cas9 based therapeutics can be fully realized. In this presentation, I will describe non-viral delivery strategies developed in our laboratory for delivering the Cas9 RNP. The first delivery strategy is termed CRISPR-Gold. CRISPR-Gold is composed of gold nanoparticles assembled with the Cas9/gRNA ribonucleoprotein (RNP) complex, donor DNA, and an endosomal disruptive polymer. CRISPR-Gold was able to correct the DNA mutation that causes Duchenne muscular dystrophy (DMD) in mdx mice via homology directed DNA repair (HDR), with an efficiency of 5.4% after an intramuscular injection. In addition, CRISPR-Gold was able to edit the brains of adult mice and rescued mice from the repetitive behaviors caused by autism. In this presentation, I will also describe other strategies for delivering the Cas9 RNP based on encapsulation in block copolymers and conjugation with peptides. Collectively, our experience suggests that non-viral strategies for delivering the Cas9 RNP have great potential for treating DMD and other genetic diseases.

**Harnessing Biomaterials to Study and Control Immune Function**

Christopher M. Jewell; University of Maryland, College Park, United States

Our research combines immunology and biomaterials to understand the interactions between synthetic materials and immune tissues, and to design more selective therapeutic vaccines for cancer and autoimmunity. This presentation will highlight our recent efforts toward these goals combining materials science and bioengineering tools, cell culture, animal models, and samples from human patients. In one example I will discuss new degradable polymer depots that could improve the selectivity of therapies for autoimmune diseases such as multiple sclerosis and diabetes by locally reprogramming the function of lymph nodes – tissues that coordinate immune function. A second area will present the lab's efforts to self-assemble immune signals into modular nanostructures. This rational design approach allows activation of programmable combinations and levels of immune pathways triggered. Modular control over these aspects of immune signaling could help improve the efficacy of vaccines for cancer and infectious disease, and enhance the efficiency of vaccine translation.

**Tip-Based Nanoscale 3D Printing**

Wonho Jhe and Sangmin An; Seoul National University, Korea (the Republic of)
Viscoelastic complex fluids exhibit rheological nonlinearity at a high shear rate. Although typical nonlinear effects, shear thinning and shear thickening, have been usually understood by variation of intrinsic quantities such as viscosity, one still requires a better understanding of the microscopic origins, currently under debate, especially on the shear-thickening mechanism. We present accurate measurements of shear stress in the bound hydration water layer using noncontact dynamic force microscopy. We find shear thickening occurs above 10^6 1/s shear rate beyond 0.3-nm layer thickness, which is attributed to the nonviscous, elasticity associated fluidic instability via fluctuation correlation. Such a nonlinear fluidic transition is observed due to the long relaxation time (1 us) of water available in the nanoconfined hydration layer, which indicates the onset of elastic turbulence at nanoscale, elucidating the interplay between relaxation and shear motion, which also indicates the onset of elastic turbulence at nanoscale above a universal shear velocity of 1 mm/s. This extensive layer-by-layer control paves the way for fundamental studies of nonlinear nanorheology and nanoscale hydrodynamics, as well as provides novel insights on viscoelastic dynamics of interfacial water. We will also discuss the tip-based microfluidic characterization and manipulation of liquids.

5:11 PM *S.SM09.01.03
Material Horizons for Volumetric Additive Manufacturing Maxim Shusteff1, Caitlyn Cook1, Johanna Schwartz1, Erika Fong1, James Oakdale1, Bryan Moran1, Allison Kaczmarek2,2, Hossein Heidari3, S.M. Luk3, Charles Rackson4, Robert McLeod4 and Hayden Taylor1; 1Lawrence Livermore National Laboratory, United States; 2Clemson University, United States; 3University of California, Berkeley, United States; 4University of Colorado Boulder, United States

As additive manufacturing (AM, also known as 3D printing) technologies have proliferated, approaches based on solidification of photosensitive liquid resins have showed great promise due to their superior resolution and precision. However, these techniques have been largely limited to prototyping applications due to the constraints on available materials and their mechanical properties, as well as slow builds and poor surface quality resulting from layer-wise fabrication. With the advent of volumetric AM (VAM), complete 3D structures with complex geometries can now be produced in a single step, leapfrogging over the traditional limitations of layer-by-layer approaches to 3D printing.

Volumetric 3D printing generates a 3D distribution of absorbed optical energy within a volume of photosensitive material, concurrently curing all points within a target geometry, on a timescale of 10s to 100s of seconds. No substrate is required as the part forms unsupported in the resin container. The most versatile implementation of VAM is known as computed axial lithography (CAL) which adapts the principles of computed tomography (CT) to generate a sequence of intensity-modulated projections, which are then beamed sequentially into a rotating resin container via a DLP projector to create the required energy dose. Because there is no fluid motion, and no hydrodynamic forces during a build, this approach is particularly compelling for very soft materials such as the hydrogels widely used in tissue engineering and regenerative medicine applications. The absence of support structure also enables complex geometries such as vasculature to be built. Successful volumetric 3D printing requires spatio-temporal control over the polymerization reaction at all points within the fabrication volume. This demands a more detailed understanding of a host of process parameters, compared with traditional layered approaches. Perhaps the most important such parameters are the absorbed volumetric energy dose $E_{VAM}$, as well as the rate at which this dose is delivered. The progress of the photochemical reaction may then be characterized in terms of a variety of metrics, such as double-bond conversion, or the evolution of mechanical and optical properties of the material. We investigate the inter-relationship of these properties, obtained from ex-situ measurements such as real-time FTIR spectroscopy, photo-rheology, and mechanical testing, developing a quantitative framework for predicting volumetric structure formation. An additional resin characteristic critical for CAL printing is nonlinear threshold behavior. This allows resin that receives a sub-threshold dose to remain liquid, and derives from the interaction of the generated radicals and inhibitory species present in the resin. For some chemistries the inhibitory effect is provided by dissolved molecular oxygen, but for other formulations, deliberately including another inhibitor is necessary. We discuss the implications of these interacting factors for photo-resin design within the volumetric AM paradigm, as well as more broadly in photopolymer-based AM methods. We also discuss several material classes for VAM, including high-performance engineering materials, as well as cell-culture compatible hydrogels.

Additive Manufacturing of Borosilicate Glass via Stereolithography Omena Okpowe1, Andriy Durygin2, Vadym Drozd2,
Nezih Pala and Chunlei Wang; University of Toronto, Canada; 2Ryerson University, Canada; 3University of British Columbia, Canada

Borosilicate glass is a type of glass material consisting SiO2 and B2O3 as network formers and alkali oxide modifiers. Their excellent optical transparency, chemical resistance, low thermal expansivity and tunable chemical composition make them useful for a wide range of applications such as lab ware, medical implants, microelectromechanical systems (MEMS), sensing and detection etc. Conventional glass fabrication techniques involve melting, casting and use of undesirable chemicals and these imply that there is little room for flexibility in shape and resolution. Recent surge in additive manufacturing efforts now show that ceramic glasses can now be fabricated via stereolithography. However this has not been shown possible for borosilicates due to their low softening temperatures.

Herein, we report a simple additive manufacturing protocol for fabricating 3D low softening temperature borosilicate glass. It entails first fabricating a liquid glass composite, printing on a layer by layer basis to form a 'green ensemble'. This 'green ensemble' must then be debound to yield a 'brown ensemble' and sintered to yield transparent and amorphous glass ensembles. The properties of the printed glass depend on thermal processing parameters (temperature, time and environment) and these can be readily tuned and optimized to yield 3D glass for a wide range of applications. The printed glass show good optical properties, show no devitrification and exhibit minimal surface roughness requiring no further polishing and finishing typically associated with other glass fabrication techniques.

Additive Manufacturing for Transdermal Biosensor Applications Roger Narayan; North Carolina State University, United States

Two photon polymerization is an additive manufacturing method that offers many advantages over conventional processes for scalable mass production of medical devices, including microneedles and other medical devices with small-scale features. First, the raw materials (e.g., inorganic-organic hybrid materials and acrylate-based polymers) used in two photon polymerization can be purchased at low cost. Second, two photon polymerization can be established in a conventional environment; no cleanroom facilities or other types of specialized facilities are required. Third, two photon polymerization is a straightforward approach for creating medical devices with complex and small-scale features. Two photon polymerization has been used to create hollow microneedles with a larger range of shapes and dimensions than conventional microneedle fabrication methods. We have prepared several types of hollow microneedle-based biosensors using microneedles that were fabricated using either two photon polymerization or digital micromirror device-based stereolithography. In these biosensors, the sensors (either colorimetric or electrochemical) are located within the bores of the microneedles or underneath the microneedles. Application-specific testing and functional testing of the microneedle-based biosensors will be considered.

5:51 PM S.SM09.01.09
Dynamically AdjustableReal-Time Tuning of Catheter-Injectable Delivery of Functional Hydrogels towards In Vivo Bioextrusion Yuta Dobashi†, Jerry Ku†, Joel Ramjist‡, Christopher Pasarikowski†, Konrad Walus†, John Madden and Victor Yang†; †University of Toronto, Canada; ‡Ryerson University, Canada; †University of British Columbia, Canada

Hydrogels have long been considered a significantly promising class of biomaterials. While the chemomechanical tunability of a multitude of hydrogels have been demonstrated in vitro, the ability to deliver these materials in a minimally invasive manner to avoid iatrogenic damages has yet to be fully explored. In the present work, we demonstrate a method of in-situ extrusion of hydrogels with compositions and chemomechanical properties that can be dynamically adjusted “on-the-fly” using a custom catheter that is utilized intravascularly. A custom UV-integrated, multi-lumen microcatheter (inner/outer lumen diameters: 0.6/1.28 mm) was assembled and a suite of low viscosity, shear thinning gelatin-based precursors were formulated for delivery. While the shear thinning property makes this precursor a suitable choice for injection through a catheter with extended length and small diameter, intensity modulation of UV to cross-link the precursor aids greatly in tuning the stiffness at the catheter tip. We show that by modulating the absolute and relative flow rates as well as the UV intensity (0–150 µW output from a 105µm core multimode fibre), we can extrude hydrogels with stiffnesses dynamically varying from <10 to 80 kPa. In addition, through the dual luminal architecture, it is also possible to sequentially switch or coaxially coextrude two types of precursor compositions. The concentrations and diffusivities of additives (as preliminarily demonstrated using food dyes) within the extruded scaffold can also be dynamically altered by 10^5 and 10^5 orders respectively, in a single piece of extruded hydrogel fibre, therefore allowing applications a highly customizable drug depot to be deployed using this technique. To demonstrate the initial utility of this system, we successfully performed embolization of a saccular aneurysm model (diameter ~ 12 mm) and a capillary vasculature model (diameter <1 mm) using a pulsatile...
vascular flow phantom. The former required the extruded hydrogels to be relatively stiffer via increased photo-cross linking to fill the aneurysm while avoiding leakage into the parent vessel. In capillary embolization, the precursor was injected with lower crosslinking leading to increased viscosity to penetrate further into the vessels to fully embolize the structure. These findings yield direct application ideas in therapeutics such as vascular embolization in a variety of disease states, including cerebral aneurysms, arterio-venous malformations, vascularized tumors, and hemorrhagic vessels. The system can also be utilized for intravascular drug delivery and targeted cell therapies, which may require the physician to constantly adapt to the state of the patient. Further, such a dynamically tunable hydrogel delivery method may be able to serve as a supporting host matrix for functional sensing devices such as microelectrode arrays and quantum dot based chemical sensors.

