De novo Design of Molecules with Low Hole Reorganization Energy Based on a Quarter-Million Molecule DFT Screen (1): DFT Computation and Design Using a Variational Autoencoder/Decoder

Nobuyuki N. Matsuzawa¹, Hiroyuki Maeshima¹, Hideyuki Arai¹, Masaru Sasago¹, Eiji Fujii¹, Karl Leswing², Mathew D. Halls², Tim Robertson³, Kyle Marshall³, Joshua Staker³, Gabriel Marques³, Tsuguo Morisato³, David Giesen³ and Alexander Goldberg³; ¹Panasonic Corporation, Japan; ²Schrödinger Incorporated, United States

Materials exhibiting higher mobilities than conventional organic semiconducting materials (e.g. fullerenes and heteroacenes [1]), are in high demand for applications such as printed electronics. In order to explore new molecules in the heteroacene family that might show improved mobility, a massive theoretical screen of hole-conducting properties of molecules were performed using a cloud computing environment. Over 7,000,000 structures of fused furans, thiophenes and selenophenes were generated, and 250,000 structures were randomly chosen for subsequent DFT (Density Functional Theory) calculations of hole reorganization energies ($\lambda_h$). Utilizing the cloud-computed DFT dataset of a quarter-million reorganization energies, the \textit{de novo} design method proposed by Gomez-Bombarelli [2] was applied to find further chemical structures with minimal reorganization energy. This method converts molecular structures into continuous variables by applying the variational autoencoder/decoder technique, which enables optimization of chemical structures in a continuous numerical space. Results of the inverse design showed that the method has the ability to generate exotic chemical matter, such as structures with a seven- and eight-membered rings, with reasonably low calculated reorganization energies.

De novo Design of Molecules with Low Hole Reorganization Energy Based on a Quarter Million Molecule DFT Screen (2)—Application of Deep Reinforcement Learning and Junction Tree Variational Autoencoder

Karl Leswing¹, Mathew D. Halls¹, Tim Robertson¹, Kyle Marshall¹, Joshua Staker¹, Gabriel Marques¹, Tsuguo Morisato¹, David Giesen¹, Alexander Goldberg¹, Nobuyuki N. Matsuzawa², Hiroyuki Maeshima², Hideyuki Arai², Masaru Sasago² and Eiji Fujii²; ¹Schrödinger Incorporated, United States; ²Panasonic Corporation, Japan

Materials exhibiting higher mobilities than conventional organic semiconducting materials, (e.g. fullerenes and heteroacenes [1]), are in high demand for applications such as printed electronics. In order to explore new molecules in the heteroacene family that might show improved mobility, over 7,000,000 structures of fused furans, thiophenes and selenophenes were generated and 250,000 structures were randomly selected for subsequent DFT (Density Functional Theory) calculations of hole reorganization energies ($\lambda_h$). Utilizing the cloud-computed DFT dataset of a quarter-million reorganization energies, the \textit{de novo} design method proposed by Gomez-Bombarelli [2] was applied to find further chemical structures with minimal reorganization energy. This method converts molecular structures into continuous variables by applying the variational autoencoder/decoder technique, which enables optimization of chemical structures in a continuous numerical space. Results of the inverse design showed that the method has the ability to generate exotic chemical matter, such as structures with a seven- and eight-membered rings, with reasonably low calculated reorganization energies.

hole reorganization energies (λh). Utilizing the cloud-computed DFT dataset of a quarter-million reorganization energies, inverse materials design methods were applied to find further chemical structures with minimal reorganization energy. The de novo design methods applied were (1) a method based on reinforcement learning of SMILES strings (the REINVENT method [2]), and (2) a junction tree variational autoencoder that directly generates molecular graphs [3]. Both methods succeeded in obtaining chemical structures whose reorganization energy was lower than the lowest energy in the DFT training dataset, suggesting that an extrapolative materials design protocol can be developed by applying two methods. Finally, these results will be compared to the results obtained from the latent-space de novo molecular design method proposed by Gomez-Bombarelli et al. [4].

Accelerated Discovery of Metal Oxide Photoanodes for Solar Fuels Applications John M. Gregoire; California Institute of Technology, United States

Solar fuel generation from H2O, CO2 and sunlight comprises a promising renewable energy technology whose future proliferation relies on materials advancements, including identification of a photoanode for the oxygen evolution reaction. A water-oxidizing photoanode can be coupled to a (photo)cathode for scalable generation of H2 and C-containing fuels. Metal oxides are the most extensively studied class of OER photoanode materials due to the availability of a multitude of metal oxide phases that may stably operate in the oxidative electrochemical environment while converting solar to photoelectrochemical (PEC) energy. Solar fuels photoanodes are quite rare due to the combined needs of solar absorption, charge carrier separation and transport, oxidative stability, and catalytic activity for the OER. The compendium of known metal oxide photoanodes that operate in the visible spectrum is being rapidly expanded via theory-guided high throughput experimentation, including our combination of combinatorial materials synthesis coupled with automated UV-vis spectroscopy and PEC experiments. Discovery of dozens of ternary metal oxide photoanodes will be discussed with focus on the lessons learned in terms of the role of theory and the importance of compositionally graded libraries, and a historical analysis of the discovery rate of metal oxide photoanodes reveals increasing chemical diversity, suggesting there may be many more materials to be discovered. The rapidly expanding portfolio of metal oxide photoanodes creates new avenues of inquiry to realize the requisite stability and efficiency for deployment of solar fuels technologies.

Probing the Water-Induced Degradation Pathways of Metal-Organic Frameworks (MOFs)—The Potential for Highly Transferrable Surface Passivation Approach Mohamed H. Alkordi1, Mohamed E. Safy1, Muhamed A. Amin2, Rana R. Haikal1, Basma Elshazly1 and Ahmed H. Ibrahim1; 1Zewail City of Science and Technology, Egypt; 2University of Groningen, Netherlands

A model describing the origin of water-induced degradation of certain Metal-Organic Frameworks (MOFs) is derived, aiming to explain experimental observations of water stability and instability of prototypal MOFs. The proposed model suggests crucial role of metal-coordinated water molecules, and solution pH, in triggering a cascade of reactions that in several cases results in pronounced irreversible degradation of several MOFs. It is suggested that such degradation pathways can be affected in neutral to basic solution by deprotonation of metal-coordinated water molecules, or bridging hydroxyl species in multinuclear clusters. Calculations of pKa values for the metal-coordinated water molecules, complemented by geometry relaxation calculations, and variable pH infrared spectroscopy techniques were all simultaneously utilized to draw a comprehensive description for the early stages in MOFs degradation in aqueous medium. Mostly dependent on the nature of metal nodes, we propose two distinct mechanisms for structural degradation of carboxylate-based MOFs. The MOFs investigated herein included MOF-5, HKUST-1, UiO-66, and MIL-101-Cr. It is suggested that for each type of MOF, a narrow pH stability range can be described, mostly determined by the pKa of metal-coordinated water molecules and the relative strength of metal-carboxylate interactions. Beyond this fundamental pH range, a relativeley wider pH window can exist, where certain MOFs can be kinetically inert. Finally, we present a highly transferrable and facile approach to induce surface passivation of MOFs crystals to effectively extend such aqueous solution stability limits, as proven by the case of appreciably maintained microporosity of HKUST-1 in neutral, acidic and basic aqueous solution.

Combinatorial Approach for Single Crystalline TaON Growth—Epitaxial β-TaON (100) /α-Al2O3 (012) Narayanachari
The Energy Landscape Governs Plasticity in Glasses

Longwen Tang and Mathieu Bauchy; University of California, Los Angeles, United States

The semiconductor photocatalyst β-TaON used for water splitting is of interest due to its promising properties, such as stability, suitable band gap for visible light photocatalysis and carrier mobility. We have implemented a combinatorial, materials discovery approach using pulse-laser deposition (PLD) for thin film growth, X-ray diffraction (XRD) for phase determination and machine learning for data reduction. A lateral compositional gradient of TaOxNy was grown across the surface of a α-Al2O3 (012) 25-mm-wide wafer by PLD at 675°C in 10 mTorr of N2. After annealing in N2 at 1000°C, small-area XRD scattering patterns were collected for 71 positions across the lateral gradient. Unsupervised machine learning separated the XRD data into 4 clusters (phases); one of which turned out to be the desired β-TaON phase. Using high-resolution XRD we determined that the β-TaON region of the film to be single crystal epitaxy with out-of-plane β-TaON (100) // α-Al2O3 (012) and in-plane β-TaON (010) // α-Al2O3 (2-10). X-ray reflectivity (XRR) analysis of the β-TaON region of the film determined the film thickness to be 260 Å with an electron density matching that expected for β-TaON. Ta 4f7/2 XPS measurements across the graded film showed Ta5+ valence state at the β-TaON region of the film. In comparison to the standard method of growing many uniform films at different compositions, this combinatorial method that produces a library of phases on a single wafer is much more efficient for materials discovery.

10:58 AM S.CT01.01.09
The Energy Landscape Governs Plasticity in Glasses
Longwen Tang and Mathieu Bauchy; University of California, Los Angeles, United States

Based on their structure, non-crystalline phases can fail in a brittle or ductile fashion. However, the nature of the linkages between structure and propensity for ductility in disordered materials has remained elusive. Here, based on molecular dynamics simulations, we investigate the fracture of several disordered phases (metallic glass, glassy silica, colloidal gel, etc.) with varying degrees of disorder. We find that that, in general, structural disorder results in an increase in ductility. By applying the activation-relaxation technique (an accelerated sampling method to identify transition states), we show that the degree of plasticity is controlled by the topography of the energy landscape.

11:10 AM S.CT01.03.02
Progress towards Autonomous Perovskite Discovery, Synthesis and Characterization Using ESCALATE+RAPID
Joshua Schrier; Fordham University, United States

The dream of autonomous materials discovery systems will only be realized if the entire design/synthesis/characterization process is described in an unambiguous machine-readable format. Specifying the experiment process in a machine-readable way facilitates both remote operation, algorithmic control of experiments, and enhanced experimental replicability. A significant challenge is that materials experiments often require a combination of instructions for human operators and machines. Furthermore, the variety of materials characterization data and experimental performance metadata during a process often require significant extraction/transformation/loading before machine learning methods can be applied. Existing tools require significant development time that is incompatible with rapidly evolving scientific needs.

In this talk, I will describe ESCALATE (Experiment Specification, Capture and Laboratory Automation Technology) an adaptable open source package for experiment description and data collection. As a specific example, I will describe its application to Robotic-Accelerated Perovskite Investigation and Discovery (RAPID). The first generation of RAPID uses inverse temperature crystallization (ITC) to grow halide perovskite single crystals for x-ray structure determination and bulk characterization using commercial liquid handling robots. Experiment plans are contributed remotely, by either human scientists or algorithms trained on the reaction data. Incoming experimental data collected by ESCALATE is used to automatically train machine learning models, evaluate model performance and feature influence on model predictions to gain human-interpretable scientific insight into the formation process, and quantify experimental reproducibility using this complete dataset of all experimental successes and failures. A live web dashboard communicates these insights to the scientist and management in visual form; furthermore experimental data can be exported in the form of interactive visualizations for use in publications. Collected characterizations includes qualitative measurements of crystal quality (including photographic images of the samples), powder X-Ray diffraction, and spectroscopic measurements along with background laboratory conditions. The second generation of RAPID has been extended to include antisolvent precipitation synthesis of perovskite single crystals and perovskite thin film synthesis and characterization including remote monitoring of long-term environmental stability. We have used the ESCALATE/RAPID platform to perform experimental tests benchmarking a variety of data-driven approaches for discovering new compounds against human-expert and random baselines. The comprehensive data collected from these experiments has also allowed us to ascertain the relative importance.
of descriptive physical models for reaction composition relative to raw experimental descriptions when constructing machine learning models for reaction outcome prediction.

11:16 AM *S.CT01.03.03
Autonomous Combinatorial Experimentation Ichiro Takeuchi; University of Maryland, United States

Machine learning has become an integral part of many aspects of materials research. As a branch of machine learning, active learning has attracted much attention which can effectively help navigate experimental sequences in materials research. We are actively incorporating active learning in screening of combinatorial libraries of functiona materials. For some physical properies, each characterization/measurement requires time/resources long/large enough that "high"-throughput measurement is not possible. Examples include detection of martensitic transformation and superconducting transitions in thin film libraries. By incorporating active learning into the protocol of combinatorial characterization, we can streamline the measurement and the analysis process substantially. We will present examples of mapping of phase change memory materials as well as others functional materials. This work is performed in colaboration with A. Gilad Kusne and V. Stanev. This work is funded by ONR and AFOSR.

11:22 AM S.CT01.03.04
Machine Learning Assisted Synthesis of Metal-Organic Nanocapcules Yunchao Xie¹, Chen Zhang², Xiangquan Hu¹, Chi Zhang¹, Steven Kelley¹, Jian Lin¹ and Jerry L. Atwood¹; ¹University of Missouri-Columbia, United States; ºNorth Carolina State University, United States

Herein, we report the successful discovery of a new hierarchical structure of metal-organic nanocapsules (MONCs) by integrating chemical intuition and machine learning algorithms. By training datasets from a set of both succeeded and failed experiments, we studied the crystallization propensity of metal-organic nanocapsules (MONCs). Among four machine learning models, XGBoost model affords the highest prediction accuracy of 91%. The derived chemical feature scores and chemical hypothesis from the XGBoost model assist to identify proper synthesis parameters showing superior performance to a well-trained chemist. This paper will shed light on the discovery of new crystalline inorganic-organic hybrid materials guided by machine learning algorithms.

11:28 AM *S.CT01.03.05
Autonomous Robotic Assembly of Two-Dimensional Crystals to Build van der Waals Superlattices Satoru Masubuchi¹, Masataka Morimoto¹, Momoko Onodera¹, Sei Morikawa¹, Takashi Taniguchi², Kenji Watanabe² and Tomoki Machida¹; ¹University of Tokyo, Japan; ºNational Institute for Materials Science, Japan

Van der Waals heterostructures are comprised of stacked atomically thin two-dimensional crystals and serve as novel materials providing unprecedented properties. However, the random natures in positions and shapes of exfoliated two-dimensional crystals have required the repetitive manual tasks of optical microscopy-based searching and mechanical transferring, thereby severely limiting the complexity of heterostructures.

To solve the problem, we develop a robotic system, powered by artificial intelligence, that automatically searches exfoliated 2D crystals and assemblies them into vdW superlattices inside glovebox [1-3]. The system can automatically scan the surface of silicon substrates, analyze optical microscope images, and detect a variety of atomically thin 2D materials without human intervention. The stacking order, positions, and crystallographic orientations of the 2D crystals are designed using the customized CAD software. The robotic assembly system of two-dimensional crystals enabled stacking four cycles of the designated two-dimensional crystals per hour with few minutes of human intervention for each stack cycle.

The system enabled fabrication of the vdW superlattice structures consisting of 29 alternating layers of the graphite and the hexagonal boron nitride (hBN) flakes. Encapsulated graphene devices exhibited high charge carrier mobilities (>1,000,000 cm²/Vs), demonstrating the applicability of the system for prototyping a variety of high-quality vdW superlattices. The wider material design freedom enabled by our system offers unprecedented opportunities for exploring the potential of vdW heterostructures. By this development, we can reduce the human intervention involved in the vdW heterostructure fabrication by orders. We believe that this work free up researchers from repetitive tasks and letting them focus on more intellectually creative tasks.

The hardware/software designs are available at https://github.com/tdmms/

Combining Experiment and Theory in a Closed-Loop Learning Cycle to Improve Perovskite Device Stability and Performance  
Tonio Buonassisi; Massachusetts Institute of Technology, United States

In my annual poster, I'll review the MIT PVLab's recent work combining experiment and theory in a closed-loop, machine-learning (ML) driven framework. Closed-loop experimentation driven by ML enables rapid and efficient convergence on optima, within vast search spaces. A review of scientific insights, as well as our latest machine-learning algorithms, will be presented.

11:40 AM S.CT01.03.07
High Throughput Nanoindentation and Machine Learning Assisted Analysis for Evaluation of Materials under In Operando Conditions  
Eric Hintsala¹, Bernard Becker¹, Youxing Chen², Benjamin Stadnick¹, Ude Hangen¹, Nathan Mara³ and Douglas D. Stauffer¹; ¹Bruker Nano Surfaces, United States; ²University of North Carolina at Charlotte, United States; ³University of Minnesota, United States

Meeting current and future demands for advanced structural materials designed to operate in extreme environments requires rigorous mechanical performance evaluation at such conditions. When considering alloy development for such applications, such as nuclear materials, multiple compositions and processing routes create many permutations of material to be evaluated at different temperatures and radiation damage levels. Where traditional bulk scale mechanical testing is relatively time consuming, high speed nanoindentation mapping techniques can provide large (and highly localized) Hardness and Modulus datasets. This allows for analysis of heterogeneous distributions of properties in multi-phase alloys, which can then be correlated to the microstructure through use of supplementary techniques, such as EBSD, which has similar resolution. However, this requires accompanying analysis methods to also be high throughput, for which machine learning based techniques are of interest. Some datasets, as large as one million indentations in a given map, are beyond the limit of reasonable human analysis.

In this study, a high vacuum, high temperature nanoindenter was utilized to produce temperature controlled mapping of three advanced types reactor materials up to 500°C while protecting the sample surface from oxidation. The materials studied were Fe-based HEAs, with varied Al content to give 3 distinct microstructures. Structure-property correlation was quantitatively explored through clustering to partition the hardness and modulus data to individual microstructural elements and evaluate their thermal stability, with irradiation studies to follow. While qualitatively these methods performed comparably to hand grouping, there is a need to quantitatively understand their systematic uncertainties without making assumptions regarding the underlying probability distribution. This is further explored for this data set by using a parametric bootstrapping method to resample the probability distribution function from the individual data points. Three different machine learning methods, Kernel Density Estimation, Gaussian Mixture and Multi-Normal, are used to generate a probability distribution function. This is then resampled to produce a simulated dataset 1000 times the original dataset in size. This allows K-means, Spectral and Gaussian Mixture clustering techniques to be applied and compared, but in principal, this can be applied to evaluate other properties as well.

11:46 AM S.CT01.03.08
Autonomous Materials Development for Fun and Profit  
Kristofer G. Reyes; State University of New York at Buffalo, United States

Closed-loop, sequential learning is a key paradigm in autonomous materials development. Within this framework, aspects of the materials system under study are modeled, and such models are used to decide subsequent experiments to be run, results of which are fed-back to update models. In the past, off-the-shelf solutions and algorithms have been employed to optimize material properties. In this talk, we describe how autonomous materials platforms can be used for problems other than materials property optimization. We will specifically highlight work on autonomous phase mapping and real-time control, and how a common framework can be used to capture problem-specific structure and objectives. Relevant to this is the development of tools to perform autonomous materials characterization. We will describe how rich characterization data such as microscopy images or three-dimensional reconstructions from atom probe tomography can be analyzed without human intervention to encode experimental results for subsequent use within the closed loop. Together, the work described demonstrates the broad applicability of autonomous platforms throughout materials science research.
A Bayesian Experimental Autonomous Researcher for Mechanical Design
Keith A. Brown\textsuperscript{1}, Aldair Gongora\textsuperscript{1}, Bowen Xu\textsuperscript{1}, Wyatt Perry\textsuperscript{1}, Chika Okoye\textsuperscript{1}, Patrick Riley\textsuperscript{2}, Kristofer G. Reyes\textsuperscript{3} and Elise Morgan\textsuperscript{1}; \textsuperscript{1}Boston University, United States; \textsuperscript{2}Google, United States; \textsuperscript{3}University at Buffalo, The State University of New York, United States

While additive manufacturing (AM) has facilitated the production of complex structures, it has also highlighted the immense challenge inherent in identifying the optimum structure for a given application. Numerical methods are important tools for optimization, but experiment remains the gold standard for studying non-linear, but critical, mechanical properties such as toughness. To address the vastness of AM design space and the need for experiment, we develop a Bayesian experimental autonomous researcher (BEAR) that combines Bayesian optimization and high-throughput automated experimentation. Using the BEAR, we explore the toughness of a parametric family of structures and observe more rapid, in terms of both experiments and time, convergence towards higher-performing structures than was obtained using a grid-based search. Specifically, we observe that the BEAR matched the performance of a grid-based search in 60 times fewer experiments. In addition to providing a platform to discover mechanical properties of AM-produced metamaterials, the BEAR provides a framework for exploring active learning in an experimental context including multi-agent decision policies, the incorporation of theory in an experimental loop, and the influence of heteroscedasticity. Collectively, these results show the value of machine learning in experimental fields where data are sparse.

Interpretable Machine Learning for Materials Design and Characterisation
Keith T. Butler; Rutherford Appleton Laboratory, United Kingdom

In this talk I will look at how we can open up the perceived 'black box' of machine learning when designing and characterising materials. I will show how being able to look at and understand the inner workings of deep neural networks increases the value of these approaches for problems in materials science. Understanding the workings is important for (i) debugging and building better models, (ii) building confidence in models that perform well, (iii) learning from models that exceed human performance in certain problem areas. I will take examples of our research where we use graph neural networks to infer and predict dielectric properties of solids and where we use deep convolutional neural networks to interpret data from inelastic neutron scattering. In the former case a mixture of deep and shallow learning allows for extraction of principles as well as construction of robust accurate models. In the latter case understanding the workings of the neural network allows us to develop a method for guiding experiments to sample the most pertinent areas of signal space.

Inverse Design of Broadband Highly Reflective Metasurfaces using Neural Networks
Eric Harper\textsuperscript{1}, Eleanor Coyle\textsuperscript{2,1}, Jonathan Vernon\textsuperscript{1} and Matthew Mills\textsuperscript{1}; \textsuperscript{1}Air Force Research Laboratory, United States; \textsuperscript{2}Azimuth Corp, United States

The next generation of high performance optical materials require precise engineering to transcend the inherent limitations of bulk materials and achieve desired optical performance. These targeted properties originate from the interactions between inherent optical properties of the constituent materials and meticulously engineered sub-wavelength inhomogeneities. However, the design of such metamaterials poses a significant challenge to researchers due to the near-infinite design space to consider, even for relatively simple metamaterials such as the two-dimensional all-dielectric metasurface. This metasurface has been the subject of intense research interest because of its unprecedented reflective performance resulting from low-loss dielectric materials and shape-dependent optical resonances. Here we employ artificial neural networks (ANNs) to invert the design process, conceiving metasurface designs with targeted reflection and transmission spectra. These ANNs are capable of coordinating the complex interactions of the eigenmodes from which these desired properties arise, delivering device designs demonstrating coefficients of reflection greater than 99% over a range of wavelengths more than 450nm.

Machine Learning-Aided Design of DNA-Stabilized Silver Clusters with Specific Fluorescence Wavelengths
Stacy Copp\textsuperscript{1,1}, Steven Swasey\textsuperscript{2}, Alexander Gorovits\textsuperscript{3}, Petko Bogdanov\textsuperscript{1} and Gwinn Elisabeth\textsuperscript{2}; \textsuperscript{1}University of California, Irvine, United States; \textsuperscript{2}University of California, Santa Barbara, United States; \textsuperscript{3}University at Albany, State University of New York, United States

DNA-templated silver clusters (Ag\textsubscript{50}-DNA) are known to exhibit a wide range of fluorescence colors for different choices of the DNA template sequence [1]. While these clusters are promising biosensors and biomarkers [2], rational design of Ag\textsubscript{50}-DNA for specific applications is challenged by the huge space of possible DNA template sequences. To understand how DNA sequence selects for silver cluster size and optical properties, we are employing high-throughput experiments and tools
from machine learning and data mining. We previously showed that machine learning methods trained on experimental data can be used to design new DNA templates that select for AgN-DNA color, for the specific and limited case of 10-base DNA oligomers [3]. An important open question is whether such a design process developed for a specific biopolymer template length is applicable at other lengths, with different numbers and diverse configurations of cluster nucleation sites. More broadly within materials informatics, it is important to determine when models learned on limited training data sets are relevant for prediction within expanded input parameter spaces.

Here, we present a newly developed flexible design approach that utilizes color-correlated DNA base motifs learned from data on > 2,000 ten-base DNA oligomers [4]. We test this motif-based design for templates ranging from 8 bases to 16 bases long, for which the sizes of the sequence spaces differ by nearly 5 orders of magnitude. The experimental data show that designed strands of all lengths are selective for AgN-DNA color in the target wavelength band of 600-660 nm, strongly suggesting that color-selective motifs learned for one template length generalize to other lengths. Thus, a motif-based design approach may be broadly suitable for future AgN-DNA applications.

SESSION S.CT01.09: Live Lightning/Flash II: Artificial Intelligence for Material Design, Processing and Characterizations Sunday Afternoon, November 29, 2020 S.CT01

7:15 PM INTRODUCTORY COMMENTS

7:16 PM *S.CT01.02.01
Data-Driven Materials Discovery for Functional Applications Jacqueline M. Cole1,2,3; 1University of Cambridge, United Kingdom; 2STFC Rutherford Appleton Laboratory, Harwell Science and Innovation Campus, United Kingdom; 3Argonne National Laboratory, United States

Large-scale data-mining workflows are increasingly able to predict successfully new materials that possess a targeted functionality. The success of such materials discovery approaches is nonetheless contingent upon having the right data source to mine, adequate supercomputing facilities and workflows to enable this mining, and algorithms that suitably encode structure-function relationships as data-mining workflows which progressively short list data toward the prediction of a lead material for experimental validation.

This talk describes how to meet these data science requirements by showing how to auto-generate large material databases of experimental information from documents, using natural language processing and machine learning, via our ChemDataExtractor tool [1-3]. The resulting large databases of chemical structures and their cognate properties are then mined for materials discovery using custom-built algorithms that are encoded forms of structure-function relationships. These molecular design rules progressively filter the parent set of chemicals until a lead candidate appears, which is experimentally validated. Case studies are demonstrated to illustrate the power of data-driven materials discovery for several functional applications.

7:22 PM S.CT01.02.02
Discovering New Hydrogen Storage Materials Using an Empirical Design Principle for Metal Hydrides Matthew Witman1, Sanliang Ling2, David Grant2, Gavin Walker2, Sapan Agarwal1, Vitalie Stavila1 and Mark D. Allendorf2; 1Sandia National Laboratories, United States; 2The University of Nottingham, United Kingdom
The development of a hydrogen economy has potentially immense benefits for addressing the crisis of global heating. However, storage remains a problem and decades of research have left us empty-handed: no known materials can satisfy all of the DOE targets for vehicular storage. Metal hydrides are among the most promising solid-state storage materials, but their complex chemistry is a major impediment to discovery of game-changing materials. Specifically, their thermodynamics are often ill-matched to hydrogen release at temperatures compatible with fuel cells. This limitation requires an equilibrium H2 pressure of at least 5 bar at the maximum delivery temperature of 80 °C. Empirical discovery approaches using, for example, high-throughput synthesis, are largely ineffective because measurement of the equilibrium H2 pressure can take days or even weeks. Machine learning (ML) methods have already shown promise for accelerating the discovery of new hydrogen sorbents and identifying key features that influence their properties. In recent application to metal hydrides, however, the use of “black-box” algorithms prohibited development of crucial vital scientific insight needed to go beyond existing compositions. We employed a gradient-boosting tree regressor, an “explainable” ML that can reveal the feature dependence of material properties. In particular, we find that the equilibrium H2 pressure of intermetallic metal hydrides strongly depends on a volume-based feature that requires only the elemental composition to be computed. Remarkably, this simple structure-property relationship is valid across a wide range of compositions, metal substitutions, and structural classes found in intermetallic metal hydrides. This result provides a rational basis for targeting novel hydrogen storage materials with thermodynamic properties appropriate for specific applications. As an illustration, we identified a known intermetallic that forms a hydride with very low stability. Although not yet validated by experiment, this result was confirmed by density functional theory modeling.

7:28 PM S.CT01.02.03
De Novo Discovery of Nanoporous Structures by Machine Learning  
Mathieu Bauchy; University of California, Los Angeles, United States

Nanoporous materials (e.g., zeolite, activated carbon, metal-organic framework, polymeric membranes, etc.) have various technological applications, including gas separation, gas storage, catalytic transformations, etc. The functionalities of nanoporous materials strongly depend on their pore size and shape distribution—which present virtually limitless degrees of freedom. Here, based on high-throughput simulations and a convolutional neural network (CNN) predictor, we present a model allowing us to predict the water sorption isotherm of hydrophilic and hydrophobic nanoporous materials. The training of a CNN generator then enables the inverse design of optimal porous microstructures featuring tailored/unusual sorption isotherms.

7:46 PM S.CT01.02.06
Machine-Based Discovery of Energetic Materials  
Peter W. Chung; University of Maryland, United States

Recent successes demonstrated by machine learning (ML) approaches have created great enthusiasm for their potential translational contributions to other fields. Among these are efforts to demonstrate the feasibility of using machine-based approaches to study and speculate on new energetic materials. This talk will discuss the performance of ML models developed to predict the detonation properties of energetic materials. A comprehensive comparison of approaches reveals that models are highly sensitive to feature selection as well as algorithm differences. But using a relatively limited volume of data and careful problem definitions, surprisingly strong cross validation scores suggest that there is promise to both improve and ultimately use ML methods widely in this field. The talk will conclude with an overview and some perspectives of other recent efforts including generative modeling and natural language processing techniques at their intersections with energetics research.

7:52 PM S.CT01.02.07
A Machine-Learning-Based Strategy for Accelerated Discovery of Novel Scintillator Chemistries  
Anjana Talapatra, Christopher R. Stanek, Blas P. Uberuaga and Ghanshyam Pilania; Los Alamos National Laboratory, United States

Inorganic scintillator-based detector materials find a wide variety of applications, ranging from medical imaging to radiation detection for global security and high energy physics experiments. These materials essentially convert a fraction of the total energy deposited by incident gamma rays or X-rays into visible or near-visible range of the spectrum. In many applications a scintillator with high light output, fast response time, and emission at suitable wavelengths, is generally required, among many other application-specific desired characteristics. However, owing to several conflicting relationships between the desired properties (e.g., brightness versus speed), no single scintillator is ideal for all uses; there is a need to design custom scintillators optimized for each application. Traditionally, the discovery and design of new detector materials have relied on a laborious, time-intensive, trial-and-error approach; yielding little physical insight and leaving a vast space of potentially
revolutionary materials unexplored. To accelerate the discovery of optimal scintillator materials with targeted properties and performance, efforts are ongoing to develop a closed-loop machine learning driven adaptive design framework based on data from literature, in-house experiments and quantum mechanical calculations. This talk will present an overview of this framework, focusing on the screening of complex wide band gaps chemistries with an aim of identifying promising materials that are amenable to band-gap/band-edge engineering to yield custom scintillation properties. The developed framework is general and is expected to prove useful for applications beyond scintillator discovery such as photovoltaics and catalysis.

8:04 PM S.CT01.02.09
Machine-Learning Guided Discovery of MOFs for Enhanced Hydrogen Storage Capacity  Samrendra Singh, Abhishek Sose, Karteeek Bejagam and Sanket A. Deshmukh; Virginia Tech, United States

In recent years the use of various machine-learning (ML) methods to discover new materials with desired properties have emerged as a powerful tool. In this research, we have designed a stacked ensemble model (SEM) by combining several supervised ML models to predict the adsorption of hydrogen in metal-organic frameworks (MOFs). The SEM model was trained by using the hydrogen adsorption data generated by screening of 1000s of MOFs by performing grand canonical monte carlo (GCMC) simulations at 1 atm and 77 K. This SEM was integrated with optimization algorithms and in-house MOF structure generation code to design MOFs with high adsorption of hydrogen. Overall, this new approach of integrating SEM with optimization algorithms accelerated the new MOF discovery process, resulting in a MOF with enhanced hydrogen storage capacity. This new ML framework is transferable and can be used to discover other porous (e.g. zeolites), soft (e.g. polymers), and hard (e.g. alloys) materials for desired applications.

Multiscale Machine Learning for Quantum Many Particle Physics with Wavelet Scattering Transforms  Matthew Hirn; Michigan State University, United States

Computing the ground state energy of quantum many particle systems is of fundamental importance in a variety of fields, including chemistry, physics and materials science, amongst others. However, the complexity of such quantum mechanical computations grows rapidly with the number of particles. Machine learning algorithms do not simulate the physical system, but instead estimate solutions by interpolating values provided by a training set of known examples. However, precise interpolations may require a number of examples that is exponential in the system dimension, and are thus intractable. Tractable algorithms compute interpolations in low dimensional approximation spaces, which leverage the underlying physical properties of the system.

In this talk I will give an overview of machine learning algorithms for computing the ground state energy of quantum many particle systems, describing the core principles of such algorithms and illustrating the common themes that emerge. I will then present in more detail our approach to the problem, which is based on a type of multiscale, multilayer convolutional neural network, called a wavelet scattering transform. Through a cascade of multiscale wavelet transforms and nonlinearities, the scattering transform encodes the appropriate invariants and regularity properties of the physical system. Wavelet scattering regressions, computed over databases of organic molecules and amorphous materials, achieve errors on the order of quantum mechanical simulations, but at a fraction of the computational cost.

Putting Scientists’ Eyes on Glass-Box Physics Rule Learner for Unraveling Nano-Scale Tribocharging Phenomena In Ho Cho1, Qiang Li1, Rana Biswas1,2 and Jaeyoun Kim1; 1Iowa State University, United States; 2Ames Laboratory, United States

This multi-disciplinary research proposes a new framework that can infuse scientists' experience and knowledge (named as scientists' eyes) into a constantly evolving, glass-box physics rule learner that can essentially extract hidden physics rules behind complex nano-scale phenomena. Recently, physics principles are gradually integrated into machine learning (ML) methods, but it is at its infancy to discover hidden physics rules. Such pursuits for hidden rules face formidable challenges when the physical experiments involve multifaceted measurements across three-dimensional (3D) specimens or objects. These remaining challenges render even advanced ML methods such as deep learning secondary, not as a primary explorer, in the broad science and engineering domains. Therefore, there exists a deep chasm still remains between materials science
and ML community.
To overcome this challenge and unravel hidden physics rule behind nano-scale complex phenomena, we reinterpreted the deep learning's successful notion of multi-layered convolutions and gave rise to a new notion of "convolved information index." The convolved information index can facilitate handling physical measurements over 3D nano-scale specimens and measurements without losing experienced perspectives of scientists in the materials science. Also, the framework proposes "link function" as a generator of mathematical expressions about the identified nano-scale physics rules, thereby pursuing "glass-box" (as opposed to the black-box) learning and prediction. Consistent evolution capability is realized by integrating Bayesian update and evolutionary algorithms.

The framework is applied to nano-scale contact electrification (CE) phenomena, which are difficult to elucidate due to length scales and complex physical interactions [1,2]. Three experimental data sets are used. Tribocharged PDMS nanocup array is fabricated by the sequence of (1) prepare a PET mold with a 750 nm-pitch triangular array of nanocones, (2) pour the liquid phase PDMS, Sylgard 184, Dow Corning, mixed with the curing agent, (3) solidify the specimen, and (4) peel off the PDMS from the PET mold (for more details see [1,2]). Atomic force microscopy (AFM) in the tapping mode is used to measure the surface topography and potential. The charge values were measured by Kelvin probe force microscopy over patterned nano-cups represented by 3D point cloud. The experimental data consist of a variety of conditions regarding geometries, demolding directions, and nano-scale patterns (3000 nm by 3000 nm square area with an interval of 5.86 nm; 4000 nm by 4000 nm, with 7.8125 nm). The nano-cup's average heights are 154 nm, 93.5 nm, and 117 nm. The proposed glass-box learning begins from horizontal-demolding test data, and then the best-so-far identified rules are inherited to the next learning with new specimens in a chained way.

The feasibility tests show promising performances of the proposed framework in unraveling transparent, reasonable "expressions" of hidden physics rule along with reasonable reproduction of complex patterned distributions of electric potentials over the 3D point cloud. The proposed framework is believed to establish a promising partnership of scientists’ eyes and the advanced ML methods, thereby enabling data and ML-driven discovery of groundbreaking physics laws in the nano-world and beyond. This presentation will cover how this new framework can facilitate materials scientists’ discovery with actual nano applications.

8:28 PM S.CT01.04.04
Materials By Design Using Artificial Intelligence—Modeling, Manufacturing and Testing Markus J. Buehler, Chi-Hua Yu and Yu-Chuan Hsu; Massachusetts Institute of Technology, United States

In this talk we will review recent studies of applying atomistic-level modeling to describe fracture processes at different scales, from molecular to macroscale levels, and to use artificial intelligence and machine learning to design fracture resistant materials. Molecular and related multiscale modeling methods can be an effective method to better understand elementary fracture processes, ranging from brittle to ductile fracture and other materials failure phenomena such as creep, and provides the basis for expansive training sets. To illustrate this framework, we report a design approach for optimizing the toughness of nanocomposite materials using artificial intelligence, implemented in a novel “AutoComp Designer” algorithm. The algorithm consists of a machine learning predictor combined with an AI improved genetic algorithm, which is capable of discovering de novo materials designs in a vast space of possible solutions. Facilitated by a deep convolutional neural network that is trained with a dataset of hundreds of thousands of combinations of soft and brittle materials originating from multiscale models. Through the algorithm, we extend the capability of physical simulations beyond property predictions to optimize the fracture toughness by altering the material distribution. The solutions are generated by our AI model at a dramatically lower computational cost compared to brute-force searching methods. We further investigate the physical mechanism for improving material performance behind the AI approach, and demonstrate the ability of AI to search for optimal designs with very limited sampling. Brute-force molecular dynamics simulations of the nanocomposite designs confirm that our AI design improves the performance by effectively decreasing the stress concentration at crack tip. This AI approach can be easily applied to other nanocomposites, biomaterials and other material classes, and provides a transferrable and reliable rapid design approach expanding current capabilities.

Fast and Accurate Interatomic Potentials by Symbolic Regression Alberto Hernandez, Adarsh Balasubramanian, Fenglin Yuan, Simon Mason and Tim Mueller; Johns Hopkins University, United States

In recent years there has been great progress in the use of machine learning algorithms to develop interatomic potential
Machine learning (ML) has emerged as a powerful tool in the study and design of materials. In this talk, I will discuss the different ways in which materials can be described and their relative merits and limitations. In particular, I will highlight the importance of choosing representations that not only satisfy known physical invariances (e.g., rotation, translation, etc.), but also incorporate known physics and chemistry in a hierarchy of knowledge. I will provide an overview of leading ML models and applications, and discuss how the problems of data scarcity and bias in materials science can be addressed using multifold, transfer learning and other approaches.

8:58 PM S.CT01.04.09
A General Machine Learning Framework for Impurity Level Prediction in Semiconductors Arun Kumar Mannodi Kanakkithodi and Maria K. Chan; Argonne National Laboratory, United States

Electronic levels introduced by impurities and defects in the middle of the band gap are critically important in semiconductors for optoelectronic, photovoltaic (PV) and quantum sensing applications. While “deep” defect levels can prove catastrophic for PV performance by causing non-radiative carrier recombination, impurity levels in the band gap could also be entangled for quantum sensing or lead to increased absorption of sub-gap photons which can enhance efficiencies. Predicting formation energies and charge transition levels for defects in semiconductors is thus paramount; density functional theory (DFT) has been widely applied for such studies to overcome experimental bottlenecks and confirm measured defect levels. However, the requirement of large supercells, advanced levels of theory, and inclusion of charge corrections make DFT computation of defect properties very expensive, and trends and knowledge from previous calculations are not exploited in subsequent ones.

In this work, we combine high-throughput DFT and machine learning (ML) to develop general predictive models for the formation enthalpy and charge transition levels of impurities in two broad semiconductor classes: (a) ABX$_3$ halide perovskites, and (b) group IV, III-V and II-VI semiconductors. DFT data is generated for impurity atoms selected from across the periodic table and simulated in various possible cation, anion or interstitial sites. Any “semiconductor + impurity” combination is converted into a unique feature vector based on the defect site coordination environment, the tabulated elemental properties (e.g., ionization energy, electronegativity, etc.) of the impurity atom, and electronic and energetic properties computed using low cost unit cell defect calculations. State-of-the-art neural networks (NN), random forest regression (RFR) and kernel ridge regression (KRR) are applied to train models for (a) impurity formation enthalpy, and (b) impurity charge transition levels, based on the input feature vector. Model performance is evaluated for different ML techniques, ML parameters such as number of hidden layers and network weights in NN, subsets of features, and size and nature of training dataset; the best predictive models thus obtained are deployed for comprehensive prediction and design purposes. It is seen that models trained on defects and impurities in pure cation/anion composition semiconductors are applicable to mixed or alloyed compositions as well: for instance, by training on data from pure canonical AB semiconductors like CdTe, ZnO, GaAs and SiC, the ML models can make accurate predictions for impurities in alloyed compositions of the same compounds, such as CdTe$_{1-x}$Se$_x$, Cd$_{1-x}$Zn$_x$O, Al$_{1-x}$Ga$_x$As$_{1-y}$Sb$_y$, etc. This versatility of the machine-learned models provides an avenue to access the optoelectronic impact of any atomic impurity in any possible pure or mixed composition semiconductor belonging to the same chemical space, which is useful for compositions that are expensive to model. We use the predictive models to efficiently screen for dominating impurities, that is impurities that shift the equilibrium Fermi level in the semiconductor as determined by dominant native defects, in hundreds of possible compositions in the halide perovskite and groups IV, III-V and II-VI semiconductor spaces. ML-based screening of impurities was tested against DFT screening for CdTe and seen to have an accuracy of 95%. The quick and accurate
estimation of interesting dopants/impurities in semiconductors is made possible by this materials design framework powered by quantum mechanical computations and machine learning, which can be easily expanded to other semiconductor classes and improved by the infusion of fresh data, new descriptors and more advanced ML techniques.

Optimization Thermal Conductivity at Interfaces Using Learning Algorithms Malachi Schram1, Anne Chaka1, Zexi Lu1, Sabiha Rustam1 and Eric Harper2; 1Pacific Northwest National Laboratory, United States; 2Air Force Research Laboratory, United States

In material science, we are frequently interested in understanding the properties and design implication of material at interfaces. These interfaces can be manipulated to improve the desired characteristics of the bulk material. In this study, we are interested in understanding and optimize the impact of interfacial atomic defects on the thermal transport across a Cu/Si junction. To that end, we developed a reinforcement learning based framework to optimize over a potentially large parameter search. Using this technique allows us to accumulate knowledge of the system of a given type of atoms and store this information into a neural network. In this study, we present our results on optimizing the thermal transport by varying the fraction and length of the interfacial atomic defects using molecular dynamics (MD) simulations with normal mode analysis (NMA) to investigate thermal transport.

9:10 PM S.CT01.04.11
Physics-Informed Machine Learning for Deep Elastic Strain Engineering of Electronic Properties of Materials Zhe Shi1, Evgenii Tsymbalov2, Ming Dao1, Subra Suresh3, Alexander Shapeev2 and Ju Li1; 1Massachusetts Institute of Technology, United States; 2Skolkovo Institute of Science and Technology, Russian Federation; 3Nanyang Technological University, Singapore

Deforming a material to a large extent without inelastic relaxation can result in unprecedented properties. However, the optimal deformation state is buried within the vast continua of choices available in the strain space. Motivated by this challenge, we hereby advance a powerful strategy to circumvent conventional trial-and-error methods and adopt a unique type of machine learning framework for rationally designing the most energy-efficient pathway to achieve a desirable material property such as the electronic bandgap. This method invokes recent advances in the field of convolutional neural networks and active learning by utilizing a limited amount of ab initio data for the training of a surrogate model, predicting electronic bandgap within an accuracy of sub-10 meV. Our model is capable of discovering the indirect-to-direct bandgap transition and semiconductor-to-metal transition in silicon by scanning the entire strain space [1]. It is also able to identify the most energy-efficient strain pathways that would transform diamond from an ultrawide-bandgap material to a narrow-bandgap semiconductor or even semimetal [2]. A broad framework is presented to tailor any target figure of merit by recourse to deep elastic strain engineering and machine learning for a variety of applications in microelectronics, optoelectronics, photonics, and energy technologies.

8:00 AM INTRODUCTORY COMMENTS

8:01 AM *S.CT01.05.01
Autonomous Research Systems for Carbon Nanotube Synthesis Benji Maruyama1, Rahul Rao2,1, Jennifer Carpena-
Autonomous Research Systems like ARES™ are disrupting the research process by using AI and Machine Learning to drive closed-loop iterative research. ARES™ is our autonomous research robot capable of designing, executing and evaluating its own experiments at a rate of up to 100 iterations per day. Previously ARES taught itself to grow carbon nanotubes at controlled rates (NPJ Comp Mat 2016). Here we discuss recent research campaigns on maximizing carbon nanotube growth rates using a Bayesian optimization planner. We also use HOLMES and knowledge gradient descent to introduce advanced decision policies with local parametric models to control nanotube diameter. Implications for nanotube materials development will be discussed. Finally, we have developed a new research robot for additive manufacturing, AM ARES™, which is at the early stages of teaching itself to print structures with unknown inks. We plan to make the AM ARES™ Robot available online so that a broad community of researchers can test concepts and approaches for AI/ML and experimental design as applied to 3D printing, thus building to the larger goal of enhancing citizen science.

Automated Construction of Materials Imaging Datasets
Eric Schwenker1,2, Weixin Jiang1,2, Trevor Spreadbury1,3, E. J. Beard4, Jacqueline M. Cole4, Nicola Ferrier1 and Maria K. Chan1; 1Argonne National Laboratory, United States; 2Northwestern University, United States; 3Massachusetts Institute of Technology, United States; 4University of Cambridge, United Kingdom

Due to recent improvements in image resolution and acquisition speed, materials microscopy is experiencing an explosion of published imaging data. Intensive human efforts, however, are required to digest such published images. In this talk, we will discuss the MaterialEyes project, in which deep learning and natural language processing tools are used to extract microscopy images from scientific literature. The process is accomplished via a suite of scientifically-informed software tools in the EXSCLAIM python package (automatic EXtraction, Separation, and Caption-based natural Language Annotation of Images from scientific figures), which is ultimately focused on the acceleration of inductive materials insights by collecting, structuring, and interpreting an aggregate of materials microscopy imaging data. In this talk, we will discuss how deep learning and NLP is used in EXSCLAIM to: (1) extract figures and caption data from open source scientific documents, (2) automate the construction of self-annotated materials imaging datasets, and then (3) leverage literature-based insights to assist in image classification and segmentation tasks. In addition, we will discuss a new pipeline for crowdsourced image labeling that was used for training some of the deep learning models.

8:13 AM S.CT01.05.03
Deep Learning Accelerated Optical Characterization System for Two-Dimensional Material Research
Yuxuan Lin1, Bingnan Han1,2, Yafang Yang1, Pablo Jarillo-Herrero1, Jihao Yin2, Jing Kong1 and Tomás Palacios1; 1Massachusetts Institute of Technology, United States; 2Beihang University, China

Characterization of nanomaterial morphologies with advanced microscopy and/or spectroscopy tools plays an indispensable role in nanoscience and nanotechnology research, as rich information about the chemical compositions, crystallography, other physical and chemical properties, as well as the growth mechanism can be extracted from morphology analysis. However, the interpretation of imaging data heavily relies on the “intuition” of experienced researchers. As a result, many of the deep graphical features are often unused because of difficulties in processing the data and finding the correlations. Such difficulties can be well addressed by deep learning. In this work, we use the optical characterization of two-dimensional (2D) materials as a case study.

Currently, the most widely used approach to obtain high-quality 2D crystals in laboratories is mechanical exfoliation, followed by 2D crystal “hunting” under an optical microscope. This task is time-consuming and difficult especially for inexperienced researchers. Very recently, there has been growing interest in automating such a process. However, existing optical contrast based identification methods could not satisfy the needs for a general-use, fully automatic optical identification and/or characterization system, as they are often very specific to types of 2D crystals, conditions and configurations of the microscopes being used, image qualities, etc. In addition, optical contrast based methods would fail for harder problems in which the classes to be differentiated are not separable in the color space, such as identifying the materials or even predicting their physical properties from unlabeled optical images.

In reality, optical microscopic (OM) images contain rich, often unused information other than optical contrast. These deep
graphical features can be extracted through deep learning, especially semantic segmentation methods based on convolutional neural networks (CNNs). In this work, an encoder-decoder semantic segmentation network called “SegNet” is configured for pixel-wise identification of OM images of 2D materials, in real time, and regardless of variations in optical setups. A fully automated system utilizing this algorithm can be used to free up tremendous amount of time for researchers. Additionally, we find that the algorithm finds correlations between the OM images and physical properties of the 2D materials and can thereby be used to anticipate the properties of new, as-yet uncharacterized 2D crystals. Finally, a transfer learning technique is applied to adapt the pretrained network to more optical characterization applications such as identifying layer numbers of chemically synthesized graphene domains. The proposed methodology can potentially be extended for identification and understanding other morphological or spectroscopic data of diverse nanomaterials.

8:19 AM S.CT01.05.04
Density Functional Theory and Deep-Learning to Accelerate Scanning Tunneling Microscopy Analysis Kamal Choudhary; National Institute of Standards and Technology, United States

We introduce the first systematic database of scanning tunneling microscope (STM) images obtained using density functional theory (DFT) for two-dimensional (2D) materials. Specifically, the database is constructed using the Tersoff-Hamann method. It currently contains data for 681 exfoliable 2D from the JARVIS-DFT database. These computational STM images can directly aid the experimental analysis of experimental STM results as they provide ideal reference images. Examples of the five possible Bravais lattice types for 2D materials are discussed and the images for all the materials are made available on the website. We validated the computational STM technique by comparing our results to a few experimental images. As the analysis of multiple STM images during an experiment could be tedious, we used our DFT-STM image database to train a high-accuracy convolution neural network (CNN) model to accelerate the characterization process.

Measurements in Machine Learning Gerald Friedland; University of California, Berkeley, United States

A major obstacle in applying machine learning to scientific and engineering tasks is the lack of engineering rules for the design of machine learning systems that allow to make these system reproducible and the limits of the systems known. Based on joint research with physicists and material engineers, this talk presents engineering principles and measurement processes[1] that aim at structured engineering of machine learning systems. While the focus of this talk is on neural networks, the principles and presented measurements are universal and applicable to a variety of machine learning systems.

8:31 AM S.CT01.05.06
Machine Learning the Magnetostriction of Polycrystalline Tb₃Dy₁₋₃Fe₂ Alloys—A Graph Neural Network Approach Minyi Dai, Mehmet F. Demirel, Yingyu Liang and Jiamian Hu; University of Wisconsin-Madison, United States

Predicting the magnetostriction of a large-scale (mm-mm) polycrystalline Tb₃Dy₁₋₃Fe₂ (Terfenol-D) alloy by direct numerical simulations is mathematically tedious and computationally expensive, because it requires solving a set of partial differential equations which describe the mutual coupling between local magnetization dynamics and polycrystal elasticity, and because it requires a large number of simulation cells (tens of millions and more). For accelerating the prediction of magnetostriction, we apply a graph-based deep learning method, namely, the Graph Neural Network (GNN), to discover the correlation between a microstructure dataset of 350 different polygrain structures and a property dataset describing the magnetic-field-induced deformation of each polygrain structure (viz., magnetostriction). In the GNN based approach, each grain is represented as a node, in which all important physical features (e.g., Euler angle, magnetization direction) inside a grain are stored. As a result, the polygrain structure is represented as a network of nodes, in which the identity information of each grain(node)’s neighboring grains(nodes) is also preserved. This in turn allows us to consider the grain-grain interaction which
Critically influences the magnetostriction of the entire alloy and interpret the contribution of each node (grain) to the magnetostriction. A >90% prediction accuracy has so far been achieved with ample space for improvement. Our results demonstrate the exciting potential of applying GNN to accelerate the discovery of microstructure-property linkage in polycrystalline materials.

8:37 AM S.CT01.05.07

Data-Driven Characterization of Structural Dynamics in Nanoparticles Peter A. Crozier, Ramon Manzorro, Carlos Fernandez-Granda, Qiang Zhu, Mahmoud Moradi, David Matteson and Roberto Rivera;

Materials are ubiquitous in society and lie at the heart of many technologies including energy, communication, buildings, transportation, the environment and medicine. The constant need to develop new materials with properties that are matched to applications is a major driver of materials research. Understanding how atoms come together, self-assemble, dissociate and undergo phase transformations under different stimuli is a critical question in materials science. Transmission electron microscopy can routinely achieve a spatial resolution of better than 1 Å allowing the projected spatial distribution of atoms to be observed. In situ methodologies allow these signals to be mapped both spatially and temporally in the presence of different stimuli. Rapid advances in detector and spectrometer technology now allow local imaging, diffraction and spectroscopic signals to be acquired at unprecedented rates, generating terabytes of data in relatively short times.

The availability of large spatially and temporally resolved datasets offers unprecedented potential to transform our understanding of the fundamental atomic level dynamic processes taking place in materials. The rate at which atomic resolution data can be generated in experiments has now outstripped our ability to process and mine scientifically important information. The complex nature of atomic resolution images necessitates intense supervision and input in most quantitative image processing operations. Such an approach is possible for a few hundred images but becomes completely impractical when millions of data frames are available. This has become a serious bottle-neck to extracting the new knowledge potentially available from advanced characterization systems. We need approaches that can recognize recurring motifs in noisy data sets, provide statistical confidence levels for detection of real structural features, track dynamic changes within the sample, and flag events which are likely to be scientifically significant.

We are focused on applying emerging data-driven techniques based on statistics and machine learning to characterize structural dynamics in nanomaterials with an initial focus on metal and oxide nanoparticles 1 – 3 nm in size. Nanoparticles have wide applications in many areas of materials science and are an ideal system for developing and benchmarking novel data-driven processing techniques because they only contain a few thousand atoms. The datasets are acquired using in situ electron microscopy and structural dynamic processes are stimulated using heat, gas or electron irradiation. We compare and contrast the performance of automated image processing algorithms designed to determine atomic coordinates and structural evolution with more conventional manual methods. The importance of understanding the confidence level that can be associated with derived structural models is critical to assess the reliability of the scientific information extracted from large data sets.

Deep Learning Based Characterization of Nanoindentation Induced Acoustic Events Antanas Daugela and David W. Peterson;

Developed as a Baushinger effect monitoring technique in polycrystalline metallic materials, passive acoustic wave monitoring has been a critical health monitoring technique in: Atomic energy pressurized tank; Power and structure monitoring in aeronautics; Automotive; As well as recent applications in spinning disk data storage (HDD) health monitoring applications [1]. Passive monitoring of acoustic waves generated during the initial contact point has been attracting the attention of material scientists since the inception of nanomechanical test instruments for nanoindentation and nanoscratch applications. The conventional acoustic wave signal treatment via RMS or integrated energy values proves that quantitative acoustic wave properties correlate well with the local contact materials phenomena such as: Yield point initiation for W(100)
Sapphire [4], phase transformation for SMA [2]; and differentiating of thin film fracture modes [5]. Several attempts have been made to look at the differentiative properties of the acoustic signatures via signal decomposition techniques such as wavelets [2, 6]. Even though acoustic wave signatures were reconstructed, the true potential of the method was not investigated from the machine learning perspective. In this work a deep learning based signal processing of nanoindentation induced acoustic events was investigated. The synergy of wavelet signal decomposition and information theory based signal presorting prepared data for the deep learning step. In the deep learning step convolutive neural networks sort wavelet coefficients by their statistical significance via provided 2D signal topographies. This creates acoustic signature libraries that are typical for the specific materials phenomena during the indent. The hardware consists of a newly developed ultrasonic probe integrated into the nanoindentation tip, thus eliminating boundary effects and ensuring that only waves that pass via the contact are being recorded. Appropriate signal conditioning and fast data acquisition hardware is synchronized with a quasi-static nanoindentation process. The machine learning routine together with wavelet decomposition and presorting algorithms are implemented into the dedicated acoustic data evaluation kernel which resides in the fast access memory of the designated controller.

Thermal Diffusivity Characterization of High-Temperature Solids Using Bayesian Statistics Yuan Hu, Bryce Boyer, Alex Pagano and Timothy S. Fisher; University of California, Los Angeles, United States

Thermal characterization in high-temperature environments is difficult because of high radiation losses and significant temperature measurement noise and inaccuracy. Ångström’s method can accurately measure thermal diffusivity in the presence of heat losses by observing the propagation of temperature perturbations through a material sample. This work applies a modified Angstrom’s method to measure thermal properties at extreme temperatures (>1000 °C). Previous studies employing Angstrom’s method at high temperatures typically have employed evenly spaced thermocouples on samples for thermal diffusivity measurements. We have recently demonstrated in preliminary room-temperature testing (copper - 1.13 x 10^(−4) m²/s, 1% uncertainty) that the uncertainty in thermal diffusivity within a Bayesian statistical framework is inversely proportional to the square root of the number of concurrent temperature measurements. In this work, we employ IR thermography for non-contact temperature measurement to greatly increase the number of measurements that can be resolved on a sample compared to the conventional thermocouple approach. To subject materials to extreme temperatures, samples are mounted vertically in a vacuum chamber and heated by concentrated thermal radiation from a 10 kW Xenon bulb. A controller is used to precisely modulate power output to produce the periodic temperature oscillation required for Angstrom’s method. Transient temperature measurements are made along the length of the sample using both an infrared camera and optical spectroscopy. Bayesian statistics then quantify the measurement uncertainty associated with the noisy high temperature environment, and this approach is shown to substantially reduce measurement uncertainty for high-temperature material characterization.

Beyond Expert-Level Performance Prediction for Rechargeable Batteries by Unsupervised Machine Learning Xin Li; Harvard University, United States

Predicting the performance of rechargeable batteries in real time is of great importance to battery research and industrial production, and hence has been a long pursuit. In this talk, a novel end-to-end unsupervised machine learning approach is shown for the battery performance prediction, which is free from feature engineering and uses only the raw images of the charge–discharge voltage profiles [1]. This model enables unsupervised real-time automatic extraction of latent physical factors that control the performance of Na-ion batteries to classify good or bad cycling performance by using only the voltage profile of the first cycle. This model can also monitor the safety of Li-metal battery systems by giving warnings when the
battery is approaching a failure. With the beyond expert-level prediction ability, the abovementioned framework can be a promising prototype to further develop and enable high accuracy predictions of battery performance for real-world applications in the future.

Causal Learning from Structural Electron and Scanning Probe Microscopy Data Sergei V. Kalinin, Rama Vasudevan, Chris T. Nelson, Ondrej Dyck, Andrew Lupini and Maxim Ziatdinov; Oak Ridge National Laboratory, United States

Machine learning has emerged as a powerful tool for the analysis of mesoscopic and atomically resolved images and spectroscopy in electron and scanning probe microscopy. The applications ranging from feature extraction to information compression and elucidation of relevant order parameters to inversion of imaging data to reconstruct structural models have been demonstrated. However, the fundamental limitation of the vast majority of machine learning methods is their correlative nature, leading to extreme susceptibility to confounding factors. While in classical statistical methods the methodology to address phenomena such as Simpson paradox are established, the complex and often non-transparent nature of modern DL tools renders them extremely prone to misinterpretation. We argue that correlative machine learning provides a reliable and powerful tool in cases when the causal links are well established, and discuss several examples of atom finding in SPM and STEM and analysis of 4D STEM data when this condition is satisfied. Notably, ML applications in theory generally fall under this category. Alternatively, ML methods work well when the confounding factors are effectively frozen via the narrowness of experimental conditions or experimental system. However, both these conditions are violated for experimental studies, when causal relationships are known only partially (and are in fact often the target of study) and confounding factors (composition uncertainty, microscope tuning, contaminations) are abundant. In this presentation, I will discuss the several examples of extending machine learning methods towards the analysis of causative physical mechanisms. One such approach is based on the Bayesian methods that allow to take into consideration the prior knowledge of the system and evaluate the changes in understanding of the behaviors given new experimental data. The second pathway explores the parsimony of physical laws and aims to extract these from the set of real-world observations. Finally, the Bayesian networks can be used to explore the causative relationships in the multimodal data sets. These concepts will be illustrated using several examples of causal machine learning, including analysis of phase transitions on a single atom level in 2D materials and interplay between physical and chemical effects in the ferroelectric perovskites. Ultimately, we seek to answer the questions such as whether electronic instability due to the average Fermi level guides the development of the local atomic structure, or frozen atomic disorder drives the emergence of the local structural distortions, whether the nucleation spot of phase transition can be predicted based on observations before the transition, and what is the driving force controlling the emergence of unique functionalities of morphotropic materials and ferroelectric relaxors.

This research is supported by the by the U.S. Department of Energy, Basic Energy Sciences, Materials Sciences and Engineering Division and the Center for Nanophase Materials Sciences, which is sponsored at Oak Ridge National Laboratory by the Scientific User Facilities Division, BES DOE.

Accelerated Discovery of Efficient Solar Cell Materials Using Quantum and Machine-Learning Methods Kamal Choudhary; National Institute of Standards and Technology, United States

Solar energy plays an important role in solving serious environmental problems and meeting the high energy demand. However, the lack of suitable materials hinders further progress of this technology. Here, we present the largest inorganic solar cell material search till date using density functional theory (DFT) and machine-learning approaches. We calculated the spectroscopic limited maximum efficiency (SLME) using the Tran–Blaha-modified Becke–Johnson potential for 5097 nonmetallic materials and identified 1997 candidates with an SLME higher than 10%, including 934 candidates with a suitable convex-hull stability and an effective carrier mass. Screening for two-dimensional-layered cases, we found 58 potential materials and performed G0W0 calculations on a subset to estimate the prediction uncertainty. As the above DFT methods are still computationally expensive, we developed a high accuracy machine-learning model to prescreen efficient materials and applied it to over a million materials. Our results provide a general framework and universal strategy for the design of high-efficiency solar cell materials. The data and tools are publicly distributed at:
Autonomous Thin-Film Growth System for Materials Discovery

Ryota Shimizu1,2, Shigeru Kobayashi1, Yasunobu Ando3 and Taro Hitosugi1; 1Tokyo Institute of Technology, Japan; 2JST-PRESTO, Japan; 3National Institute of Advanced Industrial Science and Technology, Japan

The integration of knowledge, experience, and intuition of researchers with artificial intelligence (AI) and robotics is the new direction to accelerate progress in materials research [1]. Strategies combining high-throughput synthesis with machine learning have already been producing new small organic molecules and bio-materials at ever faster rates. However, the application of the techniques to inorganic materials research is still in its infancy. Therefore, to drastically accelerate inorganic materials science research, establishing the AI and robotics inclusion into inorganic materials research is an urgent issue.

In this study, we demonstrate the autonomous synthesis of inorganic compounds using robotics and Bayesian optimization. This system fully automates sample transfer, thin film deposition, physical-property characterization, and growth condition optimization. The apparatus is equipped with a robot arm that can access each satellite chamber for growth and characterization. Based on the values obtained from the physical-property characterization, the Bayesian-optimization algorithm predicts the next growth condition (closed-loop). Here, we show the process of reducing the resistivity of Nb-doped TiO2 transparent conducting thin films [2]. The autonomous synthesis can be applied to a wide variety of functional materials including magnetic, optical, electronic, and ionic properties.

Gr-ResQ—A Database for Graphene Synthesis Recipes

Aagam Shah, Joshua Schiller, Matthew Robertson, Kristina Miller, Kevin J. Cruse, Kaihao Zhang, Mitisha Surana, Chae Seol, Darren Adams, Elif Ertekin and Sameh Tawfick; University of Illinois at Urbana-Champaign, United States

This presentation introduces Graphene Recipes for Synthesis of High Quality Materials (Gr-ResQ) (https://nanohub.org/tools/gresq). Gr-ResQ is designed to be a one stop solution for analysis of graphene synthesis by Chemical Vapor Deposition (CVD). Gr-ResQ consists of a comprehensive crowd-sourced database of synthesis recipes and results as well as a suite of software tools to analyze the database. It offers tools to analyze scanning electron microscope images and Raman spectra of graphene. It was developed as part of NSF’s nanoMFG node within nanoHUB.

Advancing the manufacturing of graphene by CVD requires the ability to make CVD more cost-effective, including synthesizing low-defect density graphene directly on relevant substrates at reasonable costs. This is currently difficult mainly due to the multi-physics nature and the multi-time, and multi-length scales of the synthesis reaction. CVD processes can have over 200 variables, many of which are difficult to precisely control. This leads to poor repeatability and lack of a quantitative distribution of the parameter space. Characterization of synthesized graphene with electron microscopy and Raman spectroscopy gives useful information about the crystallinity, coverage, nucleation density and other such physical and chemical properties. The challenge of making interpretations and correlations from this data can be met by constructing a database that ties together the variables used in a process (the recipe) with the characterization of the synthesized graphene, which allows the application of data science and machine learning techniques to graphene and other 2D materials. One such use is in the estimation of graphene coverage from SEM images, which is generally a manual and time consuming task. We are trying to replace that by training a deep neural network (DNN) image segmentation algorithm with our manual coverage data to produce high quality, automated graphene coverage metrics.

In this presentation, we will discuss the database and the various tools, showing a number of examples that uniquely take advantage of the functionality of the database.
Bridging the Gap Between Literature Data Extraction and Domain-Specific Materials Informatics Zachary Jensen, Haihao Liu, Rubayyat Mahbub, Kevin J. Huang and Elsa Olivetti; Massachusetts Institute of Technology, United States

Advances in applying natural language processing (NLP) to material science text has greatly increased the size and acquisition speed of materials science synthesis data. These methods have been successfully applied to well-studied material systems with large amounts of data. However, we need ways to leverage literature data in materials domains without thousands of papers. Applying NLP pipelines to these types of materials science systems can be challenging due to the general schema and the noisiness of automatically extraction data. In this presentation, we demonstrate how to leverage domain knowledge to build upon existing data extraction techniques and improve extraction accuracy using examples in the zeolite, alternative cement, and solid-state electrolyte fields. We present data engineering techniques and discuss an optimal balance between automatic and manual data extraction.

CAMD: An AI-Accelerated End-to-End Materials Discovery Platform Joseph H. Montoya and Muratahan Aykol; Toyota Research Institute, United States

We present an end-to-end system for computational autonomy in materials discovery (CAMD). This system is designed to sequentially augment a given dataset according to user-specified strategies for choosing new experiments and experimental procedures. The decision-making entities, called "agents," can make use of past knowledge, surrogate models, logic, thermodynamic or other physical constructs, heuristic rules, and different exploration-exploitation strategies. We show a series of examples for how discovery campaigns for finding materials satisfying a phase stability objective can be simulated to design new agents, and how those agents can be deployed in real discovery campaigns to control experiments run externally, such as the cloud-based density functional theory simulations in this work. Lastly, we present results from the cloud-based deployment of our tool that have resulted in over 2000 new inorganic crystalline materials in various crystal symmetries and compositions predicted to be within 200 meV of the phase diagram's convex hull.

Improved Structure-Informed Prediction of Formation Energy Based on the Voronoi Tessellation—New Neural Network-Based Model and Applications Adam M. Krajewski, Jonathan Siegel, Zhengqi Liu, Jinchao Xu and Zi-Kui Liu; The Pennsylvania State University, United States

Recently, machine learning (ML) is becoming an increasingly important tool for material discovery, thanks to its ability to quickly predict results of time and power-intensive calculations. Fundamentally, each ML model predicts some property and is composed of three essential elements: a database, a descriptor, and an ML algorithm. In this work, we have created and assessed a new tool for predicting formation enthalpies ($\Delta H_f$). We take an open DFT database (OQMD), Voronoi tesselation-based descriptor developed by the Wolverton group[1], and then design new neural networks that allow us to significantly improve the accuracy of predictions and reduce the computation time down to the order of 100 microseconds per prediction. During the neural network design process, we created and tested around 50 networks belonging to 19 architectures. We used cross-validation on a randomly selected test set comprising 5% of the OQMD database (21,800 test entries) to compare with competing models. We found that our best network achieved a $\Delta H_f$ mean average error of 35 meV/atom, compared with $\approx$70 meV/atom for a model based on the Random Forest algorithm[1]. In addition to simple cross-validation against a subset of the data for comparison with other models, the performance was also evaluated on more challenging systems. These included Special Quasirandom Structures (SQS) and 243 endmembers of a ternary $\sigma$ phase (topologically close packed). Using such an approach during design, allowed us to improve accuracy for structures that are significantly different from those in the original dataset, and thus require extrapolation.

In this presentation, we show not only the new model but also new applications. Most notably, we take advantage of the improved prediction speed to screen whole databases for entries that do not fit the discovered patterns, and then automatically compare flagged entries to other sources. This, in turn, combined with more in-depth analysis, allows us to pinpoint entries that are likely to contain poor quality data, as well as those at risk of having a systematic error in the DFT calculation.

Supervised and Unsupervised Machine Learning of EELS Data for Oxidation State Determination and Phase Analysis
Cassandra Pate, Mitra Taheri and Jamie Hart; Johns Hopkins University, United States

Advances in electron imaging and spectroscopy instrumentation now allow for time-resolved data acquisition at rates over 1000 frames per second. However, this acquisition speed comes at the expense of the signal-to-noise ratio. At high frame rates, the low signal-to-noise (SNR) ratio can cause datasets to be too noisy for analysis with the naked eye without significant post-processing. Another challenge (often times exacerbated by poor SNR) is quantification of oxidation state. For example, in transition metal oxides, many methods exist for valence determination, e.g. $L_3/L_2$ ratio, chemical shift, or $O K$-edge pre-peak analysis. Unfortunately, these different methods can yield contradictory results, particularly in the presence of noisy data. Here, we seek to address both of these challenges through the application of machine learning techniques. First, we will discuss supervised learning of oxidation state in SrFeO thin films. With a convolutional neural network trained on >10,000 spectra, we obtain ~70% classification accuracy in differentiating SrFeO$_3$ (Fe$^{4+}$) from SrFeO$_{2.5}$ (Fe$^{3+}$) during an in situ experiment with very noisy data collected at 400 frames / second. Next, we will discuss ongoing efforts in unsupervised learning of EELS data. Unsupervised learning makes it possible to analyze different materials without needing a comprehensive database of labelled EELS data to compare with. Because unsupervised learning works by finding its own patterns or structures within the data, via techniques such as feature extraction or clustering, applying it to real-time in-situ data could help better understand phase morphology of the materials and could expose if unintentional or incomplete transformations of the sample occurred and in turn, the ability to more precisely and predictively tune complex materials. Unsupervised learning will be applied to various in situ EELS experiments.
A model describing the origin of water-induced degradation of certain Metal-Organic Frameworks (MOFs) is derived, aiming to explain experimental observations of water stability and instability of prototypical MOFs. The proposed model suggests crucial rule of metal-coordinated water molecules, and solution pH, in triggering a cascade of reactions that in several cases results in pronounced irreversible degradation of several MOFs. It is suggested that such degradation pathways can be affected in neutral to basic solution by deprotonation of metal-coordinated water molecules, or bridging hydroxyl species in multinuclear clusters. Calculations of pKa values for the metal-coordinated water molecules, complemented by geometry relaxation calculations, and variable pH infrared spectroscopy techniques were all simultaneously utilized to draw a comprehensive description for the early stages in MOFs degradation in aqueous medium. Mostly dependent on the nature of metal nodes, we propose two distinct mechanisms for structural degradation of carboxylate-based MOFs. The MOFs investigated herein included MOF-5, HKUST-1, UiO-66, and MIL-101-Cr. It is suggested that for each type of MOF, a narrow pH stability range can be described, mostly determined by the pKa of metal-coordinated water molecules and the relaxations of the molecular frameworks.

Materials exhibiting higher mobilities than conventional organic semiconducting materials, e.g. fullerenes and heteroacenes [1], are in high demand for applications such as printed electronics. In order to explore new molecules in the heteroacene family that might show improved mobility, over 7,000,000 structures of fused furans, thiophenes and selenophenes were generated and 250,000 structures were randomly selected for subsequent DFT (Density Functional Theory) calculations of hole reorganization energies ($\lambda_h$). Utilizing the cloud-computed DFT dataset of a quarter-million reorganization energies, inverse materials design methods were applied to find further chemical structures with minimal reorganization energy. The de novo design methods applied were (1) a method based on reinforcement learning of SMILES strings (the REINVENT method [2]), and (2) a junction tree variational autoencoder that directly generates molecular graphs [3]. Both methods succeeded in obtaining chemical structures whose reorganization energy was lower than the lowest energy in the DFT training dataset, suggesting that an extrapolative materials design protocol can be developed by applying two methods. Finally, these results will be compared to the results obtained from the latent-space de novo molecular design method proposed by Gomez-Bombarelli et al. [4].

Combinatorial Approach for Single Crystalline TaON Growth—Epitaxial β-TaON (100) /α-Al2O3 (012) Narayanachari Kondapalli, D. Bruce Buchholz, Elise Goldfine, Sossina M. Haile and Michael J. Bedzyk; Northwestern University, United States

The semiconductor photocatalyst β-TaON used for water splitting is of interest due to its promising properties, such as stability, suitable band gap for visible light photocatalysis and carrier mobility. We have implemented a combinatorial, materials discovery approach using pulse-laser deposition (PLD) for thin film growth, X-ray diffraction (XRD) for phase determination and machine learning for data reduction. A lateral compositional gradient of TaOxNy was grown across the surface of a α-Al2O3 (012) 25-mm-wide wafer by PLD at 675°C in 10 mTorr of N2. After annealing in N2 at 1000°C, small-area XRD scattering patterns were collected for 71 positions across the lateral gradient. Unsupervised machine learning separated the XRD data into 4 clusters (phases); one of which turned out to be the desired β-TaON phase. Using high-resolution XRD we determined that the β-TaON region of the film to be single crystal epitaxy with out-of-plane β-TaON (100) // α-Al2O3 (012) and in-plane β-TaON (010) // α-Al2O3 (2-10). X-ray reflectivity (XRR) analysis of the β-TaON region of the film determined the film thickness to be 260 Å with an electron density matching that expected for β-TaON. Ta 4f7/2 XPS measurements across the graded film showed Ta5+ valence state at the β-TaON region of the film. In comparison to the standard method of growing many uniform films at different compositions, this combinatorial method that produces a library of phases on a single wafer is much more efficient for materials discovery.

The Energy Landscape Governs Plasticity in Glasses Longwen Tang and Mathieu Bauchy; University of California, Los Angeles, United States

Based on their structure, non-crystalline phases can fail in a brittle or ductile fashion. However, the nature of the linkages between structure and propensity for ductility in disordered materials has remained elusive. Here, based on molecular dynamics simulations, we investigate the fracture of several disordered phases (metallic glass, glassy silica, colloidal gel, etc.) with varying degrees of disorder. We find that that, in general, structural disorder results in an increase in ductility. By applying the activation-relaxation technique (an accelerated sampling method to identify transition states), we show that the degree of plasticity is controlled by the topography of the energy landscape.

Data-Driven Materials Discovery for Functional Applications Jacqueline M. Cole1,2,3; 1University of Cambridge, United Kingdom; 2STFC Rutherford Appleton Laboratory, Harwell Science and Innovation Campus, United Kingdom; 3Argonne National Laboratory, United States

Large-scale data-mining workflows are increasingly able to predict successfully new materials that possess a targeted functionality. The success of such materials discovery approaches is nonetheless contingent upon having the right data source to mine, adequate supercomputing facilities and workflows to enable this mining, and algorithms that suitably encode structure-function relationships as data-mining workflows which progressively short list data toward the prediction of a lead material for experimental validation.

This talk describes how to meet these data science requirements by showing how to auto-generate large material databases of experimental information from documents, using natural language processing and machine learning, via our
ChemDataExtractor tool [1-3]. The resulting large databases of chemical structures and their cognate properties are then mined for materials discovery using custom-built algorithms that are encoded forms of structure-function relationships. These molecular design rules progressively filter the parent set of chemicals until a lead candidate appears, which is experimentally validated. Case studies are demonstrated to illustrate the power of data-driven materials discovery for several functional applications.

Discovering New Hydrogen Storage Materials Using an Empirical Design Principle for Metal Hydrides Matthew Witman1, Sanliang Ling2, David Grant2, Gavin Walker2, Sapan Agarwal1, Vitalie Stavila1 and Mark D. Allendorf3; 1Sandia National Laboratories, United States; 2The University of Nottingham, United Kingdom

The development of a hydrogen economy has potentially immense benefits for addressing the crisis of global heating. However, storage remains a problem and decades of research have left us empty-handed: no known materials can satisfy all of the DOE targets for vehicular storage. Metal hydrides are among the most promising solid-state storage materials, but their complex chemistry is a major impediment to discovery of game-changing materials. Specifically, their thermodynamics are often ill-matched to hydrogen release at temperatures compatible with fuel cells. This limitation requires an equilibrium H2 pressure of at least 5 bar at the maximum delivery temperature of 80 °C. Empirical discovery approaches using, for example, high-throughput synthesis, are largely ineffective because measurement of the equilibrium H2 pressure can take days or even weeks. Machine learning (ML) methods have already shown promise for accelerating the discovery of new hydrogen sorbents and identifying key features that influence their properties. In recent application to metal hydrides, however, the use of “black-box” algorithms prohibited development of crucial vital scientific insight needed to go beyond existing compositions. We employed a gradient-boosting tree regressor, an “explainable” ML that can reveal the feature dependence of material properties. In particular, we find that the equilibrium H2 pressure of intermetallic metal hydrides strongly depends on a volume-based feature that requires only the elemental composition to be computed. Remarkably, this simple structure-property relationship is valid across a wide range of compositions, metal substitutions, and structural classes found in intermetallic metal hydrides. This result provides a rational basis for targeting novel hydrogen storage materials with thermodynamic properties appropriate for specific applications. As an illustration, we identified a known intermetallic that forms a hydride with very low stability. Although not yet validated by experiment, this result was confirmed by density functional theory modeling.

De Novo Discovery of Nanoporous Structures by Machine Learning Mathieu Bauchy; University of California, Los Angeles, United States

Nanoporous materials (e.g., zeolite, activated carbon, metal-organic framework, polymeric membranes, etc.) have various technological applications, including gas separation, gas storage, catalytic transformations, etc. The functionalities of nanoporous materials strongly depend on their pore size and shape distribution—which present virtually limitless degrees of freedom. Here, based on high-throughput simulations and a convolutional neural network (CNN) predictor, we present a model allowing us to predict the water sorption isotherm of hydrophilic and hydrophobic nanoporous materials. The training of a CNN generator then enables the inverse design of optimal porous microstructures featuring tailored/unusual sorption isotherms.

6:00 AM *S.CT01.02.06
Machine-Based Discovery of Energetic Materials Peter W. Chung; University of Maryland, United States

Recent successes demonstrated by machine learning (ML) approaches have created great enthusiasm for their potential translational contributions to other fields. Among these are efforts to demonstrate the feasibility of using machine-based approaches to study and speculate on new energetic materials. This talk will discuss the performance of ML models developed to predict the detonation properties of energetic materials. A comprehensive comparison of approaches reveals that models are highly sensitive to feature selection as well as algorithm differences. But using a relatively limited volume of data and careful problem definitions, surprisingly strong cross validation scores suggest that there is promise to both improve and ultimately use ML methods widely in this field. The talk will conclude with an overview and some perspectives of other
recent efforts including generative modeling and natural language processing techniques at their intersections with energetics research.

6:30 AM *S.CT01.02.07
A Machine-Learning-Based Strategy for Accelerated Discovery of Novel Scintillator Chemistries Anjana Talapatra, Christopher R. Stanek, Blas P. Uberuaga and Ghanshyam Pilania; Los Alamos National Laboratory, United States

Inorganic scintillator-based detector materials find a wide variety of applications, ranging from medical imaging to radiation detection for global security and high energy physics experiments. These materials essentially convert a fraction of the total energy deposited by incident gamma rays or X-rays into visible or near-visible range of the spectrum. In many applications a scintillator with high light output, fast response time, and emission at suitable wavelengths, is generally required, among many other application-specific desired characteristics. However, owing to several conflicting relationships between the desired properties (e.g., brightness versus speed), no single scintillator is ideal for all uses; there is a need to design custom scintillators optimized for each application. Traditionally, the discovery and design of new detector materials have relied on a laborious, time-intensive, trial-and-error approach; yielding little physical insight and leaving a vast space of potentially revolutionary materials unexplored. To accelerate the discovery of optimal scintillator materials with targeted properties and performance, efforts are ongoing to develop a closed-loop machine learning driven adaptive design framework based on data from literature, in-house experiments and quantum mechanical calculations. This talk will present an overview of this framework, focusing on the screening of complex wide band gaps chemistries with an aim of identifying promising materials that are amenable to band-gap/band-edge engineering to yield custom scintillation properties. The developed framework is general and is expected to prove useful for applications beyond scintillator discovery such as photovoltaics and catalysis.

7:00 AM S.CT01.02.09
Machine-Learning Guided Discovery of MOFs for Enhanced Hydrogen Storage Capacity Samrendra Singh, Abhishek Sose, Karteeek Bejagam and Sanket A. Deshmukh; Virginia Tech, United States

In recent years the use of various machine-learning (ML) methods to discover new materials with desired properties have emerged as a powerful tool. In this research, we have designed a stacked ensemble model (SEM) by combining several supervised ML models to predict the adsorption of hydrogen in metal-organic frameworks (MOFs). The SEM model was trained by using the hydrogen adsorption data generated by screening of 1000s of MOFs by performing grand canonical monte carlo (GCMC) simulations at 1 atm and 77 K. This SEM was integrated with optimization algorithms and in-house MOF structure generation code to design MOFs with high adsorption of hydrogen. Overall, this new approach of integrating SEM with optimization algorithms accelerated the new MOF discovery process, resulting in a MOF with enhanced hydrogen storage capacity. This new ML framework is transferable and can be used to discover other porous (e.g. zeolites), soft (e.g. polymers), and hard (e.g. alloys) materials for desired applications.

Progress towards Autonomous Perovskite Discovery, Synthesis and Characterization Using ESCALATE+RAPID Joshua Schrier; Fordham University, United States

The dream of autonomous materials discovery systems will only be realized if the entire design/synthesis/characterization process is described in an unambiguous machine-readable format. Specifying the experiment process in a machine-readable way facilitates both remote operation, algorithmic control of experiments, and enhanced experimental replicability. A significant challenge is that materials experiments often require a combination of instructions for human operators and machines. Furthermore, the variety of materials characterization data and experimental performance metadata during a process often require significant extraction/ transformation/loading before machine learning methods can be applied. Existing
tools require significant development time that is incompatible with rapidly evolving scientific needs.

In this talk, I will describe ESCALATE (Experiment Specification, Capture and Laboratory Automation Technology) an adaptable open source package for experiment description and data collection. As a specific example, I will describe its application to Robotic-Accelerated Perovskite Investigation and Discovery (RAPID). The first generation of RAPID uses inverse temperature crystallization (ITC) to grow halide perovskite single crystals for x-ray structure determination and bulk characterization using commercial liquid handling robots. Experiment plans are contributed remotely, by either human scientists or algorithms trained on the reaction data. Incoming experimental data collected by ESCALATE is used to automatically train machine learning models, evaluate model performance and feature influence on model predictions to gain human-interpretable scientific insight into the formation process, and quantify experimental reproducibility using this complete dataset of all experimental successes and failures. A live web dashboard communicates these insights to the scientist and management in visual form; furthermore experimental data can be exported in the form of interactive visualizations for use in publications. Collected characterizations includes qualitative measurements of crystal quality (including photographic images of the samples), powder X-Ray diffraction, and spectroscopic measurements along with background laboratory conditions. The second generation of RAPID has been extended to include antisolvent precipitation synthesis of perovskite single crystals and perovskite thin film synthesis and characterization including remote monitoring of long-term environmental stability. We have used the ESCALATE/RAPID platform to perform experimental tests benchmarking a variety of data-driven approaches for discovering new compounds against human-expert and random baselines. The comprehensive data collected from these experiments has also allowed us to ascertain the relative importance of descriptive physical models for reaction composition relative to raw experimental descriptions when constructing machine learning models for reaction outcome prediction.

5:30 AM *S.CT01.03.03
Autonomous Combinatorial Experimentation Ichiro Takeuchi; University of Maryland, United States

Machine learning has become an integral part of many aspects of materials research. As a branch of machine learning, active learning has attracted much attention which can effectively help navigate experimental sequences in materials research. We are actively incorporating active learning in screening of combinatorial libraries of functional materials. For some physical properties, each characterization/measurement requires time/resources long/large enough that "high"-throughput measurement is not possible. Examples include detection of martensitic transformation and superconducting transitions in thin film libraries. By incorporating active learning into the protocol of combinatorial characterization, we can streamline the measurement and the analysis process substantially. We will present examples of mapping of phase change memory materials as well as others functional materials. This work is performed in collaboration with A. Gilad Kusne and V. Stanev. This work is funded by ONR and AFOSR.

Machine Learning Assisted Synthesis of Metal-Organic Nanocapsules Yunchao Xie1, Chen Zhang2, Xiangquan Hu1, Chi Zhang1, Steven Kelley1, Jian Lin1 and Jerry L. Atwood1; 1University of Missouri-Columbia, United States; 2North Carolina State University, United States

Herein, we report the successful discovery of a new hierarchical structure of metal-organic nanocapsules (MONCs) by integrating chemical intuition and machine learning algorithms. By training datasets from a set of both succeeded and failed experiments, we studied the crystallization propensity of metal-organic nanocapsules (MONCs). Among four machine learning models, XGBoost model affords the highest prediction accuracy of 91%. The derived chemical feature scores and chemical hypothesis from the XGBoost model assist to identify proper synthesis parameters showing superior performance to a well-trained chemist. This paper will shed light on the discovery of new crystalline inorganic-organic hybrid materials guided by machine learning algorithms.

6:15 AM *S.CT01.03.05
Autonomous Robotic Assembly of Two-Dimensional Crystals to Build van der Waals Superlattices Satoru Masubuchi1, Masataka Morimoto1, Momoko Onodera1, Sei Morikawa1, Takashi Taniguchi2, Kenji Watanabe2 and Tomoki Machida1; 1University of Tokyo, Japan; 2National Institute for Materials Science, Japan

Van der Waals heterostructures are comprised of stacked atomically thin two-dimensional crystals and serve as novel materials providing unprecedented properties. However, the random natures in positions and shapes of exfoliated two-dimensional crystals have required the repetitive manual tasks of optical microscopy-based searching and mechanical transferring, thereby severely limiting the complexity of heterostructures.
To solve the problem, we develop a robotic system, powered by artificial intelligence, that automatically searches exfoliated 2D crystals and assembles them into vdW superlattices inside glovebox [1-3]. The system can automatically scan the surface of silicon substrates, analyze optical microscope images, and detect a variety of atomically thin 2D materials without human intervention. The stacking order, positions, and crystallographic orientations of the 2D crystals are designed using the customized CAD software. The robotic assembly system of two-dimensional crystals enabled stacking four cycles of the designated two-dimensional crystals per hour with few minutes of human intervention for each stack cycle.

The system enabled fabrication of the vdW superlattice structures consisting of 29 alternating layers of the graphite and the hexagonal boron nitride (hBN) flakes. Encapsulated graphene devices exhibited high charge carrier mobilities (>1,000,000 cm²/Vs), demonstrating the applicability of the system for prototyping a variety of high-quality vdW superlattices. The wider material design freedom enabled by our system offers unprecedented opportunities for exploring the potential of vdW heterostructures. By this development, we can reduce the human intervention involved in the vdW heterostructure fabrication by orders. We believe that this work free up researchers from repetitive tasks and letting them focus on more intellectually creative tasks.

The hardware/software designs are available at https://github.com/tdmms/

**Combining Experiment and Theory in a Closed-Loop Learning Cycle to Improve Perovskite Device Stability and Performance**

Tonio Buonassisi; Massachusetts Institute of Technology, United States

In my annual poster, I’ll review the MIT PVLab's recent work combining experiment and theory in a closed-loop, machine-learning (ML) driven framework. Closed-loop experimentation driven by ML enables rapid and efficient convergence on optima, within vast search spaces. A review of scientific insights, as well as our latest machine-learning algorithms, will be presented.

**High Throughput Nanoindentation and Machine Learning Assisted Analysis for Evaluation of Materials under In Operando Conditions**

Eric Hintsa1, Bernard Becker1, Youxing Chen2, Benjamin Stadnick1, Ude Hangen1, Nathan Mara1 and Douglas D. Stauffer1; 1Bruker Nano Surfaces, United States; 2University of North Carolina at Charlotte, United States; 3University of Minnesota, United States

Meeting current and future demands for advanced structural materials designed to operate in extreme environments requires rigorous mechanical performance evaluation at such conditions. When considering alloy development for such applications, such as nuclear materials, multiple compositions and processing routes create many permutations of material to be evaluated at different temperatures and radiation damage levels. Where traditional bulk scale mechanical testing is relatively time consuming, high speed nanoindentation mapping techniques can provide large (and highly localized) Hardness and Modulus datasets. This allows for analysis of heterogeneous distributions of properties in multi-phase alloys, which can then be correlated to the microstructure through use of supplementary techniques, such as EBSD, which has similar resolution. However, this requires accompanying analysis methods to also be high throughput, for which machine learning based techniques are of interest. Some datasets, as large as one million indentations in a given map, are beyond the limit of reasonable human analysis.

In this study, a high vacuum, high temperature nanoindenter was utilized to produce temperature controlled mapping of three advanced types reactor materials up to 500°C while protecting the sample surface from oxidation. The materials studied were Fe-based HEAs, with varied Al content to give 3 distinct microstructures. Structure-property correlation was quantitatively explored through clustering to partition the hardness and modulus data to individual microstructural elements and evaluate their thermal stability, with irradiation studies to follow. While qualitatively these methods performed comparably to by hand grouping, there is a need to quantitatively understand their systematic uncertainties without making assumptions regarding the underlying probability distribution. This is further explored for this data set by using a parametric bootstrapping method to resample the probability distribution function from the individual data points. Three different machine learning methods, Kernel Density Estimation, Gaussian Mixture and Multi-Normal, are used to generate a probability distribution function. This is then resampled to produce a simulated dataset 1000 times the original dataset in size. This allows K-means, Spectral and
Gaussian Mixture clustering techniques to be applied and compared, but in principal, this can be applied to evaluate other properties as well.

Autonomous Materials Development for Fun and Profit Kristofer G. Reyes; State University of New York at Buffalo, United States

Closed-loop, sequential learning is a key paradigm in autonomous materials development. Within this framework, aspects of the materials system under study are modeled, and such models are used to decide subsequent experiments to be run, results of which are fed-back to update models. In the past, off-the-shelf solutions and algorithms have been employed to optimize material properties. In this talk, we describe how autonomous materials platforms can be used for problems other than materials property optimization. We will specifically highlight work on autonomous phase mapping and real-time control, and how a common framework can be used to capture problem-specific structure and objectives. Relevant to this is the development of tools to perform autonomous materials characterization. We will describe how rich characterization data such as microscopy images or three-dimensional reconstructions from atom probe tomography can be analyzed without human intervention to encode experimental results for subsequent use within the closed loop. Together, the work described demonstrates the broad applicability of autonomous platforms throughout materials science research.

7:45 AM *S.CT01.03.09
A Bayesian Experimental Autonomous Researcher for Mechanical Design Keith A. Brown¹, Aldair Gongora¹, Bowen Xu¹, Wyatt Perry¹, Chika Okoye¹, Patrick Riley², Kristofer G. Reyes³ and Elise Morgan¹; ¹Boston University, United States; ²Google, United States; ³University at Buffalo, The State University of New York, United States

While additive manufacturing (AM) has facilitated the production of complex structures, it has also highlighted the immense challenge inherent in identifying the optimum structure for a given application. Numerical methods are important tools for optimization, but experiment remains the gold standard for studying non-linear, but critical, mechanical properties such as toughness. To address the vastness of AM design space and the need for experiment, we develop a Bayesian experimental autonomous researcher (BEAR) that combines Bayesian optimization and high-throughput automated experimentation. Using the BEAR, we explore the toughness of a parametric family of structures and observe more rapid, in terms of both experiments and time, convergence towards higher-performing structures than was obtained using a grid-based search. Specifically, we observe that the BEAR matched the performance of a grid-based search in 60 times fewer experiments. In addition to providing a platform to discover mechanical properties of AM-produced metamaterials, the BEAR provides a framework for exploring active learning in an experimental context including multi-agent decision policies, the incorporation of theory in an experimental loop, and the influence of heteroscedasticity. Collectively, these results show the value of machine learning in experimental fields where data are sparse.

8:15 AM *S.CT01.03.10
Interpretable Machine Learning for Materials Design and Characterisation Keith T. Butler; Rutherford Appleton Laboratory, United Kingdom

In this talk I will look at how we can open up the percieved 'black box' of machine learning when designing and characterising materials. I will show how being able to look at and understand the inner workings of deep neural networks increases the value of these approaches for problems in materials science. Understanding the workings is important for (i) debugging and building better models, (ii) building confidence in models that perform well, (iii) learning from models that exceed human performance in certain problem areas. I will take examples of our research where we use graph neural networks to infer and predict dielectric properties of solids and where we use deep convolutional neural network to interpret data from inelastic neutron scattering. In the former case a mixture of deep and shallow learning allows for extraction of principles as well as construction of robust accurate models. In the latter case understanding the workings of the neral network allows us to develop a method for guiding experiments to sample the most pertinent areas of signal space.

8:45 AM *S.CT01.03.11
Inverse Design of Broadband Highly Reflective Metasurfaces using Neural Networks Eric Harper¹, Eleanor Coyle², Jonathan Vernon¹ and Matthew Mills¹; ¹Air Force Research Laboratory, United States; ²Azimuth Corp, United States

The next generation of high performance optical materials require precise engineering to transcend the inherent limitations of bulk materials and achieve desired optical performance. These targeted properties originate from the interactions between inherent optical properties of the constituent materials and meticulously engineered sub-wavelength inhomogeneities.
However, the design of such metamaterials poses a significant challenge to researchers due to the near-infinite design space to consider, even for relatively simple metamaterials such as the two-dimensional all-dielectric metasurface. This metasurface has been the subject of intense research interest because of its unprecedented reflective performance resulting from low-loss dielectric materials and shape-dependent optical resonances. Here we employ artificial neural networks (ANNs) to invert the design process, conceiving metasurface designs with targeted reflection and transmission spectra. These ANNs are capable of coordinating the complex interactions of the eigenmodes from which these desired properties arise, delivering device designs demonstrating coefficients of reflection greater than 99% over a range of wavelengths more than 450nm.

9:00 AM S.CT01.03.12
Machine Learning-Aided Design of DNA-Stabilized Silver Clusters with Specific Fluorescence Wavelengths Stacy Copp1,1, Steven Swasey2, Alexander Gorovits3, Petko Bogdanov4 and Gwinn Elisabeth2; 1University of California, Irvine, United States; 2University of California, Santa Barbara, United States; 3University at Albany, State University of New York, United States

DNA-templated silver clusters (AgN-DNA) are known to exhibit a wide range of fluorescence colors for different choices of the DNA template sequence [1]. While these clusters are promising biosensors and biomarkers [2], rational design of AgN-DNA for specific applications is challenged by the huge space of possible DNA template sequences. To understand how DNA sequence selects for silver cluster size and optical properties, we are employing high-throughput experiments and tools from machine learning and data mining. We previously showed that machine learning methods trained on experimental data can be used to design new DNA templates that select for AgN-DNA color, for the specific and limited case of 10-base DNA oligomers [3]. An important open question is whether such a design process developed for a specific biopolymer template length is applicable at other lengths, with different numbers and diverse configurations of cluster nucleation sites. More broadly within materials informatics, it is important to determine when models learned on limited training data sets are relevant for prediction within expanded input parameter spaces.

Here, we present a newly developed flexible design approach that utilizes color-correlated DNA base motifs learned from data on > 2,000 ten-base DNA oligomers [4]. We test this motif-based design for templates ranging from 8 bases to 16 bases long, for which the sizes of the sequence spaces differ by nearly 5 orders of magnitude. The experimental data show that designed strands of all lengths are selective for AgN-DNA color in the target wavelength band of 600-660 nm, strongly suggesting that color-selective motifs learned for one template length generalize to other lengths. Thus, a motif-based design approach may be broadly suitable for future AgN-DNA applications.

Multiscale Machine Learning for Quantum Many Particle Physics with Wavelet Scattering Transforms Matthew Hirn; Michigan State University, United States

Computing the ground state energy of quantum many particle systems is of fundamental importance in a variety of fields, including chemistry, physics and materials science, amongst others. However, the complexity of such quantum mechanical computations grows rapidly with the number of particles. Machine learning algorithms do not simulate the physical system, but instead estimate solutions by interpolating values provided by a training set of known examples. However, precise interpolations may require a number of examples that is exponential in the system dimension, and are thus intractable. Tractable algorithms compute interpolations in low dimensional approximation spaces, which leverage the underlying physical properties of the system.

2020 MRS Virtual Spring/Fall Meeting, November 27-December 4, 2020, Spring Abstracts Final Program 2/3/21
In this talk I will give an overview of machine learning algorithms for computing the ground state energy of quantum many particle systems, describing the core principles of such algorithms and illustrating the common themes that emerge. I will then present in more detail our approach to the problem, which is based on a type of multiscale, multilayer convolutional neural network, called a wavelet scattering transform. Through a cascade of multiscale wavelet transforms and nonlinearities, the scattering transform encodes the appropriate invariants and regularity properties of the physical system. Wavelet scattering regressions, computed over databases of organic molecules and amorphous materials, achieve errors on the order of quantum mechanical simulations, but at a fraction of the computational cost.

5:15 AM S.CT01.04.03
Putting Scientists’ Eyes on Glass-Box Physics Rule Learner for Unraveling Nano-Scale Tribocharging Phenomena In Ho Cho¹, Qiang Li¹, Rana Biswas¹,2 and Jaeyoun Kim¹; ¹Iowa State University, United States; ²Ames Laboratory, United States

This multi-disciplinary research proposes a new framework that can infuse scientists' experience and knowledge (named as scientists' eyes) into a constantly evolving, glass-box physics rule learner that can essentially extract hidden physics rules behind complex nano-scale phenomena. Recently, physics principles are gradually integrated into machine learning (ML) methods, but it is at its infancy to discover hidden physics rules. Such pursuits for hidden rules face formidable challenges when the physical experiments involve multifaceted measurements across three-dimensional (3D) specimens or objects. These remaining challenges render even advanced ML methods such as deep learning secondary, not as a primary explorer, in the broad science and engineering domains. Therefore, there exists a deep chasm still remains between materials science and ML community.

To overcome this challenge and unravel hidden physics rule behind nano-scale complex phenomena, we reinterpreted the deep learning's successful notion of multi-layered convolutions and gave rise to a new notion of "convolved information index." The convolved information index can facilely handle physical measurements over 3D nano-scale specimens and measurements without losing experienced perspectives of scientists in the materials science. Also, the framework proposes "link function" as a generator of mathematical expressions about the identified nano-scale physics rules, thereby pursuing "glass-box" (as opposed to the black-box) learning and prediction. Consistent evolution capability is realized by integrating Bayesian update and evolutionary algorithms.

The framework is applied to nano-scale contact electrification (CE) phenomena, which are difficult to elucidate due to length scales and complex physical interactions [1,2]. Three experimental data sets are used. Tribocharged PDMS nanocup array is fabricated by the sequence of (1) prepare a PET mold with a 750 nm-pitch triangular array of nancones, (2) pour the liquid phase PDMS, Sylgard 184, Dow Corning, mixed with the curing agent, (3) solidify the specimen, and (4) peel off the PDMS from the PET mold (for more details see [1,2]). Atomic force microscopy (AFM) in the tapping mode is used to measure the surface topography and potential. The charge values were measured by Kelvin probe force microscopy over patterned nanocup's represented by 3D point cloud. The experimental data consist of a variety of conditions regarding geometries, demolding directions, and nano-scale patterns (3000 nm by 3000 nm square area with an interval of 5.86 nm; 4000 nm by 4000 nm, with 7.8125 nm). The nano-cup's average heights are 154 nm, 93.5 nm, and 117 nm. The proposed glass-box learning begins from horizontal-demolding test data, and then the best-so-far identified rules are inherited to the next learning with new specimens in a chained way.

The feasibility tests show promising performances of the proposed framework in unraveling transparent, reasonable "expressions" of hidden physics rule along with reasonable reproduction of complex patterned distributions of electric potentials over the 3D point cloud. The proposed framework is believed to establish a promising partnership of scientists' eyes and the advanced ML methods, thereby enabling data and ML-driven discovery of groundbreaking physics laws in the nano-world and beyond. This presentation will cover how this new framework can facilitate materials scientists’ discovery with actual nano applications.

5:25 AM S.CT01.04.04
Materials By Design Using Artificial Intelligence—Modeling, Manufacturing and Testing Markus J. Buehler, Chi-Hua Yu and Yu-Chuan Hsu; Massachusetts Institute of Technology, United States

In this talk we will review recent studies of applying atomistic-level modeling to describe fracture processes at different scales, from molecular to macroscale levels, and to use artificial intelligence and machine learning to design fracture resistant materials. Molecular and related multiscale modeling methods can be an effective method to better understand elementary fracture processes, ranging from brittle to ductile fracture and other materials failure phenomena such as creep, and provides
the basis for expansive training sets. To illustrate this framework, we report a design approach for optimizing the toughness of nanocomposite materials using artificial intelligence, implemented in a novel “AutoComp Designer” algorithm. The algorithm consists of a machine learning predictor combined with an AI improved genetic algorithm, which is capable of discovering de novo materials designs in a vast space of possible solutions. Facilitated by a deep convolutional neural network that is trained with a dataset of hundreds of thousands of combinations of soft and brittle materials originating from multiscale models. Through the algorithm, we extend the capability of physical simulations beyond property predictions to optimize the fracture toughness by altering the material distribution. The solutions are generated by our AI model at a dramatically lower computational cost compared to brute-force searching methods. We further investigate the physical mechanism for improving material performance behind the AI approach, and demonstrate the ability of AI to search for optimal designs with very limited sampling. Brute-force molecular dynamics simulations of the nanocomposite designs confirm that our AI design improves the performance by effectively decreasing the stress concentration at crack tip. This AI approach can be easily applied to other nanocomposites, biomaterials and other material classes, and provides a transferrable and reliable rapid design approach expanding current capabilities.

5:35 AM S.CT01.04.05
Fast and Accurate Interatomic Potentials by Symbolic Regression Alberto Hernandez, Adarsh Balasubramanian, Fenglin Yuan, Simon Mason and Tim Mueller; Johns Hopkins University, United States

In recent years there has been great progress in the use of machine learning algorithms to develop interatomic potential models. Machine-learned potential models are typically orders of magnitude faster than density functional theory but also orders of magnitude slower than physics-derived models such as the embedded atom method. We demonstrate that machine learning, in the form of genetic programming, can be used to develop accurate and transferable many-body potential models that are as fast as the embedded atom method, making them suitable to model materials on extreme time and length scales. The key to our approach is to explore a hypothesis space of models based on fundamental physical principles and to select models from this hypothesis space based on their accuracy, speed, and simplicity. We demonstrate our approach by developing fast and accurate interatomic potential models for copper that generalize well to properties they were not trained on, and we discuss additional applications. Our approach requires relatively small sets of training data, making it possible to generate training data using highly accurate methods at a reasonable computational cost.

Describing Materials for Machine Learning Shyue Ping Ong, Chi Chen, Yunxing Zuo, Xiangguo Li, Zhi Deng and Weike Ye; University of California, San Diego, United States

Machine learning (ML) has emerged as a powerful tool in the study and design of materials. In this talk, I will discuss the different ways in which materials can be described and their relative merits and limitations. In particular, I will highlight the importance of choosing representations that not only satisfy known physical invariances (e.g., rotation, translation, etc.), but also incorporate known physics and chemistry in a hierarchy of knowledge. I will provide an overview of leading ML models and applications, and discuss how the problems of data scarcity and bias in materials science can be addressed using multi-fidelity, transfer learning and other approaches.

6:00 AM S.CT01.04.09
A General Machine Learning Framework for Impurity Level Prediction in Semiconductors Arun Kumar Mannodi Kanakkithodi and Maria K. Chan; Argonne National Laboratory, United States

Electronic levels introduced by impurities and defects in the middle of the band gap are critically important in semiconductors for optoelectronic, photovoltaic (PV) and quantum sensing applications. While “deep” defect levels can prove catastrophic for PV performance by causing non-radiative carrier recombination, impurity levels in the band gap could also be entangled for quantum sensing or lead to increased absorption of sub-gap photons which can enhance efficiencies. Predicting formation energies and charge transition levels for defects in semiconductors is thus paramount; density functional theory (DFT) has been widely applied for such studies to overcome experimental bottlenecks and confirm measured defect levels. However, the requirement of large supercells, advanced levels of theory, and inclusion of charge corrections make DFT computation of defect properties very expensive, and trends and knowledge from previous calculations are not exploited in subsequent ones.

In this work, we combine high-throughput DFT and machine learning (ML) to develop general predictive models for the formation enthalpy and charge transition levels of impurities in two broad semiconductor classes: (a) ABX₃ halide perovskites, and (b) group IV, III-V and II-VI semiconductors. DFT data is generated for impurity atoms selected from
across the periodic table and simulated in various possible cation, anion or interstitial sites. Any “semiconductor + impurity” combination is converted into a unique feature vector based on the defect site coordination environment, the tabulated elemental properties (e.g. ionization energy, electronegativity, etc.) of the impurity atom, and electronic and energetic properties computed using low cost unit cell defect calculations. State-of-the-art neural networks (NN), random forest regression (RFR) and kernel ridge regression (KRR) are applied to train models for (a) impurity formation enthalpy, and (b) impurity charge transition levels, based on the input feature vector. Model performance is evaluated for different ML techniques, ML parameters such as number of hidden layers and network weights in NN, subsets of features, and size and nature of training dataset; the best predictive models thus obtained are deployed for comprehensive prediction and design purposes. It is seen that models trained on defects and impurities in pure cation/anion composition semiconductors are applicable to mixed or alloyed compositions as well: for instance, by training on data from pure canonical AB semiconductors like CdTe, ZnO, GaAs and SiC, the ML models can make accurate predictions for impurities in alloyed compositions of the same compounds, such as CdTe$_{1-x}$Se$_x$, Cd$_{1-x}$Zn$_x$O, Al$_{1-x}$Ga$_x$As$_{1-y}$Sb$_y$, etc. This versatility of the machine-learned models provides an avenue to access the optoelectronic impact of any atomic impurity in any possible pure or mixed composition semiconductor belonging to the same chemical space, which is useful for compositions that are expensive to model. We use the predictive models to efficiently screen for dominating impurities, that is impurities that shift the equilibrium Fermi level in the semiconductor as determined by dominant native defects, in hundreds of possible compositions in the halide perovskite and groups IV, III-V and II-VI semiconductor spaces. ML-based screening of impurities was tested against DFT screening for CdTe and seen to have an accuracy of 95%. The quick and accurate estimation of interesting dopants/impurities in semiconductors is made possible by this materials design framework powered by quantum mechanical computations and machine learning, which can be easily expanded to other semiconductor classes and improved by the infusion of fresh data, new descriptors and more advanced ML techniques.

6:10 AM S.CT01.04.10 Optimization Thermal Conductivity at Interfaces Using Learning Algorithms Malachi Schram1, Anne Chaka1, Zexi Lu1, Sabiha Rustam1 and Eric Harper2; 1Pacific Northwest National Laboratory, United States; 2Air Force Research Laboratory, United States

In material science, we are frequently interested in understanding the properties and design implication of material at interfaces. These interfaces can be manipulated to improve the desired characteristics of the bulk material. In this study, we are interested in understanding and optimize the impact of interfacial atomic defects on the thermal transport across a Cu/Si junction. To that end, we developed a reinforcement learning based framework to optimize over a potentially large parameter search. Using this technique allows us to accumulate knowledge of the system of a given type of atoms and store this information into a neural network. In this study, we present our results on optimizing the thermal transport by varying the fraction and length of the interfacial atomic defects using molecular dynamics (MD) simulations with normal mode analysis (NMA) to investigate thermal transport.

6:20 AM S.CT01.04.11 Physics-Informed Machine Learning for Deep Elastic Strain Engineering of Electronic Properties of Materials Zhe Shi3, Evgenii Tsymbalov2, Ming Dao1, Subra Suresh3, Alexander Shapeev2 and Ju Li1; 1Massachusetts Institute of Technology, United States; 2Skolkovo Institute of Science and Technology, Russian Federation; 3Nanyang Technological University, Singapore

Deforming a material to a large extent without inelastic relaxation can result in unprecedented properties. However, the optimal deformation state is buried within the vast continua of choices available in the strain space. Motivated by this challenge, we hereby advance a powerful strategy to circumvent conventional trial-and-error methods and adopt a unique type of machine learning framework for rationally designing the most energy-efficient pathway to achieve a desirable material property such as the electronic bandgap. This method invokes recent advances in the field of convolutional neural networks and active learning by utilizing a limited amount of ab initio data for the training of a surrogate model, predicting electronic bandgap within an accuracy of sub-10 meV. Our model is capable of discovering the indirect-to-direct bandgap transition and semiconductor-to-metal transition in silicon by scanning the entire strain space [1]. It is also able to identify the most energy-efficient strain pathways that would transform diamond from an ultrawide-bandgap material to a narrow-bandgap semiconductor or even semimetal [2]. A broad framework is presented to tailor any target figure of merit by recourse to deep elastic strain engineering and machine learning for a variety of applications in microelectronics,
optoelectronics, photonics, and energy technologies.