Fiber Devices for Tissue Engineering Louis A. van der Elst, Merve Gokce Kurtoglu and Alexander Gumennik; Intelligent Systems Engineering, Indiana University, United States

Bioink extrusion-printing, while capable of creating macroscopically accurate anatomic models, fails to replicate the microstructure of the natural tissue due to resolution limitation of this bottom-up fabrication approach. We re-engineer the extrusion process to co-extrude a fiber device in line with the hydrogel bioink. This allows deviation from a pure bottom-up towards a combined approach, where a bottom-up extrusion process creates the macrostructure, while the fiber device in a top-down fashion subsequently promotes the growth of natural microstructure from within the volume of the print.

Fibers can embed a range of bio-functional and biosensing devices and systems. We aim to incorporate microfluidic, ultrasonic, and shape-memory-alloy (SMA) structures mimicking the functionalities of microvasculature, innervation, and musculature, respectively, into a single fiber-device. Those functional structures are created by a thermal draw of fibers from multimaterial preforms – a process familiar from an optical communication fiber fabrication. In this process, the macroscopic preform – a thick and short rod, cross-sectionally structured to meet the desired fiber functionality – is heated to become a viscous liquid and scaled by a thermal draw into a thin and long fiber, preserving the cross-sectional geometry of the preform. Then the fiber cores are patterned axially by a spatially coherent material selective capillary instability to form arrays of ultrasonic transducers contacted in parallel and microchannels with periodic outlets spanning the entire fiber length[1].

In the extrusion process, the fiber is coated with hydrogel, contains tissue cells, extracellular matrix material, nutrients and growth-factors, forming a scaffolded print-line that is raster-layered into a printed model cross section additively constructing the final model in a layer-by-layer manner. Subsequently, the fiber-embedded microchannel structure is used as artificial vasculature supplying building material and nutrients into surrounding bioink to ignite the creation of natural vasculature and promote the proliferation of the bioink-contained tissue cells with their subsequent maturation into a natural-tissue-like structure. The ultrasonic transducers embedded in the fiber are used to sense the changes in the surrounding material density, monitoring cell-proliferation process, thus serving as artificial tactile nerves. SMA cores, contracting upon transduction of electric current, mimic the function of muscle yarns.

The proposed bioprinting approach will likely deliver a biosynthetic tissue with natural-like microstructure opening new routes in regenerative medicine, such as wound infilling and organ replacement. Moreover, it would allow creating lab-bench anatomical models of realistic tissue, in which bio-material delivery and biosensing is performed volumetrically with a microscale resolution, thus forming a novel stand-alone platform for investigation of micrometabolic processes. Such a platform would be a valuable asset to drug toxicity investigation, and real-time survivability monitoring of such artificial tissues and organs both in-vitro and in animal subjects.

6:21 PM S.SM09.01.12
Genomic-DNA Coated 3D Printed Materials for Drug Capture Daryl Yee, Robert H. Grubbs and Julia R. Greer; California Institute of Technology, United States

Since the discovery of chemotherapy in the beginning of the 20th-century, researchers around the world have been actively developing new and more effective chemotherapeutic agents to better treat cancer. Traditionally, chemotherapeutic agents work by interfering with cell division. However, by virtue of their mechanism of action, healthy normal cells can also be...
targeted and destroyed. As a result, while chemotherapy is an effective way of managing cancer, the resulting side effects limits its use. One approach currently taken to reduce these side effects is to deliver the chemotherapy drugs directly to the tumor via transarterial chemoembolization, or other similar procedures. While this has been effective in reducing systemic toxicity, more can be done to improve this. Ideally, a device that could sequester any unreacted chemotherapy agents could be installed "downstream" of the tumor prior to them entering systemic circulation. Such drug-capture materials have yet to be realized due to the difficulty in achieving materials that have the right surface chemistry and geometry for blood flow.

Working together with medical doctors, computational fluid dynamics experts, chemists, and materials scientists, we report the fabrication of DNA functionalized 3D printed porous materials that can be used to capture doxorubicin and cisplatin, two commonly used DNA-targeting chemotherapy agents. We discuss the concept behind the device, the use of 3D printed materials as an ideal substrate, and the chemistries considered in drug binding. To achieve scalability of these devices, we developed a method of attaching cheaply available genomic DNA to these materials, a departure from commonly used synthetic DNA. We characterize the surface of the structure and verify the binding of DNA to the surface via XPS, EDS and the use of chemical assays. The efficacy of these functionalized materials were demonstrated in PBS, where we observed a >70% reduction in doxorubicin concentration over a period of 20 minutes, highlighting the viability of this as a method of drug capture.

4D Printing of Advanced Scaffolds with Controlled Growth Factor Delivery for Tissue Engineering Min Wang; The University of Hong Kong, Hong Kong

Additive manufacturing, popularly known as “3D printing”, includes an array of technologies such as fused deposition modelling (FDM), selective laser sintering (SLS) and inkjet printing. Compared with conventional manufacturing technologies, 3D printing has many distinctive advantages, including the construction of 3D structures with complex shapes and functionalities. Therefore, 3D printing technologies have seen increasing popularity in many areas, such as product design and development, industrial production, consumer goods, aerospace, and education. 3D printing has already made a tremendous impact in our society. The exciting TED Talk in 2013 by Tibbits of MIT ushered in a new era in additive manufacturing: 4D printing. With 4D printing, 3D printed static objects will change their shapes over time, i.e., 4D printing uses 3D printing technologies to produce shape-morphing objects. Such objects can meet the demanding requirements in particularly applications. The concept of 4D printing has been evolving and one popular definition of 4D printing is that the shape, property and functionality of a 3D printed object can evolve with time in predefined and programmable designs. There have been numerous investigations into the application of 3D printing in biomedical engineering. So far, the greatest biomedical applications of 3D printing are in the tissue engineering field. Tissue engineering offers a new approach to treat difficult problems in human tissue repair. It involves using live cells to form implantable devices for body tissue regeneration. In scaffold-based tissue engineering, a scaffold provides a microenvironment for cells to adhere, proliferate and differentiate and a structural framework for new tissue formation. 3D printing has many advantages in scaffold fabrication, such as control of pore size, porosity, etc. Furthermore, 3D printing can make multilayered scaffolds with different layer characteristics. Most human body tissues are complex and hierarchical and their regeneration requires structurally complex scaffolds that resemble tissue structures and can provide biochemical cues such as growth factors (GFs). Incorporating GFs and even live cells in scaffolds can greatly facilitate tissue regeneration. Since 2004, we have been investigating 3D biomedical printing and have used different 3D printing techniques for developing bone tissue engineering scaffolds (e.g., S.H.Lee, W.Y.Zhou, W.L.Cheung, M.Wang, “Producing Polymeric Scaffolds for Bone Tissue Engineering Using the Selective Laser Sintering Technique”, Transactions of the Society For Biomaterials 30th Annual Meeting, Memphis, TN, USA, 2005, 348). We have also been exploring 4D printing in tissue engineering (e.g., C.Wang, Y.Zhou, M.Wang, “In situ Delivery of rhBMP-2 in Surface Porous Shape Memory Scaffolds Developed through Cryogenic 3D Plotting”, Materials Letters, Vol.189 (2017), 140-143). This talk will give an overview of our work in 3D/4D printing of scaffolds for
regenerating tissues such as bone and blood vessels. It will focus on the design and 4D printing of shape-morphing and GF-delivering scaffolds for tissue engineering.

3D Printed Diamond Technology—A New Material for Biomedical Applications Kate Fox, Aaqil Rifai, Nour Mani and Nkiem Tran; RMIT University, Australia

Diamond is quickly becoming an interesting material for medical implants with evidence that it provides not only a good biointerface but also an antimicrobial surface. Previously ultrananocrystalline diamond was shown to be a good bionic implant material [1] and our group have shown that a polycrystalline diamond coating can be produced on a 3D printed titanium substrate [2]. However up until now, all diamond implants have been as a coating material, with limitations as to its capacity to be used as a three dimensional surface. Here we present our recent results fabricating diamond implants using additive manufacturing including presenting for the first time a hybrid 3D diamond-titanium printed material which was recently published [3]. Diamond implants fabricated via using three different techniques (i) nanodiamond seeding, (ii) polycrystalline diamond coating and (iii) composite diamond-titanium biomaterial all showed superior cellular proliferation compared to the as-printed SLM titanium.as well as a decrease in microbial activity. The possibility of 3D diamond opens up large possibilities for new diamond technologies

10:46 AM S.SM09.01.16

Ultra-High Resolution Inkjet Printing of Vascular Structures Brian Derby; University of Manchester, United Kingdom

It is now more than 30 years since the principles of Additive Manufacturing or 3D Printing moved from a concept to practical implementation and over 20 years since the first publications on its use to fabricate implantable medical devices. In this period it has rapidly progressed from being seen as a topic for Science Fiction to now a method for the production of proto- or in vitro model tissues for tissue-on-a-chip applications and laboratory animal studies. Indeed there are several commercial organizations that have developed and market commercial Bioprinters. However, despite these not inconsiderable advances, the original target of printed cell-laden implants or tissue patches have still not been realized.

A key obstacle to the use of 3D printing for the fabrication of cell-laden constructs is the need to provide a functional vasculature for the maintenance of cell viability through the provision of oxygen and nutrients, as well as a pathway for waste removal. It is well known that the diffusion limit in the 3D culture of cells limits spheroid size to a few hundred μm and that the capillaries in healthy tissue have a diameter of 5 – 10 μm and are typically spaced around 50 μm. However, current additive manufacturing routes that are in widespread use in biofabrication have a spatial resolution > 100 μm. Hence, new approaches to producing high resolution vascular structures and models for angiogenesis are required.

Here we describe the use of ultra-high resolution inkjet printing (UHIJP) as a route to fabricate vascular structures in gelatine methacrylate (GelMA) hydrogels. This technique is related to electrospraying and electrospinning in that a local electric field is used to form a "Taylor Cone" with the meniscus of a fluid at a fine nozzle. Through using a controlled electrical pulse, individual mono-sized droplets are ejected with volume down to a single femtolitre (10^-18 m^3) with droplet diameters in the range 1 - 3 μm. UHIJP has been used to print structures from a thermoreversible hydrogel based on triblock polymers of polyethylene oxide and polypropylene oxide (Pluronic F127). These are subsequently encapsulated in GelMA and photopolymerised before removal of the Pluronic and replacement with an aqueous fluid. The exposed internal surface of the vascular structure can be modified with proteins such as laminin or fibrinogen to promote cell adhesion and this has been demonstrated through seeding with human umbilical vein endothelial cells (HUVECs) to allow fully endothelialized structures with vascular diameter as small as 20 μm.

In order to ensure continuous tubular structures without obstruction, more complex vascular designs have been fabricated with minimum diameters of approximately 60 μm and seeded with HUVECs. Confocal microscopy shows that these structures are fully endothelialized and act as an effective barrier to labelled dextran probes. As a further demonstration of the
utility of the structures, the GelMA matrix has been seeded with human dermal fibroblasts and this has been co-cultured with the HUVEC lined vasculature demonstrating cell viability is maintained after several days in culture.

11:06 AM S.SM09.01.18
3D Printing PEEK Materials as Potential Bone Replacement and Dental Applications Rigoberto C. Advincula; Case Western Reserve University, United States

3D Printing has been a highly successful method to bring new materials and complexities in design through digital manufacturing. It has enabled advancement from rapid prototyping through actual production. Because of its mechanical, chemical and biological properties, 3D-printed polyether ether ketone (PEEK) has great potential as a customized bone replacement. Its density and mechanical properties are closer to bone compared to most Ti-based alloys. In this study, PEEK samples were printed using fused deposition modeling (FDM) and evaluated in terms of their dimensional accuracy, crystallinity, and mechanical properties. The dimensional integrity and surface quality of the printed materials are important. Crystallinity and mechanical properties increased with elevated chamber temperature and post-printing annealing. In this study, we also utilized three available commercial printers. Variations of material properties from three printers are evident. Many factors affect the quality of 3D-printed PEEK. Future FDA regulations for 3D-printed products are needed for this highly customizable manufacturing process to ensure safety and effectiveness for biomedical applications. Future work will report on nanocomposite fabrication and testing.

11:16 AM *S.SM09.01.19
Light-Directed 3D Printing of Ionically Crosslinked Hydrogels for Smart Biomaterials and Microfluidics Ian Yan Wong; Brown University, United States

3D printing is a promising approach for designer biomaterial architectures with information-rich structure and dynamic functionality. In particular, stimuli-responsive hydrogels consisting of crosslinked, hydrophilic polymers could be used for tissue engineering, drug delivery and other biomedical applications. One design consideration is that these biomaterials must be responsive to at least two physicochemical stimuli – the first to pattern desired structures and additional orthogonal stimuli to trigger dynamic behaviors such as degradation, actuation, or self-adhesion. Here, we show that light-directed 3D printing based on ionic crosslinking enables smart materials with biologically-inspired functionalities. First, we demonstrate reversible 3D printing of alginate hydrogel microstructures to template hydrogel microfluidics and pattern collective cell migration. Second, we add graphene oxide into these alginate hydrogels to enhance mechanical properties and oil repulsion in seawater-like conditions. Finally, we prepare double network hydrogels that stimuli-responsive and self-adhesive as a simple “do-it-yourself” construction set for soft machines and microfluidic devices. This modular approach enables “plug-and-play” hydrogel parts for ionic soft machines that emulate actuation, sensing, and fluid transport in living systems.

11:26 AM S.SM09.01.20
Cellular Self-Assembly for Faster Maturation of Bioprinted Tissues in Autologous Tissue Engineering Ashkan Shafiee; Wake Forest Institute for Regenerative Medicine, United States

Bioprinting of autologous tissues encompasses many different steps, and accelerating the process can be very critical for patients with an urgent need of organs. The first step for the transition from “trial and error” to “predict and control” phase of the bioprinting is to understand the underlying science of this unique technology. The physical aspects of self-assembly and the dynamics of multicellular systems used with printing technologies for tissue fabrication are therefore very important. We have developed a microscopic and mathematical method to study tissue fusion, an essential element of self-assembly phenomena during tissue maturation in the post-bioprinting procedure. The model is generalized for different bioink geometries. A mathematical method is introduced, and microscopic interactions at the cellular level in the maturation of bioprinted tissues have been studied. The fusion of tissue-like cell aggregates (cellular bioinks) is elaborated with the help of bonds among their adhesion molecules. The statistical mechanics is used to describe the fusion procedure. Consequently, the partition function for the model and the system total energy are calculated and compared to understand the effect of bioink geometries on the acceleration of the maturation of bioprinted tissues. We identified the driving force and energy of the self-assembly in the maturation of bioprinted tissues. The force and energy are not only critical to control bioprinted final product but also significant for other multicellular interactions such as cancer metastasis and migrations, in which decelerating the procedure is important. Based on our microscopic and mathematical method, we introduce some topological criteria for bioinks for faster maturation of bioprinted tissues.
Modulating the Reaction of Primary Human Immune Cells to 3D Printed Scaffolds

Jürgen Groll, Tina Tylek, Carina Blum and Katrin Schlegelmilch; University of Würzburg, Germany

Influencing or ideally directing the innate immune response after implantation remains one of the major challenges in the development of biomaterials and the design of three dimensional (3D) scaffolds [1]. Macrophages are key players of the innate immune system that can roughly be divided into the pro-inflammatory M1 type and the anti-inflammatory, pro-healing M2 type. While a transient initial pro-inflammatory state is helpful in early phases, a prolonged inflammation deteriorates a proper healing and subsequent regeneration. One promising strategy to drive macrophage polarization is precise control over biomaterial geometry. For example, a concave-structured poly(2-hydroxyethyl methacrylate) hydrogel with a highly ordered architecture and exactly equally-sized pores of up to 40 μm, showed a pronounced infiltration of murine macrophages being mainly directed towards the healing phenotype in vivo [2].

For regenerative approaches, it is of particular interest to identify geometrical parameters that direct human macrophage polarization. The additive manufacturing technique of melt elec-trowriting (MEW) is an especially suitable and advantageous approach in this context as it enables the production of highly defined scaffold geometries built of fibers with diameters in the lower micrometer range [3]. Our group has demonstrated the ability of cells to attach, infiltrate, and proliferate upon seeding onto MEW scaffolds [4], and that the surface modification of MEW scaffolds results in specific interaction with cells [5, 6]. This talk will present our findings in applying MEW for the fabrication of fibrous 3D scaffolds made from poly(ε-caprolactone) (PCL) with precisely defined inter-fiber spacing from 100 μm down to 40 μm in a variety of pore geometries (rectangular, triangular and round). These scaffold facilitates primary human macrophage elongation accompanied by differentiation towards the M2 type, which was most pronounced for box-shaped pores with 40 μm inter-fiber spacing [7]. Moreover, a novel way of producing double-hierarchical scaffolds by MEW will be presented that induce an even stronger M2-type differentiation stimulus for human macrophages.

3D Printing Self-Supporting and Aligned Microfluidics

Michael C. McAlpine1, Ruitao Su1, Joshua R. Uzarski2, Michael Wiederoder2 and Steven Koester3; 1University of Minnesota, United States; 2U.S. Army Combat Capabilities Development Command (CCDC) Soldier Center, Natick, United States

Elastomer based microfluidic devices microfabricated via conventional methodologies, such as soft lithography and stereolithography, have been used for applications such as chemical species mixing, fast bio-chemical assays, controlled cell culturing etc. However, several challenges exist for these methods, including long fabrication times, limited throughput, complex manual alignment steps, and difficulty integrating functional elements such as electrodes, valves, sensing elements, and/or 3-D structures for mixing or sorting. A more freeform fabrication methodology is demanded to enable new applications in microfluidics. Here, we demonstrate a novel 3D printing strategy that can effectively overcome the above issues via precisely controlling the extrusion of polymeric inks into self-supporting microfluidic structures. Specifically, extruded silicone filaments are stacked in an orientation such that adhesion and gravity are balanced during printing, eliminating the need for sacrificial materials. This creates interconnected hollow structures, such as micro chambers and channels, with a minimum inner diameter of 100 micron. The advantage of 3D printed self-supporting microfluidic structures are further demonstrated via several types of devices. First, chemical species mixers are printed with silicone channels, embedded with micro herringbone ridge arrays that are printed with the biocompatible material, polycaprolactone (PCL).
Optimization of the mixing effect is conducted via facile adjustment of the geometric profile of the herringbone ridges. Next, a multi-channel salinity sensor is created via directly printing silicone channels and chambers aligned onto prefabricated electronic circuits. A seamless and robust bonding is formed between the microfluidic structures and the substrate as the material cures. We also demonstrate that, with this printing strategy, functional microfluidic valves and pumps can be readily printed with overlapping silicone channels and UV-curable encapsulating polymers. Finally, going beyond the planar morphology, branching microfluidic channels are printed onto a spherical surface, demonstrating the potential application of 3D printed microfluidics onto curved surfaces. In the future, this may even be the human body as directly printed physiological sensors. The demonstrated methods overcome current limitations by enabling rapid, high-throughput, high-resolution fabrication of elastomeric microfluidic devices on planar and non-planar geometries with integrated multi-material functional elements for diverse applications.