Autonomous Research Systems like ARES™ are disrupting the research process by using AI and Machine Learning to drive closed-loop iterative research. ARES™ is our autonomous research robot capable of designing, executing and evaluating its own experiments at a rate of up to 100 iterations per day. Previously ARES taught itself to grow carbon nanotubes at controlled rates (NPJ Comp Mat 2016). Here we discuss recent research campaigns on maximizing carbon nanotube growth rates using a Bayesian optimization planner. We also use HOLMES and knowledge gradient descent to introduce advanced decision policies with local parametric models to control nanotube diameter. Implications for nanotube materials development will be discussed. Finally, we have developed a new research robot for additive manufacturing, AM ARES™, which is at the early stages of teaching itself to print structures with unknown inks. We plan to make the AM ARES™ Robot available online so that a broad community of researchers can test concepts and approaches for AI/ML and experimental design as applied to 3D printing, thus building to the larger goal of enhancing citizen science.

Chan¹; ¹Argonne National Laboratory, United States; ²Northwestern University, United States; ³Massachusetts Institute of Technology, United States; ⁴University of Cambridge, United Kingdom

Due to recent improvements in image resolution and acquisition speed, materials microscopy is experiencing an explosion of published imaging data. Intensive human efforts, however, are required to digest such published images. In this talk, we will discuss the MaterialEyes project, in which deep learning and natural language processing tools are used to extract microscopy images from scientific literature. The process is accomplished via a suite of scientifically-informed software tools in the EXSCLAIM python package (automatic EXtraction, Separation, and Caption-based natural Language Annotation of Images from scientific figures), which is ultimately focused on the acceleration of inductive materials insights by collecting, structuring, and interpreting an aggregate of materials microscopy imaging data. In this talk, we will discuss how deep learning and NLP is used in EXSCLAIM to: (1) extract figures and caption data from open source scientific documents, (2) automate the construction of self-annotated materials imaging datasets, and then (3) leverage literature-based insights to assist in image classification and segmentation tasks. In addition, we will discuss a new pipeline for crowdsourced image labeling that was used for training some of the deep learning models.

5:45 AM S.CT01.05.03
Deep Learning Accelerated Optical Characterization System for Two-Dimensional Material Research Yuxuan Lin¹, Bingnan Han¹,2, Yafang Yang¹, Pablo Jarillo-Herrero¹, Jihao Yin², Jing Kong¹ and Tomás Palacios¹; ¹Massachusetts Institute of Technology, United States; ²Beihang University, China

Characterization of nanomaterial morphologies with advanced microscopy and/or spectroscopy tools plays an indispensable
role in nanoscience and nanotechnology research, as rich information about the chemical compositions, crystallography, other physical and chemical properties, as well as the growth mechanism can be extracted from morphology analysis. However, the interpretation of imaging data heavily relies on the “intuition” of experienced researchers. As a result, many of the deep graphical features are often unused because of difficulties in processing the data and finding the correlations. Such difficulties can be well addressed by deep learning. In this work, we use the optical characterization of two-dimensional (2D) materials as a case study.

Currently, the most widely used approach to obtain high-quality 2D crystals in laboratories is mechanical exfoliation, followed by 2D crystal “hunting” under an optical microscope. This task is time-consuming and difficult especially for inexperienced researchers. Very recently, there has been growing interest in automating such a process. However, existing optical contrast based identification methods could not satisfy the needs for a general-use, fully automatic optical identification and/or characterization system, as they are often very specific to types of 2D crystals, conditions and configurations of the microscopes being used, image qualities, etc. In addition, optical contrast based methods would fail for harder problems in which the classes to be differentiated are not separable in the color space, such as identifying the materials or even predicting their physical properties from unlabeled optical images.

In reality, optical microscopic (OM) images contain rich, often unused information other than optical contrast. These deep graphical features can be extracted through deep learning, especially semantic segmentation methods based on convolutional neural networks (CNNs). In this work, an encoder-decoder semantic segmentation network called “SegNet” is configured for pixel-wise identification of OM images of 2D materials, in real time, and regardless of variations in optical setups. A fully automated system utilizing this algorithm can be used to free up tremendous amount of time for researchers. Additionally, we find that the algorithm finds correlations between the OM images and physical properties of the 2D materials and can thereby be used to anticipate the properties of new, as-yet uncharacterized 2D crystals. Finally, a transfer learning technique is applied to adapt the pretrained network to more optical characterization applications such as identifying layer numbers of chemically synthesized graphene domains. The proposed methodology can potentially be extended for identification and understanding other morphological or spectroscopic data of diverse nanomaterials.

6:00 AM S.CT01.05.04
Density Functional Theory and Deep-Learning to Accelerate Scanning Tunneling Microscopy Analysis Kamal Choudhary; National Institute of Standards and Technology, United States

We introduce the first systematic database of scanning tunneling microscope (STM) images obtained using density functional theory (DFT) for two-dimensional (2D) materials. Specifically, the database is constructed using the Tersoff-Hamann method. It currently contains data for 681 exfoliable 2D from the JARVIS-DFT database. These computational STM images can directly aid the experimental analysis of experimental STM results as they provide ideal reference images. Examples of the five possible Bravais lattice types for 2D materials are discussed and the images for all the materials are made available on the website. We validated the computational STM technique by comparing our results to a few experimental images. As the analysis of multiple STM images during an experiment could be tedious, we used our DFT-STM image database to train a high-accuracy convolution neural network (CNN) model to accelerate the characterization process.

Measurements in Machine Learning Gerald Friedland; University of California, Berkeley, United States

A major obstacle in applying machine learning to scientific and engineering tasks is the lack of engineering rules for the design of machine learning systems that allow to make these system reproducible and the limits of the systems known. Based on joint research with physicists and material engineers, this talk presents engineering principles and measurement processes[1] that aim at structured engineering of machine learning systems.

While the focus of this talk is on neural networks, the principles and presented measurements are universal and applicable to a variety of machine learning systems.

6:45 AM S.CT01.05.06
Machine Learning the Magnetostriiction of Polycrystalline Tb₆Dy₁₋ₓFe₂ Alloys—A Graph Neural Network
Predicting the magnetostriction of a large-scale (mm-mm) polycrystalline Tb$_x$Dy$_{1-x}$Fe$_2$ (Terfenol-D) alloy by direct numerical simulations is mathematically tedious and computationally expensive, because it requires solving a set of partial differential equations which describe the mutual coupling between local magnetization dynamics and polycrystal elasticity, and because it requires a large number of simulation cells (tens of millions and more). For accelerating the prediction of magnetostriction, we apply a graph-based deep learning method, namely, the Graph Neural Network (GNN), to discover the correlation between a microstructure dataset of 350 different polygrain structures and a property dataset describing the magnetic-field-induced deformation of each polygrain structure (viz., magnetostriction). In the GNN based approach, each grain is represented as a node, in which all important physical features (e.g., Euler angle, magnetization direction) inside a grain are stored. As a result, the polygrain structure is represented as a network of nodes, in which the identity information of each grain(node)’s neighboring grains(nodes) is also preserved. This in turn allows us to consider the grain-grain interaction which critically influences the magnetostriction of the entire alloy and interpret the contribution of each node(grain) to the magnetostriction. A >90% prediction accuracy has so far been achieved with ample space for improvement. Our results demonstrate the exciting potential of applying GNN to accelerate the discovery of microstructure-property linkage in polycrystalline materials.

Data-Driven Characterization of Structural Dynamics in Nanoparticles

Peter A. Crozier$^1$, Ramon Manzorro$^1$, Carlos Fernandez-Granda$^2$, Qiang Zhu$^3$, Mahmoud Moradi$^4$, David Mattoxon$^2$ and Roberto Rivera$^5$; $^1$Arizona State University, United States; $^2$New York University, United States; $^3$University of Nevada Las Vegas, United States; $^4$University of Arkansas–Fayetteville, United States; $^5$Cornell University, United States; $^6$University of Puerto Rico-Mayaguez, United States

Materials are ubiquitous in society and lie at the heart of many technologies including energy, communication, buildings, transportation, the environment and medicine. The constant need to develop new materials with properties that are matched to applications is a major driver of materials research. Understanding how atoms come together, self-assemble, dissociate and undergo phase transformations under different stimuli is a critical question in materials science. Transmission electron microscopy can now routinely achieve a spatial resolution of better than 1 Å allowing the projected spatial distribution of atoms to be observed. In situ methodologies allow these signals to be mapped both spatially and temporally in the presence of different stimuli. Rapid advances in detector and spectrometer technology now allow local imaging, diffraction and spectroscopic signals to be acquired at unprecedented rates, generating terabytes of data in relatively short times.

The availability of large spatially and temporarily resolved datasets offers unprecedented potential to transform our understanding of the fundamental atomic level dynamic processes taking place in materials. The rate at which atomic resolution data can be generated in experiments has now outstripped our ability to process and mine scientifically important information. The complex nature of atomic resolution images necessitates intense supervision and input in most quantitative image processing operations. Such an approach is possible for a few hundred images but becomes completely impractical when millions of data frames are available. This has become a serious bottle-neck to extracting the new knowledge potentially available from advanced characterization systems. We need approaches that can recognize recurring motifs in noisy data sets, provide statistical confidence levels for detection of real structural features, track dynamic changes within the sample, and flag events which are likely to be scientifically significant.

We are focused on applying emerging data-driven techniques based on statistics and machine learning to characterize structural dynamics in nanomaterials with an initial focus on metal and oxide nanoparticles 1–3 nm in size. Nanoparticles have wide applications in many areas of materials science and are an ideal system for developing and benchmarking novel data-driven processing techniques because they only contain a few thousand atoms. The datasets are acquired using in situ electron microscopy and structural dynamic processes are stimulated using heat, gas or electron irradiation. We compare and contrast the performance of automated image processing algorithms designed to determine atomic coordinates and structural evolution with more conventional manual methods. The importance of understanding the confidence level that can be associated with derived structural models is critical to assess the reliability of the scientific information extracted from large data sets.

Developed as a Baushinger effect monitoring technique in polycrystalline metallic materials, passive acoustic wave monitoring has been a critical health monitoring technique in: Atomic energy pressurized tank; Power and structure monitoring in aeronautics; Automotive; As well as recent applications in spinning disk data storage (HDD) health monitoring applications [1]. Passive monitoring of acoustic waves generated during the initial contact point has been attracting the attention of material scientists since the inception of nanomechanical test instruments for nanoindentation and nanoscratch applications. The conventional acoustic wave signal treatment via RMS or integrated energy values proves that quantitative acoustic wave properties correlate well with the local contact materials phenomena such as: Yield point initiation for W(100) [2, 3]; Sapphire [4], phase transformation for SMA [2]; and differentiating of thin film fracture modes [5]. Several attempts have been made to look at the differentiative properties of the acoustic signatures via signal decomposition techniques such as wavelets [2, 6]. Even though acoustic wave signatures were reconstructed, the true potential of the method was not investigated from the machine learning perspective.

In this work a deep learning based signal processing of nanoindentation induced acoustic events was investigated. The synergy of wavelet signal decomposition and information theory based signal presorting prepared data for the deep learning step. In the deep learning step convolutive neural networks sort wavelet coefficients by their statistical significance via provided 2D signal topographies. This creates acoustic signature libraries that are typical for the specific materials phenomena during the indent. The hardware consists of a newly developed ultrasonic probe integrated into the nanoindentation tip, thus eliminating boundary effects and ensuring that only waves that pass via the contact are being recorded. Appropriate signal conditioning and fast data acquisition hardware is synchronized with a quasi-static nanoindentation process. The machine learning routine together with wavelet decomposition and presorting algorithms are implemented into the dedicated acoustic data evaluation kernel which resides in the fast access memory of the designated controller.

Thermal characterization in high-temperature environments is difficult because of high radiation losses and significant temperature measurement noise and inaccuracy. Ångström’s method can accurately measure thermal diffusivity in the presence of heat losses by observing the propagation of temperature perturbations through a material sample. This work applies a modified Angstrom’s method to measure thermal properties at extreme temperatures (>1000 °C). Previous studies employing Angstrom’s method at high temperatures typically have employed evenly spaced thermocouples on samples for thermal diffusivity measurements. We have recently demonstrated in preliminary room-temperature testing (copper - 1.13 x 10^(-4) m2/s, 1% uncertainty) that the uncertainty in thermal diffusivity within a Bayesian statistical framework is inversely proportional to the square root of the number of concurrent temperature measurements. In this work, we employ IR thermography for non-contact temperature measurement to greatly increase the number of measurements that can be resolved on a sample compared to the conventional thermocouple approach. To subject materials to extreme temperatures, samples are mounted vertically in a vacuum chamber and heated by concentrated thermal radiation from a 10 kW Xenon bulb. A controller is used to precisely modulate power output to produce the periodic temperature oscillation required for Angstrom’s method. Transient temperature measurements are made along the length of the sample using both an infrared camera and optical spectroscopy. Bayesian statistics then quantify the measurement uncertainty associated with the noisy high temperature environment, and this approach is shown to substantially reduce measurement uncertainty for high-temperature material characterization.
Beyond Expert-Level Performance Prediction for Rechargeable Batteries by Unsupervised Machine Learning

Xin Li; Harvard University, United States

Predicting the performance of rechargeable batteries in real time is of great importance to battery research and industrial production, and hence has been a long pursuit. In this talk, a novel end-to-end unsupervised machine learning approach is shown for the battery performance prediction, which is free from feature engineering and uses only the raw images of the charge–discharge voltage profiles [1]. This model enables unsupervised real-time automatic extraction of latent physical factors that control the performance of Na-ion batteries to classify good or bad cycling performance by using only the voltage profile of the first cycle. This model can also monitor the safety of Li-metal battery systems by giving warnings when the battery is approaching a failure. With the beyond expert-level prediction ability, the abovementioned framework can be a promising prototype to further develop and enable high accuracy predictions of battery performance for real-world applications in the future.

Accelerated Discovery of Efficient Solar Cell Materials Using Quantum and Machine-Learning Methods Kamal Choudhary; National Institute of Standards and Technology, United States

Solar energy plays an important role in solving serious environmental problems and meeting the high energy demand. However, the lack of suitable materials hinders further progress of this technology. Here, we present the largest inorganic solar cell material search till date using density functional theory (DFT) and machine-learning approaches. We calculated the spectroscopic limited maximum efficiency (SLME) using the Tran–Blaha-modified Becke–Johnson potential for 5097 nonmetallic materials and identified 1997 candidates with an SLME higher than 10%, including 934 candidates with a suitable convex-hull stability and an effective carrier mass. Screening for two-dimensional-layered cases, we found 58 potential materials and performed G0W0 calculations on a subset to estimate the prediction uncertainty. As the above DFT methods are still computationally expensive, we developed a high accuracy machine-learning model to prescreen efficient materials and applied it to over a million materials. Our results provide a general framework and universal strategy for the design of high-efficiency solar cell materials. The data and tools are publicly distributed at: https://www.ctcms.nist.gov/~knc6/JVASP.html, https://www.ctcms.nist.gov/jarvisml/, https://jarvis.nist.gov/, and https://github.com/usnistgov/jarvis.

Autonomous Thin-Film Growth System for Materials Discovery Ryota Shimizu1,2, Shigeru Kobayashi1, Yasunobu Ando3 and Taro Hitosugi1; 1Tokyo Institute of Technology, Japan; 2JST-PRESTO, Japan; 3National Institute of Advanced Industrial Science and Technology, Japan

The integration of knowledge, experience, and intuition of researchers with artificial intelligence (AI) and robotics is the new direction to accelerate progress in materials research [1]. Strategies combining high-throughput synthesis with machine learning have already been producing new small organic molecules and bio-materials at ever faster rates. However, the application of the techniques to inorganic materials research is still in its infancy. Therefore, to drastically accelerate inorganic materials science research, establishing the AI and robotics inclusion into inorganic materials research is an urgent issue.

In this study, we demonstrate the autonomous synthesis of inorganic compounds using robotics and Bayesian optimization. This system fully automates sample transfer, thin film deposition, physical-property characterization, and growth condition optimization. The apparatus is equipped with a robot arm that can access each satellite chamber for growth and characterization. Based on the values obtained from the physical-property characterization, the Bayesian-optimization algorithm predicts the next growth condition (closed-loop). Here, we show the process of reducing the resistivity of Nb-doped TiO₂ transparent conducting thin films [2]. The autonomous synthesis can be applied to a wide variety of functional materials including magnetic, optical, electronic, and ionic properties.

Gr-ResQ—A Database for Graphene Synthesis Recipes Aagam Shah, Joshua Schiller, Matthew Robertson, Kristina Miller, Kevin J. Cruse, Kaishao Zhang, Mitisha Surana, Chae Seol, Darren Adams, Elif Ertekin and Sameh Tawfick; University of Illinois at Urbana-Champaign, United States

This presentation introduces Graphene Recipes for Synthesis of High Quality Materials (Gr-ResQ) (https://nanohub.org/tools/gresq). Gr-ResQ is designed to be a one stop solution for analysis of graphene synthesis by Chemical Vapor Deposition (CVD). Gr-ResQ consists of a comprehensive crowd-sourced database of synthesis recipes and results as well as a suite of software tools to analyze the database. It offers tools to analyze scanning electron microscope images and Raman spectra of graphene. It was developed as part of NSF’s nanoMFG node within nanoHUB.

Advancing the manufacturing of graphene by CVD requires the ability to make CVD more cost-effective, including synthesizing low-defect density graphene directly on relevant substrates at reasonable costs. This is currently difficult mainly due to the multi-physics nature and the multi-time, and multi-length scales of the synthesis reaction. CVD processes can have
over 200 variables, many of which are difficult to precisely control. This leads to poor repeatability and lack of a quantitative
distribution of the parameter space. Characterization of synthesized graphene with electron microscopy and Raman
spectroscopy gives useful information about the crystallinity, coverage, nucleation density and other such physical and
chemical properties. The challenge of making interpretations and correlations from this data can be met by constructing a
database that ties together the variables used in a process (the recipe) with the characterization of the synthesized graphene,
which allows the application of data science and machine learning techniques to graphene and other 2D materials. One such
use is in the estimation of graphene coverage from SEM images, which is generally a manual and time consuming task. We
are trying to replace that by training a deep neural network (DNN) image segmentation algorithm with our manual coverage
data to produce high quality, automated graphene coverage metrics.

In this presentation, we will discuss the database and the various tools, showing a number of examples that uniquely take
advantage of the functionality of the database.

Bridging the Gap Between Literature Data Extraction and Domain-Specific Materials Informatics Zachary Jensen,
Haihao Liu, Rubayyat Mahbub, Kevin J. Huang and Elsa Olivetti; Massachusetts Institute of Technology, United States

Advances in applying natural language processing (NLP) to material science text has greatly increased the size and
acquisition speed of materials science synthesis data. These methods have been successfully applied to well-studied material
systems with large amounts of data. However, we need ways to leverage literature data in materials domains without
thousands of papers. Applying NLP pipelines to these types of materials science systems can be challenging due to the
general schema and the noisiness of automatically extraction data. In this presentation, we demonstrate how to leverage
domain knowledge to build upon existing data extraction techniques and improve extraction accuracy using examples in the
zeolite, alternative cement, and solid-state electrolyte fields. We present data engineering techniques and discuss an optimal
balance between automatic and manual data extraction.

6:30 AM S.CT01.06.07
CAMD: An AI-Accelerated End-to-End Materials Discovery Platform Joseph H. Montoya and Muratahan Aykol; Toyota
Research Institute, United States

We present an end-to-end system for computational autonomy in materials discovery (CAMD). This system is designed to
sequentially augment a given dataset according to user-specified strategies for choosing new experiments and experimental
procedures. The decision-making entities, called “agents,” can make use of past knowledge, surrogate models, logic,
thermodynamic or other physical constructs, heuristic rules, and different exploration-exploitation strategies. We show a
series of examples for how discovery campaigns for finding materials satisfying a phase stability objective can be simulated
to design new agents, and how those agents can be deployed in real discovery campaigns to control experiments run
externally, such as the cloud-based density functional theory simulations in this work. Lastly, we present results from the
cloud-based deployment of our tool that have resulted in over 2000 new inorganic crystalline materials in various crystal
symmetries and compositions predicted to be within 200 meV of the phase diagram’s convex hull.

6:45 AM S.CT01.06.08
Improved Structure-Informed Prediction of Formation Energy Based on the Voronoi Tessellation—New Neural
Network-Based Model and Applications Adam M. Krajewski, Jonathan Siegel, Zhengqi Liu, Jinchao Xu and Zi-Kui Liu;
The Pennsylvania State University, United States

Recently, machine learning (ML) is becoming an increasingly important tool for material discovery, thanks to its ability to
quickly predict results of time and power-intensive calculations. Fundamentally, each ML model predicts some property and
is composed of three essential elements: a database, a descriptor, and an ML algorithm. In this work, we have created and
assessed a new tool for predicting formation enthalpies (ΔHf). We take an open DFT database (OQMD), Voronoi tesselation-
based descriptor developed by the Wolverton group[1], and then design new neural networks that allow us to significantly
improve the accuracy of predictions and reduce the computation time down to the order of 100 microseconds per prediction.

During the neural network design process, we created and tested around 50 networks belonging to 19 architectures. We used
cross-validation on a randomly selected test set comprising 5% of the OQMD database (21,800 test entries) to compare with
competing models. We found that our best network achieved a ΔHf mean average error of 35 meV/atom, compared with ≈70
meV/atom for a model based on the Random Forest algorithm[1]. In addition to simple cross-validation against a subset of the
data for comparison with other models, the performance was also evaluated on more challenging systems. These included
Special Quasirandom Structures (SQS) and 243 endmembers of a ternary σ phase (topologically close packed). Using such an approach during design, allowed us to improve accuracy for structures that are significantly different from those in the original dataset, and thus require extrapolation.

In this presentation, we show not only the new model but also new applications. Most notably, we take advantage of the improved prediction speed to screen whole databases for entries that do not fit the discovered patterns, and then automatically compare flagged entries to other sources. This, in turn, combined with more in-depth analysis, allows us to pinpoint entries that are likely to contain poor quality data, as well as those at risk of having a systematic error in the DFT calculation.

Supervised and Unsupervised Machine Learning of EELS Data for Oxidation State Determination and Phase Analysis Cassandra Pate, Mitra Taheri and Jamie Hart; Johns Hopkins University, United States

Advances in electron imaging and spectroscopy instrumentation now allow for time-resolved data acquisition at rates over 1000 frames per second. However, this acquisition speed comes at the expense of the signal-to-noise ratio. At high frame rates, the low signal-to-noise (SNR) ratio can causes datasets to be too noisy for analysis with the naked eye without significant post-processing. Another challenge (often times exacerbated by poor SNR) is quantification of oxidation state. For example, in transition metal oxides, many methods exist for valence determination, e.g. L3/L2 ratio, chemical shift, or O K-edge pre-peak analysis. Unfortunately, these different methods can yield contradictory results, particularly in the presence of noisy data. Here, we seek to address both of these challenges through the application of machine learning techniques. First, we will discuss supervised learning of oxidation state in SrFeOx thin films. With a convolutional neural network trained on >10,000 spectra, we obtain ~70% classification accuracy in differentiating SrFeO3 (Fe4+) from SrFeO2.5 (Fe3+) during an in situ experiment with very noisy data collected at 400 frames / second. Next, we will discuss ongoing efforts in unsupervised learning of EELS data. Unsupervised learning makes it possible to analyze different materials without needing a comprehensive database of labelled EELS data to compare with. Because unsupervised learning works by finding its own patterns or structures within the data, via techniques such as feature extraction or clustering, applying it to real-time in-situ data could help better understand phase morphology of the materials and could expose if unintentional or incomplete transformations of the sample occurred and in turn, the ability to more precisely and predictively tune complex materials. Unsupervised learning will be applied to various in situ EELS experiments.

S.CT01.07.02

Any sensor material, even if proved as an excellent performer at the research level, it can be put to less use if it does not meet the product criteria. The salient parameters include sensitivity, selectivity, recovery and re-usability. In order to thoroughly evaluate these parameters, huge amount of data is required; using which definite conclusions can be drawn. Calibration, life of the sensor and its scope of selectivity can be well defined. The most crucial part of any successful sensor system is its selectivity and close to 100% accuracy. In this regard statistical analysis along with the sensor design play a crucial role. It can decide how many sensors are required in an array of sensors to determine the presence of a particular analyte and its concentration with highest accuracy. In this context, through this abstract, we present the work done on a metamaterial-inspired ring resonator circuit, which works as an excellent sensor for chemically hazardous gases and liquids, which are
propellant materials. Since the molecules in this category mostly have SOx / NOx groups, their chemical differentiation
becomes difficult for sensing. We have already shown that metamaterial-inspired ring resonator works on the principle of
sensing the changes in the dielectric media in its vicinity, thereby generating a change in the resonant frequency.
In this work we further discuss the approach towards sensor optimization for sensing fixed library of propellant molecules by
first. Machine learning algorithms like, Linear Discriminant analysis, Random Forrest and so on, would be optimized to
achieve maximum selectivity and accuracy in the sensor. The data would be collected for the sensor operating at 430 MHz,
and Vector Network Analyser is used to measure the sensor response. Sensing time, power shift, frequency shift and the
recovery time are the basic parameters which would be measured. Sensor output is calibrated for the ppm concentration
varying from 10 ppm to 1000 ppm. The data is submitted to the machine learning algorithm and the algorithm is
subsequently trained for the unknown sample of the propellant material with unknown concentration, to establish the
correctness of the device developed. The emerging data-driven techniques based on statistics collected from the actual sensor
testing, and use of machine learning, and artificial intelligence (AI) to unlock predictions of the performance of resonator-
based sensor, will be discussed elaborately in this presentation.

S.CT01.07.04
PLIM—Phosphorescence Lifetime Imaging Microscopy with Adapted Excitation Christian Oelsner, Volker Buschmann,
Felix Koberling, Matthias Patting and Rainer Erdmann; PicoQuant GmbH, Germany

The combination of microscopic techniques with time-resolved luminescence detection is a valuable and powerful toolbox to
investigate photophysical properties not only of different classes molecular systems, but also semiconductors, nanoparticles
and QDs, polymers, solid-states as well as nano structures. Understanding of both photophysical processes as well as
structure-property relationships are important steps toward optimization of properties and efficiencies in practical
applications.
Investigating fast processes with short lifetimes as well as really long lived excited states (in the µs to ms range) do impose
vastly different requirements. On one hand, monitoring fast dynamic processes necessitate high time resolution that can be
achieved by using picosecond pulsed lasers and fast detectors along with appropriate time-correlated single photon counting
(TCSPC) units. On the other hand, studying long-lived excited states normally require pulsed lasers with low repetition rates,
detectors with good efficiency and sensitivity up to NIR, and counting electronics capable of multi-channel scaling mode for
acquiring signal on the µs / ms time scale.
Here we demonstrate another way to investigate long lifetime decays (e.g., phosphorescence or delayed fluorescence) of
samples by using adapted excitation in combination with a microscope for good spatial resolution, better signal quality, and
faster measurement time. This PLIM setup uses a special laser driver with appropriate laser heads and suited photon counting
electronics which enables experiments with higher photon flux, even with low laser repetition rates. Resulting intensity
images clearly show an almost 7 fold higher intensity using the adapted excitation instead of excitation with a low repetition rate.
Therefore we can reduce the acquisition time significantly because of the increased emission intensities and by
recording lifetime images with a focus on detecting of photons with longer lifetimes in combination with fast electronics, that
are not limited by dead-time effects.

S.CT01.07.06
Rapid Identification of X-Ray Diffraction Spectra Based on Very Limited Data by Convolutional Neural
Networks Hong Wang, Yun-chao Xie, Dawei Li, Heng Deng, Ming Xin and Jian Lin; University of Missouri-Columbia,
United States

Large volumes of data generated during high-throughput synthesis and rapid characterizations call for rapid and automatic
data analysis to accelerate material discovery. Herein, we report a convolution neural network (CNN) that was trained based
on theoretic data and very limited experimental data for fast identification of experimental X-ray diffraction (XRD) spectra of
metal-organic frameworks (MOFs). To augment the theoretical spectra as the training datasets, noise extracted from
experimental spectra was applied to the theoretic spectra. The optimized CNN model can successfully identify all individual
spectrum within Top 2 choice. Data dimension reduction analysis on the experimental XRD spectra by the local linear
embedding (LLE) shows that the spectra from the same material are clustered in groups in the LLE component map. Some
groups are highly distinguishable, while others are very close or overlapped. The reported CNN model together with the data-
augmentation technique and procedure for interpreting the black box would not only open the numerous potential
applications for identifying XRD spectra for different materials, but also pave avenues to autonomously analyze data by other
characterization tools such as FTIR, Raman, and NMR.

S.CT01.07.07
Estimating Sound-Induced Piezoelectric Voltage—PDE and Machine Learning Approach Jason J. Kim; Korea
We suggest a practical and scientific method to select the optimal piezoelectric material to generate electricity from vibration induced by sound. The proposed method begins by modeling deflections caused by given voltages using partial differential equations (PDE), then implementing machine learning (shallow neural network) to estimate the generated electricity from varying deflections. During the PDE computations, while the geometry such as width and length is fixed, material properties such as the Poisson’s Ratio, Shear Modulus, and Elastic modulus are changed according to the selected piezoelectric material. By running a machine learning simulation trained by these data, we obtain the relationship between voltage changes and deflections which provides the way to select optimal materials. Among the 33 easily accessible, mostly commercialized piezoelectric materials, the trained learning model predicts voltage from given sound/deflection. Upon analysis, it is observed that the Steel Stainless Austenitic 304, Nickel Alloys, and Cork performed highest for our application by showing higher sensitivity between induced voltage to the deflections. This result demonstrates the versatile applicability of our scheme. It shows its transferability and, in other words, how readily the simulation can be applied to other materials with different properties and deflection variations.

S.CT01.07.09
Big Data-Driven and Machine Learning Approaches to Processing Large Atomic-Resolution In Situ TEM Image Datasets of Structural Reconfigurations in Catalytic Nanomaterials Joshua L. Vincent, Barnaby D. Levin and Peter A. Crozier, Arizona State University, United States

Heterogenous catalysts are an important class of materials that receive considerable research attention due to their large impact on energy and the environment. Aberration-corrected in situ environmental transmission electron microscopy (ETEM) is a powerful catalyst characterization tool capable of providing atomic-scale structural information from active catalysts under reaction conditions. Recent advancements in the realization of highly efficient direct electron detectors now enable atomically-resolved ETEM images to be acquired with a temporal resolution in the millisecond or sub-millisecond regime where catalytically relevant structural reconfigurations are thought to occur [1,2,3]. While there is potentially much to be gained from applying these new detectors to catalytic nanomaterials characterization, acquiring ETEM image series with high temporal resolution necessarily produces datasets that can be unwieldy in size and severely degraded by noise, rendering traditional image processing approaches impractical and ineffective at extracting useful scientific information. For example, recording a 64 megapixel in situ ETEM movie at 2.5 millisecond time resolution would produce around 100 gigabytes and many hundreds of frames of image data every second. We are interested in exploring innovative approaches to image processing that leverage new advances in data science on large, noisy, atomic-resolution in situ ETEM data sets.

Currently our efforts have focused on simple and scalable real-space processing techniques that involve fitting atomic columns with two-dimensional Gaussian functions [4]. This method yields information on the time-resolved position and intensity of atomic columns throughout the ETEM image series. Additionally, the results of this method serve as a starting point for comparison to results produced from advanced image processing done via artificial intelligence and machine learning-based approaches. We are also working toward the generation of an extremely large dataset of simulated ETEM images (10,000+), which could serve as the training set for a convolutional neural network that identifies the best possible match between an experimentally acquired image and a given structural model that was used in the image simulation. Developing a methodology that assigns a confidence level to the structural model that best matches the experimental image is important to assess the reliability of the results produced through such approaches, which could ultimately provide highly desirable information on the atomic scale structural evolution of catalyst nanomaterials [5].

S.CT01.07.11
Transferable Neural Networks for High-Throughput Discovery of Supramolecular Chemistries Wujie Wang, William H. Harris and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States

Neural network potentials based on atomic embeddings have demonstrated accurate force and energy evaluations to simulate
physical systems [1-5]. Moreover, it also shows good force field transferability across the chemical space of interests, which are critical for efficient computational screening. We propose an active learning strategy [6] that accelerates the sampling and training of transferable neural networks, particularly to capture supramolecular interactions that are critical for applications like designing chelating agents and electrolytes. The proposed method combines deep neural network training and active sampling of both chemical and configurational space in an end-to-end fashion to leverage the transferable configurational information across different but chemically similar species. This workflow has also enabled a high throughput virtual screening over the Ether-ion chemical space, which consists of $10^3 \sim 10^4$ molecules, and successfully discovered candidate highly ion-conducting Ether molecules for organic electrolyte applications[7-10].

S.CT01.07.12 Highly Accurate Neural Network-Based Structure-Informed Prediction of Formation Energy Based on the Voronoi Tessellation

Recently Machine Learning (ML) is becoming an increasingly important tool for material discovery, thanks to its ability to predict results of time and cost-intensive calculations like first-principles calculations based on the density functional theory (DFT)[1]. In simple terms, each ML model predicts some property and is composed of three equally important elements: a database, a descriptor, and a ML technique.

In this project, we are predicting formation enthalpies ($\Delta H_f$) of arbitrarily defined compounds. To create the model, we have taken an open-source DFT database (OQMD), state of the art Voronoi tesselation-based descriptor developed by the Wolverton group[1], and then designed a new neural network which allowed us to improve the predictability of formation energy significantly.

The neural network architecture design was done in an empirical fashion. We started with a simple neural network and made iterative modifications to structure and hyper-parameters until we reached Mean Average Error (MAE) around uncertainty in the data. Our best performing network achieved MAE of 35 meV/atom when cross-validated on the test set of randomly selected 5% of the entire OQMD (21,800 entries).

When compared to competing models based on the Random Forest technique, this MAE value represents a two-fold improvement compared with the model using the same descriptor ($\approx$70 meV/atom)[1] and a three-fold improvement compared to the Coulomb Matrix descriptor ($\approx$100 meV/atom)[1,2].

Furthermore, we have used our model to investigate the OQMD data set and have found a small number of OQMD entries that had non-physical $\Delta H_f$. After the removal of three such entries from our test set (3/21,800), the cross-validation MAE has dropped to 28 meV/atom.
Our model provides excellent predictability, takes milliseconds to run, and is available ready-to-use in open-source MXNet format, that can be easily deployed on any device ranging from a supercomputer to an iPhone 5S.

Using Machine Learning to Predict the Critical Temperature of New Ternary Superconductors Sumner B. Harris, Cheng-Chien Chen and Renato P. Camata; The University of Alabama at Birmingham, United States

Superconductivity has been an area of intense research for more than a century, yet the intentional design of new superconductors remains a daunting challenge. The massive databases of experimental and calculated materials properties that have developed over recent years makes the use of a data-driven search for new superconducting materials possible. In this study, machine learning is used to model the \( T_c \) for 21,000+ known metallic and oxide superconductors in the SuperCon database [1]. The model uses 60 features that are generated based on a compound’s chemical composition. The accuracy of a random forest model with 10-fold cross validation is found to be 92%. Using this model, the \( T_c \) of ~4,500 new theoretically stable ternary compounds, with unknown structure, is predicted. Of these compounds, 571 are predicted to have a \( T_c \) within 30-77 K and 8 with \( T_c \) expected in the range 85-100 K. Examples of identified materials include chalcogen-containing compounds such as BeSe\(_5\)Cs\(_8\), BiCs\(_2\)Se\(_2\)\(_5\), and TeBa\(_2\)O\(_7\); as well as hydrogen-rich compounds such as TeO\(_3\)H\(_4\), CuO\(_3\)H\(_5\), and AgO\(_5\)H\(_9\). Evolutionary structural prediction of identified promising compounds will enable ab-initio studies and provide guidance for corresponding material synthesis and characterization.

S.CT01.07.16
Accelerated Exploration of Stability between Layered and Complex Structures in PrBa\(_{1-x}\)Sr\(_x\)Co\(_{2-y}\)Fe\(_y\)O\(_{5.5}\) Jun-Young Jo, Ingyu Choi and Yeong-Cheol Kim; KoreaTech, Korea (the Republic of)

Layered perovskite structures show high performance as an air electrode in solid oxide fuel cells and proton ceramic fuel cells [1]. Radii difference among metal elements at site A of ABO\(_3\) is a prerequisite for conversion of perovskite structure from complex to layered [2]. In this study, we study energetically favorable structures according to change in composition of site A elements (Pr, Ba, Sr) and site B elements (Co, Fe).

25 compositions were determined by changing \( x \) and \( y \) in PrBa\(_{1-x}\)Sr\(_x\)Co\(_{2-y}\)Fe\(_y\)O\(_{5.5}\) (\( x = 0, 0.25, 0.5, 0.75, 1, \) and \( y = 0, 0.5, 1, 1.5, 2 \)). The \( 2 \times 2 \times 2 \) supercells with the compositions were studied using DFT. Since the number of possible atomic arrangements for each composition is very large, however, a genetic algorithm was used to search energetically favorable structure efficiently [3]. The highest energy difference between complex and layered structures among the 25 compositions was obtained at \( x = 0 \) and \( y = 1 \).

In this work we further discuss the approach towards sensor optimization for sensing fixed library of propellant molecules by first. Machine learning algorithms like, Linear Discriminant analysis, Random Forrest and so on, would be optimized to achieve maximum selectivity and accuracy in the sensor. The data would be collected for the sensor operating at 430 MHz, and Vector Network Analyser is used to measure the sensor response. Sensing time, power shift, frequency shift and the recovery time are the basic parameters which would be measured. Sensor output is calibrated for the ppm concentration varying from 10 ppm to 1000 ppm. The data is submitted to the machine learning algorithm and the algorithm is subsequently trained for the unknown sample of the propellant material with unknown concentration, to establish the correctness of the device developed. The emerging data-driven techniques based on statistics collected from the actual sensor testing, and use of machine learning, and artificial intelligence (AI) to unlock predictions of the performance of resonator-based sensor, will be discussed elaborately in this presentation.

**PLIM—Phosphorescence Lifetime Imaging Microscopy with Adapted Excitation** Christian Oelsner, Volker Buschmann, Felix Koberling, Matthias Patting and Rainer Erdmann; PicoQuant GmbH, Germany

The combination of microscopic techniques with time-resolved luminescence detection is a valuable and powerful toolbox to investigate photophysical properties not only of different classes molecular systems, but also semiconductors, nanoparticles and QDs, polymers, solid-states as well as nano structures. Understanding of both photophysical processes as well as structure-property relationships are important steps toward optimization of properties and efficiencies in practical applications.

Investigating fast processes with short lifetimes as well as really long lived excited states (in the µs to ms range) do impose vastly different requirements. On one hand, monitoring fast dynamic processes necessitate high time resolution that can be achieved by using picosecond pulsed lasers and fast detectors along with appropriate time-correlated single photon counting (TCSPC) units. On the other hand, studying long-lived excited states normally require pulsed lasers with low repetition rates, detectors with good efficiency and sensitivity up to NIR, and counting electronics capable of multi-channel scaling mode for acquiring signal on the µs / ms time scale.

Here we demonstrate another way to investigate long lifetime decays (e.g., phosphorescence or delayed fluorescence) of samples by using adapted excitation in combination with a microscope for good spatial resolution, better signal quality, and faster measurement time. This PLIM setup uses a special laser driver with appropriate laser heads and suited photon counting electronics which enables experiments with higher photon flux, even with low laser repetition rates. Resulting intensity images clearly show an almost 7 fold higher intensity using the adapted excitation instead of excitation with a low repetition rate. Therefore we can reduce the acquisition time significantly because of the increased emission intensities and by recording lifetime images with a focus on detecting of photons with longer lifetimes in combination with fast electronics, that are not limited by dead-time effects.

**Rapid Identification of X-Ray Diffraction Spectra Based on Very Limited Data by Convolutional Neural Networks** Hong Wang, Yunchao Xie, Dawei Li, Heng Deng, Ming Xin and Jian Lin; University of Missouri-Columbia, United States

Large volumes of data generated during high-throughput synthesis and rapid characterizations call for rapid and automatic data analysis to accelerate material discovery. Herein, we report a convolution neural network (CNN) that was trained based on theoretic data and very limited experimental data for fast identification of experimental X-ray diffraction (XRD) spectra of metal-organic frameworks (MOFs). To augment the theoretical spectra as the training datasets, noise extracted from
experimental spectra was applied to the theoretic spectra. The optimized CNN model can successfully identify all individual spectrum within Top 2 choice. Data dimension reduction analysis on the experimental XRD spectra by the local linear embedding (LLE) shows that the spectra from the same material are clustered in groups in the LLE component map. Some groups are highly distinguishable, while others are very close or overlapped. The reported CNN model together with the data-augmentation technique and procedure for interpreting the black box would not only open the numerous potential applications for identifying XRD spectra for different materials, but also pave avenues to autonomously analyze data by other characterization tools such as FTIR, Raman, and NMR.

Estimating Sound-Induced Piezoelectric Voltage—PDE and Machine Learning Approach Jason J. Kim; Korea International School, Korea (the Republic of)

We suggest a practical and scientific method to select the optimal piezoelectric material to generate electricity from vibration induced by sound. The proposed method begins by modeling deflections caused by given voltages using partial differential equations (PDE), then implementing machine learning (shallow neural network) to estimate the generated electricity from varying deflections. During the PDE computations, while the geometry such as width and length is fixed, material properties such as the Poisson’s Ratio, Shear Modulus, and Elastic modulus are changed according to the selected piezoelectric material. By running a machine learning simulation trained by these data, we obtain the relationship between voltage changes and deflections which provides the way to select optimal materials. Among the 33 easily accessible, mostly commercialized piezoelectric materials, the trained learning model predicts voltage from given sound/deflection. Upon analysis, it is observed that the Steel Stainless Austenitic 304, Nickel Alloys, and Cork performed highest for our application by showing higher sensitivity between induced voltage to the deflections. This result demonstrates the versatile applicability of our scheme. It shows its transferability and, in other words, how readily the simulation can be applied to other materials with different properties and deflection variations.

Big Data-Driven and Machine Learning Approaches to Processing Large Atomic-Resolution In Situ TEM Image Datasets of Structural Reconfigurations in Catalytic Nanomaterials Joshua L. Vincent, Barnaby D. Levin and Peter A. Crozier; Arizona State University, United States

Heterogenous catalysts are an important class of materials that receive considerable research attention due to their large impact on energy and the environment. Aberration-corrected in situ environmental transmission electron microscopy (ETEM) is a powerful catalyst characterization tool capable of providing atomic-scale structural information from active catalysts under reaction conditions. Recent advancements in the realization of highly efficient direct electron detectors now enable atomically-resolved ETEM images to be acquired with a temporal resolution in the millisecond or sub-millisecond regime where catalytically relevant structural reconfigurations are thought to occur [1,2,3]. While there is potentially much to be gained from applying these new detectors to catalytic nanomaterials characterization, acquiring ETEM image series with high temporal resolution necessarily produces datasets that can be unwieldy in size and severely degraded by noise, rendering traditional image processing approaches impractical and ineffective at extracting useful scientific information. For example, recording a 64 megapixel in situ ETEM movie at 2.5 millisecond time resolution would produce around 100 gigabytes and many hundreds of frames of image data every second. We are interested in exploring innovative approaches to image processing that leverage new advances in data science on large, noisy, atomic-resolution in situ ETEM data sets.

Currently our efforts have focused on simple and scalable real-space processing techniques that involve fitting atomic columns with two-dimensional Gaussian functions [4]. This method yields information on the time-resolved position and intensity of atomic columns throughout the ETEM image series. Additionally, the results of this method serve as a starting point for comparison to results produced from advanced image processing done via artificial intelligence and machine learning-based approaches. We are also working toward the generation of an extremely large dataset of simulated ETEM images (10,000+), which could serve as the training set for a convolutional neural network that identifies the best possible match between an experimentally acquired image and a given structural model that was used in the image simulation. Developing a methodology that assigns a confidence level to the structural model that best matches the experimental image is important to assess the reliability of the results produced through such approaches, which could ultimately provide highly desirable information on the atomic scale structural evolution of catalytic nanomaterials [5].

Transferable Neural Networks for High-Throughput Discovery of Supramolecular Chemistries

Wujie Wang, William H. Harris and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States

Neural network potentials based on atomic embeddings have demonstrated accurate force and energy evaluations to simulate physical systems [1-5]. Moreover, it also shows good force field transferability across the chemical space of interests, which are critical for efficient computational screening. We propose an active learning strategy [6] that accelerates the sampling and training of transferable neural networks, particularly to capture supramolecular interactions that are critical for applications like designing chelating agents and electrolytes. The proposed method combines deep neural network training and active sampling of both chemical and configurational space in an end-to-end fashion to leverage the transferable configurational information across different but chemically similar species. This workflow has also enabled a high throughput virtual screening over the Ether-ion chemical space, which consists of $10^3 \sim 10^4$ molecules, and successfully discovered candidate highly ion-conducting Ether molecules for organic electrolyte applications [7-10].

Highly Accurate Neural Network-Based Structure-Informed Prediction of Formation Energy Based on the Voronoi Tessellation

Adam M. Krajewski, Jonathan Siegel, Zhengqi Liu, Jinchao Xu and Zi-Kui Liu; The Pennsylvania State University, United States

Recently Machine Learning (ML) is becoming an increasingly important tool for material discovery, thanks to its ability to predict results of time and cost-intensive calculations like first-principles calculations based on the density functional theory (DFT) [4]. In simple terms, each ML model predicts some property and is composed of three equally important elements: a database, a descriptor, and a ML technique.

In this project, we are predicting formation enthalpies ($\Delta H_f$) of arbitrarily defined compounds. To create the model, we have taken an open-source DFT database (OQMD), state of the art Voronoi tessellation-based descriptor developed by the Wolverton group [6], and then designed a new neural network which allowed us to improve the predictability of formation energy significantly.

The neural network architecture design was done in an empirical fashion. We started with a simple neural network and made iterative modifications to structure and hyper-parameters until we reached Mean Average Error (MAE) around uncertainty in
the data. Our best performing network achieved MAE of 35 meV/atom when cross-validated on the test set of randomly selected 5% of the entire OQMD (21,800 entries). When compared to competing models based on the Random Forest technique, this MAE value represents a two-fold improvement compared with the model using the same descriptor (≈70 meV/atom)[1] and a three-fold improvement compared to the Coulomb Matrix descriptor (≈100 meV/atom)[1,2]. Furthermore, we have used our model to investigate the OQMD data set and have found a small number of OQMD entries that had non-physical ΔHf. After the removal of three such entries from our test set (3/21,800), the cross-validation MAE has dropped to 28 meV/atom. Our model provides excellent predictability, takes milliseconds to run, and is available ready-to-use in open-source MXNet format, that can be easily deployed on any device ranging from a supercomputer to an iPhone 5S.

Using Machine Learning to Predict the Critical Temperature of New Ternary Superconductors Sumner B. Harris, Cheng-Chien Chen and Renato P. Camata; The University of Alabama at Birmingham, United States

Superconductivity has been an area of intense research for more than a century, yet the intentional design of new superconductors remains a daunting challenge. The massive databases of experimental and calculated materials properties that have developed over recent years makes the use of a data-driven search for new superconducting materials possible. In this study, machine learning is used to model the Tc for 21,000+ known metallic and oxide superconductors in the SuperCon database [1]. The model uses 60 features that are generated based on a compound’s chemical composition. The accuracy of a random forest model with 10-fold cross validation is found to be 92%. Using this model, the Tc of ~4,500 new theoretically stable ternary compounds, with unknown structure, is predicted. Of these compounds, 571 are predicted to have a Tc within 30-77 K and 8 with Tc expected in the range 85-100 K. Examples of identified materials include chalcogen-containing compounds such as BeSe5Cs8, BiCs2Se2.5, and TeBa4O7, as well as hydrogen-rich compounds such as TeO5H8, CuO5H9, and AgO5H9. Evolutionary structural prediction of identified promising compounds will enable ab-initio studies and provide guidance for corresponding material synthesis and characterization.

Accelerated Exploration of Stability between Layered and Complex Structures in PrBa1-xSrxCo2-yFe5-yO5.5 Jun-Yeong Jo, Ingyu Choi and Yeong-Cheol Kim; KoreaTech, Korea (the Republic of)

Layered perovskite structures show high performance as an air electrode in solid oxide fuel cells and proton ceramic fuel cells [1]. Radii difference among metal elements at site A of ABO3 is a prerequisite for conversion of perovskite structure from complex to layered [2]. In this study, we study energetically favorable structures according to change in composition of site A elements (Pr, Ba, Sr) and site B elements (Co, Fe). 25 compositions were determined by changing x and y in PrBa1-xSrxCo2-yFe5-yO5.5 (x = 0, 0.25, 0.5, 0.75, 1, and y = 0, 0.5, 1, 1.5, 2). The 2×2×2 supercells with the compositions were studied using DFT. Since the number of possible atomic arrangements for each composition is very large, however, a genetic algorithm was used to search energetically favorable structure efficiently [3]. The highest energy difference between complex and layered structures among the 25 compositions was obtained at x=0 and y=1.

IFF-R Model to Accurately Simulate Stress-Strain and Failure Properties of Carbon Allotropes and Polymer
Composites  
Jordan Winetrout\textsuperscript{1}, Krishan Kanhaiya\textsuperscript{1}, Ravindra Pandey\textsuperscript{2}, Gregory Odegard\textsuperscript{2} and Hendrik Heinz\textsuperscript{1}; \textsuperscript{1}University of Colorado Boulder, United States; \textsuperscript{2}Michigan Technological University, United States

Stress induced mechanical failure of polymeric materials is a result of the breakage of covalent bonds. The occurrence of bond breakage and formation is only observed during reactions. This study focuses on the novel bond-breaking capabilities of the Interface Forcefield (IFF-R). Traditional IFF models simulated systems using harmonic potentials. The IFF-R model incorporates Morse potentials; thereby, eliminating the restoring force experienced by bonded atoms stretched at large distances. This enables accurate predictions of mechanical responses in a variety of periodic systems. This study shows moduli and strength predictions of a single-walled carbon nanotube, poly(acrylonitrile) crystal, cellulose \(\beta\) crystal, and steel FCC lattice to be comparable to experimental values. Mechanical property predictions using IFF-R models are realized magnitudes faster than reactive forcefield (ReaxFF).

Porous Materials – Graphene Hybrid Nanostructures with Tailored Interfaces as Membrane and Adsorbent Components in Gas Separation  
Anish Varghese, Swati Singh, Suresh Kuppireddy and Georgios Karanikolos; Khalifa University, United Arab Emirates

Combinations of different materials into hybrid/composite structures are highly sought after as to enable multifunctionality in many of today’s demanding applications. 2-dimensional graphene can combine with porous nanostructures, such as metalorganic frameworks (MOFs), zeolites, and porous carbons, to yield hybrids with improved surface, interface, and activity characteristics. In this work, we will present examples of such material hybridizations via in-situ microstructural tuning of the interface between the involved counterparts. The resulting composites were tested for their gas separation performance, and specifically optimized to exhibit enhanced capture activity for carbon dioxide as adsorbents, as well as nanofillers in mixed matrix polymer-based membranes.

S.CT04.07.06  
Site-Specific Surface Modification and Functionalization of Porous Nanostructured Scaffolds for Tunable Adsorption Applications  
Adetola Ogungbenro, Suresh Kuppireddy, Maryam Khaleel and Georgios Karanikolos; Khalifa University, United Arab Emirates

To reveal the full potential of high surface area materials, strategies to tailor their surface characteristics and tune their active sites with high spatial precision and order are needed. In this work, we employ porous materials having surface areas of several hundreds of m\(^2\) per g and we apply customized chemistry based surface tailoring as to spatially create active sites and subsequently graft functional molecules on them. Such examples of surface features can have a multitude of applications, yet we focus on tuning the affinity of the materials to bound with selective species from mixtures as to enable separation. In particular, innovative CO\(_2\)-philic amines are immobilized on the treated surfaces to yield multifunctional adsorbents for carbon dioxide capture. Examples of silica- and graphene-based materials with controlled covalent positioning of various aminosilanes on the modified surface sites will be presented. Controlled grafting ensured stability and sustainable adsorption, tuned effects of locality, spacing, orientation, and interconnectivity of the functionalities on the surface, and minimized diffusion limitations while maximizing capture and release performance for the adsorbate species.

Improving Oxidative Stability of MXenes via Tailoring Surface Chemistry  
Bryan T. Seymour\textsuperscript{1,2}, James E. Heckler\textsuperscript{1,2}, Gregory R. Neher\textsuperscript{1,2}, David B. Lioi\textsuperscript{1,2}, Ali Jawaid\textsuperscript{1,2}, Faisal Mehmoody\textsuperscript{1,2}, Ruth Pachter\textsuperscript{2}, Richard A. Vaia\textsuperscript{2}, W. J. Kennedy\textsuperscript{2} and Dhriti Nepal\textsuperscript{2}; \textsuperscript{1}Universal Technology Corporation, United States; \textsuperscript{2}Air Force Research Laboratory, United States; \textsuperscript{3}UES, Inc., United States

MXenes are an emerging class of two-dimensional layered transition metal carbides, carbonitrides, and nitrides. Their intriguing properties have attracted significant attention as promising materials for next-generation coatings and devices. One of the significant challenges of this material (e.g. Ti\(_3\)C\(_2\)T\(_x\)) is the rapid oxidation into TiO\(_2\) anatase through hydrolysis in water, though water has proved to be the most effective solvent for solubilizing exfoliated Ti\(_3\)C\(_2\)T\(_x\). Organic solvents routes for processing of MXenes and functionalization of its surface with specific ligands provide avenues to tailor the surface properties, which could eventually influence the colloidal stability as well as oxidative stability. Herein, we discuss the influence of various organic solvents such as ethanol, isopropanol, toluene, and N, N-Dimethylformamide on Ti\(_3\)C\(_2\)T\(_x\) colloidal stability, oxidative stability at room temperature, and thermo-oxidative properties. We also demonstrate the use of silane and catechol ligands for tailoring the physical properties of Ti\(_3\)C\(_2\)T\(_x\).
High Response Nitric Oxide (NO) Gas Sensor with Noise Limited Detectivity Approaching 10 ppb of ZnO/Si NWs p-n Heterojunction Array

Chandan Samanta, Ankita Ghatak, A. K. Raychaudhuri and Barnali Ghosh; S N Bose National Centre For Basic Sciences, India

Currently Gas sensors have a great impact in direct monitoring of environmental hazardous gas as well widely used in healthcare such as exhaled breath analysis. In this work we report a ZnO/Silicon nanowires (ZnO/p-Si NWs) based p-n heterojunction array based Nitric Oxide (NO) gas sensor operating at room temperature with extremely high response at least down to 0.5 ppm with noise limited response ~ 10 ppb. Utilization of cost effective chemical technique for fabrication of sensor on silicon is compatible with wafer level processing and easily connecting with silicon IC technology. The vertically aligned Si NWs array has been made by electroless etching method and the ZnO nanostructure was made by chemical solution deposition and spin-coating. We observe that the heterostructure leads to a synergetic effect where the sensing response is more than the sum total of the individual components, namely the ZnO and the Si NWs. The response is much enhanced in the p-n junction when the n-ZnO nanostructure interfaces with p-Si NW compared to that in the n-n junction formed by ZnO on n-Si NW. Extensive cross-sectional electron microscopy and composition analysis by line EDS allowed us to make a physical model. The comparison of the simulation results with the experiment point out the device parameters that enhance the device response. The characteristics values of the parameters of ZnO/Si NWs heterojunction for the best fits obtained from the simulation and it can be seen that all the parameters undergo change in the electrical model and this leads to enhancement of current in the device on gas exposure. The top layer of ZnO takes part in electrical current conduction. The Si NWs also has an all-round layer of ZnO that also acts as chemical sensing gate to modulate the depletion layer on the surface of the NW. The main inference from the simulation is that the observed high performances of the sensor device depends on change in resistances of the constituents as well change in the reverse saturation current at the ZnO/p-Si NW p-n junction.

Additive Manufacturing of Hybrid Silicon Carbide/Carbon Fiber Nano-Composites

Saja M. Al-ajrash; University of Dayton, United States

A novel route to fabricate a hybrid ceramic matrix composite by utilizing preceramic polymers, chopped carbon nanofiber (CNF) precursors and subsequent additive manufacturing was introduced in this study. An allyl hydrido polycarbosilane (SMP-10) and 1,6-dexanediol diacrylate (HDDA) were mixed with a photo initiator to form a photo sensitive resin. The resulting resin was loaded with distinct weight percentages of polyacrylonitrile (PAN) nanofiber. These mixtures were 3D printed followed by pyrolysis. The end objective of the pyrolysis cycle is that the preceramic resin is converted into a silicon carbide matrix, with the PAN converted into reinforcing carbon nanofibers. The impact of the CNF percentages on structural and mechanical properties was investigated using scanning electron microscopy, transmission electron microscopy, and nano-indentation characterization techniques, respectively. The prepared precursor resin proved to have outstanding photo-curing properties and the ability to transform to the silicon carbide phase at temperatures as low as 850 °C. The result of this work showed that ceramic matrix composite components can be successfully fabricated using 3D printing and a specific pyrolysis cycle. The obtained ceramic hybrid composite was fully dense with nearly linear shrinkage and a shiny, smooth surface after pyrolysis. Furthermore, around 60% retained weight after pyrolysis to 1350 °C was confirmed by thermogravimetric analysis. In terms of crystallography, the ceramic matrix composite appeared to have three coexisting phases including silicon carbide, silicon oxy carbide, and turbostratic carbon. The results are very promising to fabricate hybrid composites working at high temperatures with improved mechanical properties and complex geometries.

Systematic Study of the Effect of Incorporation of Carbon Nanotubes into Ge<sub>x</sub>Se<sub>1−x</sub> Glass System

Chari Ramkumar, John Rademacher, Jake Anderson and Wayne Bresser; Northern Kentucky University, United States

We successfully synthesized Ge<sub>x</sub>Se<sub>1−x</sub> (x = 0.225) glass samples and doped the samples with commercially produced (Protein Mods) carbon nanotubes (CNTs). We investigated the glass transition temperature (T_g) using Modulated Differential Scanning Calorimetry (MDSC). The glass samples without the CNTs have a a T_g of ~220°C and the T_g was found to be independent of starting materials from different suppliers as well as water-bath temperature. CNTs, being a very hygroscopic material as well as oxygen absorbing material, needed to be cleaned under vacuum with the hot water-bath. We found that the T_g decreases when 5% and 10 % CNTs by mass is added to the glass samples as compared to the base Ge<sub>x</sub>Se<sub>1−x</sub> glass. The decrease in T_g indicates the occurrence of an intermediate phase (reduced-stress glass phase) at lower temperature, which could be potentially useful in material science applications.
Optimization of Geometry and Edge Passivation for High-Performance Si Heterojunction (SHJ) Microcells

S.CT07.11.02
Optimization of Geometry and Edge Passivation for High-Performance Si Heterojunction (SHJ) Microcells

Marjorie Potter¹, Megan E. Phelan², Pradeep Balaji³, Phillip Jahelka⁴, Rebecca Glaudell⁵, Michael Enright¹, André Augusto¹, Harry A. Atwater⁶ and Ralph G. Nuzzo⁷; ¹University of Illinois at Urbana Champaign, United States; ²California Institute of Technology, United States; ³Arizona State University, United States

Perimeter recombination in micron-sized III-V photovoltaic (PV) materials has been studied extensively for performance at high concentrations, but minimal work toward understanding and optimizing edge recombination for Si-based photovoltaics has been pursued. Here, through both modelling and microcell fabrication, we explore the performance of Si heterojunction (SHJ) solar cells with varying edge to total surface area ratios by examining performance characteristics at different micron-scale lateral dimensions (between 200 µm x 200 µm and 1000 µm x 1000 µm microns) and device thicknesses (80 - 200 microns). We explore edge passivation strategies by determining the impact of a-Si:H and oxide- and nitride-based passivation coating materials on recombination at the edges and consequently device open-circuit voltage, V_{OC}. Finally, we compare the impact of deep reactive ion etching (DRIE) and micro-laser cutting for solar cell dicing on edge surface quality and process scalability. Modelling results indicate that microcell device short-circuit current, J_{SC}, increases with device thickness (up to 35 mA/cm²) and is generally independent of lateral dimensions, while device V_{OC} decreases with thickness and increases with lateral dimensions, exceeding 700 mV at most geometries with high quality edge passivation. Consequently, device power conversion efficiency (PCE) is largely independent of thickness and increases with lateral dimensions, with a maximum PCE of ~ 20% at the largest lateral sizes. Notably, we found that edge passivation quality, rather than device geometry, dictates performance via the magnitude of edge recombination and is therefore the most important variable in this study to optimizing performance; high-quality a-Si:H was determined to be the best passivation material by virtue of minimizing edge recombination velocity (as indicated by dark current measurements) and thus maximizing V_{OC}. Corroboration of modelling results with that of fabricated and tested SHJ microcell devices will be discussed, along with DRIE and micro-laser cutting routes to fabrication of micron-sized SHJ PV devices and the associated high-level cost-benefit analyses. This work will contribute to understanding of micro-scale Si-based PV and provide a framework for optimizing device parameters for integration with large-scale energy-harvesting systems.
One-dimensional (1D) carbons, namely carbon nanofibers (CNF), will be demonstrated as an example here due to their locally from highly anisotropic to isotropic. Hence, this manufacturing enables the design and fabrication of composites with site-specific optimization of particle orientations, programmable surface morphology, and designable interfacial transitions. The samples with different roughness and pattern features were compared for with the cross-section directions. We used 3D printing for surface morphologies controls and the CNFs were deposited via layer-by-layer self-assembly (LBL) techniques. The electricity characterizations showed a strong anisotropy along with the fiber alignment directions, showing resistivity of 0.27 kW/sqr along with the CNF band as compared to 1.21 kW/sqr along with the normal directions. This phenomenon was taken advantage of their superior anisotropic properties especially the higher conductivity or sensitivity along the fiber axis as compared to that along with the cross-section directions. We used 3D printing for surface morphologies controls and the CNFs were deposited via layer-by-layer self-assembly (LBL) techniques. The samples with different roughness and pattern features were compared for the efficiency of directed self-assembly. The solid-liquid-air interfaces were proven to be critical in determining the selective deposition of CNF for surface conductive paths and sensitivity degrees. The printing and deposition mechanisms from the two-step manufacturing are compatible on the same processing platform that can greatly improve the precision and throughput.

Our proposed 3D printing mechanism will control the processing and material parameters along the working path such that each voxel of printed material itself can be a spatially varying architecture of particles giving rise to a response that differs locally from highly anisotropic to isotropic. Hence, this manufacturing enables the design and fabrication of composites with site-specific optimization of particle orientations, programmable surface morphology, and designable interfacial transitions. One-dimensional (1D) carbons, namely carbon nanofibers (CNF), will be demonstrated as an example here due to their superior anisotropic properties especially the higher conductivity or sensitivity along the fiber axis as compared to that along with the cross-section directions. We used 3D printing for surface morphologies controls and the CNFs were deposited via layer-by-layer self-assembly (LBL) techniques. The samples with different roughness and pattern features were compared for the efficiency of directed self-assembly. The solid-liquid-air interfaces were proven to be critical in determining the selective deposition of CNF for surface conductive paths and sensitivity degrees. The electricity characterizations showed a strong anisotropy along with the fiber alignment directions, showing resistivity of 0.27 kW/sqr along with the CNF band as compared to 1.21 kW/sqr along with the normal directions. This phenomenon was taken advantage of their sensing capabilities. We observed significantly improved sensitivity to strain, temperature, and chemical liquid/gas as compared to randomly distributed CNF microstructures. The high sensitivity with exposure to different volatile chemicals was obtained from our research and suggests the potential in health monitoring, human-robotics interactions, microelectronics design, and environmental sustainability.

S.CT07.11.04
Self-Aligned Copper Oxide Passivation Layer? A Study on the Reliability Effect Yue Kuo and Jia Quan Su; Texas A&M Univ, United States

Due to its high conductivity, copper is an important interconnect material for high density as well as large area electronic and optoelectronic products, such as ICs, TFT LCDs, and OLEDs. The reliability of the copper line is critical to these applications. In general, the copper interconnect line needs a bottom adhesion layer as well as a passivation layer. The adhesion layer effect on the line reliability has been well studied. The passivation layer is commonly formed by adding a CVD or sputter deposited dielectric or metallic layer. There are some studies on the influence of these passivation layers on the reliability of the copper line (1,2). However, there are few studies on the copper oxide passivation effect on the copper line's reliability.

Since oxide can be easily formed on the copper pattern under a well-controlled condition, it can be an effective self-aligned passivation layer. In this paper, authors report the reliability study of the copper oxide passivated copper line that is etched with the plasma-based etch process (3,4,5). The copper oxide layer was formed from the oxygen plasma method. Copper lines of various thicknesses and widths with and without the oxide passivation layer were prepared. The line breakdown phenomena under the constant current density stress condition are discussed. The composition and structure of the passivation layer before and after the high current stress condition have been examined and discussed. In summary, copper oxide is a potentially important passivation layer for the copper interconnect line in many products.

In the past several decades, the US has experienced a rising concern over toxic pollution from heavy metal sources. For example, the pollution based natural disaster of Flint, Michigan garnered an abundance of media attention for its devastating impact on the lives of those in the local community. Although this negative press was rightly deserved, there are many places in America with much higher recorded heavy metal poisoning rates – three thousand to be exact. A big concern of much of this pollution comes in the form of water toxicity. Often, heavy metals find their way into water supplies for local communities which results in the indirect poisoning of citizens. Therefore, there is great need for a commercially available and portable device which would provide an easy method to test the level of poisonous elements in community water supplies.

Herein, the creation of a novel microfluidic device for the measurement of trace heavy metal ions is described. The work presented within focuses on these ions due to their health hazards and low concentration limits lending to an interesting challenge in detection.

The first effort in this project revolved around determining the form factor of a MEMS device which would act as an environmental sensor for minute concentrations of lead. Much background research into similar devices was performed before starting to conceptualize the preliminary design. Taking the equipment of the San Diego State University Clean Room facility into consideration, a rough model was presented and refined over several weeks. A final design then followed with a basic 3D model and fabrication process presented.

After much time testing and redesigning, results were generated for the measurements of trace heavy metal ions in solutions of water. Additional results were then obtained by altering various parameters within the experiment such as the analyte concentration. They were then compared to other experimental and commercial devices to determine the efficacy and practicality of the device. Finally, a study was performed to determine future work and technological extensions of the tool presented within.

For more than a decade, researchers have studied cell-to-cell signaling peptides using various analytical methods. Signaling peptides have been known to have important role in the physiological mechanisms. Currently available approaches for analyzing peptides have drawbacks such as loss of peptides and complicated steps for sample preparation. We developed an efficient platform for mass analysis of neuropeptides that simultaneously concentrates and desalts the analytes via coffee ring effect. Our approach is to use C18-Au coated patterned substrate. When peptide solution with high salt content is dropped onto the patterned C18-Au surrounded by donut-shaped hydrophilic anchors, salts are removed by outward flow generated during evaporation, while peptides are collected onto the central C18-Au region. Our approach greatly simplifies the sample preparation for matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS). We also found that our patterns can be regenerated and used 5 times or more without any performance degradation. We have developed a simple kinetic model that describes the correlation between the evaporation rate and the surface coverage of peptides. Moreover, the performance could be dramatically increased by concentrating absorbed peptides into a crystal using PDMS contact printing. Applying these drop-dry methods to MALDI-MS sample preparation potentially enables high-throughput analyses, including time-lapse mass analysis. Our approach is easily accessible to researchers who do not have special expertise in mass spectrometry, so it is possible to contribute to bringing new ideas to neuropeptide analysis.

Since the nano world can be observed with SEM and SPM, nanomaterials have been actively developed. Among them, nanoparticles are often used for both metals and non-metals, such as cosmetics, home appliances / electrical electronic products, paints / inks, etc. In general, nanoparticles are produced by a vapor phase method or a liquid phase method. However, it is still difficult to produce nanoparticles with a desired shape such as raspberry particles. For example, the prototype raspberry particles are on the order of the micro level at the minimum.

In this study, the surface of two kinds of large and small nano level silica nanoparticles were coated with different reactive chemically adsorbed monomolecular film. Thereafter, the particles were bonded to each other by the interaction of the
functional groups at the ends of the chemically adsorbed monomolecular film on the surface of each particle to produce nano sized raspberry particles. As an application example of nano raspberry particles, the nano raspberry particles were coated on the surface of a glass substrate to form a nano fractal surface structure. Furthermore, a light transmitting super water repellent glass substrates could be produced by forming a fluorocarbon based chemical adsorbed monomolecular film on the surface without damaging the surface of the fractal structure.

Nano-Engineering in Confined Spaces—Size- and Shape-Controlled Growth of Functional Nanostructures in Self-Assembled Block Copolymer Nanoreactors
Naman Arora¹, Anna Perdikaki², Paschalis Alexandridis³, T. J. (Lakis) Mountziaris⁴ and Georgios Karanikolos¹,¹; ¹Khalifa University, United Arab Emirates; ²Demokritos National Research Center, Greece; ³University at Buffalo, The State University of New York, United States; ⁴University of Massachusetts Amherst, United States

Self-Assembly of amphiphilic block copolymers in selective solvents can yield a variety of organized structures at the nanoscale of different sizes, shapes, and interfacial characteristics. Such rich structural polymorphism has been tuned and subsequently utilized in this work to controllably prepare a variety of colloidal systems of nanoparticles by templated growth in the self-assembled nanodomains. Nanomaterials spanning compound semiconductors with 0-, 1-, and 2-D morphologies to metallic nanostructures grown in poly(ethylene oxide)-b-poly(propylene oxide)-b-poly(ethylene oxide) assemblies will be presented. The metallic systems in particular were applied as antibacterial agents exhibiting enhanced and sustainable performance due to the block copolymer colloidal configuration.

Characterization of Device Edge Illumination of Si Heterojunction (SHJ) Microcells for Luminescent Solar Concentrator (LSC) Applications
Megan E. Phelan¹, Maggie Potter², Pradeep Balaji³, André Augusto³, David Needell¹, Ralph G. Nuzzo² and Harry A. Atwater¹; ¹California Institute of Technology, United States; ²University of Illinois at Urbana-Champaign, United States; ³Arizona State University, United States

In dense urban environments, with limited rooftop space, communities must look towards new photovoltaic (PV) technologies that can be integrable into the existing building envelope. Luminescent solar concentrators (LSCs), which sustain performance in both direct and diffuse lighting conditions and boast tunable transparencies, present an attractive option for building integrated (BI) PV. In this talk, we report performance optimization and characterization for varied illumination conditions of Si heterojunction (SHJ) microcells embedded within an LSC for BIPV applications. For this design, we propose a grid-like array of SHJ microcells, beneath a poly-lauryl methacrylate (PLMA) waveguide that has embedded InAs/InP/ZnSe quantum dots as the luminophore. Given the proposed architecture, the microcell can be illuminated from the top surface of the cell as well as each of its device edges; this illumination results from each direct sunlight and from quantum dot photoluminescence (PL) within the LSC waveguide, respectively.

In this talk, we compare SHJ microcell performance when illuminated on each i) the top surface, ii) one device edge, and iii) all four device edges simultaneously. We present both simulated and experimental measurements to corroborate our results around photonic interactions at each surface, and perform the following characterizations and measurements: light current-voltage (LIV), dark current-voltage, photocurrent mapping, external quantum efficiency (EQE), and internal quantum efficiency (IQE). By varying the dimensions (width and length) of the SHJ micro cell (from 400um to 800um), we further report how cell performance for each surface illumination (top vs. edge) varies for different sized devices. Results of these measurements show that Jsc increases when illuminating the microcell on the edge (in comparison to top surface illumination) due to an increased absorption depth. However, Voc drops for edge illumination vs. top illumination, due to an additional darkness factor and increased recombination. The mechanisms and photonics behind the contrasting microcell performance at each of these surfaces will be discussed during this talk. By understanding microcell performance at each interface, we are able to better design a SHJ/LSC integrated device, with optimized luminophore PL to match the edge illumination performance, for BIPV applications.

Superlattice Nucleation and Underlying Mechanism of Magnetite Nanocube Assembly
Xin Huang and Zhongwu Wang; Cornell University, United States

The self-assembly of colloidal nanoparticles into ordered superlattices provides significant expansions for the capability of functional materials design. As the new type of building blocks, the geometric shapes of nanocrystals, such as sphere, cube and octahedron, play critical roles in determining the structure of assembled supercrystal. In the nanocube system, the
observed superlattices were dominated by the three phases of simple cubic (SC), rhombohedral (Rh), and face-centered cubic (FCC), but how they nucleate and grow and transform from one to another remain largely unknown. In this work, we applied highly monodisperse magnetite nanocubes with an average side length of 12.5 nm, and controlled various assembly environments, and revealed the formation and growth of three major phases (SC, acute Rh and FCC). Taking advantage of synchrotron-based SAXS techniques, we also explored the structural correlations between three superlattices phases. With additional simulations and computations, we further discussed the driving forces and constructed a reasonable superlattice phase diagram of nanocube-based assembly. Our results not only dramatically expand our understanding on the shape-dependent phase behaviors of nanocrystal, but also provide insights for design and fabrication of novel functional materials.

DFT Study of Graphene Formation in Carbon Droplets Condensed in Stellar Atmospheres Chathuri Silva, Philip Fraundorf, Eric H. Majzoub and Philip Chrostoski; University of Missouri-St. Louis, United States

Because macroscopic clusters of elemental carbon at low (ambient) pressure sublimate to vapor near 4000K, liquid carbon is seldom considered to play a role in nature even though quenched carbon droplets have been reported in laboratory laser ablation studies [1,2]. However, a subset of meteoritic carbon particles from red giant atmospheres show a “graphene-core”/graphite-rim structure [3,4], likely following condensation of super-cooled carbon droplets from the vapor phase, which nucleated graphene sheets on randomly-oriented 5-member rings before solidification and subsequent coating with a graphite rim. Similar core-rim particles can be formed by slow cooling of carbon vapor in the lab [5].

It remains a challenge to study the properties of liquid carbon in a lab due to the difficulty of experimentation under extreme conditions. Therefore, we investigated nucleation and growth of carbon rings and graphene sheets using density functional theory (DFT). We assume low pressure, with an experimental 1.8 g/cc density estimate, and relax randomized positions of liquid-like 13/20-carbon atom clusters in a cubic supercell. Inter-atom distances characteristic of covalent vs. metallic interactions (with a gap in 1.7-2.0 Å range) allow us to identify covalent “bonds” with small separation. Local energy minima at T = 0K show a mix of sp² and sp, plus few sp³ coordination numbers as in the literature which reports that liquid carbon favors sp coordination at lower densities, sp³ coordination at higher densities, and a mix of sp and sp³ coordination at intermediate densities [6-10]. Ring sizes vary from triangle to heptagon, but pentagons are more abundant than hexagons, also consistent with previous reports [9,10]. Further work remains to see if such ab initio studies can confirm that abundant pentagonal rings at this density, during slow cooling of the liquid, can nucleate the growth of faceted pentacones as suggested by electron phase-contrast imaging of the presolar cores [11].

In summary DFT relaxation of random configurations of 13/20-atom clusters in a supercell, along with literature reports of the same, suggest that: (a) covalent bonds can be identified by interatom spacings below 1.85Å, (b) sp² coordination is expected at that density, and (c) pentagonal rings are more abundant than hexagonal rings as possible nucleation seeds. The properties of unlayered graphene sheets in a frozen liquid matrix, e.g. as a diffusion barrier, should be interesting to explore further both experimentally and computationally.

Fabricating Polystyrene Core-Shell Fibers Dharnedar Ravichandran, Weiheng Xu, Rahul Franklin, Namrata Kanth, Sayli Jambhulkar, Ali Alshami, Sumedh Shukla and Kenan Song; Arizona State University, United States

Core/shell fibers have many broad applications in the biomedical field, such as drug delivery and tissue engineering, and are also used in environmental-related applications like water treatment and CO₂ absorption. This research demonstrated an alternative technique of gel-spinning for fabricating core/shell structures other than the traditionally used melt spinning or electrospinning technique. These fibers were porous in the shell and had capabilities to load particles in the core. Polystyrene
(PS) and polyethylene glycol (PEG) were used as an example for demonstrating the feasibility of the core/shell fiber fabrication. A two-phase liquid-state microstructure was first achieved via the co-axial spinneret with the exterior layer composed of PS pellets (PSp)/PEG/organic solvent (e.g., xylene or dimethylformamide) solutions and the interior layer containing dispersed PS spheres (PSs)/PEG/water solutions. Procedures of coagulation, heat-treatment, and phase-separation-based selective dissolution were used to generate the porous-shell/particle-core fibers. The pore sizes and density were controlled by the porogen (i.e., PEG) concentrations and examined using scanning electron microscopy (SEM). The fiber formation dynamics and microstructural features were studied via rheology tests and gelation measurements, tensile tests, thermogravimetric analyzer (TGA) and differential scanning calorimetry (DSC).

Hematite Mesocrystal Formation through Near Interface Nucleation and Oriented Aggregation
Guomin Zhu1, Maria Sushko2, John Loring2, Miao Song2, Benjamin Legg1, Xiaopeng Huang2, Kevin Rosso2 and James J. De Yoreo2,1; 1University of Washington, United States; 2Pacific Northwest National Laboratory, United States

A diverse class of materials exhibit characteristics of mesocrystals: single crystals constituting distinct nano-sized domains that are atomically aligned. The formation of such structures is often attributed to crystallization through oriented attachment. However, many questions about the fundamental drivers and dynamic progression of this phenomenon remain. And the process become more complexed when coupled with phase transformation. Here we focus on the crystallization of hematite (hm, Fe2O3) mesocrystals from ferrihydrite (fh) nanoparticles. In the oxalate-free solution, the resulting hm crystals are well-faceted rhombohedron, while in the presence of oxalate, hm forms nanoporous spindle-shaped mesocrystals. We applied in situ liquid phase TEM with heating temperatures of 80 °C to investigate the formation. We directly observed both the dissolution of fh and the nucleation of new hm particles, which formed within close proximity (~ 1 nm) of the hm/solution interface. Immediately after nucleation, the hm particles attached to the nearby seed to form a hm mesocrystal. Post analyses using EDX mapping and electron diffraction after disassembling the liquid cell confirmed the growth of spindle-shaped hematite during the liquid phase TEM experiments. In addition, we utilized a quasi in situ approach of using indexed TEM grids to cycle samples between the growth reactor and the TEM in order to track the pathway of crystallization. The results were consistent with those of the in situ experiments and confirmed that the fh serves as a buffer and the Hm grow by creation of new particles in the solution near the hm interface. Based on ATR FTIR measurements, ion chromatography and classic DFT calculation we propose that oxalate plays the role of inhibiting classical monomer-by-monomer growth of the hematite particles while promoting the nucleation of new hm particles at the hm/solution interface by modifying the interfacial energy of hm close to the hm/solution interface. In this way, the oxalate ligands bias the growth process away from classical mechanisms and towards oriented attachment.

Bypassing the Computational Bottleneck of Quantum-Embedding Theories for Strong Electron Correlations with Machine Learning
John Rogers¹, Tsung-Han Lee², Sahar Pakdel³, Vladimir Dobrosavljevic⁴, Ove Christiansen⁵ and Nicola Lanata⁶; ¹Texas A&M University, United States; ²Rutgers, The State University of New Jersey, United States; ³Aarhus University, Denmark; ⁴Florida State University, United States

A cardinal obstacle to performing quantum-mechanical simulations of strongly-correlated matter is that, with the theoretical tools presently available, sufficiently-accurate computations are often too expensive to be ever feasible. Here we design a computational framework combining quantum-embedding (QE) methods with machine learning. This allows us to bypass altogether the most computationally-expensive components of QE algorithms, making their overall cost comparable to bare Density Functional Theory (DFT). We perform benchmark calculations of a series of actinide systems, where our method describes accurately the correlation effects, reducing by orders of magnitude the computational cost. We argue that, by producing a larger-scale set of training data, it will be possible to apply our method to systems with arbitrary stoichiometries and crystal structures, paving the way to virtually infinite applications in condensed matter physics, chemistry and materials science.

The JRC Surface Science Labstation—A Unique Set-Up to Investigate Actinides in Support of Nuclear Safety and Non-Power Application of Nuclear Materials
Rachel Eloirdi¹, Thomas Gouder¹, Ghada El Jamal², Concettina Andrello¹, Frank Huber¹ and Roberto Caciuffo¹; ¹JRC Karlsruhe, Germany; ²KTH Royal Institute of Technology, Sweden

Knowledge about the interaction of UO₂ with the environment is of high importance to assess its stability in oxidizing and in reducing condition. For this reason, understanding the UO₂ oxidation process is central to the performance assessment of nuclear fuels. Oxidizing condition can convert UO₂ into U₃O₈ leading, in some cases, to powdering of the fuel matrix or to failure of the cladding [1]. The redox behaviour of UO₂ is also relevant for the management of nuclear waste forms, as oxidation results in the production of soluble uranyl cations, UO₂²⁺, that can easily migrate in the biosphere.

This talk summarizes surface science research activities carried out at JRC Karlsruhe in support of nuclear safety and non-power application of nuclear materials. I will also describe a unique set-up developed in-house, the Labstation [2], including sample preparation modules, by DC Sputtering or evaporation, and several surface characterisation techniques. Among the latter, High-resolution X-ray Photoelectron Spectroscopy (XPS) and Bremstrahlung Isochromat Spectroscopy (BIS) are particularly useful to characterize the uranium oxidation state in single and mixed oxides. In a first example, I will show the process of oxidation and reduction of U oxides using O₂, H₂O and H₂ plasma. For the first time, U₃O₈ films [3-4] could be produced and studied, filling a gap in the knowledge about U⁵⁺ oxidation state. While U⁴⁺, U⁵⁺ and U⁶⁺ have representative satellite peaks positioned, respectively, at 7, 8 and 10 eV out of the main 4f⁵/₂,7/₂ excitation lines, a satellite peak at 9 eV is observed when UO₂+x in contact with sodium is heated at 400 °C under oxygen. In a second example, we report the first in-situ preparation of ThF₄ [5] whose band gap of 10.2(2) eV is significantly larger than the 229mTh excitation energy, making ThF₄ a possible candidate material for a solid-state nuclear clock based on the vacuum ultraviolet γ decay.

**Hybridization Effect on the X-Ray Absorption Spectra for Actinide Materials**

Jian-Xin Zhu$^1$, Wei-ting Chiu$^{1,2}$, Roxanne Tutchton$^1$, Giacomo Resta$^2$, Tsung-Han Lee$^3$, E.D. Bauer$^1$, Filip Ronning$^1$ and Richard T. Scalettar$^2$; 1Los Alamos National Laboratory, United States; 2University of California, Davis, United States; 3Rutgers, The State University of New Jersey, United States

Studying the local moment and 5f-electron occupations sheds insight into the electronic behavior in actinide materials. X-ray absorption spectroscopy (XAS) has been a powerful tool to reveal the valence electronic structure when assisted with theoretical calculations. In this work, we employed the DFT+Gutzwiller rotationally-invariant slave boson method to obtain the local Hamiltonian of the single-impurity Anderson model (SIAM), and used exact diagonalization (ED) method to calculate the XAS spectra from the model. An in-house built computational code was developed for the ED method. By applying this technique to the recently discovered 5f-electron topological Kondo insulator plutonium tetraboride (PuB$_4$), we were able to determine the signature of 5f-electronic correlation effects in the theoretical X-ray spectra. We found that the Pu 5f-6d hybridization effect provides an extra channel to mix the $j=5/2$ and 7/2 orbitals in the 5f valence. As a consequence, the resultant electron occupation number and spin-orbit coupling strength deviate from the intermediate coupling regime. We have also applied this approach to the d-phase of Pu.

**Role of Electronic Interactions on Structural Properties of Actinides and Phases of Plutonium**

Bernard Amadon, Jean Baptiste Morée and Boris Dorado; CEA DAM DIF, France

We discuss the impact of 5f electron interactions on structural properties of pure actinides and phase of plutonium[1][2]. We first use an ab initio calculation of effective Coulomb interactions and we find that the calculated interactions in plutonium and americium are much smaller than usually expected. With these interactions, we reproduce the experimental transition from low volume early actinides (uranium, neptunium, α-plutonium) to high- volume late actinides (δ-plutonium, americium, and curium) and a good agreement of volume of phases of plutonium with experiment. We also discuss phonon spectra of plutonium. Then we discuss our values of effective 5f electron interactions U. In some lanthanides and actinides [3], higher values are expected to reproduce experimental photoemission spectra and structural properties. We discuss general ways to improve the calculation to be more predictive.

**Electronic Correlation Induced Expansion of Compensated Electron and Hole Fermi Pockets in δ-Plutonium**

Roxanne Tutchton$^1$, Wei-ting Chiu$^2$, Robert C. Albers$^1$, Gabriel Kotliar$^3$ and Jian-Xin Zhu$^{1,4}$; 1Los Alamos National Lab, United States; 2University of California, Davis, United States; 3Rutgers, The State University of New Jersey, United States; 4Center for Integrated Nano Technologies, United States
Due to its position at the boundary between the light and heavy actinides, Plutonium (Pu) has liminal characteristics that make modeling its 5f-orbital electrons especially challenging. Consequently, a complete understanding of the electronic structure of this elemental solid remains in question. In order to explore the role of strong electronic correlations in the δ-phase of Pu, we have performed Fermi surface calculations using the generalized gradient approximation with dynamical mean-field theory and the Gutzwiller wavefunction approximation to compare their differing approaches to electron correlation effects. The de Haas-van Alphen (dHvA) frequencies and effective masses were then calculated to analyze correlation induced renormalization effects on the Fermi surface topologies. We have predicted that the electronic correlation gives rise to a volume expansion of 200% in both the hole and electron pockets of the Fermi surface in addition to an intermediate mass enhancement. This is in agreement with the band renormalization theory for strongly correlated materials.

1:50 PM S.CT03.06.05
Probing the Limits of 5f Ferromagnetism in UCu2P2
Ladislav Havela1, Jiri Prchal1, Jaroslav Valenta1, Martin Divis1, Fuminori Honda2, Ilja Turek1, Dariusz Kaczorowski3, Dexin Li2, Arvind Maurya2 and Dai Aoki2; 1Charles University, Czechia; 2Tohoku University, Japan; 3Polish Academy of Sciences, Poland

Magnetic order in 5f materials offers interesting benefits, based in principle on very strong spin-orbit interaction, bringing large orbital moments into systems with itinerant, i.e. bonding, states. This yields very strong magnetocrystalline anisotropy, determined not by CEF effects as in lanthanides, but by bonding anisotropy. Hybridization of the 5f states with other states having low effective mass means that a re-orientation of 5f magnetic moments can have a dramatic effect of electrical conduction, bringing a giant magnetoresistance effect. Other related prominent characteristics include a giant Kerr rotation as one of important magnetooptical phenomena. Although highly tunable by composition and external variable, the 5f magnetism remained restricted to low temperature range, discarding e.g. inexpensive uranium from the pool of prospective magnetic materials. For example, Curie temperatures of U-based 5f-ferromagnets only exceptionally exceeds the limit of 200 K. The trick of mixing the f magnetism with 3d magnetism of transition metals, so successful in lanthanide-based permanent magnets, does not work in the case of light actinides. Both 3d and 5f states being band-like, they strongly hybridize, which degrades both the 3d and 5f desirable characteristics. Due to the same reason U-compounds very rich in Fe or Co simply lose any distinct 5f contribution. Heavy actinides (from Am onwards), in principle analogous to heavy lanthanides, undergo a fast radioactive decay.

We have been trying to understand which type of tuning can support the 5f magnetism besides the traditional game with inter-actinide spacing. The case of uranium hydrides showed that using a ionic-covalent bonding can lead to a suppression of the 5f-6d hybridization, which is an undesirable mechanism, contributing the washout of U moments. The 6d hybridization with ligand states can efficiently liberate the 5f states, although they can still maintain their band character. A general hint is to look at U compounds with a certain charge transfer and to use external pressure for fine tuning of crystal structure. We have focused on U pnictides, and chose UCu3P2 as the material with record high $T_C = 216$ K [1]. Applying hydrostatic pressure the $T_C$ value increases, reaching a maximum of 290 K in $p = 7$-8 GPa, i.e. first time obtaining a room temperature ferromagnetism with pure 5f ferromagnet. Details of electronic structure and their pressure variations have been provided by ab initio calculations.

Identifying Structural Features That Result in Activation and Coupling of Vibrational Modes in Actinyl Materials
Tori Forbes; University of Iowa, United States

The actinyl cation ($D_{3h}$ point group) possesses symmetric and asymmetric stretching modes that are typically Raman and Infrared active, respectively. Lowering the symmetry of the actinyl moiety will activate both modes causing two stretching
bands to be present within the spectral window. While activation of these bands suggests perturbation to the actinyl bond, there is currently a limited understanding on how intermolecular forces influence this process or the extent of the effect on the actinyl bond in solid state compounds. In this presentation, I will focus on the analysis of Raman spectra associated with neptunyl (NpO$_2^+$/NpO$_2^{2+}$) compounds and explore activation and vibrational coupling effects of these materials. Specifically, the impacts of counterions and hydrogen bonding will be explored experimentally and compared to theoretical calculations. In addition, the neptunyl system will be compared to the related uranyl complexes to further explore the subtle differences in bonding within actinyl cations.

Electronic Structures of Uranium Compounds Studied by Photoelectron Spectroscopy

Shin-Ichi Fujimori; Japan Atomic Energy Agency, Japan

The electron correlation effect gives rise to an abundant variety of physical properties particularly in the d- and f-based materials. Among this class of materials, the actinide compounds share a unique position due to the interplay between their magnetic and superconducting properties. Particularly, the coexistence of a large magnetic moment and unconventional superconductivity is the most significant aspect of uranium-based compounds. These distinctive behaviors are due to the strongly correlated U 5f states which are located at the boundary between simple localized and itinerant pictures of electrons. To understand the origin of these remarkable physical properties, it is essential to unveil the U 5f electronic structures.

In this talk, I will review the electronic structure studies of strongly correlated uranium compounds by photoelectron
spectroscopies with soft X-ray synchrotron radiation [1,2]. The following subjects will be discussed.

**Resonant photoelectron spectroscopy study of heavy fermion superconductors**

We have elucidated the nature of the electron correlation effect in heavy fermion superconductors UPd$_2$Al$_3$ [3] and UTe$_2$ [4] by imaging their partial U 5f density of states (pDOS) using U 4d-5f resonant photoelectron spectroscopy. It was found that incoherent peaks emerge on the higher binding energy side in their U 5f pDOS, suggesting that the electron correlation effect takes an essential role in their electronic structures.

**Three-dimensional angle-resolved photoelectron spectroscopy study of URu$_2$Si$_2$**

The complete volume electronic structure of the heavy fermion superconductor URu$_2$Si$_2$ in the paramagnetic phase was revealed by the three-dimensional (3D) angle resolved photoelectron spectroscopy (ARPES). It was found that the electronic structure of URu$_2$Si$_2$ has a strong dependence along the perpendicular $k_z$ direction, suggesting that it has a considerable 3D nature. Furthermore, the U 5f states in URu$_2$Si$_2$ form dispersive bands with their energy dispersions of sub-electron volts, and contribute to the Fermi energy. This suggests that U 5f electrons in URu$_2$Si$_2$ have an itinerant aspect.

**Electronic Structure and Magnetism of UGa$_2$: LDA+DMFT Study**

Banhi Chatterjee and Jindrich Kolorenc; Institute of Physics, Czech Academy of Sciences, Czechia

The debate whether uranium 5f electrons are closer to being localized or itinerant in the intermetallic compound UGa$_2$ is not yet fully settled, partly due to inconclusive spectroscopic observations of the uranium 5f electrons [1,2]. The present state of the theoretical understanding of the UGa$_2$ electronic structure is not satisfactory either. The magnetic moments carried by the uranium atoms in the low-temperature ferromagnetic phase are severely underestimated by the band theory (LDA), and although the correlated band theory (LDA+U) makes the moments larger, the increase is still not large enough to match the experiment [3,4].

We attempt to gain more insight into the electronic structure of UGa$_2$ by means of LDA+DMFT calculations using exact diagonalization as the impurity solver [5]. The LDA+DMFT definitely improves the description of magnetism with respect to LDA, but obtaining magnetic moments as large as in experiments turns out to be difficult even for this advanced electronic structure method – even though the uranium 5f electrons come out as rather localized. Apart from the magnetism, we calculate and analyze also the spectral properties to be compared with experimental valence-band photoemission and M-edge x-ray absorption.

Identifying Structural Features That Result in Activation and Coupling of Vibrational Modes in Actinyl Materials

Tori Forbes; University of Iowa, United States

The actinyl cation (D_{18h} point group) possesses symmetric and asymmetric stretching modes that are typically Raman and Infrared active, respectively. Lowering the symmetry of the actinyl moiety will activate both modes causing two stretching bands to be present within the spectral window. While activation of these bands suggests perturbation to the actinyl bond, there is currently a limited understanding on how intermolecular forces influence this process or the extent of the effect on the actinyl bond in solid state compounds. In this presentation, I will focus on the analysis of Raman spectra associated with neptunyl (NpO_{2}/NpO_{2}^{2-}) compounds and explore activation and vibrational coupling effects of these materials. Specifically, the impacts of counterions and hydrogen bonding will be explored experimentally and compared to theoretical calculations. In addition, the neptunyl system will be compared to the related uranyl complexes to further explore the subtle differences in bonding within actinyl cations.

Crystal Structures of CdUO₄: Space Group Symmetry and Phase Transformations

Zhaoming Zhang¹, Gabriel L. Murphy¹,²,³, Maxim Avdeev¹,² and Brendan J. Kennedy²; ¹Australian Nuclear Science and Technology Organisation, Australia; ²The University of Sydney, Australia; ³Forschungszentrum, Germany

Inspired by our recent discoveries of the remarkable and unexpected structural behaviors in SrUO₄ [1] and CaUO₄ [2], which both show reversible oxygen-vacancy ordering and symmetry lowering with increasing temperature, we have revisited the closely related CdUO₄ using synchrotron X-ray and neutron powder diffraction supported by X-ray absorption spectroscopic measurements and thermogravimetric analysis. Depending on synthesis conditions, CdUO₄ was previously reported to form two structural types based on laboratory X-ray powder diffraction [3]. One polymorph (α-CdUO₄) was described as isostructural to α-SrUO₄ and CaUO₄, having a rhombohedral structure in space group R-3m. The other polymorph (β-CdUO₄) was described as orthorhombic in space group Cmmm. A high temperature third polymorph, denoted as γ-CdUO₄, was also suggested based on a thermogravimetric study [4]. The structure of γ-CdUO₄ was not solved but described as a form of the rhombohedral α-CdUO₄ that is substoichiometric.

We have synthesized both α- and β-CdUO₄ and determined their crystal structures using high resolution synchrotron X-ray and neutron powder diffraction for the first time. While the structure of α-CdUO₄ was confirmed as previously reported rhombohedral structure in R-3m, we propose that the correct space group for the orthorhombic β-CdUO₄ is Ibbm, isostructural to β-NiUO₄ [5].

In situ synchrotron X-ray diffraction measurements were also carried out with both α- and β-CdUO₄ from room temperature to 1000°C in sealed quartz capillaries. β-CdUO₄ was found to undergo an irreversible reconstructive structural phase transformation around 900°C. Although the X-ray diffraction pattern of the high temperature phase has a passing resemblance to that of α-CdUO₄, there are clear peak splittings that cannot be accounted for by the rhombohedral structural model. Note that these splittings are too small to be resolved by laboratory X-ray diffractometers, therefore they were not observed in previous studies. Using a similar approach to that in our earlier study of SrUO₄ [1], the high temperature structure of CdUO₄ denoted as δ-CdUO₄, was solved for the first time as triclinic in space group P-1. When α-CdUO₄ was heated to around 750°C it also underwent a first order phase transformation to a mixture of the β and δ phases. Similar to SrUO₄, oxygen vacancies are believed to play a key role in the phase transformation behavior of CdUO₄. The results of this study will be discussed with the other related monouranates.

Development of Rapid Measurement Techniques to Aid in Pu Development at LANL John D. Auxier; Los Alamos National Laboratory, United States

The focus of this talk highlight on-going research efforts on laser spectroscopy. At present, there are a number of challenges that are involved with meeting the 30 ppy (pits/year) and some of them are scientific and engineering. In this presentation, an overview of hand-held laser induced breakdown spectroscopy (HH-LIBS) an initial measurements on alpha and delta Pu metal standards. There will also be collaborative research that involves the use of chemometric techniques that have been applied to Ce samples for the purpose of method development. Highlights from on-going USMA/LANL collaboration will be discussed.

Multiplatform Microanalysis of Plutonium Oxide Scales for Nuclear Forensics Brandon W. Chung, David J. Roberts, William A. Talbot, Denise D. Ashley, Scott Donald and Art J. Nelson; Lawrence Livermore National Laboratory, United States

Nuclear forensics requires accurate identification of distinguishing material characteristics to determine the history of interdicted nuclear materials. Key material signatures, such as morphological and chemical variations, that pinpoint recent provenance can reside within the bulk oxide scale formed over nuclear materials. This paper identifies improvements in extracting and analyzing key material signatures that exists within the oxide scale formed at the surface of Pu metals. We will describe our multiplatform approach using high-resolution microscopic techniques to identify spatially resolved morphological and chemical features of Pu oxide scales. The approach involves electron microanalysis with scanning electron microscopy (SEM), focused ion-beam (FIB) tomography with SEM, three-dimensional (3D) spatial modeling, chemical analysis with Auger and X-ray photoemission spectroscopies. Our work shows the distinguishing morphological and chemical characteristics between the original oxide scale formed from the controlled storage environment and the scale that is formed during subsequent exposure to external environments. Internal chemical composition, structure, and pore geometry of oxide scales are different, attributable to oxidative corrosion from exposure to outside the storage environment. These altered oxide scales provide distinguishing characteristics for recent environmental exposures. Furthermore, we will discuss our continuing effort to improve understanding internal morphologies and methods to generate database of morphological and chemical features including quantification applicable to nuclear forensics. Prepared by LLNL under Contract DE-AC52-07NA27344. Searching for Clues—Nuclear Forensic Signatures Naomi Marks; Lawrence Livermore National Laboratory, United States
Nuclear forensic science is the science of identifying the purpose and provenance of radiological and/or nuclear material found outside of regulatory control. Because the ability to perform a nuclear forensics examination can help to identify gaps or weaknesses in physical security or safeguards of nuclear material, (which can then be strengthened in response) it is increasingly recognized as an integral part of a robust nuclear security program.

Nuclear forensics science matured as a discipline in the mid-1990s, coincident with an increasing number of nuclear smuggling incidents (Kristo et al., 2016). Labs were tasked with responding to incidents involving interdictions of low enriched uranium (LEU), highly enriched uranium (HEU), and even Pu in Russia, Lithuania, Germany, Bulgaria and elsewhere (IAEA, 2011; Kristo, 2012). As the casework increased throughout the mid-1990’s, so too did the sophistication of the analytical approaches to nuclear forensics examinations. Nuclear forensics practitioners seek to identify not only what materials are on the most basic level, but what might have been their intended use as well as how, when and where the materials were produced, used or stored. As the casework and policy implications of the field have evolved, so too has the science of nuclear forensics.

A combination of geochemical, materials science, and radiochemical analysis methods have traditionally formed the basis for nuclear forensics examination approaches. These methods exploit the characteristics of front end materials produced through mining, milling, and conversion in which the geologic and materials processing signatures are significant. Methods with a geochemical basis are also important for materials from the back end of the fuel cycle, including radiocronometric techniques that allow age-dating of the purification of materials (e.g. Mayer et al., 2013; Eppich et al., 2013; Kristo et al., 2016).

The search for identifying characteristics, or signatures, has been the focus of nuclear forensics research since the beginning. In the context of a nuclear forensics examination, signatures are defined as characteristics or sets of characteristics of a given sample that enables the assessment and evaluation of that sample’s provenance. The most valuable signatures are both readily measurable and also persistent through the fuel cycle. Some examples of signatures that persist up to the point of enrichment might include REE patterns, U isotopic compositions, or isotopic compositions of certain trace elements including $^{87}\text{Sr}/^{86}\text{Sr}$ or $^{98}\text{Mo}/^{96}\text{Mo}$ (Varga et al., 2009; Brennecka et al., 2010; Rolison et al., 2019).

Other signatures, while not persistent, are characteristic of specific places or processes. These could include enrichment, minor U isotopic composition, parameters associated with grinding and metallurgy, trace elements, or even trace organic compounds (e.g. Pajo et al, 2001; Svedkauskaite-LeGore et al., 2008; Badaut et al., 2009; Kennedy, 2013).

The future of nuclear forensics research is focused on developing a greater understanding of signatures, both those that are persistent, as well as those that are characteristics of places, production methods, and design parameters.

Recently, we have acquired and analyzed samples of uranium ore material and uranium ore concentrate for a variety of analytes in order to assess the behavior of isotopic and elemental signatures during processing. This work is focused on identifying persistent signatures that may serve as a predictive indicator of material provenance. Results of this work will be presented, as well as an overview of the current state of nuclear forensic signatures for materials from the front end of the nuclear fuel cycle. The talk will conclude with a discussion of some promising future directions for the field.
nuclear materials due to their high resistance to radiation damage. Here, we will present a review done on a series of monazites having the crystalline structure \( \text{La}_n\text{M}_{1-n}\text{PO}_4 \) (M=RE, An, 0<\\text{z}<1). We have studied their local structure using high resolution \(^{31}\)P solid-state NMR. The experiments were done using the dedicated NMR facility for transuranic materials which is available at JRC-Karlsruhe. In a second part, in order to understand the magnetic nature of these samples, we also performed magnetic susceptibility measurements. Analyses of the magnetic susceptibility data were carried out using the free ion model, crystal field theory and/or ab initio calculations allowing to extract the electronic structure. All of these data will be discussed and a comparison between the actinide monazites and their lanthanide surrogates will be presented.

5:15 AM *S.CT03.06.04
The JRC Surface Science Labstation—A Unique Set-Up to Investigate Actinides in Support of Nuclear Safety and Non-Power Application of Nuclear Materials Rachel Eloirdi1, Thomas Gouder1, Ghada El Jamal2, Concettina Andrello1, Frank Huber1 and Roberto Caciuffo1; 1JRC Karlsruhe, Germany; 2KTH Royal Institute of Technology, Sweden

Knowledge about the interaction of UO2 with the environment is of high importance to assess its stability in oxidizing and in reducing condition. For this reason, understanding the UO2 oxidation process is central to the performance assessment of nuclear fuels. Oxidizing condition can convert UO2 into U2O3 leading, in some cases, to powdering of the fuel matrix or to failure of the cladding [1]. The redox behaviour of UO2 is also relevant for the management of nuclear waste forms, as oxidation results in the production of soluble uranyl cations, UO2\(^{2+}\), that can easily migrate in the biosphere.

This talk summarizes surface science research activities carried out at JRC Karlsruhe in support of nuclear safety and non-power application of nuclear materials. I will also describe a unique set-up developed in-house, the Labstation [2], including sample preparation modules, by DC Sputtering or evaporation, and several surface characterisation techniques. Among the latter, High-resolution X-ray Photoelectron Spectroscopy (XPS) and Bremsstrahlung Isochromat Spectroscopy (BIS) are particularly useful to characterize the uranium oxidation state in single and mixed oxides. In a first example, I will show the process of oxidation and reduction of U oxides using \( \text{O}_2 \), \( \text{H}_2\text{O} \) and \( \text{H}_2 \), plasma. For the first time, \( \text{U}_2\text{O}_5 \) films [3-4] could be produced and studied, filling a gap in the knowledge about U\(^{5+}\) oxidation state. While U\(^{4+}\), U\(^{5+}\) and U\(^{6+}\) have representative satellite peaks positioned, respectively, at 7, 8 and 4 & 10 eV out of the main 4f\(_{5/2,7/2}\) excitation lines, a satellite peak at 9 eV is observed when UO\(_{2-x}\) in contact with sodium is heated at 400 °C under oxygen. In a second example, we report the first in situ preparation of ThF\(_4\) [5] whose band gap of 10.2(2) eV is significantly larger than the 229mTh excitation energy, making ThF\(_4\) a possible candidate material for a solid-state nuclear clock based on the vacuum ultraviolet \( \gamma \) decay.

Probing the Limits of 5f Ferromagnetism in UCu2P2
Ladislav Havela1, Jiri Prchal1, Jaroslav Valenta1, Martin Divis1, Fuminori Honda2, Ilja Turek1, Dariusz Kaczorowski3, Dexin Li2, Arvind Maurya2 and Dai Aoki2; 1Charles University, Czechia; 2Tohoku University, Japan; 3Polish Academy of Sciences, Poland

Magnetic order in 5f materials offers interesting benefits, based in principle on very strong spin-orbit interaction, bringing large orbital moments into systems with itinerant, i.e. bonding, states. This yields very strong magnetocrystalline anisotropy, determined not by CEF effects as in lanthanides, but by bonding anisotropy. Hybridization of the 5f states with other states having low effective mass means that a re-orientation of 5f magnetic moments can have a dramatic effect of electrical conduction, bringing a giant magnetoresistance effect. Other related prominent characteristics include a giant Kerr rotation as on of important magnetooptical phenomena.

Although highly tunable by composition and external variable, the 5f magnetism remained restricted to low temperature
range, discarding e.g. inexpensive uranium from the pool of prospective magnetic materials. For example, Curie temperatures of U-based 5f-ferromagnets only exceptionally exceeds the limit of 200 K. The trick of mixing the f magnetism with 3d magnetism of transition metals, so successful in lanthanide-based permanent magnets, does not work in the case of light actinides. Both 3d and 5f states being band-like, they strongly hybridize, which degrades both the 3d and 5f desirable characteristics. Due to the same reason U-compounds very rich in Fe or Co simply lose any distinct 5f contribution. Heavy actinides (from Am onwards), in principle analogous to heavy lanthanides, undergo a fast radioactive decay. We have been trying to understand which type of tuning can support the 5f magnetism besides the traditional game with inter-actinide spacing. The case of uranium hydrides showed that using a ionic-covalent bonding can lead to a suppression of the 5f-6d hybridization, which is an undesirable mechanism, contributing the washout of U moments. The 6d hybridization with ligand states can efficiently liberate the 5f states, although they can still maintain their band character. A general hint is to look at U compounds with a certain charge transfer and to use external pressure for fine tuning of crystal structure. We have focused on U pnictides, and chose UCu2P2 as the material with record high $T_C = 216$ K [1]. Applying hydrostatic pressure the $T_C$ value increases, reaching a maximum of 290 K in $p = 7-8$ GPa, i.e. first time obtaining a room temperature ferromagnetism with pure 5f ferromagnet. Details of electronic structure and their pressure variations have been provided by ab initio calculations.

**Development of Liquid Fuel for Molten Salt Nuclear Reactors—The Physical Chemistry of Molten Fluoride Salts**
Raluca Scarlat; University of California, Berkeley, United States

Molten fluoride salts are used as solvents for uranium and thorium fuel for molten salt nuclear reactors. The relatively low volatility and high solubility of actinides and fission products in fluoride salt mixtures at temperatures in the range of 500 to 800°C render fluorides highly attractive solvents for liquid nuclear fuel. While a molten salt reactor experimental reactor operated in the 1960s and was supported by an extensive experimental campaign on the chemistry and physical chemistry of actinide-bearing molten fluoride salts, important data gaps still remain, and important fundamental understanding questions remain to be explored. This talk will provide a review of recent advances in on the physical chemistry of liquid fluoride salt fuel, in the context of development and licensing of molten salt reactors.