Tip-Based Nanoscale 3D Printing Wonho Jhe and Sangmin An; Seoul National University, Korea (the Republic of)

Viscoelastic complex fluids exhibit rheological nonlinearity at a high shear rate. Although typical nonlinear effects, shear thinning and shear thickening, have been usually understood by variation of intrinsic quantities such as viscosity, one still requires a better understanding of the microscopic origins, currently under debate, especially on the shear-thickening mechanism. We present accurate measurements of shear stress in the bound hydration water layer using noncontact dynamic force microscopy. We find shear thickening occurs above 10¹⁶ 1/s shear rate beyond 0.3-nm layer thickness, which is attributed to the nonviscous, elasticity associated fluidic instability via fluctuation correlation. Such a nonlinear fluidic transition is observed due to the long relaxation time (1 us) of water available in the nanoconfined hydration layer, which indicates the onset of elastic turbulence at nanoscale, elucidating the interplay between relaxation and shear motion, which also indicates the onset of elastic turbulence at nanoscale above a universal shear velocity of 1 mm/s. This extensive layer-by-layer control paves the way for fundamental studies of nonlinear nanorheology and nanoscale hydrodynamics, as well as provides novel insights on viscoelastic dynamics of interfacial water. We will also discuss the tip-based microfluidic characterization and manipulation of liquids.

5:15 AM *S.SM09.01.03
Material Horizons for Volumetric Additive Manufacturing Maxim Shusteff¹, Caitlyn Cook¹, Johanna Schwartz¹, Erika Fong¹, James Oakdale¹, Bryan Moran¹, Allison Kaczmarek¹,², Hossein Heidari³, S.M. Luk³, Charles Rackson⁴, Robert McLeod⁴ and Hayden Taylor⁴; ¹Lawrence Livermore National Laboratory, United States; ²Clemson University, United States; ³University of California, Berkeley, United States; ⁴University of Colorado Boulder, United States

As additive manufacturing (AM, also known as 3D printing) technologies have proliferated, approaches based on solidification of photosensitive liquid resins have showed great promise due to their superior resolution and precision. However, these techniques have been largely limited to prototyping applications due to the constraints on available materials and their mechanical properties, as well as slow builds and poor surface quality resulting from layer-wise fabrication. With the advent of volumetric AM (VAM), complete 3D structures with complex geometries can now be produced in a single step, leaping over the traditional limitations of layer-by-layer approaches to 3D printing.

Volumetric 3D printing generates a 3D distribution of absorbed optical energy within a volume of photosensitive material, concurrently curing all points within a target geometry, on a timescale of 10s to 100s of seconds. No substrate is required as the part forms unsupported in the resin container. The most versatile implementation of VAM is known as computed axial lithography (CAL) which adapts the principles of computed tomography (CT) to generate a sequence of intensity-modulated projections, which are then beamed sequentially into a rotating resin container via a DLP projector to create the required energy dose. Because there is no fluid motion, and no hydrodynamic forces during a build, this approach is particularly compelling for very soft materials such as the hydrogels widely used in tissue engineering and regenerative medicine applications. The absence of support structure also enables complex geometries such as vasculature to be built. Successful volumetric 3D printing requires spatio-temporal control over the polymerization reaction at all points within the
fabrication volume. This demands a more detailed understanding of a host of process parameters, compared with traditional layered approaches. Perhaps the most important such parameters are the absorbed volumetric energy dose $E_{\text{VOL}}$, as well as the rate at which this dose is delivered. The progress of the photochemical reaction may then be characterized in terms of a variety of metrics, such as double-bond conversion, or the evolution of mechanical and optical properties of the material. We investigate the inter-relationship of these properties, obtained from ex-situ measurements such as real-time FTIR spectroscopy, photo-rheology, and mechanical testing, developing a quantitative framework for predicting volumetric structure formation. An additional resin characteristic critical for CAL printing is nonlinear threshold behavior. This allows resin that receives a sub-threshold dose to remain liquid, and derives from the interaction of the generated radicals and inhibitory species present in the resin. For some chemistries the inhibitory effect is provided by dissolved molecular oxygen, but for other formulations, deliberately including another inhibitor is necessary. We discuss the implications of these interacting factors for photo-resin design within the volumetric AM paradigm, as well as more broadly in photopolymer-based AM methods. We also discuss several material classes for VAM, including high-performance engineering materials, as well as cell-culture compatible hydrogels.

Additive Manufacturing of Borosilicate Glass via Stereolithography

Omena Okpowe¹, Andriy Durygin², Vadym Drozd², Nezih Pala² and Chunlei Wang¹,²,¹ Florida International University, United States;² Florida International University, United States

Borosilicate glass is a type of glass material consisting SiO₂ and B₂O₃ as network formers and alkali oxide modifiers. Their excellent optical transparency, chemical resistance, low thermal expansivity and tunable chemical composition make them useful for a wide range of applications such as lab ware, medical implants, microelectromechanical systems (MEMS), sensing and detection etc. Conventional glass fabrication techniques involve melting, casting and use of undesirable chemicals and these imply that there is little room for flexibility in shape and resolution. Recent surge in additive manufacturing efforts now show that ceramic glasses can now be fabricated via stereolithography. However this has not been shown possible for borosilicates due to their low softening temperatures. Herein, we report a simple additive manufacturing protocol for fabricating 3D low softening temperature borosilicate glass. It entails first fabricating a liquid glass composite, printing on a layer by layer basis to form a ‘green ensemble’. This ‘green ensemble’ must then be debound to yield a ‘brown ensemble’ and sintered to yield transparent and amorphous glass ensembles. The properties of the printed glass depend on thermal processing parameters (temperature, time and environment) and these can be readily tuned and optimized to yield 3D glass for a wide range of applications. The printed glass show good optical properties, show no devitrification and exhibit minimal surface roughness requiring no further polishing and finishing typically associated with other glass fabrication techniques.

Dynamically Adjustable Real-Time Tuning of Catheter-Injectable Delivery of Functional Hydrogels towards In
Vivo Bioextrusion Yuta Dobashi¹, Jerry Ku¹, Joel Ramjist², Christopher Pasarikovski¹, Konrad Walus³, John Madden³ and Victor Yang¹; ¹University of Toronto, Canada; ²Ryerson University, Canada; ³University of British Columbia, Canada

Hydrogels have long been considered a significantly promising class of biomaterials. While the chemomechanical tunability of a multitude of hydrogels have been demonstrated in vitro, the ability to deliver these materials in a minimally invasive manner to avoid iatrogenic damages has yet to be fully explored. In the present work, we demonstrate a method of in-situ extrusion of hydrogels with compositions and chemomechanical properties that can be dynamically adjusted “on-the-fly” using a custom catheter that is utilized intravascularly. A custom UV-integrated, multi-lumen microcatheter (inner/outer lumen diameters: 0.6/1.28 mm) was assembled and a suite of low viscosity, shear thinning gelatin-based precursors were formulated for delivery. While the shear thinning property makes this precursor a suitable choice for injection through a catheter with extended length and small diameter, intensity modulation of UV to cross-link the precursor aids greatly in tuning the stiffness at the catheter tip. We show that by modulating the absolute and relative flow rates as well as the UV intensity (0–150 µW output from a 105µm core multimode fibre), we can extrude hydrogels with stiffnesses dynamically varying from <10 to 80 kPa. In addition, through the dual luminal architecture, it is also possible to sequentially switch or coaxially coextrude two types of precursor compositions. The concentrations and diffusivities of additives (as preliminarily demonstrated using food dyes) within the extruded scaffold can also be dynamically altered by 10^3 and 10^2 orders respectively, in a single piece of extruded hydrogel fibre, therefore allowing applications a highly customizable drug depot to be deployed using this technique. To demonstrate the initial utility of this system, we successfully performed embolization of a saccular aneurysm model (diameter ~ 12 mm) and a capillary vasculature model (diameter <1 mm) using a pulsatile vascular flow phantom. The former required the extruded hydrogels to be relatively stiffer via increased photo-cross linking to fill the aneurysm while avoiding leakage into the parent vessel. In capillary embolization, the precursor was injected with lower crosslinking leading to increased viscosity to penetrate further into the vessels to fully embolize the structure. These findings yield direct application ideas in therapeutics such as vascular embolization in a variety of disease states, including cerebral aneurysms, arterio-venous malformations, vascularized tumors, and hemorrhagic vessels. The system can also be utilized for intravascular drug delivery and targeted cell therapies, which may require the physician to constantly adapt to the state of the patient. Further, such a dynamically tunable hydrogel delivery method may be able to serve as a supporting host matrix for functional sensing devices such as microelectrode arrays and quantum dot based chemical sensors.

Fiber Devices for Tissue Engineering Louis A. van der Elst, Merve Gokce Kurtoglu and Alexander Gumennik; Intelligent Systems Engineering, Indiana University, United States

Bioink extrusion-printing, while capable of creating macroscopically accurate anatomic models, fails to replicate the microstructure of the natural tissue due to resolution limitation of this bottom-up fabrication approach. We re-engineer the extrusion process to co-extrude a fiber device in line with the hydrogel bioink. This allows deviation from a pure bottom-up towards a combined approach, where a bottom-up extrusion process creates the macrostructure, while the fiber device in a top-down fashion subsequently promotes the growth of natural microstructure from within the volume of the print.

Fibers can embed a range of bio-functional and biosensing devices and systems. We aim to incorporate microfluidic, ultrasonic, and shape-memory-alloy (SMA) structures mimicking the functionalities of microvasculature, innervation, and musculature, respectively, into a single fiber-device. Those functional structures are created by a thermal draw of fibers from multimaterial preforms – a process familiar from an optical communication fiber fabrication. In this process, the macroscopic preform – a thick and short rod, cross-sectionally structured to meet the desired fiber functionality – is heated to become a viscous liquid and scaled by a thermal draw into a thin and long fiber, preserving the cross-sectional geometry of the preform. Then the fiber cores are patterned axially by a spatially coherent material selective capillary instability to form arrays of ultrasonic transducers contacted in parallel and microchannels with periodic outlets spanning the entire fiber length[1].

In the extrusion process, the fiber is coated with hydrogel, contains tissue cells, extracellular matrix material, nutrients and growth-factors, forming a scaffolded print-line that is raster-layered into a printed model cross section additively constructing the final model in a layer-by-layer manner. Subsequently, the fiber-embedded microchannel structure is used as artificial vasculature supplying building material and nutrients into surrounding bioink to ignite the creation of natural vasculature and promote the proliferation of the bioink-contained tissue cells with their subsequent maturation into a natural-tissue-like structure. The ultrasonic transducers embedded in the fiber are used to sense the changes in the surrounding material density, monitoring cell-proliferation process, thus serving as artificial tactile nerves. SMA cores, contracting upon transduction of electric current, mimic the function of muscle yarns.

The proposed bioprinting approach will likely deliver a biosynthetic tissue with natural-like microstructure opening new
routes in regenerative medicine, such as wound infilling and organ replacement. Moreover, it would allow creating lab-bench anatomical models of realistic tissue, in which bio-material delivery and biosensing is performed volumetrically with a microscale resolution, thus forming a novel stand-alone platform for investigation of micrometabolic processes. Such a platform would be a valuable asset to drug toxicity investigation, and real-time survivability monitoring of such artificial tissues and organs both in-vitro and in animal subjects.

6:10 AM *S.SM09.01.11
The Investigation of Nano-Liter Droplets for Bioprinting Applications Wai Yee Yeong1,2, Wei Long Ng1,2, Christie Dudenhofer1 and Keith Moore1; 1Nanyang Technological University, Singapore; 2HP-NTU Digital Manufacturing Corporate Lab, Singapore; 3HP Inc., United States

The use of drop-on-demand (DOD) bioprinting has attracted numerous attention for numerous biological applications due to its precise control over material volume and deposition pattern in a contactless printing approach to facilitate important cell-cell and cell-matrix interactions. In this work, a HP d300e Digital Dispenser will be used for precise deposition of nano-liter droplets. Here, we propose the use of a general purpose polyvinylpyrrolidone (PVP)-based bio-inks for printing of nano-liter cell droplets. Different PVP-based bio-inks (0 – 3% w/v) are prepared and evaluated for their printability in term of droplet formation and droplet impact on substrate surface; the short-term and long-term viability of printed cells (primary human skin fibroblasts) are also evaluated. We will discuss the range of printable cell concentration and its corresponding droplet resolution, cell viability and proliferation over time post-printing. Furthermore, we also will demonstrate different DOD printing strategies to initiate the hydrogel cross-linking mechanism and achieve tunable material properties within the hydrogel constructs.

6:20 AM *S.SM09.01.12
Genomic-DNA Coated 3D Printed Materials for Drug Capture Daryl Yee, Robert H. Grubbs and Julia R. Greer; California Institute of Technology, United States

Since the discovery of chemotherapy in the beginning of the 20th century, researchers around the world have been actively developing new and more effective chemotherapeutic agents to better treat cancer. Traditionally, chemotherapeutic agents work by interfering with cell division. However, by virtue of their mechanism of action, healthy normal cells can also be targeted and destroyed. As a result, while chemotherapy is an effective way of managing cancer, the resulting side effects limits its use. One approach currently taken to reduce these side effects is to deliver the chemotherapy drugs directly to the tumor via transarterial chemoembolization, or other similar procedures. While this has been effective in reducing systemic toxicity, more can be done to improve this. Ideally, a device that could sequester any unreacted chemotherapy agents could be installed "downstream" of the tumor prior to them entering systemic circulation. Such drug-capture materials have yet to be realized due to the difficulty in achieving materials that have the right surface chemistry and geometry for blood flow.

Working together with medical doctors, computational fluid dynamics experts, chemists, and materials scientists, we report the fabrication of DNA functionalized 3D printed porous materials that can be used to capture doxorubicin and cisplatin, two commonly used DNA-targeting chemotheraphy agents. We discuss the concept behind the device, the use of 3D printed materials as an ideal substrate, and the chemistries considered in drug binding. To achieve scalability of these devices, we developed a method of attaching cheaply available genomic DNA to these materials, a departure from commonly used synthetic DNA. We characterize the surface of the structure and verify the binding of DNA to the surface via XPS, EDS and the use of chemical assays. The efficacy of these functionalized materials were demonstrated in PBS, where we observed a >70% reduction in doxorubicin concentration over a period of 20 minutes, highlighting the viability of this as a method of drug capture.

4D Printing of Advanced Scaffolds with Controlled Growth Factor Delivery for Tissue Engineering Min Wang; The University of Hong Kong, Hong Kong

Additive manufacturing, popularly known as “3D printing”, includes an array of technologies such as fused deposition modelling (FDM), selective laser sintering (SLS) and inkjet printing. Compared with conventional manufacturing technologies, 3D printing has many distinctive advantages, including the construction of 3D structures with complex shapes.
and functionalities. Therefore, 3D printing technologies have seen increasing popularity in many areas, such as product design and development, industrial production, consumer goods, aerospace, and education. 3D printing has already made a tremendous impact in our society. The exciting TED Talk in 2013 by Tibbits of MIT ushered in a new era in additive manufacturing: 4D printing. With 4D printing, 3D printed static objects will change their shapes over time, i.e., 4D printing uses 3D printing technologies to produce shape-morphing objects. Such objects can meet the demanding requirements in particularly applications. The concept of 4D printing has been evolving and one popular definition of 4D printing is that the shape, property and functionality of a 3D printed object can evolve with time in predefined and programmable designs. There have been numerous investigations into the application of 3D printing in biomedical engineering. So far, the greatest biomedical applications of 3D printing are in the tissue engineering field. Tissue engineering offers a new approach to treat difficult problems in human tissue repair. It involves using live cells to form implantable devices for body tissue regeneration. In scaffold-based tissue engineering, a scaffold provides a microenvironment for cells to adhere, proliferate and differentiate and a structural framework for new tissue formation. 3D printing has many advantages in scaffold fabrication, such as control of pore size, porosity, etc. Furthermore, 3D printing can make multilayered scaffolds with different layer characteristics. Most human body tissues are complex and hierarchical and their regeneration requires structurally complex scaffolds that resemble tissue structures and can provide biochemical cues such as growth factors (GFs). Incorporating GFs and even live cells in scaffolds can greatly facilitate tissue regeneration. Since 2004, we have been investigating 3D biomedical printing and have used different 3D printing techniques for developing bone tissue engineering scaffolds (e.g., S.H. Lee, W.Y. Zhou, W.L. Cheung, M. Wang, “Producing Polymeric Scaffolds for Bone Tissue Engineering Using the Selective Laser Sintering Technique”, Transactions of the Society For Biomaterials 30th Annual Meeting, Memphis, TN, USA, 2005, 348). We have also been exploring 4D printing in tissue engineering (e.g., C. Wang, Y. Zhou, M. Wang, “In situ Delivery of rhBMP-2 in Surface Porous Shape Memory Scaffolds Developed through Cryogenic 3D Plotting”, Materials Letters, Vol.189 (2017), 140-143). This talk will give an overview of our work in 3D/4D printing of scaffolds for regenerating tissues such as bone and blood vessels. It will focus on the design and 4D printing of shape-morphing and GF-delivering scaffolds for tissue engineering.

3D Printed Diamond Technology—A New Material for Biomedical Applications Kate Fox, Aaqil Rifai, Nour Mani and Nhiem Tran; RMIT University, Australia

Diamond is quickly becoming an interesting material for medical implants with evidence that it provides not only a good biointerface but also an antimicrobial surface. Previously ultrananocrystalline diamond was shown to be a good bionic implant material [1] and our group have shown that a polycrystalline diamond coating can be produced on a 3D printed titanium substrate [2]. However up until now, all diamond implants have been as a coating material, with limitations as to its capacity to be used as a three dimensional surface. Here we present our recent results fabricating diamond implants using additive manufacturing including presenting for the first time a hybrid 3D diamond-titanium printed material which was recently published [3]. Diamond implants fabricated via using three different techniques (i) nanodiamond seeding, (ii) polycrystalline diamond coating and (iii) composite diamond-titanium biomaterial all showed superior cellular proliferation compared to the as-printed SLM titanium.as well as a decrease in microbial activity. The possibility of 3D diamond opens up large possibilities for new diamond technologies

6:55 AM S.SM09.01.16
Ultra-High Resolution Inkjet Printing of Vascular Structures Brian Derby; University of Manchester, United Kingdom

It is now more than 30 years since the priciples of Additive Manufacturing or 3D Printing moved from a concept to practical implementation and over 20 years since the first publications on its use to fabricate implantable medical devices. In this period it has rapidly progressed from being seen as a topic for Science Fiction to now a method for the production of prototype or in vitro model tissues for tissue-on-a-chip applications and laboratory animal studies. Indeed there are several commercial organizations that have developed and market commercial Bioprinters. However, despite these not inconsiderable advances,
the original target of printed cell-laden implants or tissue patches have still not been realized.

A key obstacle to the use of 3D printing for the fabrication of cell-laden constructs is the need to provide a functional vasculature for the maintenance of cell viability through the provision of oxygen and nutrients, as well as a pathway for waste removal. It is well known that the diffusion limit in the 3D culture of cells limits spheroid size to a few hundred μm and that the capillaries in healthy tissue have a diameter of 5 – 10 μm and are typically spaced around 50 μm. However, current additive manufacturing routes that are in widespread use in biofabrication have a spatial resolution > 100 μm. Hence, new approaches to producing high resolution vascular structures and models for angiogenesis are required.