**Species-Specific Mapping of Uranium Oxides in Spent Nuclear Fuel Focused Ion Beam Sections by Oxygen K-edge Spectromicroscopy**
Alexander Ditter¹, Danil Smiles¹, Jason M. Harp², Daniel J. Lussier¹,³, Michael W. Mara¹,³, Lingfeng He², Claude Delguedre², Mitchell K. Meyer² and David K. Shuh¹; ¹Lawrence Berkeley National Laboratory, United States; ²Idaho National Laboratory, United States; ³University of California, Berkeley, United States; ⁴University of Lancaster, United Kingdom

The specific nature of uranium oxides in spent nuclear fuel is a primary concern in the storage of nuclear fuels resulting from both the volumetric expansion of uranium oxides and change in solubility with an increase in oxygen content. In particular, the growth of hyperstoichiometric uranium dioxide has been linked to fracturing of spent fuel, resulting in further oxidation and the release of short-lived radionuclides trapped within the UO$_2$ matrix. Oxygen K-edge x-ray absorption spectroscopy is an excellent method to distinguish between different uranium oxide stoichiometries, but samples are limited to 1-2 µm thick as a result of the short penetration length of soft x-rays. To address this, low burnup pressurized water reactor (PWR) spent nuclear fuel samples were processed at Idaho National Laboratories utilizing focused ion beam (FIB) sectioning, resulting in samples ideal for soft x-ray spectroscopy. Here we present the first measurements of oxygen K-edge near-edge x-ray absorption spectroscopy using the Beamline 11.0.2 scanning transmission x-ray microscope (STXM) at the Advanced Light Source, on FIB sections of spent nuclear fuel. The FIB sections present unique challenges in normalization and data analysis which will be discussed in this presentation. The sensitivity of the oxygen K-edge x-ray absorption spectrum between the different uranium oxides has allowed for species-specific mapping of the spent nuclear fuel at the sub-micron scale, showing...
UO$_2$ as the bulk of the fuel, with U$_3$O$_7$ localized near a defected area in the spent nuclear fuel. In addition, spectra at the uranium N$_{4,5}$ edges and the cerium M$_{4,5}$ edges are analyzed and discussed, showing preliminarily a Ce$^{3+}$ oxidation state. This is all presented in the context of comparisons with transmission electron microscopy measurements of the same FIB sections.

5:00 AM S.CT03.08.01

**Radiation Damage in Actinide Compounds** William J. Weber; University of Tennessee, United States

The principal sources of radiation damage in actinide compounds are spontaneous fission and alpha-decay, and self-radiation damage from these processes affect microstructural evolution, phase stability, and thermodynamic properties. In general, alpha-decay is the dominant process for most actinides, and because of the long half-lives of the actinides and their daughter products in used nuclear fuel and actinide waste forms, alpha-decay damage is a concern over very long timescales. Alpha decay produces energetic alpha particles (4.5 to 5.5 MeV) and recoil nuclei (70 to 100 keV), which result in both radiation damage and the accumulation of helium. The evolution of radiation damage due to alpha-decay has been studied using short-lived actinides, such as $^{238}$Pu and $^{244}$Cm, in several candidate glasses and ceramics for the immobilization of actinides, and fission tracks from the spontaneous fission of $^{244}$Cm have been observed in crystalline ceramics. Ion beam irradiations have been more frequently employed to study radiation damage in relevant materials due to decreased costs, shorter irradiation timescales and the non-radioactive nature of the irradiated materials. Furthermore, ion irradiations can be performed over a wider range of irradiation conditions to implant helium, study radiation damage kinetics, understand the separate and combined effects of alpha particles and alpha recoils, and benchmark against alpha-decay damage due to short-lived actinides. At ion energies typically used to study alpha-decay damage in actinide compounds, the electronic and nuclear energy losses are both important, and local ionization along the ion path can affect damage production and evolution, and atomic-level simulations have provided insights into these processes. While alpha particles are much less damaging than alpha recoils, the electronic energy loss from the alpha particles can also cause athermal annealing of heavy ion damage (i.e., alpha-recoil damage) that can impact the evolution of radiation damage. Helium implantation studies have shown that the accumulation of helium and heavy ion damage leads to the formation of helium bubbles above a threshold helium concentration. These results have significant implications for interpreting and modeling the radiation response of actinide compounds.

5:30 AM S.CT03.08.02

**Kinetic Response of the δ-phase 239Pu-Ga Alloy Lattice to Self-Irradiation and Thermal Cycling** Alice I. Smith, Franz J. Freibert, Sven C. Vogel, Jianzhong Zhang, Joan E. Siewenie, Scott Richmond and Michael Ramos; Los Alamos National Laboratory, United States

Self-irradiation in plutonium metal at room temperature introduces defect accumulation into the lattice, such as He bubbles and other daughter product impurities, interstitials and vacancies. X-ray diffraction and dilatometry studies have shown that the room temperature self-irradiation of δ-phase Pu-Ga alloys results in swelling of the lattice that saturates after 0.1-0.2 dpa of accumulated lattice damage. For a more complete picture of the poorly understood “aging” processes of defect accumulation and damage evolution δ-phase Pu-Ga alloys, dose, dose rate, thermal history and alloy composition must be considered. This work investigates with time-of-flight neutron diffraction the influence on long-range order of room temperature self-irradiation defects in δ-phase 239Pu-Ga alloys as they influence the lattice throughout a varied history of damage accumulation and thermal cycling.

In-situ time-of-flight neutron diffraction measurements were performed on the High-pressure Preferred Orientation (HIPPO) diffractometer at Lujan Center, Los Alamos Neutron Science Center. Data were collected between room temperature and 35K in an investigation of ambient aging impact on the lattice effects detectable during thermal cycling on the lattice of a δ-phase 239PuGa alloys. Repeated thermal cycling of PuGa alloys immediately after annealing at 450°C exhibits lattice swelling similar to ambient temperature isostructural lattice swelling, but at much shorter time scales. Reported here, the amount of lattice swelling for each cycle decreased in magnitude relative to the time before indicative of a saturating strain due to stress
of local defect evolution to damage accumulation and impact on long-range order. Longer idling times, as observed during the FY16 and FY17 measurements, resulted in incomplete lattice recovery, and a contracted lattice. This study is an attempt at unravelling the complex history dependence of induced stress states and corresponding lattice strain on the kinetic processes of self-irradiation damage and thermal cycling.

Maximizing Property Enhancements in Polymer Nanocomposites via Interfacial Effects—Examples Involving Polymer-Grafted Nanofiller and Optimal Matrix Molecular Weight
John M. Torkelson; Northwestern University, United States

Nanocomposite property enhancements originate substantially from interfacial effects. We focus on two examples of nanocomposite interfacial effects. In Example 1, modification of filler surfaces can improve dispersion and compatibilize the polymer-filler interface, leading to property enhancements relative to nanocomposites containing unmodified filler prepared by conventional melt mixing or solvent blending. For the first time, we isolate the effect of interactions between matrix
polymer and polymer-grafted nanoparticles from dispersion quality, revealing how the interactions affect the properties of polypropylene/halloysite nanotube (PP-HNT) hybrids. PP-HNT nanocomposites with pristine filler or PP-grafted filler were prepared by solid-state shear pulverization, leading to excellent dispersion in both cases. Optimal interactions with PP-grafted nanofiller leads to faster PP crystallization and higher yield strength; in contrast, Young’s modulus is determined by the filler dispersion and not filler modification. In Example 2, for the first time, we have decoupled chain dynamics in nanocomposite interfacial layers from chain dynamics of the matrix in poly(2-vinylpyridine) (P2VP)-silica nanocomposites. The interfacial $T_g$ (glass transition temperature) and the matrix $T_g$ (both associated with $\alpha$-relaxation dynamics) were determined by fluorescence. The interfacial layer $T_g$ is higher than the matrix $T_g$ due to H-bonding between P2VP and hydroxyl groups on the silica surface. At the same filler dispersion, 2.1 kg/mol P2VP matrix polymer leads to much greater $T_g$ enhancements in both the interfacial regions and the matrix relative to the use of 110 kg/mol P2VP. We hypothesize that low molecular weight P2VP preferentially aligns at the filler interface, leading to higher H-bonding density and increased $T_g$.

Molecular Dynamics Simulations Integrated Machine-Learning Study of Bottlebrush Polymers of Different Shapes Soumil Joshi, Samrendra Singh and Sanket A. Deshmukh; Virginia Tech, United States

Thermosensitive bottlebrush polymers (BBPs) are a type of graft copolymers in which thermosensitive polymer side-chains are grafted on a linear polymer backbone. These side-chains can undergo a coil-to-globule conformational change in response to a change in the surrounding temperature. These results in a change in the overall shape of the BBPs because of which they can be used for biomedical applications. Here, we will present the results of our recent coarse-grained (CG) molecular dynamics (MD) simulations study of poly(N-isopropylacrylamide) (PNIPAM; transition temperature= 305 K) BBPs of Worm-like, Cone-like, Dumbbell-like shapes. The CG MD simulations were performed at 300 K (below transition temperature) and 320 K (above transition temperature). The analysis of simulation trajectories showed that the shape of BBPs has significant impact on the conformations of individual side-chains.

3:03 PM *S.CT04.01.11
Design of Interphases for High Dielectric Performance in Polymer-Matrix Nanocomposites Evangelos Manias; The Pennsylvania State University, United States

Polyolefin (polyethylene, and ethylene-propylene-diene (EPDM) elastomers) composites were studied in order to elucidate and quantify the effects of the interfaces with ceramic and carbon nanofillers, and particularly of the interphase contributions on the dielectric properties of the composites. For ceramic nanoparticles, it was shown that the interphase contributions dominate the composites’ dielectric properties, often being antagonistic to the contributions of the ceramic fillers: Ceramic fillers with systematically varied dielectric nature – spanning orders of magnitude in dielectric constants – were studied, and the interphasial contributions effectively overwhelmed the ceramic filler permittivities and dominated the dielectric performance of the composites. For composites containing both ceramic and carbon-black nanofillers, proper design of the interphases is crucial, so as to capitalize on the high effective permittivity provided by the carbon while, at the same time, preventing mobile charges to undertake large lengthscale transport (conductivity) or high dissipation of energy in localized vibrations (dielectric loss); in these systems, a third nanofiller is introduced as a means to control conductivity and minimize losses and E-field breakdown.

3:10 PM *S.CT04.01.12
Hybrid Nanocomposites at the Extreme Limits of Molecular-Scale Confinement with Tailored Internal Interfaces Reinhold H. Dauskardt; Stanford University, United States

We review the state-of-the-art in the molecular design and processing of low density organic-inorganic nanocomposite hybrids at the extreme limits of molecular-scale confinement with tailored internal interface chemistry. We probe the mechanical and thermal properties of nanocomposite hybrids where a stiff inorganic matrix phase confines polymer chains to dimensions far smaller than their bulk radius of gyration. We describe a synthesis strategy which involves tailoring the internal interface chemistry between the matrix and the polymer phase. Tuning the interface allows access to extreme levers of molecular “hyper-confinement” where the confined polymer dynamics and resulting thermal behavior are markedly altered. We demonstrate the strategy with polystyrene and polyimide phases. The infiltration of individual polyimide precursors into a nanoscale porous network where imidization reactions under such confinement increase the molecular backbone stiffness. We find that polyimide oligomers can then undergo crosslinking reactions even in such molecular-scale
confinement, increasing the molecular weight of the organic phase and toughening the nanocomposite through a
confinement-induced energy dissipation mechanism. This work demonstrates that a confinement-induced molecular bridging
mechanism can be extended to thermoset polymers with multifunctional properties, such as excellent thermo-oxidative
stability and high service temperatures (> 350 °C).

3:24 PM *S.CT04.02.01
Interfacial Behavior and Self-Organization of Nano-Inclusions in Vesicles Meenakshi Dutt; Rutgers, The State
University of New Jersey, United States

The distribution of nano-inclusions at the interface or within soft films is determined by multiple key factors. These factors
include the molecular composition, interfacial profile, morphology of the films and the characteristics of the inclusions along
with predominant interactions in the systems. We will discuss the role of these factors on the interfacial behavior of nano-
inclusions on the surface of spherical soft films, or vesicles. Furthermore, we will discuss the organization of the inclusions in
vesicles as a function of nano-inclusion effective chemistry, dimension and concentration. These investigations have been
contingent upon the ability to resolve large spatiotemporal scales. Hence, the studies have required the adoption of coarse-
grained models used in conjunction with mesoscale simulation methods such as Dissipative Particle Dynamics and Molecular
Dynamics. Our observations have the potential to guide the design of composite materials which require precise control on
their characteristics including their shape or the dispersion of the inclusions.

3:31 PM *S.CT04.02.03
Chemical and Topological Design of Bioinspired Polymer Adhesives—Interfacial Molecular Mechanics and
Applications Yiran Li1,2, Peyman Delparastan1, Cody Higginson1, Katerina Matollari1, Jing Cheng1, Haoqi Wang2, Brylee
Tiu1, Kyueui Lee1, Yi Cao1 and Phillip B. Messersmith1,3; 1University of California, Berkeley, United States; 2Nanjing
University, China; 3Lawrence Berkeley National Laboratory, United States

In mussels, the adhesive proteins that are instrumental for attachment to wet surfaces are known to contain high levels of 3,4-
dihydroxy-L-alanine (DOPA), often located adjacent to amino residues such as lysine (Lys). The special synergistic
relationship between catechols and amines is a subject of high interest, not only for understanding native proteins but also for
informing the design of bioinspired polymer systems. Other research groups have shown that catechol and amine functional
groups act synergistically to enhance adhesion at wet surfaces, however reports of catechol-amine interfacial phenomena on a
single molecule level have been limited. In this talk we will describe single molecule force spectroscopy (SMFS)
measurements that are providing new insights into interactions between Lys-DOPA peptides and various surfaces. Molecular
mechanics investigations of catechol and catecholamine polymers are providing new insights into design of novel polymer
adhesives, for example pressure sensitive adhesives and high-strength thermost set adhesives.

Optical Devices From Covalent Functionalized, Redox-Exfoliated, Layered Transition Metal Dichalcogenides Ali
Jawaid, Peter Stevenson, Luke Baldwin, Ruth Pachter and Richard A. Vaia; Air Force Research Laboratory, United States

Exfoliated Transition Metal Dichalcogenides (TMDs, MX2) have attracted considerable attention for infrared optical
elements due to their high refractive index and extreme nonlinearities (e.g. MoS2, TiS2). Recent high-yield, sonication-free,
surfactant-free, exfoliation methods (i.e. Redox Exfoliation) now provide access to oxidatively-resistant and colloidally-
stable dispersions at high TMD content (10% v/v), and in an expanded range of polar solvents (e.g. acetonitrile, acetone,
alcohols). In addition to transforming approaches to nanocomposite fabrication, ink formulation, and film processing, these
characteristics enable direct organic hybridization of Group IV-VI TMDs. For example, Grignards (R-MgBr) are not
accessible via traditional Liquid Phase or Li-Intercalation methods due to their extreme reactivity with labile hydrogens
(water), amides (NMP), and oxygen. However, the availability of Group VI TMDs dispersions in anhydrous THF enables
synthesis of alkyl grafted MoX2, which has zero surface charge, is dispersible in chloroform, and affords subsequent surface-
initiated polymerization, all while retaining optoelectronic monolayer properties. In addition, classic redox intercalation
chemistries can be applied to Group V monolayer dispersions. For example, a primary alkyl amine reacts at 70°C in
anhydrous acetonitrile with semi-metallic, single layer NbS2 via charge transfer from the amine to the half-filled Nb d-
orbitals. The resultant organic-grafted NbS2 is a semiconductor, with enhanced oxidative stability (> 7 days ambient) and
dispersibility in non-polar dichloromethane that allows for ambient handling and processing. Such access to numerous
hybridization approaches will greatly expand the electrical, optical, and chemical property suite of TMDs and enhance the
ability to fabricate device quality films and hetero-structures for optical filters, GRIN optics, and non-linear absorbers.

Organic-Inorganic Interfaces—Insight from First Principles Calculations Ruth Pachter; Air Force Research Laboratory, United States

Elucidating the role of organic ligands that are attached to or incorporated within inorganic nanostructures, for example, at the interface of colloidal nanocrystals or as included in the inorganic framework of two-dimensional hybrid organic-inorganic perovskites, is essential in realizing desired functional properties for applications. However, although general guidelines are provided by experimental explorations, an understanding of the underlying mechanisms for efficient materials development is often lacking. Herein, by employing first principles calculations for the design of materials that exhibit optical tunability characteristics, we first discuss atomically precise quantum dots. We highlight challenges in modeling the structure of semiconductor nanoclusters with organic ligands. In this context, we report on the derivation of a potential energy surface using machine learning that overcomes, in part, some of these limitations, and on the importance of the level of theory applied for accurate prediction of the optical response. In addition, we discuss effects of incorporating large chromophores as the ammonium cation in 2D hybrid organic-inorganic perovskites, which have proven promising for optoelectronic applications. Dependent on the organic moiety type, band alignments indicate variability in quantum-well types for a range of materials we examined, as well as structural distortion. Absorption spectra demonstrate tunability in the optical properties, including enhanced absorption and red-shifts, providing recommendation for the choice of the organic cation and motivation for further synthesis and experimental characterization.

Exploring Structure, Defects and Behavior of Nanotube Assemblies by Multiscale Modeling Boris I. Yakobson; Rice University, United States

Hetero- or homo-interfaces formed by carbon nanostructures of different C hybridizations are ubiquitous in electronic, structural, and energy-functional materials. Understanding how weak interactions and/or chemical bonding at the interface lead to a meso- and macroscopic behavior warrants a multiscale modeling framework. This will be illustrated with the example of carbon nanotube (CNT) fibers. Starting from the energetics and kinetics of various crosslinks (~nm, ~fs) accessible from accurate DFT calculations, we derive scaling relations of their tensile mechanical response from a μm-long coarse-grained model of a CNT bundle. These inter-tube crosslinks can be expected to behave as “hook-and-loop” fasteners, operational in Velcro, which can have the ability to break and reform and thus resist relative motion in a continuous manner. Such a model can incorporate the effect of interface friction due to inter-tube crosslinks or tube-polymer matrix connects, quantitatively evaluate toughness and fatigue processes and look for ways of performance improvement. Same coarse-grained model allows us to also explore the fundamental problem of basic packing defects in the aligned CNT bundles: the ‘twists’ and ‘inclusions’. We show how a finite characteristic size/length \( L \) of such defects emerge as a result of interplay between their intrinsic bending stiffness and the elastic response of the surrounding CNT matrix-crystal, and quantify their energetics scaling. In conjunction with synthesis efforts and novel experimentation, such models are crucial in developing novel carbon nanomaterials.

Molecular Dynamics Modeling of Flattened CNT/Polymer Interfaces Matthew Radue1, William Pisani1, Sagar Patil1, Prathamesh Deshpande1, Prashik Gaikwad1, Swapnil Bamane1, Susanta Ghosh1, Traian Dumitrica2 and Gregory Odegard1; 1Michigan Technological Univ, United States; 2University of Minnesota Twin Cities, United States

Current state-of-the-art carbon fiber reinforced composite materials have become a standard structural material used in the aircraft industry. Their relatively high strength-to-density and stiffness-to-density ratios make them useful for reducing vehicle mass and thus improving fuel efficiency. However, for manned space exploration beyond the moon (deep space), further decreases in mass are needed for fuel efficiency. Thus, increases in the strength-to-density and stiffness-to-density ratios are necessary.

Carbon nanotube (CNT)-reinforced composites can potentially provide the needed reductions in composite laminate mass. Relative to carbon fiber, CNTs can have higher strength and modulus, and can potentially provide a larger surface area for polymer interaction and load transfer. Further, flattened CNTs (fCNTs) can form self-assembled arrays with a higher
packing than round CNTs [1]. Although countless studies have examined CNT/polymer interaction on the molecular level [2], little effort has been devoted to understanding fCNT/polymer interaction.

The objective of this research is to use molecular dynamics (MD) simulation to explore the interaction and load transfer characteristics for a range of different polymer resins with fCNTs. Specifically, the interfacial interaction energy, pull-out frictional force, pull-apart force, and resin wetting contact angles have been predicted. These predictions have been performed for two polyimide systems, two cyanate ester systems, polyurea, and PEEK. The results of these studies will be presented, and the best polymer candidates for these fCNT/polymer composites will be discussed.

Molecular Engineering of Hairy Nanoparticles with Reversible Self-Assembly and Tailored Plasmonic and Luminescence Properties

Zhiqun Lin; Georgia Institute of Technology, United States

Polymer-ligated nanoparticles (NPs) exhibit an exciting variety of physical properties that depend sensitively on the dimension and composition of NPs as well as the surface chemistry of tethered polymer hairs. Herein, we report on a robust nanoreactor strategy for in-situ crafting of monodisperse stable polymer-ligated NPs with well-controlled size and shape as well as tunable plasmonic (e.g., Au) and luminescence (e.g., perovskite MAPbBr3 and CsPbBr3) properties. Central to this strategy is to judiciously design unimolecular amphiphilic star-like block copolymer as nanoreactor for yielding NPs intimately and permanently ligated by polymer hairs. The diameter of polymer-ligated NPs can be precisely tuned by modulating the length of inner hydrophilic block of star-like block copolymers. In the case of Au NPs, the perpetual anchoring of photoresponsive or thermo-responsive polymers on the surface renders the attractive feature of self-assembly and disassembly of NPs on demand by capitalizing on light of different wavelengths or heating/cooling, respectively. Such self-assembly/disassembly process is revealed by tunable surface-plasmon resonance absorption of Au NPs and the reversible transformation of Au NPs between their dispersed and aggregated states. For perovskite NPs, the resulting polymer-ligated MAPbBr3/SiO2 core/shell NPs and CsPbBr3 plain NPs display concurrently a stellar set of significantly improved stabilities (i.e., colloidal stability, chemical composition stability, photostability, water stability), while possessing appealing solution processability, which are unattainable by conventional methods. We envision that the amphiphilic star-like block copolymer nanoreactor strategy may provide a versatile platform for crafting diverse organic-inorganic nanohybrids stably-ligated with polymer of different functionalities (e.g., semiconducting, ferroelectric, photo-responsive, thermal-responsive, or pH-sensitive) for a spectrum of applications in bioimaging, biosensors, photonic materials and devices, perovskite-based LEDs, lasers, high-energy ionization radiation detections, multiphoton emission, and scintillators.

Molecular Simulation and Theory Studies Linking Design of Polymer Grafted Nanoparticles to the Polymer Nanocomposite Morphology

Arthi Jayaraman; University of Delaware, United States

In this talk I will present our recent work studying polymer nanocomposites (PNCs) using molecular dynamics (MD) simulations and Polymer Reference Interaction Site Model (PRISM) theory calculations with coarse-grained (CG) models. Specifically, we are interested in linking molecular design of PNCs comprised of grafted nanoparticles in a polymer matrix to their morphology. In this talk I will focus our work on the impact of strength of graft-matrix attraction on interpenetration of matrix and graft chains (known as grafted layer wetting) and dispersion/aggregation of grafted particles in matrix. Previously
for PNCs with attractive graft-matrix interactions, we had shown that wetting/dewetting and dispersion/aggregation are two distinct phase transitions, the former being a continuous transition and the latter being a first-order transition as a function of graft-matrix interaction or temperature. Recently, we found that as the strength of graft-matrix attraction increases, we can also tune the effective size and the hardness of the polymer grafted particle in the PNC. As the attraction between the graft and matrix chains increases, the graft polymer chains extend to make favorable graft-matrix contacts and increase the grafted layer wetting by matrix chains. This leads to larger and ‘harder’ grafted particles compared to analogous fillers with purely entropic (athermal) graft-matrix interactions. Due to the increasing size and hardness of grafted particles with increasing graft-matrix attraction, the PNC structure changes from an aggregated/dispersed morphology governed by entropic driving forces at athermal graft-matrix interaction to a dispersed morphology due to favorable weak graft-matrix attraction, and ultimately, to a correlated fluid of hard grafted particles at stronger graft-matrix attraction. We see these trends in PNCs with high (densely grafted) and low grafting density, and with equal graft and matrix chain lengths as well as cases where the matrix chain lengths are greater than the graft chain lengths.

Advances in Using Surface-Initiated Atom Transfer Radical Polymerization and Its Application to Tailoring Particle Interactions and the Design of Functional Materials
Michael R. Bockstaller; Carnegie Mellon Univ, United States

Surface Initiated Atom Transfer Radical Polymerization (SI-ATRP) in its various modifications has emerged as a versatile toolbox to control and tailor the properties and interactions of interfaces and to enable the synthesis of hybrid materials with unprecedented property combinations. The resulting materials have attracted interest not only because the high-level structural control of the architecture of polymer-tethered surfaces enables tailoring of the interactions, microstructure and properties of particulate-based materials but also because the confinement of chains on surfaces alters the mechanism of termination reactions that limit conventional polymerization processes.

This presentation will review recent examples of the application of SI-ATRP for the synthesis of functional polymer materials. Examples to be covered include the synthesis of ultra-high molecular weight polymers, materials for optical applications as well as thermal interface materials. Recent examples of the interplay between phononic and photonic properties in brush particle-based materials will be shown to illustrate how the subtle control of polymer chains at interfaces can instigate novel physical properties in hybrid materials that cannot be realized in ‘classical’ composite materials that are fabricated by mixing of particle and polymer constituents. This will provide the basis for a discussion of ‘guidelines’ for the fabrication of novel functional materials that harness ‘chemical confinement’ of polymer chains.

Nano Materials Hybridization and Its Interfaces for Simultaneous Multifunctionality
Ajit K. Roy; Air Force Research Laboratory, United States

For optimal materials usage in numerous defense applications, as well as in aerospace systems, materials are to operate in episodes requiring simultaneous multifunctionality. For example, electronics in munitions and high temperature sensor modules are expected to retain its expected electrical, thermal, and mechanical properties or attributes even in extremely high strain gradient operation. Similarly, in hypersonics coatings, high temperature material oxidation stability plus tailored thermal conductivity are needed in extreme high temperature operation. In this presentation, materials design approaches for simultaneous exhibit of selected multifunctionality will be discussed. Further, such desired multifunctionality is expected to be more optimally feasible by taking the materials design to small scale (say, at atomic level) and then linking that to bulk materials performance. Also, materials hybridization at small (atomic or molecular) scale and optimizing the associated heterostructure phases significantly opens up materials performance domain and its multifunctionality. Examples of several
computational tools (atomistic, Mesa, continuum scale - ab initiation, NEGF, MD, MD Wave Packets, Tight Binding MD, Molecular Mechanics) will be illustrated for tailoring materials functionalities (thermal, electrical, structural) in the material compositional design, along with a few design cases (thermal interface, nano porous carbon, strain-resilient electronics).

8:10 AM *S.CT04.02.04
Biomimetic Nanocomposites for Energy Technologies and Meta Optics Nicholas A. Kotov; University of Michigan, United States

Materials with difficult-to-attain combination of multiple properties - mechanical, electrical, chemical, optical, thermal, and transport, – represent the quintessential bottleneck for nearly all modern technologies. Nanocomposites with molecular, nano-, meso-, and microscale levels of structural engineering can provide such property combinations, while intrinsic ability of nanoscale components to self-assemble make them suitable for simplicity of synthesis.

Biomimetic nanocomposites exemplified by a variety of nanostructured nacre-like materials provide a generalized approach to engineer materials with multiple difficult-to-attain properties. As the continuation of this research, we learn that the unique mechanics of tooth enamel can be replicated combining out-of-plane nanoscale columns with molecular precision of layer-by-layer (LBL) assembly between them. As a result of that, these composites reveal remarkably high vibrational damping unusual for stiff materials that imparts them resilience to aging.

The novel type of biomimetic nanocomposites are those based on aramid nanofibers (ANFs). They spontaneously assemble into three-dimensional percolating networks reminiscent of cartilage. The nanoscale structure of ANF composites reveal nanoscale porosity that can be controlled by nanofiber branching. The latest results from multiple groups demonstrate that ANF composites resolve some of the essential property bottlenecks for ion-selective membranes, dendrite-resistant electrolytes, and structural batteries.

One of the emerging fields for biomimetic nanocomposites are optical devices. The high strain and strong polarization rotation make possible metaoptical devices with wide-angle diffraction gratings for LIDARs and highly efficient quarter wave plates for THz scanners. Both devices can be used for machine vision and biomaterials imaging.

8:17 AM *S.CT04.02.05
Colour with a Twist—Cellulose Photonic Materials with Tailored Visual Appearance Silvia Vignolini; University of Cambridge, United Kingdom

Plant-based polysaccharides such as cellulose and its derivatives are receiving increasing interest in a large variety of applications because they represent an environmentally friendly alternative to plastic. Many of them are commonly used in diverse industrial applications, such as food additives and for biomedical devices due to their non-toxic and water-soluble nature. Moreover, the self-assembly nature and responsiveness of cellulosic bio-polymers makes them also extremely attractive for smart photonic applications including sensing. Among various types of cellulose and its derivatives, hydroxypropyl cellulose (HPC) encompasses all these desirable properties.

Hydroxypropyl cellulose is a liquid crystal polymer, which can form a cholesteric liquid-crystalline phase allowing Bragg-like reflection. The reflected colours can be simply controlled by changing the nature of the solvent, concentration, temperature. Recently, we demonstrated for the first time that a simple aqueous solution of HPC can be used as a photonic strain sensor that displays the applied strain by shifting its colour.

In this seminar, I will introduce how such properties can be enhanced to create a solid-state film with desired optical appearance.

Enhanced Multifunctional Nanocomposites with Two-Dimensional Transition Metal Carbides/Nitrides (MXenes) Christine B. Hatter and Yury Gogotsi; Drexel University, United States

Composites offer a wide variety of uses in aerospace, automotive industry, additive manufacturing, and energy storage applications. Discovered in 2011, MXenes have emerged as a new class of two dimensional (2D) materials consisting of transition metal carbides and nitrides. Synthesized MXenes have rich chemistry and 2D morphology offering a combination of high metallic conductivity and hydrophilicity for easy solution processing. Additionally, MXenes have been shown to have excellent mechanical properties with Young’s modulus of 330 GPa, surpassing both GO and rGO making it one of the strongest solution-processable 2D materials. Thus, they can improve mechanical and thermal stability as well as electrical
conductivity of polymers. They can also reinforce ceramics and metals.

The most commonly studied MXene, titanium carbide (Ti3C2), has been combined with various polymer systems producing new multifunctional nanocomposites. When introduced into thermoplastics like PVA, improved mechanical properties were observed at 10 wt% polymer loading with a 34% increase in tensile strength compared to pure Ti3C2 films. Additional studies have shown electrical properties can be successfully transferred to the polymer composite extending its use to electrodes in energy storage systems as well as electromagnetic interference shielding for future electronics. In addition to simple direct mixing with polymers, Ti3C2 MXene has also been incorporated into more complex polymer fibers for integration into textile applications. A recent study on electrospinning of MXene-PAN nanofibers showed MXene content could be increased up to 35 wt% and retain high areal capacitance three times that of pure PAN nanofibers. This presentation will provide an overview of the current MXene-reinforced composites field, including ceramic- and metal-matrix, and the various applications.

Interfacial Dynamics of Nanoconfined Molecules and Macromolecules Younjin Min; University of California, Riverside, United States

The properties of fluids, when confined at nanometer scales, differ greatly from their bulk properties and are generally dominated by interfacial effects. In this interfacial region, the nature of the wall–fluid intermolecular interactions can have a significant effect on the fluids, introducing symmetry breaking, structural frustration and confinement-induced entropy loss into nanoscale interactions under confinement. In this presentation, several examples regarding how different degrees of nanoconfinement alter the structural organization and interfacial properties of soft matter ranging from non-biological (e.g. ionic liquids and silica colloidal suspensions) to biological ones (e.g. biopolymer solutions) will be introduced. This talk will particularly focus on describing the mechanisms of how biomacromolecules such as silk fibroin (SF) proteins self-assemble into hierarchical structures at the multiple-length levels in greater details. The presentation will conclude with some perspectives on new fundamental insights for rational design of SF-based materials with desired interfacial features in use of their fabricating superior functional materials and devices.

8:38 AM *S.CT04.05.02
Understanding Self-Assembly of Functional Nanostructures with Actuation Capabilities George C. Schatz; Northwestern University, United States

Molecular self-assembly involves the use of hydrogen bonds and other noncovalent interactions between molecules to create supramolecular structures. A goal of theory is to be able to predict and understand what structures will arise for any given set of conditions, and how the self-assembly can be directed so as to produce useful functional structures. In this talk I will describe recent studies in my group in collaboration with the Stupp and Mirkin groups at Northwestern, and with others, with the goal of making nanostructured materials with broad applications including actuation with various stimuli. One area of interest concerns studies of peptide amphiphile self-assembly to produce cylindrical micelles and ultimately fiber materials that can be used for applications in biomedicine and for making materials that can be photoactivated for robotic functions. Here we have developed all-atom and coarse-grained models, and specialized molecular dynamics methods, that are capable of describing assembly into fibers, leading to an understanding of biological functions and photoactuation. In a second direction we are interested in the coupling of self-assembly chemistry involving DNA attached silver and gold nanoparticles to create a new generation of bottom-up nanomaterials of interest for sensing and optical devices. Here we show both coarse-grained and all-atom approaches to the assembly, and how these can be used to understand the formation of plasmonic array structures, including recent studies aimed at understanding programmability of dynamic optical properties.

Robust Organized Composites from Synthetic Nanostructures and Polysaccharide Materials for Nanophotonic Applications Vladimir Tsukruk; Georgia Institute of Technology, United States
We summarize recent results from our research group on assembling of robust functional synthetic and biocomposite materials from orthogonal nanoscale components for advanced nanophotonic applications. For flexible biophotonic materials, uniformly aligned chiral structures is critically important to be stabilized to improve mechanical performance without compromising controlled helical morphologies and propagating phase separation. In this aspect, we discuss mixed amorphous polysaccharide polymers and nanocrystals in terms of their hierarchical organization, intercalated structures, ability to form periodic patterned surfaces, and resulting chiral optical properties. Furthermore, we consider how highly emissive semiconducting and carbon quantum dots can be integrated into synthetic polymer matrices, chiral biomolecular structures, and survive microfabrication/printing processing for arresting quenching trends, stimulating bright patterned emission, and prompting directed lasing phenomena.

Effect of the Interface Topology on the Mechanical Performance of Hybrid Carbon Fiber Carbon Nanotubes Composite Marwan S. Al-Haik1, Suma Ayyagari1, Ren Yixin2 and Dhriti Nepal2; 1Embry-Riddle Aeronautical Univ, United States; 2Air Force Research Laboratory, United States

This study elucidates the effects of interface tailoring in carbon fiber reinforced polymer (CFRP)s composites with surface grown carbon nanotubes (CNTs) on the quasistatic, rheological, and viscoplastic performance of CFRPs. Carbon nanotubes were grown on the surface of PAN-based carbon fibers using a non-destructive technique to enhance the adhesion between the fibers and the polymeric matrices. The topology of the growth was controlled by patterning the catalyst deposition via physical vapor deposition. Quasistatic tensile tests were utilized to probe the effect of the CNTs growth topology on the strength and stiffness of the hybrid composites. The rheological behavior of the composites was elucidated using dynamic mechanical analysis (DMA). The viscoplastic behavior was investigated using creep and load relaxation tests at different thermomechanical environments. The patterned growth of the CNTs improves both the mechanical and rheological performance of the composite. This study demonstrates “interlocking” mechanism improves adhesion due to the enhanced surface area of the interface between the hybrid fibers and the epoxy matrix. Furthermore, results show that tailoring the interface with patterned grown CNTs reduces the stress relaxation and hinders the steady-state creep strain rate.

5:45 AM S.CT04.01.04
Mechanical Property Enhancements in Assemblies of Colloidal Nanocrystals and Magic-Sized-Clutsters via Ligand
Exchange Processes Zhongyong Wang and Robert Wang; Arizona State University, United States

Assemblies of colloidal nanocrystals and magic-sized-clusters (MSCs) are widely used in a variety of applications due to their unique electronic, optical and magnetic properties. However, these materials show a surprisingly limited range of elastic moduli (~0.5-5 GPa) and hardnesses (50-500 MPa), which presents a challenge for applications in which mechanical robustness is critical. These poor mechanical properties originate from the organic ligands during nanocrystal synthesis that result in weak interparticle interactions in particle assemblies. In this work, we conduct ligand strategies to significantly improve the mechanical properties of colloidal nanocrystal solids. We also report on our ongoing efforts to extrapolate these strategies to assemblies of MSCs.

Our preliminary result shows that inorganically linked nanocrystal solids possess significantly increased elastic moduli and hardness. More specifically, in the case of 3.5 nm CdSe nanocrystal material system, we demonstrate an elastic moduli and hardness increase by a factor of 50 once the native long oleic acid ligand is substituted with a few atomic layers of SnS$_2$ phase. Ligand exchange is carried out through a solution phase ligand exchange and is confirmed through a combination of FTIR, TEM&EDS, and nanoindentation experiments. The nanoindentation experiments demonstrates that the elastic moduli/hardness of 3.5 nm CdSe nanocrystal solid increase from 0.43GPa/34MPa to 30GPa/1.6GPa once native long oleic acid ligand is replaced with a few atomic layers of SnS$_2$ phase.

This observed mechanical reinforcement is due to greatly enhanced mechanical coupling between the neighboring nanocrystals. First of all, the covalent Sn-S bond is much stronger than the van der waals interaction between organic molecules. Second, inorganic ligands occupy much smaller spacing as compared long oleic acid molecules, which suggests enhanced van der waals interaction and electrostatic interaction between the neighboring nanocrystals. In order to quantitatively understand the underlying mechanism, we performed molecular dynamics (MD) simulations. These simulations also allow us to predict other mechanical properties (bending moduli, fracture toughness etc) that are hard to measure directly on inorganically linked nanocrystal solids.

The similarities between colloidal nanocrystals and MSCs suggest it may be possible to extrapolate these ligand exchange strategies to MSCs. MSCs have the advantage of being perfectly monodisperse as well as small enough for full-fidelity density functional theory simulations. This opens possibilities for an in-depth understanding of the mechanical properties enhancements afforded by ligand exchange strategies.

In Situ Characterization of Dynamic Mechanical Response and Adiabatic Shear Band Evolution in AZ31B Magnesium Alloys During High Strain Rate Impact Using 3D-Digital Image Correlation Technique Francis Tetteh and Solomon Boakye-Yiadom; York University, Canada

The deployment of Magnesium (Mg) alloys have increased significantly in the automotive, aerospace and defense industries due to their lightweight structural integrity. In structural applications, these materials components are exposed to a wide range of strain rates such as explosive forming, high speed impact and shock loadings. These alloy components are placed in extreme loading environments where high strain rates are commonly achieved. Therefore, the evolution of failure mechanisms from strain localization and formation of adiabatic Shear Bands (ASBs) and the mechanical behavior at high strain rates is of desirable interest by the aerospace and automotive industries. However, studies on how failure emanate from ASBs formation to crack initiation and propagation in these materials with regard to their mechanical responses under high strain rates such as shock loadings and impact are limited. Deformation anddamage accumulation in Mg alloys at high strain rate loading conditions such as impact are not fully understood. Thus, the correlation between the accuracy of the reported mechanical data and microstructural features that leads to the credence of failure mechanisms within Mg is not well understood. It is therefore critical to extend the understanding of the mechanism of failure of Mg at high strain rates of loadings by exploiting other techniques. In this work, the dynamic mechanical impact response and ASBs nucleation of heat
treated AZ31B Mg alloys at different strain rates and impact momentums are characterized in-situ during impact at room temperature using the Direct Impact Hopkinson Pressure Bar (DIHPB) coupled with an in-situ 3D Digital Image correlation (DIC) and high speed and high resolution thermal imaging techniques. DIC provides an independent measurement of surface strains directly on test specimen during deformation to monitor stain evolution and strain localizations. Both the microstructure of the initial un-deformed and post deformed specimen were characterized. It is found that the flow stress increased gradually to (~50 %) with increasing strain rates and impact momentums and the AZ31B Mg exhibits strain rate sensitivity at dynamic loadings. This is due to an increasing selective and intensive grain refinement evolving at grain boundaries (GBs) which increases strain hardening under dynamic compression. Strain to failure decreases at higher impact momentum. Evaluation of DIC results indicated that strain occurrence is linear at the onset of deformation but becomes heterogeneous at later stage of deformation with multiple nucleation sites of strain localization leading to ASB at ~80% of the specimen length after ~340 us of deformation. Region of peak nonlinearity of maximum strain concentration leads to ASB formation with characteristic fine grains, voids and crack initiation at grain boundaries observed at the extreme end of specimen using DIC with ~22 °C temperature rise observed with insitu high speed and high resolution thermal imaging camera. The temperature rise is however, lower with respect to the homologous temperature of Mg and hence higher degree of strain hardening behaviour is induced after deformation. Sub grains ~0.3um sizes is found with disintegrated precipitate in voids at ASBs regions and mostly at GBs. In addition, deformation twinning frequency increases(~30 %) with broader thickness at higher impact momentum with disintegrated precipitates on micro-twins boundaries and GBs during plastic deformation at ASB surroundings. Meanwhile at lower impact momentum, freckled pattern selective grain refinement is observed. These results suggest that ASB forms in AZ31B Mg alloy despite its brittle nature that leads to crack initiation and ultimate failure under high strain rates and large strains of deformation and can be used to extend the understanding of the mechanism of failure in Mg alloys.

6:15 AM S.CT04.01.07
Quantitative Analysis of Twinning Occurring During Plastic Deformation of Cobalt Mayerling Martinez1,2, Eric Hug1, Peter Minárik2, František Chmelík2, Michal Knapek2 and Patrik Dobron2; 1CRISMAT/ENSICAEN/CNRS, France; 2Charles University, Czechia

Plasticity in most metallic materials depends essentially on dislocation glide. Metals, which display a wealth of gliding systems, are those having a face centered cubic lattice. On the other hand, metals with hexagonal close packed (hcp) structure, like Mg, or Ti, have a complex deformation behavior [1-2]. In these materials, both dislocation glide and twinning are fundamental mechanisms of plastic deformation. Another hcp metal, cobalt, with distinctly lower stacking fault energy, has been so far studied much less.

The straining mechanisms of cobalt, as shown by acoustic emission experiments and electron microscopy observations, is characterized by two principal stages: the first stage of work hardening is driven by planar glide of dislocations, while twinning is the most active deformation mechanism in the second stage [3]. Important insight into twinning has been recently provided by advanced electron microscopy techniques, such as scanning electron microscopy coupled with the electron backscatter diffraction technique, which is a powerful tool to capture the twinning process appearing in different stages of plastic straining [4]. In the present work, polycrystalline cobalt was monotonously strained in tensile test up to a plastic strain corresponding to the second stage of work hardening. The electron backscattered diffraction technique was used to acquire a large quantity of data, which allows for statistical analyses. The relationships between grain orientation, grain size, twin volume fraction, twinning modes, and twin variants have been established.

The results show that the principal twin mode is the {10-12} tension type and that multiple twin variants of this mode can be present inside the same grain. The occurrence of a specific twin variant in a grain is related to the local strain accommodation within this grain; consequently, the higher frequency of the occurrence corresponds to the variants with larger misorientations between them. The statistical analysis shows that the grain orientation has a more pronounced impact on twinning characteristics than the grain size. The Schmid Factor analysis adapted to twinning is used to give a general view of the cobalt behavior, taking into account the significance of grains oriented favorably for twin formation. This approach may also explain cases, in which grains are not favorably oriented, twinning is not expected, but it occurs in reality. The results will be compared with the behavior of other hcp metals.

Tensile tests on Cu/Zr-based metallic-glass (MG) micro-wires show observable first yield point, followed by shear fracture on further straining. Microscopy examination reveals discrete shear bands decorating the free surfaces of yielded and fractured MG micro-wires. Both the first-yield and the fracture stress scatter statistically as expected, but surprisingly, they do not exhibit any significant dependence on the wire length.

Fundamentally, while it has been widely accepted that glass plasticity takes place via shear transformation zones (STZs), the knowledge gap between such atomic-sized STZs and the above-mentioned micro/macroscopic plasticity phenomena remains huge. In this work, molecular dynamics (MD) simulations were carried out to delineate the detailed process by which shear bands form from discrete STZs. The results show that the STZs have an increasing tendency to emerge and operate close to one another in a correlated manner along the strain path. This process leads to shear localization in the form of shear bands. An analytical model is then proposed to relate the probability of the successive operation of discrete STZs, to their nucleation density. The model predicts that, as prior shear events triggers the emergence of new STZs, successive occurrence of discrete shear events speeds up rapidly to an asymptotic state which is exactly the condition of shear localization.

Finally, the MD simulations also indicate that the first observable yield point cannot be due to the emergence and operation of one single STZ. Instead, yield or fracture is controlled by the average or extreme behavior of many STZs or shear bands operated in different locations in the wire, which explains length independence of the MG wire strength – a fact also observed in other glass wires.

**The Stochastics of Strain Localization in Metallic-Glass Microwires**

Alfonso H. Ngan\(^1\), Kefu Gan\(^1\), S.S. Jiang\(^2\), H.B.C. Yin\(^2\) and Yongjiang Huang\(^2\); \(^1\)University of Hong Kong, Hong Kong; \(^2\)Harbin Institute of Technology, China

Nanocomposite property enhancements originate substantially from interfacial effects. We focus on two examples of nanocomposite interfacial effects. In Example 1, modification of filler surfaces can improve dispersion and compatibilize the polymer-filler interface, leading to property enhancements relative to nanocomposites containing unmodified filler prepared by conventional melt mixing or solvent blending. For the first time, we isolate the effect of interactions between matrix polymer and polymer-grafted nanoparticles from dispersion quality, revealing how the interactions affect the properties of polypropylene/halloysite nanotube (PP-HNT) hybrids. PP-HNT nanocomposites with pristine filler or PP-grafted filler were prepared by solid-state shear pulverization, leading to excellent dispersion in both cases. Optimal interactions with PP-grafted nanofiller leads to faster PP crystallization and higher yield strength; in contrast, Young’s modulus is determined by the filler density. The model predicts that, as prior shear events triggers the emergence of new STZs, successive occurrence of discrete shear events speeds up rapidly to an asymptotic state which is exactly the condition of shear localization.

Finally, the MD simulations also indicate that the first observable yield point cannot be due to the emergence and operation of one single STZ. Instead, yield or fracture is controlled by the average or extreme behavior of many STZs or shear bands operated in different locations in the wire, which explains length independence of the MG wire strength – a fact also observed in other glass wires.

**Maximizing Property Enhancements in Polymer Nanocomposites via Interfacial Effects—Examples Involving Polymer-Grafted Nanofiller and Optimal Matrix Molecular Weight**

John M. Torkelson; Northwestern University, United States

Nanocomposite property enhancements originate substantially from interfacial effects. We focus on two examples of nanocomposite interfacial effects. In Example 1, modification of filler surfaces can improve dispersion and compatibilize the polymer-filler interface, leading to property enhancements relative to nanocomposites containing unmodified filler prepared by conventional melt mixing or solvent blending. For the first time, we isolate the effect of interactions between matrix polymer and polymer-grafted nanoparticles from dispersion quality, revealing how the interactions affect the properties of polypropylene/halloysite nanotube (PP-HNT) hybrids. PP-HNT nanocomposites with pristine filler or PP-grafted filler were prepared by solid-state shear pulverization, leading to excellent dispersion in both cases. Optimal interactions with PP-grafted nanofiller leads to faster PP crystallization and higher yield strength; in contrast, Young’s modulus is determined by the filler dispersion and not filler modification. In Example 2, for the first time, we have decoupled chain dynamics in nanocomposite interfacial layers from chain dynamics of the matrix in poly(2-vinylpyridine) (P2VP)-silica nanocomposites. The interfacial \(T_g\) (glass transition temperature) and the matrix \(T_g\) (both associated with \(\alpha\)-relaxation dynamics) were determined by fluorescence. The interfacial layer \(T_g\) is higher than the matrix \(T_g\) due to H-bonding between P2VP and hydroxyl groups on the silica surface. At the same filler dispersion, 2.1 kg/mol P2VP matrix polymer leads to much greater \(T_g\) enhancements in both the interfacial regions and the matrix relative to the use of 110 kg/mol P2VP. We hypothesize that low molecular weight P2VP preferentially aligns at the filler interface, leading to higher H-bonding density and increased \(T_g\).

**Computational Study of MOF-Polymer Interface**

Abhishek Sose, Samrendra Singh and Sanket A. Deshmukh; Virginia Tech, United States

Gas separations via selective transport in polymer membranes are dominating the membrane technologies due to their ease of processing and inexpensive production. However, these polymer membranes fall short of selectivity and permeability. Due to their exceptional structural features, metal organic frameworks (MOFs) have emerged as promising fillers to enhance the performance of a polymer membrane. In these MOF-polymer mixed matrix membranes (MMMs), the polymer-MOF interface is known to play an important role in determining the gas separation mechanism. However, understanding the structure of this MOF-polymer interface and the factors that govern their compatibility using existing experimental characterization methods is very challenging. In this research, we have performed all-atom molecular dynamics (MD) simulation of a model polymer-MOF MMMs with IRMOF-1 and 5 different polymers. Simulation trajectories were analyzed.
to understand the effect of different functional groups and rigidity of polymers on the structure of the MOF-polymer interface. Results of this study can be useful for creating MMMs with IRMOF for separation applications.

7:30 AM *S.CT04.01.11
Design of Interphases for High Dielectric Performance in Polymer-Matrix Nanocomposites Evangelos Manias; The Pennsylvania State University, United States

Polyolefin (polyethylene, and ethylene-propylene-diene (EPDM) elastomers) composites were studied in order to elucidate and quantify the effects of the interfaces with ceramic and carbon nanofillers, and particularly of the interphase contributions on the dielectric properties of the composites. For ceramic nanoparticles, it was shown that the interphase contributions dominate the composites’ dielectric properties, often being antagonistic to the contributions of the ceramic fillers: Ceramic fillers with systematically varied dielectric nature—spanning orders of magnitude in dielectric constants—were studied, and the interphasic contributions effectively overwhelmed the ceramic filler permittivities and dominated the dielectric performance of the composites. For composites containing both ceramic and carbon-black nanofillers, proper design of the interphases is crucial, so as to capitalize on the high effective permittivity provided by the carbon while, at the same time, preventing mobile charges to undertake large lengthscale transport (conductivity) or high dissipation of energy in localized vibrations (dielectric loss); in these systems, a third nanofiller is introduced as a means to control conductivity and minimize losses and E-field breakdown.

8:00 AM *S.CT04.01.12
Hybrid Nanocomposites at the Extreme Limits of Molecular-Scale Confinement with Tailored Internal Interfaces Reinhold H. Dauskardt; Stanford University, United States

We review the state-of-the-art in the molecular design and processing of low density organic-inorganic nanocomposite hybrids at the extreme limits of molecular-scale confinement with tailored internal interface chemistry. We probe the mechanical and thermal properties of nanocomposite hybrids where a stiff inorganic matrix phase confines polymer chains to dimensions far smaller than their bulk radius of gyration. We describe a synthesis strategy which involves tailoring the internal interface chemistry between the matrix and the polymer phase. Tuning the interface allows access to extreme levers of molecular “hyper-confinement” where the confined polymer dynamics and resulting thermal behavior are markedly altered. We demonstrate the strategy with polystyrene and polyimide phases. The infiltration of individual polyimide precursors into a nanoscale porous network where imidization reactions under such confinement increase the molecular backbone stiffness. We find that polyimide oligomers can then undergo crosslinking reactions even in such molecular-scale confinement, increasing the molecular weight of the organic phase and toughening the nanocomposite through a confinement-induced energy dissipation mechanism. This work demonstrates that a confinement-induced molecular bridging mechanism can be extended to thermoset polymers with multifunctional properties, such as excellent thermo-oxidative stability and high service temperatures (> 350 °C).

8:30 AM S.CT04.01.14
Identification of the Vitrimer Transesterification Temperature (Tv): Implications for Nanocomposites Amber M. Hubbard, Yixin Ren, Shusil Bhusal, Gary Kedziora, Vikas Varshney, Ajit K. Roy and Dhriti Nepal; Air Force Research Laboratory, United States

Vitrimer materials have gained increasing attention since their introduction in 2011, due to their recyclable and dynamic nature. In addition to a traditional glass transition temperature (T_g), vitrimers have a second vitrimer transesterification temperature (T_v) above which dynamic covalent bonds allow for rapid stress relaxation, self-healing, and shape reprogramming. However, in order to take advantage of these unique properties, it is crucial to correctly identify the T_v and understand the impact of various experimental parameters (e.g., heating and applied force) upon its identification. Herein, we present a unique method to identify the T_v and discuss the impact of catalyst concentration upon the T_v. In addition, we present vitrimer nanocomposites with a variety of nanofillers (e.g., graphene and gold-coated graphene nanoplatelets) and identify the impact of nanofiller addition upon the composite T_v. By embedding graphene nanofillers into the vitrimer matrix, the resulting composite demonstrates increased mechanical properties as well as a photothermal response when exposed to near-infrared (NIR) light. These photothermally activated composites exhibit shape memory and shape reconfigurability for actuators and self-healing behaviors.

8:45 AM S.CT04.01.15
Nano Materials Hybridization and Its Interfaces for Simulteneous Multifunctionality Ajit K. Roy; Air Force Research Laboratory, United States
For optimal materials usage in numerous defense applications, as well as in aerospace systems, materials are to operate in episodes requiring simultaneous multifunctionality. For example, electronics in munitions and high temperature sensor modules are expected to retain its expected electrical, thermal, and mechanical properties or attributes even in extremely high strain gradient operation. Similarly, in hypersonics coatings, high temperature material oxidation stability plus tailored thermal conductivity are needed in extreme high temperature operation. In this presentation, materials design approaches for simultaneous exhibit of selected multifunctionality will be discussed. Further, such desired multifunctionality is expected to be more optimally feasible by taking the materials design to small scale (say, at atomic level) and then linking that to bulk materials performance. Also, materials hybridization at small (atomic or molecular) scale and optimizing the associated heterostructure phases significantly opens up materials performance domain and its multifunctionality. Examples of several computational tools (atomistic, Mesa, continuum scale - ab initiation, NEGF, MD, MD Wave Packets, Tight Binding MD, Molecular Mechanics) will be illustrated for tailoring materials functionalities (thermal, electrical, structural) in the material compositional design, along with a few design cases (thermal interface, nano porous carbon, strain-resilient electronics).

Interfacial Behavior and Self-Organization of Nano-Inclusions in Vesicles Meenakshi Dutt; Rutgers, The State University of New Jersey, United States

The distribution of nano-inclusions at the interface or within soft films is determined by multiple key factors. These factors include the molecular composition, interfacial profile, morphology of the films and the characteristics of the inclusions along with predominant interactions in the systems. We will discuss the role of these factors on the interfacial behavior of nano-inclusions on the surface of spherical soft films, or vesicles. Furthermore, we will discuss the organization of the inclusions in vesicles as a function of nano-inclusion effective chemistry, dimension and concentration. These investigations have been contingent upon the ability to resolve large spatiotemporal scales. Hence, the studies have required the adoption of coarse-grained models used in conjunction with mesoscale simulation methods such as Dissipative Particle Dynamics and Molecular Dynamics. Our observations have the potential to guide the design of composite materials which require precise control on their characteristics including their shape or the dispersion of the inclusions.

5:30 AM *S.CT04.02.02
Interfacial Dynamics of Nanoconfined Molecules and Macromolecules Younjin Min; University of California, Riverside, United States

The properties of fluids, when confined at nanometer scales, differ greatly from their bulk properties and are generally dominated by interfacial effects. In this interfacial region, the nature of the wall–fluid intermolecular interactions can have a significant effect on the fluids, introducing symmetry breaking, structural frustration and confinement-induced entropy loss into nanoscale interactions under confinement. In this presentation, several examples regarding how different degrees of nanoconfinement alter the structural organization and interfacial properties of soft matter ranging from non-biological (e.g. ionic liquids and silica colloidal suspensions) to biological ones (e.g. biopolymer solutions) will be introduced. This talk will particularly focus on describing the mechanisms of how biomacromolecules such as silk fibroin (SF) proteins self-assemble into hierarchical structures at the multiple-length levels in greater details. The presentation will conclude with some perspectives on new fundamental insights for rational design of SF-based materials with desired interfacial features in use of their fabricating superior functional materials and devices.

6:00 AM *S.CT04.02.03
Chemical and Topological Design of Bioinspired Polymer Adhesives—Interfacial Molecular Mechanics and Applications Yiran Li1,2, Peyman Delparastan1, Cody Higginson1, Katerina Malollari1, Jing Cheng1, Haoqi Wang2, Brylee Tiu1, Kyueui Lee1, Yi Cao3 and Phillip B. Messersmith1,2; 1University of California, Berkeley, United States; 2Nanjing University, China; 3Lawrence Berkeley National Laboratory, United States
In mussels, the adhesive proteins that are instrumental for attachment to wet surfaces are known to contain high levels of 3,4-dihydroxy-L-alanine (DOPA), often located adjacent to amino residues such as lysine (Lys). The special synergistic relationship between catechols and amines is a subject of high interest, not only for understanding native proteins but also for informing the design of bioinspired polymer systems. Other research groups have shown that catechol and amine functional groups act synergistically to enhance adhesion at wet surfaces, however reports of catechol-amine interfacial phenomena on a single molecule level have been limited. In this talk we will describe single molecule force spectroscopy (SMFS) measurements that are providing new insights into interactions between Lys-DOPA peptides and various surfaces. Molecular mechanics investigations of catechol and catecholamine polymers are providing new insights into design of novel polymer adhesives, for example pressure sensitive adhesives and high-strength thermoset adhesives.

6:30 AM *S.CT04.02.04
Biomimetic Nanocomposites for Energy Technologies and Meta Optics Nicholas A. Kotov; University of Michigan, United States

Materials with difficult-to-attain combination of multiple properties - mechanical, electrical, chemical, optical, thermal, and transport – represent the quintessential bottleneck for nearly all modern technologies. Nanocomposites with molecular, nano-, meso-, and microscale levels of structural engineering can provide such property combinations, while intrinsic ability of nanoscale components to self-assemble make them suitable for simplicity of synthesis. Biomimetic nanocomposites exemplified by a variety of nanostructured nacre-like materials provide a generalized approach to engineer materials with multiple difficult-to-attain properties. As the continuation of this research, we learn that the unique mechanics of tooth enamel can be replicated combining out-of-plane nanoscale columns with molecular precision of layer-by-layer (LBL) assembly between them. As a result of that, these composites reveal remarkably high vibrational damping unusual for stiff materials that imparts them resilience to aging.

One of the emerging fields for biomimetic nanocomposites are optical devices. The high strain and strong polarization rotation make possible metaoptical devices with wide-angle diffraction gratings for LIDARs and highly efficient quarter wave plates for THz scanners. Both devices can be used for machine vision and biomaterials imaging.

7:00 AM *S.CT04.02.05
Colour with a Twist—Cellulose Photonic Materials with Tailored Visual Appearance Silvia Vignolini; University of Cambridge, United Kingdom

Plant-based polysaccharides such as cellulose and its derivatives are receiving increasing interest in a large variety of applications because they represent an environmentally friendly alternative to plastic. Many of them are commonly used in diverse industrial applications, such as food additives and for biomedical devices due to their non-toxic and water-soluble nature. Moreover, the self-assembly nature and responsiveness of cellulosic bio-polymers makes them also extremely attractive for smart photonic applications including sensing. Among various types of cellulose and its derivatives, hydroxypropyl cellulose (HPC) encompasses all these desirable properties. Hydroxypropyl cellulose is a liquid crystal polymer, which can form a cholesteric liquid-crystalline phase allowing Bragg-like reflection. The reflected colours can be simply controlled by changing the nature of the solvent, concentration, temperature. Recently, we demonstrated for the first time that a simple aqueous solution of HPC can be used as a photonic strain sensor that displays the applied strain by shifting its colour.

In this seminar, I will introduce how such properties can be enhanced to create a solid-state film with desired optical appearance.

**Optical Devices From Covalent Functionalized, Redox-Exfoliated, Layered Transition Metal Dichalcogenides**

Ali Jawaid, Peter Stevenson, Luke Baldwin, Ruth Pachter and Richard A. Vaia; Air Force Research Laboratory, United States

Exfoliated Transition Metal Dichalcogenides (TMDs, MX$_2$) have attracted considerable attention for infrared optical elements due to their high refractive index and extreme nonlinearities (e.g. MoS$_2$, TiS$_2$). Recent high-yield, sonication-free, surfactant-free, exfoliation methods (i.e. Redox Exfoliation) now provide access to oxidatively-resistant and colloidally-stable dispersions at high TMD content (10% v/v), and in an expanded range of polar solvents (e.g. acetonitrile, acetone, alcohols). In addition to transforming approaches to nanocomposite fabrication, ink formulation, and film processing, these characteristics enable direct organic hybridization of Group IV-VI TMDs. For example, Grignards (R-MgBr) are not accessible via traditional Liquid Phase or Li-Intercalation methods due to their extreme reactivity with labile hydrogens (water), amides (NMP), and oxygen. However, the availability of Group VI TMDs dispersions in anhydrous THF enables synthesis of alkyl grafted MoX$_2$, which has zero surface charge, is dispersible in chloroform, and affords subsequent surface-initiated polymerization, all while retaining optoelectronic monolayer properties. In addition, classic redox intercalation chemistries can be applied to Group V monolayer dispersions. For example, a primary alkyl amine reacts at 70°C in anhydrous acetonitrile with semi-metallic, single layer NbS$_2$ via charge transfer from the amine to the half-filled Nb d-orbitals. The resultant organic-grafted NbS$_2$ is a semiconductor, with enhanced oxidative stability (> 7 days ambient) and dispersibility in non-polar dichloromethane that allows for ambient handling and processing. Such access to numerous hybridization approaches will greatly expand the electrical, optical, and chemical property suite of TMDs and enhance the ability to fabricate device quality films and hetero-structures for optical filters, GRIN optics, and non-linear absorbers.

**5:30 AM *S.CT04.03.03**

**Molecular Dynamics Simulations Integrated Machine-Learning Study of Bottlebrush Polymers of Different Shapes**

Soumil Joshi, Samrendra Singh and Sanket A. Deshmukh; Virginia Tech, United States

Thermosensitive bottlebrush polymers (BBPs) are a type of graft copolymers in which thermosensitive polymer side-chains are grafted on a linear polymer backbone. These side-chains can undergo a coil-to-globule conformational change in response to a change in the surrounding temperature. This also results in a change in the overall shape of the BBPs because of which they can be used for biomedical applications. Here, we will present the results of our recent coarse-grained (CG) molecular dynamics (MD) simulations study of poly(N-isopropylacrylamide) (PNIPAM; transition temperature= 305 K) BBPs of Worm-like, Cone-like, Dumbbell-like shapes. The CG MD simulations were performed at 300 K (below transition temperature) and 320 K (above transition temperature). The analysis of simulation trajectories showed that the shape of BBPs has significant impact on the conformations of individual side-chains.

**6:00 AM *S.CT04.03.04**

**Organic-Inorganic Interfaces—Insight from First Principles Calculations**

Ruth Pachter; Air Force Research Laboratory, United States

Elucidating the role of organic ligands that are attached to or incorporated within inorganic nanostructures, for example, at the interface of colloidal nanocrystals or as included in the inorganic framework of two-dimensional hybrid organic-inorganic perovskites, is essential in realizing desired functional properties for applications. However, although general guidelines are provided by experimental explorations, an understanding of the underlying mechanisms for efficient materials development is often lacking. Herein, by employing first principles calculations for the design of materials that exhibit optical tunability characteristics, we first discuss atomically precise quantum dots. We highlight challenges in modeling the structure of semiconductor nanoclusters with organic ligands. In this context, we report on the derivation of a potential energy surface using machine learning that overcomes, in part, some of these limitations, and on the importance of the level of theory applied for accurate prediction of the optical response. In addition, we discuss effects of incorporating large chromophores as the ammonium cation in 2D hybrid organic-inorganic perovskites, which have proven promising for optoelectronic applications. Dependent on the organic moiety type, band alignments indicate variability in quantum-well types for a range of materials we examined, as well as structural distortion. Absorption spectra demonstrate tunability in the optical properties, including enhanced absorption and red-shifts, providing recommendation for the choice of the organic cation and motivation for further synthesis and experimental characterization.

**6:30 AM *S.CT04.03.05**

**Enhanced Multifunctional Nanocomposites with Two-Dimensional Transition Metal Carbides/Nitrides**
MXenes

Christine B. Hatter and Yury Gogotsi; Drexel University, United States

Composites offer a wide variety of uses in aerospace, automotive industry, additive manufacturing, and energy storage applications. Discovered in 2011, MXenes have emerged as a new class of two dimensional (2D) materials consisting of transition metal carbidides and nitrides. Synthesized MXenes have rich chemistry and 2D morphology offering a combination of high metallic conductivity and hydrophilicity for easy solution processing. Additionally, MXenes have been shown to have excellent mechanical properties with Young’s modulus of 330 GPa, surpassing both GO and rGO making it one of the strongest solution-processable 2D materials. Thus, they can improve mechanical and thermal stability as well as electrical conductivity of polymers. They can also reinforce ceramics and metals.

The most commonly studied MXene, titanium carbide (Ti3C2), has been combined with various polymer systems producing new multifunctional nanocomposites. When introduced into thermoplastics like PVA, improved mechanical properties were observed at 10 wt% polymer loading with a 34% increase in tensile strength compared to pure Ti3C2 films. Additional studies have shown electrical properties can be successfully transferred to the polymer composite extending its use to electrodes in energy storage systems as well as electromagnetic interference shielding for future electronics. In addition to simple direct mixing with polymers, Ti3C2 MXene has also been incorporated into more complex polymer fibers for integration into textile applications. A recent study on electrospinning of MXene-PAN nanofibers showed MXene content could be increased up to 35 wt% and retain high areal capacitance three times that of pure PAN nanofibers. This presentation will provide an overview of the current MXene-reinforced composites field, including ceramic- and metal-matrix, and the various applications.
structural, and energy-functional materials. Understanding how weak interactions and/or chemical bonding at the interface lead to a meso- and macroscopic behavior warrants a multiscale modeling framework. This will be illustrated with the example of carbon nanotube (CNT) fibers. Starting from the energetics and kinetics of various crosslinks (~nm, ~fs) accessible from accurate DFT calculations, we derive scaling relations of their tensile mechanical response from a µm-long coarse-grained model of a CNT bundle. These inter-tube crosslinks can be expected to behave as “hook-and-loop” fasteners, operational in Velcro, which can have the ability to break and reform and thus resist relative motion in a continuous manner. Such a model can incorporate the effect of interface friction due to inter-tube crosslinks or tube-polymer matrix connects, quantitatively evaluate toughness and fatigue processes and look for ways of performance improvement. Same coarse-grained model allows us to also explore the fundamental problem of basic packing defects in the aligned CNT bundles: the ‘twists’ and ‘inclusions’. We show how a finite characteristic size/length L of such defects emerge as a result of interplay between their intrinsic bending stiffness and the elastic response of the surrounding CNT matrix-crystal, and quantify their energetics scaling. In conjunction with synthesis efforts and novel experimentation, such models are crucial in developing novel carbon nanomaterials.

8:00 AM *S.CT04.04.07
Molecular Dynamics Modeling of Flattened CNT/Polymer Interfaces Matthew Radue¹, William Pisani¹, Sagar Patil¹, Prathamesh Deshpande¹, Prashik Gaikwad¹, Swapnil Bamane¹, Susanta Ghosh¹, Traian Dumitrica² and Gregory Odegard¹; ¹Michigan Technological Univ, United States; ²University of Minnesota Twin Cities, United States

Current state-of-the-art carbon fiber reinforced composite materials have become a standard structural material used in the aircraft industry. Their relatively high strength-to-density and stiffness-to-density ratios make them useful for reducing vehicle mass and thus improving fuel efficiency. However, for manned space exploration beyond the moon (deep space), further decreases in mass are needed for fuel efficiency. Thus, increases in the strength-to-density and stiffness-to-density ratios are necessary.

Carbon nanotube (CNT)-reinforced composites can potentially provide the needed reductions in composite laminate mass. Relative to carbon fiber, CNTs can have higher strength and modulus, and can potentially provide a larger surface area for polymer interaction and load transfer. Further, flattened CNTs (fICNTs) can form self-assembled arrays with a higher packing than round CNTs [1]. Although countless studies have examined CNT/polymer interaction on the molecular level [2], little effort has been devoted to understanding fICNT/polymer interaction.

The objective of this research is to use molecular dynamics (MD) simulation to explore the interaction and load transfer characteristics for a range of different polymer resins with fICNTs. Specifically, the interfacial interaction energy, pull-out frictional force, pull-apart force, and resin wetting contact angles have been predicted. These predictions have been performed for two polyimide systems, two cyanate ester systems, polyurea, and PEEK. The results of these studies will be presented, and the best polymer candidates for these fICNT/polymer composites will be discussed.

Molecular Engineering of Hairy Nanoparticles with Reversible Self-Assembly and Tailored Plasmonic and
Luminescence Properties  **Zhiqun Lin;** Georgia Institute of Technology, United States

Polymer-ligated nanoparticles (NPs) exhibit an exciting variety of physical properties that depend sensitively on the dimension and composition of NPs as well as the surface chemistry of tethered polymer hairs. Herein, we report on a robust nanoreactor strategy for in-situ crafting of monodisperse stable polymer-ligated NPs with well-controlled size and shape as well as tunable plasmonic (e.g., Au) and luminescence (e.g., perovskite MAPbBr₃ and CsPbBr₃) properties. Central to this strategy is to judiciously design unimolecular amphiphilic star-like block copolymer as nanoreactor for yielding NPs intimately and permanently ligated by polymer hairs. The diameter of polymer-ligated NPs can be precisely tuned by modulating the length of inner hydrophilic block of star-like block copolymers. In the case of Au NPs, the perpetual anchoring of photoresponsive or thermoresponsive polymers on the surface renders the attractive feature of self-assembly and disassembly of NPs on demand by capitalizing on light of different wavelengths or heating/cooling, respectively. Such self-assembly/disassembly process is revealed by tunable surface-plasmon resonance absorption of Au NPs and the reversible transformation of Au NPs between their dispersed and aggregated states. For perovskite NPs, the resulting polymer-ligated MAPbBr₃/SiO₂ core/shell NPs and CsPbBr₃ plain NPs display concurrently a stellar set of significantly improved stabilities (i.e., colloidal stability, chemical composition stability, photostability, water stability), while possessing appealing solution processability, which are unattainable by conventional methods. We envision that the amphiphilic star-like block copolymer nanoreactor strategy may provide a versatile platform for crafting diverse organic-inorganic nanohybrids stably-ligated with polymer of different functionalities (e.g., semiconducting, ferroelectric, photo-responsive, thermal-responsive, or pH-sensitive) for a spectrum of applications in bioimaging, biosensors, photonic materials and devices, perovskite-based LEDs, lasers, high-energy ionization radiation detections, multiphoton emission, and scintillators.

**Understanding Self-Assembly of Functional Nanostructures with Actuation Capabilities**  **George C. Schatz;** Northwestern University, United States

Molecular self-assembly involves the use of hydrogen bonds and other noncovalent interactions between molecules to create supramolecular structures. A goal of theory is to be able to predict and understand what structures will arise for any given set of conditions, and how the self-assembly can be directed so as to produce useful functional structures. In this talk I will describe recent studies in my group in collaboration with the Stupp and Mirkin groups at Northwestern, and with others, with the goal of making nanostructured materials with broad applications including actuation with various stimuli.

One area of interest concerns studies of peptide amphiphile self-assembly to produce cylindrical micelles and ultimately fiber materials that can be used for applications in biomedicine and for making materials that can be photoactivated for robotic functions. Here we have developed all-atom and coarse-grained models, and specialized molecular dynamics methods, that are capable of describing assembly into fibers, leading to an understanding of biological functions and photoactuation.

In a second direction we are interested in the coupling of self-assembly chemistry involving DNA attached silver and gold nanoparticles to create a new generation of bottom-up nanomaterials of interest for sensing and optical devices. Here we show both coarse-grained and all-atom approaches to the assembly, and how these can be used to understand the formation of plasmonic array structures, including recent studies aimed at understanding programmability of dynamic optical properties.

6:00 AM *S.CT04.05.03
**Molecular Simulation and Theory Studies Linking Design of Polymer Grafted Nanoparticles to the Polymer Nanocomposite Morphology**  **Arthi Jayaraman;** University of Delaware, United States

In this talk I will present our recent work studying polymer nanocomposites (PNCs) using molecular dynamics (MD) simulations and Polymer Reference Interaction Site Model (PRISM) theory calculations with coarse-grained (CG) models. Specifically, we are interested in linking molecular design of PNCs comprised of grafted nanoparticles in a polymer matrix to their morphology. In this talk I will focus our work on the impact of strength of graft-matrix attraction on interpenetration of matrix and graft chains (known as grafted layer wetting) and dispersion/aggregation of grafted particles in matrix. Previously for PNCs with attractive graft-matrix interactions, we had shown that wetting/dewetting and dispersion/aggregation are two distinct phase transitions, the former being a continuous transition and the latter being a first-order transition as a function of
graft-matrix interaction or temperature. Recently, we found that as the strength of graft-matrix attraction increases, we can also tune the effective size and the hardness of the polymer grafted particle in the PNC. As the attraction between the graft and matrix chains increases, the graft polymer chains extend to make favorable graft-matrix contacts and increase the grafted layer wetting by matrix chains. This leads to larger and ‘harder’ grafted particles compared to analogous fillers with purely entropic (athermal) graft-matrix interactions. Due to the increasing size and hardness of grafted particles with increasing graft-matrix attraction, the PNC structure changes from an aggregated/dispersed morphology governed by entropic driving forces at athermal graft-matrix interaction to a dispersed morphology due to favorable weak graft-matrix attraction, and ultimately, to a correlated fluid of hard grafted particles at stronger graft-matrix attraction. We see these trends in PNCs with high (densely grafted) and low grafting density, and with equal graft and matrix chain lengths as well as cases where the matrix chain lengths are greater than the graft chain lengths.

Advances in Using Surface-Initiated Atom Transfer Radical Polymerization and Its Application to Tailoring Particle Interactions and the Design of Functional Materials Michael R. Bockstaller; Carnegie Mellon Univ, United States

Surface Initiated Atom Transfer Radical Polymerization (SI-ATRP) in its various modifications has emerged as a versatile toolbox to control and tailor the properties and interactions of interfaces and to enable the synthesis of hybrid materials with unprecedented property combinations. The resulting materials have attracted interest not only because the high-level structural control of the architecture of polymer-tethered surfaces enables tailoring of the interactions, microstructure and properties of particulate-based materials but also because the confinement of chains on surfaces alters the mechanism of termination reactions that limit conventional polymerization processes.

This presentation will review recent examples of the application of SI-ATRP for the synthesis of functional polymer materials. Examples to be covered include the synthesis of ultra-high molecular weight polymers, materials for optical applications as well as thermal interface materials. Recent examples of the interplay between phononic and photonic properties in brush particle-based materials will be shown to illustrate how the subtle control of polymer chains at interfaces can instigate novel physical properties in hybrid materials that cannot be realized in ‘classical’ composite materials that are fabricated by mixing of particle and polymer constituents. This will provide the basis for a discussion of ‘guidelines’ for the fabrication of novel functional materials that harness ‘chemical confinement’ of polymer chains.

7:00 AM S.CT04.05.06

MXenes represent an emerging class of two-dimensional layered transition metal carbides and nitrides with intriguing properties, which have attracted significant attention as a promising material for next-generation functional composites. Control of size (lateral and thickness), layered spacing, and surface chemistry enables tuning of optoelectronic properties and improvement of processibility. To this end, we present fundamental studies aimed at understanding the role of surface terminations and functional groups on the electronic, chemical, and structural properties of MXene flakes. Ultra-thin nanosheets of MXenes are surface modified with catechol [dopamine, pyrocatechol, and tetrachlorocatechol (TCC)] chemistries. UV-Vis spectroscopy shows oxidation of catechol to quinone, confirming the formation of a charge transfer complex with the MXene layer. The reaction kinetics and subsequent colloidal stability are different each catechols, reflecting the different terminal groups (NH2 vs. Cl). FT-IR, XPS, Raman, and AFM-IR support surface binding; XRD reveals changes in layer spacing, further confirming surface modification. These experimental studies are corroborated by theoretical calculations of the electronic properties of both the native and functionalized MXene surfaces. Finally, these functionalized thin flakes exhibit significantly improved thermo-oxidative stability and dispersibility in non-aqueous solvents. Overall, such approaches to surface termination opens up new avenues for synthesis of hybrid functional architectures based on MXenes.

7:15 AM S.CT04.05.07
Spatiotemporal Deformation and Microstructural Evolution Mechanisms During High-Speed Shear Deformation of Metallic Alloys Arun Devraj1, Tingkun Liu1, Changyong Park2, Bharat Gwalani1, Mathew Olszta1, Tiffany Kaspar1, Yang He1, Jinhui Tao1, Tamas Varga2, Chongmin N. Wang3, Aashish Rohatgi1, Peter V. Sushko1, Suveen Mathaudhu1 and Cynthia Powell1; 1Pacific Northwest National Laboratory, United States; 2Argonne National Laboratory, United States; 3Environment Molecular Science, United States
In order to develop shear-based solid phase processing methods for achieving bulk nanostructured metallic alloys, we aim to better understand the fundamental atomic scale mechanisms of local and global deformation mechanisms and microstructural evolution in polycrystalline materials under shear deformation. To achieve this aim, we employed synchrotron-based in situ and ex situ high-energy x-ray diffraction capabilities under high pressure and shear deformation, using a newly designed high-speed rotational diamond anvil cell. The obtained synchrotron-based XRD results were also correlated with detailed microstructural characterization before and after shear deformation using transmission electron microscopy and atom probe tomography. Atomic scale computational modeling using density functional theory and molecular dynamics was additionally complemented with experimental results to obtain mechanistic insights. Our results on shear induced structural and chemical modifications of several model metallic alloys such as Al-Si, Cu-Nb and Cu-Ni provide new insights on the unique role of shear deformation in formation of metastable states, as well as in modifying the phase transformation pathways of these alloy systems.

Ordering at the BNNT/Water Interface Using Cryo-EM Techniques
Hsin-Yun Chao1,2, Alline Myers2, Dmitri Golberg3, Renu Sharma4 and John Cumings1; 1University of Maryland, United States; 2National Institute of Standards and Technology, United States; 3Queensland University of Technology, Australia

Nanotubes used as nanochannels for fluid transport have been of increasing interest. It has been observed that carbon nanotubes (CNT) have uniformly higher permeability compared to other nanochannels, such as polycarbonate membranes, albeit CNTs can achieve smaller diameters [1]. Previous theories attribute the high permeability to nanotube atomic smoothness [2]. However, recent molecular dynamics simulations show that the structure of water at higher densities can align to that of CNTs of small diameter [3]. Furthermore, there are conflicting analyses as to whether the fluid flux is higher for CNT or boron nitride nanotubes (BNNT) [4]–[6]. Therefore, we want to better understand the structural ordering at the atomic scale of nanotube-water interfaces using empirical methods. Here, we use cryogenic electron microscopy (Cryo-EM) techniques to hyperquench water with BNNT into a vitrified state and observe the BNNT/water interface using a transmission electron microscope (TEM) at 80kEV. A cryo-transfer holder capable of maintaining the sample at 90-125K facilitates the sample transfer into the TEM. Raman spectroscopy performed in-situ during TEM imaging will enable direct observation of beam-induced phase transformations. We will present results relevant to the preferential ordering of water at the interface with BNNT.

Covalent Sizing of Carbon Fibres—A Route to Optimising Interfacial Phenomena in Composites
Luke Henderson,
Daniel J. Eyckens, Filip Stojcevski and James D. Randall; Deakin University, Australia

Continuing on our work in the surface modification of carbon fibres, we investigated the validity of tethering polymers to a
Evaluation of both ‘Graft To’ and ‘Graft From’ approaches were undertaken and how these modifications affected performance/the-innate physical properties of the underlying material was determined. During our ‘Graft From’ study, we found that the use of an in situ polymerisation protocol resulted in the generation of carbon fibres with an electric blue colour. The source of colour is proposed to be thin-film interference, similar to that observed in the Morpho butterfly. Swelling the polymer with a solvent resulted in a cascade of colours through the visible spectrum during evaporation and polymer shrinkage.

In addition to this, the tensile strength of the fibre increased (13-30%), the interfacial shear strength increases in epoxy polymers (180-320%), and an unusual ability to reversibly form and reshape the fibre was also found. (1)

5:30 AM S.CT04.06.05
Understanding CNT/Polymer Interphase Assembly and Mechanical Strength Using Simulation and Machine Learning Hendrik Heinz; University of Colorado Boulder, United States

Debundling and dispersion of carbon nanotubes (CNTs) in polymer solutions play a major role in the preparation of carbon nanofibers due to early effects on interfacial ordering and mechanical properties. First, we analyzed the propensity to achieve homogeneous dispersions of CNTs in polyacrylonitrile (PAN) and poly(methyl methacrylate) (PMMA) precursor solutions in the solvents DMSO, DMAc, and DMF. Molecular dynamics simulations at 25 and 75 °C with accurate interatomic potentials for graphitic materials that include virtual π electrons show tendencies for PMMA wrapping while PAN exhibits significant interactions only as the concentration is increased or solvent evaporated. Computed conformations, solubility, and temperature dependences correlate well with experimental data from spectroscopy, light scattering, and viscosity measurements.

Subsequent heating and drawing of the precursor gels results in PAN/CNT composites. MD simulations reveal the structure at the atomic scale and relationships to mechanical and thermal properties for different degrees of polymer crystallinity and CNT diameter. Glass transition temperatures correlate with the amount of CNT/polymer interfacial area per unit volume and were predictable with +/-5 K accuracy relative to experiments. Tg increases for higher CNT volume fraction and inversely with CNT diameter. An important aspect is the knowledge of CNT bundle size from experiment, which affects the effective surface area. Computed interfacial shear strengths increase when PAN has at least some degree of crystallinity (at least 50% crystalline).

Third, testing of mechanical properties up to failure has been performed for a wide range of over 500 CNT and defective CNT morphologies to explore the role of structural defects and new information from machine learning models. Hereby, we utilize a new force field, IFF-R, that enables bond breaking in high accuracy and computational speed. Suitable feature representations and processing of the data through reinforcement learning and Bayesian uncertainty quantification will be discussed, and the resulting correlations between structure, Young’s modulus, and tensile strength.

Ongoing questions include the application of supervised learning approaches to polymer composites that have more degrees of freedom and to experimental data from tomography and X-ray diffraction that will become available in large quantities. Progress and opportunities will be discussed.

Characterization of Electroless Copper Deposits on Electrospun PAN Fibers in Aligned and Random Configurations Temitope Q. Aminu1, Molly Brockway2, Jack L. Skinner2 and David F. Bahr1; 1Purdue University, United States; 2Montana Tech, United States

The functionalization of electrospun polymer fibers has created potentially radical materials for sensing, tissue scaffolds, flexible electronics and filtration. Fundamentally, the composite material design is enabled by electroless deposition, wherein...
conformal coatings (either as complete films or individual nanoparticles of copper) can be achieved on the default random configurations of electrospun fibers through solution-based precipitation reactions. Advantageously, fiber alignment can also be achieved through design modifications in the electrospinning process. We have electrolessly deposited copper on random and aligned PAN fibers utilizing silver nanoparticles as catalytic seeds. Fiber sizes range from diameters of hundreds of nanometers to a few microns. Prior work has established that coating conformity is strongly modulated by density of catalytic seeds: metallic films are obtained with a high density of silver seeds (48 particles/μm²), and discrete particles are observed for low density seeding (15 particles/μm²). X-ray crystallography has been used for phase identification and crystallite size measurements of both the seeds and subsequent copper coatings.

We investigate the changes in the chemistry of the fibers due to the exposure to the electroless plating solutions using Raman spectroscopy, focusing on effects of fiber dimensions on surface chemistry and amenability to nucleation events. In addition, tensile tests are carried out on the metallized aligned fibers at distinct strain levels to investigate possible delamination events. Previous strain-to-failure tests on conformally coated, randomly aligned fibers mats showed good adhesion of the copper particles on the fibers. In parallel, we examine the mechanical behavior of the metallized fibers under an equi-biaxial stress state utilizing a novel “leaky” bulge testing system. We demonstrate the links between the mechanics of coated fiber mats in aligned and random configurations to identify the impact of plating on the stiffness of the resulting structure, a critical parameter for use in filtration applications where fluid pressure can alter the achievable minimum pore size.

7:00 AM S.CT04.06.09
Multifunctional Polyurethane Composite Sheets Incorporating Nanotubes at High Loading—Mechanical and Morphological Characterization Yadienka Martinez-Rubi, Behnam Ashrafi, Michael Jakubinek, Shan Zou, Keun Su Kim, Zygmunt Jakubek, Stephane Denommee and Benoit Simard; National Research Council Canada, Canada

Light-weight one-dimensional nanomaterials such as carbon nanotubes (CNTs) and boron nitride nanotubes (BNNTs) possess impressive physical, chemical and mechanical properties and are promising reinforcement agents for the development of enhanced multifunctional composite materials. Although BNNTs and CNTs share similar mechanical properties and thermal conductivity they can impart a different set of functionalities in composite material. CNTs are electrically conductive and are usually employed to improve the electrical conductivity of a matrix. On the other hand, BNNTs show transparency in the visible region and are electrically insulating. Thus, BNNTs are very promising nano-fillers for insulating polymer composites. Additionally, BNNTs have higher resistance to oxidation and the ability to shield neutron radiation.

High nanotube (NT) contents are often necessary in order to achieve thermal or electrical conductivities requirements for a particular application. However, the incorporation of well dispersed nanotubes into polymer composites can be challenging, especially at high loadings due to re-agglomeration of the nano-filler and a significant increase in viscosity. Here we show the fabrication of CNT-polyurethane (TPU) and BNNT-TPU composite sheets of variable composition using a scalable one-step filtration process. Using this fabrication method the composition of the nanocomposites, which defines the characteristics and properties of the material, can be precisely controlled. Consequently, materials with tailorable properties (e.g. porosity, stiffness, strength and toughness), shapes and functionalities can be fabricated. The trend in mechanical and electrical properties was understood in terms of the NT-TPU interfacial interactions and morphological changes occurring in the nanocomposite sheets as a function of increasing the TPU content. At specific NT-TPU weight ratios (e.g. 35:65 weight ratio for CNT-TPU composites) a better NT exfoliation and optimal NT surface coverage was achieved, which in turn led to an optimal packing of NT–TPU fibers. This optimal packing produced the highest improvement in tensile properties and electrical conductivity in CNT-TPU sheets. Due to their straightforward production and handling, high nanotube content, and superior properties in comparison to dispersed nanotube composites, the resulting conductive, lightweight sheets are of interest for various applications including improved damage tolerance, fire retardancy and electrical properties of laminate composites, and electromagnetic shielding. On the other hand, thermally conductive (4 W/mK), electrically insulating sheets were produced with BNNT materials of different quality/purity. The quality of the BNNT materials was evaluated using several characterization techniques and a recently reported methodology for assessment of relative quality by absorption spectroscopy of regiorandom poly(3-hexyl-thiophene) aggregated on BNNTs. Nano-microscale roughness, which is essential for superhydrophobicity, can also be integrated on the NT-TPU fabrics surface by a novel approach that incorporates a nanometer size array of functionalized nanotubes on the sheet surface producing highly non-wetting surfaces. Sheets can also be applied as coatings on other structures (e.g. glass fiber reinforced plastics) to create a multifunctional self-cleaning surfaces.

7:15 AM S.CT04.06.10
Interphase Engineering for 1D and 2D Nanocarbon-Included Functional Composites Weiheg Xu, Sayli Jambhulkar, Dharneedar Ravichandran and Kenan Song; Arizona State University, United States

The interface and interphase between a matrix and the fillers will influence the stress transfer, energy transport, stabilization
of dispersant, degree of confinement or bonding, and, other new property generations. Both physical (e.g., molecular wrapping on filler surfaces or self-assembly) and chemical (e.g., surface functionalization) can modify the matrix-filler interfacial interactions. This talk will introduce two kinds of interface/interphase manipulations for precisely controlling nanoparticle morphologies. Our unique manufacturing and the resulted advanced composites have potential applications in wearable, robotics, biomedical, and other areas.

The first example was the use of polymer-graphene interphase design to achieve two dimensional (2D) nanoparticle orientation management. As well known that atomically thin 2D materials are challenging to be aligned as compared with their allotropes, such as carbon nanotubes. Free-standing graphene in ambient conditions will wrinkle, crumple or fold due to their instability of thermodynamic states. Our unique design of the different phases consisted of macromolecules and 2D graphene allowed the material system to take advantage of the interphase structural evolutions for confining, exfoliating and aligning the nanoparticles. Different polymers such as semicrystalline polyvinyl alcohol (PVA) and thermoplastic polyurethane were used to study the interphase engineering and their influence on graphene or similar nanocarbons for mechanical enhancement or functionality incorporations. The unique material system of composite fibers were used as piezo- and chemi-resistive sensors.

The second demonstration utilized layer-by-layer-based deposition techniques. Both additive manufacturing (e.g., 3D printing) and dip-coating methods were used on the same processing platform. One dimensional carbon nanofibers (CNF) were used as an example to be selectively deposited on polymer surfaces with pre-printed patterns. The control of the surface patterns and the nanoparticle assembly conditions (e.g., thermodynamic parameters, nanoparticle interactions, solid-liquid-air contact lines, etc.) led to selective deposition and preferential alignment of CNF. As a result, the conductive paths on the substrate were developed to be anisotropic; following this characterization, the multifunctional sensitivity to strain, temperature, chemical liquids and volatile organic compounds (VOCs) were also displayed.

7:30 AM S.CT04.06.11
Trans-Esterification in Vitrimer Polymers—Catalytic Efficiency and Mechanism Using Density Functional Theory Shusil Bhusal, Gary Kedziora, Vikas Varshney, Ren Yixin, Amber M. Hubbard, Dhruti Nepal and Ajit K. Roy; Air Force Research Laboratory, United States

Thermoset vitrimer polymers have recently shown tremendous promise for structural applications such as reshaping and remodeling. The trans-esterification reaction plays a vital role in the vitrimer mechanism, in which the efficiency of the reaction is controlled by organic or organometallic catalysts. Understanding the mechanistic insights of the trans-esterification reaction in the bulk phase is difficult due to the highly cross linked complex structure of thermosetting vitrimers. In this work, we employ density functional theory (DFT) to investigate catalytic efficiency and the mechanism of the trans-esterification reaction using transition state theory with model systems that include alkoxy and carboxylic groups as reacting sites for mimicking the trans-esterification reaction. The catalytic efficiency of a number of catalysts, including triazabicyclodecene (TBD), zinc acetate Zn(OAc)2, Dibutyl tin oxide (DBTO) and Methylimidazole (1-MI) is explored. The mechanism of trans-esterification reaction is explored based on results from fukui indices (i.e measure of electrophilicity and nucleophilicity of atomic sites), partial charges, and transition state theory.

7:45 AM S.CT04.06.12
Hierarchical Structures of Gold Nanoparticles Decorated on Graphene Nanoplateletbes Yixin Ren1,2, Rahul Rao1, Amber M. Hubbard1, Chen Li3, Shusil Bhusal1, Gary Kedziora2, Zhiting Tian1, Vikas Varshney2, Ajit K. Roy2 and Dhruti Nepal2; 1Universal Technology Company, United States; 2 Wright-Patterson Air Force Base, United States; 3Cornell University, United States

Hierarchical assembly of plasmonic nanoparticles such as gold nanoparticles (AuNPs) into two-dimensional materials (graphene) is of significant interest for nearfield imaging, sensing, and inducing a photo-thermal response in a material.
However, uniform decoration of AuNPs onto graphene nano-platelets (GNP) is a significant challenge. This is because GNPs tend to aggregate easily via van der Waals force to form graphite, which perturbs the reaction at the interface. Here we demonstrate a simple solution-phase mixing technique to prepare AuNPs decorated GNPs hybrid materials (AuNPs-GNPs). By carefully optimizing the reaction condition, we were successful in maintaining the structural integrity of GNPs and simultaneously decorating it uniformly with AuNPs. High-resolution transmission electron microscopy (TEM) and high-angle annular dark-field imaging (HAADF-STEM) showed few-layered GNPs (< 10 nm thickness, ~ 200 nm lateral dimension) decorated with AuNPs. Here the diameter of AuNP ranges from 10 to 20 nm, which is controlled by the stoichiometry ratio of gold and carbon. Similarly, the average spacing between AuNP can be controlled by the density of defects on the graphene surface and the reaction conditions. Raman spectroscopy confirms the strain sensitivity of G and 2D modes as a result of the covalent interaction at the interface. Finally, these hybrid structures are embedded in a polymer matrix for studying thermal conductivity and plasmon-phonon interactions. Overall, this kind of hierarchical structure opens up new avenues for the next generation of smart coatings and composites.

8:00 AM S.CT04.06.13
Application of Nanoengineered Resin to Improve the Interlaminar Strength of Non-Crimp Carbon Fibre Composites
Ajit D. Kelkar and Vishwas S. Jadhav; North Carolina A&T State University, United States

Due to superior strength and stiffness properties, the use of textile composites for aerospace, automotive and marine applications has increased dramatically. The next generation of reinforcements, namely non-crimp fabric (NCF) is being explored for various structural applications. NCF can exploit low angle plies and can also be stacked as non-symmetric plies about the mid-plane. NCF provides excellent laminate strength, and the cost of fabrication is usually substantially lower than traditional composite manufacturing. Composite laminates are bonded together by a thin layer of resin between them, and the interface layer transfers the displacement and force from one layer to another layer. When these layers damage or weaken, adjacent layers separate, which forms the crack between adjacent plies. This also reduces the strength and stiffness of the laminate and can have a significant impact on the useful life of composites. Eventually, this separation of layers causes stress concentration in the plies which leads to the growth of delamination and results in failure of the laminate. Carbon nanofillers, such as nanoparticles, CNTs or CNFs, within the matrix material of composites has offered new avenues for improving the multifunctional properties of polymer matrix composites due to their high aspect ratio. In the present work, the laminates were manufactured using non-crimp carbon fabric in conjunction with and without nanoengineered enhanced epoxy resin. Mode I fracture toughness was evaluated for the composite panels with and without nanoengineered enhanced laminates. A detailed fractographic examination of the failed interfaces was performed by using state of the art imaging equipment such as Helium Ion, Axio Image upright microscope and scanning electron microscope. The study indicated that nanoengineered composites have significantly higher interlaminar properties as compared to the conventional composite laminates.

IFF-R Model to Accurately Simulate Stress-Strain and Failure Properties of Carbon Allotropes and Polymer Composites
Jordan Winetrout1, Krishan Kanhaiya1, Ravindra Pandey2, Gregory Odegard2 and Hendrik Heinz1; 1University of Colorado Boulder, United States; 2Michigan Technological University, United States

Stress induced mechanical failure of polymeric materials is a result of the breakage of covalent bonds. The occurrence of bond breakage and formation is only observed during reactions. This study focuses on the novel bond-breaking capabilities of the Interface Forcefield (IFF-R). Traditional IFF models simulated systems using harmonic potentials. The IFF-R model incorporates Morse potentials; thereby, eliminating the restoring force experienced by bonded atoms stretched at large distances. This enables accurate predictions of mechanical responses in a variety of periodic systems. This study shows moduli and strength predictions of a single-walled carbon nanotube, poly(acrylonitrile) crystal, cellulose β crystal, and steel FCC lattice to be comparable to experimental values. Mechanical property predictions using IFF-R models are realized
magnitudes faster than reactive forcefield (ReaxFF).

**Porous Materials – Graphene Hybrid Nanostructures with Tailored Interfaces as Membrane and Adsorbent Components in Gas Separation** Anish Varghese, Swati Singh, Suresh Kuppireddy and Georgios Karanikolos; Khalifa University, United Arab Emirates

Combinations of different materials into hybrid/composite structures are highly sought after as to enable multifunctionality in many of today’s demanding applications. 2-dimensional graphene can combine with porous nanostructures, such as metalorganic frameworks (MOFs), zeolites, and porous carbons, to yield hybrids with improved surface, interface, and activity characteristics. In this work, we will present examples of such material hybridizations via in-situ microstructural tuning of the interface between the involved counterparts. The resulting composites were tested for their gas separation performance, and specifically optimized to exhibit enhanced capture activity for carbon dioxide as adsorbents, as well as nanofillers in mixed matrix polymer-based membranes.

**S.CT04.07.06**
**Site-Specific Surface Modification and Functionalization of Porous Nanostructured Scaffolds for Tunable Adsorption Applications** Adetola Ogungbenro, Suresh Kuppireddy, Maryam Khaleel and Georgios Karanikolos; Khalifa University, United Arab Emirates

To reveal the full potential of high surface area materials, strategies to tailor their surface characteristics and tune their active sites with high spatial precision and order are needed. In this work, we employ porous materials having surface areas of several hundreds of m² per g and we apply customized chemistry based surface tailoring as to spatially create active sites and subsequently graft functional molecules on them. Such examples of surface features can have a multitude of applications, yet we focus on tuning the affinity of the materials to bound with selective species from mixtures as to enable separation. In particular, innovative CO₂-philic amines are immobilized on the treated surfaces to yield multifunctional adsorbents for carbon dioxide capture. Examples of silica- and graphene-based materials with controlled covalent positioning of various aminosilanes on the modified surface sites will be presented. Controlled grafting ensured stability and sustainable adsorption, tuned effects of locality, spacing, orientation, and interconnectivity of the functionalities on the surface, and minimized diffusion limitations while maximizing capture and release performance for the adsorbate species.

**S.CT04.07.07**
**Improving Oxidative Stability of MXenes via Tailoring Surface Chemistry** Bryan T. Seymour¹², James E. Heckler¹², Gregory R. Neher¹², David B. Lioi¹², Ali Jawaid¹², Faisal Mehmood¹², Ruth Pachter¹², Richard A. Vaia², W. J. Kennedy² and Dhriti Nepal²; ¹Universal Technology Corporation, United States; ²Air Force Research Laboratory, United States; ³UES, Inc., United States

MXenes are an emerging class of two-dimensional layered transition metal carbides, carbonitrides, and nitrides. Their intriguing properties have attracted significant attention as promising materials for next-generation coatings and devices. One of the significant challenges of this material (e.g. Ti₃C₂Tx) is the rapid oxidation into TiO₂ anatase through hydrolysis in water, though water has proved to be the most effective solvent for solubilizing exfoliated Ti₃C₂Tx. Organic solvents routes for processing of MXenes and functionalization of its surface with specific ligands provide avenues to tailor the surface properties, which could eventually influence the colloidal stability as well as oxidative stability. Herein, we discuss the influence of various organic solvents such as ethanol, isopropanol, toluene, and N, N-Dimethylformamide on Ti₃C₂Tx, colloidal stability, oxidative stability at room temperature, and thermo-oxidative properties. We also demonstrate the use of silane and catechol ligands for tailoring the physical properties of Ti₃C₂Tx.

**S.CT04.07.08**
**High Response Nitric Oxide (NO) Gas Sensor with Noise Limited Detectivity Approaching 10 ppb of ZnO/Si NWs p-n Heterojunction Array** Chandan Samanta, Ankita Ghatak, A. K. Raychaudhuri and Barnali Ghosh; S N Bose National Centre For Basic Sciences, India

Currently Gas sensors have a great impact in direct monitoring of environmental hazardous gas as well widely used in healthcare such as exhaled breath analysis. In this work we report a ZnO/Silicon nanowires (ZnO/p-Si NWs) based p-n heterojunction array based Nitric Oxide (NO) gas sensor operating at room temperature with extremely high response at least down to 0.5 ppm with noise limited response ~ 10 ppb. Utilization of cost effective chemical technique for fabrication of sensor on silicon is compatible with wafer level processing and easily connecting with silicon IC technology. The vertically
aligned Si NWs array has been made by electroless etching method and the ZnO nanostructure was made by chemical solution deposition and spin-coating. We observe that the heterostructure leads to a synergetic effect where the sensing response is more than the sum total of the individual components, namely the ZnO and the Si NWs. The response is much enhanced in the p-n junction when the n-ZnO nanostructure interfaces with p-Si NW compared to that in the n-n junction formed by ZnO on n-Si NW. Extensive cross-sectional electron microscopy and composition analysis by line EDS allowed us to make a physical model. The comparison of the simulation results with the experiment point out the device parameters that enhance the device response. The characteristics values of the parameters of ZnO/Si NWs heterojunction for the best fits obtained from the simulation and it can be seen that all the parameters undergo change in the electrical model and this leads to enhancement of current in the device on gas exposure. The top layer of ZnO takes part in the electrical current conduction. The Si NWs also has an all-round layer of ZnO that also acts as chemical sensing gate to modulate the depletion layer on the surface of the NW. The main inference from the simulation is that the observed high performances of the sensor device depends on change in resistances of the constituents as well change in the reverse saturation current at the ZnO/p-Si NW p-n junction.

S.CT04.07.11
Additive Manufacturing of Hybrid Silicon Carbide/Carbon Fiber Nano-Composites Saja M. Al-ajrash; University of Dayton, United States

A novel route to fabricate a hybrid ceramic matrix composite by utilizing preceramic polymers, chopped carbon nanofiber (CNF) precursors and subsequent additive manufacturing was introduced in this study. An allyl hydrido polycarbosilane (SMP-10) and 1,6-dexanediol diacrylate (HDDA) were mixed with a photo initiator to form a photo sensitive resin. The resulting resin was loaded with distinct weight percentages of polyacrylonitrile (PAN) nanofiber. These mixtures were 3D printed followed by pyrolysis. The end objective of the pyrolysis cycle is that the pycarbosilane resin is converted into a silicon carbide matrix, with the PAN converted into reinforcing carbon nanofibers. The impact of the CNF percentages on structural and mechanical properties was investigated using scanning electron microscopy, transmission electron microscopy, and nano-indentation characterization techniques, respectively. The prepared precursor resin proved to have outstanding photo-curing properties and the ability to transform to the silicon carbide phase at temperatures as low as 850 °C. The result of this work showed that ceramic matrix composite components can be successfully fabricated using 3D printing and a specific pyrolysis cycle. The obtained ceramic hybrid composite was fully dense with nearly linear shrinkage and a shiny, smooth surface after pyrolysis. Furthermore, around 60% retained weight after pyrolysis to 1350 °C was confirmed by thermogravimetric analysis. In terms of crystallography, the ceramic matrix composite appeared to have three coexisting phases including silicon carbide, silicon oxy carbide, and turbostratic carbon. The results are very promising to fabricate hybrid composites working at high temperatures with improved mechanical properties and complex geometries.

S.CT04.07.12
Systematic Study of the Effect of Incorporation of Carbon Nanotubes into Ge<sub>x</sub>Se<sub>1-x</sub> Glass System Charri Ramkumar, John Rademacher, Jake Anderson and Wayne Bresser; Northern Kentucky University, United States

We successfully synthesized Ge<sub>x</sub>Se<sub>1-x</sub> (x = 0.225) glass samples and doped the samples with commercially produced (Protein Mods) carbon nanotubes (CNTs). We investigated the glass transition temperature (T<sub>g</sub>) using Modulated Differential Scanning Calorimetry (MDSC). The glass samples without the CNTs have a a T<sub>g</sub> of ~220°C and the T<sub>g</sub> was found to be independent of starting materials from different suppliers as well as water-bath temperature. CNTs, being a very hygroscopic material as well as oxygen absorbing material, needed to be cleaned under vacuum with the hot water-bath. We found that the T<sub>g</sub> decreases when 5% and 10 % CNTs by mass is added to the glass samples as compared to the base Ge<sub>x</sub>Se<sub>1-x</sub> glass. The decrease in T<sub>g</sub> indicates the occurrence of an intermediate phase (reduced-stress glass phase) at lower temperature, which could be potentially useful in material science applications.

S.CT04.07.16
Interfacial Tailoring in CdS/CdTe Heterojunction Solar Cells by Glancing Angle Deposition Niva K. Jayswal, Dipendra Adhikari and Nikolas J. Podraza; The University of Toledo, United States

Abstract:
Glancing angle deposition (GLAD) radio frequency (RF) magnetron sputtering enables production of polycrystalline CdTe with different microstructural properties including grain size, grain orientation, and crystal phase. In GLAD sputtering, the normals extending from the centers of the sample and sputtering target are at controllable angles with respect to each other. At lower source flux angles, films grow as the expected more energetically stable cubic zinc blende CdTe phase whereas at higher source flux angles the metastable wurtzite phase forms. During the GLAD process different microstructure and crystal
phases are produced in the film due to increased atomic scale self-shadowing effects at higher source flux angles which result in limited diffusion of ad-atom precursors on the substrate. This wurtzite phase CdTe produced at high source flux angles is used to tailor the interface between the n-type hexagonal wurtzite CdS window layer and p-type cubic zinc blende CdTe absorber in the standard CdS/CdTe solar cell. Application of this wurtzite phase CdTe interlayer results in better lattice matching to both hexagonal CdS and cubic CdTe leading to higher photovoltaic device performance. Using spectroscopic ellipsometry (SE) and x-ray diffraction (XRD), the optical and microstructural properties of the GLAD CdTe interlayers before and after CdCl₂ treatment are obtained. CdS/CdTe heterojunction solar cells are fabricated with GLAD interlayers prepared using source flux angles from 0° (normal incidence) to 80°, at substrate temperatures from room temperature to 250 °C, and with CdCl₂ post-deposition treatment times up to 30 minutes. Photovoltaic device performances are compared between devices with and without the introduction of these GLAD CdTe interlayers. Improvements in photovoltaic device performance parameters including open circuit voltage, short circuit current, fill factor, and power conversion efficiency are related to GLAD CdTe interlayer characteristics.

Layered Atomic Arrangements in Fluorite Derivative Tungstates and Uranates Kurt E. Sickafus; University of Tennessee, United States

In this presentation, we will compare and contrast the structures of oxide compounds containing lanthanum (La) and either tungsten (W) or uranium (U). We will interrogate the structures of La-tungstates (LWO) versus La-uranates (LUO) using a geometric model based on layer stacking sequences of pseudo close-packed layers. The individual atomic layers in the stacking model considered here have hexagonal symmetry and are based on triangular atom nets or hexanets. The layers in the LWO and LUO compounds can be described based on geometric subdivisions of a triangular atom net, subdivisions originally described by Shuichi Iida. One unusual layered atom structure involves the LWO compound, La₇W₁O₁₃.₅. This compound has a stoichiometry very close to La₆W₁O₁₂, which is the stoichiometry associated with 6-1-12 delta (δ) phase oxides (actually, the 6-1-12 compound is not observed in LWO). However, the structure of the 7-1-13.₅ stoichiometry is very different compared to the δ-phase. The layer stacking model we develop for the 7-1-13.₅ compound is closer to that of pyrochlore, rather than δ-phase. Interestingly, in LUO, the 6-1-12 phase is observed and we can describe the layer stacking in this compound as consistent with a δ-phase structure. We will perform a detailed comparison between layered atom arrangements in La₇W₁O₁₃.₅ and La₆U₁O₁₂ in an effort to rationalize why the structures of these two compounds, both containing hexavalent metal cations (W⁶⁺ and U⁶⁺), are so different.

Understanding Electrical Properties of Nanocrystalline, Mesoporous Composite Ce$_{0.9}$Gd$_{0.1}$O$_2$-d Thin Films

Christel Laberty¹ and Armelle Ringuede²; ¹Sorbonne Université, France; ²PSL, France

Crystalline, mesoporous NiO/GDC thin films with thicknesses ranging from 50 nm to 250 nm were synthesized through templated sol–gel chemistry coupled with the dip-coating process and heat-treatment in air. The thin films' microstructure is composed of two interpenetrated networks made of mesopores and inorganic components. Efficient coupling between the temperature and the NiO volume fraction (vol%) allows tuning of both the pore size with dimensions ranging from macro- to meso-size and the NiO or GDC crystallite size with a diameter below 10 nm. X-ray diffraction and impedance spectroscopy performed in 10% H$_2$ in Ar allowed the *in situ* study of the reduction process of NiO to metallic Ni. Coalescence of Ni particles generated by the reduction step and percolation phenomena controls the resulting conductivity of the final materials. Thin films with an initial content of 50 vol% of NiO exhibit lower electrical properties compared to those with an initial content of 70 vol% NiO. Electrical properties in a reducing atmosphere were also studied as a function of microstructure such as the pore dimension and the thickness of the pore wall. Excellent electrical properties are obtained for Ni70/GDC30-porous thin films synthesized with the block-co-polymer PS40-PEO36 that have a final conductivity of $9 \times 10^4$ S m$^{-1}$ at 500 °C. These mesostructured nanocomposite thin films exhibit a connected pore network that ensures good gas diffusion and good particle–particle contact for GDC and Ni, which gives satisfactory electrical properties. These films have all the attributes to be used as anodes in micro-SOFCs. This approaches was also extended to mesostructured composite LSCF$_x$/GDC$_{1-x}$ thin films. This technique allows us to define the heat-treatment, the LSCF content in the composite film and the thickness of the film to achieve good electrical conductivity. Electrical conductivity of 250 S cm$^{-1}$ was achieved for the pure, mesoporous LSCF film at 700 °C.

Local Structure of Uranium-Neptunium and Uranium-Plutonium Mixed Oxides Using High Resolution Solid-State 17O NMR

Laura Martel, Jean-François Vigier, Sarah Nourry, Antony Guiot, Jacobus Boshoven and Joseph Somers; European Commission, Germany

U$_{1-x}$Np$_x$O$_2$ and U$_{1-x}$Pu$_x$O$_2$ mixed dioxides with the fluorite Fm-3m crystalline structures are considered as fuels and targets for the transmutation of the minor actinides in fast neutron reactors. We present an atomic scale structural analysis on a series of U$_{1-x}$An$_x$O$_2$ synthesized by the sol–gel external gelation method, for which longer range structural analysis indicates that the process yields solid solutions. The atomic scale structure is probed using high resolution $^{17}$O solid-state NMR in a unique manner. Indeed, this technique allows a particular insight into the local structure of these solid-solutions as different oxygen signals attributed to the O(Np)$_y$(U)$_{4-y}$ (with 0 ≤ y ≤ 4) units can be identified by increasing Np content. We thus show how the use of solid-state high resolution NMR opens new routes for the fine characterization of local order in these radioactive materials.

Investigating Cerium Doped Indium Oxide as a High Mobility Transparent Conducting Oxide

Joe Willis¹,²,³, Thomas J. Featherstone², Benjamin A. Williamson³, Jack Swallow⁴, Leanne A. Jones⁴, Tien-Lin Lee¹, Pardeep K. Thakur³, Takeshi Koida⁶, Tim Veal⁴ and David O. Scanlon¹,²,³; ¹University College London, United Kingdom; ²Thomas Young Centre, United Kingdom; ³Diamond Light Source, United Kingdom; ⁴University of Liverpool, United Kingdom; ⁵Norwegian University of Science and Technology, Norway; ⁶AIST Japan, Japan

Transparent Conducting Oxides are fundamental components of modern optoelectronic devices, bringing together the unusual combination of optical transparency and electrical conductivity. Presently, the champion material is Sn-doped In$_2$O$_3$ (ITO), capable of reaching resistivity as low as $10^{-5}$ Ω cm and mobility around 40 cm$^2$ V$^{-1}$ s$^{-1}$. However, it has emerged that the use of alternative dopants returns greater mobility on the order of 100 cm$^2$ V$^{-1}$ s$^{-1}$, and in turn can match or even surpass the levels of conductivity reached by ITO.[1] Higher mobility affords a lower carrier concentration, allowing for improvements in NIR transparency due to a lower resonant plasmon frequency, ultimately leading to increased efficiencies in
Here Ce-doped In$_2$O$_3$ (ICO) films grown by rapid plasma deposition demonstrate electron mobility upward of 130 cm$^2$ V$^{-1}$ s$^{-1}$.[3] Hybrid DFT calculations show that Ce 4f states lie well above the conduction band minimum, thereby not affecting its dispersion. A low electron effective mass is maintained at the band edge and therefore high electron mobility is achieved, a feature shared with other successful resonant donors in In$_2$O$_3$.

Defect formation energies place the transition level of the Ce donor from 1+ (active) to neutral (inactive) around 0.1 eV above the CBM – this suggests that only a small shift in the Fermi level will cause Ce (III) to begin to occupy In sites rather than Ce (IV). This is observed in Hard X-ray Photoelectron Spectroscopy, where Ce (III) states begin to emerge as a function of increasing carrier concentration. This potentially places an upper limit on Ce-doping of In$_2$O$_3$ but does not prevent films achieving equal levels of conductivity and surpassing electron mobility of commercial ITO films, with feasible applications in concentrated multi-layer solar cells and beyond.

New Insight into the Disordering Mechanism in Fluorite-Related Compounds Maik K. Lang; University of Tennessee, United States

Structural disorder plays a critical role in many technological applications to enhance specific functionalities, such as increasing conductivity via chemical doping in semiconductors or improving flux pinning in high-temperature superconductors. Recent results from neutron total scattering experiments have shown that the atomic arrangements of many disordered crystalline materials are not random nor are they represented by the long-range structure observed from diffraction experiments. This structural heterogeneity at different length-scales appears to be a general characteristic of disordered crystalline materials, but the underlying mechanisms are not well understood. This presentation reviews neutron total scattering experiments on a range of fluorite-related compounds that show complex disordering behavior across different length scales. Structural information from pair distribution functions with sensitivity to both cation and anion sublattices were utilized to investigate in detail the disordering process of A$_2$B$_2$O$_7$ pyrochlore oxides. The order-disorder transformation can be understood as a rearrangement of atomic-scale building blocks. The same concept can be used to describe disordering in weberite-type oxides (A$_3$BO$_7$). This knowledge has implications for tailoring the structural response of complex oxides to extreme environments. For example, by choosing a material with specific structural building blocks the resistance to ion irradiation can be greatly improved.

Elucidating the Relationship between Chemical Order and Mass Transport in Pyrochlores Blas P. Uberuaga, Cortney Kreller, Matthew T. Janish, James Valdez, Romain Perriot, Ghanshyam Pilania and Yongqiang Wang; Los Alamos National Laboratory, United States

It is becoming ever more apparent that, in complex compounds such as pyrochlores, the detailed arrangement of the cations drives functionality. For example, both radiation tolerance and ionic conductivity have been linked to how easily cations can mix across sublattices. This is due to the fact that mass transport in these materials is a strong function of the cation distributions. However, the actual relationship between the cation, or chemical, structure of these compounds and the rates of transport are still not well established. While some reports find enhanced ionic conductivity in disordered materials, others find higher conductivity in ordered phases. Many of these studies use chemistry to influence the disorder, essentially changing multiple variables at once. However, the degree to which cations mix can be finely controlled using radiation
damage without changing chemistry. Here, we use radiation damage as a tool to induce changes in the cation structure of thin-film model pyrochlores. We then characterize the extent to which those changes impact mass transport. We combine these experimental efforts with state-of-the-art simulation methodologies to understand how atomic scale mechanisms dictating mass transport change when the cation structure is modified. We have found that even small changes in cation structure can lead to large changes in the transport characteristics of the material. Our results provide new insight into mass transport in materials that exhibit chemical complexity well beyond the model systems studied where chemical disorder dictates the fundamental behavior of the material.

Understanding the Phase Behaviour of Pyrochlore Bi$_2$Sn$_2$O$_7$ Warda Rahim$^1$, Jonathan M. Skelton$^2$, Aron Walsh$^3$ and David O. Scanlon$^1$; $^1$University College London, United Kingdom; $^2$University of Manchester, United Kingdom; $^3$Imperial College London, United Kingdom

Ternary oxides with pyrochlore structure (A$_2$B$_2$O$_7$) exhibit a range of interesting properties, including ionic conduction, ferromagnetism, superconductivity, high dielectric character and colossal magnetoresistance. Unlike the majority of the tin-based pyrochlores, Bi$_2$Sn$_2$O$_7$ exists in a number of polymorphic forms, with an α-Bi$_2$Sn$_2$O$_7$ to β-Bi$_2$Sn$_2$O$_7$ transition occurring at ≈400 K and β-Bi$_2$Sn$_2$O$_7$ to γ-Bi$_2$Sn$_2$O$_7$ transition occurring above 900 K. The structural model for the highest temperature γ-Bi$_2$Sn$_2$O$_7$ is undisputed (Fd-3m) but there has been a controversy over the structural models for its lower temperature polymorphs. Previous studies by Evans et al. suggested the room temperature polymorph belongs to space group 7 (P411) with 352 atoms per cell. Recently, a simpler model for α-Bi$_2$Sn$_2$O$_7$ belonging to space group 9 (C2c1) with 88 atoms per cell, and the first ever detailed structural model for β-Bi$_2$Sn$_2$O$_7$ belonging to space group 41 (Aba2) has been reported. We perform first principles lattice dynamics calculation using Phonopy$^2$ with gradient corrected density functional theory, starting from the highest symmetry γ phase, and map out the potential energy surfaces$^6$ spanned out by imaginary mode eigenvectors, with the aim of elucidating the lowest energy structure. This approach successfully takes us from the highest temperature structure to the new structural model suggested for α. It also demonstrates that β is a thermal average of a lower symmetry structure separated by a very small energetic barrier. The success of the method highlights the strength of ab-initio lattice dynamics in predicting the dynamically stable structural model of a compound that undergoes displacive phase transitions and can speed up the exploration of different structures for solid-state applications.

6:15 AM S.C.T05.02.05
Investigation of Disorder in Ho$_2$Ti$_2$Zr$_x$O$_7$: Pyrochlore to Defective Fluorite Chemical Series Devon L. Drey$^1$, Eric O’Quinn$^1$, Igor Gussev$^1$, Antonio Fuentes$^2$, Joerg Neuefeind$^3$, Michelle Everett$^3$, Gianguido Baldinozzi$^4$ and Maik K. Lang$^1$; $^1$University of Tennessee at Knoxville, United States; $^2$Cinvestav Unidad Saltillo, Mexico; $^3$Oak Ridge National Laboratory, United States; $^4$Université Paris-Saclay, France

Pyrochlore oxides (A$_2$B$_2$O$_7$) – and other fluorite-derived complex oxides – are interesting for not only their wide variety of desirable properties, such as ionic conduction and radiation tolerance, but also for their complex defect formation and disordering mechanisms that often give rise to their properties. We have used neutron total scattering to study in detail all structural aspects of the disordering of pyrochlore which involves randomization of both cation and anion sublattices. By means of diffraction and pair distribution function analysis we have determined the room temperature polymorphs for Ho$_2$Ti$_2$Zr$_x$O$_7$ ($x = 0.0-2.0$) solid solution series, the disordering mechanism was studied simultaneously over multiple material length scales with novel insight into the local atomic arrangements. With increasing Zr-content, the series exhibits an order-disorder transformation from pyrochlore (space group: Fd-3m) to defective fluorite (space group: Fm-3m) across a narrow compositional range ($x = 1.0-1.5$) over the long length-scale, while the local atomic arrangement changes gradually to a weberite-type structure (space group: C2221) over the whole compositional range. This distinct disordering scheme can be explained by the movement of a 48f oxygen to a vacant 8a site, creating 7-coordinated Zr$^{4+}$ sites that produce local weberite-type building blocks. These building blocks accumulate until a critical Zr-content ($x ~ 1.2$) is reached which triggers the rearrangement of weberite-type units into long-range structural defective fluorite.

2020 MRS Virtual Spring/Fall Meeting, November 27-December 4, 2020, Spring Abstracts Final Program 2/3/21
Phonon Lifetimes and Thermal Conductivity of La$_2$Zr$_2$O$_7$  Maud Einhorn$^1$, Joe Willis$^{1,2}$, Kieran B. Spooner$^1$, Warda Rahim$^1$ and David O. Scanlon$^{1,2}$;  $^1$University College London, United Kingdom; $^2$Harwell Science and Innovation Campus, United Kingdom

High-temperature thermal-barrier coatings are an essential component of modern gas-turbine engines. Despite remaining the standard industrial thermal barrier coating, yttria-stabilised zirconia (YSZ) top-coat suffers profound performance issues at very high-temperatures, principally resulting from high-temperature phase instability limiting the maximum operating temperature.$^1$ As a result, alternative materials with superior insulation properties and stability are essential for higher operating temperatures and improve engine efficiencies. To this end, novel ceramic materials, rare-earth zirconates pyrochlores including La$_2$Zr$_2$O$_7$, have been looked to due to their low lattice thermal conductivity, phase stability across a wide temperature range, high melting point and low thermal expansion coefficient.$^2$

Recent work by Voneshen et al. ascribed the exceptionally low thermal conductivity in La$_2$Zr$_2$O$_7$ to a strongly anharmonic phonon mode associated with the kagome planes in the material, observed from inelastic neutron scattering (INS) data.$^3$ In this work we calculate the thermal conductivity and phonon lifetimes of La$_2$Zr$_2$O$_7$ using ab initio lattice dynamics calculations using both the linearised Boltzmann transport theory (LBTE) within the single mode relaxation time approximation (RTA) and the temperature dependent effective potential (TDEP) methods.$^4,5$ These results are supported by new experimental data measuring the phonon-phonon scattering rates of the individual modes in La$_2$Zr$_2$O$_7$.

Disorder and Local Arrangement in the Crystallographic Lattice of UO$_2$ Nuclear Fuel  Lionel Desgranges; CEA, France

Uranium dioxide is the main constituent of most current nuclear fuels that is doped with fission products during its use in nuclear power plants. This industrial topic motivated many studies of UO$_2$ and doped UO$_2$. UO$_2$ crystalline structure is fluorite and it is considered to form ideal solid solutions with most of the cationic dopants generated as fission products during its operation. However, this historical description is now challenged by new experimental results that enlighten the existence of disorder and non-ideal solid solution behaviour. In this presentation, we will discuss some of these results and their implication on some key features regarding nuclear fuel behaviour will be analysed.

Firstly, the disorder at oxygen atom crystallographic site will be reviewed using neutron diffraction data on UO$_2$ as a function of temperature. Its implications on UO$_2$ properties will be discussed regarding specific heat and UO$_2$ irradiation resistance. Secondly, the oxidation mechanism of UO$_2$ will be considered. Neutron diffraction data evidenced the existence of oxygen clusters, named cuboctahedra that accumulate in the pristine UO$_2$ lattice with several crystallographic arrangements. The morphological evolution of spent UO$_2$ fuel submitted to air atmosphere at temperature above 200°C, which is representative of an accidental scenario during air storage of spent nuclear fuel, will be analysed as a function of these crystallographic changes.

Finally, fission product incorporation in UO$_2$ will be presented and we will discuss some new research challenges this issue brings up.

Complex Oxides in the Nuclear Fuel Cycle Context  Sarah C. Finkeldei; University of California, Irvine, United States
Complex oxides with fluorite derived structures play a key role in the context of the nuclear fuel cycle. We enhanced wet-chemical synthesis routes, e.g. co-precipitation or internal gelation, to fabricate tailor-made precursors for advanced nuclear fuel forms as well as potential nuclear waste forms with the defect fluorite or pyrochlore crystal structure. The internal gelation route enabled the fabrication of high-performance UO₂ fuel candidates using 1) dopants, such as Cr and Mn, to improve the fission gas retention, and 2) a second phase, here Mo, to enhance the thermal conductivity of UO₂-based nuclear fuel. Characterization of the thermal properties of enhanced UO₂-Mo fuel candidates fabricated via different approaches revealed significant differences in the thermal conductivity of the final fuel candidates. An in-depth understanding about the correlation between the synthesis approaches and the materials properties is underway. Fabrication of Pu-doped Nd₂Zr₂O₇ pyrochlores as potential nuclear waste forms revealed the enormous flexibility of the pyrochlore crystal structure to accommodate Pu(IV) at the usually trivalent A-site. Charge neutrality is achieved by surplus oxygen at formerly oxygen vacant sites. The immobilization of actinides in a zirconate based pyrochlore is known to result in an order/disorder transition from a pyrochlore to a defect fluorite structure, a consequence to self-irradiation. For this order/disorder transition of Nd₂Zr₂O₇ a combined experimental approach of oxide melt solution calorimetry with ab initio thermodynamic modeling revealed a transition enthalpy of ~30 kJ/mol. This transition enthalpy corresponds to an entropy of disordering of ~16 kJ/mol. This presentation will summarize recent activities about developing suitable fabrication routes of fluorite-structure derived ceramics in the nuclear context, how the fabrication avenues affect their properties as well as the effect of radiation induced structural order/disorder transitions towards the materials properties and performance.

6:00 AM S.C.T05.03.03
Radiation Effects in UO₂ and Other Oddities of the Unstable Valences Steven D. Conradson¹, ², ³, Janne Pakarinen⁴ and Gianguido Baldinozzi⁵; ¹Institut Jozef Stefan, Slovenia; ²Washington State University, United States; ³Polaronix Corporation, United States; ⁴Studsvik Nuclear AB, Sweden; ⁵SPMS, CNRS CentraleSupelec, France

Since the stable valences of U in its oxides are IV, V, and VI, the formation of reduced species in UO₂ is problematic. This is demonstrated in XAFS measurements of UO₂ irradiated with protons and helium nuclei. The addition of O occurs by clustering that results in UO₂-U₄O₉ phase separation, facilitated by the virtually identical U sublattices of these two species. Ion beam irradiation that displaces O ions could give the same behavior, but whereas disorder is observed the signatures of U₄O₉ are not. This is most likely because, whereas the O-enriched regions with mixed valence U(IV,V) would be stable, the U(III) formed in the O-depleted regions is not. An different mechanism is activated. This could also be important in the chemistry of the fuel and the O potential formed in response to the temperature gradient.

6:30 AM S.C.T05.03.05
Effects of Grain Size on the Radiation Response of CeO₂, ThO₂, and UO₂ William Cureton¹, Raul Palomares¹, ², Cameron Tracy³, ⁴, Eric O’Quinn¹, Rodney Ewing⁴, Gianguido Baldinozzi⁵, Jie Lian⁶, Christina Trautmann⁷, ⁸ and Maik K. Lang¹; ¹The University of Tennessee, Knoxville, United States; ²The Boeing Company, United States; ³Harvard University, United States; ⁴Stanford University, United States; ⁵University of Paris Saclay, France; ⁶Rensselaer Polytechnic Institute, United States; ⁷GSI Helmholtzzentrum für Schwerionenforschung, Germany; ⁸Technische Universität Darmstadt, Germany

Radiation stability is often a key limiting factor in performance of fluorite-structured materials and determining their suitability for use in energy-related applications. In an effort to mitigate the effects of radiation, nanostructured materials are of interest as they incorporate high defect sink strengths [Rose et al., Nanostructured Materials (1995), Nita et al., Journal of Nuclear Materials (2004)]. Recently, it has been shown that the response of CeO₂, ThO₂, and UO₂ to highly ionizing radiation is strongly dependent on the material’s redox response [Tracy et al., Nature Communications (2015)]. When exposed to swift heavy ions, cations in the material are subject to changes in valence which drives swelling and microstrain as irradiation-induced defects accumulate. In this work, we present new insights into how crystallite size affects irradiation-induced redox response and defect accumulation in fluorite-structured simple oxides. Using 946 MeV Au ions at the UNILAC accelerator of the GSI Helmholtzzentrum, we irradiated microcrystalline and nanocrystalline materials of different compositions containing cations known to reduce (CeO₂), remain univalent (ThO₂), and oxidize (UO₂) under ionizing conditions. Irradiated samples were characterized by synchrotron X-ray diffraction/absorption, neutron total scattering with pair distribution function (PDF) analysis, transmission electron microscopy, and Raman spectroscopy. Each composition exhibits a distinct response between microcrystalline and nanocrystalline forms, such as magnitude of volumetric swelling and secondary phase formation, driven mainly by redox processes. PDF analysis reveals small peroxide-like defects in CeO₂ and mono- and di-interstitial clusters in UO₂. Our findings imply that nanocrystallinity has negative effects on a material’s response to highly ionizing radiation. These results shed more light onto the interplay of particle size and cation...
redox behavior and their effect on defect production in an important class of materials, an insight that is essential in developing advanced materials for energy-related applications.

**Self-Irradiation-Induced Disorder in (U_{0.9238}Pu_{0.1})O_{2}**
Emanuele De Bona¹², Bert Cremer¹, Jean-Yves Colle¹, Thierry Wiss¹, Gianguido Baldinozzi³ and Rudy Konings¹; ¹European Commission - JRC, Germany; ²Helmholtz-Zentrum Dresden-Rossendorf, Germany; ³Université Paris-Saclay, France

Spent nuclear fuel (SNF) of light water reactors (LWR) is constituted of a matrix of unfissioned UO₂ containing a small fraction of fission products (FP) and minor actinides (MA). These MA are mainly α-emitters with very long half-lives: therefore, SNF will keep α-self-irradiating for millennia after discharge from the reactor, resulting in widespread changes of the thermophysical properties of the material. In order to properly coordinate and license any disposal strategy for SNF, the long-term effect of α-self-irradiation has to be known and anticipated.

Due to the lack of real old SNF, a proxy system to study the effect of α-irradiation on the SNF matrix is provided by the synthesis of UO₂ doped with short-lived α-emitters. In this way, a significant amount of radiation damage can be stockpiled over a laboratory timescale in a simpler surrogate system that does not combine radiation damage with chemical or density gradients (built-in in real SNF).

In the present work, UO₂ doped with ²³⁸Pu was produced to study the effect of α-self-irradiation on the crystalline disorder and lattice swelling. The composition of the samples was carefully chosen, based on the dopant specific activity, in order to reach saturation of the lattice parameter swelling within the 3 years timespan of the project. Samples were periodically characterized by means of XRD and Raman spectroscopy up to 0.4 dpa, equivalent to a spent nuclear fuel with a 40 GWd/t UO₂ burnup stored during 300 years, or representative of a 65 GWd/t spent MOX fuel (45 % Pu) after 25 years of storage.

Lattice swelling as a function of dpa was assessed with very good accuracy and benchmarked against literature data: saturation was reached at a value of 0.3 % around 0.4 dpa. For the first time, microstrain was also monitored in (U,Pu)O₂ as a function of self-irradiation.

Periodic Raman spectroscopy acquisitions on (U,Pu)O₂ as a function of the dose represent an innovative probe, and they showed fast and progressive degradation of the structural order up to 0.1 dpa, and a slow but persistent increase up to 0.4.

SEM characterizations were additionally performed and highlighted that no loss of structural integrity is associated with this microstructural evolution, at least within the measured dpa range.

---

**Order/Disorder in Fluorites—Determination and Impact**
Karl R. Whittle; University of Liverpool, United Kingdom

The basic fluorite structure allows for both ordering and disorder, with multiple options in each such as those that are regular integer repeats of the unit cell, such as with pyrochlore, or those that repeat with a different repeat length. The degree of order/disorder within the atomic structure can often lead to modification of properties, such as ionic conductivity, or how they respond to induced radiation damage. Enhanced understanding of the degree of short/long range order greatly improves the design and development of new materials. The determination of the degree or order/disorder can be challenging given the cubic nature of the fluorite structure. To get round such challenges a combination of experimental techniques can be applied, however each technique in itself has different sensitivities and ability to provide structural information. This presentation provides an overview of multiple options and how they can be applied to the determination of order/disorder in fluorites, and how the derived information can be used to develop new material options.

5:30 AM **S.CT05.04.03**
**Global and Local Structural Modifications in Swift Heavy Ion Irradiated Sc₄Hf₃O₁₂**
Maulik K. Patel¹, Kurt E. Sickafus² and Gianguido Baldinozzi³; ¹University of Liverpool, United Kingdom; ²The University of Tennessee, Knoxville, United States; ³University of Paris-Saclay, France

Aliovalent cation-doped fluorite oxide structures are ideal candidates to understand phase stability and their transformation...
pathways under radiation. These systems are relevant models for nuclear fuels and waste forms. Sc₄Hf₃O₁₂ is a delta phase crystallising in a trigonal symmetry. This and other AₓB₃O₁₂-type systems were observed to transform into a long-range defect fluorite phase upon low energy ion irradiations. On one instance Sc₄Hf₃O₁₂ was also observed to partially turn into a bixbyite phase, however, the reasons behind this were never clearly understood. Thus, in the present study, swift heavy ion irradiated Sc₄Hf₃O₁₂ was investigated as a function of fluence using x-ray diffraction. Structural parameters obtained from quantitative Rietveld analysis reveal that, while the long-range average structure develops into a defect fluorite, the local structure tends to convert into a bixbyite-like arrangement. Similarities in the polyhedra suggest this bixbyite-related local phase is a metastable system that effectively provides radiation resistance by creating large numbers of bixbyite-related replicas within an aristotype fluorite mesocrystal.

5:45 AM S.CT05.04.04
Multicomponent Equiatomic Rare-Earth Oxide Ceramics Matheus Pianassola¹,², Madeline Loveday¹,², Jake McMurray³, Merry Koschan⁴, Charles Melcher⁴,⁵ and Mariya Zhuravleva¹,²; ¹University of Tennessee, Knoxville, United States; ²The University of Tennessee, Knoxville, United States; ³Oak Ridge National Laboratory, United States

Phase formation in multicomponent rare-earth oxides is defined by a competition between the fluorite structure typical of rare-earth dioxides and the hexagonal, monoclinic, and bixbyite structures typical of sesquioxides. This competition is determined by a combination of composition, sintering atmosphere, and cooling rate. Polycrystalline ceramics comprising various combinations of Ce, Gd, La, Nd, Pr, Sm, and Y oxides in equiatomic proportions were synthesized by solid-state sintering. This synthesis method allows a rapid evaluation of the effects of composition (type and number of cations), sintering atmosphere (oxidizing, inert, and reducing), and cooling rate on phase formation. Single fluorite, bixbyite, or monoclinic phase compositions were obtained with a slow cooling of 3.3°C/min, indicating that rare-earth oxides follow a different phase stabilization process than that of transition metal high-entropy oxides. In an oxidizing atmosphere, both Ce and Pr induce the formation of fluorite or bixbyite phases, while only Ce plays that role in an inert or reducing atmosphere. Samples without Ce or Pr develop a single monoclinic phase. The phases formed at initial synthesis may be converted to a different one when the ceramics are annealed in an atmosphere different than the original sintering atmosphere. Additionally, phase evolution of a five-cation composition was studied as a function of sintering temperature. The binary oxides used as raw materials completely dissolve into a single bixbyite structure at 1450°C in air.

6:00 AM S.CT05.04.05
High-Solute Grain Boundary Compositional Effects in Ca- and Ba-Doped Ceria Tara M. Boland, Arunima Singh, Peter Rez and Peter A. Crozier; Arizona State University, United States

Ceramic oxides are used for a wide variety of technologically relevant applications from electrochemical devices, novel resistive switching devices, and oxygen sensors. Applications such as these typically rely upon the ability of oxides to conduct ions efficiently through the lattice. However, the grain boundaries (GBs) can be orders of magnitude more resistive than their bulk counterparts. While methods developed for bulk-doping have been successful, they have provided little insight when optimizing the GB ionic conductivity in polycrystalline ceramic oxides such as CeO₂. In recent years, nanoscale compositional characterization of GB composition has revealed different nominal concentrations of solutes at the GBs which could result in orders of magnitude increase in GB ionic conductivity relative to the undoped samples. This study focuses on the impact which concentration plays in modulating the potential energy landscape for two potentially promising solutes, Ca and Ba, which may increase the ionic conductivity across the GB. Computational modeling is employed using density functional theory to optimize the GB interfacial structure for one GB misorientation in CeO₂. This study further develops our understanding of high solute GB composition enabling the development of methods such as selective doping to improve macroscopic ionic conductivity for both the grain and GB.

To understand the key factors which influence GB properties, spin-polarized density functional theory calculations were performed using VASP[1] within the generalized gradient approximation (GGA)[2,3] with the Perdew-Burke-Ernzerhof exchange correlation functional. The strong correlation effects were treated with the Hubbard U correction (GGA+U) formulated by Dudarev et. al.[4]. The GB structures are doped with a local GB solute concentration of 0%, 20%, and 40%. The local bond strain, coordination, electronic structure, and thermodynamic energies are computed for each distinct substitutional solute location at the GB core. The oxygen vacancy binding energy along a few select [0,0,1] paths are computed to assess how changes in the local GB composition impacts the potential energy landscape for oxygen migration. This study further develops our understanding of the interplay between nanoscale GB composition and structure with high solute concentrations enabling the development of methods such as selective doping to improve macroscopic ionic
conductivity for both the grain and GB.

Atomic-Scale Simulation of Defects and Thermophysical Properties in Actinide Mixed Oxides
Paul C. Fossati1, Conor O. Galvin2, Patrick A. Burr2, Michael W. Cooper3 and Robin W. Grimes4; 1CEA, France; 2University of New South Wales, Australia; 3Los Alamos National Laboratory, United States; 4Imperial College London, United Kingdom

Defects are known to play an important role in several thermophysical properties of actinide oxides, from ionic self-diffusion to heat transport.
Point defects are also related to high-temperature superionic transitions observed with many single actinide oxides and mixed oxides (MOX).

Recent advances in potential development have enabled accurate molecular dynamics (MD) simulations of a broad range of actinide oxide compositions, and have been shown to reproduce defects properties well.
This has been used in this work to investigate the effect of defects populations on thermophysical properties such as elastic constants and vibrational properties of several mixed oxides containing U, Pu, and Th.
Both the low-temperature fluorite structure and the high-temperature superionic phase have been considered.
These results are important to improve our understanding of the behaviour and high-temperature thermodynamics of actinide oxides beyond the superionic transition.

6:30 AM S.CT05.04.09
Locating Facile Oxygen Vacancy Creation and Annihilation Sites on CeO2 Nanoparticle Surfaces
Ethan L. Lawrence, Barnaby D. Levin, Tara M. Boland, Shery Chang and Peter A. Crozier; Arizona State University, United States

Reducible oxides can be employed in solid oxide fuel cell anodes and cathodes largely because their redox properties enable fuel oxidation and oxygen exchange [1]. These processes involve creation and annihilation of oxygen vacancies at the surface and transport through the bulk. Here, we show that electron microscopy can be employed to identify the most active sites for vacancy creation/annihilation on the surface of CeO2 (ceria). Under reducing conditions, ceria releases oxygen through the formation of an oxygen vacancy coupled with a cation transition from Ce4+ to Ce3+. Moreover, a lattice expansion (~0.2-0.3 Å) occurs once oxygen vacancies are created on CeO2 surfaces [2]. The relative ease with which oxygen vacancies are created/annihilated on CeO2 is strongly dependent on particle surface structure, and theoretical calculations have predicted significant variations in activation energies for lattice oxygen removal at different surface sites, which is likely to be associated with orders of magnitude differences in local oxygen exchange rates [3]. We are interested in probing and correlating local exchange activity with atomic surface structure and have used time-resolved aberration-corrected transmission electron microscopy (AC-TEM) to observe and analyze dynamic atomic-level cation displacements associated with oxygen vacancy creation and annihilation.

A FEI Titan AC-TEM equipped with a Gatan K2 IS direct detection camera (with high detective quantum efficiency) was used to image CeO2 nanocubes at 40 frames/second and 5000 e-/(Å²s). Ce atomic column displacements were analyzed with picometer precision over time-resolved image sequences using MATLAB codes. By monitoring the frequency of cation displacements at a surface, a local indicator of activation energy for oxygen vacancy creation was obtained. A considerable degree of diversity and heterogeneity in the type of surface sites that show high activity was observed, with low coordination number sites such as steps and edges, as well as locally strained sites, exhibiting the highest displacement frequency and therefore enhanced oxygen exchange activity. Our approach directly links atomic surface structure to vacancy creation, indicating that the ability to quantitatively characterize nanoparticle surfaces to locate active sites can contribute to understanding and tailoring their exchange properties.

Influence of Defects on the Structure and Properties of Fluorite-Based Nanostructured Oxides Pratik P. Dholabhai; Rochester Institute of Technology, United States
Fluorite-based nanostructured oxides are promising materials for wide-ranging applications. In these applications, due to the reduced dimensions, surfaces and interfaces play a critical role in influencing novel functionalities. In nanostructured oxides, defects are ubiquitous at surfaces, grain boundaries, and heterointerfaces. The interaction of defects with such structural anomalies are often found to dictate the atomic-scale structure and correlated properties of oxides. Based on atomistic simulations, we elucidate the influence of defects on structure and properties in three different cases – (i) Misfit dislocations in CeO2/MgO heterostructures: We find that dopant–defect complexes at misfit dislocations have extended stability revealing that they would influence ionic transport at heterointerfaces of fluorite-structured thin film electrolytes.(ii) Grain boundaries in nanocrystalline doped CeO2: We find that segregation energies, availability of favorable sites, and overall stronger binding of dopant–defect complexes would influence ionic transport across grain boundaries in nanocrystalline doped ceria. (iii) Steps and trenches at low-index surfaces of pyrochlores oxides: We find that one fundamental mechanism to eliminate the surface dipole in pyrochlores is the formation of structural defects such as steps and trenches, which explain the enhanced reactivity and extraordinary surface-driven properties of pyrochlores. Overall, our results shed light on the complex interplay between defects and structural anomalies, and assist in disentangling the multifaceted role of defects in fluorite-based nanostructured oxides.

An Atomic Level Study of Local Strain Fields on Multiple Low-Index Ceria Nanoparticle Surfaces Piyush Haluai, Ethan L. Lawrence, Barnaby D. Levin and Peter A. Crozier; Arizona State University, United States
The surface strain of oxide nanoparticles plays a crucial role in tuning a materials’ properties [1]. For example, surface strain can regulate and control surface diffusion processes and can change the ability of the surface atoms to bond with adsorbates and thus modify the reactivity of a material [2]. In reducible oxides such as CeO2, the degree of strain can be tuned by different means such as particle size, shape, non-stoichiometry, structural deformations (e.g. oxygen vacancies) etc. A critical step in understanding the properties of nanoparticle surfaces is to measure the surface strain on different crystal facets and in the vicinity of surface defects. We have developed a method to determine the surface strain in oxide nanoparticles with atomic resolution using high resolution transmission electron microscopy (HRTEM). In a typical TEM image, the signal from the heavier Ce atomic columns is much stronger than the signal from the lighter oxygen columns. Consequently, more precise measurements can be made on the cation sublattice in order to map the strain on or near the nanoparticle surface.
CeO2 nanoparticles were synthesized by the hydrothermal method [4] and imaged using negative Cs imaging in a FEI Titan AC-ETEM with a single-electron-detection K2 camera operated in the counting mode. The K2 camera allowed high quality electron imaging to be performed. (111), (110), and (100) CeO2 nanoparticle surfaces were imaged in a [110] projection at 5000 eÅ²s⁻¹ with Ce and O atomic columns visible at the surface. Custom written MATLAB codes are used to identify and determine the positions of atomic columns. Atomic resolution strain maps were created to visualize cation sublattice deformations at different locations in the nanoparticle. The bulk of the nanoparticle is relatively strain free, but the surfaces show varying degrees of compressive and tensile strain along different crystallographic directions of the nanoparticle. The surface strain field varies in a complicated fashion with the highest tensile and compressive strains along different directions occurring at different points on the surface. The highest degree of strain is associated with defects such as step sites. These local strain fields on CeO2 nanoparticle surfaces are correlated with local activity for oxygen vacancy creation and annihilation.

Deviation of Stoichiometry in Yttria Stabilized Zirconia and Amorphous Zirconia Simon C. Middleburgh1, Michael J. Rushton1, Lee J. Evitts1, Iuliia Ipatova1 and William E. Lee1,2; 1Bangor University, United Kingdom; 2Imperial College London, United Kingdom

Yttria partially stabilized zirconia (ZrO2)x(Y2O3)½-x and amorphous zirconia have been investigated to understand accommodation of excess oxygen into its structure. Yttria stabilized zirconia was investigated experimentally and through atomic scale simulation methods. A new Raman peak was observed after treatment at 840 cm⁻¹, consistent with previous reports of solid state peroxide ions (O2²⁻). This was corroborated using atomic scale simulation based on density functional theory; these also highlighted the near-zero solution enthalpy for excess oxygen in the monoclinic structure via the formation of a peroxide ion defect.

Amorphous zirconia (a-ZrO2) was simulated using a combination of state-of-the-art atomic scale methods. This combination has enabled the complex chemistry of the amorphous system to be efficiently investigated. Notably, the a-ZrO2 system was observed to accommodate excess oxygen readily – through the formation of neutral peroxide (O2²⁻) defects - the same defect observed in the yttria stabilized zirconia system. This has implications not only in the a-ZrO2 system, but also in other systems employing network formers, intermediates and modifiers.

Operando Visualization of Catalytically Driven Oxygen Transfer at Three-Phase Boundaries on CeO2 Nanoparticles during CO Oxidation Joshua L. Vincent and Peter A. Crozier; Arizona State University, United States

Oxygen transfer is a critical functionality in many technologies involved in automotive exhaust control and clean energy conversion. In these applications, catalytically active metal nanoparticles (e.g., Pt) are typically dispersed on reducible oxides (e.g., fluorite CeO2), since reducible oxides can transfer their lattice oxygen to reactive adsorbates at the metal-support interface, the so-called three-phase boundary [1,2]. Attaining an atomic-level understanding of the catalytically-driven oxygen transfer process is of great interest to the scientific community and is required to design more efficient catalysts. This work employs aberration-corrected environmental transmission electron microscopy (ETEM) to investigate the atomic-scale structural dynamics that occur at the Pt/CeO2 three-phase boundary under reaction conditions (i.e., in situ) and during catalysis (i.e., operando).

Nanostructured CeO2 cubes and rods were synthesized, loaded with 17 wt.% Pt nanoparticles (NPs), and used as model systems. An ISRI RIG-150 microreactor coupled to a Varian 450 gas chromatograph was used to characterize the CO oxidation performance of the catalysts. An image-corrected FEI Titan ETEM was used to visualize the atomic structures that form under reaction conditions. Modified specimen preparation techniques and in situ electron energy-loss spectroscopy (EELS) was implemented to track the gas composition during catalysis [3,4]. In this way it became possible to correlate active site dynamics with catalytic turnover frequency (TOF) for CO oxidation. It was observed that as the TOF increases, frequent oxygen transfer disrupts the bonds that anchor the ~2 nm Pt nanoparticles, leading to dynamic reconfigurations of the entire nanoparticles and their translational motion ~2-5 Å across the support. Interestingly, proximal Ce surface structures up to ~1 nm away from the Pt/CeO2 interface undergo concurrent dynamics, which is consistent with a Mars-van Krevelen mediated interfacial oxygen transfer process.

An additional investigation was done by coupling a high frame-rate direct electron detector to the ETEM, which enabled the transient dynamic behavior to be observed at higher time resolution (25 milliseconds). During this experiment a Pt NP on the (111) surface of a CeO2 rod was observed to restructure dynamically in a 10 mTorr atmosphere of CO and O2, although the same particle was stable in 0.5 mTorr of inert N2. Interestingly, an examination of the time- series in CO and O2 shows the Pt NP undergoes a sequence of structural reconfigurations that correlate with dynamics at interfacial Ce sites. This paper will present results from both experiments [5].

Emergent Oxygen Framework Correlations and Cation Disorder in Fluorite-Related Systems Gianguido Baldinozzi1 and Maulik K. Patel2,1; University of Paris Saclay, France; 2University of Liverpool, United Kingdom

Systems with strong local correlations but looser long-range cationic order are a challenging curiosity both from an academic and technological perspective. Describing structural features at different length scales is crucial for understanding the properties these systems can exhibit. Metal-oxide frameworks like many fluorite-derived structures seem capable to produce flexible long-range structures, allowing more freedom for tuning properties than most strictly periodic systems. Diffuse scattering (eventually condensing as weak superlattice spots) in such materials has been often discounted as intricate and burdensome but it is attracting greater attention recently, with advances in techniques and more flexible model paradigms. This experimental information provides invaluable feedback for modelling. We review some structural features encountered in pristine and irradiated oxygen-deficient fluorite-related structures that have promising potential for tackling the problems of frustration between nanoscale and long-range correlations.

Prediction of U Self-Diffusion and Xe Diffusion in UO2 and Cr-Doped UO2 from Cluster Dynamics Simulations Anders D. Andersson1, Christopher Matthews1, Michael Cooper1, Romain Perriot1, Benjamin Liu1, Giovanni Pastore2, Blas P. Uheruaga3 and Christopher R. Stanek1; 1Los Alamos National Laboratory, United States; 2University of Liverpool, United Kingdom

Diffusion in UO2 nuclear fuel is important for fuel performance, because it connects to key phenomena such as release of fission gas to the plenum, swelling and fuel creep. Fission gas retention and release also impact nuclear fuel performance in indirect ways by, for example, influencing the fuel thermal conductivity. Diffusion coefficients in fluorite UO2, which here refer to U self-diffusion and fission gas diffusion, are among the properties with highest uncertainty, especially in irradiation environments. This directly translates to fission gas release, swelling and creep predictions. In this talk, we will highlight the development of new mechanistic models for U and Xe diffusion within the grains of UO2, both under out-of-pile (no irradiation) and in-pile (irradiation) conditions. The models are applied to standard UO2 as well as to UO2 fuel doped with Cr. The point defect and Xe-vacancy cluster properties determining the defect concentrations and diffusion rates are calculated using a combination of density functional theory and empirical potential methods. With this data as input, the interaction of point defects under irradiation, leading to the formation of highly mobile Xe-vacancy clusters, is modeled using a methodology labeled free energy cluster dynamics (FECD). As suggested by the name, this method is based on traditional cluster dynamics but with an explicit connection to the free energy representing the driving force of defect reactions. In addition, this model accounts for the non-stoichiometry in UO2±x, as governed by the O chemical potential, which strongly influences the diffusion rates by changing the the equilibrium concentration of U and O vacancies. In order to build confidence in the modeling approach, our predictions are first validated against experiments for U self-diffusion. Good agreement is found for intrinsic diffusion, but some discrepancies emerge under irradiation, which we speculate may be related to sample non-stoichiometry. Application of the methodology to simulations of Xe diffusion shows that at high temperature, also equivalent to intrinsic (no irradiation) conditions, transport is dominated by the XeU2O cluster (a Xe atom occupying a trap site formed by two U and one O vacancy) and at intermediate temperatures the XeU4O3 cluster takes over, followed by atomic mixing due to irradiation damage at the lowest temperatures. The predicted Xe diffusion rates as function of temperature and fission rate are in good agreement with experimental data. Next, this model is adapted to Cr-doped UO2 by changing the O chemical potential and then used to predict the Xe diffusion rate. The Xe diffusivity increases compared to standard UO2, both at high and intermediate temperatures, while there is no effect at low temperatures where atomic mixing dominates. Finally, the importance of interstitial U and O clusters will be discussed in the context of rapid diffusion mechanisms, recombination rates and dislocation loop formation.

Defect-Engineered Multinary Chalcogenide Solar Absorber Materials David B. Mitzi; Duke University, United States

Zinc-blende-related chalcogenide semiconductors CdTe and Cu(In,Ga)(S,Se)2 (CIGS) currently represent the fastest growing commercial thin-film photovoltaic (PV) technologies. To address prospective scalability issues related to elemental scarcity (Te, In) and/or heavy-metal toxicity (Cd), Cu2ZnSn(S,Se)4 (CZTS) has also been vigorously pursued as a prospective drop-in...
replacement for CIGS, but efficiency improvement has been hindered by adverse defect characteristics (band tailing and deep defects), in part due to the similarity in chemistry among component metals and associated anti-site disordering. This talk will discuss promising emerging alternative multinary chalcogenides based on earth-abundant Cu$_2$BaSn(S,Se)$_4$ (CBTS) as an example, which offer similarities to CZTS in terms of electronic structure, but with introduced atomic size and coordination preference differences that reduce likelihood of atomic disordering—i.e., the much larger Ba ion, occupying a site that has 8-fold coordination rather than 4-fold (as for Cu, Zn and Sn in CZTS), reduces the probability of anti-site disordering and associated defects [1,2]. Simple solution- and vacuum-based film deposition processes enable fabrication of absorber layers with initial PV device sunlight-to-electricity power conversion efficiencies exceeding 5% for CBTS [3,4] and analogous photoelectrochemical (PEC) cells yielding a stable (over 10 hr) 12 mA/cm$^2$ photocurrent at 0 V/RHE [5]. This talk will discuss aspects of defect engineering within this family, as well thoughts on design strategies for expanding the known members of the I$_2$–II–IV–VI$_4$ family beyond CBTS (e.g., [6]). If desirable electronic structure tunability associated with a multi-element stoichiometry can be combined with earth-abundant components and control over defect formation, multinary chalcogenides may provide a bright path forward in the quest for high-performance, low-cost and scalable PV and PEC devices.

Several applications to nano/micro-electronics have been reported. Such as patterned magnetic media for a hard disk drive (HDD), light extraction structures of light-emitting diodes (LEDs), organic light-emitting diodes (OLEDs), anti-reflection (AR) structures for displays, metal wire-grid polarizers (WGP), and transparent conductive film (TCF) using nano-meshed metal thin film were demonstrated by these manners. The guided, aligned, or directed self-assembly (DSA) is a key technique, that the larger guides are made by conventional top-down methods then bottom-up self-assembled structures are formed along the guides. The challenges are continuing to fabricate the semiconductor memories. We would explain these potential applications fabricated by self-assembly.

A Scalable Micro-Object Assembly and Printing Platform Brad Rupp, Jeng Ping Lu, Anne Plochowietz, Yunda Wang, Dave Biegelsen, Lara Crawford, Sergey Butylkov, Julie Bert, Sourobh Raychaudhuri, Jamie Kalb, Qian Wang, Yu Wang, Pat Maeda and Eugene M. Chow; PARC, United States

Conventional manufacturing is able to assemble products composed of many parts of the size approximately 1mm and above. At the nanometer scale, techniques such as deposition, lithography, and self-assembly are used to make a myriad of heterogeneous products. However, at the mesoscale (1-1000μm) these techniques don’t overlap to produce structures at scale. There is a need for robust and scalable technologies which are able to join structures which can be developed on the micro-scale into large area, heterogeneous assemblies. To address this, we are developing a printing platform which is able to use micro-objects as ink—microLEDs, sensor chips, integrated circuits, micro- and nanoparticles. These objects are dispersed in a dielectric fluid and can be printed similar to a xerographic process, but maintain single object precision and orientation. To do this, an optically-addressed electrostatic actuator array manipulates the particles to move to target locations. From there, an integrated transfer system removes the particles from the assembly platform to be placed on a final substrate while maintaining their relative positioning. This transfer system can either be batch with adhesive transfer, or continuous with a non-contact electrostatic belt. This talk will describe the process in which we are able to rapidly sort, manipulate, orient, assemble, and transfer particles in parallel over a 1-inch wide area. We have demonstrated 1-μm registration, assembly of hundreds of particles in seconds, and roll-to-roll like transfer. With the use of computer vision to aid the assembly process, the technology has the potential to produce highly ordered, custom-patterned, heterogeneous assemblies accurately over a large area much faster than traditional manufacturing techniques while still maintaining fidelity.

Stochastic Assembly of microLED Displays Paul J. Schuele; eLux, Inc., United States

Direct emission displays made with inorganic μLEDs can potentially challenge LCD and OLED displays with better performance, efficiency and lifetime. Markets where microLED displays are likely to first appear are large information displays requiring high brightness, home theater applications benefitting from increased dynamic range and automotive displays in which high contrast and reliability are necessary. These displays are made possible by the integration of two mainstream technologies, namely GaN LED developed for general lighting and the large area active matrix backplanes developed for LCD displays.

The unique manufacturing challenge for μLED displays is development of a technology to position and connect millions of small devices with zero defects and low cost. Conventional pick and place tools are capable of positioning μLEDs but the throughput of serial assembly is inadequate while mass-transfer methods have difficulty changing the pixel pitch. To address these challenges eLux has developed a massively parallel fluidic assembly technology which positions each μLED by capture of the device in a well structure that also contains the connecting electrodes. Fluidic assembly technology uses simple low-cost equipment to achieve assembly rates up to 50 million μLEDs per hour and it is anticipated that production equipment could assemble an 8K display with 100 million LEDs in a few minutes. The technology is suitable for μLEDs from 10 to 200 μm diameter offering flexibility to make a wide variety of displays with resolutions from 400 to 10 ppi. Similarly, the microLED emitter area can be changed independently of the assembly technique to increase brightness and it is possible to produce displays over 5,000 cd/m². Fluidic assembly applies relatively low force on the device so brittle materials such as red μLEDs fabricated from AlGaInP can be assembled in the same way as blue and green emitting GaN μLEDs.

A fully integrated manufacturing system for μLED fluidic assembly will ensure that the assembled μLEDs have acceptable performance with special emphasis on eliminating shorted or high resistance devices. Testing and binning used in the general lighting industry are not practical at the micron scale, so wafers are mapped by cathodoluminescence to identify defective μLEDs. Based on the defect map, a selective harvest technique diverts bad μLEDs from the suspension so only known good die are used for assembly. Fluidic assembly relies on an excess of μLEDs to ensure sufficient capture attempts for complete assembly, so it is also necessary to capture, filter and recycle unassembled μLEDs.

With a suitable choice of complementary characteristic for the device and the trap site, it is possible to use fluidic assembly...
techniques to position nanowires or nanoparticles as well as µLEDs. The presentation will give an overview of the integration issues with some suggestions for other possible applications and approaches.

MicroLED Manufacturing-Specific Issues and Its Manufacturing Solution  
Ayano Honda, Katsumi Terada, Yoshiyuki Arai and Eiji Mori; Toray Engineering Co., Ltd., Japan

Studies on the manufacture of displays, smartphones, wearable devices, etc. using MicroLED have become active in recent years. Manufacturing process of MicroLED requires a fast pick and place assembly as there are so many MicroLED chips to be placed onto its substrate and wafer. Such placing shall be accurate and reliable and ideally repairable of each individual MicroLED chip as it takes much time to complete sizable panel. However, it has been very difficult to transfer a large number of microchips with high accuracy. In order to achieve solution against such transfer requirement, a large amount of chip transfer technology, inspection technology for detecting defects on microchips, and repair technology are necessary. We have been successful in both the semiconductor and FPD industries as a business area based on the concept of E & M (engineering and manufacturing).

To date, we have made a series of processes necessary to manufacture MicroLED displays (to provide a total solution). We have developed the following three types of equipment that apply our core technology such as inspection, bonding, laser process for semiconductor and so on.
1. Non-contact inspection
2. Laser trimming only NG chips based on inspection results
3. MicroLED bonder for high productivity

Especially MicroLED bonder of Toray Engineering Co., Ltd. is enable to place such precise MicroLED chips very fast. In this presentation we will introduce our solution technology for MicroLED manufacturing method.

Heterogeneous Integration of Silicon Nanoneedles onto Diverse Soft Elastomer Substrates for Enhanced Interaction with Biological System  
Yale Jeon¹, Chi Hwan Lee²,² and Dong Rip Kim¹; ¹Hanyang University, Korea (the Republic of); ²Purdue University, United States

Enhanced interaction of nanoscale structures with soft and curvilinear biological systems requires to reduce their large mechanical mismatches at the interface. Recently, successful development of vertically-aligned silicon nanoneedle (SiNN) arrays integrated onto flexible substrates provides a mechanically elastic interface between SiNNs and biological systems to enable their effective interactions, resulting high-efficacy delivery of biomolecules. To create more versatile platforms, transfer printing methods to integrate vertically-aligned SiNN arrays onto diverse, soft and flexible substrates necessitates further development. Here, we introduce two different transfer printing techniques to integrate vertically-aligned SiNN arrays onto diverse soft elastomer substrates for enhanced interaction between SiNNs and biological systems. First, we discuss the swelling-driven transfer printing technique which employs the volume expansion phenomena of elastomers soaked in solvents to controllably break the SiNNs for their transferring from rigid Si substrates to soft and flexible substrates. Second, we develop the double transfer printing method to realize the heterogeneous integration of the vertically-aligned SiNN arrays onto soft and flexible substrates vulnerable to dissolution in solvents. Both methods successfully transfer the targeted nanoscale structures to diverse, soft and flexible substrates that can benefit the enhancement of interaction between nanoscale devices and biological systems for wide applications.

Electronically Integrated, Microscopic Robots  
Marc Miskin; University of Pennsylvania, United States

Fifty years of microelectronics scaling have opened up new opportunities for building complex robotic systems that are microscopic in size. Electronic, magnetic, and optical systems now offer an unprecedented combination of complexity, small size, and low cost, and could readily be appropriated to form the intelligent core robots that are too small to be resolved by unaided human vision. But one major roadblock exists: there is no micron-scale actuator system that seamlessly integrates
with semiconductor processing and responds to standard electronic control signals. In this talk, I show how to overcome this barrier, enabling a new generation of microscale robots that utilize on-board, integrated silicon electronics. First, I will present a new class of voltage-controllable electrochemical actuators that operate at low voltages (200 mV), low power (10 nW), and are completely compatible with silicon processing. Next, I'll present a full process flow that uses lithographic fabrication and release techniques to build sub-hundred micrometer robots that walk. Every step in this process is performed massivley in parallel, producing over one million robots per 4-inch wafer. I'll show that in spite of their small size, microscopic robots are remarkably robust: they can survive harsh chemistries, large changes in temperature, and can even be injected through hypodermic needles. Finally, I will close by showing our first steps towards transforming sophisticated CMOS circuitry into programmable, autonomous robots too small to be seen by the naked eye.

8:40 PM *S.CT07.04.01
Transfer-Printed Microscale LEDs and ICs for High Performance Emissive Displays Christopher A. Bower; X-Celeprint Ltd, United States

Displays that use combinations of microscale LEDs and ICs within each pixel to control and direct light emission have the potential to be colorful, bright, fast and power efficient. High-throughput mass transfer technologies that accurately and cost-effectively integrate large arrays of wafer-fabricated microscale LEDs onto non-native display substrates with high yield are key enablers for microLED displays. Transfer-printing with elastomer stamps is a candidate mass transfer technology for making next generation displays. A variety of displays, including displays driven by transfer-printed microICs, have been designed and fabricated using transfer-printed microscale microLEDs.

Micro/Milli Robotic Assembly Using Diamagnetic Surfaces Allen Hsu, Annjoe Wong-Foy and Ronald Pelrine; SRI International, United States

As Moore’s law for digital computation reaches its inevitable limits, future advances in system level integration will lead to the next generation of electronics. Approaches such as heterogeneous integration will enable small and high-performance micro-systems (optical and electronic integration or System-In-Package) necessary for the growing consumer areas such as
wearables, the Internet of Things, and Augmented Reality. Beyond electronics, tools and techniques for heterogenous micro-assembly can lead towards new smart materials (i.e. defect-free constructed materials, digitally tailored electro-mechanical active materials with micro-scale properties and macro-scale performance, etc.) and the micro-assembly of biological and soft components.

While there are many research approaches towards tackling heterogenous micro-assembly (i.e. self-assembly, transfer printing, etc.), in this work, we will discuss our approach of directed robotic assembly using micro/milli robots. Directed micro/milli-robotic assembly has some unique advantages over other methods, such as being relative task agnostic and generalizable to various assembly problems. Furthermore, unlike many batch processes that are open-loop, directed micro-robotic assembly can be closed-loop by integration of metrology and material validation during the assembly process. Thereby swarms of micro/milli-robots can parallelize not only micro-assembly but also micro-metrology, enabling a method of overcoming statistical and thermodynamic limitations of conventional approaches.

Inspired by massive swarms of ants or termites assembling macro-scale objects from micro-scale parts, we utilize arrays of magnetic actuators in conjunction with diamagnetic graphite to create a magnetic collective of levitated micro/milli sized magnetic robots with nm level motion precision for 3D micro-assembly. By leveraging diamagnetic levitation, we can reduce factors such as hysteresis and stiction to enable high-precision and repeatable motion of micro/milli-robots. These passively levitated, but electromagnetically steerable micro/milli-robotic platforms can serve many roles: (1) compact high-precision motion platform for the manipulation and delivery of micro-components, (2) high precision sensors, and (3) motion platform for other micro-scaled MEMS sensors and actuators. We will discuss multiple independently controlled robots (mm-sized) with dexterous behavior for assembling carbon fiber trusses and performing micro-assembly and micro-manipulation of 3d microspheres and silicon microparts, as well as some of the control issues for coordinating parallel robotic swarms for micro-assembly. In addition, by using robots cooperatively, we also demonstrate how teams of micro/milli robots can achieve new functionality and enable extremely high densities of independent micro-manipulation as compared to conventional standard robotic solutions.

Open Electrodeposition of Stimuli-Responsive Metal Hydroxides/Oxides for Direct Fabrication of Origami Micro-Robots Alfonso H. Ngan, Runni Wu, Kenneth K.W. Kwan, Wenrui Ma and Pingyu Wang; University of Hong Kong, Hong Kong

Flexible origami structures can mimic the complicated motions of small creatures that are otherwise difficult to be achieved by rigid robots with limited degree of motion freedom. However, actuating origami structures in a compact and self-contained way has been a critical challenge. Here, we demonstrate a versatile approach of actuating origami micro-robots, by printing self-folding creases on compliant polymer membrane substrates. The self-folding creases are made of a type of stimuli-responsive transition metal hydroxides/oxides that can undergo large actuation under electrochemical or light stimulations. Direct printing of the stimuli-responsive material via a microfluidic electrochemical writing method at the locations of the creases enables the creases to self-fold independently “on demand”, with folding curvatures exceeding 1 mm\(^{-1}\) under low-intensity visible-light stimulation in ambient conditions, or low-potential electrochemical stimulation in electrolytic environments, with response time as fast as in seconds. Based on the high performance of such active creases, complex miniaturized origami designs powered by hinges activated in an independently controllable way are demonstrated, including self-folding Miura and a full micro-robotic hand with independently programmable finger joints. These results prove a new, versatile paradigm for micro-robotics, where a transferrable approach is applicable to design and fabricate a wide variety of customizable micro-robots with compact construction and complex motions using different stimuli-responsive ceramic-based materials.

Extreme Miniaturization of Passive Electronic Components by Strain-Induced Self-Rolled-Up Membrane Nanotechnology Zhendong Yang, Mark Kraman, Derek Wood, Jialiang Zhang, Julian Arthur Michaels, Apratim Khandelwal and Xiuling Li; University of Illinois at Urbana-Champaign, United States

Complex 3D structures enable advanced functionalities that are otherwise out of reach. However, processing issues such as mechanical stability, conformity, alignment, as well as cost, are challenging to address. The overarching physical principle of the Self-Rolled-up Membrane (S-RuM) nanotechnology is strain-driven spontaneous deformation of 2D membranes into 3D architectures. It opens up a new paradigm to achieve 3D functional hierarchical architectures without the difficulties of processing in 3D, and promises to break the constraints of size, weight, and performance of many types of devices. In this talk, we demonstrate S-RuM inductors, transformers, capacitors, and filters with > 10X smaller footprint and unique
1:30 PM *S.CT07.01.03
In Situ Investigation of Mechanisms Underlying Material Synthesis and Processing Dongsheng Li and Miao Song; Pacific Northwest National Laboratory, United States

Understanding the mechanisms of material structures forming processes enables the design and fabrication of structures with improved or tailored properties. The objective of our work is to investigate the mechanisms underlying materials synthesis and processing, including crystal growth, particle self-assembly, and phase transformation, etc., and thus to tune the structures and functions of materials.

For example, particle aggregation, such as oriented attachment, is accepted as a common pathway and leads to well-organized structures and twin interfaces that possess unique or improved properties. However, many fundamental aspects remain unknown, such as the interplay of structures and factors that control them. Here we use in situ transmission electron microscopy and atomic force microscopy to directly observe process of materials synthesis and processing, such as particle assembly and phase transformation. Integrating theoretical calculations and simulations, we revealed the orientation-dependent attachments of particles, interfacial structures, and the factors that affect them, such as temperature, pH, ionic strength, particle shapes, and solvents, etc. In addition, we also demonstrated that defects (edge dislocation), induced via oriented attachments, improving photoactivity of TiO₂. Phase transformation and its role in materials functions are also investigated. The specific systems that we investigate are metal (Ag and Au), oxides (TiO₂), and minerals (mica), etc. The work provides a deep understanding of mechanisms of materials synthesis and processing and thus provides a guide to design and fabricate the morphologies and structures, which are closely related to material properties and functions.

A Sono-Assisted Dry Dip Coating Method for Ultra-Fast Nanomaterials Assembly on PDMS Substrate Dong Zhou and Bo Li; Villanova University, United States

While dip coating is a widely used solution-based assembly method to achieve large scale assembly of nanomaterials, its integration with the flexible substrate is hindered by the difficulty to choose a good wetting system of solvent, nanomaterials and polymer substrate. The good wetting solvent may swell or even dissolve the polymer substrate. Here, to the contrary, we utilize the hydrophobic nature of a Polydimethylsiloxane (PDMS) substrate and nanomaterials (e.g., graphene) and create a “dry” dip coating method by choosing water as the solvent. Unlike the traditional dip coating method, there are two important innovations. First, the dip coating speed can reach 5.4 m/min (in comparison with 0.001-0.2 m/min for commercial dip coater) because solvent evaporation is required. A dry substrate with assembly nanomaterial is removed from the solution because water does not wet PDMS and nanomaterials. Second, a weak sono field is applied to the solution during the dip coating process to significantly speed up the assembly process and maintain the disperse status of nanomaterials. The film thickness can be controlled through dip coating times and solution concentration. This strategy can be further integrated with microfabrication processes such as lithography to manufacture arrays of hybrid multilayer devices with different nanomaterials. As a proof-of-concept, strain sensor, electromagnetic interference (EMI) shielding coating, and multilayer capacitor are demonstrated. This ultra-fast dry dip coating strategy paves the way towards affordable flexible devices.
placed onto its substrate and wafer. Such placing shall be accurate and reliable and ideally repairable of each individual MicroLED chip as it takes much time to complete sizable panel. However, it has been very difficult to transfer a large number of microchips with high accuracy. In order to achieve solution against such transfer requirement, a large amount of chip transfer technology, inspection technology for detecting defects on microchips, and repair technology are necessary. We have been successful in both the semiconductor and FPD industries as a business area based on the concept of E & M (engineering and manufacturing).

To date, we have made a series of processes necessary to manufacture MicroLED displays (to provide a total solution). We have developed the following three types of equipment that apply our core technology such as inspection, bonding, laser process for semiconductor and so on.

1. Non-contact inspection
2. Laser trimming only NG chips based on inspection results
3. MicroLED bonder for high productivity

Especially MicroLED bonder of Toray Engineering Co., Ltd. is enable to place such precise MicroLED chips very fast. In this presentation we will introduce our solution technology for MicroLED manufacturing method.

In Situ Investigation of Mechanisms Underlying Material Synthesis and Processing Dongsheng Li and Miao Song; Pacific Northwest National Laboratory, United States

Understanding the mechanisms of material structures forming processes enables the design and fabrication of structures with improved or tailored properties. The objective of our work is to investigate the mechanisms underlying materials synthesis and processing, including crystal growth, particle self-assembly, and phase transformation, etc., and thus to tune the structures and functions of materials.

For example, particle aggregation, such as oriented attachment, is accepted as a common pathway and leads to well-organized structures and twin interfaces that possess unique or improved properties. However, many fundamental aspects remain unknown, such as the interplay of structures and factors that control them. Here we use in situ transmission electron microscopy and atomic force microscopy to directly observe process of materials synthesis and processing, such as particle assembly and phase transformation. Integrating theoretical calculations and simulations, we revealed the orientation-dependent attachments of particles, interfacial structures, and the factors that affect them, such as temperature, pH, ionic strength, particle shapes, and solvents, etc. In addition, we also demonstrated that defects (edge dislocation), induced via oriented attachments, improving photoactivity of TiO2. Phase transformation and its role in materials functions are also investigated. The specific systems that we investigate are metal (Ag and Au), oxides (TiO2), and minerals (mica), etc. The work provides a deep understanding of mechanisms of materials synthesis and processing and thus provides a guide to design and fabricate the morphologies and structures, which are closely related to material properties and functions.

Liquid Crystalline Behavior of LaPO4 Nanorods in Apolar Solvent Jeongmo Kim, Khalid Lahlil, Jongwook Kim and Thierry Gacoin; Ecole Polytechnique, Institut Polytechnique de Paris, France

Concentrated suspensions of colloidal nanorods can exhibit liquid crystalline (LC) behavior: spontaneous and reversible assembly of nanorods into orientationally ordered nematic phase. Considering to Onsager’s theory predicting the rod concentration threshold (Φ) where the isotropic-to-nematic phase transition occurs, the increased effective radius of charge-stabilized rods can significantly reduce Φ compared to the same rods that are stabilized sterically[i]. This has allowed to prepare relatively dilute colloidal LCs (Φ < 5 vol%) with strongly charged LaPO4 nanorods in polar media[ii]. However, we recently observed a contradictory phenomenon where the ligand stabilized LaPO4 nanorods in apolar media self-assemble into a nematic phase at even lower Φ near 0.5 vol% while the theoretically estimated Φ is 17%. Moreover, Φ varies with the concentration of additional surfactants in a similar way as in polar media when increasing a salt concentration leads to surface charge screening. This observation suggests that the ligand-functionalized surface of nanorods may still be partially charged and thus contributes to a largely extended Debye length (effective radius of rods) when suspended in apolar media with low dielectric constants. Such colloidal systems, both sterically and electrostatically stabilized, have an intriguing potential for exquisitely controlling the dynamics of charged colloids avoiding the common problem of aggregation. We present the LC behavior of the dilute nanorod suspension, their control under external electric field, and the impact of the amphiphilic surfactants on phenomena associated to electrostatic surface charging in apolar media.

**Open Electrodeposition of Stimuli-Responsive Metal Hydroxides/Oxides for Direct Fabrication of Origami Micro-Robots**  
Alfonso H. Ngan, Runni Wu, Kenneth K.W. Kwan, Wenrui Ma and Pingyu Wang; University of Hong Kong, Hong Kong

Flexible origami structures can mimic the complicated motions of small creatures that are otherwise difficult to be achieved by rigid robots with limited degree of motion freedom. However, actuating origami structures in a compact and self-contained way has been a critical challenge. Here, we demonstrate a versatile approach of actuating origami micro-robots, by printing self-folding creases on compliant polymer membrane substrates. The self-folding creases are made of a type of stimuli-responsive transition metal hydroxides/oxides that can undergo large actuation under electrochemical or light stimulations. Direct printing of the stimuli-responsive material via a microfluidic electrochemical writing method at the locations of the creases enables the creases to self-fold independently “on demand”, with folding curvatures exceeding 1 mm under low-intensity visible-light stimulation in ambient conditions, or low-potential electrochemical stimulation in electrolytic environments, with response time as fast as in seconds. Based on the high performance of such active creases, complex miniaturized origami designs powered by hinges activated in an independently controllable way are demonstrated, including self-folding Miura and a full micro-robotic hand with independently programmable finger joints. These results prove a new, versatile paradigm for micro-robotics, where a transferrable approach is applicable to design and fabricate a wide variety of customizable micro-robots with compact construction and complex motions using different stimuli-responsive ceramic-based materials.

6:45 AM S.CT07.01.08  
**High Symmetry Ordered Multigrain Nanocrystals to Reveal and Maximize the Effect of Grain Boundary Defects**  
Myounghwan Oh; Lawrence Berkeley National Laboratory, United States

Grain boundary defects-topological defects around grain boundaries (GB)-play an essential role in the optoelectronic, magnetic, mechanical, and chemical properties of the polycrystalline materials. When the grain size of the materials decreases to the nanometer scale, the grain boundary defects predominantly determine those properties, opening up a variety of new applications. Although researchers have sought ways to study the contribution of specific grain boundary defects to the properties, non-uniformity in grain size and shape and random misorientation between the grains make these tasks challenging. This presentation will first discuss controlling 3D heteroepitaxy of colloidal faceted nanocrystals to grow uniform multiple grains organized into a well-defined geometry, which gives a new opportunity for overcoming such limitations from the non-uniformity and randomness. Within the resulting nanocrystals, we will see that the 3D patterned strain field exists in the form of disclinations and dislocations. We will then discuss how we can apply the 3D heteroepitaxy to investigate the effect of microscopic grain geometry on the macroscopic properties. For example, we can obtain a correlation between the GB defects and the catalytic property, because the patterned strain creates exact GB structure in a periodic fashion that serves as the active sites for catalysis. Lastly, we will highlight that the epitaxy-based design principles can significantly extend the library of grain structures in the nanocrystalline materials.

5:00 AM *S.CT07.02.01  
**Stochastic Assembly of microLED Displays**  
Paul J. Schuele; eLux, Inc., United States

Direct emission displays made with inorganic µLEDs can potentially challenge LCD and OLED displays with better performance, efficiency and lifetime. Markets where microLED displays are likely to first appear are large information displays requiring high brightness, home theater applications benefitting from increased dynamic range and automotive displays in which high contrast and reliability are necessary. These displays are made possible by the integration of two mainstream technologies, namely GaN LED developed for general lighting and the large area active matrix backplanes developed for LCD displays. The unique manufacturing challenge for µLED displays is development of a technology to position and connect millions of
small devices with zero defects and low cost. Conventional pick and place tools are capable of positioning µLEDs but the
throughput of serial assembly is inadequate while mass-transfer methods have difficulty changing the pixel pitch. To address
these challenges eLux has developed a massively parallel fluidic assembly technology which positions each µLED by capture
of the device in a well structure that also contains the connecting electrodes.
Fluidic assembly technology uses simple low-cost equipment to achieve assembly rates up to 50 million µLEDs per hour and
it is anticipated that production equipment could assemble an 8K display with 100 million LEDs in a few minutes. The
technology is suitable for µLEDs from 10 to 200 µm diameter offering flexibility to make a wide variety of displays with
resolutions from 400 to 10 ppi. Similarly, the microLED emitter area can be changed independently of the assembly
technique to increase brightness and it is possible to produce displays over 5,000 cd/m². Fluidic assembly applies relatively
low force on the device so brittle materials such as red µLEDs fabricated from AlGaNp can be assembled in the same way as
blue and green emitting GaN µLEDs.
A fully integrated manufacturing system for µLED fluidic assembly will ensure that the assembled µLEDs have acceptable
performance with special emphasis on eliminating shorted or high resistance devices. Testing and binning used in the general
lighting industry are not practical at the micron scale, so wafers are mapped by cathodoluminescence to identify defective
µLEDs. Based on the defect map, a selective harvest technique diverts bad µLEDs from the suspension so only known good
die are used for assembly. Fluidic assembly relies on an excess of µLEDs to ensure sufficient capture attempts for complete
assembly, so it is also necessary to capture, filter and recycle unassembled µLEDs.
With a suitable choice of complementary characteristic for the device and the trap site, it is possible to use fluidic assembly
techniques to position nanowires or nanoparticles as well as µLEDs. The presentation will give an overview of the integration
issues with some suggestions for other possible applications and approaches.

5:30 AM S.CT07.02.02
A Scalable Micro-Object Assembly and Printing Platform  Brad Rupp, Jeng Ping Lu, Anne Plochowietz, Yunda Wang,
Dave Biegelsen, Lara Crawford, Sergey Butylkov, Julie Bert, Sourobh Raychaudhuri, Jamie Kalb, Qian Wang, Yu Wang, Pat
Maeda and Eugene M. Chow; PARC, United States

Conventional manufacturing is able to assemble products composed of many parts of the size approximately 1mm and above.
At the nanometer scale, techniques such as deposition, lithography, and self-assembly are used to make a myriad of
heterogeneous products. However, at the mesoscale (1-1000µm) these techniques don’t overlap to produce structures at scale.
There is a need for robust and scalable technologies which are able to join structures which can be developed on the micro-
 scale into large area, heterogeneous assemblies. To address this, we are developing a printing platform which is able to use
micro-objects as ink—microLEDs, sensor chips, integrated circuits, micro- and nanoparticles. These objects are dispersed in
a dielectric fluid and can be printed similar to a xerographic process, but maintain single object precision and orientation. To
do this, an optically-addressed electrostatic actuator array manipulates the particles to move to target locations. From there,
an integrated transfer system removes the particles from the assembly platform to be placed on a final substrate while
maintaining their relative positioning. This transfer system can either be batch with adhesive transfer, or continuous with a
non-contact electrostatic belt. This talk will describe the process in which we are able to rapidly sort, manipulate, orient,
assemble, and transfer particles in parallel over a 1-inch wide area. We have demonstrated 1-µm registration, assembly of
hundreds of particles in seconds, and roll-to-roll like transfer. With the use of computer vision to aid the assembly process,
the technology has the potential to produce highly ordered, custom-patterned, heterogeneous assemblies accurately over a
large area much faster than traditional manufacturing techniques while still maintaining fidelity.

Heterostructures of Layered Carbon Nanocomposites and Engineered Resonator Array Structures for Wide-Band
Electromagnetic Shielding Vivek Kale, Shravani Kale, Shankar Gaware and Sangeeta N. Kale; Defence Institute of
Advanced Technology, India

Radar technology is a field in which the measures (and hence the counter-measures) are continuously emerging. Constant
vigilance on the air borders require stringent performance of the Radar stations and hence the counter measures are required
to be developed using either the improved engineered structures of aircrafts or improved materials (which could be coated on
the body of the aircrafts). A combination of both these approaches would yield much smarter and effective approach.
Micro-assembled, engineered thin film structures of silver arrays have been used along with different carbon nanocomposite
thin films on flexible substrates for shielding the X-Band (8.2 GHz to 12.4 GHz) Radar range of the electromagnetic
spectrum. In this presentation, we discuss on synthesis of flexible thin films of silver arrays of split ring resonators, with
varied unit cell dimensions, which are deposited using standard micro-printing technology. These layers are stacked with
carbon nanocomposite films (either of multiwalled carbon nanotubes (MWCNTs), graphene sheets and carbon conducting
ink; in Polyvinyl dimethyl fluoride / polyacrylonitrile matrix) to obtain wide band electromagnetic shielding.
Nanocomposites were synthesised using standard chemical methods and thin films were synthesised using dip-coating method. The sandwiched (2 layers of nanocomposites and one layer of resonator array) was packed using hydraulic press and standard lamination technique to yield a compact flexible film, which can be inserted in the X-Band wave guide for further testing. Vector Network Analyser was used for further studies of absorption. Shielding in entire X-band with the power loss of 27 dB (99.98 % loss) and a minimum of 21 dB (99.92 % loss) is demonstrated here, for MWCNT. Similar results for other carbon composites are discussed in this presentation. A strong interplay of carbon nanocomposites with the array of L-C-R equivalent resonators of varied resonant frequencies shows concomitant suppression in the incident electromagnetic power; the results supported by simulation (CST Microwave Studio) studies as well. This work opens up a strategy to obtain wide band shielding using a combination of optimised nanomaterial composites, heterostructured with engineered metallic resonators.

Light Induced Self-Writing and Phase Separation in Monomer-Nanoparticle Mixtures Shreyas Pathreeker, Fu-Hao Chen, Saed Biria and Ian D. Hosein; Syracuse University, United States

We report direct fabrication of nanoparticle-polymer composite microstructures via a novel light-induced self-writing approach. Light-induced self-writing is an optical phenomenon wherein a light beam permanently inscribes ‘channels’ or ‘fibers’ across the depth of a photo-reactive medium. Self-writing is a scalable, safe and rapid technique that offers a direct single-step route for precise fabrication of polymer composite structures. Herein, we investigated the organization of nanoparticles during light-induced self-writing to assess feasibility of control over composite morphology, as core-shell and nanoparticle embedded structures have found use in various applications such as anodes for secondary batteries, as chemical sensors, and MEMS. By varying the light intensity and beam size employed in self-writing, the photopolymerization kinetics and path length of nanoparticle diffusion can be controlled, which enables directed assembly of nanoparticles and tunable morphology. In this work, a mixture of Silicon nanoparticles in an acrylate type monomer was used to self-write vertically aligned composite pillar-like structures that were then pyrolysed to obtain Carbon/Silicon structures. Use of these structures as an anode for Li-storage is examined. Scanning electron microscopy, X-ray diffraction and Raman spectroscopy were used to characterize morphology and composition of the structures, and other monomer-nanoparticle mixtures are under investigation. This work provides a novel technique to fabricate microscale architectures for energy storage applications and explores ways to control structure morphology by varying photopolymerization process parameters.

Manipulation and Assembly of Particles Using Acoustic Field Gradient and Electromagnetic Needle Quan Zhou; Aalto University, School of Electrical Engineering, Finland

Robotic instruments are miniature robots and mechatronic systems that can manipulate small objects and precisely interact with different surfaces. In this talk, I will discuss our recent work in robotic instruments for manipulation and assembly using two techniques: 1) acoustic manipulation devices that can automatically manipulate/assembly a large amount of particles on a surface using the field gradient generated by a single acoustic transducer, both in ambient air and submerged; 2) robotic electromagnetic needle that can precisely extract and independently manipulate/assemble magnetic microparticles in the presence of neighboring magnetic particles by contact or contactless.

Assembly of Thick Nanoparticle Films via Electrophoretic Deposition Prabal Tiwari, Noah D. Ferson and Jennifer Andrew; University of Florida, United States

Materials scientists have been fabricating nanomaterials with unique functionalities for decades. However, there remains a need to develop tools to assemble these materials into devices. To date, there are a variety of assembly techniques that utilize electric fields, magnetic fields, inertial forces, capillary forces, as well as robotic pick and place methods to obtain the desired structure. Among these techniques, electrophoretic deposition (EPD) has the advantage of being cost-effective, fast, and easy to perform for most material systems and substrate geometries. EPD uses electrophoresis to assemble charged nanomaterials from a suspension onto a substrate. However, EPD is currently limited by the fact that the deposition rate decreases with time, limiting the overall yield and thickness of the resulting material. Previously, this limitation has been attributed to the decrease in both the particle concentration as well as the electric field in the suspension during deposition. But, more recent studies have shown that the electrophoretic mobility of the electrostatically stabilized particles is also decreasing with time. Here, we show that decreasing particle mobility is the most critical factor in determining the EPD yield. To demonstrate this, we used alumina nanoparticles suspended in ethanol as a model system. By monitoring the changes in the pHe (pH in non-aqueous solvents) of the suspension during EPD, we observed the particle mobility of the alumina nanoparticles decreased with time. We also showed that this decrease in particle mobility significantly decreased the deposition rate. To overcome this, we developed a new suspension replenish EPD approach that allows us to maintain near constant particle mobility and particle concentration with time. This suspension replenish method results in a linear increase in the mass of the deposited film with time, overcoming the limitation of decreasing deposition rate in conventional EPD. We also saw a 6x improvement in the thickness of the film compared to the conventional EPD. This approach is applicable to a wide range of materials that can be electrostatically stabilized/charged by the adjustment of the pH of the suspension. Thereby, enabling a path to significantly improve the ability to assemble thick films of nano- and micro- materials.

Carbon Nanotube Alignment Dynamics Under Electric Fields in Different Solutions Atiqr Rahman and Ahmed Zubair; Bangladesh University of Engineering and Technology, Bangladesh

Controlled macroscopic assembly of carbon nanotubes (CNTs) while preserving their excellent optoelectronic properties still remain a key challenge. Here, we investigated the molecular dynamics of single-wall carbon nanotube (SWCNT) alignment inside various viscous media under electric fields. An analytical model based on dielectrophoresis induced torque considering the viscosity and conductivity of the medium was used to obtain molecular dynamics of the SWCNTs. An alternating current electric field was applied to a liquid solution of SWCNT containing several solvents/surfactants such as DIW, DMF, DPSF, SDS, and DOC. The time required for the SWCNTs to get aligned to the applied AC electric field was calculated for different initial conditions for all the solutions. The effects of CNT length, CNT diameter, and frequency of the electric field on the SWCNT network formation were theoretically studied. Longer and thinner SWCNTs prompted to faster alignment in the
SWCNT network. Furthermore, the effect of the concentration of surfactant on arrangement time was examined. Slower SWCNT alignment was observed in medium with higher viscosity. The findings of this report will be helpful for establishing an effective technique of producing large-scale aligned CNT films for diverse applications.

Transfer Print Integration of InP to Si for Photonic Integrated Circuits Fatih Atar, Thomas S. Wilhelm, James O'Callaghan, Agnieszka Gocalinska, Emanuele Pelucchi and Brian Corbett; University College Cork, Ireland

Indium Phosphide based materials are essential for realisation of lasers, modulators and detectors operating in the 1300 nm to 1600 nm range enabling widespread applications in telecommunications, data communications and sensing. The material structure for different devices are different expensive resulting in expensive components. With the emergence of silicon photonics (SiPh) as a platform for integrated photonics there is an urgent practical need to identify a scalable integration technology that can combine the unique functionality provided by InP with the routing and electronic capability enabled by SiPh in a low cost manner. We have developed a heterogeneous integration approach by using micro-transfer printing of InP devices to Si using either direct bonding or by using a thin intermediate adhesive polymer layer. The performance of transferred lasers is equal or superior to those on the native substrate after transfer due to enhanced thermal dissipation through Si. The lasers are coupled to the silicon waveguides either by butt coupling or by evanescent coupling methods. Here, we perform an in-depth study on the adhesion properties of directly bonded InP coupons to Si. Coupons of 1 micron thick InP layer with lateral dimensions of 600 mm x 60 mm are formed by dry etching. The coupons are released from the InP substrate by selective undercut etching of an AlInAs release layer in a FeCl3 solution while being registered and held in place on the substrate by resist tethers. The coupons are picked and transferred to silicon wafers using a PDMS stamp. The silicon has been prepared with different surface treatments to make the surface hydrophobic (HF) or hydrophilic (H2SO4, O2 plasma). Additionally, coupons are transferred to gold coated silicon for potential electrical injection. Following transfer, the resist tethers are removed by an O2 plasma. A high pick and transfer yield is obtained for coupons to all surfaces. Post-print treatments include annealing in different atmospheric environments and under vacuum. The adhesion is assessed by scratch test, acoustic microscopy and Raman spectroscopy. Experiments to perform epitaxy on the transferred coupons will be described.

5:45 AM S.CT07.04.03
Heterogeneous Integration of Silicon Nanoneedles onto Diverse Soft Elastomer Substrates for Enhanced Interaction with Biological System Yale Jeon1, Chi Hwan Lee2,2 and Dong Rip Kim1; 1Hanyang University, Korea (the Republic of); 2Purdue University, United States

Enhanced interaction of nanoscale structures with soft and curvilinear biological systems requires to reduce their large mechanical mismatches at the interface. Recently, successful development of vertically-aligned silicon nanoneedle (SiNN) arrays integrated onto flexible substrates provides a mechanically elastic interface between SiNNs and biological systems to enable their effective interactions, resulting high-efficacy delivery of biomolecules. To create more versatile platforms, transfer printing methods to integrate vertically-aligned SiNN arrays onto diverse, soft and flexible substrates necessitates

2020 MRS Virtual Spring/Fall Meeting, November 27-December 4, 2020, Spring Abstracts Final Program 2/3/21
further development. Here, we introduce two different transfer printing techniques to integrate vertically-aligned SiNN arrays onto diverse soft elastomer substrates for enhanced interaction between SiNNs and biological systems. First, we discuss the swelling-driven transfer printing technique which employs the volume expansion phenomena of elastomers soaked in solvents to controllably break the SiNNs for their transferring from rigid Si substrates to soft and flexible substrates. Second, we develop the double transfer printing method to realize the heterogeneous integration of the vertically-aligned SiNN arrays onto soft and flexible substrates vulnerable to dissolution in solvents. Both methods successfully transfer the targeted nanoscale structures to diverse, soft and flexible substrates that can benefit the enhancement of interaction between nanoscale devices and biological systems for wide applications.

Integration of Inductor with Magnetic Thin Films in Substrate Hongbin Yu and Yanze Wu; Arizona State University, United States

With increasing demand for electronics System on Chip (SoC) and System in Package (SiP) design in many applications, including consumer electronics and automotive electronics, integrated inductor, which is an essential passive component, has been widely used in numerous integrated circuits (ICs) such as voltage regulators and RF circuits, and the pursuit of its heterogeneous integration into various platforms for intended use has attracted intense interest.

There are inductor in package demonstrations or even early product, however, they are either air core without magnetic core materials that render large size yet low inductance density. Other types using close to surface mount type that can incorporate magnetic core materials, that has larger thickness around 1mm, not suitable for low profile, high inductance density in-package applications, where each organic substrate layer can be much thinner in the tens of µm range. There are prior attempts to make low height profile magnetic core materials in in-package inductor applications, yet typically using ferrite that has low relative permeability, and other processing challenges such as temperature restriction.

There have been work of integrating magnetic core inductor on package substrate, without achieving high inductance increase and small foot print, typically with low inductance increase after incorporation of magnetic core materials, typically ferrite that has low permeability. We plan to use high performance magnetic core materials such as CoZrTaB to achieve high inductance density, and low cost integration process.

In this work, soft ferromagnetic core material, for e.g. amorphous Co-Zr-Ta-B, are incorporated into in-package inductors in order to scale down inductors and improve inductors performance in both inductance density and quality factor. Design of the select inductor structure are performed and optimized through electromagnetic simulation; while magnetic film screening and selection for in package application, deposition, as well as characterization of films in both DC and AC modes are carried out.

5:15 AM S.CT07.05.03
Open-Air Plasma-Deposited Silica Films in a Heterogenous Multilayer Barrier for Improved Stability of Moisture Sensitive Devices Oliver Zhao, Yichuan Ding, Ziyi Pan, Nicholas Rolston and Reinhold H. Dauskardt; Stanford University, United States

In order to maintain performance over multiyear lifetimes, many existing and emerging wearable, flexible devices require robust packaging strategies to inhibit water ingress and prevent premature failure. We report on a scalable, open-air plasma process to deposit highly transparent and dense SiO₂ thin film barriers to prevent moisture ingress. Our plasma process is
suitable for direct deposition on thermally sensitive devices and is compatible with flexible, polymeric substrates as shown by 100 cycles of bending tests with a 1.25mm bending radius. Additionally, the open-air plasma process is suitable for large area devices. We show that over a field of view of over 10cm², there is a pinhole density of only 2.67 pinholes/cm². Considering that the deposition process occurs in an open-air system, where there is no regulation of particles in the deposition environment, the low pinhole density confirms the high film quality and is a key reason for its excellent barrier functionality.

We then incorporate the SiO₂ film into a multilayer barrier design comprising heterogenous organic and inorganic layers—all of which are deposited using solely open-air processes—and achieve low water vapor transmission rates on the order of 10⁻³ g/m²/day at an accelerated aging condition of 38°C and 90% relative humidity (RH). When deposited directly onto devices, they retained over 80% of their initial performance for over 660 hours in a 50°C 50%RH accelerated aging environment. The ability of the multilayer barrier to enable device resistance to humid environments is crucial towards realizing longer operating lifetimes of emerging biomedical devices and flexible/wearable electronics.

Extreme Miniaturization of Passive Electronic Components by Strain-Induced Self-Rolled-Up Membrane

Zhendong Yang, Mark Kraman, Derek Wood, Jialiang Zhang, Julian Arthur Michaels, Apratim Khandelwal and Xiuling Li; University of Illinois at Urbana-Champaign, United States

Complex 3D structures enable advanced functionalities that are otherwise out of reach. However, processing issues such as mechanical stability, conformity, alignment, as well as cost, are challenging to address. The overarching physical principle of the Self-Rolled-up Membrane (S-RuM) nanotechnology is strain-driven spontaneous deformation of 2D membranes into 3D architectures. It opens up a new paradigm to achieve 3D functional hierarchical architectures without the difficulties of processing in 3D, and promises to break the constraints of size, weight, and performance of many types of devices. In this talk, we demonstrate S-RuM inductors, transformers, capacitors, and filters with > 10X smaller footprint and unique performance characteristics, through global and local strain engineering and material hierarchical integration.

SESSION S.CT07.07: Heterogeneous Integration for Robotic Motion

Electronically Integrated, Microscopic Robots

Marc Miskin; University of Pennsylvania, United States

Fifty years of microelectronics scaling have opened up new opportunities for building complex robotic systems that are microscopic in size. Electronic, magnetic, and optical systems now offer an unprecedented combination of complexity, small size, and low cost, and could readily be appropriated to form the intelligent core robots that are too small to be resolved by unaided human vision. But one major roadblock exists: there is no micron-scale actuator system that seamlessly integrates with semiconductor processing and responds to standard electronic control signals. In this talk, I show how to overcome this barrier, enabling a new generation of microscale robots that utilize on-board, integrated silicon electronics. First, I will present a new class of voltage-controllable electrochemical actuators that operate at low voltages (200 mV), low power (10 nW), and are completely compatible with silicon processing. Next, I'll present a full process flow that uses lithographic fabrication and release techniques to build sub-hundred micrometer robots that walk. Every step in this process is performed massively in parallel, producing over one million robots per 4-inch wafer. I'll show that in spite of their small size, microscopic robots are remarkably robust: they can survive harsh chemistries, large changes in temperature, and can even be
injected through hypodermic needles. Finally, I will close by showing our first steps towards transforming sophisticated CMOS circuitry into programmable, autonomous robots too small to be seen by the naked eye.

5:30 AM *S.CT07.07.02
Micro/Milli Robotic Assembly Using Diamagnetic Surfaces Allen Hsu, Annjoe Wong-Foy and Ronald Pelrine; SRI International, United States

As Moore’s law for digital computation reaches its inevitable limits, future advances in system level integration will lead to the next generation of electronics. Approaches such as heterogeneous integration will enable small and high-performance micro-systems (optical and electronic integration or System-In-Package) necessary for the growing consumer areas such as wearables, the Internet of Things, and Augmented Reality. Beyond electronics, tools and techniques for heterogeneous micro-assembly can lead towards new smart materials (i.e. defect-free constructed materials, digitally tailored electro-mechanical active materials with micro-scale properties and macro-scale performance, etc.) and the micro-assembly of biological and soft components.

While there are many research approaches towards tackling heterogenous micro-assembly (i.e. self-assembly, transfer printing, etc.), in this work, we will discuss our approach of directed robotic assembly using micro/milli robots. Directed micro/milli-robotic assembly has some unique advantages over other methods, such as being relative task agnostic and generalizable to various assembly problems. Furthermore, unlike many batch processes that are open-loop, directed micro-robotic assembly can be closed-loop by integration of metrology and material validation during the assembly process. Thereby swarms of micro/milli-robots can parallelize not only micro-assembly but also micro-metrology, enabling a method of overcoming statistical and thermodynamic limitations of conventional approaches.

Inspired by massive swarms of ants or termites assembling macro-scale objects from micro-scale parts, we utilize arrays of magnetic actuators in conjunction with diamagnetic graphite to create a magnetic collective of levitated micro/milli sized magnetic robots with nm level motion precision for 3D micro-assembly. By leveraging diamagnetic levitation, we can reduce factors such as hysteresis and stiction to enable high-precision and repeatable motion of micro/milli-robots. These passively levitated, but electromagnetically steerable micro/milli-robotic platforms can serve many roles: (1) compact high-precision motion platform for the manipulation and delivery of micro-components, (2) high precision sensors, and (3) motion platform for other micro-scale MEMS sensors and actuators. We will discuss multiple independently controlled robots (mm-sized) with dexterous behavior for assembling carbon fiber trusses and performing micro-assembly and micro-manipulation of 3d microspheres and silicon microparts, as well as some of the control issues for coordinating parallel robotic swarms for micro-assembly. In addition, by using robots cooperatively, we also demonstrate how teams of micro/milli robots can achieve new functionality and enable extremely high densities of independent micro-manipulation as compared to conventional standard robotic solutions.

6:00 AM S.CT07.07.03
Scale-Free, Programmable Design of Morphable Chain Loops of Kilobots and Colloidal Motors Mayank Agrawal and Sharon C. Glotzer; University of Michigan-Ann Arbor, United States

Achieving robotics at the micron and nano scale enables building reconfigurable machines and metamaterials that will create an unprecedented impact on fields such as healthcare, manufacturing, and smart materials. These applications demand scale-free and material-agnostic systems that can morph into arbitrary but programmable target configurations with precision as controlled by external agents such as heat, light, electricity and chemical environment. Such diverse actuation can be accomplished using active colloids—propellers that harness environmental energy source—that can act as motors, triggered and powered by these stimuli. However, unlike macro-scale motors, self-propelled colloids lack memory and ability to compute required by the conventional swarm-based algorithms to program the organization of motors into prescribed configurations. Here we present a design strategy that is both programmable and compatible with the sub-micron scale physics. Our strategy is to connect these motors such that the interactions among the motors are purely mechanical. The sequence of forces on these motors causes the system to morph into a unique configuration. We show how to reverse engineer the system’s design given a target configuration using kilobot (centimeter-scale robot) experiments and Brownian dynamics simulations. We also discuss methods of navigation and reconfiguration of the system. We demonstrate designing complex behavior such as a dynamic gripper, a dynamic Pacmac, and the letter M.

6:15 AM S.CT07.07.04
Directed Assembly of Magnetic Particles in a Magnetic-Field Assisted Inkjet Printing Process Karam N. Al-Milaji1, Ravi L. Hadimani1, Shalahb Gupta2, Vitalij K. Pecharsky2,3 and Hong Zhao1; 1Virginia Commonwealth University, United
Unique properties of one-dimensional assemblies of particles have attracted great attention during the past decades, particularly with respect to the potential for anisotropic magnetism. We have demonstrated directed assembly of ferromagnetic particles of Gd₅Si₄ into one-dimensional chains in a magnetic field-assisted inkjet printing process. The chains exhibit anisotropic magnetic properties, and are much easier to manufacture than, for example, corresponding single crystals. We have shown that three characteristic times, namely, the critical time for solvent imbibition into the porous substrate ($t_{im}$), the time it takes for particles to form chains in the presence of the magnetic field ($t_{ch}$), and the time in which the particles reach the substrate in the direction normal to the substrate ($t_{pz}$), control the assembly process. The characteristic time ratios of $t_{pz}/t_{ch}>>1$ and $t_{pz}/t_{im}<<1$, favor particle chaining and uniform particle deposition, respectively. Such an ability to control magnetic particle deposition and assembly through inkjet printing is a promising approach for many engineering applications.

Work at Ames Laboratory is supported by the Division of Materials Science and Engineering of the Office of Basic Energy Sciences, Office of Science of U.S. Department of Energy (DOE). Ames Laboratory is operated for the U.S. DOE by Iowa State University of Science and Technology under Contract No. DE-AC02-07CH11358. Work at Virginia Commonwealth University (VCU) is partially supported by National Science Foundation (1357565 and 1726617) and VCU startup funds.

Capillary Self-Assembly Challenges on Multichip 3D Stacking and Scaling Down Chip Size Takafumi Fukushima; Tohoku University, Japan

3D chip stacking approaches with TSV (thorough-silicon vias) are mainly classified into three categories: chip-to-chip, wafer-to-wafer, and chip-to-wafer 3D integration. The chip-to-chip technologies are widely used for traditional microelectronic packaging in which KGDs (known good dies) are assembled using one-by-one pick-and-place techniques. Although the assembly yield is high due to the use of KGDs, the assembly throughput is not sufficiently high, compared with wafer-to-wafer approaches. However, wafer-to-wafer technologies have a serious issue in total production yield that is exponentially decreased with the number of stacked layers because the failure dies cannot be removed from the wafers to be stacked. Therefore, chip-to-wafer 3D integration is thought to be a promising candidate to satisfy both the throughput and yield issues. However, chip-to-wafer 3D integration potentially has a trade-off between assembly throughput and alignment accuracies in the conventional robotic pick-and-place techniques. In order to address the problems, we have proposed and developed multichip-to-wafer 3D integration using liquid surface tension. From the technical point of view of chip-to-wafer bonding, we talk about the basic concept and recent studies of the self-assembly based 3D integration. These approaches using surface tension-driven multichip assembly are divided into two methodologies: one is non-transfer stacking without carrier wafers and the other one is transfer stacking with them. These carrier wafers are typically used for temporary wafer bonding in standard 3D integration processes. Here, we also introduce temporary multichip bonding technologies applicable to 3D integration with multichip transfer stacking in which an inorganic temporary adhesive and a debonding layer sensitive to near UV lasers are utilized. In this presentation, we introduce our multichip-to-wafer 3D integration studies with non-transfer and transfer stacking particularly focused on solder microbump bonding, oxide-oxide direct bonding, and hybrid bonding through a new material of Cu nano-pillars. Finally, I will show the massively parallel self-assembly works with tiny dies with the side of less than 100 μm for micro-LED display application.

5:15 AM S.CT07.08.02
Macroscopic Conjugated Polymer Fibers Assembled under Electric Field Song Guo; University of Southern Mississippi, United States

It is often desirable to assemble conjugated polymer molecules into highly ordered macroscopic structures to fully utilize their potentials in a variety of organo-electronic applications. However, due to their intrinsic flexibility, conjugated polymer chains tend to entangle and form disordered bundles in solution. Here we show that centimeter-long conjugated polymer
(poly(3-hexylthiophene) (P3HT)) fibers can be assembled under an external DC electric field. In general, assembly under external stimuli such as magnetic or electric fields provides a way to arrange samples without using template materials, leading to a relatively simple procedure. The electric field is chosen here because of its low cost and tunability of field strengths and orientation during the assembly process. In this work P3HT molecules are pre-aggregated into high aspect ratio nanowires, then these nanowires can be further aligned and bundled into macroscopic fibers in solution under the applications of external electric field. To fully understand the assembly process, its dependences on nanowire microstructure types, the DC electric field strength, and solvent polarity are investigated by characterization methods including UV-Vis, AFM, and GIWAXS. It is proposed that the electric field-induced dipole in the nanowires aligns the nanowires along the electric field direction, then the dipole-dipole interactions will lead to further assembly of the nanowires into larger bundles. The macroscopic fibers will retain its morphology in solution even after the electric field is removed. Furthermore, curved macroscopic fibers can also be prepared under curved electric field lines. This hierarchy method provides a general way to assemble flexible molecules into macroscopic fibers by pre-forming high aspect ratio secondary nanostructures, then align and bundle them under external fields to retain the anisotropic properties. We hope this method can be extended to other flexible molecules that are difficult to be directly fabricated into macroscopic structures under electric fields.

Heterogeneous Integration of Self-Assembled Materials and Nano/Micro Devices in Electronics Koji Asakawa; Institute of Memory Technology Research, Kioxia Corporation, Japan

The bottom-up approaches recently become quite attractive for nano-scale fabrication. For example, block copolymers, nano-colloidal particles, and anodized aluminum are known to form nano-scale patterns. In addition, these bottom-up self-assembly can be combined with conventional top-down lithography resulting large scale periodic pattern can be fabricated. Several applications to nano/micro-electronics have been reported. Such as patterned magnetic media for a hard disk drive (HDD), light extraction structures of light-emitting diodes (LEDs), organic light-emitting diodes (OLEDs), anti-reflection (AR) structures for displays, metal wire-grid polarizers (WGP), and transparent conductive film (TCF) using nano-meshed metal thin film were demonstrated by these manners. The guided, aligned, or directed self-assembly (DSA) is a key technique, that the larger guides are made by conventional top-down methods then bottom-up self-assembled structures are formed along the guides. The challenges are continuing to fabricate the semiconductor memories. We would explain these potential applications fabricated by self-assembly.

5:30 AM S.CT07.09.03
Directed Self-Assembly Technology with Block Co-Polymer/Metal Nanocomposites for Ultrafine-Feature Metallization Takafumi Fukushima; Tohoku University, Japan

In this work, a new metallization to form metal nano wires are studied with nanocomposite consisting of block co-polymer and metal compounds or metal nano particles by advanced directed self-assembly (DSA) technology. To evaluate the impact of the metals, we simply characterize the standard DSA behavior with block co-polymer alone. Si trenches with a length of 10 μm and width of 3 μm are fabricated by dry Si etch processes used for 3D integration with TSV (Though-Silicon Via) applications. This trench size is quite larger than that used for typical DSA works. Surprisingly, we have successfully formed lamella (multiple annular) and nano cylindrical structures in the large Si trenches by using polystyrene-block-polymethacrylate (PS-b-PMMA) with the PS:PMMA composition of 1:1 and 2:1, respectively. When we used PS-b-PMMA with a PS:PMMA molecular weight ratio of 15K:15K and 57K:25K, the resulting lamella and cylinder pitches are 20 nm and 40 nm. The pitches depend on the molecular weight of the nanostructure. We evaluate the impact of DSA parameters such as heating time and temperature on morphological behavior and the resulting nanostructure of the block copolymers. The nanostructures were formed even at below 200degreeC. In addition, it is found that the nanostructure can be controlled by adding the homo polymer of PS or PMMA into the block copolymers. From mean field approximation simulation based on Self-Consistent Field (SCF) theory, if a metal compound well interacted with the PMMA or PS block is added into PS-b-PMMA, the metal in the nanocomposite will be kept to be distributed into nanocylindrical PMMA or PS to fabricate lateral
or vertical ultrafine-pitch interconnection. Here, we employed a nanocomposite with an Fe compound and PS-b-PMMA for nano wire formation by DSA. According to Moore’s law limitation, metal nano wires are promising candidate to breakthrough the interconnect scaling. It was interesting to note that SEM observation revealed Fe nano wires were induced by the phase separation of the PS-b-PMMA in the Si microstructure. The EDX analyses confirmed the added metal was either attached or aligned near the PMMA of the block copolymer. In addition, another nanocomposite is prepared with PS-b-PMMA and PMMA-modified Au nano particles. By DSA processing with simple heating, the nanocomposite shows nano wires with a width of 30 m and the length of 500 nm or more. The electrical characterization is done with a nano probing system, indicating the liner relationship between current and voltage although the resistance is relatively high. By using DSA with the block co-polymer/metal nanocomposite, this is the first time to show the ohmic behavior applicable to interconnection. In this presentation, another DSA approach without nanocomposites will be proposed and their feasibility works are introduced.

Boundary-Directed Epitaxy of Block Copolymers Robert M. Jacobberger1, Vikram Thapar2, Guangpeng Wu3, Tzu-Hsuan Chang4, Vivek Saraswat4, Austin J. Way1, Katherine R. Jinkins1, Zhenqiang Ma1, Paul Nealey4, Su-Mi Hur2, Shisheng Xiong6 and Michael Arnold1; 1University of Wisconsin-Madison, United States; 2Chonnam National University, Korea (the Republic of); 3Zhejiang University, China; 4National Taiwan University, Taiwan; 5University of Chicago, United States; 6Fudan University, China

Directed self-assembly of block copolymers (BCPs) provides a scalable route for rationally fabricating dense nanoscale patterns beyond the resolution of conventional lithography at highly precise locations on a surface. Historically, there have been two strategies—graphoepitaxy and chemoepitaxy—for directing the self-assembly of BCPs into useful patterns. We have recently discovered a third paradigm—termed “boundary-directed epitaxy”—in which templates consisting only of planar, low-resolution features are used to drive the formation of more complex BCP patterns with enhanced feature resolution. The templates are comprised of spatial boundaries separating regions on a surface with different composition, formed at the edges of isolated stripes on a background substrate.

Vertical BCP lamellae are pinned by chemical contrast at each stripe/substrate boundary, align parallel to the boundaries, selectively form on the stripes (whereas horizontal lamellae form on the background substrate), and register to wide and incommensurate stripes to multiply the feature density. Isolated BCP line arrays with half-pitch of 6.4 nm are demonstrated on stripes wider than 80 nm. Directed assembly of isolated line arrays, superstructures of isolated line arrays, and complex features such as T-junctions, jogs, and bends is demonstrated, which may be particularly useful for fabricating critical features in integrated circuits. Boundary-directed epitaxy circumvents the need for topographic structures used in graphoepitaxy or ultra-narrow guiding features used in chemoepitaxy to direct assembly of sub-10 nm BCP features, and provides an attractive path towards nanofabrication beyond the resolution of conventional lithography.

5:00 AM S.CT07.10.01
Hetero-Integration of CdS Nanorods on Carbon Substrates for Enhanced Photoelectrocatalytic Performance Min Soo Jeon, Youngshik Cho and Dong Rip Kim; Hanyang University, Korea (the Republic of)

Cadmium sulfide (CdS) has been highlighted due to the excellent photoelectrocatalytic properties and activities. Hetero-integrated CdS nanoscale structures onto diverse substrates can bring more enhanced performances in wide photocatalytic applications. Herein, we demonstrate a facile strategy to synthesize CdS nanorods on three-dimensional conductive carbon structures with the enhanced photoelectrocatalytic performance by using hydrothermal methods. The hetero-integrated CdS nanorods with high uniformity on highly conductive carbon substrates not only exhibit the enhanced photocatalytic efficiency in reduction of organic pollutant, but also perform the excellent photoelectrochemical activity and photostability, compared to control samples. The superior performance of the hetero-integrated CdS nanorods on carbon substrates is attributed to the improved charge separation and transport of photo-generated electrons in highly crystalline CdS nanorods and the effective photo-generated electron transfer to carbon substrates from CdS nanorods. Finally, we demonstrate the hetero-integrated CdS
nanorods on three-dimensional carbon supports with a variety of shapes by using the developed method. Our strategy to integrate CdS nanoscale structures on diverse substrates can be utilized to achieve high performance photoelectrocatalytic systems in wide energy and environmental applications.

Freestanding Layers of Silicon Nanocrystals—Photoluminescence and Mechanical Properties Cameron Papson, Alborz Izadi, Mayank Sinha, Sara Roccabianca and Rebecca J. Anthony; Michigan State University, United States

Silicon nanocrystals (SiNCs) have many applications in electronic devices due to their efficient and tunable optoelectronic properties. In the many methods for creating SiNCs, they are nearly always either embedded in an inorganic matrix or supported by a substrate. While this has not hindered their use in technologies such as light-emitting devices (LEDs) and solar photovoltaics, it also raises questions about SiNC properties in standalone layers. It is well-known that the local environment of nanocrystals can influence their optical properties, and many of the methods for testing the mechanical behavior of thin layers of SiNCs rely on substrate-supported techniques. Here we present our work on fabrication of freestanding layers of SiNCs, and their optical and mechanical behavior.

SiNCs were synthesized in a nonthermal radiofrequency plasma reactor using silane, argon, and hydrogen gases. Transmission electron microscopy (TEM) and x-ray diffraction (XRD) measurements indicate that the SiNCs are crystalline with an average diameter of 4-5 nm. We created freestanding layers by using inertial impaction of SiNCs directly out of the reactor onto sacrificial layers, such as NaCl and sucrose. We used thermal evaporation to deposit thin layers of NaCl onto substrates such as glass, silicon wafer, and polydimethylsiloxane (PDMS). We also used block-like substrates entirely from NaCl and sucrose, as well as other surface coatings of sucrose, as our sacrificial bolsters for the SiNCs. We deposited SiNC layers of varying thicknesses onto these substrates using the inertial impaction process. We then liberated the SiNC layers via dissolution in water at controlled temperature. The SiNCs, which are hydrophobic, rose to the surface of the water where we collected them. Our ongoing experiments include testing the SiNC layers' photoluminescence and mechanical properties without the support of a substrate beneath, helping to elucidate their properties as a single system rather than as a layer supported by a bolster.

5:30 AM S.CT07.10.03
Enhanced High-Voltage Cycling Stability of Ni-Rich Cathode Materials via Self-Assembly of Mn-Rich and Li-Rich Shells Jianqing Zhao; Soochow University, China

Ni-rich layered LiNi_{x+y}Mn_xCo_yO_{2} (NMC, x+y<0.5) oxides have been demonstrated to be dominant cathode materials for high-energy lithium ion batteries. However, NMC cathode materials with high Ni contents usually show unsatisfied capacity decay and voltage fading cycled at high voltages, owing to aggravated side reactions and electrochemical irreversibility during prolonged lithiation/delithiation cycles. Here, we report the Mn-rich Li_{1/2-y}Mn_{0.5}Ni_{1/2}Co_{y}O_{2} (marked as LMNCO) nanocomposite that is integrated of layered Li_{2}MnO_{3} and spinel LiMn_{1.5}Ni_{0.5}O_{4}-type phases as a desired shell for improving high-voltage cycling stability of the Ni-rich LiNi_{1/2}Mn_{0.5}Co_{0.5}O_{2} (marked as NMC811) cathode material. The core-shell NMC811@x% LMNCO nanostructure has been fabricated in satisfied structural conformity by using an initial sonofragmentation, followed by the solvent evaporation-induced self-assembly (EISA) and post-annealing processes. The optimized NMC811@x% LMNCO cathode material can deliver an initial discharge capacity of 150.0 mAh g^{-1} at 5 C (1 C=200 mA g^{-1}) in a voltage range of 2.7-4.6 V vs. Li^{+}/Li with 83.4 % retention up to 500 cycles, significantly superior to 75.6 % of the bare NMC811 material. The Mn-rich shell also enables to effectively stabilize Ni-rich cathode materials for long-term cycles in such a high voltage range at 55 °C. In addition, the in-situ X-ray diffraction (XRD) has been carried out to probe structural evaluations of the Ni-rich NMC811 cathode material during charge/discharge processes. The operando XRD results demonstrate undesired structural irreversibility of the NMC811 cathode material in the first cycle. Enhanced structural stability for continuous phase transformations in next electrochemical cycles can be implemented via a self-assembly of the Li-rich Li_{2}MnO_{3} coating. The optimized NMC811@LMO-3% cathode can retain initial discharge capacities of 92.9 % at 0.1 C after 100 cycles and 80.4 % at 1 C after 500 cycles, significantly superior to 73.8 % and 61.3 % of the bare NMC811 cathode. This work sheds lights on structural evaluations of Ni-rich cathode materials during lithiation/delithiation processes, and further offers a synthetic prototype for the conformal core-shell-structured fabrications, which could be
adopted for the surface modification of various functional materials to achieve enhanced performance in device applications.

5:45 AM S.CT07.10.04
Colloidal Self-Assembly in Nanostructured Tribo-Electrically Charged Templates Pratik Ray1,2, Qiang Li2, Akshit Peer2, Lopamudra Palodhi1, In Ho Cho2, Rana Biswas2,3 and Jaeyoun Kim2; 1IIT-Ropar, India; 2Iowa State University, United States; 3Ames Laboratory, United States

It is of great scientific interest to integrate nanoscale materials onto non-native substrates to synthesize structured architectures with novel functionalities that cannot be achieved by traditional means. To achieve this, we explore the crystallization of nanoparticles on periodically nanostructured substrates.

For the structured substrate we utilize a periodic array of nanocups of pitch 750 nm formed on a poly(dimethylsiloxane) (PDMS) substrate through replication from a polymer mold [1]. The novel feature of the nanocup array is the existence of surface tribo-charge strongly localized at the rims of the nanocups in an annular ring pattern, which was confirmed through Kelvin probe force microscopy of the surface electric potential [1,2]. Dielectric nanoparticles may be polarized by the strong electric fields in the vicinity of the tribo-charge. We expect that such dielectric nanoparticles in a colloidal suspension may be preferentially attracted to the charged regions and driven into nucleation, forming unusual structural motifs, including ring-like patterns, that could not otherwise be produced in conventional nucleation experiments. We hypothesize that the tribo-charge provides a new control variable to fabricate novel colloidal structures within the existing nanostructure.