Here we describe the use of ultra-high resolution inkjet printing (UHIJP) as a route to fabricate vascular structures in gelatine methacrylate (GelMA) hydrogels. This technique is related to electrospaying and electrospinning in that a local electric field is used to form a "Taylor Cone" with the meniscus of a fluid at a fine nozzle. Through using a controlled electrical pulse, individual mono-sized droplets are ejected with volume down to a single femtolitre (10^-18 m^3) with droplet diameters in the range 1 - 3 μm. UHIJP has been used to print structures from a thermoreversible hydrogel based on triblock polymers of polyethylene oxide and polypropylene oxide (Pluronic F127). These are subsequently encapsulated in GelMA and photopolymerised before removal of the Pluronic and replacement with an aqueous fluid. The exposed internal surface of the vascular structure can be modified with proteins such as laminin or fibrinogen to promote cell adhesion and this has been demonstrated through seeding with human umbilical vein endothelial cells (HUVECs) to allow fully endothelialized structures with vascular diameter as small as 20 μm.

In order to ensure continuous tubular structures without obstruction, more complex vascular designs have been fabricated with minimum diameters of approximately 60 μm and seeded with HUVECs. Confocal microscopy shows that these structures are fully endothelialized and act as an effective barrier to labelled dextran probes. As a further demonstration of the utility of the structures, the GelMA matrix has been seeded with human dermal fibroblasts and this has been co-cultured with the HUVEC lined vasculature demonstrating cell viability is maintained after several days in culture.

7:05 AM S.SM09.01.18
3D Printing PEEK Materials as Potential Bone Replacement and Dental Applications Rigoberto C. Advincula; Case Western Reserve University, United States

3D Printing has been a highly successful method to bring new materials and complexities in design through digital manufacturing. It has enabled advancement from rapid prototyping through actual production. Because of its mechanical, chemical and biological properties, 3D-printed polyether ether ketone (PEEK) has great potential as a customized bone replacement. Its density and mechanical properties are closer to bone compared to most Ti-based alloys. In this study, PEEK samples were printed using fused deposition modeling (FDM) and evaluated in terms of their dimensional accuracy, crystallinity, and mechanical properties. The dimensional integrity and surface quality of the printed materials are important. Crystallinity and mechanical properties increased with elevated chamber temperature and post-printing annealing. In this study, we also utilized three available commercial printers. Variations of material properties from three printers are evident. Many factors affect the quality of 3D-printed PEEK. Future FDA regulations for 3D-printed products are needed for this highly customizable manufacturing process to ensure safety and effectiveness for biomedical applications. Future work will report on nanocomposite fabrication and testing.

7:15 AM *S.SM09.01.19
Light-Directed 3D Printing of Ionically Crosslinked Hydrogels for Smart Biomaterials and Microfluidics Ian Yan Wong; Brown University, United States

3D printing is a promising approach for designer biomaterial architectures with information-rich structure and dynamic functionality. In particular, stimuli-responsive hydrogels consisting of crosslinked, hydrophilic polymers could be used for tissue engineering, drug delivery and other biomedical applications. One design consideration is that these biomaterials must be responsive to at least two physicochemical stimuli – the first to pattern desired structures and additional orthogonal stimuli to trigger dynamic behaviors such as degradation, actuation, or self-adhesion. Here, we show that light-directed 3D printing based on ionic crosslinking enables smart materials with biologically-inspired functionalities. First, we demonstrate reversible 3D printing of alginate hydrogel microstructures to template hydrogel microfluidics and pattern collective cell migration. Second, we add graphene oxide into these alginate hydrogels to enhance mechanical properties and oil repulsion in seawater-like conditions. Finally, we prepare double network hydrogels that stimuli-responsive and self-adhesive as a simple “do-it-yourself” construction set for soft machines and microfluidic devices. This modular approach enables “plug-and-play” hydrogel parts for ionic soft machines that emulate actuation, sensing, and fluid transport in living systems.

7:30 AM S.SM09.01.20
Cellular Self-Assembly for Faster Maturation of Bioprinted Tissues in Autologous Tissue Engineering Ashkan Shafiee;
Bioprinting of autologous tissues encompasses many different steps, and accelerating the process can be very critical for patients with an urgent need of organs. The first step for the transition from “trial and error” to “predict and control” phase of the bioprinting is to understand the underlying science of this unique technology. The physical aspects of self-assembly and the dynamics of multicellular systems used with printing technologies for tissue fabrication are therefore very important. We have developed a microscopic and mathematical method to study tissue fusion, an essential element of self-assembly phenomena during tissue maturation in the post-bioprinting procedure. The model is generalized for different bioink geometries. A mathematical method is introduced, and microscopic interactions at the cellular level in the maturation of bioprinted tissues have been studied. The fusion of tissue-like cell aggregates (cellular bioinks) is elaborated with the help of bonds among their adhesion molecules. The statistical mechanics is used to describe the fusion procedure. Consequently, the partition function for the model and the system total energy are calculated and compared to understand the effect of bioink geometries on the acceleration of the maturation of bioprinted tissues. We identified the driving force and energy of the self-assembly in the maturation of bioprinted tissues. The force and energy are not only critical to control bioprinted final product but also significant for other multicellular interactions such as cancer metastasis and migrations, in which decelerating the procedure is important. Based on our microscopic and mathematical method, we introduce some topological criteria for bioinks for faster maturation of bioprinted tissues.

**Modulating the Reaction of Primary Human Immune Cells to 3D Printed Scaffolds** [Jürgen Groll, Tina Tylek, Carina Blum and Katrin Schlegelmilch; University of Würzburg, Germany]

Influencing or ideally directing the innate immune response after implantation remains one of the major challenges in the development of biomaterials and the design of three dimensional (3D) scaffolds [1]. Macrophages are key players of the innate immune system that can roughly be divided into the pro-inflammatory M1 type and the anti-inflammatory, pro-healing M2 type. While a transient initial pro-inflammatory state is helpful in early phases, a prolonged inflammation deteriorates a proper healing and subsequent regeneration. One promising strategy to drive macrophage polarization is precise control over biomaterial geometry. For example, a concave-structured poly(2-hydroxyethyl methacrylate) hydrogel with a highly ordered architecture and exactly equally-sized pores of up to 40 μm, showed a pronounced infiltration of murine macrophages being mainly directed towards the healing phenotype in vivo [2]. For regenerative approaches, it is of particular interest to identify geometrical parameters that direct human macrophage polarization. The additive manufacturing technique of melt electrowriting (MEW) is an especially suitable and advantageous approach in this context as it enables the production of highly defined scaffold geometries built of fibers with diameters in the lower micrometer range [3]. Our group has demonstrated the ability of cells to attach, infiltrate, and proliferate upon seeding onto MEW scaffolds [4], and that the surface modification of MEW scaffolds results in specific interaction with cells [5, 6]. This talk will present our findings in applying MEW for the fabrication of fibrous 3D scaffolds made from poly(ε-caprolactone) (PCL) with precisely defined inter-fiber spacing from 100 μm down to 40 μm in a variety of pore geometries (rectangular, triangular and round). These scaffolds facilitate primary human macrophage elongation accompanied by differentiation towards the M2 type, which was most pronounced for box-shaped pores with 40 μm inter-fiber spacing [7]. Moreover, a novel way of producing double-hierarchical scaffolds by MEW will be presented that induce an even stronger M2-type differentiation stimulus for human macrophages.

**Literature**

**7:55 AM *S.SM09.01.23**
Elastomer based microfluidic devices microfabricated via conventional methodologies, such as soft lithography and stereolithography, have been used for applications such as chemical species mixing, fast bio-chemical assays, controlled cell culturing etc. However, several challenges exist for these methods, including long fabrication times, limited throughput, complex manual alignment steps, and difficulty integrating functional elements such as electrodes, valves, sensing elements, and/or 3-D structures for mixing or sorting. A more freeform fabrication methodology is demanded to enable new applications in microfluidics. Here, we demonstrate a novel 3D printing strategy that can effectively overcome the above issues via precisely controlling the extrusion of polymeric inks into self-supporting microfluidic structures. Specifically, extruded silicone filaments are stacked in an orientation such that adhesion and gravity are balanced during printing, eliminating the need for sacrificial materials. This creates interconnected hollow structures, such as micro chambers and channels, with a minimum inner diameter of 100 micron. The advantage of 3D printed self-supporting microfluidic structures are further demonstrated via several types of devices. First, chemical species mixers are printed with silicone channels, embedded with micro herringbone ridge arrays that are printed with the biocompatible material, polycaprolactone (PCL). Optimization of the mixing effect is conducted via facile adjustment of the geometric profile of the herringbone ridges. Next, a multi-channel salinity sensor is created via directly printing silicone channels and chambers aligned onto prefabricated electronic circuits. A seamless and robust bonding is formed between the microfluidic structures and the substrate as the material cures. We also demonstrate that, with this printing strategy, functional microfluidic valves and pumps can be readily printed with overlapping silicone channels and UV-curable encapsulating polymers. Finally, going beyond the planar morphology, branching microfluidic channels are printed onto a spherical surface, demonstrating the potential application of 3D printed microfluidics onto curved surfaces. In the future, this may even be the human body as directly printed physiological sensors. The demonstrated methods overcome current limitations by enabling rapid, high-throughput, high-resolution fabrication of elastomeric microfluidic devices on planar and non-planar geometries with integrated multi-material functional elements for diverse applications.
the matrix or onto the surface of 3D scaffolds for enhancing tissue regeneration. Scaffolds mimicking the natural extracellular matrix of human tissues can serve very well as a substrate for cell attachment, proliferation, and differentiation and thus facilitate new tissue formation in vivo. The architectures (pore size, shape, interconnectivity, porosity, etc.) and properties (biological and mechanical) of scaffolds should be carefully controlled to match the defect shape and size and features of the target tissue. 3D printing technologies enable us to fabricate porous scaffolds with accurate control over their architectures and properties. On the other hand, 3D printing of shape morphing polymers has attracted great attentions in tissue engineering as scaffolds with shape morphing ability can reshape themselves after implantation to match the defect and anatomy of host tissues. Biomolecules such as growth factors have been often used in tissue engineering to accelerate tissue regeneration; and vascular endothelial growth factors (VEGF) is used in the regeneration of gastrointestinal tract and vasculature. In this study, an extrusion-based 3D printing system was used to construct porous scaffolds which have abilities of self-folding upon heating to the body temperature and controlled release of VEGF. For 3D printed scaffolds, the self-folding ability was achieved by using a shape memory polymer poly(D, L-lactide-co-trimethylene carbonate) (PDLLA-TMC) which could change shape at a temperature greater than 37°C, while the controlled release of growth factor was achieved by using gelatin methacrylate (GelMA) as the functional layer to load VEGF. In scaffold fabrication, a planar porous structure was firstly fabricated by accurate deposition of viscous PDLLA-TMC solution. The permanent tubular shape of PDLLA-TMC was made by folding printed planar porous structure into a tube on a glass stick at 80°C. Then PDLLA-TMC tubular porous structure was flattened at 25°C. Finally, GelMA loaded with VEGF was printed onto the PDLLA-TMC planar porous scaffold layer and crosslinked by UV. Shape morphing of PDLLA-TMC/GelMA-VEGF scaffolds was studied by immersing scaffolds in water at 37°C. Planar porous scaffolds could fold automatically into tubes within 60s. SEM examinations showed that interconnected macropores were regularly arranged on the scaffolds. In vitro release tests revealed a sustained and steady release of VEGF in the 21 day tests. For rat mesenchymal stem cells (rMSCs) seeded on scaffolds, LIVE/DEAD assay results indicated very good cell viability. MTT assay results showed good cell proliferation after 1, 4, 7-day culture. This study has demonstrated a good strategy to develop unique scaffolds for tubular tissues or organs such as vasculature and gastrointestinal tract.