To test this hypothesis, a PDMS nanostructured array with annular tribo-charge was immersed in a colloidal alumina suspension (5% alumina by volume) for ten minutes and then removed from the suspension. The mean particle size of the suspension was ~50 nm. The array was slowly dried, allowing crystallization. The dried PDMS array was characterized by scanning electron microscopy (SEM). We observed a high density of colloidal nanoparticles crystallized within each nanocup. It is very probable that the charged template has attracted the colloidal nanoparticles to the nanocup wall in the initial phase of growth. This is followed by agglomeration of the nanoparticles within each nanocup. Certain regions of the nanostructure reveal agglomerates of alumina nanoparticles with nearly spherical agglomeration shapes, neatly filling the entire nanocups. There is negligible agglomeration on the flat top surface between the nanocups.

It will be necessary to tailor the microscale assembly conditions that nucleate the colloids or loading material in the first phase, but prevent further agglomeration within the nanocups. This may be achieved by i) using a lower density of nanoparticles in the solution and ii) increasing the concentration of dispersants to reduce agglomeration kinetics of crystallization will be discussed. These experiments will create a pathway for tailored growth of colloidal crystals and other drug coatings within these charged templates. These can be biomedically utilized for loading of nano-arrays with drugs since it leads to complete filling of the nanocups with negligible coating left on the flat surface. Thus drug elution would require dissolution of nanoparticles from the nanocups, starting with outer nanoparticles in the outer shell of the agglomerated clusters. Microstructures created by bottom-up technologies can serve as 2-dimensional photonic crystals where strong diffractive effects can be present.

6:00 AM S.CT07.10.05
Using Defects to Reshape Colloidal Assemblies Bryan VanSaders and Sharon C. Glotzer; University of Michigan, United States

Directed assembly at the colloidal scale remains challenging despite advances in using optical forces to manipulate nanoparticles. Optical holography allows for precise positioning of components, but does not scale well to thousands or millions of particles. However in dense colloidal systems particle positions are highly correlated, and so not every particle need be controlled in order to enact reconfigurations of the dense assembly. In this work we use simulation to study how a small number of particles embedded within a colloidal monolayer can exert forces that lead to long-range permanent deformation of the monolayer edges. By framing the problem in terms of the creation and migration of mobile dislocation defects, we uncover design principles for the embedded cluster shapes that result in the accumulation of large shear deformations on lattice planes. We show that arbitrary control of shear deformation localized to a single plane is sufficient to carry out a variety of useful reshaping operations on crystalline colloidal monolayers. This work provides a method to increase the length scale of control achieved with optical forces without imposing additional complexity on the optical system required.

Optimization of Geometry and Edge Passivation for High-Performance Si Heterojunction (SHJ) Microcells
Marjorie Potter¹, Megan E. Phelan², Pradeep Balaji³, Phillip Jahelka², Rebecca Glaudell², Michael Enright¹, André Augusto³, Harry A. Atwater² and Ralph G. Nuzzo¹; ¹University of Illinois at Urbana Champaign, United States; ²California Institute of Technology, United States; ³Arizona State University, United States

Perimeter recombination in micron-sized III-V photovoltaic (PV) materials has been studied extensively for performance at high concentrations, but minimal work toward understanding and optimizing edge recombination for Si-based photovoltaics has been pursued. Here, through both modelling and microcell fabrication, we explore the performance of Si heterojunction (SHJ) solar cells with varying edge to total surface area ratios by examining performance characteristics at different micron-scale lateral dimensions (between 200 µm x 200 µm and 1000 µm x 1000 µm microns) and device thicknesses (80 - 200 microns). We explore edge passivation strategies by determining the impact of a-Si:H and oxide- and nitride-based passivation coating materials on recombination at the edges and consequently device open-circuit voltage, VOC. Finally, we compare the impact of deep reactive ion etching (DRIE) and micro-laser cutting for solar cell dicing on edge surface quality and process scalability. Modelling results indicate that microcell device short-circuit current, JSC, increases with device thickness (up to 35 mA/cm²) and is generally independent of lateral dimensions, while device VOC decreases with thickness and increases with lateral dimensions, exceeding 700 mV at most geometries with high quality edge passivation. Consequently, device power conversion efficiency (PCE) is largely independent of thickness and increases with lateral dimensions, with a maximum PCE of > 20% at the largest lateral sizes. Notably, we found that edge passivation quality, rather than device geometry, dictates performance via the magnitude of edge recombination and is therefore the most important variable in this study to optimizing performance; high-quality a-Si:H was determined to be the best passivation material by virtue of minimizing edge recombination velocity (as indicated by dark current measurements) and thus maximizing VOC. Corroboration of modelling results with that of fabricated and tested SHJ microcell devices will be discussed, along with DRIE and micro-laser cutting routes to fabrication of micron-sized SHJ PV devices and the associated high-level cost-benefit analyses. This work will contribute to understanding of micro-scale Si-based PV and provide a framework for optimizing device parameters for integration with large-scale energy-harvesting systems.

S.CT07.11.03
Surface Morphology-Directed Nanoparticle Assembly for Versatile Sensors
Sayli Jambhulkar, Weiheng Xu, Dhaneedar Ravichandran and Kenan Song; Arizona State University, United States

Well-controlled 'pick-and-place' of nanoparticles has vast potential in technological applications such as sensing, energy harvesting and transport, data storage, light composites, interfacial and functional modifiers, as well as other applications. These nanoparticles are anisotropic, including two-dimensional (2D) (e.g., nanosheets, nanolayers, nanoplatelets, nanoribbons) and one-dimensional (1D) (e.g., nanorods, nanotubes, nanowhiskers, nanofibers) nanomaterials that are chemically composed of carbon, semiconductor, and metal elements. While the organization and alignment of anisotropic nanosomic materials have been explored in many pathways, each method has its strengths and weaknesses. For example, non-directed methods (e.g., casting and drying) are simple and quite elegant but are somewhat limited in the morphologies they can access. As well, non-directed methods can be susceptible to factors such as solution concentrations and drying thermodynamics. Surface modification significantly expands the versatility of anisotropic nanomaterial assembly, but often requires challenging surface chemistry to modulate nanomaterial properties. Traditional use of prefabricated templates can control both the positional and orientational orders but requires the potentially difficult fabrication of a template. Therefore, our research aims to develop improved assembly strategies at microscales, coherently implemented into additive manufacturing (AM) infrastructure, to readily and simultaneously achieve orientational and positional control of anisotropic nanomaterials over arbitrarily large areas and volumes. The AM proposed here is an in-house designed process supported by layer-by-layer deposition of polymers with alternative and selective addition of nanoparticles. The printing and deposition mechanisms from the two-step manufacturing are compatible on the same processing platform that can greatly improve the precision and throughput.

Our proposed 3D printing mechanism will control the processing and material parameters along the working path such that
each voxel of printed material itself can be a spatially varying architecture of particles giving rise to a response that differs locally from highly anisotropic to isotropic. Hence, this manufacturing enables the design and fabrication of composites with site-specific optimization of particle orientations, programmable surface morphology, and designable interfacial transitions. One-dimensional (1D) carbons, namely carbon nanofibers (CNF), will be demonstrated as an example here due to their superior anisotropic properties especially the higher conductivity or sensitivity along the fiber axis as compared to that along with the cross-section directions. We used 3D printing for surface morphologies controls and the CNFs were deposited via layer-by-layer self-assembly (LBL) techniques. The samples with different roughness and pattern features were compared for the efficiency of directed self-assembly. The solid-liquid-air interfaces were proven to be critical in determining the selective deposition of CNF for surface conductive paths and sensitivity degrees. The electricity characterizations showed a strong anisotropy along with the fiber alignment directions, showing resistivity of 0.27 kW/sqr along with the CNF band as compared to 1.21 kW/sqr along with the normal directions. This phenomenon was taken advantage of their sensing capabilities. We observed significantly improved sensitivity to strain, temperature, and chemical liquid/gas as compared to randomly distributed CNF microstructures. The high sensitivity with exposure to different volatile chemicals was obtained from our research and suggests the potential in health monitoring, human-robotics interactions, microelectronics design, and environmental sustainability.

Self-Aligned Copper Oxide Passivation Layer? A Study on the Reliability Effect Yue Kuo and Jia Quan Su; Texas A&M Univ, United States

Due to its high conductivity, copper is an important interconnect material for high density as well as large area electronic and optoelectronic products, such as ICs, TFT LCDs, and OLEDs. The reliability of the copper line is critical to these applications. In general, the copper interconnect line needs a bottom adhesion layer as well as a passivation layer. The adhesion layer effect on the line reliability has been well studied. The passivation layer is commonly formed by adding a CVD or sputter deposited dielectric or metallic layer. There are some studies on the influence of these passivation layers on the reliability of the copper line (1,2). However, there are few studies on the copper oxide passivation effect on the copper line's reliability.

Since oxide can be easily formed on the copper pattern under a well-controlled condition, it can be an effective self-aligned passivation layer. In this paper, authors report the reliability study of the copper oxide passivated copper line that is etched with the plasma-based etch process (3,4,5). The copper oxide layer was formed from the oxygen plasma method. Copper lines of various thicknesses and widths with and without the oxide passivation layer were prepared. The line breakdown phenomena under the constant current density stress condition are discussed. The composition and structure of the passivation layer before and after the high current stress condition have been examined and discussed. In summary, copper oxide is a potentially important passivation layer for the copper interconnect line in many products.

Design, Microfabrication and Characterization of Bismuth and Glassy Carbon Based Sensor for Heavy-Metal in Drinking Water Ryan Butler and Sammuel Kassegne; San Diego State University, United States

In the past several decades, the US has experienced a rising concern over toxic pollution from heavy metal sources. For example, the pollution based natural disaster of Flint, Michigan garnered an abundance of media attention for its devastating impact on the lives of those in the local community. Although this negative press was rightly deserved, there are many places in America with much higher recorded heavy metal poisoning rates – three thousand to be exact. A big concern of much of this pollution comes in the form of water toxicity. Often, heavy metals find their way into water supplies for local communities which results in the indirect poisoning of citizens. Therefore, there is great need for a commercially available and portable device which would provide an easy method to test the level of poisonous elements in community water supplies.

Herein, the creation of a novel microfluidic device for the measurement of trace heavy metal ions is described. The work presented within focuses on these ions due to their health hazards and low concentration limits lending to an interesting challenge in detection.
The first effort in this project revolved around determining the form factor of a MEMS device which would act as an environmental sensor for minute concentrations of lead. Much background research into similar devices was performed before starting to conceptualize the preliminary design. Taking the equipment of the San Diego State University Clean Room facility into consideration, a rough model was presented and refined over several weeks. A final design then followed with a basic 3D model and fabrication process presented.

After much time testing and redesigning, results were generated for the measurements of trace heavy metal ions in solutions of water. Additional results were then obtained by altering various parameters within the experiment such as the analyte concentration. They were then compared to other experimental and commercial devices to determine the efficacy and practicality of the device. Finally, a study was performed to determine future work and technological extensions of the tool presented within.

S.CT07.11.07
Mass Analysis of Neuropeptides in Salty Environment Using Hydrophilic Ring-Shaped Anchors Sook Yoon and Chang Young Lee; Ulsan National Institute of Science and Technology, United States

For more than a decade, researchers have studied cell-to-cell signaling peptides using various analytical methods. Signaling peptides have been known to have important role in the physiological mechanisms. Currently available approaches for analyzing peptides have drawbacks such as loss of peptides and complicated steps for sample preparation. We developed an efficient platform for mass analysis of neuropeptides that simultaneously concentrates and desalts the analytes via coffee ring effect. Our approach is to use C18-Au coated patterned substrate. When peptide solution with high salt content is dropped onto the patterned C18-Au surrounded by donut-shaped hydrophilic anchors, salts are removed by outward flow generated during evaporation, while peptides are collected onto the central C18-Au region. Our approach greatly simplifies the sample preparation for matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS). We also found that our patterns can be regenerated and used 5 times or more without any performance degradation. We have developed a simple kinetic model that describes the correlation between the evaporation rate and the surface coverage of peptides. Moreover, the performance could be dramatically increased by concentrating absorbed peptides into a crystal using PDMS contact printing. Applying these drop-dry methods to MALDI-MS sample preparation potentially enables high-throughput analyses, including time-lapse mass analysis. Our approach is easily accessible to researchers who do not have special expertise in mass spectrometry, so it is possible to contribute to bringing new ideas to neuropeptide analysis.

Preparation of Nano Raspberry Particles Using Chemically Adsorbed Monolayers Teruyoshi Sasaki, Kazufumi Ogawa and Yoshifumi Suzaki; Kagawa University, Japan

Since the nano world can be observed with SEM and SPM, nanomaterials have been actively developed. Among them, nanoparticles are often used for both metals and non-metals, such as cosmetics, home appliances / electrical electronic products, paints / inks, etc. In general, nanoparticles are produced by a vapor phase method or a liquid phase method. However, it is still difficult to produce nanoparticles with a desired shape such as raspberry particles. For example, the prototype raspberry particles are on the order of the micro level at the minimum. In this study, the surface of two kinds of large and small nano level silica nanoparticles were coated with different reactive chemically adsorbed monomolecular film. Thereafter, the particles were bonded to each other by the interaction of the functional groups at the ends of the chemically adsorbed monomolecular film on the surface of each particle to produce nano sized raspberry particles. As an application example of nano raspberry particles, the nano raspberry particles were coated on the surface of a glass substrate to form a nano fractal surface structure. Furthermore, a light transmitting super water repellent glass substrates could be produced by forming a fluorocarbon based chemical adsorbed monomolecular film on the surface without damaging the surface of the fractal structure.

Nano-Engineering in Confined Spaces—Size- and Shape-Controlled Growth of Functional Nanostructures in Self-Assembled Block Copolymer Nanoreactors Naman Arora¹, Anna Perdikaki², Paschalis Alexandridis³, T. J. (Lakis) Mourtziaris⁴ and Georgios Karamikoles¹,¹; ¹Khalifa University, United Arab Emirates; ²Demokritos National Research Center, Greece; ³University at Buffalo, The State University of New York, United States; ⁴University of Massachusetts Amherst, United States

Self-Assembly of amphiphilic block copolymers in selective solvents can yield a variety of organized structures at the nanoscale of different sizes, shapes, and interfacial characteristics. Such rich structural polymorphism has been tuned and subsequently utilized in this work to controllably prepare a variety of colloidal systems of nanoparticles by templated growth.
in the self-assembled nanodomains. Nanomaterials spanning compound semiconductors with 0-, 1-, and 2-D morphologies to metallic nanostructures grown in poly(ethylene oxide)-b-poly(propylene oxide)-b-poly(ethylene oxide) assemblies will be presented. The metallic systems in particular were applied as antibacterial agents exhibiting enhanced and sustainable performance due to the block copolymer colloidal configuration.

**Characterization of Device Edge Illumination of Si Heterojunction (SHJ) Microcells for Luminescent Solar Concentrator (LSC) Applications**

Megan E. Phelan¹, Maggie Potter², Pradeep Balaji³, André Augusto¹, David Needell¹, Ralph G. Nuzzo² and Harry A. Atwater¹; ¹California Institute of Technology, United States; ²University of Illinois at Urbana-Champaign, United States; ³Arizona State University, United States

In dense urban environments, with limited rooftop space, communities must look towards new photovoltaic (PV) technologies that can be integrable into the existing building envelope. Luminescent solar concentrators (LSCs), which sustain performance in both direct and diffuse lighting conditions and boast tunable transparencies, present an attractive option for building integrated (BI) PV. In this talk, we report performance optimization and characterization for varied illumination conditions of Si heterojunction (SHJ) microcells embedded within an LSC for BIPV applications. For this design, we propose a grid-like array of SHJ microcells, beneath a poly-lauryl methacrylate (PLMA) waveguide that has embedded InAs/InP/ZnSe quantum dots as the luminophore. Given the proposed architecture, the microcell can be illuminated from the top surface of the cell as well as each of its device edges; this illumination results from each direct sunlight and from quantum dot photoluminescence (PL) within the LSC waveguide, respectively.

In this talk, we compare SHJ microcell performance when illuminated on each 

1) the top surface, 

2) one device edge, 

and 

3) all four device edges simultaneously. We present both simulated and experimental measurements to corroborate our results around photonic interactions at each surface, and preform the following characterizations and measurements: light current-voltage (LIV), dark current-voltage, photocurrent mapping, external quantum efficiency (EQE), and internal quantum efficiency (IQE). By varying the dimensions (width and length) of the SHJ micro cell (from 400um to 800um), we further report how cell performance for each surface illumination (top vs. edge) varies for different sized devices. Results of these measurements show that Jsc increases when illuminating the microcell on the edge (in comparison to top surface illumination) due to an increased absorption depth. However, Voc drops for edge illumination vs. top illumination, due to an additional darkness factor and increased recombination. The mechanisms and photonics behind the contrasting microcell performance at each of these surfaces will be discussed during this talk. By understanding microcell performance at each interface, we are able to better design a SHJ/LSC integrated device, with optimized luminophore PL to match the edge illumination performance, for BIPV applications.

5:00 PM OPENING COMMENTS

5:03 PM *S.CT08.01.02
Direct Imaging of Nucleation and Growth of Colloidal Nanoparticle Superlattices Qian Chen; University of Illinois at Urbana-Champaign, United States

We use liquid-phase transmission electron microscopy to directly image a series of crystallization pathways of colloidal nanoparticles into superlattices. We find that there exist similarities to the prevalent model system of micron-sized colloids, such as a non-classical two-step crystallization pathway, where amorphous intermediates in the form of nanoparticle clusters exist preceding the nucleation. Capillary wave theory can be used to describe the fluctuation and energy of the surfaces. But there are also differences, in particular, a universal layer-by-layer growth mode that we observe consistently for diverse nanoparticle shapes. Single particle tracking, trajectory analysis, and simulations combined unravel the energetic and kinetic features rendering this crystal growth mode possible and universal at the unexplored nanoscale, enabling advanced crystal engineering.

5:12 PM *S.CT08.01.10
How Do Additives “Get the Job Done” During Nanoparticle-Mediated Crystallization? Alexander E. Van Driessche; CNRS - Univ. Grenoble-Alpes, France

Crystallization from solution follows either a single or a multistep pathway. The latter case involves the formation, aggregation and transformation of precursor/intermediate particles to the final crystalline phase. This has been observed for several important minerals, such as CaCO₃, CaPO₄, CaSO₄ or CSH [e.g. 1-3], but also for macromolecular crystals [e.g. 4,5]. Moreover, this particle-mediated crystallization pathway can be “fossilized” in the structure of the final crystals [e.g. 6]. In the idealized laboratory environment pure solutions are often studied, but in real-world natural and engineered crystallization processes soluble additives, e.g. inorganic or organic molecules, are omnipresent. In fact, they frequently play a key role in the formation of crystalline phases and are a central part of biomineralization, functional material synthesis and anti-scaling strategies [e.g. 7]. Traditionally, models of additive-controlled crystallization have considered a single step nucleation with additives adsorbing on the surface of nuclei, impeding their further growth. Hence, to advance our understanding and gain a better control of multistep crystallization processes, the interaction of additives with the precursors and/or intermediate particles needs to be unraveled.

To achieve this, we constructed a holistic nanoscopic view of a particle-mediated crystallization pathway in an additive free system [e.g. 5-8], based on in situ nanoscale observations. Subsequently, we conducted macroscopic and microscopic observations of additive-controlled crystal formation. Opposing the classical view, we found that the inhibition of nucleation can be ascribed to additives that hinder the formation of precursor species and/or their aggregation/transformation by prevailing in their vicinity and thereby reducing their interaction probability [e.g. 7, 10-11].

Synthesis, Phase Transformation and Structural Development in Magnetic Biocomposites Taifeng Wang¹, Anna Pohl¹, Steven Herrera¹, Yuka Narahara², Michiko Nemoto² and David Kisailus¹; ¹University of California, Riverside, United States; ²Okayama University, Japan

There is an increasing need for the development of multifunctional lightweight materials with high strength and toughness.
Natural systems have evolved efficient strategies, exemplified in the biological tissues of numerous animal and plant species, to synthesize and construct composites from a limited selection of available starting materials that often exhibit exceptional mechanical properties that are similar, and frequently superior to, mechanical properties exhibited by many engineering materials. These biological systems have accomplished this feat by establishing controlled synthesis and hierarchical assembly of nano- to micro-scaled building blocks. This controlled synthesis and assembly require organic that is used to transport mineral precursors to organic scaffolds, which not only precisely guide the formation and phase development of minerals, but also significantly improve the mechanical performance of otherwise brittle materials.

Here, we investigate an organism that have taken advantage of hundreds of millions of years of evolutionary changes to derive structures, which are not only strong and tough, but also demonstrate abrasion resistance. All of this is controlled by the underlying organic-inorganic components. Specifically, we discuss the formation of heavily crystallized radular teeth the chitons, a group of elongated mollusks that graze on hard substrates for algae.

Our investigation of the formation of a fully mature radular tooth from Cryptochiton stelleri found in the eastern Pacific, occurs over a series of more than 40 teeth. The initial stage of tooth formation begins with the synthesis of a three-dimensional fibrous α-chitin organic matrix, prior to the onset of crystallization. Microscope analysis of early stage teeth shows ferrihydrite mineral particles growing on α-chitin fibers. Synchrotron x-ray, combined with TEM analyses show that ferrihydrite exists as randomly oriented aggregates, but undergoes a phase transformation to magnetite within a few rows of teeth. We discuss potential mechanisms of nucleation of ferrihydrite, its transformation to magnetite as well as its subsequent mesoscale ordering, crystal growth and the resulting mechanical properties. From the investigation of synthesis-structure-property relationships in these unique organisms, we are now developing and fabricating multifunctional engineering materials for energy and water purification based applications.

5:30 PM S.CT08.01.03
Direct Imaging of Atom-Mimicking Oriented Attachment of Nanoparticle Superlattices by Liquid-Phase TEM Chang Liu and Qian Chen; University of Illinois at Urbana-Champaign, United States

We utilize nanoparticle superlattice as a model system to study the fundamental laws of order emergence and evolution from a dispersion of nanosized entities. Liquid-phase TEM makes it possible to directly conduct single-particle level imaging in real time and real space, to reveal pathways of nanoparticle crystallization. To be specific, we observe how different types of diffusion events (e.g., surface and volume diffusion) involved in the layer-by-layer growth of a nanoparticle superlattice, where the high spatiotemporal resolution enables us to identify single particles throughout the whole process and to map out their trajectories sampling the energy landscape. Furthermore, oriented attachment of different nanoparticle lattice domains is observed, where fast translational and rotational diffusions of the domains drive the neck formation. The single-particle analysis aids correlating order evolution to differently ranged interactions. Such crystallization behavior is distinct from that of micron-sized colloids, resembling more the faceted crystals formed from atoms. Our study provides new dynamic information on the superlattice development at high spatial and temporal resolution, which can serve as a general guideline for bottom-up material design.

5:35 PM S.CT08.01.04
Unraveling Nonclassical Crystallization Pathways of Nanoparticle Superlattices via In Situ TEM Imaging Zihao Ou and Qian Chen; University of Illinois at Urbana-Champaign, United States

Nucleation and growth are universally important in systems from the atomic to the micrometer scale as they dictate structural and functional attributes of crystals. However, at the nanoscale, the pathways toward crystallization have been largely unexplored owing to the challenge of resolving the motion of individual building blocks in a liquid medium. Here we address this gap by directly imaging the full transition of dispersed nanoparticles to a superlattice at the single-particle level. We utilize liquid-phase transmission electron microscopy at low dose rates to control nanoparticle interactions without affecting their motions. Combining particle tracking with Monte Carlo simulations, we reveal that positional ordering of the superlattice emerges from orientational disorder. Otherwise elusive parameters including line tension and phase coordinates are measured, charting the nonclassical nucleation pathway involving a dense, amorphous intermediate. We elucidate the origin of this two-step crystallization by experimentally measuring the energy barrier for nucleation, which is lower in the presence of the amorphous precursor. We demonstrate the versatility of our approach via crystallization of different nanoparticles, pointing the way to more general applications. Our real space nanoscopic imaging platform not only offers new understanding on the crystallization kinetics, but also opens opportunities to other nanoscale fluctuating systems, from biofouling, lubrication, melting, phonon transport, to dendrite formation.
Hypoxia-Induced Biosynthesis of Gold Nanoparticles in the Living Brain  
Elena A. Rozhkova¹, Byeongdu Lee¹, Judy A. Prasad², Yuzi Liu¹ and Elena Shevchenko¹; ¹Argonne National Laboratory, United States; ²The University of Chicago, United States

Biosynthesis of NPs is a striking phenomenon in nature. Inspiring examples include storage and transport of iron atoms in a non-toxic form of a ferric oxyhydroxide cluster in the ferritin protein cage, using metal salts as terminal sinks in electron transfer pathways and formation of metal particles by bacteria, and biomineralization of magnetite nanocrystals in specific organelle magnetosome that enables coordinated movement of magnetotactic bacteria. Under certain experimental conditions, metal complexes and nanoclusters can be obtained in mammalian cells or in a whole animal, mainly for use in imaging. However, the mechanisms of this biosynthesis are often spontaneous, poorly understood and, therefore, difficult to control. In our approach, a pathological process, namely hypoxia of the brain accompanied by changes in the NADH/NAD⁺ co-enzymes ratio, initiates and controls the biosynthesis of biocompatible Au nanoparticles from precursor salts in the immediate vicinity of the hypoxia site, thereby restoring the redox status of the brain.

Supercluster-Coupled Crystal Growth in Metallic Glass Forming Liquids  
Yujun Xie¹,², Jan Schroers¹ and Judy Cha¹,²; ¹Yale University, United States; ²Yale West Campus, United States

Crystallization induced microstructure plays a central role in tailoring materials properties, yet our understanding of its formation process is limited due to its complexity. Classical crystallization theories assume that nucleation and growth are separate processes and growth ought to be temperature-dependent only. Local thermodynamically unstable clusters are considered to fluctuate in the nucleation stage but do not participate in the later growth. Here, we apply in-situ transmission electron microscope (TEM) to nanostructured metallic glasses (MGs) and directly probe crystallization kinetics at the unprecedented time and spatial resolution¹, ², ³, ⁴. In particular, the growth kinetics of single crystalline Pt57.5Cu14.6Ni5.3P22.5 MG nanorods were studied in situ by observing isothermal crystallization at the atomic level. We found that the crystal growth rates of heated metallic glass are much higher than those of cooled metallic liquid despite the same isothermal crystallization temperature. The observation is in direct contrast to one would expect from classical growth models. We, therefore, propose a supercluster-coupled growth model and hypothesize that structural ordering can strongly enhance the crystal growth. The asymmetric growth upon heating is thus attributed to the higher degree of structural ordering and a greater number of clusters in the MGs nanorods. The structure-coupled growth is further supported by manipulating the density of the small clusters through nanoscale confinement and thermal treatment of the MG nanorods. In addition, molecular dynamics simulations of binary Lennard-Jones glasses quenched at different cooling rates show a growth rate trend that agrees with experimental observations. The present results demonstrate the inadequacy of the classical crystallization model on modern complex materials systems.

**Interfacial Structure, Interparticle Forces and Assembly Dynamics During Crystal Growth by Oriented Attachment**

James J. De Yoreo1,2, Lili Liu1, Guomin Zhu1, Xin Zhang1, Dongsheng Li1, Sebastien Kerisit1, Maria Sushko1, Jaehun Chun1, Elias Nakouzi1, Chongmin N. Wang1, Gregory Schenter1, Kevin Rosso1 and Chris Mundy1; 1Pacific Northwest National Laboratory, United States; 2University of Washington, United States

Crystallization by assembly of primary nanocrystals is a widespread phenomenon in synthetic and natural environments. In mineral systems, this process exhibits diverse styles ranging from oriented attachment of like phases to mis-oriented aggregation of disparate phases followed by coarsening to single crystals. While descriptions of these systems must share a commonality with continuum-based DLVO-type theories for simple colloids, mineral systems present additional complexities, including face-specificity of dielectric properties, inherent diopolar interactions, structured nanoscale interfaces, and solvent-responses of a length scale comparable to particle size. To understand the relationship between nanocrystal structure, interparticle forces and assembly dynamics, we are investigating colloidal assembly of titanium, iron and zinc oxides. For ZnO, in situ TEM demonstrates that direction-specific forces align diffusing particles at distances far in excess of what is expected based on DLVO theory. Particles approach one another in a diffusion limited regime and then attach lattice matched via a sudden jump to contact unopposed by any significant energy barrier. Direct AFM-based measurements of the forces between both TiO2 and ZnO surfaces reveal orientation dependent attractive interactions exhibiting the symmetry of the underlying lattice. MD simulations for both systems predict that solvation forces are responsible for the orientation dependence, creating solvent separated minima and barriers to contact. However, classical density functional theory applied to ZnO predicts that ion correlation forces lead to generally attractive interactions with little or no barrier, enabling random attachment, which is not observed. The long range nature of the forces and torques in the ZnO system are shown to be a consequence of the inherent dipole moments of ZnO particles and it is these dipole-dipole interactions that enforce alignment even in the absence of solvation-defined orientation dependent forces. Addition of organic ligands, like oxalate, to the FeOOH system produces a dramatically different pathway and outcome: Nanoparticles of Fe2O3 nucleate sporadically from the FeOOH and, once formed, are covered with oxalate, which drives all new Fe2O3 particles to nucleate within about 1 nm of the interface, after which they jump to contact. The oxalate inhibits growth and coarsening of the particles, leading to spindle-shaped aggregates of coaligned particles with a fixed and constant aspect ratio. Thus the random assembly process seen in the pure FeOOH system is replaced with one that is deterministic.

**Reaction Pathway and Assembly of Pt Nanostructures Revealed with Low-Dose In Situ Microscopy**

Wenpei Gao, Peter Tieu, Christopher Addiego and Xiaoqing Pan; University of California, Irvine, United States

The progress of energy and electronic industry relies on the design and engineering of new nanostructures with fine control in the atomic scale. Examples include the use of twisted two-dimensional materials for the tuning of electronic structure, the surface engineering to create surface steps in metal nanowires that show enhanced catalytic activity. Manipulation of the nanostructures with more precise control requires the understanding of how atoms interplay with various stimuli, which must be characterized by advanced imaging tools that can not only reveal the materials behavior during growth and use, but also provides insights on the change of composition and bonding. Recent development of aberration-corrected transmission electron microscopy (TEM) or scanning transmission electron microscopy (STEM) allows the combination of low-dose imaging with in situ methods to study the materials dynamics at high spatial resolution, when coupled with high-speed direct electron detectors, the electric potential and field that can influence the materials interaction can also be imaged. Here we first demonstrate the atomic resolution imaging of a Pt precursor compound and the dynamics of its transformation to Pt nanoclusters.[1] Specifically, under an ultra-low electron dose, the atomic structure of pristine K3PtCl4 crystallite is resolved in the image captured by the CMOS-based direct electron detector. With further electron beam irradiation, the dynamics of staged reduction of Pt compound and nucleation of Pt cluster are captured and identified. Results show that the ionic bond between K+ and PtCl62− is first broken, which is followed by PtCl62− forming PtCl4−; reduction of the dual-valent Pt then leads to the formation of Pt clusters. The solid-state transition is deciphered in real time and real space. Later, using a gas cell, we show that the sintering process of Pt clusters can be modified by gas adsorbates:[2] in H2, the Pt nuclei approach and attach to each other only along specific orientations, and gradually form short nanowires. In ex situ experiment, we successfully synthesized extended long Pt and PtNi nanowires in solid state assisted by H2. Compared to the Pt-based NWs grown by other methods, our catalysts showed both enhanced mass specific activity and stability in ORR. We will also show our four-dimensional STEM study at the interface of complex oxides that reveals the penetration of electric field from the ferroelectric BiFeO3 into the insulating SrTiO3,[3] and discuss how advanced electron microscopy can further our study of nanostructures.

Multi-Step Crystallization of Self-Organized Spiral Eutectics

Saman Moniri and Ashwin J. Shahani; University of Michigan, United States

A novel method for the solidification of metallic alloys involving spiral self-organization is presented as a new strategy for producing large-area chiral patterns with emergent structural and optical properties, with attention to the underlying mechanism and dynamics. This study reports the discovery of a new growth mode for metastable, two-phase spiral patterns from a liquid metal. Crystallization proceeds via a non-classical, two-step pathway consisting of the initial formation of a polytetrahedral seed crystal, followed by ordering of two solid phases that nucleate heterogeneously on the seed and grow in a strongly coupled fashion. Crystallographic defects within the seed provide a template for spiral self-organization. These observations demonstrate the ubiquity of defect-mediated growth in multi-phase materials and establish a pathway towards bottom-up synthesis of chiral materials with an inter-phase spacing comparable to the wavelength of infrared light. Given that liquids often possess polytetrahedral short-range order, our results are applicable to many systems undergoing multi-step crystallization.

Temperature Induced Strain Relaxation in Epitaxially Connected Quantum Dot Superlattices Probed by In Situ STEM

Michelle A. Smeaton, Daniel M. Balazs, Tobias Hanrath and Lena F. Kourkoutis; Cornell University, United States

The self-assembly of quantum dots (QDs) into epitaxially connected superlattices called quantum dot solids (QDSs), made possible by a growing library of synthesis methods for precisely controllable QD building blocks, represents exciting opportunities for advancing optoelectronic devices and realizing exotic electronic phenomena. However, the myriad complex interactions at play during the assembly and oriented attachment processes lead to imperfections in epitaxial connections between QDs. Such imperfections affect electronic coupling between QDs and lead to local translational disorder, which propagates through the film and hinders tunable miniband formation. Heating QDSs is a promising method for annealing out defects, thus improving electronic properties. Understanding the nuanced effects on epitaxial connections, however, requires visualization of atomic-scale structure over large enough fields of view to access a statistically meaningful number of QDs. Here, we use in situ MEMS heating in combination with aberration-corrected HAADF-STEM and image analysis to assess the effects of heating on epitaxial connections in QDSs over extended fields of view. We analyze PbS QDs self-assembled into square SLs and epitaxially connected along the <100> directions. Localized heating provided by the MEMS device maintains stage stability such that a region of interest can be tracked throughout a heating cycle and images can be acquired at atomic-resolution over ~100 nm. We identify four distinct strain states in epitaxial connections: tension, shear, bending and torsion, noting that they appear concurrently in some cases. Using a local sine wave fitting technique similar to the phase lock-in method, we visualize the tension, shear and bending strain states. Given the limitation of STEM to projection imaging, torsion is investigated indirectly by identifying the out-of-plane orientation of each QD, nearest neighbor mismatches in which indicate torsion and out-of-plane bending strain states between connected QDs. The orientation data, in combination with wave fitting analysis, reveal that mild annealing between 150 and 200°C causes dramatic relaxation of tensile, shear and torsional strains, while bending strain is more persistent. These results give insight into the energetics of the types of defects present in epitaxial connections and represent a path toward improved carrier delocalization and miniband formation.

Real Time Imaging of the 3D-2D Transformations of Nanocrystals through Liquid Cell Transmission Electron Microscopy

Haimei Zheng1,2; 1Lawrence Berkeley National Laboratory, United States; 2University of California, Berkeley, United States

In recent years, significant achievements have been made in the synthesis of various colloidal nanostructures. The anisotropic nanostructures, such as nanowires or two-dimensional (2D) materials have attracted a lot of attention due to their unique properties. However, their formation mechanisms have not been fully understood. They seem to be contradictory to the
predictions based on the conventional crystal growth theories. And, it adds to the complexity that nanocrystals often change structure and morphology during growth. We explore the growth mechanisms of anisotropic nanocrystals using in situ liquid cell transmission electron microscopy (TEM). In this talk, I will show the growth of 2D transition metal oxide nanosheets, e.g. cobalt oxide and cobalt nickel oxide. The 2D nanosheets have been achieved in a liquid cell, which resemble those synthesized in flasks. Our direct observations reveal that 3D nanoparticles are initially formed from the molecular precursor solution and then transform into 2D nanosheets. Ab initio calculations show that a small nanocrystal is dominated by positive edge energy, but when it grows to a certain size, the negative surface energy becomes dominant, driving the transformation of the 3D nanocrystal into a 2D structure. Uncovering these growth pathways, including the 3D-to-2D transition, provides opportunities for the future design and solution synthesis of novel materials.

Gypsum—Anhydrite Phase Transformation and Crystal Growth Induced by Microorganisms Living in the Atacama Desert
Wei Huang1, Emine Ertekin2, Taifeng Wang1, Luz Cruz1, Jocelyne DiRuggiero2 and David Kisailus1; 1University of California, Riverside, United States; 2Johns Hopkins University, United States

Microorganisms have been found living in one of the driest and oldest deserts on the earth, the Atacama Desert in Chile. In this hyper-arid environment, microbial communities colonize the interior of rocks and obtaining water is critical for their survival. Gypsum (CaSO4●2H2O) is one of the main components in rocks from the Atacama Desert and is a main source of water for these communities, which are mainly constituted of cyanobacteria and heterotrophic bacteria. We report that these microorganisms extract crystalline water from the gypsum rock, inducing a phase transformation from gypsum (CaSO4●2H2O) to anhydrite (CaSO4). Cyanobacteria cultures were inoculated on gypsum rock samples to investigate and validate the water extraction and phase transformation mechanisms found in the geological environment. It is shown that cyanobacteria attach on high surface energy crystal planes and generate a thin biofilm on the gypsum samples. Due to the acidic nature of the biofilm, gypsum dissolution is observed, accompanied with water extraction and subsequent transformation to anhydrite via reprecipitation and oriented attachment of mesocrystals. This is the first time showing gypsum – anhydrite phase transformation and non-classical crystal growth induced by microorganisms. The results in the present work not only shed light on how these organisms survive in such extreme environments, but also can provide insight into potential life in xeric environments such as Mars as well as offer strategies for advanced water storage methods.

Engineering of Chiral Inorganic Nanostructures
Nicholas A. Kotov; University of Michigan, United States

The early observation of strong circular dichroism for individual nanoparticles and their assemblies have developed into a rapidly expanding field of chiral inorganic nanostructures. The chiral inorganic nanostructures encompass sophisticated constructs from metals, semiconductors, ceramics, and nanocarbons with multiple chiral geometries with characteristic scales from Ångströms to microns. Such versatility enables their functional engineering over a broad range of physical and chemical properties but the relationship between the chirality of surface ligands, NP cores, and resulting assemblies remains obscure. Similarly, the relationship between their chiral geometries and their chiroptical properties. This talk will address (1) the origin of the uniquely high values of optical anisotropy; (2) the mechanisms of chirality transfer in inorganic materials; and (3) differences/similarities with chiral supramolecular, liquid crystal, and biological assemblies. Long-range correlations and critical phenomena in chiral nanoassemblies leading to the emergence of geometrically complex structures will be demonstrated. The novel venues for practical realizations of chiral nanoassemblies included in the talk will be photocatalytic C-C coupling in biomimetic chiral supraparticles and polarization spectroscopy in terahertz (THz) spectral window with chiroplasmonic kirigami composites.

Cluster-Coupled Crystallization of Metallic Glasses at the Nanoscale
Judy Cha; Yale University, United States

Common growth models assume a structure-less liquid composed of atomic flow units and describe crystal growth as a phenomenon of transferring atoms at the interface between a growing solid and a structure-less liquid. However, for liquid metals and polymers, structural ordering has been shown, raising the possibility of structure-coupled crystal growth. By performing in situ transmission electron microscopy (TEM) crystallization experiments on Pt-based metallic glass nanorods, we show that local structural order of the glass strongly affects crystal growth, in contrast to assumptions from conventional growth models [1].

Metallic glasses serve as a good model system to study crystallization due to their non-directional metallic bonds, relatively slow crystallization kinetics, and moderate crystallization temperatures, which readily allow direct visualization of crystallization events at the atomic scale via in situ TEM experiments. At the nanoscale, we have observed crystallization phenomena that deviate greatly from the macroscopic behaviors due to the geometrical confinement effects. These include suppression of crystallization for very small metallic glass nanorods [2], emergence of a metastable, single crystalline phase out of multi-component metals [3], and the structure-coupled crystallization [1]. The structure-coupled crystallization was inferred from the asymmetric growth rates of a heated metallic glass versus a cooled metallic liquid. We demonstrate that thermodynamically unstable structural ordering in the glass state can be kinetically stable enough to enhance crystal growth during crystallization. Thus our works highlight crystallization via non-classical pathways.

The Diverse and Complex Nonclassical Pathways of Nanoporous Aluminosilicate Crystallization
Jeffrey D. Rimer; University of Houston, United States

The unique properties of nanoporous aluminosilicates (zeolites) are exploited in a variety of applications spanning from ion exchange and separations to catalysis and drug delivery. The ability to selectively control zeolite synthesis to achieve desired physicochemical properties relies upon detailed understandings of the thermodynamic and kinetic factors regulating crystal nucleation and growth, which are generally lacking. Designing innovative approaches to tailor zeolite crystallization and elucidate structure-performance relationships has the potential to produce materials with superior properties beyond what is achievable by conventional routes. In this talk, I will discuss efforts to characterize the complex mechanisms of zeolite crystallization, which occur by nonclassical pathways involving the self-assembly and structural evolution of amorphous precursors. There is still much that we do not understand regarding the role of precursors in nucleation and the influence of growth conditions on the selection of crystal topology, which underscores the need for molecular-level studies of zeolite
crystallization. Our group addresses these challenges using a broad range of techniques that include the use solvothermal atomic force microscopy to capture time-resolved images of growing zeolite surfaces in real time. This technique has led to the first in situ characterization of zeolite growth with the capability of resolving surface dynamics at the spatiotemporal scales necessary to elucidate mechanistic pathways of crystallization. Based on our findings, we observe that growth occurs via multiple (cooperative) pathways that differ from one material to the next. In this talk, we will summarize our findings for several zeolite structures.

Slow-Injection Synthesis of Indium Phospide Quantum Dots as a Route to Large Size and Low Size Disparsity Odin B. Achorn and Moungi G. Bawendi; Massachusetts Institute of Technology, United States

The color purity of indium phosphide (InP) quantum dots (QDs) lags behind that of cadmium selenide (CdSe) QDs, especially at their largest sizes and reddest wavelengths. In order to improve the quality of InP QDs, we have developed a new synthetic method that features a slow precursor injection rate in contrast to the rapid injection rates that have worked so well for CdSe QD syntheses and that have traditionally been applied to InP. The absorption features of the InP QD batches produced by our method are redder than those of batches of comparably-disperse InP QDs and narrower than those of batches of comparably-sized InP QDs that are produced by other methods. We prepared InP QDs with first excitonic absorption peaks that are redder than 630 nm and have half widths at half maximum less than 85 meV. After adding a zinc selenide shell, we achieved core/shell QDs that are redshifted slightly with respect to the core and have photoluminescence full widths at half maximum under 55 nm. Our method also allows us to synthesize even larger InP cores with defined first excitonic absorption peaks that are redder than 660 nm. We used MALDI mass spectrometry to characterize the size and size dispersity of the QDs and to investigate the presence of low molecular weight clusters and secondary populations. Lastly, we find that the concentration of QDs increases throughout the entire course of the reaction, and we propose a nucleation and growth model to explain our observations.

Non-Centrosymmetric Metal Tetrel-Pnictides—Synthesis, Structure and Properties Georgiy Akopov1,2, Juyeon Won2, Justin Mark2,1 and Kovnir Kirill2,1; 1Ames Lab, United States; 2Iowa State University of Science and Technology, United States

A scarcely investigated class of compounds, tetrel-pnictides of rare-earth and transition metals, R(M)-T-Pn (M = transition metal; T = Si, Ge; Pn = P, As), possess complex structural chemistry and potentially interesting properties. By combining rare-earth and transition metals, new quaternary tetrel-pnictide phases (R-M-T-Pn), both doping phases and new structural types, can be formed. The synthesis of these compounds is a challenge and it prompted us to look for new approach. Due to the volatility of phosphorus and arsenic, it is not possible to directly melt the reactants without strong depleting of sample with pnictogen due to evaporation. Target phases decompose peritectically below 1000°C, below this temperature Si and Ge are inert. Multicomponent nature of the target phase prevents effective use of molten flux reactions due to different solubility

2020 MRS Virtual Spring/Fall Meeting, November 27-December 4, 2020, Spring Abstracts Final Program 2/3/21
and dissolution rates of constituent components, Pn>R>M>>T. Gas transport reactions also appeared to be ineffective for quaternary systems. As such, a synthesis using pre-reacted \{R, M, and T\} quasi- or true ternary compositions with phosphorus or arsenic becomes very appealing. Although R-M-T binaries and ternaries typically have melting points above 1000°C, our in-situ X-ray diffraction studies show that they are reactive in the presence of a pnictogen-rich atmosphere at temperatures as low as 650°C, thereby forming desired tetrel-pnictide compounds. Therefore, careful optimization of the starting reactant ratios can yield phase-pure single-phase compounds, where excess P and As can be sublimed away from the phase of interest. Furthermore, this method can generate single crystals for structural characterization due to the P and As acting as transport agents in addition to being reactants. The structural chemistry, polymorphism, and properties of the family of \{R,T\}-Si-Pn compounds will be discussed.

Non-Classical Crystallization of Thin Films and Nanostructures in the Chemical Vapor Deposition Process

Nong-Moon Hwang; Seoul National University, Korea (the Republic of)

Although non-classical crystallization has been studied extensively in the solution growth, not much attention has been paid to the non-classical crystallization in the gas phase synthesis of thin films and nanostructures by chemical vapor deposition (CVD). Extensive studies were made in CVD processes and the non-classical crystallization was shown to be a general growth mechanism of thin films and nanostructures [1], where the charged nanoparticles become the building block. Generation of charged nanoparticles was confirmed in most CVD processes, including the growth of films and nanostructures of diamond, carbon nanotubes, ZrO2, Si, ZnO and GaN. Small charged nanoparticles are favorable for epitaxial growth whereas large ones are favorable for nanostructure growth.

Understanding made from the non-classical crystallization behaviour in the CVD process can provide the valuable information as to the non-classical crystallization in solution. For example, building block of nanoparticles are electrically charged in the CVD process and the presence of charge plays a critical role in the growth of thin films and nanostructures. The charge is responsible for not only self-assembly but also liquid-like coalescence, which result in the evolution of dense films and nanostructures. The role of charge could be clearly revealed by comparing the deposition behavior of silicon charged nanoparticles between electrically floating and grounded silicon substrates. Single crystalline silicon nanowires grew on the floating substrate whereas nanoparticles grew on the grounded substrate. In other processing conditions, a dense silicon film grew on the floating substrate whereas a porous silicon film grew on the grounded substrate.

The fact that charged nanoparticles can be a building block of films and nanowires without leaving any void behind indicates that charged nanoparticles are quasi-solid, having a liquid-like property in diffusion. This means that the charge enhances the atomic diffusion, which is a newly discovered physical phenomenon. The charge-enhanced kinetics could be analyzed by comparing the behavior of Au nanoparticles on conducting and insulating membranes during transmission electron microscopy (TEM) observation. Au nanoparticles on insulating membranes were actively changing their orientation during TEM observation whereas those on conducting membranes were not. Also plasma dewetting behavior of sputtered Sn films was compared between grounded and floating conditions. The dewetting kinetics of Sn films in the floating condition was much higher than that in the grounded condition. Both experimental results support charge-enhanced kinetics.

In this presentation, some important aspects of the non-classical crystallization in the CVD process would be introduced, emphasizing that the non-classical crystallization occurs not only in solution but also in the gas phase synthesis.

11:21 AM *S.CT08.03.01
How Solution-Phase Additives Control the Shapes of Metal Nanocrystals in Solution

Kristen A. Fichthorn; The Pennsylvania State University, United States

Metal nanocrystals have gained tremendous attention due to their superior performance in various applications, ranging from selective catalysis to electronic devices to plasmonic applications, such as photovoltaics and sensing. The properties of nanocrystals are highly sensitive to their size and shape. To this end, solution-phase synthetic protocols have been highly successful at producing a variety of nanocrystal structures. However, great challenges remain in achieving high selectivity to particular nanostructures. A significant difficulty lies in understanding and controlling shape evolution in these systems.

A common adage is that solution-phase additives, such as capping molecules, can direct the shapes of colloidal nanocrystals by adsorbing selectively to certain facets. Though our first-principles-based studies indicate that capping molecules alone can
direct the formation of nanocrystal shapes in certain systems, experiments demonstrate that more robust syntheses can be achieved in the co-presence of halide additives. We use DFT-based ab initio thermodynamics calculations to probe the influence of chloride on Ag nanoshapes. Consistent with experiment, these calculations indicate that chloride adsorption alone can lead to truncated Ag cubes. We find that adsorbed chlorine works synergistically with PVP, a common capping agent for Ag, to enhance the tendency for Ag cubes. We also demonstrate that adsorbed Cl works synergistically with HDA capping molecules to facilitate the growth of Cu nanowires via a kinetic pathway - consistent with experiment. These studies indicate that halides and capping molecules can be a powerful combination to create selective nanoshapes in solution-phase syntheses.

The Role of Carbon and SiC Crystallinities in the Oxidation and Mechanical Property Improvement of Hybrid Nano-Fibers Saja M. Al-ajrash; University of Dayton, United States

In this study, electrospinning was successfully used to fabricate hybrid Carbon-Silicon Carbide (C-SiC) fibers using polyacrylonitrile (PAN) and Silicon (Si) nanoparticles as precursors. Silicon-to-carbon precursor ratios and heat treatment were optimized to fabricate hybrid nano-fibers with high oxidation resistance. After heat treatment, the nano-fibers showed two-dimensional ordered carbons and SiC nano-phases formation. As a result, a noticeable improvement in mechanical and thermal properties was achieved. Samples with 90wt% PAN/10wt% Si showed about four-time improvements in char yield as compared with 100 wt % PAN. In addition, after the heat treatment of the fiber at 1250 °C, SiC was formed. The carbon and SiC crystallinities had a great impact on the oxidation and mechanical property improvement of hybrid nanofibers. The determination of crystal size was carried out using X-ray results obtained at different temperatures and holding times. The SiC grain growth was predicted using kinetic models and its exponent was found to be around n = 4 with activation energy around 35 KJ/mol.K. For such growth, the dominant grain growth mechanism was grain boundary diffusion.

Fabrication of High-Performance Carbon Fibers Using Template Induced Crystallization Rahul Franklin, Weiheng Xu, Dharneedar Ravichandran and Kenan Song; Arizona State University, United States

Carbon fibers have broad applications in aerospace, automobiles, wind turbines, medical devices, and implants, among many others. Carbon fibers with high-end applications have previously been manufactured from precursor fibers of rayon, pitch, and polyacrylonitrile (PAN) fibers. New precursor fibers have been conventionally fabricated by homogenously mixing the reinforcement/nanofiller and polymer matrix mechanically and spinning the dope into a coagulation bath, such as PAN processing in the case of dry-jet wet spinning followed by the drawing stage and heat treatment at different temperatures. Mechanical properties of this fiber are dependent on the continuity, density and interfacial action of the hierarchical graphic structures. The presence of voids formed during crystallization due to the random dispersion of reinforcement/nanofiller in pre-carbon fibers (pCFs) deteriorates these properties.

In this project, a specialized templating graphene channel was developed via an in-house designed spinneret. This channel containing graphene and varied PAN solutions running along the axial direction of the fiber was parallel to the outer and inner PAN channels. On drawing the as-spun fibers the GNP was aligned in the axial direction. This channel then allowed for crystallization along the axial direction and minimizes the formation of voids leading to enhanced mechanical properties. The mechanical test showed the composite as-spun fiber with GNP templating channel has 18.5% and 51.4% increased Young’s modulus and tensile strength, respectively, as compared to the pure PAN fiber. The thermodynamics and kinetics of the heat-treatment procedures were analyzed to correlate the microstructure features and mechanical/thermal properties of obtained carbon fibers.

Liquid Phase TEM Study of 2D Indium Chloride Nanosheets Growth at Various Temperatures Junyi Shangguan¹², Xinxing Peng¹ and Haimei Zheng¹²; ¹Lawrence Berkeley National Laboratory, United States; ²University of California, Berkeley, United States

Two-dimensional (2D) materials have attracted significant attention due to their unique structure and fascinating properties. However, our understanding of their growth mechanisms in solution is still limited. Here, using indium chloride (InCl₃) as a model system, we performed liquid phase transmission electron microscopy (TEM) study of the 2D growth in situ. We combined the low temperature techniques with liquid phase TEM. The nucleation and growth of 2D nanosheets in solution via both classical and non-classical pathways were observed with the atomic resolution in real time at room temperature as well as low temperature (e.g. 1-2 °C). We found the drastically decreased growth kinetics at the low temperature compared to that at the room temperature. Observation also showed that the fast growth induced the high density of crystal defects (e.g.,
Comparatively, perfect 2D nanocrystals were obtained through the low temperature growth. In addition, we did the atomic structural analysis of the nanosheets and chemical mapping of the reaction front at the Cryogenic temperature using the same liquid cell sample. The results revealed the growth mechanisms of InCl₃ 2D nanosheets and the formation of nanotwins in solution. And, the liquid phase TEM with variable temperature control opens many opportunities for future depth study of nanoscale materials growth and transformations.

Leveraging Pourbaix Diagrams for Design and Understanding of Hydrothermal Synthesis

Lauren N. Walters, Chi Zhang, Vinayak Dravid, Kenneth R. Poeppelmeier and James M. Rondinelli; Northwestern University, United States

Synthesis design remains a paramount problem in materials science. Significant research has been dedicated to advancing tools to predict and aid in synthesis development. Here we describe an ab-initio approach to evaluate water-based synthesis processes such as hydrothermal synthesis. We show how to use electrochemical Pourbaix diagram, constructed from first principles density functional theory (DFT) calculations, to understand thermodynamic forces of complex Cu oxides and Cu oxychalcogenides in aqueous environments. We discuss how to construct these complex diagrams consisting of many degrees-of-freedom, including multiple elemental species, compounds, and complexes as well as nonstandard state conditions. We describe how the driving forces for the products evolve with changes in pH, oxidation state, and the activity of reactants; this understanding is then used to justify successful experimental synthesis of the targeted phase. Scale dependent nucleation is also examined. Last, we propose Pourbaix diagrams are a useful synthesis-processing design tool for accelerated discovery.

12:00 PM CLOSING COMMENTS
and coarsening of the particles, leading to spindle-shaped aggregates of coaligned particles with a fixed and constant aspect ratio. Thus the random assembly process seen in the pure FeOOH system is replaced with one that is deterministic.

Direct Imaging of Nucleation and Growth of Colloidal Nanoparticle Superlattices Qian Chen; University of Illinois at Urbana-Champaign, United States

We use liquid-phase transmission electron microscopy to directly image a series of crystallization pathways of colloidal nanoparticles into superlattices. We find that there exist similarities to the prevalent model system of micron-sized colloids, such as a non-classical two-step crystallization pathway, where amorphous intermediates in the form of nanoparticle clusters exist preceding the nucleation. Capillary wave theory can be used to describe the fluctuation and energy of the surfaces. But there are also differences, in particular, a universal layer-by-layer growth mode that we observe consistently for diverse nanoparticle shapes. Single particle tracking, trajectory analysis, and simulations combined unravel the energetic and kinetic features rendering this crystal growth mode possible and universal at the unexplored nanoscale, enabling advanced crystal engineering.

6:00 AM S.CT08.01.03
Direct Imaging of Atom-Mimicking Oriented Attachment of Nanoparticle Superlattices by Liquid-Phase TEM Chang Liu and Qian Chen; University of Illinois at Urbana-Champaign, United States

We utilize nanoparticle superlattice as a model system to study the fundamental laws of order emergence and evolution from a dispersion of nanosized entities. Liquid-phase TEM makes it possible to directly conduct single-particle level imaging in real time and real space, to reveal pathways of nanoparticle crystallization. To be specific, we observe how different types of diffusion events (e.g., surface and volume diffusion) involved in the layer-by-layer growth of a nanoparticle superlattice, where the high spatiotemporal resolution enables us to identify single particles throughout the whole process and to map out their trajectories sampling the energy landscape. Furthermore, oriented attachment of different nanoparticle lattice domains is observed, where fast translational and rotational diffusions of the domains drive the neck formation. The single-particle analysis aids correlating order evolution to differently ranged interactions. Such crystallization behavior is distinct from that of micron-sized colloids, resembling more the faceted crystals formed from atoms. Our study provides new dynamic information on the superlattice development at high spatial and temporal resolution, which can serve as a general guideline for bottom-up material design.

6:15 AM S.CT08.01.04
Unraveling Nonclassical Crystallization Pathways of Nanoparticle Superlattices via In Situ TEM Imaging Zihao Ou and Qian Chen; University of Illinois at Urbana-Champaign, United States

Nucleation and growth are universally important in systems from the atomic to the micrometer scale as they dictate structural and functional attributes of crystals. However, at the nanoscale, the pathways toward crystallization have been largely unexplored owing to the challenge of resolving the motion of individual building blocks in a liquid medium. Here we address this gap by directly imaging the full transition of dispersed nanoparticles to a superlattice at the single-particle level. We utilize liquid-phase transmission electron microscopy at low dose rates to control nanoparticle interactions without affecting their motions. Combining particle tracking with Monte Carlo simulations, we reveal that positional ordering of the superlattice emerges from orientational disorder. Otherwise elusive parameters including line tension and phase coordinates are measured, charting the nonclassical nucleation pathway involving a dense, amorphous intermediate. We elucidate the origin of this two-step crystallization by experimentally measuring the energy barrier for nucleation, which is lower in the presence of the amorphous precursor. We demonstrate the versatility of our approach via crystallization of different nanoparticles, pointing the way to more general applications. Our real space nanoscopic imaging platform not only offers new understanding on the crystallization kinetics, but also opens opportunities to other nanoscale fluctuating systems, from biofouling, lubrication, melting, phonon transport, to dendrite formation.

Temperature Induced Strain Relaxation in Epitaxially Connected Quantum Dot Superlattices Probed by In Situ STEM Michelle A. Smeaton, Daniel M. Balazs, Tobias Hanrath and Lena F. Kourkoutis; Cornell University, United States

2020 MRS Virtual Spring/Fall Meeting, November 27-December 4, 2020, Spring Abstracts Final Program 2/3/21
The self-assembly of quantum dots (QDs) into epitaxially connected superlattices called quantum dot solids (QDSs), made possible by a growing library of synthesis methods for precisely controllable QD building blocks, represents exciting opportunities for advancing optoelectronic devices and realizing exotic electronic phenomena. However, the myriad complex interactions at play during the assembly and oriented attachment processes lead to imperfections in epitaxial connections between QDs. Such imperfections affect electronic coupling between QDs and lead to local translational disorder, which propagates through the film and hinders tunable miniband formation. Heating QDSs is a promising method for annealing out defects, thus improving electronic properties. Understanding the nuanced effects on epitaxial connections, however, requires visualization of atomic-scale structure over large enough fields of view to access a statistically meaningful number of QDs.

Here, we use in situ MEMS heating in combination with aberration-corrected HAADF-STEM and image analysis to assess the effects of heating on epitaxial connections in QDSs over extended fields of view. We analyze PbS QDs self-assembled into square SLs and epitaxially connected along the <100> directions. Localized heating provided by the MEMS device maintains stage stability such that a region of interest can be tracked throughout a heating cycle and images can be acquired at atomic-resolution over ~100 nm. We identify four distinct strain states in epitaxial connections: tension, shear, bending and torsion, noting that they appear concurrently in some cases. Using a local sine wave fitting technique similar to the phase lock-in method, we visualize the tension, shear and bending strain states. Given the limitation of STEM to projection imaging, torsion is investigated indirectly by identifying the out-of-plane orientation of each QD, nearest neighbor mismatches in which indicate torsion and out-of-plane bending strain states between connected QDs. The orientation data, in combination with wave fitting analysis, reveal that mild annealing between 150 and 200°C causes dramatic relaxation of tensile, shear and torsional strains, while bending strain is more persistent. These results give insight into the energetics of the types of defects present in epitaxial connections and represent a path toward improved carrier delocalization and miniband formation.

Synthesis, Phase Transformation and Structural Development in Magnetic Biocomposites Taifeng Wang1, Anna Pohl1, Steven Herrera1, Yuka Narahara2, Michiko Nemoto2 and David Kisailus3; 1University of California, Riverside, United States; 2Okayama University, Japan

There is an increasing need for the development of multifunctional lightweight materials with high strength and toughness. Natural systems have evolved efficient strategies, exemplified in the biological tissues of numerous animal and plant species, to synthesize and construct composites from a limited selection of available starting materials that often exhibit exceptional mechanical properties that are similar, and frequently superior to, mechanical properties exhibited by many engineering materials. These biological systems have accomplished this feat by establishing controlled synthesis and hierarchical assembly of nano- to micro-scaled building blocks. This controlled synthesis and assembly require organic that is used to transport mineral precursors to organic scaffolds, which not only precisely guide the formation and phase development of minerals, but also significantly improve the mechanical performance of otherwise brittle materials.

Here, we investigate an organism that have taken advantage of hundreds of millions of years of evolutionary changes to derive structures, which are not only strong and tough, but also demonstrate abrasion resistance. All of this is controlled by the underlying organic-inorganic components. Specifically, we discuss the formation of heavily crystallized radular teeth the chitons, a group of elongated mollusks that graze on hard substrates for algae.

Our investigation of the formation of a fully mature radular tooth from Cryptochiton stelleri found in the eastern Pacific, occurs over a series of more than 40 teeth. The initial stage of tooth formation begins with the synthesis of a three-dimensional fibrous α-chitin organic matrix, prior to the onset of crystallization. Microscope analysis of early stage teeth shows ferrihydrite mineral particles growing on α-chitin fibers. Synchrotron x-ray, combined with TEM analyses show that ferrihydrite exists as randomly oriented aggregates, but undergoes a phase transformation to magnetite within a few rows of teeth. We discuss potential mechanisms of nucleation of ferrihydrite, its transformation to magnetite as well as its subsequent mesoscale ordering, crystal growth and the resulting mechanical properties. From the investigation of synthesis-structure-property relationships in these unique organisms, we are now developing and fabricating multifunctional engineering materials for energy and water purification based applications.

7:15 AM S.CT08.01.08
Multi-Step Crystallization of Self-Organized Spiral Eutectics Saman Moniri and Ashwin J. Shahani; University of Michigan, United States

A novel method for the solidification of metallic alloys involving spiral self-organization is presented as a new strategy for
producing large-area chiral patterns with emergent structural and optical properties, with attention to the underlying mechanism and dynamics. This study reports the discovery of a new growth mode for metastable, two-phase spiral patterns from a liquid metal. Crystallization proceeds via a non-classical, two-step pathway consisting of the initial formation of a polytetrahedral seed crystal, followed by ordering of two solid phases that nucleate heterogeneously on the seed and grow in a strongly coupled fashion. Crystallographic defects within the seed provide a template for spiral self-organization. These observations demonstrate the ubiquity of defect-mediated growth in multi-phase materials and establish a pathway towards bottom-up synthesis of chiral materials with an inter-phase spacing comparable to the wavelength of infrared light. Given that liquids often possess polytetrahedral short-range order, our results are applicable to many systems undergoing multi-step crystallization.

7:30 AM S.CT08.01.09
Supercluster-Coupled Crystal Growth in Metallic Glass Forming Liquids Yujun Xie1,2, Jan Schroers1 and Judy Cha1,2; 1Yale University, United States; 2Yale West Campus, United States

Crystallization induced microstructure plays a central role in tailoring materials properties, yet our understanding of its formation process is limited due to its complexity. Classical crystallization theories assume that nucleation and growth are separate processes and growth ought to be temperature-dependent only. Local thermodynamically unstable clusters are considered to fluctuate in the nucleation stage but do not participate in the later growth. Here, we apply in-situ transmission electron microscope (TEM) to nanostructured metallic glasses (MGs) and directly probe crystallization kinetics at the unprecedented time and spatial resolution1, 2, 3, 4. In particular, the growth kinetics of single crystalline Pt57.5Cu14.6Ni5.3P22.5 MG nanorods were studied in situ by observing isothermal crystallization at the atomic level. We found that the crystal growth rates of heated metallic glass are much higher than those of cooled metallic liquid despite the same isothermal crystallization temperature. The observation is in direct contrast to one would expect from classical growth models. We, therefore, propose a supercluster-coupled growth model and hypothesize that structural ordering can strongly enhance the crystal growth. The asymmetric growth upon heating is thus attributed to the higher degree of structural ordering and a greater number of clusters in the MGs nanorods. The structure-coupled growth is further supported by manipulating the density of the small clusters through nanoscale confinement and thermal treatment of the MG nanorods. In addition, molecular dynamics simulations of binary Lennard-Jones glasses quenched at different cooling rates show a growth rate trend that agrees with experimental observations. The present results demonstrate the inadequacy of the classical crystallization model on modern complex materials systems.

How Do Additives “Get the Job Done” During Nanoparticle-Mediated Crystallization? Alexander E. Van Driessche; CNRS - Univ. Grenoble-Alpes, France

Crystallization from solution follows either a single or a multistep pathway. The latter case involves the formation, aggregation and transformation of precursor/intermediate particles to the final crystalline phase. This has been observed for several important minerals, such as CaCO3, CaPO4, CaSO4 or CSH [e.g. 1-3], but also for macromolecular crystals [e.g. 4,5]. Moreover, this particle-mediated crystallization pathway can be “fossilized” in the structure of the final crystals [e.g. 6]. In the idealized laboratory environment pure solutions are often studied, but in real-world natural and engineered crystallization processes soluble additives, e.g. inorganic or organic molecules, are omnipresent. In fact, they frequently play a key role in the formation of crystalline phases and are a central part of biomineralization, functional material synthesis and
anti-scaling strategies [e.g. 7]. Traditionally, models of additive-controlled crystallization have considered a single step nucleation with additives adsorbing on the surface of nuclei, impeding their further growth. Hence, to advance our understanding and gain a better control of multistep crystallization processes, the interaction of additives with the precursors and/or intermediate particles needs to be unraveled.

To achieve this, we constructed a holistic nanoscopic view of a particle-mediated crystallization pathway in an additive free system [e.g. 5-8], based on in situ nanoscale observations. Subsequently, we conducted macroscopic and microscopic observations of additive-controlled crystal formation. Opposing the classical view, we found that the inhibition of nucleation can be ascribed to additives that hinder the formation of precursor species and/or their aggregation/transformation by prevailing in their vicinity and thereby reducing their interaction probability [e.g. 7, 10-11].

8:15 AM *S.CT08.01.11

Reaction Pathway and Assembly of Pt Nanostructures Revealed with Low-Dose In Situ Microscopy Wenpei Gao, Peter Tieu, Christopher Addiego and Xiaqing Pan; University of California, Irvine, United States

The progress of energy and electronic industry relies on the design and engineering of new nanostructures with fine control in the atomic scale. Examples include the use of twisted two-dimensional materials for the tuning of electronic structure, the surface engineering to create surface steps in metal nanowires that show enhanced catalytic activity. Manipulation of the nanostructures with more precise control requires the understanding of how atoms interplay with various stimuli, which must be characterized by advanced imaging tools that can not only reveal the materials behavior during growth and use, but also provides insights on the change of composition and bonding. Recent development of aberration-corrected transmission electron microscopy (TEM) or scanning transmission electron microscopy (STEM) allows the combination of low-dose imaging with in situ methods to study the materials dynamics at high spatial resolution, when coupled with high-speed direct electron detectors, the electric potential and field that can influence the materials interaction can also be imaged. Here we first demonstrate the atomic resolution imaging of a Pt precursor compound and the dynamics of its transformation to Pt nanoclusters. [1] Specifically, under an ultra-low electron dose, the atomic structure of pristine K2PtCl4 crystallite is resolved in the image captured by the CMOS-based direct electron detector. With further electron beam irradiation, the dynamics of staged reduction of Pt compound and nucleation of Pt cluster are captured and identified. Results show that the ionic bond between K+ and PtCl42- is first broken, which is followed by PtCl42- forming PtCl2; reduction of the dual-valent Pt then leads to the formation of Pt clusters. The solid-state transition is deciphered in real time and real space. Later, using a gas cell, we show that the sintering process of Pt clusters can be modified by gas adsorbates: [2] in H2, the Pt nuclei approach and attach to each other only along specific orientations, and gradually form short nanowires. In ex situ experiment, we successfully synthesized extended long Pt and PtNi nanowires in solid state assisted by H2. Compared to the Pt-based NWs grown by other methods, our catalysts showed both enhanced mass specific activity and stability in ORR. We will also show our four-dimensional STEM study at the interface of complex oxides that reveals the penetration of electric field from the ferroelectric BiFeO3 into the insulating SrTiO3,[3] and discuss how advanced electron microscopy can further our study of nanostructures.

Hypoxia-Induced Biosynthesis of Gold Nanoparticles in the Living Brain Elena A. Rozhkova1, Byeongdu Lee1, Judy A. Prasad2, Yuzi Liu1 and Elena Shevchenko1; 1Argonne National Laboratory, United States; 2The University of Chicago, United States

Biosynthesis of NPs is a striking phenomenon in nature. Inspiring examples include storage and transport of iron atoms in a

2020 MRS Virtual Spring/Fall Meeting, November 27-December 4, 2020, Spring Abstracts Final Program 2/3/21
non-toxic form of a ferric oxyhydroxide cluster in the ferritin protein cage, using metal salts as terminal sinks in electron transfer pathways and formation of metal particles by bacteria, and biomineralization of magnetite nanocrystals in specific organelle magnetosome that enables coordinated movement of magnetotactic bacteria. Under certain experimental conditions, metal complexes and nanoclusters can be obtained in mammalian cells or in a whole animal, mainly for use in imaging. However, the mechanisms of this biosynthesis are often spontaneous, poorly understood and, therefore, difficult to control. In our approach, a pathological process, namely hypoxia of the brain accompanied by changes in the NADH/NAD+ co-enzymes ratio, initiates and controls the biosynthesis of biocompatible Au nanoparticles from precursor salts in the immediate vicinity of the hypoxia site, thereby restoring the redox status of the brain.

Engineering of Chiral Inorganic Nanostructures Nicholas A. Kotov; University of Michigan, United States

The early observation of strong circular dichroism for individual nanoparticles and their assemblies have developed into a rapidly expanding field of chiral inorganic nanostructures. The chiral inorganic nanostructures encompass sophisticated constructs from metals, semiconductors, ceramics, and nanocarbons with multiple chiral geometries with characteristic scales from Ångströms to microns. Such versatility enables their functional engineering over a broad range of physical and chemical properties but the relationship between the chirality of surface ligands, NP cores, and resulting assemblies remains obscure. Similarly, the relationship between their chiral geometries and their chiroptical properties. This talk will address (1) the origin of the uniquely high values of optical anisotropy; (2) the mechanisms of chirality transfer in inorganic materials; and (3) differences/similarities with chiral supramolecular, liquid crystal, and biological assemblies. Long-range correlations and critical phenomena in chiral nanoassemblies leading to the emergence of geometrically complex structures will be demonstrated. The novel venues for practical realizations of chiral nanoassemblies included in the talk will be photocatalytic C-C coupling in biomimetic chiral supraparticles and polarization spectroscopy in terahertz (THz) spectral window with chiroplasmonic kirigami composites.

5:30 AM S.CT08.02.04
Solid-State Phase Transformation and Self-Assembly of Amorphous Nanoparticles into Higher-Order Mineral Structures Stanislas Von Euw and Paul Falkowski; Rutgers, The State University of New Jersey, United States

Exerting control over non-classical pathways to crystallization to direct the growth, polymorphism, and self-assembly of inorganic nanoparticles into higher-order structures shapes the future of materials science [1]. To achieve this, the dominant strategy currently under development is directed towards our ability to govern the nucleation stage in a multitude of precipitation reactions occurring far from thermodynamic equilibrium [2]. These reactions share the common purpose of converting solution precursors into solid mineral materials, and, hence, are based on a number of different approaches that overcome the free-energy barrier to nucleation. We have examined the feasibility of an alternative approach that could not only overcome the limitations associated with the dominant strategy mentioned above, but also shape our way of manufacturing novel materials suitable for modern needs. We believe that future approaches will deliberately skip over the nucleation stage on which little control can be exercised, and will focus on the conversion of solid, metastable amorphous nanoparticles into their crystalline counterparts. Such metastable amorphous nanoparticles that latter transform into higher-order, hierarchical mineral structures have been observed across various biomineralizing taxa such as stony corals [3], but their use in synthetic systems remains extremely limited. Here we used Amorphous Calcium Magnesium Carbonate (ACMC) nanoparticles as models, and we monitored their pathway to crystallization in aqueous medium to show their potential usefulness in the development of novel materials. To this end, we applied a combination of ultrahigh-resolution three-dimensional imaging, and in situ, solid-state nuclear magnetic resonance (ssNMR) spectroscopy.

Our results reveal the underlying mechanism of the phase transformation of these Amorphous Calcium Magnesium Carbonate (ACMC) nanoparticles into crystals in wet conditions. First, they suggest that these amorphous nanoparticles are
coated by a rigid hydration shell of bound H$_2$O molecules when soaked in water. Our results also show that fast chemical exchanges occur between hydrogens from the nanoparticles and those from the free H$_2$O molecules of the surrounding aqueous medium. Crystallization spontaneously occurs after the amorphous nanoparticles were soaked in water. Using two-dimensional ssNMR spectroscopy, we especially show that the nascent crystalline environments, together with the starting amorphous materials, belong to the same particles. This is a clear spectroscopic evidence of a solid-state phase transformation of the starting amorphous nanoparticles into crystals. In addition, we reveal that the starting amorphous nanoparticles remain hydrated while crystallization progresses. There is also evidence of fast chemical exchanges between hydrogens from the amorphous nanoparticles partially converted into crystals, and those from the free H$_2$O molecules of the surrounding aqueous medium. Hence, our results question the role played by these unceasing chemical exchanges towards crystallization. We imagine that they are likely to be associated with an enhanced mobility of the ions/molecules that compose the amorphous nanoparticles which, in turn, allows for rearrangement of these ions/molecules into crystalline domains. Lastly, using ultrahigh-resolution three-dimensional imaging, we show that these amorphous nanoparticles aggregate to form ordered crystalline structures through crystal growth by particle attachment; and this conclusion is further supported by our ssNMR results. As such, these metastable amorphous nanoparticles open new avenues to develop novel ceramic or inorganic-organic hybrid materials through strategies that are no longer limited by the nucleation stage.

Real Time Imaging of the 3D-2D Transformations of Nanocrystals through Liquid Cell Transmission Electron Microscopy **Haimei Zheng**1,2; **1**Lawrence Berkeley National Laboratory, United States; **2**University of California, Berkeley, United States

In recent years, significant achievements have been made in the synthesis of various colloidal nanostructures. The anisotropic nanostructures, such as nanowires or two-dimensional (2D) materials have attracted a lot of attention due to their unique properties. However, their formation mechanisms have not been fully understood. They seem to be contradictory to the predictions based on the conventional crystal growth theories. And, it adds to the complexity that nanocrystals often change structure and morphology during growth. We explore the growth mechanisms of anisotropic nanocrystals using in situ liquid cell transmission electron microscopy (TEM). In this talk, I will show the growth of 2D transition metal oxide nanosheets, e.g. cobalt oxide and cobalt nickel oxide. The 2D nanosheets have been achieved in a liquid cell, which resemble those synthesized in flasks. Our direct observations reveal that 3D nanoparticles are initially formed from the molecular precursor solution and then transform into 2D nanosheets. Ab initio calculations show that a small nanocrystal is dominated by positive edge energy, but when it grows to a certain size, the negative surface energy becomes dominant, driving the transformation of the 3D nanocrystal into a 2D structure. Uncovering these growth pathways, including the 3D-to-2D transition, provides opportunities for the future design and solution synthesis of novel materials.

Gypsum—Anhydrite Phase Transformation and Crystal Growth Induced by Microorganisms Living in the Atacama Desert **Wei Huang**1, Emine Ertekin2, Taifeng Wang1, Luz Cruz1, Jocelyne DiRuggiero2 and David Kisailus1; 1University of California, Riverside, United States; 2Johns Hopkins University, United States

Microorganisms have been found living in one of the driest and oldest deserts on the earth, the Atacama Desert in Chile. In
this hyper-arid environment, microbial communities colonize the interior of rocks and obtaining water is critical for their survival. Gypsum (CaSO₄•2H₂O) is one of the main components in rocks from the Atacama Desert and is a main source of water for these communities, which are mainly constituted of cyanobacteria and heterotrophic bacteria. We report that these microorganisms extract crystalline water from the gypsum rock, inducing a phase transformation from gypsum (CaSO₄•2H₂O) to anhydrite (CaSO₄). Cyanobacteria cultures were inoculated on gypsum rock samples to investigate and validate the water extraction and phase transformation mechanisms found in the geological environment. It is shown that cyanobacteria attach on high surface energy crystal planes and generate a thin biofilm on the gypsum samples. Due to the acidic nature of the biofilm, gypsum dissolution is observed, accompanied with water extraction and subsequent transformation to anhydrite via reprecipitation and oriented attachment of mesocrystals. This is the first time showing gypsum – anhydrite phase transformation and non-classical crystal growth induced by microorganisms. The results in the present work not only shed light on how these organisms survive in such extreme environments, but also can provide insight into potential life in xeric environments such as Mars as well as offer strategies for advanced water storage methods.

How Solution-Phase Additives Control the Shapes of Metal Nanocrystals in Solution
Kristen A. Fichthorn; The Pennsylvania State University, United States

Metal nanocrystals have gained tremendous attention due to their superior performance in various applications, ranging from selective catalysis to electronic devices to plasmonic applications, such as photovoltaics and sensing. The properties of nanocrystals are highly sensitive to their size and shape. To this end, solution-phase synthetic protocols have been highly successful at producing a variety of nanocrystal structures. However, great challenges remain in achieving high selectivity to particular nanostructures. A significant difficulty lies in understanding and controlling shape evolution in these systems.

A common adage is that solution-phase additives, such as capping molecules, can direct the shapes of colloidal nanocrystals by adsorbing selectively to certain facets. Though our first-principles-based studies indicate that capping molecules alone can direct the formation of nanocrystal shapes in certain systems, experiments demonstrate that more robust syntheses can be achieved in the co-presence of halide additives. We use DFT-based ab initio thermodynamics calculations to probe the influence of chloride on Ag nanoshapes. Consistent with experiment, these calculations indicate that chloride adsorption alone can lead to truncated Ag cubes. We find that adsorbed chlorine works synergistically with PVP, a common capping agent for Ag, to enhance the tendency for Ag cubes. We also demonstrate that adsorbed Cl works synergistically with HDA capping molecules to facilitate the growth of Cu nanowires via a kinetic pathway - consistent with experiment. These studies indicate that halides and capping molecules can be a powerful combination to create selective nanoshapes in solution-phase syntheses.

The Role of Carbon and SiC Crystallinities in the Oxidation and Mechanical Property Improvement of Hybrid Nano-Fibers
Saja M. Al-ajrash; University of Dayton, United States

In this study, electrospinning was successfully used to fabricate hybrid Carbon-Silicon Carbide (C-SiC) fibers using polycrylonitrile (PAN) and Silicon (Si) nanoparticles as precursors. Silicon-to-carbon precursor ratios and heat treatment were optimized to fabricate hybrid nano-fibers with high oxidation resistance. After heat treatment, the nano-fibers showed two-dimensional ordered carbons and SiC nano-phases formation. As a result, a noticeable improvement in mechanical and thermal properties was achieved. Samples with 90wt% PAN/10wt% Si showed about four-time improvements in char yield as compared with 100 wt % PAN. In addition, after the heat treatment of the fiber at 1250 °C, SiC was formed. The carbon and SiC crystallinities had a great impact on the oxidation and mechanical property improvement of hybrid nanofibers. The determination of crystal size was carried out using X-ray results obtained at different temperatures and holding times. The SiC grain growth was predicted using kinetic models and its exponent was found to be around n = 4 with activation energy around 35 KJ/mol.K. For such growth, the dominant grain growth mechanism was grain boundary diffusion.
The Diverse and Complex Nonclassical Pathways of Nanoporous Aluminosilicate Crystallization

Jeffrey D. Rimer
University of Houston, United States

The unique properties of nanoporous aluminosilicates (zeolites) are exploited in a variety of applications spanning from ion exchange and separations to catalysis and drug delivery. The ability to selectively control zeolite synthesis to achieve desired physicochemical properties relies upon detailed understandings of the thermodynamic and kinetic factors regulating crystal nucleation and growth, which are generally lacking. Designing innovative approaches to tailor zeolite crystallization and elucidate structure-performance relationships has the potential to produce materials with superior properties beyond what is achievable by conventional routes. In this talk, I will discuss efforts to characterize the complex mechanisms of zeolite crystallization, which occur by nonclassical pathways involving the self-assembly and structural evolution of amorphous precursors. There is still much that we do not understood regarding the role of precursors in nucleation and the influence of growth conditions on the selection of crystal topology, which underscores the need for molecular-level studies of zeolite crystallization. Our group addresses these challenges using a broad range of techniques that include the use solvothermal atomic force microscopy to capture time-resolved images of growing zeolite surfaces in real time. This technique has led to the first in situ characterization of zeolite growth with the capability of resolving surface dynamics at the spatiotemporal scales necessary to elucidate mechanistic pathways of crystallization. Based on our findings, we observe that growth occurs via multiple (cooperative) pathways that differ from one material to the next. In this talk, we will summarize our findings for several zeolite structures.

References
starting reactant ratios can yield phase-pure single-phase compounds, where excess P and As can be sublimed away from the phase of interest. Furthermore, this method can generate single crystals for structural characterization due to the P and As acting as transport agents in addition to being reactants. The structural chemistry, polymorphism, and properties of the family of \( \{R,T\}\)-Si-Pn compounds will be discussed.

Fabrication of High-Performance Carbon Fibers Using Template Induced Crystallization  Rahul Franklin, Weiheng Xu, Dharneedar Ravichandran and Kenan Song; Arizona State University, United States

Carbon fibers have broad applications in aerospace, automobiles, wind turbines, medical devices, and implants, among many others. Carbon fibers with high-end applications have previously been manufactured from precursor fibers of rayon, pitch, and polyacrylonitrile (PAN) fibers. New precursor fibers have been conventionally fabricated by homogenously mixing the reinforcement/nanofiller and polymer matrix mechanically and spinning the dope into a coagulation bath, such as PAN processing in the case of dry-jet wet spinning followed by the drawing stage and heat treatment at different temperatures. Mechanical properties of this fiber are dependent on the continuity, density and interfacial action of the hierarchical graphitic structures. The presence of voids formed during crystallization due to the random dispersion of reinforcement/nanofiller in pre-carbon fibers (pCFs) deteriorates these properties. In this project, a specialized templating graphene channel was developed via an in-house designed spinneret. This channel containing graphene and varied PAN solutions running along the axial direction of the fiber was parallel to the outer and inner PAN channels. On drawing the as-spun fibers the GNP was aligned in the axial direction. This channel then allowed for crystallization along the axial direction and minimizes the formation of voids leading to enhanced mechanical properties. The mechanical test showed the composite as-spun fiber with GNP templating channel has 18.5% and 51.4% increased Young’s modulus and tensile strength, respectively, as compared to the pure PAN fiber. The thermodynamics and kinetics of the heat-treatment procedures were analyzed to correlate the microstructure features and mechanical/thermal properties of obtained carbon fibers.

Non-Classical Crystallization of Thin Films and Nanostructures in the Chemical Vapor Deposition Process  Nong-Moon Hwang; Seoul National University, Korea (the Republic of)

Although non-classical crystallization has been studied extensively in the solution growth, not much attention has been paid to the non-classical crystallization in the gas phase synthesis of thin films and nanostructures by chemical vapor deposition (CVD). Extensive studies were made in CVD processes and the non-classical crystallization was shown to be a general growth mechanism of thin films and nanostructures [1], where the charged nanoparticles become the building block. Generation of charged nanoparticles was confirmed in most CVD processes, including the growth of films and nanostructures of diamond, carbon nanotubes, ZrO2, Si, ZnO and GaN. Small charged nanoparticles are favorable for epitaxial growth whereas large ones are favorable for nanostructure growth.

Understanding made from the non-classical crystallization behaviour in the CVD process can provide the valuable information as to the non-classical crystallization in solution. For example, building block of nanoparticles are electrically charged in the CVD process and the presence of charge plays a critical role in the growth of thin films and nanostructures. The charge is responsible for not only self-assembly but also liquid-like coalescence, which result in the evolution of dense films and nanostructures. The role of charge could be clearly revealed by comparing the deposition behavior of silicon charged nanoparticles between electrically floating and grounded silicon substrates. Single crystalline silicon nanowires grew on the floating substrate whereas nanoparticles grew on the grounded substrate. In other processing conditions, a dense silicon film grew on the floating substrate whereas a porous silicon film grew on the grounded substrate.

The fact that charged nanoparticles can be a building block of films and nanowires without leaving any void behind indicates that charged nanoparticles are quasi-solid, having a liquid-like property in diffusion. This means that the charge enhances the atomic diffusion, which is a newly discovered physical phenomenon. The charge-enhanced kinetics could be analyzed by comparing the behavior of Au nanoparticles on conducting and insulating membranes during transmission electron microscopy (TEM) observation. Au nanoparticles on insulating membranes were actively changing their orientation during TEM observation whereas those on conducting membranes were not. Also plasma dewetting behavior of sputtered Sn films was compared between grounded and floating conditions. The dewetting kinetics of Sn films in the floating condition was much higher than that in the grounded condition. Both experimental results support charge-enhanced kinetics.

In this presentation, some important aspects of the non-classical crystallization in the CVD process would be introduced, emphasizing that the non-classical crystallization occurs not only in solution but also in the gas phase synthesis.

[1] N.M. Hwang, Non-Classical Crystallization of Thin Films and Nanostructures in CVD and PVD Processes, vol. 60,
Two-dimensional (2D) materials have attracted significant attention due to their unique structure and fascinating properties. However, our understanding of their growth mechanisms in solution is still limited. Here, using indium chloride (InCl₃) as a model system, we performed liquid phase transmission electron microscopy (TEM) study of the 2D growth in situ. We combined the low temperature techniques with liquid phase TEM. The nucleation and growth of 2D nanosheets in solution via both classical and non-classical pathways were observed with the atomic resolution in real time at room temperature as well as low temperature (e.g., 1-2 °C). We found the drastically decreased growth kinetics at the low temperature compared to that at the room temperature. Observation also showed that the fast growth induced the high density of crystal defects (e.g., nanotwins). Comparatively, perfect 2D nanocrystals were obtained through the low temperature growth. In addition, we did the atomic structural analysis of the nanosheets and chemical mapping of the reaction front at the Cryogenic temperature using the same liquid cell sample. The results revealed the growth mechanisms of InCl₃ 2D nanosheets and the formation of nanotwins in solution. And, the liquid phase TEM with variable temperature control opens many opportunities for future depth study of nanoscale materials growth and transformations.

Synthesis design remains a paramount problem in materials science. Significant research has been dedicated to advancing tools to predict and aid in synthesis development. Here we describe an ab-initio approach to evaluate water-based synthesis processes such as hydrothermal synthesis. We show how to use electrochemical Pourbaix diagram, constructed from first principles density functional theory (DFT) calculations, to understand thermodynamic forces of complex Cu oxides and Cu oxychalogenides in aqueous environments. We discuss how to construct these complex diagrams consisting of many degrees-of-freedom, including multiple elemental species, compounds, and complexes as well as nonstandard state conditions. We describe how the driving forces for the products evolve with changes in pH, oxidation state, and the activity of reactants; this understanding is then used to justify successful experimental synthesis of the targeted phase. Scale dependent nucleation is also examined. Last, we propose Pourbaix diagrams are a useful synthesis-processing design tool for accelerated discovery.

Common growth models assume a structure-less liquid composed of atomic flow units and describe crystal growth as a phenomenon of transferring atoms at the interface between a growing solid and a structure-less liquid. However, for liquid metals and polymers, structural ordering has been shown, raising the possibility of structure-coupled crystal growth. By performing in situ transmission electron microscopy (TEM) crystallization experiments on Pt-based metallic glass nanorods, we show that local structural order of the glass strongly affects crystal growth, in contrast to assumptions from conventional growth models [1].

Metallic glasses serve as a good model system to study crystallization due to their non-directional metallic bonds, relatively slow crystallization kinetics, and moderate crystallization temperatures, which readily allow direct visualization of crystallization events at the atomic scale via in situ TEM experiments. At the nanoscale, we have observed crystallization phenomena that deviate greatly from the macroscopic behaviors due to the geometrical confinement effects. These include suppression of crystallization for very small metallic glass nanorods [2], emergence of a metastable, single crystalline phase out of multi-component metals [3], and the structure-coupled crystallization [1]. The structure-coupled crystallization was inferred from the asymmetric growth rates of a heated metallic glass versus a cooled metallic liquid. We demonstrate that thermodynamically unstable structural ordering in the glass state can be kinetically stable enough to enhance crystal growth during crystallization. Thus our works highlight crystallization via non-classical pathways.

Strain Localization and Dynamic Recrystallization in Polycrystalline Metals—Thermodynamic Theory and Simulation Framework
Charles Lieou1, Hashem Mourad1 and Curt Bronkhorst2,1; 1Los Alamos National Laboratory, United States; 2University of Wisconsin–Madison, United States

We describe a theoretical and computational framework for adiabatic shear banding (ASB) and dynamic recrystallization (DRX) in polycrystalline materials. The work is based on the thermodynamic dislocation theory (TDT) by Langer et al., to which we add the grain boundary density as an internal state variable. TDT provides a convenient and thermodynamically consistent way to represent the viscoplastic and thermal behavior of the material, with minimal ad-hoc assumptions regarding the initiation of yielding or onset of shear banding. Within the TDT framework, dynamic recrystallization emerges as an entropic effect arising from the competition between dislocation creation and grain boundary formation, and contributes to material weakening and failure. We implement the TDT-DRX theory in conjunction with a finite-element computational framework. Favorable comparison to experimental measurements on a top-hat AISI 316L stainless steel sample compressed with a split-Hopkinson pressure bar suggests the accuracy and usefulness of the TDT-DRX framework, and demonstrates the crucial role of DRX in strain localization.

8:30 AM S.CT08.03.16
Slow-Injection Synthesis of Indium Phosphide Quantum Dots as a Route to Large Size and Low Size Dispersity
Odin B. Achorn and Moungi G. Bawendi; Massachusetts Institute of Technology, United States

The color purity of indium phosphide (InP) quantum dots (QDs) lags behind that of cadmium selenide (CdSe) QDs, especially at their largest sizes and reddest wavelengths. In order to improve the quality of InP QDs, we have developed a new synthetic method that features a slow precursor injection rate in contrast to the rapid injection rates that have worked so well for CdSe QD syntheses and that have traditionally been applied to InP. The absorption features of the InP QD batches produced by our method are redder than those of batches of comparably-disperse InP QDs and narrower than those of batches of comparably-sized InP QDs that are produced by other methods. We prepared InP QDs with first excitonic absorption peaks that are redder than 630 nm and have half widths at half maximum less than 85 meV. After adding a zinc selenide shell, we achieved core/shell QDs that are redshifted slightly with respect to the core and have photoluminescence full widths at half maximum under 55 nm. Our method also allows us to synthesize even larger InP cores with defined first excitonic absorption peaks that are redder than 660 nm. We used MALDI mass spectrometry to characterize the size and size dispersity of the QDs and to investigate the presence of low molecular weight clusters and secondary populations. Lastly, we find that the concentration of QDs increases throughout the entire course of the reaction, and we propose a nucleation and growth model to explain our observations.

Superlattice Nucleation and Underlying Mechanism of Magnetite Nanocube Assembly
Xin Huang and Zhongwu Wang; Cornell University, United States

The self-assembly of colloidal nanoparticles into ordered superlattices provides significant expansions for the capability of functional materials design. As the new type of building blocks, the geometric shapes of nanocrystals, such as sphere, cube and octahedron, play critical roles in determining the structure of assembled supercrystal. In the nanocube system, the observed superlattices were dominated by the three phases of simple cubic (SC), rhombohedral (Rh), and face-centered cubic
(FCC), but how they nucleate and grow and transform from one to another remain largely unknown. In this work, we applied highly monodisperse magnetite nanocubes with an average side length of 12.5 nm, and controlled various assembly environments, and revealed the formation and growth of three major phases (SC, acute Rh and FCC). Taking advantage of synchrotron-based SAXS techniques, we also explored the structural correlations between three superlattices phases. With additional simulations and computations, we further discussed the driving forces and constructed a reasonable superlattice phase diagram of nanocube-based assembly. Our results not only dramatically expand our understanding on the shape-dependent phase behaviors of nanocrystal, but also provide insights for design and fabrication of novel functional materials.

S.CT08.04.02
DFT Study of Graphene Formation in Carbon Droplets Condensed in Stellar Atmospheres Chathuri Silva, Philip Fraundorf, Eric H. Majzoub and Philip Chrostoski; University of Missouri-St. Louis, United States

Because macroscopic clusters of elemental carbon at low (ambient) pressure sublimate to vapor near 4000K, liquid carbon is seldom considered to play a role in nature even though quenched carbon droplets have been reported in laboratory laser ablation studies [1,2]. However, a subset of meteoritic carbon particles from red giant atmospheres show a “graphene-core”/graphite-rim structure [3,4], likely following condensation of super-cooled carbon droplets from the vapor phase, which nucleated graphene sheets on randomly-oriented 5-member rings before solidification and subsequent coating with a graphite rim. Similar core-rim particles can be formed by slow cooling of carbon vapor in the lab [5].

It remains a challenge to study the properties of liquid carbon in a lab due to the difficulty of experimentation under extreme conditions. Therefore, we investigated nucleation and growth of carbon rings and graphene sheets using density functional theory (DFT). We assume low pressure, with an experimental 1.8 g/cc density estimate, and relax randomized positions of liquid-like 13/20-carbon atom clusters in a cubic supercell. Inter-atom distances characteristic of covalent vs. metallic interactions (with a gap in 1.7-2.0 Å range) allow us to identify covalent “bonds” with small separation. Local energy minima at T = 0K show a mix of sp2 and sp, plus few sp3 coordination numbers as in the literature which reports that liquid carbon favors sp coordination at lower densities, sp3 coordination at higher densities, and a mix of sp and sp3 coordination at intermediate densities [6-10]. Ring sizes vary from triangle to heptagon, but pentagons are more abundant than hexagons, also consistent with previous reports [9,10]. Further work remains to see if such *ab initio* studies can confirm that abundant pentagonal rings at this density, during slow cooling of the liquid, can nucleate the growth of faceted pentacones as suggested by electron phase-contrast imaging of the presolar cores [11].

In summary DFT relaxation of random configurations of 13/20-atom clusters in a supercell, along with literature reports of the same, suggest that: (a) covalent bonds can be identified by interatom spacings below 1.85Å, (b) sp2 coordination is expected at that density, and (c) pentagonal rings are more abundant than hexagonal rings as possible nucleation seeds. The properties of unlayered graphene sheets in a frozen liquid matrix, e.g. as a diffusion barrier, should be interesting to explore further both experimentally and computationally.

Fabricating Polystyrene Core-Shell Fibers Dharnedar Ravichandran, Weiheung Xu, Rahul Franklin, Namrata Kanth, Sayli Jambhulkar, Ali Alshami, Sumedh Shukla and Kenan Song; Arizona State University, United States

Core/shell fibers have many broad applications in the biomedical field, such as drug delivery and tissue engineering, and are also used in environmental-related applications like water treatment and CO2 absorption. This research demonstrated an alternative technique of gel-spinning for fabricating core/shell structures other than the traditionally used melt spinning or electrospinning technique. These fibers were porous in the shell and had capabilities to load particles in the core. Polystyrene (PS) and polyethylene glycol (PEG) were used as an example for demonstrating the feasibility of the core/shell fiber
fabrication. A two-phase liquid-state microstructure was first achieved via the co-axial spinneret with the exterior layer composed of PS pellets (PSp)/PEG/organic solvent (e.g., xylene or dimethylformamide) solutions and the interior layer containing dispersed PS spheres (PSs)/PEG/water solutions. Procedures of coagulation, heat-treatment, and phase-separation-based selective dissolution were used to generate the porous-shell/particle-core fibers. The pore sizes and density were controlled by the porogen (i.e., PEG) concentrations and examined using scanning electron microscopy (SEM). The fiber formation dynamics and microstructural features were studied via rheology tests and gelation measurements, tensile tests, thermogravimetric analyzer (TGA) and differential scanning calorimetry (DSC).

**Hematite Mesocrystal Formation through Near Interface Nucleation and Oriented Aggregation** Guomin Zhu¹, Maria Sushko², John Loring², Miao Song², Benjamin Legg¹, Xiaopeng Huang², Kevin Rosso² and James J. De Yoreo²,¹; ¹University of Washington, United States; ²Pacific Northwest National Laboratory, United States

A diverse class of materials exhibit characteristics of mesocrystals: single crystals constituting distinct nano-sized domains that are atomically aligned. The formation of such structures is often attributed to crystallization through oriented attachment. However, many questions about the fundamental drivers and dynamic progression of this phenomenon remain. And the process become more complexed when coupled with phase transformation. Here we focus on the crystallization of hematite (hm, Fe₂O₃) mesocrystals from ferrihydrite (fh) nanoparticles. In the oxalate-free solution, the resulting hm crystals are well faceted rhombohedron, while in the presence of oxalate, hm forms nanoporous spindle-shaped mesocrystals. We applied in situ liquid phase TEM with heating temperatures of 80 °C to investigate the formation. We directly observed both the dissolution of fh and the nucleation of new hm particles, which formed within close proximity (~ 1 nm) of the hm/solution interface. Immediately after nucleation, the hm particles attached to the nearby seed to form a hm mesocrystal. Post analyses using EDX mapping and electron diffraction after disassembling the liquid cell confirmed the growth of spindle-shaped hematite during the liquid phase TEM experiments. In addition, we utilized a quasi in situ approach of using indexed TEM grids to cycle samples between the growth reactor and the TEM in order to track the pathway of crystallization. The results were consistent with those of the in situ experiments and confirmed that the fh serves as a buffer and the Hm grow by creation of new particles in the solution near the hm interface. Based on ATR FTIR measurements, ion chromatography and classic DFT calculation we propose that oxalate plays the role of inhibiting classical monomer-by-monomer growth of the hematite particles while promoting the nucleation of new hm particles at the hm/solution interface by modifying the interfacial energy of hm close to the hm/solution interface. In this way, the oxalate ligands bias the growth process away from classical mechanisms and towards oriented attachment.
Energy Storage Devices and Optoelectronic Sensors from Solution-Processed Polymers

Conducting polymers are an important class of Faradaic materials for energy storage, as they present opportunities to create energy dense supercapacitors. The vast majority of conducting polymers are p-type cathodes and already operating at or close to the upper voltage limit of non-aqueous electrolytes. On the other hand, it is generally safe for electrolytes to operate down to -2 V vs Standard Hydrogen Electrode. Therefore, extending the operational voltage in the negative range is an attractive route to increase energy density. Here we present promising n-type polymers that retained 90% of initial capacitance after 5000 charge-discharge cycles. The polymers are processed with solution based methods to ensure that the devices are scalable to large area. The electronic and ionic transport in the conducting polymers are monitored in operando by current-voltage and spectroscopic measurements, where spatial variations of film absorption would be mapped to discern electronic versus ionic degradation. We infer the mechanisms that lead to capacitance fade and suggests structural and electrochemical strategies to realize high-endurance energy storage devices for flexible printed systems.

In addition to energy storage, the narrow bandgap polymers are used to realize photodetectors that is relevant to a variety of applications including environmental monitoring and medical diagnosis. Here we show how the infrared polymers are processed into bulk heterojunction photodiodes with photoresponse up to wavelength of 1.7 micron. The performances of devices with different polymer structures were compared through metrics including detectivity, quantum efficiency, response time and rectification ratio. Example applications including hemodynamics and tissue composition measurements will be demonstrated.

Solution Chemistry of Semiconducting Metal Oxides at the Atomic Scale

Semiconducting metal oxides, particularly transparent conducting oxides, have attracted a great deal of attention for a variety of applications. Nevertheless, the solution chemistry and solution functionalization of these materials has been much less explored than that of traditional semiconductors, such as silicon. One challenge in the stable functionalization of these materials is that their semiconducting nature enables efficient generation of long-lived photocarriers that can initiate chemical reactions that degrade the functionalization. This reactivity has typically been attributed to the undercoordinated metal cation sites at the surface, although direct evidence has been lacking. We have developed a new photochemical reaction that leads to the fluorination of all exposed metal cation sites on TiO₂. In contrast to approaches that use fluoride or HF-containing solutions, our method produces covalently bonded fluorine which is stable in aqueous solutions. To our surprise, these fluorine-terminated TiO₂ surfaces display higher photoreactivity than comparable “clean” surfaces. Possible origins of this behavior will be discussed.

We have also investigated the structure of solution-deposited monolayers on TiO₂ and demonstrated a rational approach to tuning intermolecular interactions and enabling long-range ordering. We show that simple electrostatic insights can be used to engineer away unfavorable intermolecular interactions, producing monolayers with exceptional long-range ordering. Quantitative measurements of the intermolecular interaction energies from molecularly resolved STM images are a factor of ~7 larger than those predicted by dispersion-corrected density functional theory (DFT). This finding suggests a new path to the production of highly ordered monolayers and superstructures of large molecules.

Atomic Layer Deposition from Dissolved Precursors for the Preparation of Accurately Nanostructured...
Heterojunctions Maïssa Barr¹, Vanessa Koch¹, Soheila Nadiri¹, Ceyla Asker¹, Dong-Hui Chen², Peter G. Weidler², Felix Hoga¹, Tobias Stubhan¹, Engelbert Redel², Helmut Baumgart³, Christoph J. Brabec¹ and Julien Bachmann¹,⁴; ¹Friedrich Alexander University, Germany; ²Karlsruhe Institute of Technology, Germany; ³Old Dominion University, United States; ⁴Saint Petersburg State University, Russian Federation

An interdigitated geometry of the interface between semiconductors remains a Graal in the photovoltaic field. Nanocylindrical solar cells based on a coaxial p-n or p-i-n junction have been generated in a small number of materials systems only so far, mostly among the classical semiconductors. The generalization of this interface geometry to alternative semiconductors, which are expected to profit of it most, has been hampered by the lack of appropriate deposition methods suited to coating complex three-dimensional structures in a conformal manner. Atomic layer deposition (ALD) provides this capability, but is limited by the necessity to use gaseous precursors in vacuum conditions. Modern classes of semiconductors such as the hybrid perovskites are not accessible by ALD due to their ionic nature.

In this perspective, we have transferred the principles of ALD to precursors dissolved in liquid solvents. The ‘solution ALD’ (sALD) method can be implemented in a variety of microfluidic or slot-die processing devices. We have demonstrated that the principles of classical, gas-based ALD —self-limiting surface reactions— are reproduced in sALD. Furthermore, sALD allows the experimentalist to design new, advantageous, reactions of known semiconductors (oxides, heavier chalcogenides), or to deposit materials otherwise inaccessible to ALD altogether, such as polymers, ionic solids, and metal-organic frameworks. They may be obtained in highly pure, crystalline form at room temperature, either as planar films or as conformal coatings of porous substrates. Based on these advances, we have been able to make the first sALD-derived hybrid perovskite cells.
The atomic layer deposition of cobalt using Co(DAD)$_2$ and tertiary-butyl amine (TBA) has nearly infinite selectivity (>1000 cycles) on metal vs. insulator (SiO$_2$ or low-k SiCOH) planar samples. However, on patterned samples, selectivity under identical ALD conditions is limited, due to the diffusion of molecularly-adsorbed metal precursor from reactive to non-reactive surfaces. Three strategies have been found to improve Co ALD selectivity: adding a passivant to remove insulator defect sites, increasing the purge time, decreasing the precursor dose, and periodic annealing. The periodic annealing technique allows reabsorption of the Co nuclei from the insulator surface to the growth surface and is consistent with a low temperature reflow process. This technique has the added advantage of allowing a lower temperature for reflow, potentially allowing a scaling of the diffusion barrier between the Co and the SiCOH which is normally employed. Co ALD was performed using Co(DAD)$_2$ + TBA at 180°C on 85 nm wide Cu stripes on SiO$_2$. The planar structure of these stripes is used to demonstrate the effectiveness of passivation, as top-down SEM imagery and XPS quantification can be used to monitor growth and presence of unwanted Co nuclei on insulator. To control precursor dose, multiple precursor pulses were employed in each cycle to limit the maximum pressure. XPS is performed without breaking vacuum to prevent oxidation of Co. This work is supported by the Applications and Systems Driven Center for Energy-Efficient Integrated Nanotechnologies (ASCENT), a Semiconductor Research Corporation program sponsored by JUMP and DARPA.

Electronic Structure of Technologically Important Interfaces and Heterostructures Richard Haight; IBM T.J. Watson Research Ctr, United States

From thin film solar cells to metal-oxide-semiconductor devices in leading edge integrated circuits, the electronic structure at and near the interfaces between component materials determines the most important fundamental operating characteristics of those devices such as turn-on voltage, power dissipation and off-state current leakage. Fermi level location at buried interfaces, semiconductor band-bending, charge transfer, oxide defects and work functions of the constituent materials all contribute to device performance. In this talk I will describe how these important parameters can be determined by employing femtosecond photovoltage spectroscopy (FPS)[1], an extension of ultraviolet photoelectron spectroscopy (UPS) using ultrafast lasers. While UPS is fundamentally a surface sensitive spectroscopy, I will describe how pump/probe techniques add a new dimension to this venerable spectroscopy, permitting the accurate extraction of the underlying band bending in Si. When combined with valence band edge location of the semiconductor and oxide, and determination of the system Fermi level, full characterization of the electronic structure of an MOS stack can be obtained providing key insights on device operating properties. I will describe the use of FPS to investigate device stacks ranging from Si and III-V based MOS structures to thin film solar cells formed from earth-abundant elements. In each case surprising new details were uncovered.
that led to performance optimization of these technologically important devices.

**Correlating Hansen Solubility Parameters to Morphology for Printable Organic Electronics**

Natalie P. Holmes¹,², Matthew Marcus³, Jan van Stam¹, Paul Dastoor² and Ellen Moons³; ¹Karlstad University, Sweden; ²University of Newcastle, Australia; ³Advanced Light Source, Lawrence Berkeley National Laboratory, United States

Printed organic electronics is an expanding field with numerous advantages, including scalability, solution processability of the organic semiconductors, biocompatibility, mechanical flexibility, semi-transparency, color-tunability and low-cost manufacture.¹ Transitioning to eco-friendly printing inks for the large-scale manufacture of printed organic electronics is the next step on the horizon, as the use of halogenated solvents is environmentally hazardous, harmful to the health of workers, and will increase the cost of production.² Our recent work involves applying Hansen solubility theory, based on solution thermodynamics, to propose a Hansen solubility parameters (HSP)-based method that is a general platform for the rational design of ink formulations for solution-based organic electronics.³ Which will facilitate the green solvent transition of organic photovoltaics (OPV), in particular. A series of bulk heterojunction films were spin coated from green solvent ink formulations and X-ray spectromicroscopy was utilised to measure donor–acceptor domain size and domain composition. This seminar demonstrates that we can now engineer a nanostructured donor–acceptor thin film from green solvents, with donor and acceptor domain sizes closely matched to the exciton diffusion length in organic semiconductor systems.³,⁴ The HSP approach is versatile for different organic semiconducting material systems, and we have detailed the pathway for using the HSP semi-empirical tool to predict morphologies, screen suitable ink formulations, and importantly design nanostructured donor–acceptor thin film morphologies for efficient OPV device production. By carefully considering HSP and choosing solvent blends with relative solubilities for the two materials, donor and acceptor can be driven to precipitate in the necessary
order for forming a nano-structured interdigitated network morphology.

**Activating Conductivity in Liquid Metal Particle Films by Laser and Thermal Sintering**
Rebecca Kramer-Bottiglio; Yale University, United States

Metallic inks with superior conductivity and printability are necessary for high-throughput manufacturing of printed electronics. In particular, gallium-based liquid metal inks have shown great potential in creating soft, flexible and stretchable electronics. Despite their metallic composition, as-printed liquid metal nanoparticle films are non-conductive due to the surrounding metal oxide shells which are primarily Ga2O3, a wide-bandgap semiconductor. Hence, these films require a sintering process to recover their conductivity. For conventional solid metallic nanoparticles, thermal and laser processing are two commonly used sintering methods, and the sintering mechanism is well understood. Nevertheless, laser sintering of liquid metal nanoparticles was only recently demonstrated, and to date, the effect of thermal sintering has rarely been investigated. In this talk, eutectic gallium–indium nanoparticle films processed separately by laser or thermal sintering in an ambient environment will be presented. Laser and thermally sintered films will be compared with respect to electrical conductivity, elemental composition, crystallinity and surface morphology. Both methods impart thermal energy onto the films and generate thermal stress in the particles, resulting in rupture of the gallium oxide shells and achieving electrical conductivity across the film. For laser sintering, extensive oxide rupture allows liquid metal cores to flow out and coalesce into conductive pathways. For thermal sintering, due to less thermal stress and more oxidation, the oxide shells only rupture locally and extensive phase segregation occurs, leading to non-liquid particle films at room temperature. Electrical conductivity is instead attributed to segregated metal layers and gallium oxide which becomes crystalline and conductive at high temperatures. This comprehensive comparison confirms the necessity of oxidation suppression and significant thermal stress via instantaneous laser irradiation to achieve conductive liquid metal patterns.

**Understanding the Contact of Screen-Printable Cu Paste for Si Solar Cells through One-Step Atmospheric Firing**
Keming Ren1, Krishnamraju Ankireddy2, Thad Druffel2, Sandra Huneycutt1 and Abasifreke Ebong1; 1University North Carolina at Charlotte, United States; 2Bert Thin Films, LLC, United States

Screen-printing and fire through the anti-reflective coating of the front gridline for crystalline silicon solar cell is cost-effective due to the high throughput and simplicity. Silver is the metal of choice because of high conductivity and the understanding that has been gained in decades of research. However, the cost of silver is high and it is the second most expensive layer of a solar cell. In order to penetrate the solar electricity, it is essential to fabricate cheaper solar cells and one of the feasible ways is to replace the expensive Ag front contacts by Cu which has been studied. However, despite the oxidation of copper in the atmosphere, it is challenging to have Cu directly contact with Si because (1) Cu diffuses into Si under high temperature and forms recombination sites; (2) Cu reacts with Si and form micro-sized Cu3Si to shunt the p-n junction; Thus, a diffusion barrier to block Cu from diffusion into Si is required for Cu front contacts on Si. Although people have used electroplating or two-step printing to fabrication diffusion barriers before fabricating Cu contacts, these methods include extra manufacturing steps and are too expensive to be commercialized. Thus, there is a need to replace the costly silver with copper and use the low-cost and high throughput process that will not require additional equipment in production. In this case, the most cost-effective method is using Cu to fully replace the Ag in the paste to make screen-printable pure Cu paste but it requires the paste to prevent the Cu from diffusing into the Si during the high-temperature sintering. According to our previous work, extra Cu in commercial Ag paste with glass frits results in increased transition temperature of glass frits and causes poor etching of SiNx layer, leading to low Voc. In this work, antimony is added into pure Cu paste without glass frits. Here, we are reporting the successful printing and sintering of metal gridlines with pure copper paste. After the one-step atmospheric firing process, the pure Cu fingers formed effective contacts on the Si emitter with Voc larger than 600 mV. In addition to the electrical output parameters of the solar cell, the microstructure analysis to elucidate the contact quality is reported. The preliminary studies showed that uniform pure Cu contacts were formed under < 800 °C with a low ratio of Cu2O and the antimony formed an effective diffusion barrier to prevent the Cu diffusion into the Si and ensured high Voc. The contact path should either through direct contact with Cu gridlines or tunneling through a thin glass layer.

Solution Chemistry of Semiconducting Metal Oxides at the Atomic Scale

Melissa A. Hines; Cornell University, United States

Semiconducting metal oxides, particularly transparent conducting oxides, have attracted a great deal of attention for a variety of applications. Nevertheless, the solution chemistry and solution functionalization of these materials has been much less explored than that of traditional semiconductors, such as silicon. One challenge in the stable functionalization of these materials is that their semiconducting nature enables efficient generation of long-lived photocarriers that can initiate chemical reactions that degrade the functionalization. This reactivity has typically been attributed to the undercoordinated metal cation sites at the surface, although direct evidence has been lacking. We have developed a new photochemical reaction that leads to the fluorination of all exposed metal cation sites on TiO₂. In contrast to approaches that use fluoride or HF-containing solutions, our method produces covalently bonded fluorine which is stable in aqueous solutions. To our surprise, these fluorine-terminated TiO₂ surfaces display higher photoreactivity than comparable “clean” surfaces. Possible origins of this behavior will be discussed.

We have also investigated the structure of solution-deposited monolayers on TiO₂ and demonstrated a rational approach to tuning intermolecular interactions and enabling long-range ordering. We show that simple electrostatic insights can be used to engineer away unfavorable intermolecular interactions, producing monolayers with exceptional long-range ordering. Quantitative measurements of the intermolecular interaction energies from molecularly resolved STM images are a factor of ~7 larger than those predicted by dispersion-corrected density functional theory (DFT). This finding suggests a new path to the production of highly ordered monolayers and superstructures of large molecules.

atomic layer deposition from dissolved precursors for the preparation of accurately nanostructured heterojunctions

Maïssa Barr¹, Vanessa Koch¹, Soheila Nadiri¹, Ceyla Asker¹, Dong-Hui Chen², Peter G. Weidler², Felix Hoga¹, Tobias Stubhan¹, Engelbert Redel², Helmut Baumgart¹, Christoph J. Brabec¹ and Julien Bachmann³,⁴; ¹Friedrich Alexander University, Germany; ²Karlsruhe Institute of Technology, Germany; ³Old Dominion University, United States; ⁴Saint Petersburg State University, Russian Federation

An interdigitated geometry of the interface between semiconductors remains a Graal in the photovoltaic field. Nanocylindrical solar cells based on a coaxial p-n or p-i-n junction have been generated in a small number of materials systems only so far, mostly among the classical semiconductors. The generalization of this interface geometry to alternative semiconductors, which are expected to profit of it most, has been hampered by the lack of appropriate deposition methods suited to coating complex three-dimensional structures in a conformal manner. Atomic layer deposition (ALD) provides this capability, but is limited by the necessity to use gaseous precursors in vacuum conditions. Modern classes of semiconductors such as the hybrid perovskites are not accessible by ALD due to their ionic nature.

In this perspective, we have transferred the principles of ALD to precursors dissolved in liquid solvents. The ‘solution ALD’ (sALD) method can be implemented in a variety of microfluidic or slot-die processing devices. We have demonstrated that the principles of classical, gas-based ALD —self-limiting surface reactions— are reproduced in sALD. Furthermore, sALD allows the experimentalist to design new, advantageous, reactions of known semiconductors (oxides, heavier chalcogenides), or to deposit materials otherwise inaccessible to ALD altogether, such as polymers, ionic solids, and metal-organic frameworks. They may be obtained in highly pure, crystalline form at room temperature, either as planar films or as conformal coatings of porous substrates. Based on these advances, we have been able to make the first sALD-derived hybrid perovskite cells.

Understanding Area Selective Atomic Layer Deposition by a Comparative Study of Precursors

Il-Kwon Oh¹, Tzu-Ling Liu¹, Tania Sandoval², Ralf Tonner³ and Stacey F. Bent¹; ¹Stanford University, United States; ²Technical University Federico Santa Maria, Chile; ³Philipps-Universitat, Germany
The rapid growth of technologies such as machine learning and autonomous vehicles is fueling a need for more powerful electronic devices requiring complex nanoscale structures. With the growing demands on nanostructure fabrication, selective deposition is gaining attention as a process to enable pattern features at the sub-10 nm length scale. This talk will focus on area selective atomic layer deposition (AS-ALD), a bottom-up growth strategy in which material is added only where desired, without the need for subsequent lithography and etch steps. ALD is a good choice for selective deposition because its chemical specificity provides a means to achieve selectivity on a spatially patterned substrate. One popular approach to AS-ALD uses inhibitory layers such as self-assembled monolayers (SAMs) to alter the native surface reactivity, allowing ALD selectivity to be achieved. There have been a number of studies demonstrating that different types of SAMs, including organosilanes, phosphonic acids and thiols, can successfully block ALD processes. However, the efficacy of the blocking varies strongly across different ALD processes. For example, for the same SAM system, the blocking selectivity of Al₂O₃ is limited to only ~6 nm whereas ZnO can be blocked for over ~30 nm. The difference in blocking highlights the importance of precursor chemistry for AS-ALD. In this work, we describe our studies to elucidate the mechanism of AS-ALD based on a comparative study of ALD precursors. Several precursors are studied, including trichloroaluminum (TCA), dimethylaluminum chloride (DMACl), trimethylaluminum (TMA), and triethylaluminum (TEA), each used for Al₂O₃ ALD, allowing comparison between polarity and steric effects of the precursors. Results of quantum chemical calculations of the reaction pathways show product energetics that are correlated with experimental observations, and Monte Carlo simulations address the role of steric on surface coverage. AS-ALD of Al₂O₃ using octadecylchlorosilane SAMs as an inhibitor is also investigated; the blocking properties of the ALD precursors will be compared and the results discussed based on the growth mechanism. By pursuing first principles design of selective ALD processes, this work may enable new methods for additive nanoscale patterning.

In Operando XPS Study of Atomic Layer Etching of Fe, Co and FeCoB Robert L. Opila, Zijian Wang, Omar Melton, David Angel and Bo Yuan; University of Delaware, United States

Etching of transition metals is one of the major challenges in magnetoresistive random-access memory (MRAM) device fabrication. In this work, atomic layer etching of iron and cobalt surfaces in sequential steps of exposure to halogen and an organic molecule was studied. We successfully performed etching of Fe Co, and FeCoB thin films through the formation of volatile metal complexes at low temperature with cyclic reactions of Cl₂and acetylacetone (acacH) or hexafluoroacetylacetone (hfacH). The etching reaction mechanism of acac and hfac reacting with chlorine-modified Fe, Co, and FeCoB surfaces was investigated: the surface was first activated with Cl₂gas, and subsequently, the top layer of chlorinated metal was removed by reaction with a diketone (acacH/hfacH) as shown in the photoemission spectra. The extent of Cl₂reaction determines the etching rate of the metal. At substrate temperatures lower than 135°C, acac could remove the chlorinated Fe metal layer from Fe surfaces, but not chlorinated Co from Co surfaces (Table 1 and 2). In-operando x-ray photoelectron spectroscopy (XPS) and density functional theory (DFT) simulation shows that the reaction of acacH or hfacH with chlorinated Fe or Co surfaces is likely following a complex reaction pathway instead of a simple diketone substitution for the metal chloride. Reactions of FeCoB with Cl₂results in the removal of B. The atomic layer etching cycle described above results in enrichment of the surface in Co. Diketone decomposition likely plays an important role in the etching process on all these surfaces. Moreover, the surface morphology becomes smoother as etching proceeds. The mechanisms for all of these observations will be discussed.

6:00 AM *S.EL01.02.03
Passivation of Surfaces and Interfaces by Atomic Layer Deposited Oxide Nanolayers Erwin Kessels; Eindhoven University of Technology, Netherlands

Passivation of electronic defects on surfaces and interfaces is vital for many (opto)electronic devices in the field of electronics, photonics and photovoltaics. In the last decade it has been demonstrated that a high level of passivation of surface and interfaces can be achieved by nanolayers of oxides prepared by atomic layer deposition (ALD). This passivation can be achieved by termination of bonds of the semiconductor surface but also by shielding of charges from the interface by fixed or trapped charges in the oxide. In this presentation the growth of nanolayers by ALD on a variety of semiconductors (Si, Ge, InP, …) will be discussed, both for planar wafers and for nanowires as used in the aforementioned devices. Results will be presented for various oxides such as Al₂O₃, TiO₂, Nb₂O₅, PO₃, MoO₃ and ZnO and including data as obtained with a wide set of analytical techniques for electrical and structural interface characterization.

6:30 AM *S.EL01.02.05
Nanoscale Proximity Effects in Selective Metal ALD Michael Breeden, Steven Wolf, Ashay Anurag, Victor
Wang and Andrew C. Kummel; University of California, San Diego, United States

The atomic layer deposition of cobalt using Co(DAD)₂ and tertiary-butyl amine (TBA) has nearly infinite selectivity (>1000 cycles) on metal vs. insulator (SiO₂ or low-k SiCOH) planar samples. However, on patterned samples, selectivity under identical ALD conditions is limited, due to the diffusion of molecularly-adsorbed metal precursor from reactive to non-reactive surfaces. Three strategies have been found to improve Co ALD selectivity: adding a passivant to remove insulator defect sites, increasing the purge time, decreasing the precursor dose, and periodic annealing. The periodic annealing technique allows reabsorption of the Co nuclei from the insulator surface to the growth surface and is consistent with a low temperature reflow process. This technique has the added advantage of allowing a lower temperature for reflow, potentially allowing a scaling of the diffusion barrier between the Co and the SiCOH which is normally employed. Co ALD was performed using Co(DAD)₂ + TBA at 180°C on 85 nm wide Cu stripes on SiO₂. The planar structure of these stripes is used to demonstrate the effectiveness of passivation, as top-down SEM imagery and XPS quantification can be used to monitor growth and presence of unwanted Co nuclei on insulator. To control precursor dose, multiple precursor pulses were employed in each cycle to limit the maximum pressure. XPS is performed without breaking vacuum to prevent oxidation of Co. This work is supported by the Applications and Systems Driven Center for Energy-Efficient Integrated Nanotechnologies (ASCENT), a Semiconductor Research Corporation program sponsored by JUMP and DARPA.

7:00 AM S.EL.01.02.06
Area-Selective Deposition of Titanium Oxide and Titanium Nitride for Nanoscale Patterning Solutions Based on Self-Aligned Tone Reversal Scheme
Mikhail Krishtab¹², Li Zheng¹, Rob Ameloot², Silvia Armini¹, Joey Hung³, Roy Koret⁴, Igor Turovets⁴, Kavita Shah³, Srinivasan Rangarajan³, Laxmi Warad³ and Vanessa Zhang³; ¹imec, Belgium; ²Katholieke Universiteit Leuven, Belgium; ³Nova Measuring Instruments, Inc., United States; ⁴Nova Measuring Instruments, LTD, Israel

Area-selective deposition (ASD)-driven processes gained recently a lot of attention from the microelectronics industry as a potential solution for the issues associated with top-down pattern formation at the nanoscale. However, the defectivity of typical ASD processes relying on delayed nucleation on a non-growth area is one of the key concerns for the adoption of this technology. Among the strategies addressing the defectivity issue, repetitive refreshment of the non-growth surface and selective etching of undesired nuclei are particularly promising.

This work is focused on the ASD of TiO₂ and TiN deposited by atomic layer deposition (ALD). In this respect, as an ALD inhibition route, we have been investigating both halogen plasma surface modification of amorphous carbon materials (non-growth area) and methyl-terminated monomolecular organic films on SiO₂ (non-growth area) substrates. On one side, on a-C non-growth area, we examined the possibility to combine the two defect-reduction strategies by employing low power Cl₂ or CF₄ plasmas for both surface functionalization/re-functionalization and for removal of nuclei. We employed prototypical water-based metal oxide process such as ALD TiOₓ (TiCl₄/H₂O) to demonstrate area-selective deposition on top of silicon oxide using both blanket films and 45-60 nm half-pitch patterns of a-C. At first, the plasma parameters were optimized to minimize etching of a-C and silicon oxide. Then the selectivity of the ALD processes under study was checked on the plasma halogenated a-C films using a standard ALD sequence and a sequence interrupted by the appropriate plasma treatment steps. On the other side, self-assembled monolayers (SAMs) derived from octadecyltrimethoxysilanes allow ASD of >10nm of TiN (TiCl₄/NH₃) at temperatures as high as 325°C. Patterning of SAMs has been deployed to demonstrate successful selectivity and ASD surface dependency.

Special attention in this work is paid to the defectivity analysis of patterned a-C, which typically has surface composition deviating from that of the original coating as a result of employed dry etching. The efficiency of the proposed defect elimination strategy and its impact on resulting pattern quality are assessed using advanced wafer-level metrology including scatterometry and XPS.

5:00 AM *S.EL.01.03.03
Surface Functionalization for Area-Selective Atomic Layer Deposition Adrie Mackus; Eindhoven University of Technology, Netherlands
Future nanoelectronics requires area-selective deposition to eliminate the alignment challenges in the fabrication of multilayered device structures. For example, area-selective atomic layer deposition (ALD) processes of both oxides and nitrides are currently being considered for various applications in interconnect technology, with especially the fabrication of fully self-aligned vias receiving much attention. Most work in the field of area-selective ALD relies on local deactivation of the ALD growth by selective functionalization of the non-growth area. Previous research predominantly focused on surface functionalization using self-assembled monolayers (SAMs), which so far is the most successful approach for achieving a high selectivity.

Our approach to area-selective ALD involves vapor-phase dosing of small molecule inhibitors in ABC-type (i.e. three-step) ALD cycles. One of the main merits of this alternative approach is that it is compatible with industrial process flows, while it also allows for the use of a plasma as the co-reactant and therefore for area-selective ALD of a wider range of materials. It is however more challenging to block the ALD precursor adsorption using small molecules. In order to improve the selectivity of this approach, our current research aims at identifying and designing molecules that can effectively inhibit the ALD growth.

In this presentation, the requirements for the inhibitor molecules will be discussed, which will be illustrated with examples from our experimental and theoretical studies. Results for area-selective ALD of TiN, Al₂O₃, and SiO₂ will be presented, with a focus on the mechanisms of precursor blocking. Special attention will be given on our recent work on using aromatic molecules as inhibitor on metal surfaces.

5:30 AM *S.EL01.03.04
Interface Control between Semiconductor and Gate Dielectric Layer for Highly Stable High Mobility Oxide TFT
Sang-Hee K. Park, Jong Beom Ko and Seung-Hee Lee; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The amorphous oxide thin film transistor (TFT) had been widely applied not only to the display but other electronics such as sensors and semiconductor devices. To secure long term stability of TFT, minimizing charge trapping defects in the interface and gate insulator (GI) would be the most important concern. In the case of amorphous oxide semiconductor, oxygen vacancy (V₀), cation interstitial, ionized Vₐ, oxygen interstitial (Oᵢ), hydrogen interstitial (Hᵢ), hydrogen substitutional are well known defects. Among these, Oᵢ, which is known as oxygen excess, weakly bonded oxygen, peroxide, or metal vacancy is known to be major source of charge trapping center. Meanwhile, Hᵢ, which is known as a shallow donor in oxide semiconductor, can passivate the Oᵢ charge trapping center as does the dangling bonding Si. Therefore, optimization of Oᵢ and Hᵢ is one of the most important processes to secure the stability of oxide TFT. The charge trapping centers in the active and/or interface between active and GI are formed during the process generating oxygen related reactive species such as sputtering for active and PECVD or PEALD process for GI. Comparing these processes, PECVD generates less defects in the channel of TFT thus, top gate TFTs yield better PBTS stability than that of bottom gate TFT. Meanwhile, it still needs careful and precise control of O and H to result in high bias stability with proper Vₐ for the high mobility oxide TFT of which semiconductor has high concentration of carrier amount. It is because Vₐ of high mobility oxide TFT is more sensitive to the addition of H into the active layer than that of typical IGZO TFT. For these reasons, deposition of GI in top gate oxide TFT is carried out at relatively low temperature to minimize the H incorporation into the active layer, giving rise to the degrading stability than that of IGZO TFT. Therefore, optimization of GI process and controlling interface are very important in materialization of high mobility top gate structured oxide TFT with highly stability and proper Vₐ. Here, we scrutinize the effect of Oᵢ and Hᵢ on the formation of the interface of top gate structured high mobility Al: ITZO TFT with double GI consisting of ALD grown alumina (Al₂O₃) and PECVD deposited SiNₓ film. Oxygen plasma treatment was conducted on the active surface and diffusion of H into the interface and/or active layer during thermal annealing was induced from the Al₂O₃ GI to inspect the effect of Oᵢ and Hᵢ, respectively. Here thermal ALD (T-ALD) Al₂O₃ provides H which plays as a passivator of the charge trapping centers in the interface as well as the shallow donor. To control the amounts of H and Oᵢ in the active and/or interface, we did O₂ and N₂O plasma treatment prior to the Al₂O₃ deposition to yield TFTs with improved on/off characteristics. The TFTs with O₂ and N₂O plasma treatment showed 2.08V and 2.34V of Vₐ, respectively. We confirmed that both O₂ and N₂O plasma treatment increase the portion of M-O bonding and reduced the V₀. The O₂ plasma-treated
TFTs with T-ALD GI yield high field-effect mobility over the 35.3 cm²/Vs with improved bias stability compared with that of TFT of which AlOₓ deposited by just PE-ALD. Therefore, we conclude that the T-ALD process for the thin GI deposition can be applied to fabricate even high mobility top-gate structured oxide TFTs by using O₂ or N₂O plasma treatment. The AlOₓ deposited by T-ALD can passivate extra trap sites generated during the supply of the oxygen for the carrier control process of high mobility oxide TFT. This enabled us to obtain high mobility TFTs with high stability and proper Vth. The TFTs fabricated by oxygen plasma treatment, followed by the T-ALD GI deposition resulted in excellent bias stability because of both fine defect control of interface and the carrier concentration.

In situ Ellipsometry Study of Gallium Oxide Plasma-Enhanced Atomic Layer Deposition

Florian Maudet¹, Sourish Banerjee¹, Hanno Kröncke¹, Mattia Mulazzi¹, Veeresh Deshpande¹ and Catherine Dubourdieu¹,²; ¹Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; ²Freie Universität Berlin, Germany

Gallium oxide has attracted renewed interest as an ultrawide band-gap transparent semiconductor. Monoclinic b-Ga₂O₃ is expected to be highly suitable for various applications such as high temperature and ultra-high voltage electronics, photon detectors, gas sensors as well as thin tunneling barriers in various devices. Amorphous gallium oxide has recently been shown to be an effective electron transport layer or an effective passivation layer in solar cells.

In this talk, we will discuss the growth and the characterization of amorphous gallium oxide thin films. The films were grown on (001) Si by plasma-enhanced atomic layer deposition (PE-ALD) using trimethyl gallium as the gallium precursor and oxygen plasma as the oxidizing agent. We will focus on the effects of the starting surface and of the oxygen plasma exposure time. In a temperature range of 100-360°C, the growth per cycle in the ALD growth regime is of ~ 0.67-0.70Å/cycle and the resulting films are amorphous.

In situ characterization during the synthesis was performed by spectroscopic ellipsometry. By applying an expansion of the three-phase equation (air, thin film, substrate) in the thin film limit [1], we were able to determine unambiguously the optical properties (index and extinction coefficient) and the thickness of the thin film unlike with classic ellipsometry modelling that is limited by the non-uniqueness of the possible solutions. With this method, we could precisely determine the thickness evolution of each step of the ALD cycle. We evidenced the reduction of gallium oxide absorption for longer plasma times that can be attributed to a lower defect density. Finally, the leakage currents measured on MOS capacitors will be discussed as a function of the oxygen plasma exposure time. We will show that leakage current densities can be lowered by more than 3 orders of magnitude by adjusting this parameter.

Multi-Metal Coordination Polymers Deposition through a Ternary Hybrid Molecular Layer Deposition Process

Nathaniel Richey, Shirin Borhan and Stacey F. Bent; Stanford University, United States

Atomic layer deposition (ALD) utilizes self-limiting surface reactions to deposit approximately one atomic layer of material per precursor exposure. As such, ALD is a promising technique for the deposition of highly conformal thin films for a wide variety of inorganic materials. Molecular layer deposition (MLD) is a related technique that also relies on self-limiting surface reactions but aims to deposit entire organic molecules instead of single atoms. Hybrid ALD/MLD combines these techniques to deposit coordination polymers in which metal atoms are connected through organic linkers which are typically referred to as “metalcones”. In this talk, we will discuss the deposition of metalcones comprised of more than one metal. We will specifically discuss ternary metalcones formed from mixtures of trimethylaluminium (TMA) and diethylzinc (DEZ) as well as from DEZ and tetrakis(dimethylamido)hafnium (TDMAHf). The growth properties of the multi metalcone films will be discussed, with a specific focus on the challenges these ternary films face due to transmetalation reactions which occur during the deposition and result in non-ideal compositions of the two metals.

Growth of Inorganic Carboxylates as Thin Films

Ola Nilsen; University of Oslo, Norway

The MLD technique could be considered as the ultimate in additive manufacturing where it builds materials one molecular layer at the time from the gas phase. It is based on chemistry and relies on availability of building units from the gas phase. The current presentation will focus on growth of such materials with emphasis on building units containing carboxylic acids. Inorganic carboxylates are mostly stable, offering high saturation of the metal centre’s coordination sphere, leading up to the plethora of such structures as metalorganic frameworks (MOF). Such materials can be grown via the gas phase, and examples
from growth of the UiO-66 series with variations in linker length and complexity will be given, in addition to alternative systems. This introduces concepts such as modulation of growth, reservoir effects, tuning of chemical reactivity, and amorphous porosity. The current contribution will provide highlights from such growth of organic-inorganic hybrid materials including MOF materials.

Electronic Structure of Technologically Important Interfaces and Heterostructures Richard Haight; IBM T.J. Watson Research Ctr, United States

From thin film solar cells to metal-oxide-semiconductor devices in leading edge integrated circuits, the electronic structure at and near the interfaces between component materials determines the most important fundamental operating characteristics of those devices such as turn-on voltage, power dissipation and off-state current leakage. Fermi level location at buried interfaces, semiconductor band-bending, charge transfer, oxide defects and work functions of the constituent materials all contribute to device performance. In this talk I will describe how these important parameters can be determined by employing femtosecond photovoltage spectroscopy (FPS)[1], an extension of ultraviolet photoelectron spectroscopy (UPS) using ultrafast lasers. While UPS is fundamentally a surface sensitive spectroscopy, I will describe how pump/probe techniques add a new dimension to this venerable spectroscopy, permitting the accurate extraction of the underlying band bending in Si. When combined with valence band edge location of the semiconductor and oxide, and determination of the system Fermi level, full characterization of the electronic structure of an MOS stack can be obtained providing key insights on device operating properties. I will describe the use of FPS to investigate device stacks ranging from Si and III-V based MOS structures to thin film solar cells formed from earth-abundant elements. In each case surprising new details were uncovered that led to performance optimization of these technologically important devices.

5:30 AM S.EL01.04.05
Imaging the Electronic Properties of Graphene with Photoemission Electron Microscopy (PEEM) Sujitra Pookpanratana, Steven W. Robey and Randolph E. Elmquist; National Institute of Standards and Technology, United States

The drive for high performance and lower power consumption compels the semiconductor industry to consider novel nanoscale device structures based on non-silicon-based materials. Continued innovation and progress towards novel nanoelectronic materials and devices in turn requires metrology sensitive to electronic properties at these length scales. The electronic properties of a material at length scales relevant to the nanoscale electronic devices define how it will be used and integrated into device functional form. Angle-resolved photoemission (ARPES) is the traditional work horse to determine the electronic band structure of crystalline solids, but typically requires crystalline uniformity on the scale of 1 mm². Tip-based scanning probe techniques provide electronic contrast with sub-nanometer resolution, and therefore is a local technique. Photoemission electron microscopy (PEEM) can be employed to allow access to this vital information, providing full-field imaging capabilities sensitive to a variety of electronic contrast mechanisms at 10’s of nanometers length scales. The new generation of PEEM has energy filtering capability which now allows for ARPES measurements at smaller length scales (100 μm²; known as μ-ARPES). Here, we will discuss the commissioning of a recently installed PEEM at NIST, using results of graphene to demonstrate imaging capability and energy resolution of this instrument.

Graphene was grown epitaxially on 4H-SiC (0001) in a custom vacuum furnace at NIST [1] and transferred into the PEEM vacuum chamber. The PEEM instrument is equipped with continuous wave excitation sources in the deep ultraviolet (UV) regime, and a magnetic prism array for electron energy filtering. The terraces due to the underlying SiC substrate can easily be discerned since the PEEM provides imaging contrast due to topography and electronic contrast, and the terrace edges can be resolved to 50 nm. There are three primary regions in PEEM images that we assign as the (i) interfacial layer, (ii) 1-2 layer graphene, and (iii) “bulk” graphite regions. The sample surface is mostly dominated by regions with 1-2 layers of graphene for which μ-ARPES was performed at 8 μm length scales. The electronic structure of these regions is consistent with
previous reports (e.g., [2]), with the \( \pi \) band and \( \sigma \) band dispersions clearly resolved. The Dirac point lies below the Fermi energy, consistent with n-doping present in graphene grown on SiC. We will also use confocal laser microscopy to correlate with the PEEM results. Finally, we will discuss our plans on advancing the lab-based PEEM capability with coherent, monochromatic laser-based photon sources.

near the band edge of a Si photovoltaic cell. Multishell luminophore systems with CsSnI₃ and InAs cores are synthesized to improve luminophore quantum yield and to reduce parasitic self-absorption. The advantage of incorporation of these NIR emissive cores into shelled systems is multifaceted: (1) wider bandgap protective shells improve quantum yields through passivation of surface traps, (2) large shell to core volume ratios reduce parasitic self-absorption by separating the energies of absorbance by the shell and emission from the core, and (3) the surface of the outer shell can be post-synthetically modified to tune the luminophore’s aggregation properties and interactions with polymer waveguides without damaging the emissive properties of the core. Despite their clear potential role in LSCs, NIR emissive quantum dots have lagged behind their visible region fluorescent counterparts due to lower quantum yields and more limited precursor availability. This work develops synthetic and post-synthetic strategies for obtaining bright, near infrared emissive heterostructure quantum dots with a specific interest to incorporate them in LSCs with Si microcells.

5:30 AM S.EL01.05.05

Anisotropic emitters such as gold nanorods[1], quantum rods[2] and organic dye-doped rods[3] have been exploited as orientation probes. Their orientation analysis is based on comparing the emitted light intensities measured with different excitation and emission polarizations. However, the practical use of this technique requires overcoming several problems: (i) various sources of signal fluctuation: blinking and bleaching of emitters, unstable excitation power, instrumental noise… (ii) Polydispersity of emitter particles affecting the signal’s degree of polarization (DOP), (iii) complicated optical setup with multiple directions of excitation and emission.

Here we present a straightforward and accurate orientation analysis through a purely spectroscopic method using lanthanide luminescence. Nanocrystals doped with europium ions (Eu³⁺) exhibit unique photoluminescence (PL) spectra composed of a number of sharp peaks originating from the multiple 4f transitions and degenerate sub-levels due to the crystal-field splitting. Each of those sub-level peaks is polarized along a certain direction independent to others. Therefore, the orientation of a nanocrystal can be represented simply by the line shape of the polarized emission spectra regardless of its global intensity that can fluctuate due to other causes. This spectroscopic method enables three-dimensional (3D) orientation analysis on a single measurement plane not even taking into account the excitation polarization[4]. The polarization of Eu³⁺ emission is determined only by the crystal structure and not by the particle morphology, which makes the analysis reliable even with polydisperse particles. Moreover, the Eu³⁺ emission is highly photo-stable and free from photo-bleaching or blinking. We used Eu³⁺-doped monocrystalline NaYF₄ nanorods as a proof of concept 3D orientation probes. The nanorods were solvothermally synthesized and randomly suspended in a polymer matrix (PVA - Polyvinylalcohol). By performing the conventional scanning confocal microscopy, polarized fluorescence spectra of single nanorods were obtained, from which the spherical angles (θ, φ) of rod orientation were calculated with high accuracy.

This new spectroscopic method to determine 3D orientation of nanoprobe offers a unique opportunity to unveil the complex dynamics of bio-molecular systems (e.g. rotating proteins) and also the ensemble behavior of nanoparticles (e.g. self-assembly).

5:45 AM S.EL01.05.07
Synthesis of Highly Luminescent CsPbX₃ (X = Cl, Br, and I) Nanoplates via AlX₃-Ligand Mediated Anion Exchange of CsPbCl₃ Nanocubes at Room Temperature Md Aslam Uddin and Kenneth R. Graham; University of Kentucky, United States

Two-dimensional metal halide perovskite nanoparticles show great potential for use in optoelectronic devices because of blue-shifted absorption relative to their 3D counterparts, narrow emission line widths, high absorption cross sections, and high radiative recombination. Two-dimensional CsPbX₃ nanoparticles have been synthesized using hot injection methods, solid state crystallization methods, microwave-assisted assisted methods, as well as high temperature-and-pressure methods. Herein, we show a different approach relying on rapid anion exchange between CsPbCl₃ nanocubes and a mixture of dodecanethiol (DDT) & AlX₃ (X = Cl, Br, I) to transform CsPbCl₃ nanocubes into CsPbX₃ nanoplates at room temperature. The combination of both DDT and AlX₃ is necessary to facilitate nanoplate formation and maximize the photoluminescence quantum yield, Φₚᵢᵢ, and stability. Either DDT or AlX₃ addition alone will result in improved Φₚᵢᵢ, but without the formation
Measurement is Scanning Spreading Resistance Microscopy (SSRM). This technique simultaneously measures both electrical and lateral force from continuous tip-sample contact. In addition, the integration of these methods with AFM enables acquiring electrical information during a scan. This method operates in an approach-retract manner ensuring a frictionless operation, which eliminates the problems encountered in electrical property measurement. Scanning Spreading Resistance Microscopy (SSRM). This technique simultaneously measures both electrical and mechanical properties of electrode surfaces during continuous tip-sample contact during scanning. Recently, a new operational AFM mode developed by Park Systems called PinPoint™ can be coupled with SSRM to offer scientists and engineers an innovative solution to avoid the troublesome frictional forces during a scan. This method operates in an approach-retract manner ensuring a frictionless operation, which eliminates the lateral force from continuous tip-sample contact. In addition, the integration of these methods with AFM enables acquiring topography as well as electrical/mechanical property data simultaneously without changing the sample or tip. Here, we demonstrate that PinPoint™ SSRM effectively measures both electrical and mechanical properties of LIBs electrode surfaces at a much higher quality in high vacuum environment than in ambient condition using a Park NX-Hivac AFM system.

Electrical and Mechanical Characterization of Li-Ion Battery Electrode Using Pinpoint™ Scanning Spreading Resistance Microscopy
Byong Kim, John Paul Pineda, Cathy Lee and Keibock Lee; Park Systems, Inc., United States

Lithium ion batteries (LIBs) are key components of modern electronics and are regularly utilized as their primary power source. LIBs have become ubiquitous in a variety of applications ranging from portable devices to electric vehicles because of their high energy density, flexible and lightweight design, lower self-discharge, low cost and longer lifespan compared to other battery technologies. Despite these advantages, the reliability and performance of LIBs still need to be upgraded to meet the requirements of applications such as large-scale energy storage and hybrid electric vehicles. Extensive research has focused on the development of four cell materials in particular to achieve better performance: positive and negative electrode active materials as well as separators and electrolytes. Understanding the electrical and mechanical properties of electrode materials plays a major role in the performance improvement of LIBs. It has been shown that improved adhesion between electrode particles, electrode films and current collectors leads to better retention of discharge capacity during cycling, especially when electrode materials exhibit faster and/or larger volume expansion. Moreover, enhanced electronic conductivities and ionic diffusivities in electrodes also lead to LIB capacity improvements. As devices are becoming more compact, optimizing electrical and mechanical properties on a nanometer scale becomes more relevant and leads to improved interfaces.

There are several methods which can measure these local properties; the more common methods include impedance spectroscopy and nanoindentation. However, even using both methods, one cannot get the full local information about the aforementioned properties. Impedance spectroscopy needs an exact model and only distinguishes between interfaces, and therefore does not have local information for each interface. Nanoindentation is destructive and does not provide any electrical information. One of the more effective tools used to overcome the problems encountered in electrical property measurement is Scanning Spreading Resistance Microscopy (SSRM). This technique simultaneously measures both electrical properties and topography. However, SSRM has some disadvantages, such as rapid wearing of the tip, degradation of image resolution and low signal-to-noise ratio. These disadvantages stem from the high frictional force arising from continuous tipsample contact during scanning. Recently, a new operational AFM mode developed by Park Systems called PinPoint™ can be coupled with SSRM to offer scientists and engineers an innovative solution to avoid the troublesome frictional forces during a scan. This method operates in an approach-retract manner ensuring a frictionless operation, which eliminates the lateral force from continuous tip-sample contact. In addition, the integration of these methods with AFM enables acquiring topography as well as electrical/mechanical property data simultaneously without changing the sample or tip. Here, we demonstrate that PinPoint™ SSRM effectively measures both electrical and mechanical properties of LIBs electrode surfaces at a much higher quality in high vacuum environment than in ambient condition using a Park NX-Hivac AFM system.

Approaching the Conductivity Limits of Aerosol Jet Printed Silver
Eva S. Rosker1,2, Michael T. Barako3, Rajinder Sandhu3, Mark Goorsky1 and Jesse Tice2; 1University of California, Los Angeles, United States; 2Northrop Grumman Aerospace Systems, United States

Most efforts to directly write conductive metal traces have focused on nanoparticle ink suspensions that require aggressive sintering (>200°C) yet exhibit low density, small grains, and a maximum electrical conductivity of ~25% of bulk silver [1]. Here, we demonstrate an alternative approach to printing high conductivity metals using a reactive ink solution, where a molecular precursor reacts into a highly dense (>90%) silver film at a low temperature (80°C) compatible with conventional additive manufacturing processes. We show that by reducing porosity and transitioning from interface-rich sintered nanoparticles to dense solid metals, we achieve DC conductivities up to ~75% of bulk silver for aerosol jet printed conductive traces, which aligns with our predictive microstructural transport model. Furthermore, we show through an initial demonstration that the RF performance of these devices far exceeds that of standard printed transmission lines and competes with conventional electroplating techniques. This work demonstrates a path toward high performance printed RF passive components that are robust and reliable for disruptive opportunities in aerospace materials and manufacturing processes.

6:30 AM S.EL01.05.13
Nanotribology of Phosphonium Phosphate Ionic Liquid—A Combined Atomic Force Microscopy and Surface Spectroscopic Study Filippo Mangolini1, Zixuan Li1, Oscar Morales-Collazo1, Jerzy T. Sadowski2, Hugo Celio1, Andrei Dolocan1 and Joan F. Brennecke1; 1The University of Texas at Austin, United States; 2Brookhaven National Laboratory, United States

Ionic liquids (ILs) have gained considerable attention in the last two decades owing to their unique and tunable physico-chemical properties (e.g., low vapor pressure, and high thermal stability), which have made them potentially useful for a range of applications, including batteries, fuel cells, catalysis, and lubrication. Ionic liquids are particularly attractive in lubrication, since their properties make them suitable for components working under extreme conditions (e.g., high temperatures, low pressures), such as those found in engines, spacecraft, and micro-electromechanical systems. When ILs are used as lubricants, the interface between the IL and the surfaces of the components in relative motion plays a pivotal role in controlling the friction and wear response. Despite the scientific weight of published studies on the tribology of ILs, remarkably little is still known about the underpinning lubrication mechanism of ILs. The development of a fundamental understanding of the mechanism by which ILs reduce friction and/or wear requires shedding light on the processes occurring at nanoscale asperities within macroscale contacts. This constitute a significant challenge since observing and understanding the nanoscale mechanisms at play is inhibited by the hidden nature of the buried interface and the challenge of performing observations at the nanometer scale.

Here, we used atomic force microscopy (AFM) to visualize and quantify the processes occurring at sliding interfaces in situ, in single-asperity nanocontacts1. In contrast to macroscale tribological experiments, where the multi-asperity nature of the contact does not allow for the accurate control of local contact stresses and geometries, in situ AFM studies, where the AFM tip mimics a single asperity in a multi-asperity macroscale contact, enable the precise control of critical parameters (e.g., contact stress) affecting mechano-chemical reactions, the visualization and quantification of phenomena occurring at tip/substrate interfaces (e.g., mechanically-induced nucleation and growth of films), and the local characterization of nanoscale properties (e.g., friction and adhesion). The AFM experiments, in which a diamond tip was slid on steel in phosphonium phosphate IL (PP-IL) at high contact pressure (>5 GPa), indicated a significant friction reduction only after the removal of the native surface oxide from steel. Even though the AFM experiments allowed for the identification of changes in topography and friction in situ while sliding in PP-IL, they could not provide any information about the composition and structure of the regions scanned by AFM. The analysis of these regions is a challenging surface science problem owing to their limited dimensions and the small thickness of the surface material modified by the mechanical action of AFM tips. To address this challenge and elucidate the origin of the friction reduction observed during AFM experiments, laterally-resolved ex situ analyses of the surface chemistry of steel were performed by synchrotron-based X-ray photoemission electron microscopy (X-PEEM), low energy electron microscopy (LEEM), and time-of-flight secondary ion mass spectrometry (ToF-SIMS). The analytical results indicated that the mechanically-induced exposure of metallic iron during AFM tests carried out in PP-IL leads to an increase in surface coverage of adsorbed phosphate anions together with a change in surface potential. Based on these results and atomistic simulations of the configuration geometry of phosphate ions on metallic and oxidized iron2, a simple phenomenological model is proposed to account for the observed lubrication behavior.

Photovoltaic and Photoconductive Action Due to PbS Quantum Dots on Graphene/SiC Schottky Diodes from NIR to
UV Mathew Kelley, Joshua Letton, Grigory Simin, Fiaz Ahmed, Cole Love-Baker, Andrew B. Greytak and MVS Chandrashekhar; University of South Carolina, United States

We demonstrate photovoltaic and photoconductive responses to near-infrared light in a new class of devices formed by depositing a film of gel permeation chromatography purified PbS quantum dots (QDs) on top of n-SiC epitaxial layers with natively grown, 10-15 monolayer thick epitaxial graphene (EG) Schottky contacts. The QD-film was removable by selective chemical etching, resetting the EG/SiC Schottky diode to its pristine state for multiple PbS-QD depositions. EG in these devices simultaneously forms Schottky contacts to SiC and ohmic contacts to PbS-QD, enabling electrical screening and isolation of these interfaces from each other. After PbS-QD deposition, the diodes exhibit photovoltaic and photoconductive response at photon energies far below the SiC bandgap, extending to the NIR gap of the QD film. Scanning photocurrent microscopy illustrates that this is due to charge transfer from the QD-film to the n-type 4H-SiC through a trap-limited, rectifying PbS-QD/SiC heterojunction with ideality n=2 in parallel with the EG/SiC Schottky diode. The photoconductive gain at this QD/SiC interface could be useful for IR detection in wide bandgap platforms. Response times as fast as 40 ms are suitable for imaging applications, although careful contact design is required to optimize work-function matching and spreading resistance.

S.EL01.06.13

A Review on Controlling Nano-Scale Chemically Modified Thin Films for CMP Processes Development

G. Bahar Basim; University of Florida, United States

As the microelectronics manufacturing faces the challenges related to the Beyond Moore’s Scale adaptation, Chemical Mechanical Planarization (CMP) process control becomes much more critical yet difficult simultaneously. The need for planarizing larger scale wafers at an atomic scale precision with superior removal rate selectivity and zero-defect focus demands a nano-scale control on the process performance. This study reviews the atomic-scale chemical and mechanical interactions on CMP as it applies to traditional as well as the next generation materials in microelectronics manufacturing. Once the behavior of the wafer surface is understood at an atomic level, the process control metrics can be tuned accordingly.

In an attempt to come up with the design criteria for the slurry chemistry, chemically modified layer formation is evaluated on conducting, semiconducting and insulating materials as a function of evaluating the nano-scale surface topography and change in surface energy. Metallic films are studied in terms of their corrosion and passivation behavior through macro-scale electrochemical evaluations as well as surface-sensitive characterization techniques such as XRR, XRD and FTIR [1, 2]. In addition, a modeling approach is introduced through Cahn Hilliard Equation (CHE) approximation to the surface energy minimization on the metal-oxide formation by nucleation [3]. Furthermore, removal rate selectivity properties of the semiconductor materials are discussed on conventional and III-V semiconductors and insulators as a function of chemically modified film alteration [4-5]. Some high-end applications such as (i) tungsten T-gate transistors, (ii) new liner/barrier materials [6], (iii) germanium based high-speed, shallow trench isolation transistors and (iv) high-power transistors and LED applications where III/V semiconductors are deliberated. As a new challenge, 3-D implementations of the CMP process, where the chemically modified nano-films impact the performance of the materials are also introduced.

Investigation of Buried Junctions in CdSexTe1-x / CdTe Devices Sean Jones1,2, John Moseley2, Harvey Guthrey2 and Brian Gorman1; 1Colorado School of Mines, United States; 2National Renewable Energy Laboratory, United States

CdSexTe1-x alloys now used in state-of-the-art CdTe solar cell technology can be further characterized and optimized. Se alloying can significantly reduce the bandgap of the CdTe absorber due to the strong bandgap bowing between CdTe and CdSe. This has been demonstrated to enhance quantum efficiency in the infrared and boost the device short-circuit current (Jsc). Interestingly, despite having a lower bandgap, devices using Se have achieved open-circuit voltages (Voc) on par with (unalloyed) CdTe-based devices. Recent time-resolved photoluminescence and cathodoluminescence data suggest that the CdSe/CdTe interfaces have lower recombination rates and improved grain-boundary passivation relative to CdTe, and this appears to be making up for bandgap-related Voc losses[1]. Further characterization studies should reveal additional relationships between absorber processing and the CdSexTe1-x composition, current collection, recombination, etc., that can be used to optimize device performance.

There are two methods of CdSexTe1-x growth. The first method creates a CdSe window layer for a CdTe device then allows diffusion to create a dopant gradient. The second processing method deposits a CdSexTe1-x alloy layer and then a CdTe layer. Previous characterization studies have focused on the CdSe/CdTe device structure and the effects of changing window layer thickness and composition. A study by Poplawsky, et al. [2], indicated that, as CdSe window thickness increased, device performance increased then quickly decreased. Quantum efficiencies and correlative SEM/TEM analysis indicated that if the Se concentration was above 40 at%, grains could change phases from zinc-blende to wurtzite and stop contributing to the device photocurrent. In the CdSexTe1-x/CdTe structure, the Se concentration can be kept below 40 at% to prevent the formation of the wurtzite phase.

To better understand the impact of Selenium concentration on device photo-collection, an Electron Beam Induced Current (EBIC) study is presented which studies the impact of Selenium on device collection for the CdSexTe1-x/CdTe device structure. EBIC is an SEM-based characterization technique which uses an electron beam to locally excite carriers, which are subsequently collected and analyzed to understand microstructural effects on recombination. A current collection map can thus be created with sub-micron resolution. EBIC has been previously used to identify local variation in collection current such as microstructural features such as heterojunction interfaces and grain boundaries[2]. In this study, selenium concentration was varied in the alloy layer from 0 to 40 atomic percent while maintaining constant deposited layer thickness.

EBIC analyses of these alloy junctions indicate that the highest carrier collection was near the CdSexTe1-x/CdTe interfaces with a second collection peak near the TCO/CdSexTe1-x interface. This finding is indicative of a buried junction in the CdSexTe1-x/CdTe device. Previous studies on the CdSe/CdTe structure have shown highest collection near the TCO contact with no buried junctions. The position and strength of this buried junction could decrease the efficiency of interface recombination at the TCO interface, but it could also decrease drift velocity, negatively impacting performance. These competing effects need to be better understood for the optimization of CdSexTe1-x/CdTe device performance.

The presence of a buried junction in the CdSexTe1-x/CdTe device implies a complex change in carrier concentrations and band structure within these devices. In order to better understand the implications of this observation, these results are correlated with a finite element device model. Using this model, it is possible to calculate the equilibrium band structure of the device and estimate the built-in potential between each junction.

S.E.L01.06.31
Experimental Study of Fundamental Material Properties of Alkali-Antimonide Photocathodes Pallavi Saha1, Oksana Chubenko1, Howard A. Padmore2 and Siddharth Karkare1; 1Arizona State University, United States; 2Lawrence Berkeley National Laboratory, United States

Alkali antimonides (such as Cs,Sb, K,CsSb and Na,KSb ) constitute a rather interesting class of materials, exhibiting high quantum efficiency (>10%) and high brightness in visible light making them interesting materials for use in photon detectors and as photoemission based electron sources for large linear particle accelerators (used for X-ray Free Electron Lasers, Electron Colliders and Hadron Beam Coolers) and time resolved electron microscopes. Despite ongoing work on these extremely vacuum sensitive materials for the last several decades, there has been no conclusive understanding and little/ no consensus on its opto-electronic properties like band gap, electron affinity, optical constants etc. Lack of knowledge of these vital properties has stood in the way of understanding the process of photoemission in these materials near the photoemission threshold. The objective of our work is to grow high quality alkali-antimonide films with smooth surfaces and perform different spectroscopic characterizations like photoluminescence, photoconductivity and ellipsometry on them, in order to explore their opto- electronic properties in ultra high vacuum. It is believed that this detailed experimental study will elucidate the exact process responsible for efficient photoemission from these materials and allow us to develop state-of-the-
art electron sources with maximized brightness.

S.EL01.06.07
Comparative Study of Surface Energy Engineering for Low Temperature (< 453 K) Nanobonding™ of LiTaO₃ and LiNbO₃ to Si and α-Quartz SiO₂
Mohammed Sahal, Brian Baker, Nicole Herbots, Nikhil C Suresh, Shaurya Khanna, Amber A Chow, Saaketh R. Narayan, Aashi R. Gurijala, Robert J. Culbertson, Lauren Puglisi and Thilina N. Balasooriya; Arizona State University, United States

Opto-electronic integration yields high density and high complexity electronic devices by improving speed and reducing interconnection bottle-necks. Heteroepitaxy and wafer bonding are the main technologies to achieve monolithic integration of heterogeneous materials. However, heteroepitaxy is limited by the mismatches between dissimilar lattice constants and between different coefficients of thermal expansion (CTE).

Direct Wafer Bonding (DWB) is the fusion of two mirror-polished, flat wafers, which overcomes the limitations of heteroepitaxy. DWB can be applied to many materials including bonding III–V, II-IV semiconductors and piezoelectrics to Si.

In this work, low-temperature DWB via NanoBonding™ is investigated to bond LiTaO₃ and LiNbO₃ to Si(100) and α-quartz SiO₂(100). Low-temperature NanoBonding™ of piezoelectrics such as LiTaO₃ and LiNbO₃ on Si-based materials can avoid issues arising from their CTE mismatch, since conventional DWB requires anneal temperature > 673 K.

The highly anisotropic CTE of LiTaO₃ ranges from ~ 4 x 10⁻⁶/K along the c-axis to up to ~ 16 x 10⁻⁶/K along the a-axis. Thus, the CTE for LiTaO₃ is 2-10 times larger than the CTE for Si, 2.6 - 2.77 x 10⁻⁶/K, and 10-30 times larger than the CTE for fused SiO₂ and α-quartz SiO₂, which ranges 0.54 - 0.76 x 10⁻⁶/K. Thus even a low T anneal at 473 K is found to shatter a 6” LiTaO₃/Si bonded pair. Nano-Bonding™ at T < 473 K uses Surface Energy Engineering (SEE) instead of high temperature anneal to bond surfaces. In addition, processing temperatures for LiTaO₃ are found to be limited by thermal decomposition LiTaO₃ into Ta₂O₅ at T ≥ 453 K due to Li out-diffusion, as much as by LiTaO₃ fractures due to CTE mismatch.

SEE is guided by surface energy and hydro-affinity measurements, using Three Liquid Contact Angle Analysis (3LCAA) and the Van-Oss-Chaudhury-Good theory. 3LCAA is conducted with high statistics, by mapping wafers for three surface interactions, namely van der Waals interactions, electron donors, electron acceptors interactions. Multiple metered 10-µl drops of three liquids, water, glycerin, and α-bromo-naphthalene are used. The contact angles are extracted from a large set of drops and their reflection via an automated, fast, accurate algorithm, DROP™. The “as received” surfaces are characterized at equilibrium, to yield insights for SEE into modifying the initial surface energy and hydro-affinity to a far-from-equilibrium state.

As received 6’’ Si(100) wafers are initially hydrophilic with a uniform average water contact angle of 37.7 ± 0.6°, and an average surface energy γT of 57.6 ± 0.5 mJ/m². As-received α-quartz SiO₂(100) wafers surface were hydrophobic with an average water contact angle of 66.7 ±1.7° and an average γT of 33.2 ± 0.8 mJ/m². 6’’ wafers of LiTaO₃ are initially mostly hydrophobic with an average water contact angle of 64.4 ± 2.7°, while water contact angle average 54.2 ± 8.1° LiTaO₃ and LiNbO₃ surface energies γT are low and very close: 38.8 ± 4 mJ/m² and 39 ± 2.5 mJ/m² respectively.

SEE via aqueous HF creates far-from-equilibrium Si surfaces by decreasing the initial γT of Si(100) from 57.6 ± 0.5 mJ/m² to 35 ± 0.03 mJ/m² and increasing the γT of α-quartz SiO₂(100) was increased from 33.2 ± 0.8 mJ/m² to 48.7 ± 1.5 mJ/m². Likewise, LiTaO₃ and LiNbO₃ were made hydrophilic via SC1(H₂O:NH₄OH:H₂O₂) solution (4:1:1) followed by aqueous HF etching.

Nano-contacting of LiNbO₃, LiTaO₃ on Si(100) and α-quartz SiO₂(100) and subsequent anneal at T < 453 K was performed to create a bonded interfacial phase. However, nano-contacting was only observed for hydrophobic LiTaO₃ and LiNbO₃ with hydrophilic Si-based surfaces. Results show that bonding hydrophobic LiTaO₃ and LiNbO₃ to hydrophilic Si or SiO₂ without anneal is much more effective than trying to bond hydrophilic LiTaO₃ to hydrophobic Si or SiO₂. This can be attributed to the modification of surface polarity and will be discussed based on the surface crystallography of LiTaO₃ and LiNbO₃.

Enhancing Nucleation of Metal ALD by Pre-Dosing Small Organometallic Molecules
Camila de Paula, Nathaniel Richey, Li Zeng and Stacey F. Bent; Stanford University, United States
The process of thermal atomic layer deposition (ALD) of metals on non-metal surfaces is sought for many applications, but often suffers from nucleation delays that result in poor-quality films. These growth delays can result from a lack of suitable chemisorption sites on the non-metal surface. Various strategies have been explored to improve nucleation in these systems. Vapor phase pre-treatments have proven to be an especially promising nucleation enhancement strategy due to the minimal substrate-modification induced, its robustness, and its uniformity.

In this work, we demonstrate that pre-functionalizing the surface with a sub-monolayer of small organometallic molecules such as ZnEt₂, AlMe₂, and AlMe₂Cl, from the vapor phase can lead to a significant increase in the surface coverage of the metal deposited by ALD at low cycle numbers. This process is demonstrated using Pt ALD as a model process, using (methylcyclopentadienyl)trimethylplatinum (MeCpPtMe₃) and O₂ as reactants. Pt coverage was enhanced by ~3-fold after 100 ALD cycles and even larger enhancements were observed at lower cycle numbers following the pre-treatment. We hypothesize that the high coverage of the small organometallic molecules provides an alternative chemisorption mechanism for the platinum precursor leading to increased MeCpPtMe₃ chemisorption during the first ALD cycle. This alternative chemisorption mechanism was investigated through in-situ X-ray photoelectron spectroscopy and mass spectrometry.

Nanoparticle growth was monitored using grazing incidence small angle X-ray scattering and scanning electron microscopy. We determined that chemisorption of MeCpPtMe₃ on the treated substrate originates from a Brønsted acid-base reaction (i.e., proton transfer reaction), where the MeCpPtMe₃ acts as the Brønsted acid and the pre-treatment molecules serves as the Brønsted base. Growth analysis indicates that the pre-treatment leads to growth of highly dense, ordered Pt nanoparticles with improved wettability at low cycle numbers, leading to continuous and pinhole free Pt films.

Low Temperature c-Si/4H-SiC Heterojunction Growth Using Metal Induced Crystallization Fabian Trienkl, Georg Pfusterschmied, Christopher Zellner, Sabine Schwarz, Werner Artner and Ulrich Schmid; Technische Universität Wien, Austria

Metal induced crystallization is a well-known technique to reduce the crystallization temperature of amorphous semiconductors like a-Si using a catalytic metal. Crystallization temperatures even below 200 °C have been realized making it compatible with organic materials or other applications where only a limited temperature budget is acceptable. A combination of the wide band gap semiconductor 4H-SiC and such a low temperature process is barely investigated, although the Si/4H-SiC heterojunction offers huge potential in the field of e.g. heterojunction diodes, bipolar junction transistors and optical detectors. Conventional growth methods like chemical vapor deposition (CVD) need temperatures well above 800 °C to achieve epitaxial growth of Si on SiC. A low temperature method could make this heterojunction more practical, also in combination with other materials and temperature sensitive processes.

We present the first results to achieve partially epitaxial c-Si/4H-SiC interfaces using Al as catalytic metal. Sputter deposited amorphous silicon has been successfully crystallized on 4H-SiC at temperatures ranging from 350 to 700 °C. Annealing led to an almost complete layer exchange of Al and Si as well as to a heteroepitaxial interface of crystallized Si islands and the SiC surface. Si <111> was found to be the dominating crystallographic orientation of the re-crystallized Si. X-ray diffraction measurements show the change in Si crystallinity and the crystallographic impact of the underlying SiC substrate in this temperature range. TEM and SEM imaging was performed to investigate the film microstructure and the interface quality, thus revealing a clean and abrupt interface of large Si grains and the SiC substrate.

S.EL01.06.87
Strongly Structure-Directed Phonon Dynamics in GaAs Observed by Ultrafast Electron Microscopy Elisah VandenBussche and David J. Flannigan; University of Minnesota Twin Cities, United States

The process by which strongly-photoexcited semiconductors return to their ground state consists of a series of complex, strongly-correlated many-body interactions which overlap in space and time, resulting in an evolution of behaviors that is both difficult to study and valuable, both for fundamental insights into the quantum nature of matter and for control of device and material behaviors in electronic and optoelectronic applications. Extensive work has been done in this regard, illuminating the sequence of hot carrier excitation, carrier-carrier scattering, carrier-lattice scattering and thermalization, recombination, and lattice heat diffusion. After strong photoexcitation creates a high-energy bath of “hot” carriers, electron-phonon coupling results in the emission of optical phonons, which decay into lower-energy phonons, either optical or acoustic. The resulting nonequilibrium phonon populations can in turn influence hot carrier relaxation and transport, an inextricability which has been demonstrated through transient Raman scattering [1-3]. The inseparable nature of structural behavior from that of excited electron-hole plasmas is further demonstrated by the result that when not in equilibrium, acoustic mode phase velocities change as a function of time due to residual Coulomb interaction caused by imperfect
As electronic devices continue to shrink, the associated increased importance of device surfaces, interfaces, and defects add an additional layer of complexity to the structural behavior. Techniques typically employed to investigate post-excitation responses operate in reciprocal or momentum space and require spatial averaging, reducing real-space resolution. It is known that interfaces change the electronic structure in their surrounding regions, strongly influencing carrier dynamics, and it has been shown in our previous work that phonons are structure-directed, propagating specifically from interfaces and repeatedly traveling perpendicularly to the launching interface [5]. In sum, electron-phonon coupling behaviors are known to be influenced by structure, making real-space information relevant to a complete picture of post-excitation behavior.

Here we use ultrafast electron microscopy (UEM) to image phonons in real space and thereby demonstrate the influence of both the meso-scale and atomic structure of GaAs on the post-excitation phonon behavior. Making use of combined picosecond-nanometer real-space resolutions, we have directly imaged excitation of GHz coherent strain waves propagating exclusively from specimen-vacuum interfaces with initial hypersonic velocities which decay over time to the speed of sound in GaAs. We also report the change in the properties of these waves upon laser annealing of the specimen, epitaxially crystallizing the focused-ion-beam-induced amorphous surface layer and resulting in measurable hardening of the specimen. This appears in the phonon behavior as an increase in the velocity of the phonons. By imaging the phonon interactions with both the specimen-vacuum interface and the amorphous-crystalline interface within the specimen, we demonstrate the importance of interfaces in fully understanding the phonon dynamics in photoexcited GaAs.

Direct Write Waveguides Using Multiphoton Lithography Michael Gallegos, Daryl Dagel, Amber Dagel, Andrew Pomerene, Allen Vawter, Erik Skogen and Bryan Kaehr; Sandia National Laboratories, United States

Abilities to capture, guide, and direct light into pixelated detectors (CCDs, CMOS sensors, FPAs, etc.) using free-form trajectories would be transformative for a range of technologies that currently use traditional optics (lenses, mirrors, prisms, etc.) for light coupling. However, few manufacturing techniques provide the appropriate scale and surface quality to address this task. In this work, we consider “free-form waveguides” using the high-resolution 3D printing technique of multiphoton lithography (MPL; also known as direct laser writing, DLW). First, we printed hollow and solid core vertical waveguide arrays spanning millimeters with single (5 micron) and multimode (30 micron) compatible cross-sections. Unsupported 5-micron diameter pillars generally succumbed to capillary forces during development and drying and thus sheathed waveguides were designed by anchoring fibers to a support scaffold. In addition, we examined direct printing onto active devices (coupling a source to a sensor) using an air-clad multimode design. Efficient light coupling was observed with scattering losses primarily from fabrication artifacts such as stitch lines. To address these issues, we considered stitch-free cores using a clad-only design resulting in encapsulated photoresist in the interior that is subsequently cured (UV, thermal) following development. These initial results, combined with the limitless design space afforded the MPL technique, provide a promising path forward to develop ultra-wide-field and highly compact imaging devices.

Effect of Si Nanoparticles on Reflectance Spectra for Ge and Ge/Si Substrates Sabina Abdul Hadi1, Ayman Z. Rezk2 and Ammar Nayfeh2; 1University of Dubai, United Arab Emirates; 2Khalifa University, United Arab Emirates

The continuous innovation in nano materials has allowed the development of new antireflective coats (ARCs) for optical lenses, solar cells, data storage, displays and others that require a reduced reflectance to increase efficiency. Multi-layered ARCs particularly have attracted attention lately for demonstrating low and tunable spectral reflectance.

This paper presents a simple approach for forming anti-reflective coating stacks on bulk Ge and PECVD Ge grown on Si employing colloidal dispersions of Si nanoparticles (NPs).

The Si NPs have a diameter of 2.85 nm and are prepared by chemical etching of crystalline Si wafers in HF and H2O2 using electrical or hexachloroplatinic acid catalyst. The nanoparticles are recovered by sonicating the wafers in isopropyl alcohol, forming a stable colloid with concentration of 10 µM [1].
Each antireflective coat is applied by the drop casting of monodispersed Si NPs on a 3 by 3 cm pieces of both Ge bulk and PECVD Ge grown on Si. A total of 5 drops are applied with each drop consisting of 100 µL. After each drop, the samples are left to dry for an hour and a half.

For bulk Ge, (110) Sb doped (n-type) Ge with a resistivity of 0.1–0.5 Ωcm were used, while for the PECVD Ge growth, (100) P doped (n-type) Si with a resistivity of 0.01–0.02 Ωcm are used as starting substrates. An Oxford Instrument System 100 PECVD activated by 13.56 MHz radio frequency signal is used to grow Ge layers on Si substrates. High purity germane (GeH₄), H₂, and Ar gases are used as precursors for Ge growth. The undoped Ge film was grown using the two-step approach, which has been described in detail in our previous work [2].

The impact of multiple drop casting of Si NPs on the antireflective properties of the Ge surfaces were investigated by the analysis of their reflection spectra. The reflectance of the coating was measured at four locations on each sample by a UV–VIS spectrophotometer (Lambda 850, PerkinElmer). The samples were qualified by controlling the reflectance at the four points within an error of 1.2%. The corresponding reflection spectra were captured as a function of the incident wavelength, ranging from 250 nm to 1500 nm.

For PECVD Ge grown on Si substrates, the average reduction in reflectance has shown to increase as the incident wavelength decreases, with a decrease of ~2% after each 100 µL coating. After 5 drops (100 µL ×5), the overall reflectance across the whole spectra is on average 9.35% lower compared to the uncoated samples. The minimum decrease in reflectance was of 2.49% at 1290 nm and the maximum of 34% at 250 nm.

For Bulk Ge, the average reduction in reflectance has shown to increase as the incident wavelength decreases from 1500 nm to 320 nm. At 500 µL, the reduction in reflectance had an average of 6.16% (Min.: 2.73% at 1500 nm, Max.: 13.75% at 320 nm and Median: 5.1%). At lower wavelengths range from 250 nm to 320 nm), the amount of reflectance reduction is less compared to wavelengths above 320 nm.

After 5 drops (100 µL ×5) on PECVD Ge samples, the incident wavelength where the minimum reflectance occurred (λₘᵢₙ), shifted from 1050 nm where reflectance is lowered by 34.5%, to 410 nm with 25.2% reduction in reflectance. While for bulk Ge sample, λₘᵢₙ shift occurs from ~1480 nm to ~420 nm with a decrease in reflectance of 37.9% and 28%, respectively.

Results demonstrate that it is feasible to deposit a coating of Si NPs with tunable reflectivity over a wide range by drop casting multiple layers of the nanoparticles.

Towards Scalable Fabrication of Atomic Wires in Silicon by Nano-Patterning Self-Assembled Molecular Monolayers Chufan Zhang and Yaping Dan; Shanghai Jiao Tong University, China

Developing a scalable method to fabricate atomic wires is an important step for building solid-state semiconductor quantum computers. In recent years, self-assembled molecular monolayer doping (MLD) has attracted intensive research interests due to its capability of facilitating mass production and forming ultra-shallow junctions with atomic precision[1]. MLD is believed to have a great potential in controllable dopant manipulation at sub-10 nm scale[2]. However, there is still no general method for effectively patterning dopant-containing monolayer at nanoscale. In this work, a novel selective doping strategy is proposed by patterning self-assembled monolayer to a few nanometers using standard nanofabrication processes, which significantly improves the lateral doping resolution of monolayer doping from microscale to nanoscale.

We first found an effective way to remove the self-assembled monolayer via oxygen plasma followed by HF etching, which is confirmed by X-Ray photoelectron spectroscopy and Van der Pauw measurements. Electron beam resist HSQ (XR1541-002, Dow Corning) was used to create patterns that protect part of the self-assembled DVP monolayers from being oxidized by oxygen plasma, since HSQ will turn into amorphous SiO₂ after electron beam exposure. To increase the resistance of the HSQ SiO₂ against HF etching, a second time of high dosage exposure was performed on the HSQ structure. The high dosage electron beam exposure might induce a thin amorphous carbon layer covering the HSQ structures and dramatically improved the resistance of HSQ against HF etching.

Using this method, we further explore the possibility to fabricate phosphorus atomic wires in silicon by patterning self-assembled diethyl vinylphosphonate monolayers into lines with a width ranging from 500 nm to 10 nm. The phosphorus
dopants are driven into silicon by rapid thermal annealing, forming dopant wires. Four-probe and Hall effect measurements are employed to characterize the dopant wires. The results show that the conductance is linear with the width for the wires, showing the success of the monolayer patterning process to nanoscale. To fabricate atomic wires made of one or a few lines of phosphorus atoms, we need to shorten the thermal diffusion length and increase the dopant incorporation rate at the same time. Pulsed laser annealing may be a promising solution. The present work provides a promising pathway for mass fabrication of atomic wires in silicon that may find important applications in quantum computing.

Role of Carbon and Oxygen Coverage in the Modification of Surface Energy and Hydro-Affinity of GaAs and Si for Low Temperature Wafer Bonding

Aashi R. Gurijala1, Shaurya Khanna1, Amber A. Chow1, Nikhil Suresh1, Mohammed Sahal1, Sukesh Ram1,2, Nicole Herbots1, Thilina N. Balasooriya1, Robert J. Culbertson1 and Karen Kavanagh1; 1Arizona State University, United States; 2Yale University, United States

Native oxides increase electrical resistance and inhibit epitaxy on semiconductors. Their removal is key in opto-electronic integration for devices such as tandem solar cells. Besides heteroepitaxy, Direct Wafer Bonding (DWB) is a viable integration technology for GaAs and Si. NanoBonding™ is DWB conducted at low T (<200°C) by modifying surface energy and hydro-affinity to reach far-from-equilibrium states and activate cross-bonding and electron exchange between the surfaces.

Hence, the surface energy has to be increased (if it is initially low), or decreased (if it is high). One of the surfaces in the pair has to be made hydrophilic if it is initially hydrophobic, and the other one hydrophilic if it is initially hydrophobic. Moreover, the surfaces have to be modified in a complementary way to so that electrons are transferred from electron donors from one surface to electron acceptors on the other.

To conduct Surface Energy Engineering (SEE) of GaAs and Si into a bonding pair, the initial surface energy, hydro-affinity, surface composition, and oxidation levels of as-received GaAs(100) and Si(100) are initially characterized. Next, the initial surface energies and hydro-affinities are modified not only by oxygen removal via chemical etching, but also to maximize cross-bonding. The characterization methods are Three Liquid Contact Angle Analysis (3LCAA) for surface energy and hydro-affinity, High Resolution Ion Beam Analysis (HR-IBA) for O coverage, and X-Ray Photoelectron Spectroscopy (XPS) for oxidation and C contamination.

In 3LCAA, the total surface energy, γT, is determined by the van Oss-Chaudhury-Good theory using 3 components: Lifshitz-Van der Waals, electron donors, and acceptors. GaAs(100) native oxides are hydrophilic with a low surface energy (γT=33.4±1.1 mJ/m2) while Si(100) native oxides are hydrophilic with a high surface energy (59.7±1.7 mJ/m2). GaAs surfaces are then etched with NH4OH:H2O (1:10) to be highly hydrophilic, while their γT can be reproducibly increased by a factor of 2 to 65.5±1.4 mJ/m2. HF:CH3OH (1:20) etching makes Si(100) hydrophilic and decreases its γT by 20% to 48.2±1 mJ/m2. Nano-bonding™ of GaAs to Si does not occur between these surfaces. However, Si(100) etched by aqueous HF becomes even more hydrophilic with a 25% decrease in γT to 44.4±2.3 mJ/m2. With this SEE of Si, GaAs nano-bonds to Si reproducibly.

O etching is measured by HR-IBA, while oxidation states and C-contamination are measured by XPS to correlate to nano-bonding. HR-IBA combines <111> channeling with O nuclear resonance to measure O coverage within ±0.2 Monolayers (ML) and analyzed via SIMNRA simulations. O coverage on GaAs is found to decrease by a factor 2 from 7.2±0.5 ML to 3.6±0.2 ML after etching.

The ratio of Ga and As is found to be unaffected by C-contamination, and remains ~54:46 within 1 atomic % by HR-IBA or ~1.18 within 10% by XPS. XPS shows that the relative ratio of Ga bound to GaAs versus Ga bound to Ga2O3 is initially 64:36 to within 1% with a slight increase in Ga bound to O. The relative ratio of As bound to GaAs versus As bound to O is much lower than Ga, 80:20 to within 1% and does not change with etching.

XPS analysis also shows that when C-contamination ranges between 12%-35% atomic %, the measured ratios of Ga and As bound to GaAs versus Ga and As bound to O vary less than 2%. After etching, Ga bound to Ga2O3 decreases with increasing carbon with a weak correlation factor of 0.4. C-contamination does not appear to significantly affect Ga oxidation. For As oxides, As2O5 shows a relative increase compared to As2O3 as C contamination increases with a strong correlation factor of 0.86 in native oxides before etching. After etching, the correlation factor is 0.55.
In summary, aqueous HF produces more hydrophobic Si(100) surfaces that can nano-bond to highly hydrophilic GaAs etched via dilute NH4OH while C contamination does not appear to modify GaAs surface composition nor oxidation.

S.EL01.06.24
Unraveling Vertical Inhomogeneity Effects in Vapor Phase Polymerized PEDOT:Tos Films Shangzhi Chen and Magnus P. Jonsson; Linkoping University, Sweden

Electrically conductive polymers are widely utilized in emerging electronic devices due to their excellent optoelectronic properties as a potential alternative to conventional conductors. Among them, Poly(3,4-ethylenedioxythiophene):Tosylate (PEDOT:Tos) thin films deposited by Vapor Phase Polymerization (VPP) exhibit electrical conductivity exceeding 3400 S/cm which is almost comparable to commercial ITO electrodes. [1] Systematic investigation on such films indicates a strong anisotropy in electrical and optical properties and this anisotropy is believed to be mostly caused by the preferential alignment of para-crystallines in the films. [2]

Here, I will present our recent study on the VPP PEDOT:Tos thin film system and reveal that vertical gradient could also be an important factor contributing to the electrical anisotropy. By examining the results from grazing-incidence wide-angle X-ray scattering and X-ray photo-electron spectroscopy, we observed significant differences of the top and bottom surfaces, including para-crystalline alignment preference and oxidation level (doping level). These show that the VPP PEDOT:Tos layer is not vertically homogeneous in terms of both “crystallization” fraction and charge carriers (doping level). To explain the origin of this inhomogeneity, we propose a growth mechanism for VPP based on diffusion-limiting transport of polymerization precursors. Conductive polymer thin films with certain gradient profile may find applications in functionally graded thermoelectrics, gradient-index optics, and optoelectronic devices with gradient doping.

Optimizing n-Type Dopant Incorporation in GaAsBi for Multijunction Photovoltaics Margaret A. Stevens, Kevin Grossklaus, Samuel Lenney, John H. McElearney and Thomas E. Vandervelde; Tufts University, United States

Multijunction photovoltaics employed in solar concentrator architectures can have theoretical efficiencies as high as 65% for a 4-junction cell [1]. For these devices, sub-cell band gaps of 0.96-1.18 eV are required. Epitaxially grown GaAsBi is of interest for this application due to (1) less lattice mismatch to GaAs than InGaAs for comparable band gaps [2] and (2) a proposed temperature-insensitive band gap and reduction in Auger recombination [3]. However, these materials are challenging to grow due to the surfactant-like nature and low solubility of bismuth (Bi) in this system. The low growth temperatures necessary for good bismuth incorporation is often at odds with good material quality. The need for depleted arsenic overpressure can often lead to challenging dopant incorporation [4], a critical requirement if these devices are to be employed in PN junctions.

In this work, we explore methods to improve dopant incorporation and carrier mobility in GaAsBi0.02 and GaAsBi0.06 for future photovoltaic devices. Samples were grown on a Veeco GENxplor MBE using a valved As4 source and a solid source effusion cell for group-III elements and Bi. Bismuth fraction and strain state were determined by high-resolution x-ray diffraction and absorption edge was measured by transmission spectroscopy. Select samples are grown lattice matched to InGaAs virtual substrates to decrease compressive strain which delays both Ga-Bi droplet formation and defect formation from strain relaxation [5]. Samples grown on GaAs and InGaAs substrates are doped with silicon or tellurium for n-type doping and beryllium for p-type doping. The benefits and challenges of using a group-IV n-type dopant verses using a group-VI n-type dopant in this materials system will be discussed. Mobility of GaAsBi as a function of dopant concentration was measured using Hall effect measurements and compared for the different choice of dopants. Temperature-dependent Hall measurements are utilized to explore scattering mechanisms. Additionally, the effects of ex situ thermal annealing at 500 °C on optical and electrical parameters will be discussed. Finally, mobility data will be fed into device simulations using Silvaco to evaluate best device architectures to use bulk GaAsBi films in photovoltaics.

Chalcopyrite materials based on CuInGaSe₂ is practically used for the commercially available high efficiency solar cells. The room temperature bandgap of AgGaTe₂ is about 1.3eV, hence the application of this material to the active layer of novel solar cells also attracted the attention. Among various film preparation methods, the closed space sublimation (CSS) method is suitable for the fabrication of mass production solar cells since it has various advantages toward the production cost reduction. The growth of crystallized AgGaTe₂ thin films utilizing this method on Si and Al₂O₃ substrates have performed in past, and it was discovered that the introduction of the two-step sequence was the key to realize high quality thin films. The Ag₂Te layer was deposited as the first step to avoid the melt-back etching related problems of Ga against substrate materials. Then, AgGaTe₂ thin films were formed using the mixed powder source of Ag₂Te and Ga₂Te₃. The AgGaTe₂ thin fims could be also prepared using the powder source of Ga₂Te₃. The first Ag₂Te layer was disappeared during the high temperature growth process of the second sequence, and a single phase AgGaTe₂ of the uniform layer has formed once the growth parameter was optimized.

It was clarified from the X-ray diffraction (XRD) measurement that the inclusion of AgGa₅Te₈ compounds occurred when the fraction of Ga₂Te₃ in the deposits was greater than that of Ag₂Te. On the other hand, mixed crystal of AgGaTe₂ and Ag₂Te were formed when the fraction of Ga₂Te₃ was less than that of Ag₂Te. These results corresponded to the phase diagram of the Ag₂Te–Ga₂Te₃ system. A pn-heterojunction solar cell structure was prepared using the AgGaTe₂ layer on the n-Si substrate, and the photovoltaic properties were confirmed. The AgGaTe₂ layer was also prepared on the Mo/quartz substrate using the same growth sequence.

In case of the CuInGaSe₂ layer growth on the Mo electrode layer, Se diffusion was observed in the Mo electrode layer. The advantage and disadvantage were still discussed for this structure. In this study, the interfacial diffusion of elements at AgGaTe₂/Mo was studied to understand how the diffusion of Ga could be suppressed. High resolution cross sectional TEM images of the interfacial region was analyzed using the Z-contrast images of the high angle annular dark field (HAADF) mode and EDX-mapping mode.

When AgGaTe₂ layer was directly grown on the Si substrate, Si surface was etched and became very rough, and it was considered that Ga has damaged the Si substrate surface. By introducing the two step procedure, the interface quality was substantially improved and the roughening was vanished. When the layer was grown on the Mo layer using the two step procedure, sharp interface was also observed. By careful analysis using the EDX mapping, it was confirmed that Ga was diffused into the Mo layer when the growth temperature was above 650 °C. Different from the conventional interdiffusion, Ga accumulation was also observed at the diffusion front. The diffusion depth was fairly uniform across the specimen. The diffusion of Te was also observed for samples grown at high temperatures as well as samples post annealed at the high temperature. Those samples exhibited Mo and Te condensation region with the size of around 0.2 to 0.5 micron within the AgGaTe₂ layer. It probably suggested that a part of Mo was reacted with Te, and formed the volatile MoTe₂ material, and it was migrated into the AgGaTe₂ layer.

Further investigation is ongoing to identify the diffusion characteristics at the AgGaTe₂/Mo layers. It is reconfirmed that the two step growth procedure is a very useful approach to achieve the high quality layer, but processing temperatures including the growth temperature and post growth annealing temperature are very critical parameters to achieve the high quality interface with the abrupt profile.

This work was supported in part by Waseda University Grant for Special Research Projects.

Enhancement of Electrical Characteristics of Amorphous Indium-Gallium-Zinc-Oxide Thin-Film Transistors by Inserting Carrier Induced Interlayer
Chansic Yoon, Hyung Tae Kim, Min Seong Kim, Hyukjoon Yoo, Jeong Woo Park, Dong Hyun Choi, Dongwoo Kim and Hyun Jae Kim; Yonsei university, Korea (the Republic of)

Since the development of display technology, a new type of industry, such as augmented reality (AR), virtual reality (VR), and wide screen displays, has arrived. Requirements of performance standards on new type of displays have become more severe. Therefore, improving the mobility and stability of thin-film transistors (TFTs) for using in such devices have been actively conducted. To date, low temperature polycrystalline silicon (LTPS) with high field-effect mobility of about 100
cm²/Vs has been widely used as channel material for TFTs, but some problems remain, such as poor uniformity for large area, high leakage current, and high fabrication costs. To resolve the issues mentioned above, amorphous oxide semiconductor (AOS) has been attracted attention due to low off current, large area uniformity, and relatively low fabrication cost. Especially, amorphous Indium-Gallium-Zinc-Oxide (a-IGZO) is most used semiconductor among AOS materials. However, for AOS materials to be applied to the above-mentioned next-generation displays, low field-effect mobility and low stability under bias stresses, which are lower than LTPS, must be overcome.

In this sense, we propose the fabrication of a-IGZO TFTs with high mobility and high stability through insertion of a carrier induced interlayer (CII). CII is a layer introduced between the channel layer and the gate insulator layer, which is thinly deposited to absorb oxygen in the effective channel of a-IGZO through oxidation. Consequently, mobility of a-IGZO TFTs can be improved by oxidation of CII increasing carrier concentration of the a-IGZO front channel.

In this study, thin aluminum layer was deposited for CII by RF sputtering process at 80 W with various deposition time 60, 90, and 120 s. Then, a-IGZO was deposited on the CII for channel layer while changing the oxygen partial pressure from 1.7 to 8.3%. After the activation process through thermal annealing at 300°C for 1 hour, Al was deposited by RF sputtering and used as source and drain electrodes. When the a-IGZO channel was deposited with oxygen partial pressures of 1.7, 3.3, and 5% without CII, the saturation mobility was 7.36, 5.45, and 2.83 cm²/Vs, respectively. If it exceeds 5%, it is insulated. The above phenomenon caused by the oxygen vacancy concentration in the a-IGZO thin film decreases with increasing oxygen partial pressure. If the partial pressure of oxygen is less than 5%, Al for CII cannot be completely oxidized, resulting normally conductive property. On the other hand, if the partial pressure of oxygen is more than 5%, the characteristics of the TFTs deteriorate. As a result, 5% condition achieves the best characteristics and determined as the optimize condition.

In the transfer characteristics of the TFTs with various CII thickness, the saturation mobility of the TFTs with CII of 60 s and 90, and 120 s. Then, a-IGZO was deposited on the CII for channel layer while changing the oxygen partial pressure from 1.7 to 8.3%. After the activation process through thermal annealing at 300°C for 1 hour, Al was deposited by RF sputtering and used as source and drain electrodes. When the a-IGZO channel was deposited with oxygen partial pressures of 1.7, 3.3, and 5% without CII, the saturation mobility was 7.36, 5.45, and 2.83 cm²/Vs, respectively. If it exceeds 5%, it is insulated. The above phenomenon caused by the oxygen vacancy concentration in the a-IGZO thin film decreases with increasing oxygen partial pressure. If the partial pressure of oxygen is less than 5%, Al for CII cannot be completely oxidized, resulting normally conductive property. On the other hand, if the partial pressure of oxygen is more than 5%, the characteristics of the TFTs deteriorate. As a result, 5% condition achieves the best characteristics and determined as the optimize condition.

In the transfer characteristics of the TFTs with various CII thickness, the saturation mobility of the TFTs with CII of 60 s and 90 s deposition were calculated as 11.30 and 13.96 cm²/Vs respectively. As the thickness of CII increases, the saturation mobility also increases. However, switching characteristics of the TFTs with CII are gradually degraded due to insufficient oxidation of CII with metal Al over 120 s of the CII deposition time. The CII with insufficient oxidation acts as current path at the interface between the gate insulator and the channel layer, resulting in a drastically increased conductivity. Consequently, the optimize condition was determined to be CII deposition time of 90 s.

Lastly, bias stress tests were performed to determine the stability of the TFTs. Negative bias temperature illumination stress (NBTS) test under -20 V, 50°C and 1000 lux for 3600 s was conducted on the TFT fabricated with oxygen partial pressure of 5% with CII deposition time of 90 s. When the result was compared with the a-IGZO TFT without CII (pristine), the stability characteristic was improved as the threshold voltage shifts of the pristine showed -12.05V and the device with oxygen partial pressure of 5% and with CII showed -6.73V.

Determining the Surface Chemistry of Lithiated Nickel-Manganese-Cobalt Oxide from Density Functional Theory and First-Principles Thermodynamics Josiah Roberts1, Chad Risko1 and Aashi R. Gurijala2; 1University of Kentucky, United States; 2Arizona State University, United States

Surfaces of materials such as lithiated nickel-manganese-cobalt oxide (NMC) can be characterized through experimental techniques such as photoelectron spectroscopy. These techniques take advantage of high-vacuum environments, though the vacuums are never perfect, and the materials are often exposed to ambient conditions prior to characterization or application, all of which could impact the surface composition. Hence, questions arise as to the data derived from periodic density functional theory (DFT) calculations that assume chemically clean surfaces in perfect vacuum and are used to describe these materials. To reconcile these differences, we investigate the surface chemistry of NMC through a combination of DFT and first-principles thermodynamics calculations. By examining the bulk structure, bare surfaces, and the adsorption of various atmospheric molecular and ionic species, we develop phase diagrams that reveal the expected surface chemistries as a function of various partial pressures, predicting the NMC surface chemistry as a function of the environment. Such predictions can be used to modify future computational studies of the material both in vacuum and in solution, providing additional tools for characterization.

S.E.L01.06.33
Effects of Very High Workfunction Metals or Metal Alloys (NiCr) on High Switching Speed, HV Schottky Diodes for Mixed-Signal or RF ASIC James Pan; Northrop Grumman Corporation, United States

For high switching speed HV Schottky diodes, with very high work function metal and extremely lightly doped epi, the built-in potential may be too high for thermionic emission to occur, when the applied external voltage is quite low (near the forward voltage: \( V_F = 0.07V \)). If the epi is lightly doped p type, the built-in potential (\( V_{Built-in} \)) potential difference between the metal and silicon Fermi levels) is 1.0V (measured with CV). If the external bias is 0.1V, near the measured \( V_F \), it is not enough to overcome the built-in potential for thermionic emission as illustrated in the Figures. It is likely that in addition to
thermionic emission, tunneling and diffusion currents also contribute to the total HV Schottky diode forward current. TCAD simulation of HV Schottky diodes with N' guard bands suggests the potential barrier and electric fields at the Schottky junction are relatively high for thermionic emission to occur, when external bias \( V \gg V_F \).

In the Advanced Technology Laboratory (ATL) at Northrop Grumman Corporation, high performance RF ASICs and power devices in silicon, GaAs, GaN and 4H SiC are simulated, designed, fabricated, and packaged. Extensive DC and RF tests are conducted. The performance of HV Schottky diode is superior to conventional p-n junction diode due to higher BV, lower reverse leakage, lower \( V_F \) and higher output current. We have fabricated HV Schottky Diodes. \( BV > 150V, V_F = 0.07V \). High breakdown voltage, low forward voltage drop, and low reverse leakage are achieved with very high work function metal alloys and low doping epi films.

Lightly doped p (100) or n (100) type silicon films are deposited with epitaxy. Metal or metal alloys are deposited with sputtering. Figure 1 shows the measured I-V’s for the Schottky Diodes. Avalanche breakdown voltage \( > 150V \) is recorded with low reverse leakage current. The voltage required to turn the diode on is defined as \( V_F \) when the current reaches 0.1uA.

Forward bias characteristics of Ti, Au, and NiCr are measured. These data indicate that in order to achieve low \( V_F \) and high current, very high work function metals are needed.

High frequency CV tests are conducted using the HV Schottky Diodes. These CV data are used to extract the doping profiles.

Metal work functions are extracted with the \( 1/C^2 \) vs. \( V \) plots. Interception with the x axis is \( DV \), which is the potential difference between metal and silicon Fermi levels, or built-in potential \( V_{built-in} \). Metal work function is extracted with \( DV \).

One of the Figures shows the measured doping profiles and \( 1/C^2 \) vs. \( V \) plots. From the measured I-V and C-V data we may calculate the avalanche breakdown critical electric fields and metal work functions. A summary of HV Schottky diodes fabricated with NiCr, Ti, Au in Si n and p epi films will be presented.

Energy band diagram is analyzed for HV Schottky diodes: NiCr in p epi (external bias = 0V) \( V_{built-in} = 1.00V \).

Another energy band is analyzed for HV Schottky diodes: NiCr in n epi (external bias = +0.50V). \( V_{built-in} = 1.56V \).

In conclusion: we have fabricated HV Schottky Diodes. \( BV > 150V, V_F = 0.07V \). High breakdown voltage, low forward voltage drop, and low reverse leakage are achieved with very high work function metal alloys and low doping epi films. Diffusion and tunneling currents likely contribute to the total Schottky junction current.

**Fast and Simplified Synthesis of Spiky-Like Copper Sulfide Nanoballs by Soft Chemistry Method for Optoelectronics Applications**

Anderson Klay R. Jaime, Diana V. Hernández, Judith Celina T. Córdova and Santos J. Castillo; Universidad de Sonora, Mexico

Fast synthesis of copper sulfide nanoparticles through two different methods is described in the present investigation. The first reaction was carried out by applying of heating in constant temperature water bath while in the second case the mixture was sonicated. As copper and sulfur sources, copper nitrate and thiourea solutions were used respectively. Main physicochemical properties of the synthesized samples were studied using several characterization techniques. Formation of copper sulfide with hexagonal crystalline structure was corroborated, coinciding with previously reported values for covellite. The most important results corresponded to the un-sonicated sample, which exhibited spiky-like nanoballs morphology and better size distribution. Optical tests revealed band gaps of 1.69 and 2.05 eV, while photoluminescence emissions at 421 and 430 nm, showing promising possibilities for applications in solar cells, catalysis and optoelectronic devices.

**S.EL01.06.41**

**An Improved Model of Ge Bi-Layers Incorporated CZTSe Devices with MoSe2 Interlayer**

Sanghyun Lee¹, Kent Price² and Edgardo Saucedo³; ¹Indiana State University, United States; ²Morehead State University, United States; ³Institut de Recerca en Energia de Catalunya, Spain

In conclusion: we have fabricated HV Schottky Diodes. \( BV > 150V, V_F = 0.07V \). High breakdown voltage, low forward voltage drop, and low reverse leakage are achieved with very high work function metal alloys and low doping epi films. Diffusion and tunneling currents likely contribute to the total Schottky junction current.
As environmentally benign and highly-efficient thin-film solar cells, low-cost Cu2ZnSn(S,Se)4 (or kesterite) solar cells, herein CZT(S,Se) have been steadily emerging as an alternative for the 2nd generation Cu(In,Ga)Se2 (CIGS) and CdTe solar cells in the past several years. CZT(S,Se) solar cells have several advantages such as high absorptions coefficient (>10^4 cm^-1), tunable direct band gap energy (1 to 1.4 eV), and usage of abundant elements in earth's crust, becoming an ideal platform to harvest solar energy. However, the efficiency improvement and understanding of emerging CZT(S,Se) is still in an early stage compared to the 2nd generation counterparts. In recent progress, our team reported that Germanium (Ge) incorporation into CZTSe solar cells has improved device performance, which contributed to deepening understanding of Ge-alloyed CZT(S,Se) solar cells, in particular, on the Schottky-type back-contact barrier. We present the complete set models about the Schottky barrier with the MoSe2 interlayer between the absorber and Molybdenum (Mo) back-contact. Developed analytical models with in-house MATLAB simulators agree well with TCAD numerical simulation and experimental results. A new concept of an effective back-contact barrier is introduced, which provides the mechanism of the improved device performance with lower back-contact barrier for CZTSe Ge bi-layers devices. By incorporating nanoscale Ge bi-layers below and above the CZTSe absorber, the back-contact barrier is improved by 33 %, and power conversion efficiency is improved by 1.1 % than Ge single-layer devices. Based on the back-contact model, defect concentration of Ge reference devices is estimated to be 5.4 x 10^16 cm^-3, whereas Ge bi-layers devices show an estimated <9.8 x 10^15 cm^-3 at the back-contact interface. To compare models with experimental results, we fabricated three different types of CZTSe: nanoscale Ge devices. The property of the back-contact barrier is assessed by characterizing a temperature-dependent behavior of CZTSe alloyed devices. Collectively, the reduced defect concentration by Ge incorporation in the MoSe2 interlayer improves the barrier height of back-contact. As the defect concentration of the MoSe2 interlayer increases, the benefit from the back-contact barrier lowering by the valence bands offset is reduced and essentially eliminated. Moreover, the increased effective back-contact barrier degrades the series resistance and the overall device performance. However, the barrier at the interface between MoSe2 and Mo metal contact remains the same, even with MoSe2 defect concentration increase. Incorporating thin Ge nanolayer at the interface between the absorber and MoSe2 could positively influence and possibly reduce the defect states, which lowers the effective back-contact barrier from modeling and simulation results. Hence, the Ge layer at the back-contact interface successfully improves the conversion efficiency up to 8.3 % with the improved back-contact.

Measurement of Electrical Contact Resistance at Nanoscale Gold-Graphite Interfaces Saima A. Sumaiya, Mohammad R. Vazirisereshk, Ashlie Martini and Mehmet Z. Baykara; University of California, United States

Electrical contact resistance (ECR) directly influences the performance of micro-scale devices, where contact between components occurs through nanometer-scale patches. Consequently, developing the ability to accurately measure ECR as a function of true contact size at the nanometer scale is of crucial importance. To achieve this goal, we present an approach based on conductive atomic force microscopy, which is applied on a material system comprising atomically flat interfaces formed between gold nano islands and a graphite substrate [1]. Proof-of-principle experiments are complemented by atomistic simulations, which are used to predict the maximum island sizes below which the ECR at the island-graphite junction can be reliably extracted from the measurements. This approach has the potential to contribute to fundamental studies of electron conduction, e.g. through an investigation of the transition between the diffusive and ballistic transport regimes.

S.ELO1.06.53
Design and Demonstration of Novel Spectrally Selective Thermal-Radiation Material Takashi Ando1, Maki Ito1, Naoki Maruyama2, Takanobu Kobayashi2 and Yoshitaka Takezawa2; 1Hitachi Ltd, Japan; 2Hitachi Chemical Co., Ltd., Japan

Electronic devices, such as electronic control unit, power module, mobile equipment, etc., are required downsizing and higher power density. To achieve the downsizing and higher power density, electronic parts are closely mounted together in a small external package, which causes an increase of heat density. Thermal-radiation is one of the heat dissipation methods. However, conventional thermal-radiation is not useful in the electronic devices, since most of the radiated heat is absorbed by an external package such as resin. The purpose of this study is to newly develop a thermal-radiation material, which generated heat is converted into infrared light with spectrum transmitting through the resin. The material is so-called spectrally selective thermal-radiation material (SSTRM). The studied SSTRM is composed of metallic spheres arrayed on the surface of a heating element, and resin film covering the metallic sphere array. The film is formed by applying a coating solution including metallic spheres. The optimum diameter and arrangement of the metallic sphere are founded numerically and experimentally.
The thermal-radiation spectrum was calculated by using an optical simulation tool based on Rigorous Coupled Wave Analysis. The calculation results clearly showed the localized plasmon resonance excited in the metallic spheres array. The localized plasmon resonance enhanced the emission at the resonance wavelength. The resonance wavelength was controlled by changing the diameter and arrangement of the metallic spheres. It was revealed that infrared light with spectrum transmitting through the resin film is emitted, when the spheres with a diameter of 1.5 µm are densely arrayed. The effectiveness of the SSTRM was experimentally demonstrated by evaluating thermal-radiation characteristics under the stationary atmosphere with a temperature of 298 K. Input power to a heating element was fixed at a constant value, so that the surface temperature of the heating element was 381.1 K. Three types of coating materials were prepared as follows; A. only resin film, B. metallic spheres dispersed in resin film, and C. optimized metallic sphere array covered with resin film (SSTRM). The surface temperatures of the heating elements coated with the films A, B, and C were evaluated to be 358.3K, 355.8K, and 348.1K, respectively. The film C achieved drastical temperature reduction of 33K compared with the heating element without the coating materials. The temperature of the film C was lower than that of B, due to the effect of the metallic sphere array formation. Consequently, the optimized metallic spheres array acted as the spectrally selective emitter that radiates infrared light transmitting through the resin. The SSTRM will be powerful material for heat dissipation from electronic devices packed in resin case or mold.

Directed Patterning of Quantum Dots Using Chemically Modified Surface for Light Emitting Diodes Su Hong Min, Ho-Jong Kang and Dong Hyun Lee; Dankook University, Korea (the Republic of)

Colloidal quantum dots (QDs) have been widely used for light-emitting diodes (LEDs) because of their outstanding characteristics including high color purity, narrow emission peak, high luminescent efficiency, low operating voltage and adjustable emission wavelength that are tunable as a function of their size and composition. For the fabrication of QD-based LEDs, they have been applied to several processes such as spin-casting, inkjet printing and micro contact printing. However, these processes suffer from practical limitations such as high-resolution patterning, high cost, multiple-layer structures, and long processing time. In order to overcome the issues currently suggested, micro-contact printing method using the relief patterns on a master has been introduced and utilized extensively for QD-LEDs. In this way, the regular patterns of QDs layer is transferred on the hole transport layer (HTL) by simply physical contact between the master and the HTL surface. In spite of its efficiency, however, the cyclic process of the micro-contact printing inevitably gives rise to sever damages to the master patterns. Here, we demonstrate a unique method for directed patterning of colloidal quantum dots for the light emitting diodes from chemically modified surface. The chemically modified line-type patterns are initially fabricated on the substrate by using a conventional photolithography technique and selective chemical reaction of surface-modifying molecules such as the octadecyltrichlorosilane (OTS) sequentially. The width of line-type patterns produced is varying from 40 µm to a few µm. The quantum dots of CdSe(core)-ZnS(shell) that are covered with oleic acid as capping molecules are then spin-coated on the chemically patterned surface. To transfer the QDs layer to a hole transport layer, the polymethylmethacrylate (PMMA) is first spin-coated on the QDs layer followed by placing commercial adhesive tapes on the PMMA layer. Then the QDs/PMMA layer is detached from the original substrate by peeling the adhesive tapes and due to surface energy difference during the transfer process. As the PMMA/tape layers are removed by rinsing with acetone, respectively. It is noted that the only designed QD patterns are selectively transferred from the chemically modified surface due to surface energy difference during the transfer process. As the PMMA/tape layers are removed by rinsing with acetone, which is a selective solvent, the only QD patterns remain on the HTL layer of the target substrate. For the fabrication of QD-LEDs, ZnO(ETL) and Ag(Cathode) layers are deposited on the QDs layer sequentially. Consequently, the QD-LEDs fabricated in this study are characterized by measuring their electrical properties like luminance, current density and external quantum efficiency.

Pulsed Laser Deposited Polycrystalline Thin Films of MoO3 for Sensing of High-Energy Moieties Dhanashree Sable, Swapnali Rabade and Sangeeta N. Kale; Defence Institute of Advanced Technology, India

Among various nanostructured metal oxides, molybdenum oxide (MoO3), a wide band-gap n-type semiconductor, has attracted much interest as a promising gas sensor because of its excellent sensitivity, good reproducibility, low cost, high compatibility with microelectronic processing, low electron recombination rate, and high stability. The MoO3 thin films have promising electrical properties for gas sensing applications. To synthesize two-dimensional materials under ultra-high vacuum is a key advantage for enhancing the properties of nanostructured materials. In this presentation, we demonstrate the synthesis, characterization, and gas sensing properties of MoO3 films, which were grown using Krypton-Fluoride (248 nm) excimer laser. Deposition was done under 200 mTorr Oxygen pressure at the substrate temperature of 600°C. The targets used for deposition were synthesised using hydrothermal
method. The deposition was done with the optimized parameters, to ensure good polycrystalline films on the Si (001) substrate. The optical, morphological and compositional properties of MoO3 films were studied by using UV-Visible spectroscopy, Scanning Electron Microscopy and Raman Spectroscopy. The formation of MoO3 was also confirmed using X-Ray Diffraction technique. The MoO3 films showed excellent response to NOx and NOx gas moieties, at even low gas concentrations from 100 ppm onwards. The sensor not only exhibits high sensitivity but also good selectivity towards NO2 gas.

S.E1.01.06.30
The Chemistry of Interface Defects in SiC/SiO2 Probed by Hard X-Ray Photoelectron Spectroscopy Anna Regoutz;
University College London, United Kingdom

Interfaces govern the behaviour of all electronic devices. Herbert Kroemer coined the famous phrase “the interface is the device” in his 2000 Nobel Prize lecture, and we are still applying tremendous effort to understand interfaces in new material generations, with wide-bandgap materials being no exception. If anything, wide bandgap materials are more vulnerable to defect states purely due to their larger bandgap. Understanding gained for the bulk behaviour of semiconductors can often not be extended to the behaviour of materials in structured film stacks were interfaces play a vital role. SiC/SiO2 is a prototypical wide-bandgap semiconductor/dielectric interface, which represents the challenges faced by many such material systems. A multitude of different defects leads to unacceptably large defect densities exceeding $10^{13}$ cm$^{-2}$ eV$^{-1}$ in the vicinity of the conduction band of 4H-SiC. The management of interfacial defects remains a topic of lively discussion and current interest.

Here, we present a systematic study of the 4H-SiC/SiO2 interface in industrially manufactured samples with a particular focus on the effects of nitridation in N2, NO, NH3 and NO+NH3 atmospheres. High temperature nitridation has been shown to compensate interface defects leading to an increase in device performance, however, information on the local chemistry at the interface after such processes is scarce, which limits the understanding of the interface and consequently the targeted improvement of device characteristics. Clear differences are found in both spectroscopy and electrical behaviour after high temperature treatments. The present work uses energy-dependent hard X-ray photoelectron spectroscopy (HAXPES) to systematically study the elemental distributions and chemical environments across the 4H-SiC/SiO2 interface. We combine both laboratory- and synchrotron-based HAXPES results to obtain a complete picture of this important technological interface and to benchmark the capabilities of this spectroscopic technique for the exploration of buried interfaces in device heterostructures in general.

S.E1.01.06.51
Surface Chemical Composition Evolution During In-situ Annealing of Low-Strain Ge1-xSnx Layers on Core/Shell Nanowires Michael Braun1, Ishaa Bishnoi1, Andrew C. Meng2, John Z. Lentz1 and Paul McIntyre1; 1Stanford University, United States; 2University of Pennsylvania, United States

Metastable germanium-tin has attracted significant interest as a potential group IV direct bandgap material for CMOS compatible electronics and photonics. With sufficient tin incorporation, there is experimental evidence of a direct bandgap germanium-tin material.1 Although this is a promising step for germanium-tin devices, there are further considerations for incorporating germanium-tin into a full device. Namely, the evolution of the germanium-tin surface during subsequent annealing and growth of additional device components. Previous annealing results on strained germanium-tin thin films have shown surface tin segregation and island formation.2 In this study, we report results from in-situ X-ray photoelectron spectroscopy during annealing of vertical core/shell Ge/Ge1-xSnx nanowires grown via chemical vapor deposition. We have previously shown the capability of the core/shell structure to produce a largely strain-free Ge1-xSnx shell material on a highly tensile-strained Ge core.3 This structure is utilized here to investigate the annealing characteristics of the germanium-tin surface and native oxide for tin contents in the range of 2 at% - 12 at% in air-exposed nanowires. Our results show the presence of a tin rich oxide with a composition dependent decomposition temperature. After in-situ decomposition of the native oxide, the tin content of the germanium-tin surface is observed to remain constant throughout annealing at temperatures exceeding 500 °C and for anneal durations greater than one hour. Additionally, we have measured the photoluminescence at room temperature, characterized strain by X-ray diffraction, and imaged the nanowire sidewall morphology before and after annealing to examine its effects on material performance, bulk tin distribution, and local surface structure.

Chemistry Behind Dodecanethiol Treatment of Colloidal CsPbBr$_3$ Nanocrystals with Photoluminescence Quantum Yields Reaching ~100% Md Aslam Uddin, Justin K. Mobley, Abdullah A. Masud, Tuo Liu, Rosemary L. Calabro, Doo Y. Kim, Christopher I. Richards and Kenneth R. Graham; University of Kentucky, United States

Metal halide perovskite nanocrystals (NCs) are attractive materials for optoelectronics because of their optical and electronic properties, such as tunable direct band gaps, high absorption coefficients, low exciton binding energies, relatively high electron and hole mobilities, narrow emission line-widths, and high photoluminescence quantum yields ($\Phi_{PL}$). However, further improvements in stability and reproducibility in $\Phi_{PL}$ of NCs are essential for enabling future optoelectronic applications. Inadequate surface passivation due to labile parent ligands, such as oleate and oleylammmonium ions is a major cause of instability and less than unity $\Phi_{PL}$. Herein, we probe the influence of multiple molecular and ionic ligand binding groups including thiols, thioethers, phosphine, phosphine oxide, sulfobetaine, thiocyanate, and sulfate salts on the colloidal stability and $\Phi_{PL}$ of CsPbBr$_3$ NCs. Among all the binding ligands, post-synthetic treatment with dodecanethiol reproducibly yields highly stable NCs with near unity $\Phi_{PL}$ for a range of synthetic conditions and initial $\Phi_{PL}$ of the as-synthesized NCs. A few of the other ligands can also increase the $\Phi_{PL}$, but in ambient atmosphere they are unable to maintain stability more than 5 days. A mechanistic investigation shows that thiol addition to the as-synthesized NC dispersion leads to the thiol-ene reaction with octadecene, oleic acid, & oleylamine and formation of thiolate ions and thioethers. Both thiolates and thioethers are suspected to bind to undercoordinated Pb atoms and consequently eliminate metallic Pb particles commonly observed with transmission electron microscopy on the NC surfaces. The process of enhancing PL intensity and stability can be rapidly accelerated through exposure to blue or UV light.

S.EL01.06.42
16.5% ZMO/CdTe Solar Cells with Copper Thiocyanate as Back Contact Dengbing Li, Sandip S. Bista, Fadhil K. Alfaadhili, Niraj Shrestha, Rasha A. Awni, Zhaoning Song and Yanfa Yan; University of Toledo, United States

The replacement of traditional CdS buffer layer with magnesium doped zinc oxide (ZMO) has been demonstrated helpful to boost higher CdTe solar cell performance exceeding 18% due to the reduced interface recombination and parasitic light absorption by buffer layer.1 However, due to the atmosphere sensitivity of ZMO film, the post-treatments of ZMO/CdTe stacks, including CdCl$_2$ treatment, back contact deposition et. al, which are critical for high performance CdTe solar cells, became crucial challenge. In order to maximize the expected benefit of ZMO cooperation, plenty of investigation need to be accomplished in the future. Here, copper thiocyanate (CuSCN) is demonstrated to be a powerful back-contact material with multi-advantages without degrading ZMO layer in CdTe solar cells, even with ammonium hydroxide as the solvent. The thickness of CuSCN film as well as the subsequent annealing temperature are systematically investigated and the highest efficiency 16.5% has been achieved with open-circuited voltage 850 mV, short-circuited current 26.2 mA/cm$^2$ and fill factor 74.0%.

S.EL01.06.65
Halogenated Si(100) Surface Chemistries for Atomically-Precise Fabrication Kevin J. Dwyer$^{1,2}$, Karen Gaskell$^{1}$ and Robert Butera$^{2}$; $^{1}$University of Maryland, United States; $^{2}$Laboratory for Physical Sciences, United States

The use of halogen chemistries on silicon surfaces offers a promising path towards atomic-scale manufacturing of acceptor-based devices. Atomically-precise fabrication of electronic devices in silicon has been widely demonstrated using a scanning tunneling microscope (STM) and hydrogen-based surface chemistries to precisely place phosphorous donor atoms on the surface. A lithographically patterned hydrogen resist is used to selectively incorporate PH$_3$ to produce metallic wires, quantum dots defined by electrostatic gates, and single donor atom qubits for quantum information (QI) research. However, interest in acceptor dopants and hole-based devices necessitates the development of alternate precursors and/or resist chemistries for device fabrication. To incorporate acceptors into silicon with atomic placement, halogen chemistry is potentially more favorable than hydrogen. To that end, we explore halogen-based resists including chlorine, bromine, and
iodine in conjunction with metal-halide precursors to achieve area-selective deposition of acceptor dopants in silicon. Here, we present results on the complete surface passivation of Si(100) using Cl, Br, and I. We study the stability of halogen-terminated Si(100) surfaces in ambient environments using STM and x-ray photoelectron spectroscopy (XPS) to facilitate transport of samples outside of ultra-high vacuum environments. Finally, we present STM and secondary ion mass spectroscopy (SIMS) results on the adsorption and incorporation of metal-halide precursors on Si(100) as a viable path towards acceptor doping.

S.EI01.06.59
Photothermoelectric Detection of Crystal Defects and Grain Boundaries in Gold Lucia Gan1, Charlotte Evans2, Rui Yang1, Mahdiyeh Abbasi2, Xifan Wang2, Rachel Traylor1, William Nix1, Douglas Natelson2 and Jonathan Fan1; 1Stanford University, United States; 2Rice University, United States

As devices continue to trend towards the micro- and nanoscale, the influence of individual crystal defects on their optical, electronic, and thermal properties becomes significant. As an example, the thermoelectric properties of these nanodevices are closely related to the presence of crystal defects, grain boundaries, and strain. While the effects of interfaces and grain boundaries on thermoelectric performance have been widely studied in semiconductor materials, there remains an incomplete understanding of the role that crystal defects play in metals. A major challenge in pinpointing the origins of thermoelectric variation in metallic nanodevices is the difficulty in preparing high quality crystalline thin-film metal microstructures on thermally and electrically insulating amorphous substrates.

Controlling the micro- and nanostructure of metals offers the opportunity to investigate and engineer the properties of metal nanotechnologies. Here, we report a high-throughput method for preparing patterned crystalline gold microstructures grown directly on amorphous insulating oxide via rapid melt growth. In this growth process, thin-film gold-platinum metal-seed microstructures are encapsulated in an insulating crucible and annealed at temperatures above gold’s melting point. During cooling, liquid epitaxial growth directs single crystal solidification [1]. We can extend this platform to controllably prepare single grain boundaries [2], enabling the systematic study of the role of defects in governing local thermoelectric behavior. A scanning photothermoelectric (PTE) setup to allows us to probe the microscopic variations in photovoltage across the gold single crystal and bicrystal wires. Surprisingly, we observe a photovoltage distribution where local changes in Seebeck coefficient are highly influenced by long-range strain fields and concentrated dislocations and uncorrelated with plane grain boundary defects. Our results showcase the link between the presence of elastic strain and dislocations to the PTE effect using a model material system.