A Versatile 3D Printed Layer Sandwiching Approach with Integrated Sensing for POC Diagnostics Ankit Kumar;
Indian Institute of Technology Roorkee, India

Despite the recent advances in high-sensitivity lab-on-chip assays, adapting them for point-of-care settings remains a challenge due to the complexities in fabrication, and the need for an external measurement system. In this paper, I present a novel layer-sandwiching approach with an integrated Surface-Mount-Device (SMD) based on-chip absorbance measurement system, which allows for rapid prototyping of Point-of-Care (POC) assays.

In this approach, the layers are 3D printed using a 3DS Projet MJP Multijet printer which allows for the fabrication of 100 μm thickness flexible layers and sub-100 micron width channels. While the optical transparency of the material allows for on-chip signal acquisition, the use of SMD LEDs enables low power operation and the availability of a wide range of narrow emission spectrums. The sandwiched device has the middle layer as the flow layer and is sandwiched between two layers of parafilm. These three layers are then further sandwiched between an optical readout system. The hydrophilic nature of the 3D printed flow layer allows for a capillary-driven flow of reagents and the two parafilm layers prevent leakage. Because of the stacked nature of the layers, the device could also be disassembled, cleaned and reused.

The system was tested by performing MTT assay on-chip. For this test, human prostate cancer cells were treated with 20 μM Camptothecin in a standard 96 well plate. The cells were incubated for 24 hrs at 5% CO2 and 37°C. Then MTT dye was added and after 4 hrs of incubation, DMSO was added for dissolving the formazan crystals. Absorbance measurement for each well was performed separately on a spectrophotometer, and on the 3D printed device with 595 nm emission SMD-LEDs, and a strong correlation was found.

The proposed fabrication approach is far simpler than conventional methods. The high sensitivity, capillary-driven flow and the low cost of manufacturing make this system ideal for performing POC diagnostics assays, and other field assays where it’s not possible to carry the bulky and expensive measurement systems.

S.SM09.02.13
Effect of Heat Treatment on Grainscale Stress Relaxation and Microstructure of Additively Manufactured Ti-6Al-4V Caleb Andrews1, Mitra Taheri1, Cemile Basgül2, Steven Kurtz2, Tae Wook Heo3, Ibo Matthews3 and Rongpei Shi3; 1Johns Hopkins University, United States; 2Drexel University, United States; 3Lawrence Livermore National Laboratory, United States
While additive manufacturing (AM) is capable of providing a method of producing geometrically complex and highly detailed structures that conventional manufacturing methods cannot, the generation of residual stress in many AM processes can negatively impact properties and performance. This research aims to address knowledge gaps in understanding how residual stresses are distributed at the grain and subgrain scale, the dislocation structures that accommodate these stresses, and how post-processing stress relief strategies effect this. Utilizing the selective laser melting (SLM) process, spinal cage implants were manufactured from ELI Ti64 powder which were then subjected to stress relieving heat treatment cycles above and below the Ti64 β transus as a function of time and cooling rate. Residual stress was than quantitatively measured via HR-EBSD and bulk properties informed via compression testing. It was found that grain scale stress decreased at an inversely proportional rate with heat treatment time, while the retention of β phase significantly changed the stress and dislocation distribution.

S.SM09.02.14
Thiol-ene Clickable Gelatin as Bioink for Biofabrication—Expanding the Fabrication Window through Macromolecular Cross-Linkers Sarah Bertlein¹, Alessandro Cianciosi¹, Bram G. Soliman², Gabriella Brown², Khoon S. Lim², Tomasz Jungst¹, Joerg Tessmar¹, Gary J. Hooper², Tim B. Woodfield², Krystyna Albrecht¹ and Jürgen Groll¹; ¹University of Würzburg, Germany; ²University of Otago Christchurch, New Zealand

Biofabrication is a young field of research that aims at the automated generation of hierarchical tissue-like structures from cells and materials through Bioprinting or Bioassembly [1]. However, the lack of variety in printable hydrogel systems, which are the mainly used materials for the formulation of bioinks [2], is one major drawback for the advancement of the complete field [3]. Gelatin is often adopted for this purpose, usually modified with (meth-)acryloyl functionalities for post-fabrication curing by free radical photo-polymerization, resulting in a hydrogel that is cross-linked via non-degradable polymer chains of uncontrolled length.

We have introduced GelAGE as a new thiol-ene clickable and broadly applicable alternative for gelatin-based bioinks [4]. The advantage of this system is the absence of non-degradable polymeric components after cross-linking compared to the free radical polymerization, as well as a better control over cross-linking density, and compatibility with Vis-light addressable initiator systems such as (Ru/SPS). Here we present the evolution of this system by stepwise altering the cross-linker from DTT to PEG-dithiol and star shaped 8-armed PEG-octathiol to multi-thiolated hyaluronic acid and finally a Hyaluronan-AGE / thiolated-Hyaluronan bioink as comparison. This led to a continuous improvement of the printability in terms of shape fidelity with decreasing overall polymer concentrations at constant cytocompatibility. We also present biological evaluation of this system for cartilage engineering.

Biomolecules such as growth factors have been often used in tissue engineering to accelerate tissue regeneration; and vascular endothelial growth factors (VEGF) is used in the regeneration of gastrointestinal tract and vasculature. In this study, an extrusion-based 3D printing system was used to construct porous scaffolds which have abilities of self-folding upon heating to the body temperature and controlled release of VEGF. For 3D printed scaffolds, the self-folding ability was achieved by using a shape memory polymer poly(D, L-lactide-co-trimethylene carbonate) (PDLLA-TMC) which could change shape at a temperature greater than 37°C, while the controlled release of growth factor was achieved by using gelatin methacrylate (GelMA) as the functional layer to load VEGF. In scaffold fabrication, a planar porous structure was firstly fabricated by accurate deposition of viscous PDLLA-TMC solution. The permanent tubular shape of PDLLA-TMC was made by folding printed planar porous structure into a tube on a glass stick at 80°C. Then PDLLA-TMC tubular porous structure was flattened at 25°C. Finally, GelMA loaded with VEGF was printed onto the PDLLA-TMC planar porous scaffold layer and crosslinked by UV. Shape morphing of PDLLA-TMC/GelMA-VEGF scaffolds was studied by immersing scaffolds in water at 37°C. Planar porous scaffolds could fold automatically into tubes within 60s. SEM examinations showed that interconnected macropores were regularly arranged on the scaffolds. In vitro release tests revealed a sustained and steady release of VEGF in the 21 day tests. For rat mesenchymal stem cells (rMSCs) seeded on scaffolds, LIVE/DEAD assay results indicated very good cell viability. MTT assay results showed good cell proliferation after 1, 4, 7-day culture. This study has demonstrated a good strategy to develop unique scaffolds for tubular tissues or organs such as vasculature and gastrointestinal tract.

A Versatile 3D Printed Layer Sandwiching Approach with Integrated Sensing for POC Diagnostics Ankit Kumar; Indian Institute of Technology Roorkee, India

Despite the recent advances in high-sensitivity lab-on-chip assays, adapting them for point-of-care settings remains a challenge due to the complexities in fabrication, and the need for an external measurement system. In this paper, I present a novel layer-sandwiching approach with an integrated Surface-Mount-Device (SMD) based on-chip absorbance measurement system, which allows for rapid prototyping of Point-of-Care (POC) assays.

In this approach, the layers are 3D printed using a 3DS ProJet MJP Multijet printer which allows for the fabrication of 100 μm thickness flexible layers and sub-100 micron width channels. While the optical transparency of the material allows for on-chip signal acquisition, the use of SMD LEDs enables low power operation and the availability of a wide range of narrow emission spectrums. The sandwiched device has the middle layer as the flow layer and is sandwiched between two layers of parafilm. These three layers are then further sandwiched between an optical readout system. The hydrophilic nature of the 3D printed flow layer allows for a capillary-driven flow of reagents and the two parafilm layers prevent leakage. Because of the stacked nature of the layers, the device could also be disassembled, cleaned and reused.

The system was tested by performing MTT assay on-chip. For this test, human prostate cancer cells were treated with 20 μM Camptothecin in a standard 96 well plate. The cells were incubated for 24 hrs at 5% CO2 and 37°C. Then MTT dye was added and after 4 hrs of incubation, DMSO was added for dissolving the formazan crystals. Absorbance measurement for each well was performed separately on a spectrophotometer, and on the 3D printed device with 595 nm emission SMD-
LEDs, and a strong correlation was found.

The proposed fabrication approach is far simpler than conventional methods. The high sensitivity, capillary-driven flow and the low cost of manufacturing make this system ideal for performing POC diagnostics assays, and other field assays where it’s not possible to carry the bulky and expensive measurement systems.

Effect of Heat Treatment on Grainscale Stress Relaxation and Microstructure of Additively Manufactured Ti-6Al-4V
Caleb Andrews1, Mitra Taheri1, Cemile Basgül2, Steven Kurtz2, Tae Wook Heo3, Ibo Matthews1 and Rongpei Shi3; 1Johns Hopkins University, United States; 2Drexel University, United States; 3Lawrence Livermore National Laboratory, United States

While additive manufacturing (AM) is capable of providing a method of producing geometrically complex and highly detailed structures that conventional manufacturing methods cannot, the generation of residual stress in many AM processes can negatively impact properties and performance. This research aims to address knowledge gaps in understanding how residual stresses are distributed at the grain and subgrain scale, the dislocation structures that accommodate these stresses, and how post-processing stress relief strategies effect this. Utilizing the selective laser melting (SLM) process, spinal cage implants were manufactured from ELI Ti64 powder which were then subjected to stress relieving heat treatment cycles above and below the Ti64 β transus as a function of time and cooling rate. Residual stress was than quantitatively measured via HR-EBSD and bulk properties informed via compression testing. It was found that grain scale stress decreased at an inversely proportional rate with heat treatment time, while the retention of β phase significantly changed the stress and dislocation distribution.

Thiol-ene Clickable Gelatin as Bioink for Biofabrication—Expanding the Fabrication Window through Macromolecular Cross-Linkers
Sarah Bertlein1, Alessandro Cianciosi1, Bram G. Soliman2, Gabriella Brown2, Khoon S. Lim2, Tomasz Jungst1, Joerg Tessmar1, Gary J. Hooper2, Tim B. Woodfield2, Krystyna Albrecht1 and Jürgen Groll1; 1University of Würzburg, Germany; 2University of Otago Christchurch, New Zealand

Biofabrication is a young field of research that aims at the automated generation of hierarchical tissue-like structures from cells and materials through Bioprinting or Bioassembly [1]. However, the lack of variety in printable hydrogel systems, which are the mainly used materials for the formulation of bioinks [2], is one major drawback for the advancement of the complete field [3]. Gelatin is often adopted for this purpose, usually modified with (meth-)acyryloyl functionalities for post-fabrication curing by free radical photo-polymerization, resulting in a hydrogel that is cross-linked via non-degradable polymer chains of uncontrolled length.

We have introduced GelAGE as a new thiol-ene clickable and broadly applicable alternative for gelatin-based bioinks [4]. The advantage of this system is the absence of non-degradable polymeric components after cross-linking compared to the free radical polymerization, as well as a better control over cross-linking density, and compatibility with Vis-light addressable initiator systems such as (Ru/SPS). Here we present the evolution of this system by stepwise altering the cross-linker from DTT to PEG-dithiol and star shaped 8-armed PEG-octathiol to multi-thiolated hyaluronic acid and finally a Hyaluronan-AGE / thiolated-Hyaluronan bioink as comparison. This led to a continuous improvement of the printability in terms of shape fidelity with decreasing overall polymer concentrations at constant cytocompatibility. We also present biological evaluation of this system for cartilage engineering.

The Golden Age of Materials Innovations—From High-κ/Metal Gate to AI Hardware Vijay Narayanan; IBM T.J. Watson Research Center, United States

High-κ/Metal Gates are ubiquitous in CMOS chips and are a product of intense collaborative research across academia and corporate labs. These new materials re-enabled a roadmap for CMOS scaling from FinFET (current) to Nanosheet (future) device architectures. However, CMOS scaling is slowing down with performance benefits diminishing with each node. At the same time, the need for consuming data has gone up exponentially with deep learning-based AI algorithms being deployed for this purpose and run on specialized AI hardware such as graphical processing units (GPU). However, GPUs consume significant power since data transfer occurs from memory to processor. Resistive Processing Units (RPU) envision artificial neural networks mapped to arrays of non-volatile memory (NVM) elements that execute operations in-memory and constant time, thereby enabling significant power performance benefits. Many NVM elements are being evaluated as RPU but suffer from significant non-idealities and are therefore ripe once again for innovation and collaboration across academia and industry.

Biography:
Vijay Narayanan received his BTech degree in metallurgical engineering from the Indian Institute of Technology, Madras (1995), and his MS degree (1996) and PhD degree (1999) in materials science and engineering from Carnegie Mellon University. After completing post-doctoral research at Arizona State University, Narayanan joined the IBM T. J. Watson Research Center in 2001 where he pioneered high-κ/metal gate research and development from the early stages of materials discovery to development and implementation in manufacturing. These high-κ/metal gate materials form the basis of all recent IBM systems processors and of most low-power chips for mobile devices. Currently, Narayanan is an IBM Fellow and senior manager at IBM Research where he is the strategist for Physics of AI and leads the team developing analog accelerators for AI applications. Narayanan is an IEEE Senior Member and was elected a Fellow of the American Physical Society in 2011. He is an author of over 100 journal and conference papers, holds more than 200 patents, and edited one book: Thin Films On Silicon: Electronic And Photonic Applications.

Socially-Directed Science and Technology—Opportunities and Challenges for the Field of Materials Science and Engineering Christine Ortiz; Massachusetts Institute of Technology, United States

We live in an era rife with social inequities and planetary perils, as the collective impact of humans threatens life on earth as we know it, radically transforming our societies and ecosystems. While science and technology and, in particular, the field of materials science and engineering has contributed enormous benefits to humanity, simultaneously it has also been entangled with and contributed to these formidable challenges. In re-imagining a more equitable and sustainable future, let alone bringing it into reality, we must acknowledge, interrogate and understand the historical context, root causes and systemic
structures that underpin the scientific and technological enterprise and our discipline, as well as the institutions of higher learning which serve as its foundation.

Science and technology, rooted in social inquiry, inclusion and equity, is more important than ever to our survival, let alone progress. This presentation will discuss a socially-directed approach to science and technology with a focus on the field of materials science and engineering and integration with humanistic fields such as history, the social sciences, including science, technology and society studies; social justice; and civic design and community-based participatory research, in order to interrogate, understand and shape technologically-driven societal impact towards more equitable, ethical and sustainable outcomes. Emerging areas will be considered such as circular materials design for socioresilient infrastructure, the Anthropocene, materials and environmental in/justice, fire safety materials, social inequity and disparate risks to fire, social life cycle assessment and the case of shipbreaking, ethics and socially-directed computational materials.

Biography:
Christine Ortiz is a scientist, engineer, professor, scholar, former dean and academic entrepreneur. Ortiz is the Morris Cohen Professor of Materials Science and Engineering at the Massachusetts Institute of Technology. Ortiz has over 180 scholarly publications, has supervised the research projects of more than 100 students from 10 different academic disciplines, and received 30 national and international honors, including the Presidential Early Career Award in Science and Engineering which was awarded to her at the White House by President George W. Bush. Ortiz served as the Dean for Graduate Education at MIT between 2010 and 2016, supporting approximately 7,000 graduate students from 100+ countries. With over 25 years of experience in higher education, Ortiz has led cross-institutional initiatives in global education, cross-disciplinary curriculum development, technology-enabled learning, and diversity, equity and inclusion. Ortiz was the founding principal investigator of the MIT University Center of Exemplary Mentoring sponsored by the Alfred P. Sloan Foundation. Ortiz has served on or chaired over 50 task forces, working groups, and committees in higher education. Ortiz served as a regional accreditation commissioner for the Commission on Institutions of Higher Education, New England Association of Schools and Colleges. Ortiz is the founder of a new nonprofit higher education institution, Station1, that is paving a pathway of opportunity through a new model of frontier learning and research — socially-directed science and technology.

Designing Biology Reshma Shetty: Ginkgo Bioworks, Inc., United States

Biology is the most powerful technology on the planet. It's ability to self-repair, self-replicate and make atomically precise structures is unparalleled among manufacturing technologies. At Ginkgo, we are passionate about harnessing the power of biology by designing it. Unfortunately, despite significant advancements in recent years, the tools and technology for biological design remain woefully inadequate relative to the potential of biological technology. Our limited understanding of how biology works means that, for now, biological design is essentially a search problem. At Ginkgo, we are leveraging automation and software to build a genetic engineering foundry that allows us to more cheaply and scalably search potential biological design space for functional organism designs. In particular, I will highlight the value of combining computer-aided engineering software tools, cheap gene synthesis and high resolution-accurate mass LCMS to develop engineered microbes. Then, I'll discuss how we applied these technologies for improving a "living medicine" for the treatment of a metabolic disorder.

Biography:
Reshma Shetty co-founded synthetic biology Ginkgo Bioworks, Inc. in 2008. Spun out of MIT, Ginkgo’s mission is to make biology easier to engineer. Started in a Cambridge, Massachusetts, apartment, Shetty has helped to grow the company to 200 people and raised $450M in financing. In October 2018, Ginkgo launched Bioworks4, its fourth generation facility for design, fabrication and testing of custom designed microbes. Ginkgo is concurrently engineering more than 50 organisms to spec for customers including Ajinomoto, Cargill and ADM. Shetty has been active in the field of synthetic biology for 10+ years and co-organized SB1.0, the first international conference in synthetic biology in 2004. In 2005, Shetty and colleagues founded OpenWetWare.org, a wiki for the free sharing of information among biological and biological engineering researchers. In 2006, she was an advisor to the
international Genetically Engineered Machines (iGEM) competition where she was best known for engineering bacteria to smell like bananas and mint. In 2008, Forbes magazine named Shetty one of Eight People Inventing the Future and in 2011, Fast Company named her one of 100 Most Creative People in Business. In 2014, Ginkgo became the first biotech company to participate in YCombinator. In 2018, Business Insider named her one of the most powerful female engineers. Shetty has a BS degree in computer science from the University of Utah and a PhD degree in biological engineering from MIT.