S.EI01.06.54
Improved Efficiency of Photo-Induced Electron Detection under UV Light Source by ZnO Nanowire Array on Aligned PVDF-TrFE Nanofiber Film Dong Hee Kang, Na Kyong Kim and Hyun Wook Kang; Chonnam National University, Korea (the Republic of)

Zinc oxide (ZnO) is a versatile semiconductor material used for a wide range of applications in electronics, photonics, and optics. Bulk ZnO is a wide band gap (3.37 eV) semiconductor that generates electrons under an electromagnetic wavelength shorter than the ultraviolet (UV) range. ZnO nanowires (ZnO NWs) exhibit enhanced electrical properties over ZnO thin film via a nano size effect based on the electrical resistivity of chemical under UV irradiation. The NW structure induces movement of electrons along an axial direction due to the electron confinement effect by structural features. In order to utilize the advantages of nanostructured film in commercial sensors, mass production should be achieved with simple manufacturing processes. Electrospinning with a continuous process is possible in mass production with a roll-to-roll system. The use of a high porous electrospun nanofiber (ES NF) film is advantageous in terms of fabricating dense ZnO NWs. Additionally, a highly aligned state of ES NF films is possible to fabricate via controlling the electrospinning condition without entailing additional processes. The aligned nanofiber film aids in electron movement along the direction of the fiber, thereby revealing possibilities for its application to high responsibility in UV detector. Under the UV irradiation condition, ZnO NWs on ES NF film generate electrons under light energy absorption conditions that exceed the energy required to excite electrons based on Planck’s equation. Under continuous UV irradiation on the ZnO NWs surface, electrons in the valence band are excited to the conduction band when the electrons gain sufficient energy. The excited electrons on the ZnO NWs surface along the ES NF support have a strong directionality that tends to flow into the low current density region. The electrical conductivity on ZnO NWs increases by using aligned ES NF when compared to that of random ES NF by large gradient of current density. Linearity error of the ZnO NWs on aligned and random ES NF films are less than ±0.58% and
Tin sulfide (SnS) is a desirable absorber layer for thin film solar cells. Its optical bandgap of 1.1 eV, absorption coefficient of 10^7 cm^{-1} in the visible region, inherent p-type electrical conductivity, non-toxicity, earth abundance of the constituent elements, and stability in humid and oxygen ambient are all attractive toward developing alternative solar cell technology. Nevertheless, solar cells of SnS have reached a photovoltaic conversion efficiency of only 4.8%. The presence of secondary phases (SnS2, Sn2S3) and small grains is among the efficiency limiting factors. Here, we present methods to enhance the quality of chemically deposited SnS films through using thin layers of Sn and SnCl2 as flux materials produced by thermal evaporation and/or sulfur vapor to play a key role in grain growth during heating at 450 °C, while conserving its p-type electrical conductivity.

We prepared SnS thin films of 300 nm in thickness in an autoclave at 2.5 atmospheres and 55 °C with duration of deposition of 6 h. The deposition solution contained tin chloride and sodium thiosulfate. The as-deposited SnS thin films were of orthorhombic crystal structure, with an optical bandgap of 1.33 eV (indirect) and electrical conductivity of 1×10^{-4} Ω^{-1} cm^{-1} in the dark and 1×10^{-3} Ω^{-1} cm^{-1} under illumination. The films presented compact surface and dense cross-sectional morphology. We heated this film for 30 min, in a tubular oven in nitrogen atmosphere at 450 °C. Different flux materials were added during the heating to promote grain growth: sulfur, evaporated thin films of Sn metal, or SnCl2. The film heated with sulfur powder was p-type, with electrical conductivity, 10^{-4} Ω^{-1} cm^{-1}. SnS films heated under the same conditions using Sn as well as SnCl2 as flux materials retained the single phase of SnS with the formation of well-defined columnar grains of size equivalent to film thickness. They have a bandgap of 1.1 eV (indirect) and p-type electrical conductivity, 10^{-3} Ω^{-1} cm^{-1} in the dark, which increases to 1.5 times, under illumination. Thus, heating SnS absorber films deposited at a low temperature using chemical methods, with Sn or SnCl2 as flux materials is a promising methodology to achieve grain growth. We shall illustrate the effect of this in solar cells using SnS as absorbers.

d1.60%, respectively. Under UV irradiation conditions, the sheet resistance of ZnO NWs on the aligned ES NF film (0.17MΩ/) is 9.88 times lower than that for ZnO NWs on random ES NF film (1.68MΩ/). The results for ZnO NWs on ES NF films under the UV irradiation and dark conditions indicate sheet resistance ratios (Rsq,off/Rsq,on) of 551.0 and 47.8 for ZnO NWs on the aligned ES NF film and ZnO NWs on the random ES NF film, respectively. The sheet resistance ratio of ZnO NWs on the aligned ES NF film is 11.5 times than that of ZnO NWs on the random ES NF film. The electric current on aligned ES NF surface shows higher flow rate than electric current on random ES NF surface. Even though under the identical hydrothermal conditions to fabricate ZnO NWs, a geometry of ES NF film substrate is an important factor for improving the photo detecting performance of ZnO NWs on ES NF films.

Improving the Properties of Chemically Deposited SnS Thin Films via Metal/Metal Halide Assisted Heat Treatment Rohini Neendoor Mohan, Oscar Gomez Daza, Angelica L. Espinosa Santana, Diana E. Lara Llanderal, Padmanabhan Karunakaran Nair and M.T. Santhamma Nair; Universidad Nacional Autonoma de Mexico, Mexico

Amorphous oxide semiconductor (AOS) based thin-film transistors (TFTs) have been rapidly evolved from academic curiosity to the display industry because of their many advantages such as low off-current, high uniformity over large area fabrication, and high visible light transparency compared to conventional amorphous silicon (Si) TFTs. Despite these advantages, the poor electrical performances such as low field-effect mobility compared to low-temperature polycrystalline Si TFTs have been an issue for high resolution and high frame rate displays. Thus, a wide range of research has been conducted to enhance the field-effect mobility in AOS TFTs: doping a nano-conductor in the back channel, adoption of high-k gate insulators, and capping reduction layer. Among such researches, one of the most prominent methods was applying heterostructure with different oxide semiconductors to the channel layers of TFTs; due to large on-current and high field-effect mobility. The large difference in the work function of oxide semiconductor layers results in bandgap mismatches, forming potential wells. Therefore, electrons are confined in the potential well forming a 2-dimensional electron gas (2DEG). However, to apply 2DEG-based TFTs to the actual display industry, accurate 2DEG control and formation mechanisms need to be further studied.

In this paper, high performance oxide TFTs were fabricated by sodium hydrosulfite (Na2S2O4) reducing agent treated indium-zinc-oxide (r-IZO) as the front channel of zinc-tin-oxide (ZTO)/r-IZO heterostructure. Front channel IZO film was deposited by RF sputtering at room temperature. For reducing the IZO film, the IZO film was dipped into Na2S2O4 solution. Applying the Na2S2O4 reducing agent treatment on the front channel allows controlling the amount of confined electron at the interface between the front and the back channels for heterostructure oxide TFTs. For the back channel, ZTO film was deposited by
RF sputtering at room temperature. ZTO/r-IZO heterostructure is suitable for the formation of 2DEG due to the large difference in work function, so it could produce high field-effect mobility even when fabricated at room temperature. Also, the large on-current could be achieved by precisely controlling the formation of 2DEG through Na2S2O4 reducing agent treatment on the IZO front channel. To confirm the formation of 2DEG at the interface between the ZTO film and the r-IZO film, we performed a UV-vis spectrophotometer and ultraviolet photoelectron spectroscopy (UPS) measurements. The 2DEG was successfully formed by showing the difference of 170 meV work function at the heterointerface. However, conventional 2DEG-based oxide TFTs have high off-current because 2DEG free electrons remained at the heterointerface regions even when the TFT is in the off-state. To solve this problem, the ZTO back channel was applied to different oxygen partial pressures to the lower ZTO layer (20%) and the upper ZTO layer (30%) when deposited via sputtering. As a result, the high off-current could be adjusted to near the 10-12 A range and ZTO/r-IZO TFTs exhibit field-effect mobility of 29.55 cm2/Vs, a subthreshold swing of 0.48 V/decade, and an on/off current ratio of 5.02×108.

The results show that room temperature fabricated ZTO/r-IZO heterostructure TFTs can be used as a general route for high field-effect mobility TFTs and controllable oxide semiconductor devices for offering compatibility of the flexible and high-end display technology.

Plasma-Based Modification of Superconducting/dielectric Interfaces Evgeniya H. Lock1, Sandra Rodriguez Villanueva2, Peng Xu3, Yaniv Rosen3, Michael Katz4 and Kevin Osborn4; 1US Naval Research Laboratory, United States; 2University of Puerto Rico at Rio Piedras, United States; 3University of Maryland, United States; 4Lawrence Livermore National Laboratory, United States; 5National Research Council, United States; 6Laboratory of Physical Sciences, United States

Superconducting resonators and qubits are essential for the development of quantum-computing architectures. These systems depend on high quality superconducting materials and interfaces, in which the two-level systems loss is minimal. Our previous work focused on understanding of the effects of plasma modification of vacuum/silicon and vacuum/superconductor interfaces on the performance of TiN/Si superconducting microwave resonators. In this paper, we discuss plasma-based modification of TiN/Si interface. We provide a systematic study of every step in the preparation of the TiN/Si heterostructures, namely the chemical treatment with hydrofluoric acid of SiO2/Si surface, the plasma treatment of H-terminated Si and the TiN film deposition processes. We find that both the gas environment and the plasma processing conditions affect the modification of Si, which in turn affects the composition of the TiN/Si interface. The impact of this work lay in providing new approaches to TiN/Si interface preparation which may enable reduction of metal/dielectric interface losses thus improving the superconducting microwave resonators performance. This work was partially supported by the office of Naval Research through Naval Research Laboratory Base Program.

The Effects of Etching Parameters on Surface Morphologies by Anisotropic Etching with Resist-Mask Pin Y. Chen, Yu-De Li and Kun-Dar Li; National University of Tainan, Taiwan

For a long time, the etching technique played an important role in the electronics industry, and had a critical influence on the development of modern manufacturing technologies. Regarding to the operation of electronics devices, surfaces and interfaces significantly affect the functionality and performance of the devices. To investigate the formation mechanisms for characteristic surface morphologies during chemical etching, in this study an anisotropic chemical etching model was established and the formation and evolution of surface structures with resist-masks were simulated numerically. In this theoretical model, two major crystallographic orientations in a cubic system, such as <100> and <111> directions, were taken into consideration and included in the reactions of surface diffusion and anisotropic etching. By adjusting the numerical parameters corresponded to the different experimental conditions, various surface profiles could be created and the influence of the experimental parameters on the surface morphologies would be revealed. From the calculations of anisotropic etching along <100> preferred-directions, a V-shape profile with faceted surface morphologies appeared. A larger loss of linewidth or a higher etch bias was displayed with the increase of the etching rate. While an anisotropic etching along <111> preferred-direction was examined, etch pits were firstly produced in the early stage of etching process. A different surface evolution during a chemical etching was distinctly demonstrated due to the crystallographic structure. In addition, since the resist-mask was included in the numerical model, the phenomenon of undercutting in an anisotropic chemical etching could be also discussed in this study. These numerical simulations could provide a fundamental information to understand the formation mechanism of etched surface, and broaden the applications of chemical etching in the advanced manufacturing technologies.

High Efficiency X-Band AlGaN/GaN HEMT with Improved TiN/Ti/Al/Ni/Au Ke Wei, Yichuan Zhang, Shen Zhang, Guoguo Liu, Xiaojuan Chen, Yingkui Zheng, Sen Huang, Xinghua Wang and Xinyu Liu; Chinese Academy of
GaN based high electron mobility transistors (HEMTs) are considered of great potential to be the building blocks in the next-generation microwave power amplifiers due to their excellent power handling capabilities. Ohmic contact and passivation technology are the main factors of device power and efficiency. Improving device efficiency is the premise of improving application system efficiency. Nowadays, more and more efforts are made to improve the efficiency of GaN HEMTs. In this paper, we report the AlGaN/GaN HEMT with improved ohmic contact and double layer passivation. The device shows an excellent power characteristics.

In this talk, we report the use of surface-enhanced Raman scattering (SERS) to investigate the adsorption of thiol and isocyanide molecules on colloidal Ag nanocubes in situ. In a typical process, we mixed Ag nanocubes with ligand molecule solutions at different concentrations and then collected SERS spectra at different time points. We demonstrate that 4-nitrothiophenol (4-NTP) binds to the Ag surface rapidly because of the strong Ag−S chemical bonding. By decreasing the concentration of 4-NTP, we observe red shifts of the νNO2 band, which suggests the change to the orientation of ligands on the surface. Different from thiols, the 1,4-phenylene diisocyanide (1,4-PDI) binds to the Ag surface through π-donation with weaker binding strength. By increasing the concentration of 1,4-PDI, our results indicate that the molecules tend to adopt an orientation that tilts away from the surface. More interestingly, we investigate the competitive binding behavior of these two ligands by introducing Ag nanocubes into a solution containing both 4-NTP and 1,4-PDI. Our results show that thiol is more preferential to bind onto the surface when the concentrations of the two ligands are comparable in the solution.
between any two arbitrarily-chosen surfaces by enabling the absorption of interfacial strain, mismatch, and roughness while operating conditions. The double-sided construction of the composite and integrated bonding layers facilitate integration achieving thermal conductivities up to 200 W m\(^{-1}\)K\(^{-1}\), significantly advancing the state-of-the-art in TIMs.

The MnO\(_2\)/Co\(_3\)O\(_4\) nanostructures were uniformly deposited on the well-aligned ECNFs with high porosity, achieving excellent sensitivity of 973.91 μA mM\(^{-1}\) cm\(^{-2}\) and a low detection limit of 0.02 μM (S/N=3) with satisfactory selectivity, great performance towards glucose including a rapid glucose response within 5 seconds, a wide range (5 μM to 10.89 mM), reproducibility and stability. These excellent electrochemical performances were attributed to the synergistic effect of binary metal oxides and the unique porous architecture of the electrode. These features indicate that as-synthesized MnO\(_2\)/Co\(_3\)O\(_4\) binary nanostructure decorated well-aligned ECNFs hold great potential in the development of a commercialized glucose sensor.

Optical Filter Free Color Imaging with Perovskite Alloys Md Wayesh Qurony\(^1,2\), Mohammad I. Hossain\(^1\), Haris Ahmed

Conventional thermal management solutions in microelectronics packaging suffer from an inability to effectively couple thermal conduction and mechanical compliance into a single material, routinely necessitating a sacrifice in thermal, and therefore device, performance in favor of mechanical reliability. For the past few decades, compliant thermal interface materials (TIMs) have been limited to polymers loaded with dispersions of unaligned or randomly distributed conductive elements which can only achieve thermal conductivities up to ~5 W m\(^{-1}\)K\(^{-1}\). Here, we present the processing and characterization of a compliant, vertically-aligned metal nanowire composite ideal for achieving thin, flexible interfaces with low thermal resistance. The aligned nanowire composite is fabricated by electroplating copper into a 25-45% porous, sacrificial ceramic template, liberating the nanowires by chemically dissolving the template, and infusing the resulting nanowire array with a thermally stable polymer by capillary-driven wicking. An integrated bonding layer is added by sub-filling the template with copper and sequentially electroplating metallic solder to form localized solder tips on the nanowires. The entire fabrication process can be completed at wafer-scale with a lateral area up to 12.5 inches\(^2\). The thermal performance of the composite TIM was evaluated with a modified thermal resistance measurement designed to mimic typical operating conditions. The double-sided construction of the composite and integrated bonding layers facilitate integration between any two arbitrarily-chosen surfaces by enabling the absorption of interfacial strain, mismatch, and roughness while achieving thermal conductivities up to 200 W m\(^{-1}\)K\(^{-1}\), significantly advancing the state-of-the-art in TIMs.

Co-Electrodeposited MnO\(_2\) and Co\(_3\)O\(_4\) on Well-Aligned Electrospun Carbon Nanofibers for Sensitive Glucose Detection Ziyu Yin, Xinping Zeng and Jianjun Wei; The University of North Carolina of Greensboro, United States

Binary manganese oxide/cobalt oxide (MnO\(_2\)/Co\(_3\)O\(_4\)) composites on the well-aligned electrospun carbon nanofibers (MnO\(_2\)/Co\(_3\)O\(_4\)@ECNFs) were synthesized via a simple and economical one-step template-free electrodeposition technique with a constant low-current (60μA) for 3h, and their electrocatalytic activity towards non-enzymatic glucose sensors was evaluated in detail. The MnO\(_2\)/Co\(_3\)O\(_4\) nanostructures were uniformly deposited on the well-aligned ECNFs with high porosity, effective interconnectivity and large amounts of extended number of conducting channels. The electrocatalytic performances of as-prepared MnO\(_2\)/Co\(_3\)O\(_4\)@ECNFs towards the oxidation of glucose were carried out by cyclic voltammetry (CV) and chronoamperometry (CA), and the experimental results show that the MnO\(_2\)/Co\(_3\)O\(_4\)@ECNFs exhibited a superior sensing performance towards glucose including a rapid glucose response within 5 seconds, a wide range (5 μM to 10.89 mM), excellent sensitivity of 973.91 μA mM\(^{-1}\) cm\(^{-2}\) and a low detection limit of 0.02 μM (S/N=3) with satisfactory selectivity, great reproducibility and stability. These excellent electrochemical performances were attributed to the synergistic effect of binary metal oxides and the unique porous architecture of the electrode. These features indicate that as-synthesized MnO\(_2\)/Co\(_3\)O\(_4\) binary nanostructure decorated well-aligned ECNFs hold great potential in the development of a commercialized glucose sensor.

Exciton-Trapping by Stacking Fault Defects in GaAs Peter V. Sushko\textsuperscript{1}, Steven R. Spurgeon\textsuperscript{1}, Bethany Matthews\textsuperscript{1}, Xiayu Linpeng\textsuperscript{2}, Mikhail Durnev\textsuperscript{3}, Mikhail Glazov\textsuperscript{3}, Maria Viitaniemi\textsuperscript{2}, Andreas Wieck\textsuperscript{4}, Arne Ludwig\textsuperscript{4} and Kai-Mei Fu\textsuperscript{5}; \textsuperscript{1}Pacific Northwest National Laboratory, United States; \textsuperscript{2}University of Washington, United States; \textsuperscript{3}Ioffe Institute, Russian Federation; \textsuperscript{4}Lehrstuhl für Angewandte Festkörperphysik, Germany

The need to increase coherence times in quantum devices simulates the search for materials systems that can exhibit electronic states not affected by structural and chemical inhomogeneities. Owing to the advances in synthesis of III-V semiconductors, concentrations of point defects and impurities in these materials can be well controlled, while stacking faults (SFs) provide asymmetric quasi-2-dimensional potential wells that behave as internal interfaces capable of trapping excitons [1]. Here we use \textit{ab initio} simulations to examine how the stability and electronic properties of SFs change as a function of the distance between them and how the details of their configuration affect spatial distribution of the electron and hole components of excitons and their effective masses. Our simulations suggest that a potential drop of the order of 10 meV is associated with an isolated SF, which is sufficient for the hole to localize predominantly at the SF and to induce an asymmetric distribution of the excited electron density in the vicinity of the SF. For interacting SFs, we find that the electron distribution is sensitive to both the type of the SFs and the distance between them. This coupling provides a pathway to the
design of materials with spatially resolved excitonic properties and photo-emission energies by controlling the density and relative arrangements of the stacking faults.

Observation of Hyperfine Interactions of Silicon Vacancies in 4H-SiC Metal-Oxide-Semiconductor Field-Effect Transistors Utilizing Ultra-Low Field Frequency Swept Electrically Detected Magnetic Resonance

James Ashton, Patrick Lenahan, Brian R. Manning and Aivars J. Lelis; 1The Pennsylvania State University, United States; 2U.S. Army Research Laboratory, United States

4H-SiC metal-oxide-semiconductor field-effect transistors (MOSFETs) have great potential in high power and high temperature applications. However, near-interface defects degrade the effective channel mobility and thus limit the performance of 4H-SiC MOSFETs. In this work, we utilize electrically detected magnetic resonance (EDMR) to study hyperfine interactions with spin-dependent recombination (SDR) of silicon vacancy defects at the 4H-SiC interface in 4H-SiC MOSFETs. The physical foundation of EDMR is electron paramagnetic resonance (EPR). In EPR and EDMR, a sample is subjected to a large, slowly varying magnetic field and an RF or microwave oscillating field at a frequency \( \nu \). In the simplest case, EPR is achieved when \( h\nu = g_e \beta H \). Here, \( h \) is Planck’s constant, \( \nu \) is the electromagnetic radiation frequency, \( g_e \) is the free electron g factor (\( g_e \approx 2.0023 \)), \( \beta \) is the Bohr magneton, and \( H \) is a large externally applied magnetic field. At resonance, the electron transitions from its \(-1/2\) to \(+1/2\) spin state (or vice versa). The analytical power of EPR and EDMR comes from deviations from this simple case caused by the paramagnetic site environment. These perturbations are, for the most part, caused by hyperfine interactions, interactions of the electron with magnetic nuclei, and spin-orbit coupling. EPR detected via SDR allows for measurements of small numbers of defects via spin-dependent changes in device current. The sensitivity of SDR/EDMR is very nearly independent of the field or frequency at which the measurement is made. Prior continuous wave EDMR (cwEDMR) studies have linked interface and near-interface defects to carbon dangling bond defects and silicon vacancy defects. The identification of silicon vacancy defects in 4H-SiC MOSFETs was based on measuring nearest neighbor carbon 13 hyperfine interactions. \( ^{29}\text{Si} \) next-nearest neighbor (NNN) hyperfine interactions are too small to resolve in an EDMR measurement due to the width of the center part of the resonance signal. The interactions of NNN \( ^{29}\text{Si} \) are isotropic with a value 2.96 G determined from conventional EPR. Broadening in EDMR obscures these \( ^{29}\text{Si} \) NNN hyperfine interactions. We have overcome the EDMR broadening problem using the Breit-Rabi effect, a shift in the hyperfine side peaks towards lower fields and frequencies. This effect is sufficiently large so that it may be detected in ultra-low field and frequency measurements. We utilize frequency swept EDMR (fsEDMR). With fsEDMR, tuning the resonance condition is performed by varying a low static field. In fsEDMR, the magnetic field \( H \) is held constant as frequency is swept. Our experiments were carried out at fields less than 10 G and frequencies less than 30 MHz. We observe a centerline with a sharp peak on the low field side only at these low fields and frequencies. We attribute the peak to otherwise unresolved hyperfine interactions made observable by shifting due to Breit-Rabi effects. The peak has a fairly large amplitude.

EasySpin was utilized to simulate the results accounting for the presence of one \( ^{29}\text{Si} \) NNN. The results of the simulation are in good agreement with our experimental observation.

S.EL01.06.80
Optical Management of Flexible Thin Crystalline Silicon Solar Cells Using Textured PDMS Optical Sticker

Inchan Hwang and Kwanyong Seo; UNIST, Korea (the Republic of)

Thin crystalline silicon (less than 50 µm thickness) with outstanding flexibility has been considered as a means for developing flexible crystalline silicon (c-Si) solar cells. However, the optical management of the thin c-Si is required for developing the highly efficient c-Si flexible solar cells due to the high surface reflection (more than 30%) and absorption loss over 900 nm wavelength region. Here, we introduce novel high efficiency c-Si flexible solar cells which include random inverted pyramidal polydimethylsiloxane (RIP-PDMS) optical sticker on the 20-µm-thick thin c-Si solar cells. Due to the enhanced light absorption at the entire wavelength region, the thin c-Si with RIP-PDMS optical stickers showed the improved integrated photon flux absorption up to 85.4% (75.0% to 85.4%). The RIP-PDMS sticker enhances the light absorption
capability of the thin c-Si by increasing the optical path length in the thin c-Si up to 10%. Further, we analyzed the optical enhancement of the thin c-Si with the RIP-PDMS optical sticker through the finite-difference time-domain (FDTD) simulation. From the optical simulation, we confirmed that the optical path length in the thin c-Si increased because the angles of incident light at the front and rear surface of the thin c-Si tilted up to 10° and 15°, respectively, by attaching the RIP-PDMS optical stickers. Notably, the thin c-Si solar cells with the RIP-PDMS optical stickers showed 18.4% power conversion efficiency while maintaining superior flexibility (bending radius of 10 mm). In addition, our flexible thin c-Si solar cells with the RIP-PDMS optical stickers showed high bending stability without any change in efficiency, even with 1000 bending cycles with a bending radius of 10 mm. Thus, we believe that the thin c-Si solar cells with RIP-PDMS optical stickers can be a promising candidate for the highly efficient flexible solar cells.

Photovoltaic and Photoconductive Action Due to PbS Quantum Dots on Graphene/SiC Schottky Diodes from NIR to UV
Mathew Kelley, Joshua Letton, Grigory Simin, Fiaz Ahmed, Cole Love-Baker, Andrew B. Greytak and MVS Chandrashekar; University of South Carolina, United States

We demonstrate photovoltaic and photoconductive responses to near-infrared light in a new class of devices formed by depositing a film of gel permeation chromatography purified PbS quantum dots (QDs) on top of n-SiC epitaxial layers with natively grown, 10-15 monolayer thick epitaxial graphene (EG) Schottky contacts. The QD-film was removable by selective chemical etching, resetting the EG/SiC Schottky diode to its pristine state for multiple PbS-QD depositions. EG in these devices simultaneously forms Schottky contacts to SiC and ohmic contacts to PbS-QD, enabling electrical screening and isolation of these interfaces from each other. After PbS-QD deposition, the diodes exhibit photovoltaic and photoconductive response at photon energies far below the SiC bandgap, extending to the NIR gap of the QD film. Scanning photocurrent microscopy illustrates that this is due to charge transfer from the QD-film to the n-type 4H-SiC through a trap-limited, rectifying PbS-QD/SiC heterojunction with ideality n=2 in parallel with the EG/SiC Schottky diode. The photoconductive gain at this QD/SiC interface could be useful for IR detection in wide bandgap platforms. Response times as fast as 40 ms are suitable for imaging applications, although careful contact design is required to optimize work-function matching and spreading resistance.

S.EL01.06.07
Comparative Study of Surface Energy Engineering for Low Temperature (< 453 K) Nanobonding™ of LiTaO_3 and LiNbO_3 to Si and α-Quartz SiO_2
Mohammed Sahal, Brian Baker, Nicole Herbots, Nikhil C Suresh, Shaurya Khanna, Amber A Chow, Saaketh R. Narayan, Aashi R. Gurijala, Robert J. Culbertson, Lauren Puglisi and Thilina N. Balasooriya; Arizona State University, United States

Opto-electronic integration yields high density and high complexity electronic devices by improving speed and reducing interconnection bottle-necks. Heteroepitaxy and wafer bonding are the main technologies to achieve monolithic integration of heterogeneous materials. However, heteroepitaxy is limited by the mismatches between dissimilar lattice constants and between different coefficients of thermal expansion (CTE).

Direct Wafer Bonding (DWB) is the fusion of two mirror-polished, flat wafers, which overcomes the limitations of heteroepitaxy. DWB can be applied to many materials including bonding III–V, II-IV semiconductors and piezoelectrics to Si.

In this work, low-temperature DWB via NanoBondingTM is investigated to bond LiTaO_3 and LiNbO_3 to Si(100) and α-quartz SiO_2(100). Low-temperature NanoBonding™ of piezoelectrics such as LiTaO_3 and LiNbO_3 on Si-based materials can avoid issues arising from their CTE mismatch, since conventional DWB requires anneal temperature > 673 K.

The highly anisotropic CTE of LiTaO_3 ranges from ~ 4 x 10^{-6} /K along the c-axis to up to ~ 16 x 10^{-6}/K along the a-axis.
Thus, the CTE for LiTaO₃ is 2-10 times larger than the CTE for Si, 2.6 - 2.77 x 10⁻⁶ /K, and 10-30 times larger than the CTE for fused SiO₂ and α-quartz SiO₂, which ranges 0.54 - 0.76 x 10⁻⁶ /K. Thus even a low T anneal at 473 K is found to shatter a 6” LiTaO₃/Si bonded pair. Nano-Bonding™ at T < 473 K uses Surface Energy Engineering (SEE) instead of high temperature anneal to bond surfaces. In addition, processing temperatures for LiTaO₃ are found to be limited by thermal decomposition LiTaO₃ into Ta₂O₅ at T ≥ 453 K due to Li out-diffusion, as much as by LiTaO₃ fractures due to CTE mismatch.

SEE is guided by surface energy and hydro-affinity measurements, using Three Liquid Contact Angle Analysis (3LCAA) and the Van-Oss-Chaudhury-Good theory. 3LCAA is conducted with high statistics, by mapping wafers for three surface interactions, namely van der Waals interactions, electron donors, electron acceptors interactions. Multiple metered 10-µl drops of three liquids, water, glycerin, and α-bromo-naphthalene are used. The contact angles are extracted from a large set of drops and their reflection via an automated, fast, accurate algorithm, DROP™. The “as received” surfaces are characterized at equilibrium, to yield insights for SEE into modifying the initial surface energy and hydro-affinity to a far-from-equilibrium state.

As received 6” Si(100) wafers are initially hydrophilic with a uniform average water contact angle of 37.7 ± 0.6°, and an average surface energy γ of 57.6 ± 0.5 mJ/m². As-received α-quartz SiO₂(100) wafers surface were hydrophobic with an average water contact angle of 66.7 ± 1.7° and an average γ of 33.2 ± 0.8 mJ/m². 6” wafers of LiTaO₃ are initially mostly hydrophobic with an average water contact angle of 64.4 ± 2.7°, while water contact angle average 54.2 ± 8.1° LiTaO₃ and LiNbO₃ surface energies γ are low and very close: 38.8 ± 4 mJ/m² and 39 ± 2.5 mJ/m² respectively.

SEE via aqueous HF creates far-from-equilibrium Si surfaces by decreasing the initial γ of Si(100) from 57.6 ± 0.5 mJ/m² to 35 ± 0.03 mJ/m² and increasing the γ of α-quartz SiO₂(100) was increased from 33.2 ± 0.8 mJ/m² to 48.7 ± 1.5 mJ/m². Likewise, LiTaO₃ and LiNbO₃ were made hydrophilic via SC1(H₂O:NH₄OH:H₂O₂) solution (4:1:1) followed by aqueous HF etching.

Nano-contacting of LiNbO₃, LiTaO₃ on Si(100) and α-quartz SiO₂(100) and subsequent anneal at T < 453 K was performed to create a bonded interfacial phase. However, nano-contacting was only observed for hydrophobic LiTaO₃ and LiNbO₃ with hydrophilic Si-based surfaces. Results show that bonding hydrophobic LiTaO₃ and LiNbO₃ to hydrophilic Si or SiO₂ without anneal is much more effective than trying to bond hydrophilic LiTaO₃ to hydrophobic Si or SiO₂. This can be attributed to the modification of surface polarity and will be discussed based on the surface crystallography of LiTaO₃ and LiNbO₃.

Low Temperature c-Si/4H-SiC Heterojunction Growth Using Metal Induced Crystallization

Fabian Triendl, Georg Pfusterschmied, Christopher Zellner, Sabine Schwarz, Werner Artner and Ulrich Schmid; Technische Universität Wien, Austria

Metal induced crystallization is a well-known technique to reduce the crystallization temperature of amorphous semiconductors like a-Si using a catalytic metal. Crystallization temperatures even below 200 °C have been realized making it compatible with organic materials or other applications where only a limited temperature budget is acceptable. A combination of the wide band gap semiconductor 4H-SiC and such a low temperature process is barely investigated, although the Si/4H-SiC heterojunction offers huge potential in the field of e.g. heterojunction diodes, bipolar junction transistors and optical detectors. Conventional growth methods like chemical vapor deposition (CVD) need temperatures well above 800 °C to achieve epitaxial growth of Si on SiC. A low temperature method could make this heterojunction more practical, also in combination with other materials and temperature sensitive processes.

We present the first results to achieve partially epitaxial c-Si/4H-SiC interfaces using Al as catalytic metal. Sputter deposited amorphous silicon has been successfully crystallized on 4H-SiC at temperatures ranging from 350 to 700 °C. Annealing led to an almost complete layer exchange of Al and Si as well as to a heteroepitaxial interface of crystallized Si islands and the SiC surface. Si <111> was found to be the dominating crystallographic orientation of the re-crystallized Si. X-ray diffraction measurements show the change in Si crystalinity and the crystallographic impact of the underlying SiC substrate in this temperature range. TEM and SEM imaging was performed to investigate the film microstructure and the interface quality, thus revealing a clean and abrupt interface of large Si grains and the SiC substrate.

A Review on Controlling Nano-Scale Chemically Modified Thin Films for CMP Processes Development

G. Bahar Basim; University of Florida, United States
As the microelectronics manufacturing faces the challenges related to the Beyond Moore’s Scale adaptation, Chemical Mechanical Planarization (CMP) process control becomes much more critical yet difficult simultaneously. The need for planarizing larger scale wafers at an atomic scale precision with superior removal rate selectivity and zero-defect focus demands a nano-scale control on the process performance. This study reviews the atomic-scale chemical and mechanical interactions on CMP as it applies to traditional as well as the next generation materials in microelectronics manufacturing. Once the behavior of the wafer surface is understood at an atomic level, the process control metrics can be tuned accordingly.

In an attempt to come up with the design criteria for the slurry chemistry, chemically modified layer formation is evaluated on conducting, semiconducting and insulating materials as a function of evaluating the nano-scale surface topography and change in surface energy. Metallic films are studied in terms of their corrosion and passivation behavior through macro-scale electrochemical evaluations as well as surface-sensitive characterization techniques such as XRR, XRD and FTIR [1, 2]. In addition, a modeling approach is introduced through Cahn Hilliard Equation (CHE) approximation to the surface energy minimization on the metal-oxide formation by nucleation [3]. Furthermore, removal rate selectivity properties of the semiconductor materials are discussed on conventional and III-V semiconductors and insulators as a function of chemically modified film alteration [4-5]. Some high-end applications such as (i) tungsten T-gate transistors, (ii) new liner/barrier materials [6], (iii) germanium based high-speed, shallow trench isolation transistors and (iv) high-power transistors and LED applications where III/V semiconductors are deliberated. As a new challenge, 3-D implementations of the CMP process, where the chemically modified nano-films impact the performance of the materials are also introduced.

Direct Write Waveguides Using Multiphoton Lithography Michael Gallegos, Daryl Dagel, Amber Dagel, Andrew Pomerene, Allen Vawter, Erik Skogen and Bryan Kaehr; Sandia National Laboratories, United States

Abilities to capture, guide, and direct light into pixelated detectors (CCDs, CMOS sensors, FPAs, etc.) using free-form trajectories would be transformative for a range of technologies that currently use traditional optics (lenses, mirrors, prisms, etc.) for light coupling. However, few manufacturing techniques provide the appropriate scale and surface quality to address this task. In this work, we consider “free-form waveguides” using the high-resolution 3D printing technique of multiphoton lithography (MPL; also known as direct laser writing, DLW). First, we printed hollow and solid core vertical waveguide arrays spanning millimeters with single (5 micron) and multimode (30 micron) compatible cross-sections. Unsupported 5-micron diameter pillars generally succumbed to capillary forces during development and drying and thus sheathed waveguides were designed by anchoring fibers to a support scaffold. In addition, we examined direct printing onto active devices (coupling a source to a sensor) using an air-clad multimode design. Efficient light coupling was observed with scattering losses primarily from fabrication artifacts such as stitch lines. To address these issues, we considered stitch-free cores using a clad-only design resulting in encapsulated photoresist in the interior that is subsequently cured (UV, thermal) following development. These initial results, combined with the limitless design space afforded the MPL technique, provide a promising path forward to develop ultra-wide-field and highly compact imaging devices.

Role of Carbon and Oxygen Coverage in the Modification of Surface Energy and Hydro-Affinity of GaAs and Si for
Low Temperature Wafer Bonding Aashi R. Gurijala, Shaurya Khanna, Amber A. Chow, Nikhil Suresh, Mohammed Sahal, Sukesh Rami, Nicole Herbots, Thilina N. Balasooriya, Robert J. Culbertson and Karen Kavanagh; Arizona State University, United States; 2Yale University, United States

Native oxides increase electrical resistance and inhibit epitaxy on semiconductors. Their removal is key in opto-electronic integration for devices such as tandem solar cells. Besides heteroepitaxy, Direct Wafer Bonding (DWB) is a viable integration technology for GaAs and Si. NanoBonding is DWB conducted at low T (≤200°C) by modifying surface energy and hydro-affinity to reach far-from-equilibrium states and activate cross-bonding and electron exchange between the surfaces.

Hence, the surface energy has to be increased (if it is initially low), or decreased (if it is high). One of the surfaces in the pair has to be made hydrophilic if it is initially hydrophobic, and the other one hydrophilic if it is initially hydrophobic. Moreover, the surfaces have to be modified in a complementary way to so that electrons are transferred from electron donors from one surface to electron acceptors on the other.

To conduct Surface Energy Engineering (SEE) of GaAs and Si into a bonding pair, the initial surface energy, hydro-affinity, surface composition, and oxidation levels of as-received GaAs(100) and Si(100) are initially characterized. Next, the initial surface energies and hydro-affinities are modified not only by oxygen removal via chemical etching, but also to maximize cross-bonding. The characterization methods are Three Liquid Contact Angle Analysis (3LCAA) for surface energy and hydro-affinity, High Resolution Ion Beam Analysis (HR-IBA) for O coverage, and X-Ray Photoelectron Spectroscopy (XPS) for oxidation and C contamination.

In 3LCAA, the total surface energy, γT, is determined by the van Oss-Chaudhury-Good theory using 3 components: Lifshitz-Van der Waals, electron donors, and acceptors. GaAs(100) native oxides are hydrophobic with a low surface energy (γT=33.4 ±1.1 mJ/m2) while Si(100) native oxides are hydrophilic with a high surface energy (59.7±1.7 mJ/m2). GaAs surfaces are then etched with NH4OH:H2O (1:10) to be highly hydrophilic, while their γT can be reproducibly increased by a factor of 2 to 65.5 ±1.4 mJ/m2. HF:CH3OH (1:20) etching makes Si(100) hydrophobic and decreases its γT by 20% to 48.2 ± 1 mJ/m2.

Nano-bonding of GaAs to Si does not occur between these surfaces. However, Si(100) etched by aqueous HF becomes even more hydrophobic with a 25% decrease in γT to 44.4 ±2.3 mJ/m2. With this SEE of Si, GaAs nano-bonds to Si reproducibly.

O etching is measured by HR-IBA, while oxidation states and C-contamination are measured by XPS to correlate to nano-bonding. HR-IBA combines <111> channeling with O nuclear resonance to measure O coverage within ±0.2 Monolayers (ML) and analyzed via SIMNRA simulations. O coverage on GaAs is found to decrease by a factor 2 from 7.2±0.5 ML to 3.6±0.2 ML after etching.

The ratio of Ga and As is found to be unaffected by C-contamination, and remains ~54:46 within 1 atomic % by HR-IBA or ~1.18 within 10% by XPS. XPS shows that the relative ratio of Ga bound to GaAs versus Ga bound to Ga2O3 is initially 64:36 to within 1% with a slight increase in Ga bound to O. The relative ratio of As bound to GaAs versus As bound to O is much lower than Ga, 80:20 to within 1% and does not change with etching.

XPS analysis also shows that when C-contamination ranges between 12%-35% atomic %, the measured ratios of Ga and As bound to GaAs versus Ga and As bound to O vary less than 2%. After etching, Ga bound to Ga2O3 decreases with increasing carbon with a weak correlation factor of 0.4. C-contamination does not appear to significantly affect Ga oxidation. For As oxides, As2O5 shows a relative increase compared to As2O3 as C contamination increases with a strong correlation factor of 0.86 in native oxides before etching. After etching, the correlation factor is 0.55.

In summary, aqueous HF produces more hydrophobic Si(100) surfaces that can nano-bond to highly hydrophilic GaAs etched via dilute NH4OH while C contamination does not appear to modify GaAs surface composition nor oxidation.

Unraveling Vertical Inhomogeneity Effects in Vapor Phase Polymerized PEDOT:Tos Films Shangzhi Chen and Magnus P. Jonsson; Linköping University, Sweden

Electrically conductive polymers are widely utilized in emerging electronic devices due to their excellent optoelectronic properties as a potential alternative to conventional conductors. Among them, Poly(3,4-ethylenedioxythiophene):Tosylate (PEDOT:Tos) thin films deposited by Vapor Phase Polymerization (VPP) exhibit electrical conductivity exceeding 3400 S/cm which is almost comparable to commercial ITO electrodes. [1] Systematic investigation on such films indicates a strong anisotropy in electrical and optical properties and this anisotropy is believed to be mostly caused by the preferential alignment of para-crystallities in the films. [2]

Here, I will present our recent study on the VPP PEDOT:Tos thin film system and reveal that vertical gradient could also be an important factor contributing to the electrical anisotropy. By examining the results from grazing-incidence wide-angle X-ray scattering and X-ray photo-electron spectroscopy, we observed significant differences of the top and bottom surfaces, including para-crystalline alignment preference and oxidation level (doping level). These show that the VPP PEDOT:Tos...
layer is not vertically homogeneous in terms of both “crystallization” fraction and charge carriers (doping level). To explain the origin of this inhomogeneity, we propose a growth mechanism for VPP based on diffusion-limiting transport of polymerization precursors. Conductive polymer thin films with certain gradient profile may find applications in functionally graded thermoelectrics, gradient-index optics, and optoelectronic devices with gradient doping.

Interface Diffusion of AgGaTe2 Layers Prepared on Mo Electrode Layers Masakazu Kobayashi; Waseda University, Japan

Chalcopyrite materials based on CuInGaSe2 is practically used for the commercially available high efficiency solar cells. The room temperature bandgap of AgGaTe2 is about 1.3eV, hence the application of this material to the active layer of novel solar cells also attracted the attention. Among various film preparation methods, the closed space sublimation (CSS) method is suitable for the fabrication of mass production solar cells since it has various advantages toward the production cost reduction. The growth of crystallized AgGaTe2 thin films utilizing this method on Si and Al2O3 substrates have performed in past, and it was discovered that the introduction of the two-step sequence was the key to realize high quality thin films. The Ag2Te layer was deposited as the first step to avoid the melt-back etching related problems of Ga against substrate materials. Then, AgGaTe2 thin films were formed using the mixed powder source of Ag2Te and Ga2Te3. The AgGaTe2 thin films could also be prepared using the powder source of Ga2Te3. The first Ag2Te layer was disappeared during the high temperature growth process of the second sequence, and a single phase AgGaTe2 of the uniform layer has formed once the growth parameter was optimized.

It was clarified from the X-ray diffraction (XRD) measurement that the inclusion of AgGa5Te8 compounds occurred when the fraction of Ga2Te3 in the deposits was greater than that of Ag2Te. On the other hand, mixed crystal of AgGaTe2 and Ag2Te were formed when the fraction of Ga2Te3 was less than that of Ag2Te. These results corresponded to the phase diagram of the Ag2Te–Ga2Te3 system. A pn-heterojunction solar cell structure was prepared using the AgGaTe2 layer on the n-Si substrate, and the photovoltaic properties were confirmed. The AgGaTe2 layer was also prepared on the Mo/quartz substrate using the same growth sequence.

In case of the CuInGaSe2 layer growth on the Mo electrode layer, Se diffusion was observed in the Mo electrode layer. The advantage and disadvantage were still discussed for this structure. In this study, the interfacial diffusion of elements at AgGaTe2/Mo was studied to understand how the diffusion of Ga could be suppressed. High resolution cross sectional TEM images of the interfacial region was analyzed using the Z-contrast images of the high angle annular dark field (HAADF) mode and EDX-mapping mode.

When AgGaTe2 layer was directly grown on the Si substrate, Si surface was etched and became very rough, and it was considered that Ga has damaged the Si substrate surface. By introducing the two step procedure, the interface quality was substantially improved and the roughening was vanished.

Further investigation is ongoing to identify the diffusion characteristics at the AgGaTe2/Mo layers. It is reconfirmed that the two step growth procedure is a very useful approach to achieve the high quality layer, but processing temperatures including the growth temperature and post growth annealing temperature are very critical parameters to achieve the high quality interface with the abrupt profile.

Determining the Surface Chemistry of Lithiated Nickel-Manganese-Cobalt Oxide from Density Functional Theory and First-Principles Thermodynamics Josiah Roberts1, Chad Risko1 and Aashi R. Gurijala2; 1University of Kentucky,
Surfaces of materials such as lithiated nickel-manganese-cobalt oxide (NMC) can be characterized through experimental techniques such as photoelectron spectroscopy. These techniques take advantage of high-vacuum environments, though the vacuums are never perfect, and the materials are often exposed to ambient conditions prior to characterization or application, all of which could impact the surface composition. Hence, questions arise as to the data derived from periodic density functional theory (DFT) calculations that assume chemically clean surfaces in perfect vacuum and are used to describe these materials. To reconcile these differences, we investigate the surface chemistry of NMC through a combination of DFT and first-principles thermodynamics calculations. By examining the bulk structure, bare surfaces, and the adsorption of various atmospheric molecular and ionic species, we develop phase diagrams that reveal the expected surface chemistries as a function of various partial pressures, predicting the NMC surface chemistry as a function of the environment. Such predictions can be used to modify future computational studies of the material both in vacuum and in solution, providing additional tools for characterization.

Measurement of Electrical Contact Resistance at Nanoscale Gold-Graphite Interfaces Saima A. Sumaiya, Mohammad R. Vazirisereshk, Ashlie Martini and Mehmet Z. Baykara; University of California, United States

Electrical contact resistance (ECR) directly influences the performance of micro-scale devices, where contact between components occurs through nanometer-scale patches. Consequently, developing the ability to accurately measure ECR as a function of true contact size at the nanometer scale is of crucial importance. To achieve this goal, we present an approach based on conductive atomic force microscopy, which is applied on a material system comprising atomically flat interfaces formed between gold nano islands and a graphite substrate [1]. Proof-of-principle experiments are complemented by atomistic simulations, which are used to predict the maximum island sizes below which the ECR at the island-graphite junction can be reliably extracted from the measurements. This approach has the potential to contribute to fundamental studies of electron conduction, e.g. through an investigation of the transition between the diffusive and ballistic transport regimes.

Directed Patterning of Quantum Dots Using Chemically Modified Surface for Light Emitting Diodes Su Hong Min, Ho-Jong Kang and Dong Hyun Lee; Dankook University, Korea (the Republic of)

Colloidal quantum dots (QDs) have been widely used for light-emitting diodes (LEDs) because of their outstanding characteristics including high color purity, narrow emission peak, high luminescent efficiency, low operating voltage and adjustable emission wavelength that are tunable as a function of their size and composition. For the fabrication of QD-based LEDs, they have been applied to several processes such as spin-casting, inkjet printing and micro contact printing. However, these processes suffer from practical limitations such as high-resolution patterning, high cost, multiple-layer structures, and long processing time. In order to overcome the issues currently suggested, micro-contact printing method using the relief patterns on a master has been introduced and utilized extensively for QD-LEDs. In this way, the regular patterns of QDs layer is transferred on the hole transport layer (HTL) by simply physical contact between the master and the HTL surface. In spite of its efficiency, however, the cyclic process of the micro-contact printing inevitably gives rise to sever damages to the master patterns. Here, we demonstrate a unique method for directed patterning of colloidal quantum dots for the light emitting diodes from chemically modified surface. The chemically modified line-type patterns are initially fabricated on the substrate by using a conventional photolithography technique and selective chemical reaction of surface-modifying molecules such as the octadecyltrichlorosilane (OTS) sequentially. The width of line-type patterns produced is varying from 40 µm to a few µm. The quantum dots of CdSe(core)-ZnS(shell) that are covered with oleic acid as capping molecules are then spin-coated on the chemically patterned surface. To transfer the QDs layer to a hole transport layer, the polymethylmethacrylate (PMMA) is first spin-coated on the QDs layer followed by placing commercial adhesive tapes on the PMMA layer. Then the QDs/PMMA layer is detached from the original substrate by peeling the adhesive tapes and transferred to the target substrate. The target substrate consists of ITO(Anode), PEDOT: PSS(HIL), and TFB-HTL, respectively. It is noted that the only designed QD patterns are selectively transferred from the chemically modified surface due to surface energy difference during the transfer process. As the PMMA/tape layers are removed by rinsing with acetone, which is a selective solvent, the only QD patterns remain on the HTL layer of the target substrate. For the fabrication of QD-LEDs, ZnO(ETL) and Ag(Cathode) layers are deposited on the QDs layer sequentially. Consequently, the QD-LEDs fabricated in this study are characterized by measuring their electrical properties like luminance, current density and external
quantum efficiency.

The Chemistry of Interface Defects in SiC/SiO2 Probed by Hard X-Ray Photoelectron Spectroscopy Anna Regoutz;
University College London, United Kingdom

Interfaces govern the behaviour of all electronic devices. Herbert Kroemer coined the famous phrase “the interface is the device” in his 2000 Nobel Prize lecture, and we are still applying tremendous effort to understand interfaces in new material generations, with wide-bandgap materials being no exception. If anything, wide bandgap materials are more vulnerable to defect states purely due to their larger bandgap. Understanding gained for the bulk behaviour of semiconductors can often not be extended to the behaviour of materials in structured film stacks were interfaces play a vital role. SiC/SiO2 is a prototypical wide-bandgap semiconductor/dielectric interface, which represents the challenges faced by many such material systems. A multitude of different defects leads to unacceptably large defect densities exceeding 10^{13} cm^{-2} eV^{-1} in the vicinity of the conduction band of 4H-SiC. The management of interfacial defects remains a topic of lively discussion and current interest.

Here, we present a systematic study of the 4H-SiC/SiO2 interface in industrially manufactured samples with a particular focus on the effects of nitridation in N2, NO, NH3 and NO+NH3 atmospheres. High temperature nitridation has been shown to compensate interface defects leading to an increase in device performance, however, information on the local chemistry at the interface after such processes is scarce, which limits the understanding of the interface and consequently the targeted improvement of device characteristics. Clear differences are found in both spectroscopy and electrical behaviour after high temperature treatments. The present work uses energy-dependent hard X-ray photoelectron spectroscopy (HAXPES) to systematically study the elemental distributions and chemical environments across the 4H-SiC/SiO2 interface. We combine both laboratory- and synchrotron-based HAXPES results to obtain a complete picture of this important technological interface and to benchmark the capabilities of this spectroscopic technique for the exploration of buried interfaces in device heterostructures in general.

Experimental Study of Fundamental Material Properties of Alkali-Antimonide Photocathodes Pallavi Saha1, Oksana Chubenko1, Howard A. Padmore2 and Siddharth Karkare1; 1Arizona State University, United States; 2Lawrence Berkeley National Laboratory, United States

Alkali antimonides (such as Cs,Sb, K₂CsSb and Na₂Ksb) constitute a rather interesting class of materials, exhibiting high quantum efficiency (>10%) and high brightness in visible light making them interesting materials for use in photon detectors and as photoemission based electron sources for large linear particle accelerators (used for X-ray Free Electron Lasers, Electron Colliders and Hadron Beam Coolers) and time resolved electron microscopes. Despite ongoing work on these extremely vacuum sensitive materials for the last several decades, there has been no conclusive understanding and little/no consensus on its opto-electronic properties like band gap, electron affinity, optical constants etc. Lack of knowledge of these vital properties has stood in the way of understanding the process of photoemission in these materials near the photoemission threshold. The objective of our work is to grow high quality alkali-antimonide films with smooth surfaces and perform different spectroscopic characterizations like photoluminescence, photoconductivity and ellipsometry on them, in order to explore their opto-electronic properties in ultra high vacuum. It is believed that this detailed experimental study will elucidate the exact process responsible for efficient photoemission from these materials and allow us to develop state-of-the-art electron sources with maximized brightness.

Enhancing Nucleation of Metal ALD by Pre-Dosing Small Organometallic Molecules Camila de Paula, Nathaniel Richey, Li Zeng and Stacey F. Bent; Stanford University, United States

The process of thermal atomic layer deposition (ALD) of metals on non-metal surfaces is sought for many applications, but often suffers from nucleation delays that result in poor-quality films. These growth delays can result from a lack of suitable chemisorption sites on the non-metal surface. Various strategies have been explored to improve nucleation in these systems. Vapor phase pre-treatments have proven to be an especially promising nucleation enhancement strategy due to the minimal substrate-modification induced, its robustness, and its uniformity.

In this work, we demonstrate that pre-functionalizing the surface with a sub-monolayer of small organometallic molecules such as ZnEt₂, AlMe₃ and AlMe₂Cl, from the vapor phase can lead to a significant increase in the surface coverage of the metal deposited by ALD at low cycle numbers. This process is demonstrated using Pt ALD as a model process, using (methylcyclopentadienyl)trimethylplatinum (MeCpPtMe₃) and O₂ as reactants. Pt coverage was enhanced by ~ 3-fold after
100 ALD cycles and even larger enhancements were observed at lower cycle numbers following the pre-treatment. We hypothesize that the high coverage of the small organometallic molecules provides an alternative chemisorption mechanism for the platinum precursor leading to increased MeCpPtMe3 chemisorption during the first ALD cycle. This alternative chemisorption mechanism was investigated through in-situ X-ray photoelectron spectroscopy and mass spectrometry. Nanoparticle growth was monitored using grazing incidence small angle X-ray scattering and scanning electron microscopy. We determined that chemisorption of MeCpPtMe3 on the treated substrate originates from a Bronsted acid-base reaction (i.e., proton transfer reaction), where the MeCpPtMe3 acts as the Bronsted acid and the pre-treatment molecules serves as the Bronsted base. Growth analysis indicates that the pre-treatment leads to growth of highly dense, ordered Pt nanoparticles with improved wettability at low cycle numbers, leading to continuous and pinhole free Pt films.

Towards Scalable Fabrication of Atomic Wires in Silicon by Nano-Patterning Self-Assembled Molecular Monolayers
Chufan Zhang and Yaping Dan; Shanghai Jiao Tong University, China

Developing a scalable method to fabricate atomic wires is an important step for building solid-state semiconductor quantum computers. In recent years, self-assembled molecular monolayer doping (MLD) has attracted intensive research interests due to its capability of facilitating mass production and forming ultra-shallow junctions with atomic precision[1]. MLD is believed to have a great potential in controllable dopant manipulation at sub-10 nm scale[2]. However, there is still no general method for effectively patterning dopant-containing monolayer at nanoscale. In this work, a novel selective doping strategy is proposed by patterning self-assembled monolayer to a few nanometers using standard nanofabrication processes, which significantly improves the lateral doping resolution of monolayer doping from microscale to nanoscale.

We first found an effective way to remove the self-assembled monolayer via oxygen plasma followed by HF etching, which is confirmed by X-Ray photoelectron spectroscopy and Van der Pauw measurements. Electron beam resist HSQ (XR1541-002, Dow Corning) was used to create patterns that protect part of the self-assembled DVP monolayers from being oxidized by oxygen plasma, since HSQ will turn into amorphous SiO2 after electron beam exposure. To increase the resistance of the HSQ SiO2 against HF etching, a second time of high dosage exposure was performed on the HSQ structure. The high dosage electron beam exposure might induce a thin amorphous carbon layer covering the HSQ structures and dramatically improved the resistance of HSQ against HF etching.

Using this method, we further explore the possibility to fabricate phosphorus atomic wires in silicon by patterning self-assembled diethyl vinylphosphonate monolayers into lines with a width ranging from 500 nm to 10 nm. The phosphorus dopants are driven into silicon by rapid thermal annealing, forming dopant wires. Four-probe and Hall effect measurements are employed to characterize the dopant wires. The results show that the conductance is linear with the width for the wires, showing the success of the monolayer patterning process to nanoscale. To fabricate atomic wires made of one or a few lines of phosphorus atoms, we need to shorten the thermal diffusion length and increase the dopant incorporation rate at the same time. Pulsed laser annealing may be a promising solution. The present work provides a promising pathway for mass fabrication of atomic wires in silicon that may find important applications in quantum computing.

Optimizing n-Type Dopant Incorporation in GaAsBi for Multijunction Photovoltaics
Margaret A. Stevens, Kevin Grossklaus, Samuel Lenney, John H. McElearney and Thomas E. Vandervelde; Tufts University, United States

Multijunction photovoltaics employed in solar concentrator architectures can have theoretical efficiencies as high as 65% for a 4-junction cell [1]. For these devices, sub-cell band gaps of 0.96-1.18 eV are required. Epitaxially grown GaAsBi is of interest for this application due to (1) less lattice mismatch to GaAs than InGaAs for comparable band gaps [2] and (2) a proposed temperature-insensitive band gap and reduction in Auger recombination [3]. However, these materials are challenging to grow due to the surfactant-like nature and low solubility of bismuth (Bi) in this system. The low growth temperatures necessary for good bismuth incorporation is often at odds with good material quality. The need for depleted arsenic overpressure can often lead to challenging dopant incorporation [4], a critical requirement if these devices are to be employed in PN junctions.

2020 MRS Virtual Spring/Fall Meeting, November 27-December 4, 2020, Spring Abstracts Final Program 2/3/21
In this work, we explore methods to improve dopant incorporation and carrier mobility in GaAsBi$_{0.02}$ and GaAsBi$_{0.06}$ for future photovoltaic devices. Samples were grown on a Veeco GENxplor MBE using a valved As$_4$ source and a solid source effusion cell for group-III elements and Bi. Bismuth fraction and strain state were determined by high-resolution x-ray diffraction and absorption edge was measured by transmission spectroscopy. Select samples are grown lattice matched to InGaAs virtual substrates to decrease compressive strain which delays both Ga-Bi droplet formation and defect formation from strain relaxation [5]. Samples grown on GaAs and InGaAs substrates are doped with silicon or tellurium for n-type doping and beryllium for p-type doping. The benefits and challenges of using a group-IV n-type dopant versus using a group-VI n-type dopant in this materials system will be discussed. Mobility of GaAsBi as a function of dopant concentration was measured using Hall effect measurements and compared for the different choice of dopants. Temperature-dependent Hall measurements are utilized to explore scattering mechanisms. Additionally, the effects of ex situ thermal annealing at 500 °C on optical and electrical parameters will be discussed. Finally, mobility data will be fed into device simulations using Silvaco to evaluate best device architectures to use bulk GaAsBi films in photovoltaics.

Surface Chemical Composition Evolution During In-situ Annealing of Low-Strain Ge$_{1-x}$Sn$_x$ Layers on Core/Shell Nanowires
Michael Braun$^1$, Ishaa Bishnoi$^1$, Andrew C. Meng$^2$, John Z. Lentz$^1$ and Paul McIntyre$^3$; $^1$Stanford University, United States; $^2$University of Pennsylvania, United States

Metastable germanium-tin has attracted significant interest as a potential group IV direct bandgap material for CMOS compatible electronics and photonics. With sufficient tin incorporation, there is experimental evidence of a direct bandgap germanium-tin material.$^1$ Although this is a promising step for germanium-tin devices, there are further considerations for incorporating germanium-tin into a full device. Namely, the evolution of the germanium-tin surface during subsequent annealing and growth of additional device components. Previous annealing results on strained germanium-tin thin films have shown surface tin segregation and island formation.$^2$ In this study, we report results from in-situ X-ray photoelectron spectroscopy during annealing of vertical core/shell Ge/Ge$_{1-x}$Sn$_x$ nanowires grown via chemical vapor deposition. We have previously shown the capability of the core/shell structure to produce a largely strain-free Ge$_{1-x}$Sn$_x$ shell material on a highly tensile-strained Ge core.$^3$ This structure is utilized here to investigate the annealing characteristics of the germanium-tin surface and native oxide for tin contents in the range of 2 at% - 12 at% in air-exposed nanowires. Our results show the presence of a tin rich oxide with a composition dependent decomposition temperature. After in-situ decomposition of the native oxide, the tin content of the germanium-tin surface is observed to remain constant throughout annealing at temperatures exceeding 500 °C and for anneal durations greater than one hour. Additionally, we have measured the photoluminescence at room temperature, characterized strain by X-ray diffraction, and imaged the nanowire sidewall morphology before and after annealing to examine its effects on material performance, bulk tin distribution, and local surface structure.

Enhancement of Electrical Characteristics of Amorphous Indium-Gallium-Zinc-Oxide Thin-Film Transistors by Inserting Carrier Induced Interlayer
Chansic Yoon, Hyung Tae Kim, Min Seong Kim, Hyukjoon Yoo, Jeong Woo Park, Dong Hyun Choi, Dongwoo Kim and Hyun Jae Kim; Yonsei university, Korea (the Republic of)
Since the development of display technology, a new type of industry, such as augmented reality (AR), virtual reality (VR), and wide screen displays, has arrived. Requirements of performance standards on new type of displays have become more severe. Therefore, improving the mobility and stability of thin-film transistors (TFTs) for using in such devices have been actively conducted. To date, low temperature polycrystalline silicon (LTPS) with high field-effect mobility of about 100 cm²/Vs has been widely used as channel material for TFTs, but some problems remain, such as poor uniformity for large area, high leakage current, and high fabrication costs. To resolve the issues mentioned above, amorphous oxide semiconductor (AOS) has been attracted attention due to low off current, large area uniformity, and relatively low fabrication cost. Especially, amorphous Indium-Gallium-Zinc-Oxide (a-IGZO) is most used semiconductor among AOS materials. However, for AOS materials to be applied to the above-mentioned next-generation displays, low field-effect mobility and low stability under bias stresses, which are lower than LTPS, must be overcome.

In this sense, we propose the fabrication of a-IGZO TFTs with high mobility and high stability through insertion of a carrier induced interlayer (CII). CII is a layer introduced between the channel layer and the gate insulator layer, which is thinly deposited to absorb oxygen in the effective channel of a-IGZO through oxidation. Consequently, mobility of a-IGZO TFTs can be improved by oxidation of CII increasing carrier concentration of the a-IGZO front channel. In this study, thin aluminum layer was deposited for CII by RF sputtering process at 80 W with various deposition time 60, 90, and 120 s. Then, a-IGZO was deposited on the CII for channel layer while changing the oxygen partial pressure from 1.7 to 8.3%. After the activation process through thermal annealing at 300°C for 1 hour, Al was deposited by RF sputtering and used as source and drain electrodes. When the a-IGZO channel was deposited with oxygen partial pressures of 1.7, 3.3, and 5% without CII, the saturation mobility was 7.36, 5.45, and 2.83 cm²/Vs respectively. If it exceeds 5%, it is insulated. The above phenomenon caused by the oxygen vacancy concentration in the a-IGZO thin film decreases with increasing oxygen partial pressure. If the partial pressure of oxygen is less than 5%, Al for CII cannot be completely oxidized, resulting in normally conductive property. On the other hand, if the partial pressure of oxygen is more than 5%, the characteristics of the TFTs deteriorate. As a result, 5% condition achieves the best characteristics and determined as the optimize condition.

In the transfer characteristics of the TFTs with various CII thickness, the saturation mobility of the TFTs with CII of 60 s and 90 s deposition were calculated as 11.30 and 13.96 cm²/Vs respectively. As the thickness of CII increases, the saturation mobility also increases. However, switching characteristics of the TFTs with CII are gradually degraded due to insufficient oxidation of CII with metal Al over 120 s of the CII deposition time. The CII with insufficient oxidation acts as current path at the interface between the gate insulator and the channel layer, resulting in a drastically increased conductivity. Consequently, the optimize condition was determined to be CII deposition time of 90 s.

Lastly, bias stress tests were performed to determine the stability of the TFTs. Negative bias temperature illumination stress (NBTIS) test under -20 V, 50°C and 1000 lux for 3600 s was conducted on the TFT fabricated with oxygen partial pressure of 5% with CII deposition time of 90 s. When the result was compared with the a-IGZO TFT without CII (pristine), the stability characteristic was improved as the threshold voltage shifts of the pristine showed -12.05V and the device with oxygen partial pressure of 5% and with CII showed -6.73V.

Design and Demonstration of Novel Spectrally Selective Thermal-Radiation Material Takashi Ando1, Maki Ito1, Naoki Maruyama2, Takanobu Kobayashi2 and Yoshitaka Takezawa2; 1Hitachi Ltd, Japan; 2Hitachi Chemical Co., Ltd., Japan

Electronic devices, such as electronic control unit, power module, mobile equipment, etc., are required downsizing and higher power density. To achieve the downsizing and higher power density, electronic parts are closely mounted together in a small external package, which causes an increase of heat density. Thermal-radiation is one of the heat dissipation methods. However, conventional thermal-radiation is not useful in the electronic devices, since most of the radiated heat is absorbed by an external package such as resin.

The purpose of this study is to newly develop a thermal-radiation material, which generated heat is converted into infrared light with spectrum transmitting through the resin. The material is so-called spectrally selective thermal-radiation material (SSTRM). The studied SSTRM is composed of metallic spheres arrayed on the surface of a heating element, and resin film covering the metallic sphere array. The film is formed by applying a coating solution including metallic spheres. The optimum diameter and arrangement of the metallic sphere are founded numerically and experimentally.

The thermal-radiation spectrum was calculated by using an optical simulation tool based on Rigorous Coupled Wave Analysis. The calculation results clearly showed the localized plasmon resonance excited in the metallic spheres array. The localized plasmon resonance enhanced the emission at the resonance wavelength. The resonance wavelength was controlled by changing the diameter and arrangement of the metallic spheres. It was revealed that infrared light with spectrum transmitting through the resin film is emitted, when the spheres with a diameter of 1.5 um are densely arrayed.

The effectiveness of the SSTRM was experimentally demonstrated by evaluating thermal-radiation characteristics under the stationary atmosphere with a temperature of 298 K. Input power to a heating element was fixed at a constant value, so that...
the surface temperature of the heating element was 381.1 K. Three types of coating materials were prepared as follows: A. only resin film, B. metallic spheres dispersed in resin film, and C. optimized metallic sphere array covered with resin film (SSTRM). The surface temperatures of the heating elements coated with the films A, B, and C were evaluated to be 358.3K, 355.8K, and 348.1K, respectively. The film C achieved drastic temperature reduction of 33K compared with the heating element without the coating materials. The temperature of the film C was lower than that of B, due to the effect of the metallic sphere array formation. Consequently, the optimized metallic spheres array acted as the spectrally selective emitter that radiates infrared light transmitting through the resin. The SSTRM will be powerful material for heat dissipation from electronic devices packed in resin case or mold.

Improved Efficiency of Photo-Induced Electron Detection under UV Light Source by ZnO Nanowire Array on Aligned PVDF-TrFE Nanofiber Film Dong Hee Kang, Na Kyong Kim and Hyun Wook Kang; Chonnam National University, Korea (the Republic of)

Zinc oxide (ZnO) is a versatile semiconductor material used for a wide range of applications in electronics, photonics, and optics. Bulk ZnO is a wide band gap (3.37 eV) semiconductor that generates electrons under an electromagnetic wavelength shorter than the ultraviolet (UV) range. ZnO nanowires (ZnO NWs) exhibit enhanced electrical properties over ZnO thin film via a nano size effect based on the electrical resistivity of chemical under UV irradiation. The NW structure induces movement of electrons along an axial direction due to the electron confinement effect by structural features. In order to utilize the advantages of nanostructured film in commercial sensors, mass production should be achieved with simple manufacturing processes. Electrospinning with a continuous process is possible in mass production with a roll-to-roll system. The use of a high porous electrosprun nanofiber (ES NF) film is advantageous in terms of fabricating dense ZnO NWs. Additionally, a highly aligned state of ES NF films is possible to fabricate via controlling the electrospinning condition without entailing additional processes. The aligned nanofiber film aids in electron movement along the direction of the fiber, thereby revealing possibilities for its application to high responsibility in UV detector. Under the UV irradiation condition, ZnO NWs on ES NF film generate electrons under light energy absorption conditions that exceed the energy required to excite electrons based on Planck’s equation. Under continuous UV irradiation on the ZnO NWs surface, electrons in the valence band are excited to the conduction band when the electrons gain sufficient energy. The excited electrons on the ZnO NWs surface along the ES NF support have a strong directionality that tends to flow into the low current density region. The electrical conductivity on ZnO NWs increases by using aligned ES NF when compared to that of random ES NF by large gradient of current density. Linearity error of the ZnO NWs on aligned and random ES NF films are less than ±0.58% and ±1.60%, respectively. Under UV irradiation conditions, the sheet resistance of ZnO NWs on the aligned ES NF film (0.17MΩ/sq.) is 9.88 times lower than that for ZnO NWs on random ES NF film (1.68MΩ/sq.). The results for ZnO NWs on ES NF films under the UV irradiation and dark conditions indicate sheet resistance ratios (Rsq,off/Rsq,on) of 551.0 and 47.8 for ZnO NWs on the aligned ES NF film and ZnO NWs on the random ES NF film, respectively. The sheet resistance ratio of ZnO NWs on the aligned ES NF film is 11.5 times than that of ZnO NWs on the random ES NF film. The electric current on aligned ES NF surface shows higher flow rate than electric current on random ES NF surface. Even though under the identical hydrothermal conditions to fabricate ZnO NWs, a geometry of ES NF film substrate is an important factor for improving the photo detecting performance of ZnO NWs on ES NF films.

S.ELO1.06.90
Effect of Yarn Structure and Processing Conditions of Screen Printing on Electrical/Antenna Performance for E-Textile Applications Jung Hun Lee and Ju-Hee So; Korea Institute of Industrial Technology, Korea (the Republic of)

Wearable wireless communication systems based on Electronic textile (E-textile) have become significant interests owing to their potential applications in sportswear, military, firefighting, health care, and tracking systems. Among the fabrication methods of conductive textile, screen printing which prints metal nanoparticle based conductive inks on a fabric substrate has been known to be a promising approach in the field of wearable electronic applications. However, the morphological characteristics of textile materials such as high surface roughness, high porosity, and capillary force in the woven fabric structures and the lack of manufacturing technology to overcome the issues are obstacles to commercialization of electronic textiles (E-textile). Herein, we compare the flat and round yarn based polyethylene terephthalate (PET) fabrics as the substrates for screen printing. We also investigate the effect of the parameters of the screen printing process such as the screen mesh size (70, 120 pixel/inch) and the printing counts. The uniformity of the screen-printed layers and their electrical properties are directly related with the shape of the yarn, the roughness of fabric substrates, and the printing processing conditions. A minimum average sheet resistance of 16 ± 3 mΩ/sq. was achieved on the flat yarn PET fabrics, and there was little change in electrical performance after the bending test (r=3mm) was carried out 1,000 times. To demonstrate, we show textile antennas operating at 2.4GHz which is most widely used for public wireless LAN service, Bluetooth, radio frequency
identification (RFID). We analyzed the effects of the uniformity and the conductivity of the printed layers on the antenna performance. The field tests of the textile antennas in open areas showed better performance than commercial antennas. This study aims to advance E-textile devices with excellent electrical properties and mechanical durability for wearable wireless communication applications.

Investigation of Buried Junctions in CdSe\textsubscript{x}Te\textsubscript{1-x} / CdTe Devices Sean Jones\textsuperscript{1,2}, John Moseley\textsuperscript{2}, Harvey Guthrey\textsuperscript{2} and Brian Gorman\textsuperscript{1}; \textsuperscript{1}Colorado School of Mines, United States; \textsuperscript{2}National Renewable Energy Laboratory, United States

CdSe\textsubscript{x}Te\textsubscript{1-x} alloys now used in state-of-the-art CdTe solar cell technology can be further characterized and optimized. Se alloying can significantly reduce the bandgap of the CdTe absorber due to the strong bandgap bowing between CdTe and CdSe. This has been demonstrated to the enhance quantum efficiency in the infrared and boost the device short-circuit current (I\textsubscript{SC}). Interestingly, despite having a lower bandgap, devices using Se have achieved open-circuit voltages (V\textsubscript{OC}) on par with (unalloyed) CdTe-based devices. Recent time-resolved photoluminescence and cathodoluminescence data suggest that the CdSe\textsubscript{x}Te\textsubscript{1-x} materials have lower recombination rates and improved grain-boundary passivation relative to CdTe, and this appears to be making up for bandgap-related V\textsubscript{OC} losses\cite{1}. Further characterization studies should reveal additional relationships between absorber processing and the CdSe\textsubscript{x}Te\textsubscript{1-x} composition, current collection, recombination, etc., that can be used to optimize device performance.

There are two methods of CdSe\textsubscript{x}Te\textsubscript{1-x} growth. The first method creates a CdSe window layer for a CdTe device then allows diffusion to create a dopant gradient. The second processing method deposits a CdSe\textsubscript{x}Te\textsubscript{1-x} alloy layer and then a CdTe layer. Previous characterization studies have focused on the CdSe/CdTe device structure and the effects of changing window layer thickness and composition. A study by Poplawsky, et al. \cite{2}, indicated that, as CdSe window thickness increased, device performance increased then quickly decreased. Quantum efficiencies and correlative SEM/TEM analysis indicated that if the Se concentration was above 40 at\%, grains could change phases from zinc-blende to wurtzite and stop contributing to the device photocurrent. In the CdSe\textsubscript{x}Te\textsubscript{1-x}/CdTe structure, the Se concentration can be kept below 40 at\% to prevent the formation of the wurtzite phase.

To better understand the impact of Selenium concentration on device photo-collection, an Electron Beam Induced Current (EBIC) study is presented which studies the impact of Selenium on device collection for the CdSe\textsubscript{x}Te\textsubscript{1-x}/CdTe device structure. EBIC is an SEM-based characterization technique which uses an electron beam to locally excite carriers, which are subsequently collected and analyzed to understand microstructural effects on recombination. A current collection map can thus be created with sub-micron resolution. EBIC has been previously used to identify local variation in collection current at microstructural features such as heterojunction interfaces and grain boundaries\cite{2}. In this study, selenium concentration was varied in the alloy layer from 0 to 40 atomic percent while maintaining constant deposited layer thickness.

EBIC analyses of these alloy junctions indicate that the highest carrier collection was near the CdSe\textsubscript{x}Te\textsubscript{1-x}/CdTe interfaces with a second collection peak near the TCO/CdSe\textsubscript{x}Te\textsubscript{1-x} interface. This finding is indicative of a buried junction in the CdSe\textsubscript{x}Te\textsubscript{1-x}/CdTe device. Previous studies on the CdSe/CdTe structure have shown highest collection near the TCO contact with no buried junctions. The position and strength of this buried junction could decrease the effect of interface recombination at the TCO interface, but it could also decrease drift velocity, negatively impacting performance. These competing effects need to be better understood for the optimization of CdSe\textsubscript{x}Te\textsubscript{1-x}/CdTe device performance.

The presence of a buried junction in the CdSe\textsubscript{x}Te\textsubscript{1-x}/CdTe device implies a complex change in carrier concentrations and band structure within these devices. In order to better understand the implications of this observation, these results are correlated with a finite element device model. Using this model, it is possible to calculate the equilibrium band structure of the device and estimate the built-in potential at each junction.

S.EL01.06.33
Effects of Very High Workfunction Metals or Metal Alloys (NiCr) on High Switching Speed, HV Schottky Diodes for Mixed-Signal or RF ASIC

James Pan; Northrop Grumman Corporation, United States

For high switching speed HV Schottky diodes, with very high work function metal and extremely lightly doped epi, the built-in potential may be too high for thermionic emission to occur, when the applied external voltage is quite low (near the forward voltage: \( V_F = 0.07 \) V). If the epi is lightly doped p type, the built-in potential (\( V_{\text{Built-in}} \)) potential difference between the metal and silicon Fermi levels) is 1.0V (measured with CV). If the external bias is 0.1V, near the measured \( V_F \), it is not enough to overcome the built-in potential for thermionic emission as illustrated in the Figures. It is likely that in addition to thermionic emission, tunneling and diffusion currents also contribute to the total HV Schottky diode forward current. TCAD simulation of HV Schottky diodes with \( N^+ \) guard bands suggests the potential barrier and electric fields at the Schottky junction are relatively high for thermionic emission to occur, when external bias \( V >> V_F \).

In the Advanced Technology Laboratory (ATL) at Northrop Grumman Corporation, high performance RF ASICs and power devices in silicon, GaAs, GaN and 4H SiC are simulated, designed, fabricated, and packaged. Extensive DC and RF tests are conducted. The performance of HV Schottky diode is superior to conventional p-n junction diode due to higher BV, lower reverse leakage, lower \( V_F \) and higher output current. We have fabricated HV Schottky Diodes. \( BV > 150V, V_F = 0.07V \). High breakdown voltage, low forward voltage drop, and low reverse leakage are achieved with very high work function metal alloys and low doping epi films.

Lightly doped p (100) or n (100) type silicon films are deposited with epitaxy. Metal or metal alloys are deposited with sputtering. Figure 1 shows the measured I-V’s for the Schottky Diodes. Avalanche breakdown voltage > 150V is recorded with low reverse leakage current. The voltage required to turn the diode on is defined as \( V_F – \) when the current reaches 0.1uA.

Forward bias characteristics of Ti, Au, and NiCr are measured. These data indicate that in order to achieve low \( V_F \) and high current, very high work function metals are needed.

High frequency CV tests are conducted using the HV Schottky Diodes. These CV data are used to extract the doping profiles .

Metal work functions are extracted with the \( 1/C^2 \) vs. \( V \) plots. Interception with the x axis is \( DV \), which is the potential difference between metal and silicon Fermi levels, or built-in potential \( V_{\text{Built-in}} \). Metal work function is extracted with DV. One of the Figures shows the measured doping profiles and \( 1/C^2 \) vs. \( V \) plots. From the measured I-V and C-V data we may calculate the avalanche breakdown critical electric fields and metal work functions. A summary of HV Schottky diodes fabricated with NiCr, Ti, Au in Si n and p epi films will be presented.

Energy band diagram is analyzed for HV Schottky diodes: NiCr in p epi (external bias = 0V) \( V_{\text{Built-in}} = 1.00V \).

Another energy band is analyzed for HV Schottky diodes: NiCr in n epi (external bias = +0.50V). \( V_{\text{Built-in}} = 1.56V \).

In conclusion: we have fabricated HV Schottky Diodes. \( BV > 150V, V_F = 0.07V \). High breakdown voltage, low forward voltage drop, and low reverse leakage are achieved with very high work function metal alloys and low doping epi films. Diffusion and tunneling currents likely contribute to the total Schottky junction current.

S.EL01.06.36
Chemistry Behind Dodecanethiol Treatment of Colloidal CsPbBr3 Nanocrystals with Photoluminescence Quantum Yields Reaching ~100%

Md Aslam Uddin, Justin K. Mobley, Abdullah A. Masud, Tuo Liu, Rosemary L. Calabro, Doo Y. Kim, Christopher I. Richards and Kenneth R. Graham; University of Kentucky, United States

Metal halide perovskite nanocrystals (NCs) are attractive materials for optoelectronics because of their optical and electronic properties, such as tunable direct band gaps, high absorption coefficients, low exciton binding energies, relatively high electron and hole mobilities, narrow emission line-widths, and high photoluminescence quantum yields (\( \Phi_{\text{PL}} \)). However, further improvements in stability and reproducibility in \( \Phi_{\text{PL}} \) of NCs are essential for enabling future optoelectronic applications. Inadequate surface passivation due to labile parent ligands, such as olate and oleyl ammonium ions is a major cause of instability and less than unity \( \Phi_{\text{PL}} \). Herein, we probe the influence of multiple molecular and ionic ligand binding
groups including thiols, thioethers, phosphine, phosphine oxide, sulfobetaine, thiocyanate, and sulfate salts on the colloidal stability and ΦPL of CsPbBr3 NCs. Among all the binding ligands, post-synthetic treatment with dodecanethiol reproducibly yields highly stable NCs with near unity ΦPL for a range of synthetic conditions and initial ΦPL of the as-synthesized NCs. A few of the other ligands can also increase the ΦPL, but in ambient atmosphere they are unable to maintain stability more than 5 days. A mechanistic investigation shows that thiol addition to the as-synthesized NC dispersion leads to the thiol-ene reaction with octadecene, oleic acid, & oleylamine and formation of thiolate ions and thioethers. Both thiolates and thioethers are suspected to bind to undercoordinated Pb atoms and consequently eliminate metallic Pb particles commonly observed with transmission electron microscopy on the NC surfaces. The process of enhancing PL intensity and stability can be rapidly accelerated through exposure to blue or UV light.

S.EL01.06.39
Fast and Simplified Synthesis of Spiky-Like Copper Sulfide Nanoballs by Soft Chemistry Method for Optoelectronics Applications
Anderson Klay R. Jaime, Diana V. Hernández, Judith Celina T. Córdova and Santos J. Castillo; Universidad de Sonora, Mexico

Fast synthesis of copper sulfide nanoparticles through two different methods is described in the present investigation. The first reaction was carried out by applying of heating in constant temperature water bath while in the second case the mixture was sonicated. As copper and sulfur sources, copper nitrate and thiourea solutions were used respectively. Main physicochemical properties of the synthesized samples were studied using several characterization techniques. Formation of copper sulfide with hexagonal crystalline structure was corroborated, coinciding with previously reported values for covellite. The most important results corresponded to the un-sonicated sample, which exhibited spiky-like nanoballs morphology and better size distribution. Optical tests revealed band gaps of 1.69 and 2.05 eV, while photoluminescence emissions at 421 and 430 nm, showing promising possibilities for applications in solar cells, catalysis and optoelectronic devices.

S.EL01.06.40
Effect of Si Nanoparticles on Reflectance Spectra for Ge and Ge/Si Substrates
Sabina Abdul Hadi1, Ayman Z. Rezk2 and Ammar Nayfeh2; 1University of Dubai, United Arab Emirates; 2Khalifa University, United Arab Emirates

The continuous innovation in nano materials has allowed the development of new antireflective coats (ARCs) for optical lenses, solar cells, data storage, displays and others that require a reduced reflectance to increase efficiency. Multi-layered ARCs particularly have attracted attention lately for demonstrating low and tunable spectral reflectance.

This paper presents a simple approach for forming anti-reflective coating stacks on bulk Ge and PECVD Ge grown on Si employing colloidal dispersions of Si nanoparticles (NPs).

The Si NPs have a diameter of 2.85 nm and are prepared by chemical etching of crystalline Si wafers in HF and H2O2 using electrical or hexachloroplatinic acid catalyst. The nanoparticles are recovered by sonicating the wafers in isopropyl alcohol, forming a stable colloid with concentration of 10 µM [1].

Each antireflective coat is applied by the drop casting of monodispersed Si NPs on a 3 by 3 cm pieces of both Ge bulk and PECVD Ge grown on Si. A total of 5 drops are applied with each drop consisting of 100 µL. After each drop, the samples are left to dry for an hour and a half.

For bulk Ge, (110) Sb doped (n-type) Ge with a resistivity of 0.1–0.5 Ωcm were used, while for the PECVD Ge growth, (100) P doped (n-type) Si with a resistivity of 0.01–0.02 Ωcm are used as starting substrates. An Oxford Instrument System 100 PECVD activated by 13.56 MHz radio frequency signal is used to grow Ge layers on Si substrates. High purity germane (GeH4), H2 and Ar gases are used as precursors for Ge growth. The undoped Ge film was grown using the two-step approach, which has been described in detail in our previous work [2].

The impact of multiple drop casting of Si NPs on the antireflective properties of the Ge surfaces were investigated by the analysis of their reflection spectra. The reflectance of the coating was measured at four locations on each sample by a UV–VIS spectrophotometer (Lambda 850, PerkinElmer). The samples were qualified by controlling the reflectance at the four points within an error of 1.2%. The corresponding reflection spectra were captured as a function of the incident wavelength, ranging from 250 nm to 1500 nm.

For PECVD Ge grown on Si substrates, the average reduction in reflectance has shown to increase as the incident wavelength decreases, with a decrease of ~2% after each 100 µL coating. After 5 drops (100 µL ×5), the overall reflectance across the whole spectra is on average 9.35% lower compared to the uncoated samples. The minimum decrease in reflectance was of
2.49% at 1290 nm and the maximum of 34% at 250 nm.

For Bulk Ge, the average reduction in reflectance has shown to increase as the incident wavelength decreases from 1500 nm to 320 nm. At 500 μL, the reduction in reflectance had an average of 6.16% (Min.: 2.73% at 1500 nm, Max.: 13.75% at 320 nm and Median: 5.1%). At lower wavelengths range from 250 nm to 320 nm), the amount of reflectance reduction is less compared to wavelengths above 320 nm.

After 5 drops (100 μL × 5) on PECVD Ge samples, the incident wavelength where the minimum reflectance occurred (λ_{\text{min}}), shifted from 1050 nm where reflectance is lowered by 34.5%, to 410 nm with 25.2% reduction in reflectance. While for bulk Ge sample, λ_{\text{min}} shift occurs from ~1480 nm to ~420 nm with a decrease in reflectance of 37.9% and 28%, respectively.

Results demonstrate that it is feasible to deposit a coating of Si NPs with tunable reflectivity over a wide range by drop casting multiple layers of the nanoparticles.

S.E.L01.06.41
An Improved Model of Ge Bi-Layers Incorporated CZTSe Devices with MoSe2 Interlayer

Sanghyun Lee¹, Kent Price² and Edgardo Saucedo³; ¹Indiana State University, United States; ²Morehead State University, United States; ³Institut de Recerca en Energia de Catalunya, Spain

As environmentally benign and highly-efficient thin-film solar cells, low-cost Cu₂ZnSn(S,Se)₄ (or kesterite) solar cells, herein CZT(S,Se) have been steadily emerging as an alternative for the 2nd generation Cu(In,Ga)Se₂ (CIGS) and CdTe solar cells in the past several years. CZT(S,Se) solar cells have several advantages such as high absorptions coefficient (>10⁴ cm⁻¹), tunable direct band gap energy (1 to 1.4 eV), and usage of abundant elements in earth's crust, becoming an ideal platform to harvest solar energy. However, the efficiency improvement and understanding of emerging CZT(S,Se) is still in an early stage compared to the 2nd generation counterparts. In recent progress, our team reported that Germanium (Ge) incorporation into CZTSe solar cells has improved device performance, which contributed to deepening understanding of Ge-alloyed CZT(S,Se) solar cells, in particular, on the Schottky-type back-contact barrier.

We present the complete set of models about the Schottky barrier with the MoSe₂ interlayer between the absorber and Molybdenum (Mo) back-contact. Developed analytical models with in-house MATLAB simulators agree well with TCAD numerical simulation and experimental results. A new concept of an effective back-contact barrier is introduced, which provides the mechanism of the improved device performance with lower back-contact barrier for CZTSe Ge bi-layers devices. By incorporating nanoscale Ge bi-layers below and above the CZTSe absorber, the back-contact barrier is improved by 33 %, and power conversion efficiency is improved by 1.1 % than Ge single-layer devices. Based on the back-contact model, defect concentration of Ge reference devices is estimated to be 5.4 x 10¹⁶ cm⁻³, whereas Ge bi-layers devices show an estimated <9.8 x 10¹⁵ cm⁻³ at the back-contact interface. To compare models with experimental results, we fabricated three different types of CZTSe: nanoscale Ge devices. The property of the back-contact barrier is assessed by characterizing a temperature-dependent behavior of CZTSe alloyed devices.

Collectively, the reduced defect concentration by Ge incorporation in the MoSe₂ interlayer improves the barrier height of back-contact. As the defect concentration of the MoSe₂ interlayer increases, the benefit from the back-contact barrier lowering by the valence bands offset is reduced and essentially eliminated. Moreover, the increased effective back-contact barrier degrades the series resistance and the overall device performance. However, the barrier at the interface between MoSe₂ and Mo metal contact remains the same, even with MoSe₂ defect concentration increase. Incorporating thin Ge nanolayer at the interface between the absorber and MoSe₂ could positively influence and possibly reduce the defect states, which lowers the effective back-contact barrier from modeling and simulation results. Hence, the Ge layer at the back-contact interface successfully improves the conversion efficiency up to 8.3 % with the improved back-contact.

S.E.L01.06.42
16.5% ZMO/CdTe Solar Cells with Copper Thiocyanate as Back Contact

Dengbing Li, Sandip S. Bista, Fadhil K. Alfadhili, Niraj Shrestha, Rasha A. Awni, Zhaoning Song and Yanfa Yan; University of Toledo, United States

The replacement of traditional CdS buffer layer with magnesium doped zinc oxide (ZMO) has been demonstrated helpful to boost higher CdTe solar cell performance exceeding 18% due to the reduced interface recombination and parasitic light absorption by buffer layer. However, due to the atmosphere sensitivity of ZMO film, The post-treatments of ZMO/CdTe
stacks, including CdCl\textsubscript{2} treatment, back contact deposition et. al, which are critical for high performance CdTe solar cells, became crucial challenge. In order to maximize the expected benefit of ZMO cooperation, plenty of investigation need to be accomplished in the future. Here, copper thiocyanate (CuSCN) is demonstrated to be a powerful back-contact material with multi-advantages without degrading ZMO layer in CdTe solar cells, even with ammonium hydroxide as the solvent. The thickness of CuSCN film as well as the subsequent annealing temperature are systematically investigated and the highest efficiency 16.5% has been achieved with open-circuited voltage 850 mV, short-circuited current 26.2 mA/cm\textsuperscript{2} and fill factor 74.0%.

S.EL01.06.46
Improving the Properties of Chemically Deposited SnS Thin Films via Metal/Metal Halide Assisted Heat Treatment Rohini Neendoor Mohan, Oscar Gomez Daza, Angelica L. Espinosa Santana, Diana E. Lara Llanderal, Padmanabhan Karunakaran Nair and M.T. Santhamma Nair; Universidad Nacional Autonoma de Mexico, Mexico

Tin sulfide (SnS) is a desirable absorber layer for thin film solar cells. Its optical bandgap of 1.1 eV, absorption coefficient of 10\textsuperscript{5} cm\textsuperscript{-1} in the visible region, inherent p-type electrical conductivity, non-toxicity, earth abundance of the constituent elements, and stability in humid and oxygen ambient are all attractive toward developing alternative solar cell technology. Nevertheless, solar cells of SnS have reached a photovoltaic conversion efficiency of only 4.8 %. The presence of secondary phases (SnS\textsubscript{2}, Sn\textsubscript{2}S\textsubscript{3}) and small grains is among the efficiency limiting factors. Here, we present methods to enhance the quality of chemically deposited SnS films through using thin layers of Sn and SnCl\textsubscript{2} as flux materials produced by thermal evaporation and/or sulfur vapor to play a key role in grain growth during heating at 450 °C, while conserving its p-type electrical conductivity.

We prepared SnS thin films of 300 nm in thickness in an autoclave at 2.5 atmospheres and 55 °C with duration of deposition of 6 h. The deposition solution contained tin chloride and sodium thiosulfate. The as-deposited SnS thin films were of orthorhombic crystal structure, with an optical bandgap of 1.33 eV (indirect) and electrical conductivity of 1×10\textsuperscript{-4} Ω\textsuperscript{-1} cm\textsuperscript{-1} in the dark and 1×10\textsuperscript{-3} Ω\textsuperscript{-1} cm\textsuperscript{-1} under illumination. The films presented compact surface and dense cross-sectional morphology. We heated this film for 30 min, in a tubular oven in nitrogen atmosphere at 450 °C. Different flux materials were added during the heating to promote grain growth: sulfur, evaporated thin films of Sn metal, or SnCl\textsubscript{2}. The film heated with sulfur powder was p-type, with electrical conductivity, 10 – 4 Ω-1 cm – 1. SnS films heated under the same conditions using Sn as well as SnCl\textsubscript{2} as flux materials retained the single phase of SnS with the formation of well-defined columnar grains of size equivalent to film thickness. They have a bandgap of 1.1 eV (indirect) and p-type electrical conductivity, 10\textsuperscript{-3} Ω\textsuperscript{-1} cm\textsuperscript{-1} in the dark, which increases to 1.5 times, under illumination. Thus, heating SnS absorber films deposited at a low temperature using chemical methods, with Sn or SnCl\textsubscript{2} as flux materials is a promising methodology to achieve grain growth. We shall illustrate the effect of this in solar cells using SnS as absorbers.

Pulsed Laser Deposited Polycrystalline Thin Films of MoO\textsubscript{3} for Sensing of High-Energy Moieties Dhanashree Sable, Swapnali Rabade and Sangeeta N. Kale; Defence Institute of Advanced Technology, India

Among various nanostructured metal oxides, molybdenum oxide (MoO\textsubscript{3}), a wide band-gap n-type semiconductor, has attracted much interest as a promising gas sensor because of its excellent sensitivity, good reproducibility, low cost, high compatibility with microelectronic processing, low electron recombination rate, and high stability. The MoO\textsubscript{3} thin films have promising electrical properties for gas sensing applications.

To synthesize two-dimensional materials under ultra-high vacuum is a key advantage for enhancing the properties of nanostructured materials. In this presentation, we demonstrate the synthesis, characterization, and gas sensing properties of MoO\textsubscript{3} films, which were grown using Krypton-Fluoride (248 nm) excimer laser. Deposition was done under 200 mTorr Oxygen pressure at the substrate temperature of 600°C. The targets used for deposition were synthesised using hydrothermal method. The deposition was done with the optimized parameters, to ensure good polycrystalline films on the Si (001) substrate. The optical, morphological and compositional properties of MoO\textsubscript{3} films were studied by using UV-Visible spectroscopy, Scanning Electron Microscopy and Raman Spectroscopy. The formation of MoO\textsubscript{3} was also confirmed using X-Ray Diffraction technique. The MoO\textsubscript{3} films showed excellent response to NO\textsubscript{x} and NO\textsubscript{2} gas moieties, at even low gas concentrations from 100 ppm onwards. The sensor not only exhibits high sensitivity but also good selectivity towards NO\textsubscript{2} gas.

**Photothermoelectric Detection of Crystal Defects and Grain Boundaries in Gold**

Lucia Gan¹, Charlotte Evans², Rui Yang¹, Mahdiyeh Abbasi², Xifan Wang², Rachel Traylor¹, William Nix¹, Douglas Natelson² and Jonathan Fan¹; ¹Stanford University, United States; ²Rice University, United States

As devices continue to trend towards the micro- and nanoscale, the influence of individual crystal defects on their optical, electronic, and thermal properties becomes significant. As an example, the thermoelectric properties of these nanodevices are closely related to the presence of crystal defects, grain boundaries, and strain. While the effects of interfaces and grain boundaries on thermoelectric performance have been widely studied in semiconductor materials, there remains an incomplete understanding of the role that crystal defects play in metals. A major challenge in pinpointing the origins of thermoelectric variation in metallic nanodevices is the difficulty in preparing high quality crystalline thin-film metal microstructures on thermally and electrically insulating amorphous substrates.

Controlling the micro- and nanostructure of metals offers the opportunity to investigate and engineer the properties of metal nanotechnologies. Here, we report a high-throughput method for preparing patterned crystalline gold microstructures grown directly on amorphous insulating oxide via rapid melt growth. In this growth process, thin-film gold-platinum metal-seed microstructures are encapsulated in an insulating crucible and annealed at temperatures above gold’s melting point. During cooling, liquid epitaxial growth directs single crystal solidification [1]. We can extend this platform to controllably prepare single grain boundaries [2], enabling the systematic study of the role of defects in governing local thermoelectric behavior. A scanning photothermoelectric (PTE) setup to allows us to probe the microscopic variations in photovoltage across the gold single crystal and bicrystal wires. Surprisingly, we observe a photovoltage distribution where local changes in Seebeck coefficient are highly influenced by long-range strain fields and concentrated dislocations and uncorrelated with plane grain boundary defects. Our results showcase the link between the presence of elastic strain and dislocations to the PTE effect using a model material system.

**Room Temperature Fabrication of Two-Dimensional Electron Gas (2DEG)-Based High Performance Oxide Thin-Film Transistors**

Dong Hyun Choi, Jeong Woo Park, Hyukjoon Yoo, Jusung Chung, Hyung Tae Kim, Min Seong Kim and Hyun Jae Kim; Yonsei University, Korea (the Republic of)

Amorphous oxide semiconductor (AOS) based thin-film transistors (TFTs) have been rapidly evolved from academic curiosity to the display industry because of their many advantages such as low off-current, high uniformity over large area fabrication, and high visible light transparency compared to conventional amorphous silicon (Si) TFTs. Despite these advantages, the poor electrical performances such as low field-effect mobility compared to low-temperature polycrystalline Si TFTs have been an issue for high resolution and high frame rate displays. Thus, a wide range of research has been conducted to enhance the field-effect mobility in AOS TFTs: doping a nano-conductor in the back channel, adoption of high-k gate insulators, and capping reduction layer. Among such researches, one of the most prominent methods was applying heterostructure with different oxide semiconductors to the channel layers of TFTs; due to large on-current and high field-effect mobility. The large difference in the work function of oxide semiconductor layers results in bandgap mismatches, forming potential wells. Therefore, electrons are confined in the potential well forming a 2-dimensional electron gas (2DEG). However, to apply 2DEG-based TFTs to the actual display industry, accurate 2DEG control and formation mechanisms need to be further studied.

In this paper, high performance oxide TFTs were fabricated by sodium hydrosulfite (Na₂S₂O₄) reducing agent treated indium-zinc-oxide (r-IZO) as the front channel of zinc-tin-oxide (ZTO)/r-IZO heterostructure. Front channel IZO film was deposited by RF sputtering at room temperature. For reducing the IZO film, the IZO film was dipped into Na₂S₂O₄ solution. Applying the Na₂S₂O₄ reducing agent treatment on the front channel allows controlling the amount of confined electron at the interface between the front and the back channels for heterostructure oxide TFTs. For the back channel, ZTO film was deposited by RF sputtering at room temperature. ZTO/r-IZO heterostructure is suitable for the formation of 2DEG due to the large difference in work function, so it could produce high field-effect mobility even when fabricated at room temperature. Also, the large on-current could be achieved by precisely controlling the formation of 2DEG through Na₂S₂O₄ reducing agent treatment on the IZO front channel. To confirm the formation of 2DEG at the interface between the ZTO film and the r-IZO film, we performed a UV-vis spectrophotometer and ultraviolet photoelectron spectroscopy (UPS) measurements. The 2DEG was successfully formed by showing the difference of 170 meV work function at the heterointerface. However, conventional 2DEG-based oxide TFTs have high off-current because 2DEG free electrons remained at the heterointerface regions even
when the TFT is in the off-state. To solve this problem, the ZTO back channel was applied to different oxygen partial pressures to the lower ZTO layer (20%) and the upper ZTO layer (30%) when deposited via sputtering. As a result, the high off-current could be adjusted to near the $10^{-12}$ A range and ZTO/r-IZO TFTs exhibit field-effect mobility of 29.55 cm$^2$/Vs, a subthreshold swing of 0.48 V/decade, and an on/off current ratio of $5.02 \times 10^8$.

The results show that room temperature fabricated ZTO/r-IZO heterostructure TFTs can be used as a general route for high field-effect mobility TFTs and controllable oxide semiconductor devices for offering compatibility of the flexible and high-end display technology.

The Effects of Etching Parameters on Surface Morphologies by Anisotropic Etching with Resist-Mask
Pin Y. Chen, Yu-De Li and Kun-Dar Li; National University of Tainan, Taiwan

For a long time, the etching technique played an important role in the electronics industry, and had a critical influence on the development of modern manufacturing technologies. Regarding to the operation of electronics devices, surfaces and interfaces significantly affect the functionality and performance of the devices. To investigate the formation mechanisms for characteristic surface morphologies during chemical etching, in this study an anisotropic chemical etching model was established and the formation and evolution of surface structures with resist-masks were simulated numerically. In this theoretical model, two major crystallographic orientations in a cubic system, such as $<100>$ and $<111>$ directions, were taken into consideration and included in the reactions of surface diffusion and anisotropic etching. By adjusting the numerical parameters corresponded to the different experimental conditions, various surface profiles could be created and the influence of the experimental parameters on the surface morphologies would be revealed. From the calculations of anisotropic etching along $<100>$ preferred-directions, a V-shape profile with faceted surface morphologies appeared. A larger loss of linewidth or a higher etch bias was displayed with the increase of the etching rate. While an anisotropic etching along $<111>$ preferred-direction was examined, etch pits were firstly produced in the early stage of etching process. A different surface evolution during a chemical etching was distinctly demonstrated due to the crystallographic structure. In addition, since the resist-mask was included in the numerical model, the phenomenon of undercutting in an anisotropic chemical etching could be also discussed in this study. These numerical simulations could provide a fundamental information to understand the formation mechanism of etched surface, and broaden the applications of chemical etching in the advanced manufacturing technologies.

High Efficiency X-Band AlGaN/GaN HEMT with Improved TiN/Ti/Al/Ni/Au
Ke Wei, Yichuan Zhang, Shen Zhang, Guoguo Liu, Xiaojuan Chen, Yingkui Zheng, Sen Huang, Xinghua Wang and Xinyu Liu; Chinese Academy of Sciences, China

GaN based high electron mobility transistors (HEMTs) are considered of great potential to be the building blocks in the next-generation microwave power amplifiers due to their excellent power handling capabilities. Ohmic contact and passivation technology are the main factors of device power and efficiency. Improving device efficiency is the premise of improving application system efficiency. Nowadays, More and more efforts are made to improve the efficiency of GaN HEMTs. In this paper, we report the AlGaN/GaN HEMT with improved ohmic contact and double layer passivation. The device show an excellent power characteristics.

The epitaxial layers consists of a 1.5nm GaN cap layer,22nm Al0.25GaN, 2nm AlN and GaN buffer layer. The process for GaN HEMT devices is as followed the steps: a)maker, b) ohmic contact etching ion; c) isolation; d) gate; e)double passivation by Al/SiN; f) via and metal. The source-drain and gate length are 2.40µm and 0.25µm the TEM result shows the cross section of recessed TiN/Ti/Al/Ni/Au. For comparison. Conventional structures of MOCVD HEMT is also fabricated simultaneously.

Measurements are performed in continuous wave (CW) mode, load-pull power measurements of this 4×50µm device at 10 GHz is carried out. The device is biased at a voltage of 35V. the output power reached 31.50dBm (7.0W/mm) with 70% power-added efficiency (PAE) and 14dB gain. Such a good RF power performance comes from the improved ohmic contact and new double passivation layer.

The interface of ohmic contact is analyzed by means of TEM. It is found that tin thin layer combined with recessed process is more conducive to the formation of low contact resistance.

Halogenated Si(100) Surface Chemistries for Atomically-Precise Fabrication
Kevin J. Dwyer$^{1,2}$, Karen Gaskell$^1$ and Robert Butera$^2$; $^1$University of Maryland, United States; $^2$Laboratory for Physical Sciences, United States

The use of halogen chemistries on silicon surfaces offers a promising path towards atomic-scale manufacturing of acceptor-
based devices. Atomically-precise fabrication of electronic devices in silicon has been widely demonstrated using a scanning tunneling microscope (STM) and hydrogen-based surface chemistries to precisely place phosphorous donor atoms on the surface. A lithographically patterned hydrogen resist is used to selectively incorporate PH\textsubscript{3} to produce metallic wires, quantum dots defined by electrostatic gates, and single donor atom qubits for quantum information (QI) research. However, interest in acceptor dopants and hole-based devices necessitates the development of alternate precursors and/or resist chemistries for device fabrication. To incorporate acceptors into silicon with atomic placement, halogen chemistry is potentially more favorable than hydrogen. To that end, we explore halogen-based resists including chlorine, bromine, and iodine in conjunction with metal-halide precursors to achieve area-selective deposition of acceptor dopants in silicon. Here, we present results on the complete surface passivation of Si(100) using Cl, Br, and I. We study the stability of halogen-terminated Si(100) surfaces in ambient environments using STM and x-ray photoelectron spectroscopy (XPS) to facilitate transport of samples outside of ultra-high vacuum environments. Finally, we present STM and secondary ion mass spectroscopy (SIMS) results on the adsorption and incorporation of metal-halide precursors on Si(100) as a viable path towards acceptor doping.

S.EL01.06.66

**Plasma-Based Modification of Superconducting/dielectric Interfaces** [Evgeniya H. Lock\textsuperscript{1}, Sandra Rodriguez Villanueva\textsuperscript{2}, Peng Xu\textsuperscript{3}, Yaniv Rosen\textsuperscript{4}, Michael Katz\textsuperscript{2} and Kevin Osborn\textsuperscript{5}; \textsuperscript{1}US Naval Research Laboratory, United States; \textsuperscript{2}University of Puerto Rico at Rio Piedras, United States; \textsuperscript{3}University of Maryland, United States; \textsuperscript{4}Lawrence Livermore National Laboratory, United States; \textsuperscript{5}National Research Council, United States; \textsuperscript{6}Laboratory of Physical Sciences, United States]

Superconducting resonators and qubits are essential for the development of quantum-computing architectures. These systems depend on high quality superconducting materials and interfaces, in which the two-level systems loss is minimal. Our previous work focused on understanding of the effects of plasma modification of vacuum/silicon and vacuum/superconductor interfaces on the performance of TiN/Si superconducting microwave resonators. In this paper, we discuss plasma-based modification of TiN/Si interface. We provide a systematic study of every step in the preparation of the TiN/Si heterostructures, namely the chemical treatment with hydrofluoric acid of SiO\textsubscript{2}/Si surface, the plasma treatment of H-terminated Si and the TiN film deposition processes. We find that both the gas environment and the plasma processing conditions affect the modification of Si, which in turn affects the composition of the TiN/Si interface. The impact of this work lay in providing new approaches to TiN/Si interface preparation which may enable reduction of metal/dielectric interface losses thus improving the superconducting microwave resonators performance. This work was partially supported by the office of Naval Research through Naval Research Laboratory Base Program.

**Monitoring the Adsorption of Thiol and Isocyanide Molecules on Silver Surface by In Situ Surface-Enhanced Raman Scattering** [Shi Shi, Jaewan Ahn and Dong Qin; Georgia Institute of Technology, United States]

In this talk, we report the use of surface-enhanced Raman scattering (SERS) to investigate the adsorption of thiol and isocyanide molecules on colloidal Ag nanocubes \textit{in situ}. In a typical process, we mixed Ag nanocubes with ligand molecule solutions at different concentrations and then collected SERS spectra at different time points. We demonstrate that 4-nitrothiophenol (4-NTP) binds to the Ag surface rapidly because of the strong Ag–S chemical bonding. By decreasing the concentration of 4−NTP, we observe red shifts of the ν\textsubscript{NO\textsubscript{2}} band, which suggests the change to the orientation of ligands on the surface. Different from thiols, the 1,4-phenylene disiocyanide (1,4−PDI) binds to the Ag surface through σ−donation with weaker binding strength. By increasing the concentration of 1,4−PDI, our results indicate that the molecules tend to adopt an orientation that tilts away from the surface. More interestingly, we investigate the competitive binding behavior of these two ligands by introducing Ag nanocubes into a solution containing both 4−NTP and 1,4−PDI. Our results show that thiol is more preferential to bind onto the surface when the concentrations of the two ligands are comparable in the solution.

S.EL01.06.70

**Vertically Aligned Metal Nanowire Composites for Flexible and Conductive Thermal Interface Materials** [Max Kuciej\textsuperscript{1,2}, Jesse Tice\textsuperscript{2}, Dwight Streit\textsuperscript{1} and Michael T. Barako\textsuperscript{2}; \textsuperscript{1}University of California, Los Angeles, United States; \textsuperscript{2}Northrop Grumman Corporation, United States]

Conventional thermal management solutions in microelectronics packaging suffer from an inability to effectively couple thermal conduction and mechanical compliance into a single material, routinely necessitating a sacrifice in thermal, and therefore device, performance in favor of mechanical reliability. For the past few decades, compliant thermal interface materials (TIMs) have been limited to polymers loaded with dispersions of unaligned or randomly distributed conductive elements which can only achieve thermal conductivities up to ~5 W m\textsuperscript{-1}K\textsuperscript{-1}. Here, we present the processing and
characterization of a compliant, vertically-aligned metal nanowire composite ideal for achieving thin, flexible interfaces with low thermal resistance. The aligned nanowire composite is fabricated by electroplating copper into a 25-45% porous, sacrificial ceramic template, liberating the nanowires by chemically dissolving the template, and infusing the resulting nanowire array with a thermally stable polymer by capillary-driven wicking. An integrated bonding layer is added by subfilling the template with copper and sequentially electroplating metallic solder to form localized solder tips on the nanowires. The entire fabrication process can be completed at wafer-scale with a lateral area up to 12.5 inches<sup>2</sup>. The thermal performance of the composite TIM was evaluated with a modified thermal resistance measurement designed to mimic typical operating conditions. The double-sided construction of the composite and integrated bonding layers facilitate integration between any two arbitrarily-chosen surfaces by enabling the absorption of interfacial strain, mismatch, and roughness while achieving thermal conductivities up to 200 W m<sup>-1</sup>K<sup>-1</sup>, significantly advancing the state-of-the-art in TIMs.

S.EL01.06.75

**Exciton-Trapping by Stacking Fault Defects in GaAs**

Peter V. Sushko<sup>1</sup>, Steven R. Spurgeon<sup>1</sup>, Bethany Matthews<sup>1</sup>, Xiayu Linpeng<sup>2</sup>, Mikhail Durnev<sup>3</sup>, Mikhail Glazov<sup>3</sup>, Maria Viitaniemi<sup>2</sup>, Andreas Wieck<sup>4</sup>, Arne Ludwig<sup>4</sup> and Kai-Mei Fu<sup>2</sup>; 1Pacific Northwest National Laboratory, United States; 2University of Washington, United States; 3Ioffe Institute, Russian Federation; 4Lehrstuhl für Angewandte Festkörperphysik, Germany

The need to increase coherence times in quantum devices simulates the search for materials systems that can exhibit electronic states not affected by structural and chemical inhomogeneities. Owing to the advances in synthesis of III-V semiconductors, concentrations of point defects and impurities in these materials can be well controlled, while stacking faults (SFs) provide asymmetric quasi-2-dimensional potential wells that behave as internal interfaces capable of trapping excitons [1]. Here we use *ab initio* simulations to examine how the stability and electronic properties of SFs change as a function of the distance between them and how the details of their configuration affect spatial distribution of the electron and hole components of excitons and their effective masses. Our simulations suggest that a potential drop of the order of 10 meV is associated with an isolated SF, which is sufficient for the hole to localize predominantly at the SF and to induce an asymmetric distribution of the excited electron density in the vicinity of the SF. For interacting SFs, we find that the electron distribution is sensitive to both the type of the SFs and the distance between them. This coupling provides a pathway to the design of materials with spatially resolved excitonic properties and photo-emission energies by controlling the density and relative arrangements of the stacking faults.

S.EL01.06.76

**Observation of Hyperfine Interactions of Silicon Vacancies in 4H-SiC Metal-Oxide-Semiconductor Field-Effect Transistors Utilizing Ultra-Low Field Frequency Swept Electrically Detected Magnetic Resonance**

James Ashton<sup>1</sup>, Patrick Lenahan<sup>1</sup>, Brian R. Manning<sup>1</sup> and Aivars J. Lelis<sup>2</sup>; 1The Pennsylvania State University, United States; 2U.S. Army Research Laboratory, United States

4H-SiC metal-oxide-semiconductor field-effect transistors (MOSFETs) have great potential in high power and high temperature applications. However, near-interface defects degrade the effective channel mobility and thus limit the performance of 4H-SiC MOSFETs. In this work, we utilize electrically detected magnetic resonance (EDMR) to study hyperfine interactions with spin-dependent recombination (SDR) of silicon vacancy defects at the 4H-SiC/MOSFET interface. The physical foundation of EDMR is electron paramagnetic resonance (EPR). In EPR and EDMR, a sample is subjected to a large, slowly varying magnetic field and an RF or microwave oscillating field at a frequency ν. In the simplest case, EPR is achieved when hν=g<sub>e</sub>βH. Here, h is Planck’s constant, ν is the electromagnetic radiation frequency, g<sub>ε</sub> is the free electron g factor (g<sub>e</sub>≈ 2.0023), β is the Bohr magneton, and H is a large externally applied magnetic field. At resonance, the electron transitions from its +1/2 to -1/2 spin state (or vice versa). The analytical power of EPR and EDMR comes from deviations from this simple case caused by the paramagnetic site environment. These perturbations are, for the most part, caused by hyperfine interactions, interactions of the electron with magnetic nuclei, and spin-orbit coupling. EPR detected via SDR allows for measurements of small numbers of defects via spin-dependent changes in device current. The sensitivity of SDR/EDMR is very nearly independent of the field or frequency at which the measurement is made.<sup>2</sup> Prior continuous wave EDMR (cwEDMR) studies have linked interface and near-interface defects to carbon dangling bond defects<sup>3</sup> and silicon vacancy defects.<sup>4</sup> The identification of silicon vacancy defects in 4H-SiC MOSFETs was based on measuring nearest neighbor carbon 13 hyperfine interactions.<sup>4</sup> 29Si next-nearest neighbor (NNN) hyperfine interactions are too small to resolve in an EDMR measurement due to the width of the center part of the resonance signal. The interactions of NNN 29Si are isotropic with a value 2.96 G determined from conventional EPR. Broadening in EDMR obscures these 29Si...
NNN hyperfine interactions. We have overcome the EDMR broadening problem using the Breit-Rabi effect, a shift in the hyperfine side peaks towards lower fields and frequencies. This effect is sufficiently large so that it may be detected in ultra-low field and frequency measurements. We utilize frequency swept EDMR (fsEDMR). With fsEDMR, tuning the resonance condition is performed by varying a low static field. In fsEDMR, the magnetic field $H$ is held constant as frequency is swept.

Our experiments were carried out at fields less than 10 G and frequencies less than 30 MHz. We observe a centerline with a sharp peak on the low field side only at these low fields and frequencies. We attribute the peak to otherwise unresolved hyperfine interactions made observable by shifting due to Breit-Rabi effects. The peak has fairly large amplitude.

EasySpin$^6$ was utilized to simulate the results accounting for the presence of one $^{29}$Si NNN. The results of the simulation are in good agreement with our experimental observation.

The process by which strongly-photoexcited semiconductors return to their ground state consists of a series of complex, strongly-correlated many-body interactions which overlap in space and time, resulting in an evolution of behaviors that is both difficult to study and valuable, both for fundamental insights into the quantum nature of matter and for control of device and material behaviors in electronic and optoelectronic applications. Extensive work has been done in this regard, illuminating the sequence of hot carrier excitation, carrier-carrier scattering, carrier-lattice scattering and thermalization, recombination, and lattice heat diffusion. After strong photoexcitation creates a high-energy bath of “hot” carriers, electron-phonon coupling results in the emission of optical phonons, which decay into lower-energy phonons, either optical or acoustic. The resulting nonequilibrium phonon populations can in turn influence hot carrier relaxation and transport, an inextricability which has been demonstrated through transient Raman scattering [1-3]. The inseparable nature of structural behavior from that of excited electron-hole plasmas is further demonstrated by the result that when not in equilibrium, acoustic mode phase velocities change as a function of time due to residual Coulomb interaction caused by imperfect screening by electrons [4]. Thus, a thorough understanding of ultrafast post-excitation structural dynamics is essential to a full comprehension of semiconductor behavior.

As electronic devices continue to shrink, the associated increased importance of device surfaces, interfaces, and defects add an additional layer of complexity to the structural behavior. Techniques typically employed to investigate post-excitation responses operate in reciprocal or momentum space and require spatial averaging, reducing real-space resolution. It is known that interfaces change the electronic structure in their surrounding regions, strongly influencing carrier dynamics, and it has been shown in our previous work that phonons are structure-directed, propagating specifically from interfaces and repeatably traveling perpendicularly to the launching interface [5]. In sum, electron-phonon coupling behaviors are known to be influenced by structure, making real-space information relevant to a complete picture of post-excitation behavior.

Here we use ultrafast electron microscopy (UEM) to image phonons in real space and thereby demonstrate the influence of both the meso-scale and atomic structure of GaAs on the post-excitation phonon behavior. Making use of combined picosecond-nanometer real-space resolutions, we have directly imaged excitation of GHz coherent strain waves propagating exclusively from specimen-vacuum interfaces with initial hypersonic velocities which decay over time to the speed of sound in GaAs. We also report the change in the properties of these waves upon laser annealing of the specimen, epitaxially crystallizing the focused-ion-beam-induced amorphous surface layer and resulting in measurable hardening of the specimen. This appears in the phonon behavior as an increase in the velocity of the phonons. By imaging the phonon interactions with both the specimen-vacuum interface and the amorphous-crystalline interface within the specimen, we demonstrate the importance of interfaces in fully understanding the phonon dynamics in photoexcited GaAs.

S.E.L01.06.89
Bandgap Engineered III–V InAs–GaSb TYPE-II Superlattice (T2SL) Infrared Detectors for Multispectral Range Chhaya Ravi Kant; Indira Gandhi Delhi Technical University, India

Infrared detector technology has shown remarkable progress towards the selection of detector materials and device architectures. Infrared detectors are an integral part of various surveillance devices, remote sensing system, night vision, all weather surveillance, missile tracking, thermography, enhanced vision systems for aeroplanes, automobiles and gas sensing. Current InSb and HgCdTe based IR technologies have shown high performance because of excellent material properties covering near infrared (NIR 0.75-1.1mm), short-wavelength infrared (SWIR 1-3mm), mid-wavelength IR (MWIR 3-5mm), long-wavelength IR (LWIR 8-14mm) and very long-wavelength IR (VLWIR 14-30 mm) range. However, these need to be cooled to cryogenic temperatures making them bulky and power hungry. Thus future infrared photodetector systems must possess reduced cooling requirements, consume less power, exhibit longer lifetimes, and have improved manufacturability. These targets have been partly addressed by the development of nBn detector architecture raising the operation temperature, reliability, higher sensitivity and low SWaP (Small Weight and Power).

Type2Superlattice (T2SL) detectors combine key advantages of InSb and Mercury-CadmiumTelluride (MCT)-based technologies namely scalability of focal plane arrays (FPAs), high sensitivity, lower tunneling currents and suppressed Auger
recombination rates and also facilitates a higher operating temperature. A super lattice is made up of a repeated series of very thin epilayers of different materials that leads to creation of sub-bands. The corresponding bandgap energies of these subbands determine the cut-off wavelength of the sensor. The III-V InAs – GaSb materials, based on nBn unipolar photodetector architecture, with an n-type absorption layer, a barrier layer, and an n-type contact layer have been fabricated and engineered for bandgap tunability. The barrier layer is constrained to have both a negligible valence band energy offset with the absorption layer, that suppresses the Shockley-Read-Hall (SRH) generation current thereby decreasing the primary noise. In addition, detector is passivated to minimise the surface leakage current. The nBn photodetector, through the near elimination of SRH and surface leakage currents, requires less cooling to operate optimally than the p-n junction photodiodes. Bandgap engineering and optimization of the material composition to achieve maximum quantum efficiency, low dark current, maximum absorption strength and higher operating temperature.

Appropriate tools suitable for the design of T2SL material systems are not yet fully developed due to the intricacies of T2SL material system and paucity of experimental data for input and for the validation of mathematical formulations. A holistic approach has been followed involving design of graded energy-gap T2SL structure, growth of material system, characterization of material, fabrication and characterization. Our design is aimed to grow T2SL epilayers with optimized thickness, material composition, energy gap grading and varied doping concentrations by Molecular Beam Epitaxy and detector fabrication with a combination of wet and dry etching. A favorable impact ionization coefficient leads to higher bandwidth range with low excess noise. To achieve maximum quantum efficiency, low dark current, high avalanche gain, low excess noise, maximum absorption strength and higher operating temperature. Design optimisation has resulted in high quantum efficiency of 75% validated with FTIR measurements and low NETD of 18mK at an elevated operation temperature of 140K. Current-Voltage measurements, quantum efficiency, noise equivalent temperature difference (NETD) and issues related with growth of graded energy-gap T2SL material system will form part of the full paper.

S.EL01.06.94

Co-Electrodeposited MnO2 and Co3O4 on Well-Aligned Electrospun Carbon Nanofibers for Sensitive Glucose Detection

Ziyu Yin, Xinping Zeng and Jianjun Wei; The University of North Carolina of Greensboro, United States

Binary manganese oxide/cobalt oxide (MnO2/Co3O4) composites on the well-aligned electrospun carbon nanofibers (MnO2/Co3O4@ECNFs) were synthesized via a simple and economical one-step template-free electrodeposition technique with a constant low-current (60μA) for 3h, and their electrocatalytic activity towards non-enzymatic glucose sensors was evaluated in detail. The MnO2/Co3O4 nanostructures were uniformly deposited on the well-aligned ECNFs with high porosity, effective interconnectivity and large amounts of extended number of conducting channels. The electrocatalytic performances of as-prepared MnO2/Co3O4@ECNFs towards the oxidation of glucose were carried out by cyclic voltammetry (CV) and chronoamperometry (CA), and the experimental results show that the MnO2/Co3O4@ECNFs exhibited a superior sensing performance towards glucose including a rapid glucose response within 5 seconds, a wide range (5 μM to 10.89 mM), excellent sensitivity of 973.91 μA mM-1 cm-2 and a low detection limit of 0.02 μM (S/N=3) with satisfactory selectivity, great reproducibility and stability. These excellent electrochemical performances were attributed to the synergistic effect of binary metal oxides and the unique porous architecture of the electrode. These features indicate that as-synthesized MnO2/Co3O4 binary nanostructure decorated well-aligned ECNFs hold great potential in the development of a commercialized glucose sensor.
SESSION Tutorial S.EL02: Mixed Dimensional Heterostructures from Fundamentals to Device Applications
Session Chairs: Sanghoon Bae, Jeehwan Kim, Wei Kong, Hyunseong Kum, Kyusang Lee, Rachael Myers-Ward and Suresh Sundaram
Saturday Morning, November 28, 2020

Heteroepitaxy on Graphene for Transferable and Flexible Optoelectronics Kunook Chung; Ulsan National University of Science and Technology, Korea (the Republic of)

High device performance has been expected using a single crystalline inorganic compound semiconductor because of its high radiative recombination rate and mobility, as well as its excellent thermal and mechanical characteristics. Nevertheless, the high growth temperatures of single-crystalline inorganic semiconductors make it difficult to use a conventional plastic substrate with a low melting temperature. In addition, a continuous, rigid inorganic film has little tolerance for mechanical deformation. These obstacles can be overcome using inorganic microstructures and nanostructures grown on two-dimensional layered materials, such as graphene and hexagonal boron nitride as a flexible substrate, which exhibit high temperature compatibility and good mechanical flexibility. The instructor will review the current state-of-art technology of inorganic compound semiconductors heteroepitaxy on the 2D films for the transferable and flexible inorganic optoelectronics toward next-generation wearable devices and integrated devices with electronics.

Lift-Off Technology Toward Heterogeneous Integration Kyusang Lee; University of Virginia, United States

The layer-transfer technique has been in development for over a decade as a cost-saving strategy as well as a means of enabling heterointegration of dissimilar functional materials and flexible electronics. Instructor will review three major layer-transfer technologies, which are chemical lift-off, optical lift-off and mechanical lift-off. However, most of conventional layer-transfer methods lead to various issues such as surface roughening that limits substrate reusability. Instructor will
introduce new lift-off technology including two-dimensional layer transfer method that permits rapid mechanical release of epilayers leaving behind atomically smooth released surface without additional process to recondition the surface. Lift-off technology holds promise to unlock cost-efficient growth/transfer/stacking of high quality semiconductors and heterointegration of them without lattice matching restriction as well as substrate cost restrictions.

12:35 PM *S.EL02.01.18
Mixed-Dimensional Heterostructures for Electronic and Energy Applications Mark C. Hersam; Northwestern University, United States

Layered two-dimensional (2D) materials interact primarily via van der Waals bonding, which has created new opportunities for heterostructures that are not constrained by epitaxial growth [1]. However, it is important to acknowledge that van der Waals interactions are not limited to interplanar interactions in 2D materials. In principle, any passivated, dangling bond-free surface interacts with another via non-covalent forces. Consequently, layered 2D materials can be integrated with a diverse range of other materials, including those of different dimensionality, to form mixed-dimensional van der Waals heterostructures [2]. Furthermore, chemical functionalization provides additional opportunities for tailoring the properties of 2D materials [3] and the degree of coupling across heterointerfaces [4]. In order to efficiently explore the vast phase space for mixed-dimensional heterostructures, our laboratory employs solution-based additive assembly [5]. In particular, constituent nanomaterials (e.g., carbon nanotubes, graphene, transition metal dichalcogenides, black phosphorus, boron nitride, and indium selenide) are isolated in solution, and then deposited into thin films with scalable additive manufacturing methods (e.g., inkjet, gravure, and screen printing) [6]. By achieving high levels of nanomaterial monodispersity and printing fidelity [7], a variety of electronic and energy applications can be enhanced including photodetectors [8], optical emitters [9], and lithium-ion batteries [10-12]. Furthermore, by integrating multiple nanomaterials into heterostructures, unprecedented device function is realized including anti-ambipolar transistors [13], gate-tunable photovoltaics [14], and neuromorphic memtransistors [15]. In addition to technological implications for electronic and energy technologies, this talk will explore several fundamental issues including band alignment, doping, trap states, and charge/energy transfer across previously unexplored mixed-dimensional heterointerfaces [16].

Two-dimensional (2D) layered materials have strong in-plane covalent bonding and weak van der Walls interaction between the planes, which host a wide variety of interesting physical and chemical phenomena. Here I will present our research over 15 years on nanostructured 2D materials. First, I will show how we synthesize these 2D materials into rich morphologies including nanoplates, nanoribbons, layer-vertical aligned films as well as lateral and vertical heterostructures. Second, we developed liquid-gel gating, solid state ion gating, chemical and electrochemical intercalation to control the physical and chemical property of 2D materials. Third, we demonstrated exciting new exciting application of using 2D materials for batteries and catalysis applications.

Epitaxial Growth of 2D and 3D Materials Abdallah Ougazzaden 1,2; 1Georgia Institute of Technology, France; 2CNRS, France

Combined photonic and electronic systems require diverse devices to be co-integrated on a common platform. This heterogeneous integration is made possible through several separation and transfer methods where the functioning epilayers are essentially released from their growth substrate. The use of 2D layered h-BN as a mechanical release layer has been demonstrated to be a promising technique for the hybrid integration of III-nitride devices. In this talk we will give an overview regarding the epitaxial growth of Nitride-based semiconductor materials by MOVPE including GaN and h-BN, and design device structures for opto-electronic devices. In addition, results on wafer-scale growth and pick-and-place transfer of LED devices via h-BN van der Waals epitaxy, starting from sapphire growth substrates will be presented. Broader range of devices (HEMTs, solar cells, sensors, etc.) and applications (transport, environment, health, etc) will be discussed.

One Dimensional GaN Based Nano-Optoelectronic Device Structures on Layered h-BN Grown by MOVPE Suresh Sundaram 1,2,3, Xin Li3, Yacine Halfaya3, Taha Ayari3, Gilles Patriarche4, Christopher Bishop5, Saiful Alam3, Simon Gautier5, Paul L. Voss2,3, Jean Paul Salvestrini1,2,3 and Abdallah Ougazzaden2,3; 1Georgia Institute of Technology, United States; 2Georgia Tech Lorraine, France; 3CNRS UMI 2958 GT-CNRS, France; 4Université Paris-Saclay, France; 5Institut Lafayette, France

Recent advances in MOVPE enabled the high-quality growth of layered h-BN on sapphire substrates, and has resulted in the realization of series of 2D-3D III-nitride based device structures. This 2D layer also enables damage free mechanical lift-off which may drive future flexible and wearable industry with advanced high-efficient devices. Reliable wafer-scale 2D-2D heterostructure based devices have also been fabricated previously. Here we report, demonstration of MOVPE van der Waals epitaxial growth of GaN based nanostructures on 2D h-BN with a focus on large area h-BN epitaxy and successful transfer to flexible platform. This approach to the growth of III-N nanostructures on h-BN avoids transfer processes and scaling issues seen with other 2D materials, since both the 1D (GaN nanorods) and 2D (h-BN) are grown at the wafer-scale and in one growth run. Further, this process is used to grow vertical core–shell p-GaN/InGaN/n-GaN nano-PIN device structures on wafer-scale 2D h-BN on sapphire and silicon substrates. Interesting results obtained on this futuristic process and mechanisms involved will be discussed.

Vertically Stacked 0D/2D Materials Based Hybrid Infrared Phototransistor Anindita Sahoo, Peter Reiss, Etienne Quesnel, Jacques Cluzel, Luc Andre, Eric De Borniol and Berangere Hyot; Univ. Grenoble Alpes, CEA, France

Infrared (IR) photodetectors are nowadays in high demand in a wide range of fields such as telecommunication, thermal imaging, remote sensing, night assistance car driving etc. Recently, hybrid phototransistors made of highly efficient light absorbing QD 0D quantum dots and high mobility 2D materials have introduced a new technology, which dramatically increases the responsivity and gain of the photodetector. In 2012, such low dimensional IR phototransistor based on graphene/PbS QD hybrid was proposed in literature [1,2] for the first time. Later in 2017, a high-resolution broadband image sensor based on
such hybrid materials was demonstrated \cite{3}, which is sensitive to ultraviolet, visible and infrared light (300–2000 nm).

We have investigated similar graphene/PbS QD hybrid phototransistors and explored the enhancement of their photo-sensing qualities compared to bare graphene phototransistor in the visible-NIR-SWIR region of optical spectra. Initially, we studied CVD-grown single layer graphene phototransistor in the visible-NIR region, which showed a responsivity of about $10^4$ A/W, associated with the low–doped Si substrate, which acts as the primary material for optical absorption. Such responsivity is 10$^7$ orders of magnitude higher \cite{4} than conventional graphene phototransistor \cite{5}. However, the photo-sensing wavelength range of such device is limited up to 1100 nm depending on the principal absorption material Si. In order to expand the photo-sensing wavelength range up to SWIR region, we have explored the potential of graphene/PbS QD hybrid phototransistors. We synthesized the colloidal PbS QDs absorbing in the NIR as well as SWIR regions and developed a layer-by-layer dip coating with simultaneous ligand exchange procedure to deposit homogeneous PbS QD layers on graphene sheet leading to a well fabricated hybrid phototransistor. We achieved a significantly high responsivity of at 940 nm with irradiation power density of $10^{-4}$ W/m$^2$. In the NIR range, the peak responsivity appears to be $\sim 10^7$–$10^8$ A/W, whereas in the SWIR range, the observed peak responsivity is $\sim 10^6$ A/W. Moreover, graphene/PbS QD hybrid exhibits high sensitivity at low irradiation power (< 0.05 nW), where bare graphene photodetector is unable to sense such low intensity light in the visible-NIR region.

Nucleation Control in van der Waals and Remote Epitaxy Jinkyoung Yoo; Los Alamos National Laboratory, United States

Hybrid structures composed of conventional semiconductors (3D materials) and atomically thin two-dimensional (2D) materials have offered opportunities of recyclable device manufacturing, novel functionalities based on carrier transfer and exciton transport, and understanding natures of van der Waals gap. However, nucleation of 3D materials on 2D materials has not been understood straightforwardly due to absence of surface dangling bonds on 2D material though interaction the overgrown layer and 2D layer as a substrate has been explained by van der Waals interaction. Recent observation performed by the presenter’s team revealed that surface energy landscape is a key for nucleation of 3D materials on 2D materials. Increase in surface energy on 2D layer enhances nucleation probability of 2D materials significantly.

In the presentation those will be discussed several key aspects of nucleation of 3D materials on 2D materials, such as a few strategies to enhance surface energy on 2D layer, insights of the nucleation strategy on remote epitaxy, and demonstration of devices based on 3D/2D heterostructures.

2:21 PM CLOSING COMMENTS
The heterogeneous integration of dissimilar materials is a long pursuit of the material science community and has defined the material foundation for modern electronics and optoelectronics. The typical material integration approaches usually involve strong chemical bonds and aggressive synthetic conditions and are often limited to materials with strict structure match and processing compatibility. Alternatively, van der Waals integration, in which freestanding building blocks are physically assembled together through weak van der Waals interactions, offers a bond-free material integration strategy without lattice and processing limitations, as exemplified by the recent blossom of 2D van der Waals heterostructures. Here I will discuss the fundamental forces involved in van der Waals integration and generalize this approach for flexible integration of radically different materials to produce artificial heterostructures with minimum interfacial disorder and enable high-performing devices. Recent highlights include the formation of van der Waals metal/semiconductor junctions free of Fermi level pinning to reach the Schottky-Mott limit; the creation of a new class of high-order van der Waals superlattices with highly distinct constituents of atomic or molecular layers; and the development of van der Waals thin film electronics with unprecedented flexibility and stretchability. I will conclude with a brief perspective on exploring such artificial heterostructures as a versatile material platform with electronic structure by design to unlock new physical limits and enable device concepts beyond the reach of the existing materials.

2:11 PM *S.EL02.03.20
III-Nitride van der Waals Epitaxy on 2D BN for Lift-Off, Transfer and Integration Michael Snure, Eric Blanton, Nicholas Glavin and Kelson Chaback; Air Force Research Laboratory, United States

Van der Waals (vdW) surfaces of 2D materials such as graphene and BN are attractive for growth of GaN and other III-nitride films and device structures. The weak inter-planar vdW bonding between 2D layers allows for easy mechanical separation of 3D-nitride films from the growth substrate for lift-off, transfer and integration onto arbitrary substrates. This approach of vdW lift-off is suitable for transfer of delicate single devices, like 1-gate high electron mobility transistors (HEMT), as well as, wafer sized films. However, to obtain high performance devices, control over nucleation and epitaxy on 2D layers is necessary for high quality films. Additionally, to enable a simple transfer process strain and adhesion between the film and 2D layer must be balanced. In this paper, we describe the growth of high quality GaN and AlGaN/GaN HEMT structures on 2D BN. The effects of nucleation, III-nitride epitaxial growth process and BN morphology will be discussed demonstrating how they effect material quality, properties, strain and adhesion. We will then discuss transfer schemes for individual AlGaN/GaN HEMTs and large area membranes transferred to both flexible polymer substrates and a variety of rigid substrates. With access to GaN and AlGaN/GaN two dimensional electron gas (2DEG) membranes on flexible substrates, we investigate the effects of strain on basic materials properties from compressive to tensile. This is particularly powerful for probing the effects of strain on the electrical properties, like sheet carrier density and mobility, in the polarization induced AlGaN/GaN 2DEG. In transferred devices, we demonstrate exceptional transport properties with mobility > 2,000 cm²/Vs and device performance with GM of 300 mS/mm and fT and fmax > 34 GHz and 75 GHz under stain while bending. Lastly, we will cover vdW and adhesive bonding to high and low thermal conductivity substrates and the effects on device performance and self-heating. This paper will highlight the great potential of vdW epitaxy and lift-off for transfer and integration of GaN on to various platforms.

2:32 PM *S.EL02.03.13
Polar Quasi-2D Oxides via Epitaxy at Weakly-Coupled Interface Jian Shi; Rensselaer Polytechnic Institute, United States

When crystals approach 2D, their ferroelectric phase may be destabilized. How their temperature-dependent polarization behaves remains largely unknown. In this work, we attempt to answer this question using 2D pyroelectric oxides. We show that quasi-2D oxides down to a unit cell thickness can be epitaxially grown on perovskite substrate by the molten salt-assisted quasi-van der Waals epitaxy following a screw-dislocation driven mechanism. We experimentally demonstrate switchable in-plane photo-ferroelectricity and thickness-dependent pyroelectricity. Weakly-coupled interface allows us to reveal that electron-phonon renormalization leads to the observed dimensionality effect. Harnessing the dimensionality effect in pyroelectricity via novel epitaxy strategies could promote their applications in uncooled infrared cooling and thermal energy harvesting.

2:53 PM S.EL02.03.09
SiC Remote Epi—A New Paradigm for Stackable Electronics Rachael Myers-Wardl, Jeehwan Kim2, Matthew DeJarld1, Kuan Qiao2, Yunjo Kim2, S.P. Pavunny1 and Kurt D. Gaskill1; 1Naval Research Laboratory, United States; 2Massachusetts Institute of Technology, United States
Ideally, electronic heterostructures from dissimilar materials leads to enhanced functionality. Yet, experimentally forming these heterostructures is challenging due to lattice or thermal coefficient of expansion mismatch leading to defect formation or thermally driven atomic diffusion resulting in cross-doping and gradual junction transitions. These challenges may be overcome with the discovery of remote epitaxy and 2D layer transfer [1]. Here, SiC epitaxy is performed on epitaxial graphene as the electrostatic fields from the substrate penetrate the graphene and guide adatom registry. The film is easily peeled away since the graphene is not bonded to either the substrate or epilayer; the epilayer is then van der Waals bonded to a different material enabling new functionality. We will present experimental results on the remote epitaxy of SiC.

There are three necessary steps to create remote epitaxy. The first is to grow epitaxial graphene on SiC, followed by transferring the graphene to a desired substrate (if different from SiC), and finally the growth of the remote epitaxial layer. If the remote epitaxy is to be SiC, which is the focus of this paper, the second step is not necessary. Epitaxial graphene (EG) was first synthesized on 4H- and 6H-SiC in a horizontal hot-wall CVD reactor between 1540 and 1580 °C in 10 slm of Ar and 100 mbar [2]. The growth temperature was dependent upon the offcut of the substrate, where substrates with higher offcuts require a lower growth temperature to ensure 1 ML of EG, which is desired to assist in SiC adatom registry during growth. SiC remote epitaxy was then performed on the EG using silane (2% in H2) and propane precursors, where the SiC polytype replicated the underlying substrate. In an effort to transfer the remote SiC epi/EG to another substrate such as SiO2/Si, a metallization step was performed. Thin Ti and/or Ni layers were initially deposited followed by a thicker high stress metal to create strain and aid in removing the remote SiC epi/EG from the SiC substrate [1]. Once transferred, the metal was removed via a metal etch.

In this work, we will discuss the important parameters needed for successful remote SiC epitaxy, such as graphene thickness, process flows, ramping conditions and remote epitaxy growth temperature. The epitaxial morphology characterized by SEM, Nomarski microscopy and Electron Detection and graphene coverage and transfer evaluated by Raman spectroscopy will be presented.

Probing Metal Center Effects in MoS2 – Metallophthalocyanine Mixed-Dimensional Heterojunctions
Samuel Amsterdam1, Teodor K. Stanev1, Qunfei Zhou1,2, Vinod K. Sangwan1, Alexander J. Lou1, Hadallia Bergeron1, Pierre T. Darancet2, Mark C. Hersam1, Nathaniel P. Stern1 and Tobin J. Marks1; 1Northwestern University, United States; 2Argonne National Laboratory, United States

Mixed-dimensional heterojunctions, such as zero-dimensional organic molecules deposited on two-dimensional transition metal dichalcogenides (TMDs), exhibit unique interfacial effects that modify the properties of the individual constituent layers. To better understand the effect of changing molecular orbital energy on the heterojunction properties, we report here a systematic study of metallophthalocyanine (MPC) – MoS2 (M = Co, Ni, Cu, Zn, H2) heterojunctions using optical absorption, Raman spectroscopy, low temperature photoluminescence, variable temperature electrical measurements, and density functional theory. Notable phenomena include the emergence of heterojunction-specific optical absorption transitions, strong Raman enhancement, and quenching of defect emission that depend on phthalocyanine metal center identity. Temperature-dependent electrical noise measurements on field-effect transistors provide further insight into the properties of these mixed-dimensional heterojunctions. These results highlight the tunable nature of metal-organic-TMD van der Waals interfaces and the importance of the organic architecture and electronic structure in designing mixed-dimensional heterojunctions for optical and electronic applications.

3:13 PM *S.EL02.01.35
Print-in-Place Electronics Using Mixed-Dimensional Nanomaterials
Aaron D. Franklin; Duke University, United States

For decades we’ve been hearing about the promise of printing electronics directly onto any surface. However, despite significant progress in the development of inks and printing processes, reports on fully, direct-write printed electronics continue to rely on excessive thermal treatments and/or fabrication processes that are external from the printer. In this talk, recent progress towards print-in-place electronics will be discussed; print-in-place involves loading a substrate into a printer, printing all needed layers, then removing the substrate with electronic devices immediately ready to test. A key component of
these print-in-place transistors is the use of inks from various nanomaterials, including 1D carbon nanotubes (CNTs - semiconducting), 2D hexagonal boron nitride (hBN - insulating), and quasi-1D silver nanowires (AgNWs – conducting). Using an aerosol jet printer, these mixed-dimensional inks are printed into functional 1D-2D thin-film transistors (TFTs) without ever removing the substrate from the printer and using a maximum process temperature of 80 C. To achieve this, significant advancements were made to minimize the intermixing of printed layers, drive down sintering temperature, and achieve sufficient thin-film electrical properties. Devices are demonstrated on various substrates, including paper, and evidence of the potential for printing directly onto biological surfaces will be shown. From the versatile printed electronic thin films that have been developed, a diversity of biosensors are being pursued and will be discussed. With continued refinement of the inks and print processes, this print-in-place technique can bring the field of printed electronics closer to where it has been promised to go for so many years: load substrate, press print, remove functional sensors / circuit.

8:00 AM OPENING COMMENTS

8:05 AM *S.EL02.02.01
Large Area Synthesis and Doping of Two-Dimensional Semiconductors Joshua A. Robinson; The Pennsylvania State University, United States

The last decade has seen nearly exponential growth in the science and technology of two-dimensional materials. Beyond graphene, there is a huge variety of layered materials that range in properties from insulating to superconducting. Furthermore, heterogeneous stacking and doping of 2D materials also allows for additional band structure engineering. In this talk, I will discuss recent breakthroughs in two-dimensional atomic layer synthesis and properties, with an emphasis on doping 2D semiconductors. Our recent works include development of understanding of substrate impact on growth and doping of 2D materials to tune them from n- to p-type, and to create 2D magnets. Our work and the work of our collaborators has lead to a better understanding of how substrate not only impacts 2D crystal quality, but also doping efficiency in 2D materials.

8:26 AM *S.EL02.03.15
Emerging Epitaxy for Transferrable Flexible Optoelectronics—van der Waals and Remote Epitaxies Young Joon Hong; Sejong University, Korea (the Republic of)

Technological fashion of electronics has recently changed from device miniaturization to flexible device and 3-dimensional heterogeneous integration. For the flexible devices, organic or polymeric materials have been generally used, but inorganic semiconductor is ultimately desirable in terms of high performance, long lifetime, and harsh environment tolerance. Nonetheless, the rigid, brittle characteristics of semiconductor has limited its utilization in the flexible device applications. Graphene-inserted growth is promising for transferrable device fabrication because the surface of graphene has no dangling bonds. The van der Waals interfaces of overlayer/graphene/wafer enable mechanical exfoliation of overlayer from wafer via a facile sticky scotch tape technique.[1] Using the graphene interlayer, there are two epitaxy regimes, which are van der Waals and remote epitaxies,[2,3] that can be classified by the role of graphene. In addition, the growth of wire or rod-shaped semiconductor crystallites is promising for deformable device applications because of the spatially separate geometry.[4] This talk introduces the aforementioned epitaxies for transferrable flexible optoelectronics. We begin discussing the role of graphene or underlying wafer how they dictate the epitaxial relation with overlayer. As the first section, the van der Waals epitaxy of InAs nanowires on graphene is presented. Use of thinnest substrate of single-layer graphene,[5] fabrication of InAs/graphene/InAs double heterostructures using suspended graphene,[6] and position-controlled growth,[3] all of which were achieved through the van der Waals epitaxy, are presented. Then, as the second section, the remote epitaxy is
introduced. Hydrothermal remote epitaxy of ZnO microrods and metal–organic vapor-phase remote epitaxy of GaN microrods are presented.[7–9] We also discuss the remote heteroepitaxy of ZnO on GaN and GaN on Al₂O₃ for lattice less- and far-mismatched remote epitaxy, respectively.[8,9] The transfer of GaN heterostructured microrods of \( p-n \) junction with InGaN multiple quantum-wells is demonstrated for flexible microrod-light-emitting diode panel whose mechanical property is highly robust against crumpling/folding operations and repeated bending test.[9] Especially, we show the wafer recyclability for fabricating the deformable microrod-light-emitting diode panel over again on the same wafer in the remote epitaxy. We finally show how the principle of remote epitaxy, in which the limited thickness of graphene can penetrate the bonding feature of underlying wafer to the surface of graphene for epitaxial relationship, can be applied for site-selective growth.[10] The challenges and opportunities of epitaxies on/across graphene are discussed toward future flexible, transferable displays technology.

Mechanisms of Remote Epitaxy on Two Dimensional Materials Wei Kong, Kuan Qiao, Huashan Li, Jeffrey C. Grossman and Jeehwan Kim; Massachusetts Institute of Technology, United States

The fabrication of thin-film semiconductor relies on epitaxy, during which direct bonding is made between the epitaxial layer and the substrate, to ensure highly ordered crystalline lattices in the epitaxial layer as a copy of its substrate. The strong physical bonding between epitaxial layer and substrate implies strict requirements of lattice matching as well as difficulties in heterointegration. We have previously shown that the insertion of a monolayer graphene in between the epitaxial layer and its substrate, in the so-called “remote-epitaxy” process, did not change the crystalline orientation of the epitaxial layer, and the epitaxial alignment between the epitaxial layer and its substrate was maintained as if the monolayer graphene was “transparent”[1]. In this report, we further explore the fundamental mechanisms behind such an epitaxial alignment through two-dimensional materials. And the general rule governs remote-epitaxy will be introduced [2].

Specifically, the transparency of two-dimensional materials to the epitaxial relationship is linked to the polarization of related material systems. Although the potential field from non-polar materials is screened by a monolayer of graphene, that from polar materials is strong enough to penetrate through a few layers of graphene. Such field penetration is substantially attenuated by 2D hexagonal boron nitride, which itself has polarization in its atomic bonds. Based on the control of transparency, modulated by the nature of materials as well as interlayer thickness, various types of single-crystalline materials across the periodic table can be epitaxially grown on 2D material-coated substrates. The epitaxial films can subsequently be released as free-standing membranes, which provides unique opportunities for the heterointegration of arbitrary single-crystalline thin films in functional applications.

Dislocation-Carrier Dynamic in Halide Perovskites via Remote Epitaxy

Jie Jiang and Jian Shi; Rensselaer Polytechnic Institute, United States

Crystallographic defects, such as dislocation, are well known to strongly affect material’s physical properties. Electron-hole recombination mediated via dislocations (e.g. threading dislocation) is one of the predominant loss mechanisms for the sub-optimum performance in conventional semiconductors devices. However, how dislocation impacts its carrier dynamics in the ‘defects-tolerant’ halide perovskite is largely unknown. Stimulated by the successful pioneer work of remote homoepitaxy of semiconductor GaAs, researchers have also been achieved (remote heteroepitaxy) in the systems of AlN film on sapphire, copper film on sapphire, and ZnO film on GaN. In our study, we synthesize epitaxial halide perovskite with controlled dislocation density via a remote heteroepitaxy approach using polar substrates (NaCl and CaF2) coated with graphene. Density functional theory calculations have revealed the structure and magnitude of the incompletely screened electrostatic potential from the polar substrates, supporting the remote epitaxy in the present case. The regulated film-substrate interactions have further reflected themselves in controlling the wavelengths of the ferroelastic domains. Molecular-dynamics simulations reveal the kinetic process during remote epitaxy. Comparing to the ionic epitaxy with high dislocation density (both misfit and threading), the film grown via remote shows much enhanced photoluminescence intensity and increased carrier lifetime. Our successful demonstration of remote epitaxy in halide perovskite provides an approach to develop free-standing halide perovskite film with reduced dislocation density. More importantly, dislocations and their impacts on carrier dynamics and device performance in halide perovskite have to be recognized and scrutinized.

9:16 AM BREAK

Accurate Prediction of Energy Level Alignment in Mixed-Dimensional Heterojunctions

Qunfei Zhou1, Zhenfei Liu2 and Pierre T. Darancet3; 1Northwestern University, United States; 2Wayne State University, United States; 3Argonne National Laboratory, United States

Understanding energy level alignment between molecules and two-dimensional materials is conducive to controlling charge and energy transfer in mixed-dimensional heterojunctions. The competition between distinct energy scales, such as the ones associated with electronic correlations, interface dipole, orbital hybridization, and non-local dielectric screening, can lead to significant renormalization of the intrinsic energy levels of each material at these interfaces. The variety of these energy scales also complicates the theoretical description of the level alignment for mixed-heterojunctions accurately.

Here we study the electronic structure and level alignment for mixed 0D-2D heterojunctions containing transition metal phthalocyanines on MoS2 by first-principles density functional theory (DFT) calculations. By using optimally tuned range-separated hybrid (OT-RSH) functionals, a recently developed method for finding the optimal range-separated parameters for describing short-range and long-range electron exchange effect, we obtain energy level alignment consistent with known experimental results, a significant improvement comparing to standard DFT. This method can be used for other mixed-heterojunctions for better understanding of their electronic and optical properties.

Toward Non-Si Electronics—Producing Freestanding Single Crystalline 3D Thin Films and 2D Atomic Layers for Mixed Dimensional Heterostructure

Sanghoon Bae; Massachusetts Institute of Technology, United States
The current electronics has been mainly dominated by Si-based devices due to their mature processing system and exceptional cost-effectiveness. However, next generation electronics needs novel functionalities that cannot be realized by Si because of intrinsic limitation of Si. Accordingly, demand for non-Si electronics has been getting substantially high. Unfortunately, current methodology requires extremely high cost for non-Si materials, which impedes the progress in developing the non-Si based electronics. Here, I will discuss about our group’s efforts to address this issue. Our team recently conceived a new crystalline growth, termed as “remote epitaxy”, which can copy/paste crystalline information from substrates remotely through graphene, thus generating single-crystalline films on graphene. As interfacial binding energy is attenuated by inserting graphene at interface, the single-crystalline films can be easily exfoliated from the slippery graphene surface. Also, the graphene-coated substrates can be, in principle, reused infinitely to produce single-crystalline films. Thus, the remote epitaxy can produce non-Si semiconductor films with unprecedented cost efficiency while allowing additional flexible device functionality required for current ubiquitous electronics.

Next, I will discuss about a layer splitting technique which can be a potential solution to overcome the problem in obtaining large-scale and monolayer 2D materials. A 2D material-based heterostructure has been intensively studied because of its unique device functionalities and novel physics. However, it is extremely challenging to secure large-scale and monolayer 2D materials because of following issues: 1) poor scalability for laboratory fabrication processes of 2D heterostructures and 2) lack of well-defined control parameters for kinetics of 2D materials and predictable number of layers of 2D materials. To resolve this issue, we conceived a new approach called “layer-resolved splitting” which obtains multiple monolayer from multilayer 2D materials by controlling interfacial toughness contrast. As this method is versatile and universal, we can, in principle, apply to all 2D materials. We succeeded in having large-scale, monolayer 2D materials through our approach and, thereby 2D heterostructures were demonstrated for functional devices.

Lastly, I would like to discuss opportunities of mixed-dimensional heterostructure demonstrated by remote epitaxy and layer-resolved splitting. As they produce freestanding 3D bulk films and 2D atomic layers, a new type of 3D/2D heterostructures can be realized where a new physics and new device architecture are revealed. Therefore, I believe that a new opportunity will be discovered through the mixed-dimensional heterostructures.

9:52 AM S.EL02.03.03
Mechanisms for Remote Epitaxy of GaSb on Graphene-Terminated GaSb (001)  
Sebastian Manzo, Vivek Saraswat, Austin J. Way, Patrick J. Strohbeen, Chenyu Zhang, Dongxue Du, Estiaque Shourov, Paul Voyles, Michael Arnold and Jason K. Kawasaki; University of Wisconsin, United States

Remote epitaxy is a method for growing single-crystalline materials on a graphene-terminated single-crystalline substrate, in which the epitaxial registry occurs between film and substrate rather than film and graphene. This method has been realized for several homoeptaxial systems, such as GaAs, GaN, LiF and ZnO. Yet, the microscopic mechanisms that allow for remote epitaxy remain mysterious. Here we demonstrate remote homoeptaxy of GaSb and comment on the role of defects on the apparent lattice transparency of graphene. In addition, we elucidate the effect of the graphene/substrate interface quality associated with different graphene transfer methods.

We have grown our films via molecular beam epitaxy and used x-ray and electron diffraction, along with transmission electron microscopy to confirm that the single-crystalline film is in-phase with the underlying GaSb (001) substrate. Graphene grown via chemical vapor deposition is cleanly transferred to GaSb, which has been corroborated via Raman spectroscopy and scanning electron microscopy. Remote epitaxy necessitates the absence of the semiconductor substrate’s native oxide, since this amorphous layer would inhibit epitaxial registry to the underlying substrate. Therefore, the question of how the native oxide desorbs when capped with graphene is of critical importance. We have studied this desorption mechanism through in-situ photoemission and reflective high energy electron diffraction. In addition, we have investigated the nucleation selectivity of GaSb on patterned and unpatterned graphene via in-situ scanning tunneling microscopy. The GaSb overlayer can be readily exfoliated, which allows for the substrate to be recycled and for the exfoliated film to be transferred to arbitrary substrates.

Doping Approaches and Junction Structure for Antimony Selenide Solar Cells

Antimony selenide solar cells are rapidly approaching 10% efficiency however a number of key materials properties are still not fully understood. In particular the mechanism by which doping is controlled in the material has not been established and there is a high degree of variability in the literature on the level of doping attainable and even carrier type. This talk will discuss the identification of potential sources of doping in Sb$_2$Se$_3$, the influence this has on carrier concentration and the subsequent impact for device performance. Through the use of Sb$_2$Se$_3$ bulk crystals we will further demonstrate routes to achieve p, i and n doping and methods to transfer this to thin film devices.

5:30 AM *S.EL02.01.03
Photonic Crystal Enhanced Photon Collection for Quantum Dot-Based Luminescent Solar Concentrator

A luminescent solar concentrator (LSC) is a photon managing device that can harvest, direct and concentrate solar light to small areas, enabling subsequent coupling to photovoltaic devices (PVs) for enhanced solar energy conversion. However, the intrinsic photon loss through the so-called escape cone of the LSCs significantly limits their light harvesting and concentrating performance. In this talk, I will introduce a facile and low-cost approach for the fabrication of a three-dimensional (3D) macroporous photonic crystal (PC) filter as an efficient photon reflector, which can be coated onto quantum dot (QD) based LSC devices. We demonstrate that by controlling the PC reflection band to match the emission profile of the QD emitters, the light trapping efficiency of the PC coated LSC (PC-LSC) can be significantly improved from 73.3% to 95.1% as compared to the conventional PC-free LSC due to the reduced escape cone photon loss. Both experimental and simulation results show that the enhancement in LSC device performance induced by the PC reflector increases with increasing dimension. Our study sheds light on future design and fabrication of LSC devices with enhanced photon collection and concentrating efficiencies through novel and wavelength-selective photon reflectors.

Beyond Expectation—Advanced Materials Synthesis and Processing to Enable Novel Function in Ferroelectrics

Ferroic materials including oxide ferroelectrics, magnets, and multiferroics are of great interest for a range of modern applications. What’s more, these materials stand poised to revolutionize next-generation applications, if we can determine ways to overcome inherent limitations in their function. Stringent device requirements are pushing researchers to exert ever more exacting control over the chemistry, defect structures, interfaces, etc. to elicit the desired function from these materials. From the ever present need to reduce leakage currents and control imprint and fatigue to renewed interest in reducing the voltage of operation of ferroelectric and piezoelectric devices to the sub 100 mV level to the realization of beyond-binary function in the form of multi-state operation that could enable neuromorphic devices, the requirements of next-generation applications are great and varied. Such requirements have thrust materials – including ferroelectrics, piezoelectric, and multiferroics – back into the mix as candidates for many applications.

But, despite considerable research on such materials in the last few decades and advances in our ability to synthesize, control, characterize, and fabricate these materials, the requirements of these applications are already pushing these materials to their limits. In this talk, we will explore a range of materials synthesis and processing approaches that enable researchers to address these requirements. In single-layer films of materials like BaTiO$_3$, PbTiO$_3$, BiFeO$_3$, (1-x)PbMg$_{1/3}$Nb$_{2/3}$O$_3$-(x)PbTiO$_3$, and others, we will explore how the use of exacting chemical control and the ex post facto introduction of certain species (be it constituent elements themselves or specific defects) can effectively “heal” or improve ferroelectric function dramatically – improving leakage and increasing breakdown voltages. Taken further, such on demand introduction of defects can even impart exotic function – such as multi-state switching – as we leverage strong defect-polarization coupling to tune the pinning energy and, in turn, coercive voltages. One can even achieve such control at the nanoscale level, opening the door for the on-demand design of functionality. At the same time, careful synthesis and production of pristine materials and interfaces can also produce thin-film ferroelectrics that begin to approach the switching achieved in single-crystal materials. This, in turn, opens the door for record-breaking small coercive voltages and ultra-low power function and operation. In multi-layered and superlatticed materials, the careful interfacing of materials can produce new combinations of properties – including combined large polarization and large dielectric constant and tunability – in, for examples, PbxZr$_{1-x}$Ti$_3$O$_3$ superlattices controlled to have overall compositions near the morphotropic phase boundary (MPB) composition, but being built from layers far from the MPB composition. Finally, we will explore new efforts in the production, utilization, and testing of free-
standing versions of ferroelectrics. New selectively etchable layers are now enabling the production of large, free-standing epitaxial stacks. Routes to release, transfer, and measure free-standing films will be introduced and a range of properties measured therein.

6:30 AM S.EL02.01.05
Improving Functionalization of MWCNTs through Non-Covalent Interactions with Organic Molecules Pablo Quijano Velasco¹, Kyriakos Porfyryakis² and Nicole Grobert¹,²,³; ¹University of Oxford, United Kingdom; ²University of Greenwich, United Kingdom; ³Williams Advanced Engineering Limited, United Kingdom

Tailoring the surface properties of carbon nanotubes (CNTs) through covalent or non-covalent interactions with organic molecules has been highlighted for more than a decade as promising path for the fabrication of functional nanostructures that could be successful in a wide variety of application ranging from nanomedicine to reinforced structural materials¹. However, the efficient functionalization of CNTs, especially multiwalled-CNTs (MWCNTs), still faces many challenges due to the lack of understanding of the interaction mechanisms between MWCNTs and organic molecules in functionalization procedures. In this study, we compare the functionalization of MWCNTs through covalent and non-covalent methods, with the objective of elucidating clear synthetic guidelines for the efficient functionalization of MWCNTs.

To understand the mechanisms of covalent functionalization of MWCNTs we attempted the functionalization of MWCNTs with polystyrene molecules via Prato and nitrene cycloaddition reactions. Through the comparison of TGA and Raman spectroscopy of the products, we showed that the nature of the reaction has no impact on the degree of functionalization of the MWCNTs. In addition, we highlight the use of control experiments using non-reactive polystyrene molecules, that allowed us to demonstrate that the degree of functionalization of MWCNTs was comparable to the products of the covalent functionalization reactions. The independence in the degree of polymer functionalization of the reaction procedure and of the use of non-reactive polystyrene was observed for MWCNTs with different diameter sizes. These experimental evidences demonstrate that covalent bonds between polymers and pristine MWCNTs are not present and that the functionalization occurs through non-covalent forces.

Non-covalent functionalization was then performed in six different solvents to explore the impact of the solvent in the polystyrene-MWCNTs interactions. We observed a characteristic degree of functionalization for each solvent and we propose for the first time a simple model based on surface energy solubility parameter theory that can be used as a synthetic guideline for the design of polymer functionalised MWCNTs². Finally, we demonstrate that this model can be applied for the fabrication and design of nanoparticle/carbon nanotube hybrid structures. We believe that our results and the application of the surface energy based solubility parameter theory as a qualitative model for the design of functionalized MWCNTs will lead to the rational synthesis of a wide range of novel nanostructures.

Synthesis Strategies Involving Local Energy Transduction—The Optically Oriented Assembly of Metal-Semiconductor Building Blocks in Solution via Photonic Nanosoldering Matthew J. Crane, Elena P. Pandres, E. James Davis, Peter Pauzauskie and Vincent C. Holmberg; University of Washington, United States

Careful control over chemistry, composition, and morphology are critical in virtually every materials system, and new methods that enable precise control over the rational assembly of constituent building blocks are vital to the future of nanoscale fabrication efforts. Here, we will discuss our recent results published in Nature Communications on the light-driven, solution-based assembly of nanoscale building blocks into periodic, one-dimensional heterostructures, consisting of repeating metal-semiconductor junctions via a photonic nanosoldering process, as well as two other recent examples where local energy transduction is used as a strategy to drive chemistry and control nanoparticle crystal growth. Effects of anisotropic radiation pressure, heat transport, and solvent choice on material transformations and nanostructure assembly will be discussed. We believe that these approaches can be generalized to enable the additive manufacturing of nanoscale structures for numerous applications, and we hope that this demonstration will lead to wider use of optical manipulation techniques for the rational assembly of diverse sets of nanomaterials in a variety of different solvent systems.

Elastic and Plastic Relaxation in Highly Strained Core-Shell Semiconductor Nanowires Slawomir Kret, Serhii Kryvyi, Dorota Janaszko, Anna Kaleta, Jakub Plachta and Piotr Wojnar; Institute of Physics PAS, Poland
Due to high ratio of surface to volume ratio the monocristalline semiconductor core-shell nanowires (NWs) are very suitable as building blocks a of solar cells, optoelectronic, electronic and environmental sensor devices. They are also perfect model structures for studying nanomechanical behavior of defects appearing during strain relaxation in nanoscale objects. For this purpose strained ternary semiconductors core-shell nanowires were grown by molecular beam epitaxy (MBE) on Si or GaAs substrate using Vapor-Liquid-Solid (VLS) mechanism. Due to high mismatch of the lattice constant of basic compounds ZnTe, CdTe, MgTe, which can reach more than 7%, the growth of nanowires is challenging and their final shape and morphology are complex. By modification of growth conditions (temperature, stoichiometry) nonstandard crystal structure for given compound can be obtained. For example it is possible to obtain hexagonal (wurtzite) structure or polytypic superlattice in CdTe, which usually crystallizes in regular cubic structure. \[1\]. The core-shell NWs, investigated by transmission electron microscopy (TEM) are strained or partially relaxed depending on the core diameter, lattice mismatch and local thickness of the shell.

The residual strain field and core-shell interface misfit dislocation network is studied for individual nanowires by TEM. The Dislocation Density Tensor mapping is performed using extension of the Geometric Phase Analysis \[2\] performed on HRTEM and HRSTEM images obtained from different zone axis axes in planar view or/and using perpendicular FIB cross-section of the nanowires. Due to the significant deformations of the NWs (bends and twists) the high-resolution images in zone axes can be obtained only for the several tens of nanometers long fragments of the NWs having few micrometers of total length. Therefore, we use Scanning Electron NanoDiffraction (SEND) to map bending and twisting of the lattice as well as chemical lattice distortions related to the changes in elemental composition. The series of electron diffraction patterns obtained in the STEM mode is analyzed to receive the individual maps of the lattice distortions components, via combination of simulated dynamic diffraction patterns and local cross-correlation with experimental patterns. As a results, it is possible to determine local thickness, projected distortions axial and radial components, local lattice twist(alpha) as well and tilts (beta and gamma) even for bent NWs. Combination of both approaches of strain measurements allows to determine the projection of the residual strain in such complex 3D geometry as well as establish the dependence between the spatial arrangement of interfacial misfit dislocation network on the asymmetry of the shape of nanowires and shell inhomogeneity.

In the case of the CdTe/ZnTe NWs crystalizing in regular crystal structure form, the core-shell interface dislocation network consisted of 60°dislocations and dissociated Lomer dislocations. We show that lateral and radial spacing between dislocations depends strongly on the local thickness as well as the core diameter. These findings are in qualitative agreement with theoretical prediction \[3\]. In the case of NW with stacking fault, due to section of the [111] plane core stacking faults with shell formed [11-1] stacking fault the static Cottrell-Lomer Lock dislocations was observed with cation core polarity. The difference of the morphology of network of interface misfit dislocations between NW having wurtzite and morphology are complex. By modification of growth conditions (temperature, stoichiometry) nonstandard crystal structure for given compound can be obtained. For example it is possible to obtain hexagonal (wurtzite) structure or polytypic superlattice in CdTe, which usually crystallizes in regular cubic structure. \[1\]. The core-shell NWs, investigated by transmission electron microscopy (TEM) are strained or partially relaxed depending on the core diameter, lattice mismatch and local thickness of the shell.

The heterogeneous integration of dissimilar materials is a long pursuit of material science community and has defined the material foundation for modern electronics and optoelectronics. The typical material integration approaches usually involve strong chemical bonds and aggressive synthetic conditions and are often limited to materials with strict structure match and processing compatibility. Alternatively, van der Waals integration, in which freestanding building blocks are physically assembled together through weak van der Waals interactions, offers a bond-free material integration strategy without lattice and processing limitations, as exemplified by the recent blossom of 2D van der Waals heterostructures. Here I will discuss the fundamental forces involved in van der Waals integration and generalize this approach for flexible integration of radically different materials to produce artificial heterostructures with minimum interfacial disorder and enable high-performing devices. Recent highlights include the formation of van der Waals metal/semiconductor junctions free of Fermi level pinning to reach the Schottky-Mott limit; the creation of a new class of high-order van der Waals superlattices with highly distinct constituents of atomic or molecular layers; and the development of van der Waals thin film electronics with unprecedented flexibility and stretchability. I will conclude with a brief perspective on exploring such artificial heterostructures as a versatile material platform with electronic structure by design to unlock new physical limits and enable device concepts beyond the reach of the existing materials.
Vertically Stacked 0D/2D Materials Based Hybrid Infrared Phototransistor Anindita Sahoo, Peter Reiss, Etienne Quesnel, Jacques Cluzel, Luc Andre, Eric De Borniol and Berangere Hyot; Univ. Grenoble Alpes, CEA., France

Infrared (IR) photodetectors are nowadays in high demand in a wide range of fields such as telecommunication, thermal imaging, remote sensing, night assistance car driving etc. Recently, hybrid phototransistors made of highly efficient light absorbing 0D quantum dots and high mobility 2D materials have introduced a new technology, which dramatically increases the responsivity and gain of the photodetector. In 2012, such low dimensional IR phototransistor based on graphene/PbS QD hybrid was proposed in literature \cite{1, 2} for the first time. Later in 2017, a high-resolution broadband image sensor based on such hybrid materials was demonstrated \cite{3}, which is sensitive to ultraviolet, visible and infrared light (300–2000 nm).

We have investigated similar graphene/PbS QD hybrid phototransistors and explored the enhancement of their photo-sensing qualities compared to bare graphene phototransistor in the visible-NIR-SWIR region of optical spectra. Initially, we studied CVD-grown single layer graphene phototransistor in the visible-NIR region, which showed a responsivity of about $10^4$ A/W, associated with the low–doped Si substrate, which acts as the primary material for optical absorption. Such responsivity is $10^7$ orders of magnitude higher \cite{4} than conventional graphene phototransistor \cite{5}. However, the photo-sensing wavelength range of such device is limited up to 1100 nm depending on the principal absorption material Si. In order to expand the photo-sensing wavelength range up to SWIR region, we have explored the potential of graphene/PbS QD hybrid phototransistors. We synthesized the colloidal PbS QDs absorbing in the NIR as well as SWIR regions and developed a layer-by-layer dip coating with simultaneous ligand exchange procedure to deposit homogeneous PbS QD layers on graphene sheet leading to a well fabricated hybrid phototransistor. We achieved a significantly high responsivity of at 940 nm with irradiation power density of $10^{-4}$ W/m$^2$. In the NIR range, the peak responsivity appears to be $10^7$-10$^8$ A/W, whereas in the SWIR range, the observed peak responsivity is $10^6$ A/W. Moreover, graphene/PbS QD hybrid exhibits high sensitivity at low irradiation power (< 0.05 nW), where bare graphene photodetector is unable to sense such low intensity light in the visible-NIR region.

Accurate Prediction of Energy Level Alignment in Mixed-Dimensional Heterojunctions Qunfei Zhou$^1$, Zhenfei Liu$^2$ and Pierre T. Darancet$^3$; $^1$Northwestern University, United States; $^2$Wayne State University, United States; $^3$Argonne National Laboratory, United States

Understanding energy level alignment between molecules and two-dimensional materials is conducive to controlling charge and energy transfer in mixed-dimensional heterojunctions. The competition between distinct energy scales, such as the ones associated with electronic correlations, interface dipole, orbital hybridization, and non-local dielectric screening, can lead to significant renormalization of the intrinsic energy levels of each material at these interfaces. The variety of these energy scales also complicates the theoretical description of the level alignment for mixed-heterojunctions accurately.

Here we study the electronic structure and level alignment for mixed 0D-2D heterojunctions containing transition metal phthalocyanines on MoS$_2$ by first-principles density functional theory (DFT) calculations. By using optimally tuned range-separated hybrid (OT-RSH) functionals, a recently developed method for finding the optimal range-separated parameters for describing short-range and long-range electron exchange effect, we obtain energy level alignment consistent with known experimental results, a significant improvement comparing to standard DFT. This method can be used for other mixed-heterojunctions for better understanding of their electronic and optical properties.

Two-Dimensional Materials for Energy Yi Cui$^{1,2}$; $^1$Stanford University, United States; $^2$SLAC National Accelerator Laboratory, United States

Two dimensional (2D) layered materials have strong in-plane covalent bonding and weak van der Walls interaction between
the planes, which host a wide variety of interesting physical and chemical phenomena. Here I will present our research over 15 years on nanostructured 2D materials. First, I will show how we synthesize these 2D materials into rich morphologies including nanoplates, nanoribbons, layer-vertical aligned films as well as lateral and vertical heterostructures. Second, we developed liquid-gel gating, solid state ion gating, chemical and electrochemical intercalation to control the physical and chemical property of 2D materials. Third, we demonstrated exciting new exciting application of using 2D materials for batteries and catalysis applications.

Dimensional Engineering in Solid-State Quantum Simulators Na Young Kim; University of Waterloo, Canada

We engineer electronic and photonic structures to control light-matter interactions including dimension and geometries. These hybrid electronic and photonic structures, especially forming microcavity exciton-polaritons are basis to build solid-state quantum simulators. Quantum simulators are constructed with special-purpose to tackle a certain class of challenging problems for example, investigation of emerging topological quantum materials and their underlying physical mechanisms. Successful demonstration of quantum simulators relies on the controllability of engineered systems. I present our current methods to establish engineered quantum simulators based on solid-state systems with performance status and future perspectives.

9:15 AM *S.EL02.01.17
Gate-Tunable Narrow-Band Extinction of Near-Infrared and Visible Light in Graphene/LaAlO$_3$/SrTiO$_3$ Nanostructures Jeremy Levy$^{1,2}$, Erin Sheridan$^{1,2}$, Lu Chen$^{1,2}$, Jianan Li$^{1,2}$, Qing Guo$^{1,2}$, Hyungwoo Lee$^1$, Jung-Woo Lee$^1$, Chang-Beom Eom$^2$ and Patrick Irvin$^{1,2}$; $^1$University of Pittsburgh, United States; $^2$Pittsburgh Quantum Institute, United States

The absorption spectrum for pristine, undoped graphene is constant at 2.3 % across the visible to near-infrared (VIS-NIR) region of the electromagnetic spectrum. When these assumptions are relaxed, graphene can exhibit a strongly nonlinear optical response. Here, we explore the optical properties of graphene that has been integrated with LaAlO$_3$/SrTiO$_3$ nanostructures. Nanojunction devices formed at the LaAlO$_3$/SrTiO$_3$ interface enable large (~10$^8$ V/m) electric fields to be applied to graphene over a scale of ~10 nm. Nanoscale gating of the graphene in this way causes it to interact strongly with light, producing significant broadband THz emission via difference frequency mixing as well as a sum-frequency generated (SFG) response. Unexpectedly sharp spectral features show >99.99% extinction of the response. Extinction features are observed in both the VIS-NIR and SFG response, and can shift in frequency depending on the nanojunction bias and/or linear polarization. These surprisingly strong optical nonlinearities help to probe the fundamental response of nanostructured graphene, and open the way for future exploitation in optical devices.

9:45 AM *S.EL02.01.18
Mixed-Dimensional Heterostructures for Electronic and Energy Applications Mark C. Hersam; Northwestern University, United States

Layered two-dimensional (2D) materials interact primarily via van der Waals bonding, which has created new opportunities for heterostructures that are not constrained by epitaxial growth [1]. However, it is important to acknowledge that van der Waals interactions are not limited to interplanar interactions in 2D materials. In principle, any passivated, dangling bond-free surface interacts with another via non-covalent forces. Consequently, layered 2D materials can be integrated with a diverse range of other materials, including those of different dimensionality, to form mixed-dimensional van der Waals heterostructures [2]. Furthermore, chemical functionalization provides additional opportunities for tailoring the properties of 2D materials [3] and the degree of coupling across heterointerfaces [4]. In order to efficiently explore the vast phase space for mixed-dimensional heterostructures, our laboratory employs solution-based additive assembly [5]. In particular, constituent nanomaterials (e.g., carbon nanotubes, graphene, transition metal dichalcogenides, black phosphorus, boron nitride, and indium selenide) are isolated in solution, and then deposited into thin films with scalable additive manufacturing methods (e.g., inkjet, gravure, and screen printing) [6]. By achieving high levels of nanomaterial monodispersity and printing fidelity [7], a variety of electronic and energy applications can be enhanced including photodetectors [8], optical emitters [9], and lithium-ion batteries [10-12]. Furthermore, by integrating multiple nanomaterials into heterostructures, unprecedented device function is realized including anti-ambipolar transistors [13], gate-tunable photovoltaics [14], and neuromorphic memtransistors [15]. In addition to technological implications for electronic and energy technologies, this talk will explore several fundamental issues including band alignment, doping, trap states, and charge/energy transfer across previously...
Two-dimensional (2D) materials, such as graphene and transition metal dichalcogenides (TMDs) MX2 (where M = many transition metals; X = S, Se, Te), have revealed new physics and demonstrated potential for practical applications. In recent years, interest in layered van der Waals materials has expanded to quasi-one-dimensional (1D) structures. Unlike the layered MX2 materials that yield 2D layers upon exfoliation, the transition metal trichalcogenides (TMTs) MX3 contain 1D motifs, i.e. atomic threads, that are weakly bound together by van der Waals forces [1-2]. In this invited talk, we will review synthesis methods, properties and possible device applications of this unique family of quasi-1D TMT material systems. As a consequence of their structures, the exfoliation or growth of MX3 crystals results in nanowires and nanoribbons rather than 2D layers. Some of TMTs can be considered as truly 1D materials while others, which have weaker covalent bonds in directions perpendicular to the atomic threads, can be considered as mixed dimensional structures. One can also fabricate heterostructures consisting of 1D and 2D van der Waals materials [1-2]. We have discovered that some of these quasi-1D nanomaterials reveal an exceptionally high current density. For example, quasi-1D TaSe3 nanowires capped with quasi-2D h-BN layers have a breakdown current density exceeding JB~10 MA/cm², which is larger than what can be sustained by the state-of-the-art Cu interconnects. In a recent contribution, we reported uncapped ZrTe3 nanoribbons with an even more impressive breakdown current density of â100 MA/cm², which is more than an order of magnitude larger than the value obtained in DC testing of Cu wires [3]. We have used low-frequency noise (LFN) spectroscopy to investigate carrier recombination in such materials and verify reliability of the van der Waals interconnects [4-5]. It was found that LFN in ZrTe3 reveals conventional 1/f behavior near room temperature (f is frequency). However, at low temperature it is dominated by the Lorentzian bulges of the generation–recombination noise at low temperatures, which is unusual for metals. Unexpectedly, the corner frequency of the observed Lorentzian peaks revealed a strong sensitivity to the applied bias. This dependence on electric field was explained by the Frenkel–Poole effect in the scenario where the voltage drop happens predominantly on the defects, which block the quasi-1D conduction channels. The obtained results reveal the potential of quasi-1D/quasi-2D materials and heterostructures for applications in future ultimately downscaled interconnects and device technologies.

This work was supported, in part, by the National Science Foundation (NSF) through the DMREF: Collaborative Research (UCR – Stanford): Data Driven Discovery of Synthesis Pathways and Distinguishing Electronic Phenomena of 1D van der Waals Bonded Solids, and by the Semiconductor Research Corporation (SRC) contract 2018-NM-2796: One-Dimensional Single-Crystal van-der-Waals Metals: Ultimately-Downscaled Interconnects with Exceptional Current-Carrying Capacity and Reliability.

In Situ transfer. Together with the electrochemically active nature of 1T MoSe₂ and the increased amount of Co-O and Co-OH bonds more electrophilic, and Co-O and Co-OH bonds are favored owing to partial oxidation of the Co cation due to the electron transfer. In addition, localized electrochemical activity favors partial oxidation of the Co cation due to the electron transfer. Co to Mo, and the semiconducting MoSe₂ transforms to the metallic phase. In addition, LSC becomes more electrophilic, and Co-O and Co-OH bonds are favored owing to partial oxidation of the Co cation due to the electron transfer. Together with the electrochemically active nature of 1T MoSe₂ and the increased amount of Co-O and Co-OH bonds in LSC, the electrochemical activities are significantly improved for both hydrogen evolution reaction and oxygen evolution reaction. In the overall water splitting operation, LSC&MoSe₂ showed excellent stability at the high current density of 100 mA cm⁻² over 1,000 h, which is exceptionally better than the stability of the state-of-the-art Pt/C || IrO₂ couple.

Developing efficient bifunctional catalysts for overall water splitting that are earth-abundant, cost-effective, and durable is of considerable importance from the practical perspective to mitigate the issues associated with precious metal-based catalysts. In the present study, we introduce a heterostructure comprising perovskite oxides (La₀.₅Sr₀.₅CoO₃−δ (LSC)) and transition metal dichalcogenides (TMDs, MoSe₂) as an electrochemical catalyst for overall water electrolysis. Interestingly, formation of the heterostructure of LSC and MoSe₂ (LSC&MoSe₂) induces a local phase transition in MoSe₂, 2H to 1T phase, owing to electron transfer from Co to Mo, and the semiconducting MoSe₂ transforms to the metallic phase. In addition, LSC becomes more electrophilic, and Co-O and Co-OH bonds are favored owing to partial oxidation of the Co cation due to the electron transfer. Together with the electrochemically active nature of 1T MoSe₂ and the increased amount of Co-O and Co-OH bonds in LSC, the electrochemical activities are significantly improved for both hydrogen evolution reaction and oxygen evolution reaction. In the overall water splitting operation, LSC&MoSe₂ showed excellent stability at the high current density of 100 mA cm⁻² over 1,000 h, which is exceptionally better than the stability of the state-of-the-art Pt/C || IrO₂ couple.

In Situ Local Phase-Transitioned MoSe₂ in Perovskite Oxide Heterostructure and Excellent Overall Water Electrolysis

Yunesung Park and Nam Khen Oh; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Developing efficient bifunctional catalysts for overall water splitting that are earth-abundant, cost-effective, and durable is of considerable importance from the practical perspective to mitigate the issues associated with precious metal-based catalysts. In the present study, we introduce a heterostructure comprising perovskite oxides (La₀.₅Sr₀.₅CoO₃−δ (LSC)) and transition metal dichalcogenides (TMDs, MoSe₂) as an electrochemical catalyst for overall water electrolysis. Interestingly, formation of the heterostructure of LSC and MoSe₂ (LSC&MoSe₂) induces a local phase transition in MoSe₂, 2H to 1T phase, owing to electron transfer from Co to Mo, and the semiconducting MoSe₂ transforms to the metallic phase. In addition, LSC becomes more electrophilic, and Co-O and Co-OH bonds are favored owing to partial oxidation of the Co cation due to the electron transfer. Together with the electrochemically active nature of 1T MoSe₂ and the increased amount of Co-O and Co-OH bonds in LSC, the electrochemical activities are significantly improved for both hydrogen evolution reaction and oxygen evolution reaction. In the overall water splitting operation, LSC&MoSe₂ showed excellent stability at the high current density of 100 mA cm⁻² over 1,000 h, which is exceptionally better than the stability of the state-of-the-art Pt/C || IrO₂ couple.

Control of the Structure and Formation of Zero-Dimensional Nanostructures within Nanowires

Yi-Chia Chou1, Federico Panicerca², Yung-Wei Chang1, Chia-Yi Wu1, Wen-Chien Miao1 and Frances M. Ross3; 1National Chiao Tung University, Taiwan; 2University of Paris-Saclay, France; 3Massachusetts Institute of Technology, United States

Developing new types of nanoscale electronic devices, such as switches or storage elements, often requires creating both a functional nanostructure with precisely controlled properties and a well-defined connection between the nanostructure and the larger-scale circuit. Achieving sufficient control of nanostructures and their contacts is a key step that generally involves integrating different types of materials as well as bridging between length scales. For example, in Si or Ge-based circuits, metal silicides and germanides are commonly used in low-resistance contacts, while functional nanostructures can involve combinations of semiconductors with insulators and metals. Here we consider nanowires, which are especially favorable geometries for connecting nano and macro length scales, and discuss the opportunities for creating complex nanostructures within individual nanowires. In particular, we focus on silicide and germanide nanocrystals embedded within Si and Ge nanowires.

We start by illustrating how silicide and germanide nanostructures can be formed in silicon nanowires grown by the vapor-solid-liquid (VLS) mechanism. These nanocrystals are initially created by adding the appropriate metal to the liquid droplets that catalyze the nanowire growth. We show that solid silicide or germanide nanocrystals form in the liquid and have freedom to move and rotate until a low-energy interface with the nanowire is found. The crystal attaches to the nanowire, nanowire growth is then continued, and the nanocrystal becomes encapsulated within the nanowire. The process can be repeated to form multiple inclusions that are useful for contact formation as well as for modifying nanowire properties in new ways. In situ environmental TEM clarifies the sequence of phases and structures present at the atomic level during this complex process.

After the nanocrystal-nanowire contact is first made, we find that certain types of silicide and germanide nanocrystals remain attached while others break away without forming a permanent contact. Only the nanocrystals that remain attached to their nanowire can be incorporated by continued growth of the nanowire. We have examined the factors that determine nanocrystal adhesion to the nanowire and suggest that the outcome depends on the symmetry of the contact interface and hence the crystal structures of both materials. This restricts the range of nanocrystal/nanowire combinations possible. To expand the range of materials that can be encapsulated, we explore the use of phase transformations within the nanocrystal. As an example, NiGe does not attach to the growth surface of a Ge nanowire so is difficult to incorporate. But after growing a NiGe nanocrystal we can add Si to transform the nanocrystal to a silicide and this structure does attach and incorporate.

We suggest that the variety of nanostructures with incorporated nanocrystals that can be made using such reaction schemes potentially increases the opportunities for designing specific electronic and contact properties for nanostructured device applications.
Probing Metal Center Effects in MoS₂ – Metallophthalocyanine Mixed-Dimensional Heterojunctions

Samuel Amsterdam, Teodor K. Stanev, Qunfei Zhou, Vinod K. Sangwan, Alexander J. Lou, Hadallia Bergeron, Pierre T. Darançon, Mark C. Hersam, Nathaniel P. Stern and Tobin J. Marks; 1Northwestern University, United States; 2Argonne National Laboratory, United States

Mixed-dimensional heterojunctions, such as zero-dimensional organic molecules deposited on two-dimensional transition metal dichalcogenides (TMDs), exhibit unique interfacial effects that modify the properties of the individual constituent layers. To better understand the effect of changing molecular orbital energy on the heterojunction properties, we report here a systematic study of metallophthalocyanine (MPC) – MoS₂ (M = Co, Ni, Cu, Zn, H₂) heterojunctions using optical absorption, Raman spectroscopy, low temperature photoluminescence, variable temperature electrical measurements, and density functional theory. Notable phenomena include the emergence of heterojunction-specific optical absorption transitions, strong Raman enhancement, and quenching of defect emission that depend on phthalocyanine metal center identity. Temperature-dependent electrical noise measurements on field-effect transistors provide further insight into the properties of these mixed-dimensional heterojunctions. These results highlight the tunable nature of metal-organic-TMD van der Waals interfaces and the importance of the organic architecture and electronic structure in designing mixed-dimensional heterojunctions for optical and electronic applications.

Growth and Characterization of Ferromagnetic Manganese (IV) Selenide—Epitaxial Graphene Heterostructures

Ihteyaz A. Avash, Michael Pedowitz, Guy D. Cassuto and Kevin Daniels; University of Maryland, United States

In recent years, several transition metal dichalcogenides (TMDs) have been found to exhibit intrinsic ferromagnetic properties near the monolayer limit [1, 2]. However, unlike most ferromagnetic TMDs studied so far which only show weak ferromagnetic properties at extremely low temperature, the monolayer 1T polytype of manganese diselenide (MnSe₂) have been found to display long-range magnetic ordering and high magnetic moments (3μB per unit cell), as well as a high Curie temperature of 250K, tunable up to 375K via 5% biaxial strain [3]. Hence, this material has a high potential for future applications in low energy magnetic switching and non-volatile logic data storage [4]. In this study, two-dimensional heterostructures of manganese (IV) selenide are grown via chemical vapor deposition (CVD) on epitaxial graphene (EG) synthesized on 6H silicon carbide (SiC) substrates.

In our experiments, three different approaches for the CVD growth of the heterostructure have been investigated to grow MnSe₂. In our first approach, powdered manganese (IV) oxide (MnO₂) and selenium powder (Se) reactants were used. In the second method, manganese acetate (Mn(CH₃CO₂)₂) powder was used to improve manganese nucleation on EG. In our final method, δ-phase MnO₂ is electrodeposited on epitaxial graphene using a 0.1M solution of manganese acetate in a three-electrode electrochemical cell. Selenium powder is subsequently used in the selenification of δ-phase MnO₂ using the CVD method.

Characterization via Raman spectroscopy demonstrated the presence of MnSe₂ for all three approaches, which was also confirmed by SEM, AFM and EDX analysis. Although the characteristic A₅ Raman peak of MnSe₂ was visible at 269 cm⁻¹ for the first method, the very low intensity (almost 40% of the control FTA peak of the substrate at 203 cm⁻¹) of the peak indicated extremely low grain size and yield density. This conclusion was in agreement with the AFM and SEM data, which showed a sparse distribution of small growth particles (around 0.1 μm). Characterization of the second method displayed similar results, except the A₅ peak intensity displayed a relative increase of around 30%. The AFM and SEM data also showed a roughly 200% increase in grain size, which can be attributed to the relatively lower sublimation temperature of manganese acetate.

In the Raman data of the final approach, however, both characteristic E₉ and A₈ peaks of MnSe₂ are clearly visible (at 145 cm⁻¹ and 267 cm⁻¹ respectively) with extremely high peak intensity (around 400% of the mentioned substrate control peak), implying significantly higher MnSe₂ yield. The AFM and SEM data also demonstrated significantly high deposition density along graphene step edges. This remarkable improvement can be credited to the electrodeposited MnO₂ promoting manganese adhesion and selenification of the sample. This procedure shows great promise in the synthesis of single-crystal MnSe₂ heterolayer on epitaxial graphene. Samples grown using this mechanism has significant potential application in the field of spintronics on a wafer scale.

Defect-Free Assembly of Quasi-Three-Dimensional Plasmonic Nanoarrays with Arbitrary Substrate Materials and Structures  
Bongjoong Kim1, Jiyeon Jeon2, Yue Zhang3, Dae Seung Wie4, Jehwan Hwang2, Sang jun Lee2, Dennis Walker4, Don Abeysinghe3, Augustine Urbas4, Baoxing Xu2, Zaiyun Ku4 and Chi Hwan Lee1; 1Purdue University, United States; 2Korea Research Institute of Standards and Science, Korea (the Republic of); 3University of Virginia, United States; 4Air Force Research Laboratory, United States

Interaction of incident light with periodic arrays of three dimensional (3D) metal-dielectric compositied nanoarrays provide remarkable opportunities to harness light in a way that cannot be obtained with conventional optics. Diverse types of 3D or quasi-3D plasmonic nanoarrays with tailored feature shapes, sizes and configurations have been explored for a broad range of light-driven sensors and actuators, including imagers, bio-sensors, lasers and antennas. However, their practical applications remain challenged by a lack of effective manufacturing methodology. To bridge this gap, we developed a new concept of methodology that enables physical separation of precisely engineered quasi-3D plasmonic nanoarrays from their donor fabrication wafer and then transfer to a preferred foreign substrate in a defect-free manner that allows the donor wafer can be repeatedly recycled, offering a major cost- and time-saving factor in the manufacturing scheme. Unlike any of existing approaches, the entire process of this method exclusively occurs in distilled (DI) water at room temperature without the need of further chemical, thermal or mechanical treatments, and which thereby can substantially extend the types of receiver substrate to nearly arbitrary materials and structures. This approach provides versatility and modular scalability to arrange various classes of quasi-3D plasmonic nanoarrays in lateral and vertical configurations, offering a unique route to generate heterogeneous material compositions, complex device configurations and tailored functionalities. Comprehensive experimental, computational and theoretical results reported here reveal the essential design features of this method and, taken together with implementation of automated equipment, provide a technical guidance for manufacturable controllability and scalability. Pilot deterministic assembly of specifically engineered quasi-3D plasmonic nanoarrays with an industrial-grade hybrid imager, such as a mid-wavelength infrared type-II superlattice (MWIR-T2SL)-based hybrid pixel detector (HPD) successfully yields the enhancement of the detection performances and functionalities which otherwise cannot be achieved by conventional counterpart systems. The established 3D nanoassembly methodology has a great potential to extend the application of the deterministically assembled plasmonic nanoarchitectures for other types of imagers, antennas and biosensors.

Van der Waals Epitaxy of the Bismuth Iodide/Semiconductor Heterostructure via Self-Assembly-Monolayer Modification and Its Application of Nonvolatile Resistive Random-Access Memory  
Yutien Wu1, Chiashuo Li1, Sheng-Wen Kuo1, Po-Han Chang1, I-Chih Ni1, Mei-Hsin Chen2 and Chih-I Wu1; 1National Taiwan University, Taiwan; 2National Taipei University of Technology, Taiwan

As the electronics scaling down, the interfacial properties such as dangling bonds or surficial reconstructions play a critical role in functionality and performance of devices and the crystallinity of the overlayer. In addition, large roughness and pin holes of the insulator layer usually lead to leakage current and degradation in resistive random-access memory due to unrecoverable electrical breakdown. In this study, to eliminate the lattice interaction from the underlying substrate, we present a facile and easy method to achieve van der Waals epitaxy of bismuth iodide (BiI3) on the silicon wafer by using a self-assembly-monolayer of octadecyltrichlorosilane (OTS) as a buffer layer. As a result, the BiI3 layer on the silicon wafer possesses considerably flatten surface and high crystallinity, and the resistive-switching devices based on the BiI3/OTS/Si heterostructure demonstrated excellent resistive switching property with a very high on/off ratio of 106, long term stability for data retention, high endurance to write/erase cycles and the capability of multistate information-storage. The resistive switching behaviors, the roughness, morphology, and crystallinity of the BiI3 layer are systematically investigated by analyzing the current-voltage characteristics at different temperature, scanning electron microscope, atomic force microscope, X-ray photoemission spectroscopy (XPS) and x-ray diffraction patterns (XRD). Consequently, the resistive switching mechanisms is explained by formation and rupture of a conductive filament consist of metallic bismuth in the insulating layer as a result of the ion migration of iodine that changes the valence charge of BiI3 under the electrical field. This paper will help the fabrication process in large scale and the integration of BiI3 based resistive switching devices with the integrated
A Novel Technique for Fabrication of Nanowhisker Interconnects with Near Bulk Resistivity

Prajwal Rigvedi, Madhusudan Rao, and Gunther Richter; Max Planck Institute for Intelligent Systems, Germany

It has always been a challenge to fabricate devices at the nanoscale and analyse their properties, be it for the lack of equipment or the lack of techniques available. Defect free nanowhiskers attract a lot of attention as a potential candidate for interconnects. A concern regarding the resistivity of nanowires is their increased resistivity, which sometimes is 10 or 100 times larger than their bulk counterparts [1]. With this work, we are presenting a cleaner and a novel method which allows the formation of nanowhisker interconnects with near bulk resistivity facilitating a simple LASER lithography technique.

We adopt a bottom-up approach for device fabrication using what we call “Target Specific Lithography”. The whiskers which are grown by Molecular Beam Epitaxy are single crystals with a high aspect ratio and without any grain boundaries or defects [2]. These whiskers were transferred onto a Si substrate. A layer of resist is applied on this substrate and four contacts are designed in CAD and aligned with high precision so that it lies on top of an individual whisker. The contacts are exposed using a direct LASER writer. 100 nm Niobium is sputtered onto the lithographically patterned substrate. Upon liftoff, Niobium forms the contacts on the whiskers, allowing for the electrical transport measurement.

Electrical transport measurements performed on Au, Ag and Cu nanowhisker interconnects are demonstrated. The lengths of these whiskers are in the range of 18 μm to 40 μm, with an average diameter of 110 nm. The resistivity of gold at room temperature, for example, was found to be 2.20 ± 0.36 μΩcm, which is same as that of the bulk resistivity. Such results show that there is no size effect on the resistivity of the whiskers and that there are no impurities in the interface between the whisker and the contacts. We also have plans to conduct low-temperature measurements to understand the transport behaviour of the nanowhiskers as a function of temperature.

Atomically Dispersed Fe–N/C Catalysts of the New Benchmark Performance for Oxygen Reduction Reaction Synthesized by Selective Microwave Annealing

Woo Yeong Noh; Ulsan National Institute of Science and Technology, Korea (the Republic of)

The oxygen reduction reaction (ORR) is a key electrochemical reaction taking place at the cathode of various energy devices such as fuel cells and metal-air batteries. Heavily-loaded Pt catalysts are used to circumvent intrinsically sluggish kinetics of ORR, yet scarcity and high cost of Pt have triggered a recent drive toward alternative platinum group metal (PGM)-free catalysts, including non-precious metals, metal chalcogenides, metal-free, and single-atom catalysts. The single-iron-site catalyst surrounded by four nitrogen atoms (Fe–N₄) has emerged as one of the most promising electrocatalysts to replace Pt-based catalysts. To immobilize Fe–N₄ species on a conductive carbon support, however, high-temperature annealing for more than several hours is required, which induces severe aggregation of Fe metal ions along with its loose attachment on the carbon support resulting in low ORR activity and low stability. Significant deactivation is observed primarily caused by serious carbon corrosion or metal dissolution, which are common problems of carbon-supported catalysts in general because of intrinsically weak interaction of carbon with the active component. Thus, a high degree of graphitization of carbon supports is vital for the stability of a single atomic Fe–N₄ catalyst.

Carbon is one of the most common support materials for (electro)catalysts due to its high surface area, good conductivity, relative chemical inertness, and low cost. We also note that carbon is among the best microwave absorbers (susceptors) due to its high dielectric properties and short attenuation distance. Upon microwave irradiation, the carbon support can selectively absorb the radiation, keeping the catalyst precursor temperature low, and then heat is migrated from the carbon to the catalyst precursor. Because this selective and directional heat transfer mechanism dramatically reduces the chance of reaction between the catalyst precursors leading to agglomeration, and the entire process occurs in just a few seconds to minutes, the sintering of the catalyst particles is effectively mitigated. Instead, it causes strong attachment of the catalyst to the carbon surface. In this proposed new synthetic strategy, which we term “selective microwave annealing (SMA)”, there is no...
temperature limit and the reaction atmosphere [oxygen (O₂), nitrogen (N₂), and argon (Ar) gases] can be easily regulated, as in the conventional heating method. Furthermore, it does not require any additional microwave susceptor, such as those used in hybrid microwave annealing systems.

Thus, we applied this SMA technique utilizing the CNT support as a main microwave susceptor to fabricate atomic Fe–N₄ catalysts anchored strongly on CNT supports without Fe agglomeration. Structural characterizations by high-angle annular dark-field transmission electron microscopy (HAADF-STEM) combined with electron energy loss spectroscopy (EELS), X-ray absorption spectroscopy (XAS), and X-ray photoelectron spectroscopy (XPS) revealed that the single Fe atoms were uniformly dispersed in the form of Fe–N₄ and that a few-layer, graphene-like carbon structures were coated on the CNT surface in the selective microwave-annealed catalyst (MA-Fe-N/CNT), while severe agglomeration of Fe metal and amorphous carbon layers were observed for the thermally annealed catalyst (TA-Fe-N/CNT). As a result, the MA-Fe-N/CNT catalyst exhibited outstanding ORR activity with a half-wave potential of 0.92 V vs. reversible hydrogen electrode (VRHE) and excellent stability both in alkaline and acidic media. The catalytic performance and stability were superior to TA-Fe-N/CNT and even exceeded those of commercial Pt/C catalysts. We also have demonstrated that this SMA technique is generally applicable to other carbon supports, such as reduced graphene oxide and carbon black. Finally, we also have verified a Na-air battery with the as-prepared MA-Fe-N/CNT catalyst operates as effectively as the device with a Pt/C catalyst.

Print-in-Place Electronics Using Mixed-Dimensional Nanomaterials Aaron D. Franklin; Duke University, United States

For decades we’ve been hearing about the promise of printing electronics directly onto any surface. However, despite significant progress in the development of inks and printing processes, reports on fully, direct-write printed electronics continue to rely on excessive thermal treatments and/or fabrication processes that are external from the printer. In this talk, recent progress towards print-in-place electronics will be discussed; print-in-place involves loading a substrate into a printer, printing all needed layers, then removing the substrate with electronic devices immediately ready to test. A key component of these print-in-place transistors is the use of inks from various nanomaterials, including 1D carbon nanotubes (CNTs - semiconducting), 2D hexagonal boron nitride (hBN - insulating), and quasi-1D silver nanowires (AgNWs – conducting).

Using an aerosol jet printer, these mixed-dimensional inks are printed into functional 1D-2D thin-film transistors (TFTs) without ever removing the substrate from the printer and using a maximum process temperature of 80 °C. To achieve this, significant advancements were made to minimize the intermixing of printed layers, drive down sintering temperature, and achieve sufficient thin-film electrical properties. Devices are demonstrated on various substrates, including paper, and evidence of the potential for printing directly onto biological surfaces will be shown. From the versatile printed electronic thin films that have been developed, a diversity of biosensors are being pursued and will be discussed. With continued refinement of the inks and print processes, this print-in-place technique can bring the field of printed electronics closer to where it has been promised to go for so many years: load substrate, press print, remove functional sensors / circuit.

Thermoelectric and Thermionic Transport in Mixed Dimensional Structures Mona Zeebarjadi and Md Golam Rosul; University of Virginia, United States

Solid state thermionic and thermoelectric modules can operate in power generation mode to convert heat to electricity, refrigeration, active cooling and thermal switching modes. They have potential application in waste heat recovery, solar thermal energy conversion and heat management and power generation of wearable electronics. Thermoelectric efficiency is an increasing function of material figure of merit, ZT. To obtain large ZT, high electronic conductance, large open circuit voltage (i.e. large Seebeck coefficient) and low thermal conductance is needed. The three parameters are interconnected and hence the optimization and improvement of ZT is a challenging task and requires careful control of electrons and phonons. Many of advanced thermoelectric materials are multi-phase compounds wherein thermal and electrical transport are determined not only by the average of the phases but also by the interfaces and the charge transfer between the phases. In this talk I will discuss several cases in which bulk samples are designed in which electronic transport is effectively 1D or 2D, while phonon transport is 3D and I will discuss the advantage of such structures and how thermoelectric figure of merit is enhanced using such strategy. Finally, I will discuss the thermal and electrical transport across 2D van der Waals heterostructures. The layers are weakly bonded resulting in extremely low thermal conductance. At the same time, layers could be mixed and matched to fine tune the electronic transport and to optimize the thermionic figure of merit.

Molybdenum Disulfide Nanoflower/Epitaxial Graphene Heterostructure Gas Sensors for Improved Sensitivity and Selectivity Soaram Kim1,1, Jaeseo Park2,3, Daniel Lewis1,4, Seunghyun Lee4, Balaadithya Uppalapati5, Digangana Khan5, Ferhat Bayram5, Sanjay Krishna5, Goutam Koley5, Sang-Woo Kang2,3 and Kevin Daniels1,1; 1University of Maryland, United States

2020 MRS Virtual Spring/Fall Meeting, November 27-December 4, 2020, Spring Abstracts Final Program 2/3/21
Bilayer epitaxial graphene (EG) was synthesized by Si sublimation on 6H SiC, and MoS2 nanoflowers were grown on graphene/SiC directly using metal-organic chemical vapor deposition (MOCVD). The growth methods of graphene and MoS2 nanoflowers are discussed in detail elsewhere [3,4]. The structural and optical properties of the samples were investigated by scanning electron microscopy (SEM), atomic force microscope (AFM), X-ray photoelectron spectroscopy (XPS), Raman spectroscopy, photoluminescence (PL), and cyclic voltammetry (CV). To fabricate the chemical sensor, e-beam lithography and reactive ion etching (RIE, CF4) were used to prepare a simple pattern. Finally, the metal electrode (Ti/Au = 30/120 nm) was deposited using an e-beam evaporator. The prepared chemical sensor was tested with various gases such as 5 ppm of nitrogen dioxide (NO2) and ammonia (NH3), and ~1000 ppm of volatile organic compounds (VOCs) and showed superior chemical response and recovery at room temperature. It is evident that the prepared device is suitable for chemical sensing applications with high sensitivity and selectivity.

Flexible Electronics Enabled by Direct Transfer of Two-Dimensional Transition Metal Dichalcogenides with Contacts

Alwin Daus, Sam Vaziri, Victoria Chen, Ryan W. Grady, Connor Bailey, Cagil Koroglu, Kevin Brenner, Kirstin Schauble and Eric Pop; Stanford University, United States

Two-dimensional (2D) semiconducting transition metal dichalcogenides (TMDs) have been proposed for future high-performance flexible nanoelectronics [1]. However, high-quality chemical vapor deposition (CVD) growth of TMDs requires high temperatures >500°C. Thus, the fabrication process must rely on layer transfer processes for integration with temperature-sensitive flexible substrates.

Most conventional transfer techniques add a thin sacrificial polymer layer on top of the TMD. This stack is released from the growth substrate in an etching solution and picked up by the target substrate, but this technique can lead to polymer residues and damage or wrinkling of the TMD film [2,3]. An alternative method is to spin-coat the flexible substrate on the TMD before transfer, however this has its own limitations because all subsequent patterning would have to be done on the flexible substrate [4].

Here, we demonstrate a novel, alternative approach which allows us to do critical lithography steps on the rigid TMD growth substrate (SiO2/Si), then transfer the TMD films together with their metal contacts onto the flexible substrate for further integration. This approach results in the shortest channel (sub-100 nm) and highest-performance TMD transistors on flexible substrates to date, using monolayer CVD-grown MoS2. The “hybrid” fabrication/transfer method can also enable other devices, it can be used with other TMDs like WSe2 or MoSe2, and the TMD thickness can range from mono- or bilayers to thicker multilayers.

We first grow the TMDs by CVD on SiO2/Si substrates [5-7] and perform lithography and lift-off for metal contacts, with contact spacing down to 50 nm. Then, we spin-coat 6 µm flexible polyimide (PI) on top and we release the PI with the embedded TMD and metal contacts in deionized water without any other chemicals. This minimizes damage and contamination of the TMDs, as verified by Raman spectroscopy and photoluminescence. We then flip the PI/TMD stack and deposit Al2O3 by atomic layer deposition, then pattern metal gates by lift-off, thus creating staggered TMD transistors.

We have thus realized flexible transistors with CVD-grown MoS2, WSe2 and MoSe2, reaching field-effect mobility >30 cm²V⁻¹s⁻¹ for monolayer MoS2, which is the highest to date on flexible substrates. In sub-100 nm MoS2 transistors, we also obtain record high on-currents of ~600 µA/μm. Thermal simulations reveal that the intimate metal contacts assist heat spreading during device operation, enabling such high performance despite the low thermal conductivity of the PI substrate. We demonstrate that the devices are stable under tensile bending to a radius of 4 mm, with negligible changes in device characteristics. We also show preliminary data on flexible MoS2 circuits and flexible vertical devices based on TMDs.

In summary, our novel fabrication method provides a scalable approach for the integration of various types of TMD devices on a single flexible substrate, and the contact patterning before transfer enables nanoscale dimensions, down to sub-100 nm channel lengths. This method also enables vertical device structures, e.g., resistive memory and optoelectronic devices such as photodetectors or solar cells.

2. A. Gurarslan et al., ACS Nano 8, 11522 (2014).
7. J. Chen et al., ACS Photonics 6, 787 (2019).
The last decade has seen nearly exponential growth in the science and technology of two-dimensional materials. Beyond graphene, there is a huge variety of layered materials that range in properties from insulating to superconducting. Furthermore, heterogeneous stacking and doping of 2D materials also allows for additional band structure engineering. In this talk, I will discuss recent breakthroughs in two-dimensional atomic layer synthesis and properties, with emphasis on doping 2D semiconductors. Our recent works include development of an understanding of substrate impact on growth and doping of 2D materials to tune them from n- to p-type, and to create 2D magnets. Our work and the work of our collaborators has lead to a better understanding of how substrate not only impacts 2D crystal quality, but also doping efficiency in 2D materials.

High-performance semiconducting films with precisely engineered thicknesses and compositions are essential for developing next-generation electronic devices, which are becoming more integrated, complex, and multifunctional. My talk will introduce the novel processes that enable atomic-scale control of the thickness and spatial composition of semiconducting films on the wafer-scale. These processes include: (i) the wafer-scale generation of atomically-thin layered semiconductors such as metal dichalcogenides and metal oxy-dichalcogenides via metal-organic chemical vapor deposition (MOCVD), (ii) the atomic-level engineering of vertical thickness and composition through the layer-by-layer assembly of the layered semiconductors, and (iii) the interlayer engineering of the layered semiconductors for the property control. These capabilities provide a new material platform for both fundamental research and practical applications, including incorporation into existing integrated circuit technology to form hybrid materials and boost electrical and optical functionality.

The current electronics has been mainly dominated by Si-based devices due to their mature processing system and exceptional cost-effectiveness. However, next generation electronics needs novel functionalities that cannot be realized by Si because of intrinsic limitation of Si. Accordingly, demand for non-Si electronics has been getting substantially high. Unfortunately, current methodology requires extremely high cost for non-Si materials, which impedes the progress in developing the non-Si based electronics. Here, I will discuss about our group’s efforts to address this issue. Our team recently conceived a new crystalline growth, termed as “remote epitaxy”, which can copy/paste crystalline information from substrates remotely through graphene, thus generating single-crystalline films on graphene. As interfacial binding energy is attenuated by inserting graphene at interface, the single-crystalline films can be easily exfoliated from the slippery graphene surface. Also, the graphene-coated substrates can be, in principle, reused infinitely to produce single-crystalline films. Thus, the remote epitaxy can produce non-Si semiconductor films with unprecedented cost efficiency while allowing additional flexible device functionality required for current ubiquitous electronics.

Next, I will discuss about a layer splitting technique which can be a potential solution to overcome the problem in obtaining large-scale and monolayer 2D materials. A 2D material-based heterostructure has been intensively studied because of its unique device functionalities and novel physics. However, it is extremely challenging to secure large-scale and monolayer 2D
materials because of following issues: 1) poor scalability for laboratory fabrication processes of 2D heterostructures and 2) lack of well-defined control parameters for kinetics of 2D materials and predictable number of layers of 2D materials. To resolve this issue, we conceived a new approach called “layer-resolved splitting” which obtains multiple monolayer from multilayer 2D materials by controlling interfacial toughness contrast. As this method is versatile and universal, we can, in principle, apply to all 2D materials. We succeeded in having large-scale, monolayer 2D materials through our approach and, thereby 2D heterostructures were demonstrated for functional devices.

Lastly, I would like to discuss opportunities of mixed-dimensional heterostructure demonstrated by remote epitaxy and layer-resolved splitting. As they produce freestanding 3D bulk films and 2D atomic layers, a new type of 3D/2D heterostructures can be realized where a new physics and new device architecture are revealed. Therefore, I believe that a new opportunity will be discovered through the mixed-dimensional heterostructures.

5:30 AM S.EL02.03.02
Stackable Electronics Enabled by Freestanding 2D and 3D Materials Jeehwan Kim; Massachusetts Institute of Technology, United States

In this talk, I will discuss about our unique strategy to isolate wafer-scale 2D materials into monolayers and stack them into a heterostructures by using a layer-resolved splitting (LRS) technique [1,2]. This technique enables my group at MIT to explore unprecedented wafer-scale 2D heterodevices. While 2D heterostructures promise interesting futuristic devices, the performance of 2D material-based devices is substantially inferior to that of conventional 3D semiconductor materials. However, 3D materials exist as their bulk form, thus it is challenging to stack them together for heterostructures. Obviously, conformal coating of such single-crystalline bulks on 3D features is impossible. My group at MIT has recently invented a 2D materials-based layer transfer (2DLT) technique that can produce single-crystalline freestanding membranes from any compound materials including III-V, III-N, and complex oxides [3,4]. This technique is based on remote epitaxy of single-crystalline films on graphene followed by peeling from graphene. Stacking of freestanding 3D material membranes will enable unprecedented 3D heterostructures whose performance is expected to be superior to that of 2D heterostructures. I will talk about our group’s effort on 3D heterostructures as well as 2D-3D mixed heterostructured devices [5].

5:45 AM S.EL02.03.03
Mechanisms for Remote Epitaxy of GaSb on Graphene-Terminated GaSb (001) Sebastian Manzo, Vivek Saraswat, Austin J. Way, Patrick J. Strohbeen, Chenyu Zhang, Dongxue Du, Estiaque Shourov, Paul Voyles, Michael Arnold and Jason K. Kawasaki; University of Wisconsin, United States

Remote epitaxy is a method for growing single-crystalline materials on a graphene-terminated single-crystalline substrate, in which the epitaxial registry occurs between film and substrate rather than film and graphene. This method has been realized for several homoepitaxial systems, such as GaAs, GaN, LiF and ZnO. Yet, the microscopic mechanisms that allow for remote epitaxy remain mysterious. Here we demonstrate remote homoepitaxy of GaSb and comment on the role of defects on the apparent lattice transparency of graphene. In addition, we elucidate the effect of the graphene/substrate interface quality associated with different graphene transfer methods.

We have grown our films via molecular beam epitaxy and used x-ray and electron diffraction, along with transmission electron microscopy to confirm that the single-crystalline film is in-phase with the underlying GaSb (001) substrate. Graphene grown via chemical vapor deposition is cleanly transferred to GaSb, which has been corroborated via Raman spectroscopy and scanning electron microscopy. Remote epitaxy necessitates the absence of the semiconductor substrate’s native oxide, since this amorphous layer would inhibit epitaxial registry to the underlying substrate. Therefore, the question of how the native oxide desorbs when capped with graphene is of critical importance. We have studied this desorption mechanism through in-situ photoemission and reflective high energy electron diffraction. In addition, we have investigated the nucleation selectivity of GaSb on patterned and unpatterned graphene via in-situ scanning tunneling microscopy. The
GaSb overlayer can be readily exfoliated, which allows for the substrate to be recycled and for the exfoliated film to be transferred to arbitrary substrates.

6:00 AM S.EL02.03.04
Remote Epitaxial Growth of Compound Semiconductors through Graphene Kyusang Lee1 and Jeehwan Kim2; 1University of Virginia, United States; 2Massachusetts Institute of Technology, United States

Epitaxial growth has been widely used for high-quality growth of crystalline materials. However, epitaxial growth techniques usually require lattice match and similar thermal expansion coefficient between growth material and substrate, which blocks this growth technique from wide applicability. Recently, van der Waals (vdW) epitaxy has been demonstrated that allows to relax the limitation of epitaxial growth. vdW epitaxy on layered or two-dimensional (2D) materials is mediated by weak vdW interactions. In addition to these interactions, a substrate below 2D materials also plays a role to intervene in the epitaxial growth process, leaving room to realize a novel epitaxial growth process: remote epitaxy. Potential fluctuation—the difference between potential energy maxima and minima along the surface of the substrate—is influenced by this remote interaction; the fluctuation is predominant over the vdW force, due to the atomic thickness of 2D materials. The remote interactions can be controlled by modulation of polarities of 2D materials and epitaxy materials. Polar-material-based heterostructure, such as GaAs, InP, GaP and GaN with their substrate sandwiching 2D materials, enables the semiconductor film to be exfoliated from the underlying substrates through the 2D materials. This process is expected to open a novel avenue for the field of non-silicon electronics and photonics, where the ability to re-use graphene-coated substrates allows savings on the high cost of non-silicon substrates.

6:15 AM S.EL02.03.05
Remote Epitaxy of GaN Microrod Heterostructures for Fabricating Flexible Light-Emitting Panel Junseok Jeong1,2, Qingxiao Wang3,4, Janghwan Cha1,2, Sang Wook Lee1, Suklyun Hong1,2, Moon Kim4,4 and Young Joon Hong1,2; 1Sejong University, Korea (the Republic of); 2Graphene Research Institute–Texas Photonics Center International Research Center (GRI–TPC IRC), Korea (the Republic of); 3The University of Texas at Dallas, United States; 4Texas Photonics Center (TPC), United States; 5Ewha Womans University, Korea (the Republic of)

Demands on flexible lighting apparatus have been rapidly rising for the use in mobile display and wearable lighting device applications. For the device performance and stability, the use of semiconductors is ultimately desirable. Nonetheless, the rigid, brittle characteristics of inorganic semiconductor materials in a film form on wafer have so far precluded the use from the applications. In terms of growth template, graphene, which is flexible and allows delaminate of device overlayer from host substrate due to weakly bound van der Waals bonds to substrate, have begun to be utilized as an emerging epitaxy substrates for transferrable and flexible device applications.[1-3] As for the overlayer, the spatially separate arrays of lighting components are adequate for fabricating the flexible devices, and vertical wire- or rod-based structures are thought to be ideal for the purpose. Without the epitaxial relationship, the rod structures cannot be uni-directionally (or vertically) aligned, which degrades the geometrical feature for conformal electrode formation on top of rod light emitters. Meanwhile, there have recently been an emerging epitaxy technique, the so-called remote epitaxy that the crystallographic registration of single-crystalline wafer is dictated to overlayer across graphene.[4,5] Thus, single crystalline epi-layer is easily obtained for many compound semiconductors via the remote epitaxy. Likewise, once the remote epitaxy is adopted for fabricating the rod-based heterostructures, uni-directionally aligned, spatially separate lighting components can be obtained, which makes the arrays transferable and deformable after transferring on flexible target surface. Hence, the fabrication of rod heterostructures via graphene-mediated remote epitaxy enables flexibility and transferability of the overlayer rod-devices.

Herein, we demonstrate the deformable light-emitting diode (LED) panel via the remote heteroepitaxy of vertical GaN microrod (MR) radial $p$–$n$ junction arrays embedded with InGaN/GaN multiple quantum-wells on $c$-Al$_2$O$_3$ substrates with a gap of graphene interlayer. The remote epitaxy produced GaN MR arrays with uniform ordering of hexagonal sidewall facet orientation over whole graphene surface, suggesting a specific heteroepitaxial relationship between GaN MRs and $c$-Al$_2$O$_3$. Despite the presence of poly-domain graphene interlayer, the heteroepitaxial relation between GaN MR and substrate was revealed via cross-sectional transmission electron microscopy. Density-functional theoretical calculation demonstrates how/why the remote heteroepitaxy with large lattice mismatch is made possible across graphene. The use of graphene allowed exfoliation and transfer of MR LED overlayer onto flexible conducting copper plate, and the spatially separate MR arrays enabled to deform the LED device in diverse flexural forms, including folded, twisted, and even crumpled deformations. Repetitive bending test over 1,000 cycles between radii of curvatures of $\infty$ and 10 mm represented the robustness of MR LEDs. Also, the original substrate is recycled, which consistently re-yields the deformable LED panels over again. This study expands the epitaxy technique into flexible devices and substrate recycle.

Reference
Combined photonic and electronic systems require diverse devices to be co-integrated on a common platform. This heterogeneous integration is made possible through several separation and transfer methods where the functioning epilayers are essentially released from their growth substrate. The use of 2D layered h-BN as a mechanical release layer has been demonstrated to be a promising technique for the hybrid integration of III-nitride devices. In this talk we will give an overview regarding the epitaxial growth of Nitride-based semiconductor materials by MOVPE including GaN and h-BN, and design device structures for opto-electronic devices. In addition, results on wafer-scale growth and pick-and-place transfer of LED devices via h-BN van der Waals epitaxy, starting from sapphire growth substrates will be presented. Broader range of devices (HEMTs, solar cells, sensors, etc.) and applications (transport, environment, health, etc) will be discussed.

Mechanisms of Remote Epitaxy on Two Dimensional Materials

Wei Kong, Kuan Qiao, Huashan Li, Jeffrey C. Grossman and Jeehwan Kim; Massachusetts Institute of Technology, United States

The fabrication of thin-film semiconductor relies on epitaxy, during which direct bonding is made between the epitaxial layer and the substrate, to ensure highly ordered crystalline lattices in the epitaxial layer as a copy of its substrate. The strong physical bonding between epitaxial layer and substrate implies strict requirements of lattice matching as well as difficulties in heterointegration. We have previously shown that the insertion of a monolayer graphene in between the epitaxial layer and its substrate, in the so-called “remote-epitaxy” process, did not change the crystalline orientation of the epitaxial layer, and the epitaxial alignment between the epitaxial layer and its substrate was maintained as if the monolayer graphene was “transparent” [1]. In this report, we further explore the fundamental mechanisms behind such an epitaxial alignment through two-dimensional materials. And the general rule governs remote-epitaxy will be introduced [2].

Specifically, the transparency of two-dimensional materials to the epitaxial relationship is linked to the polarization of related material systems. Although the potential field from non-polar materials is screened by a monolayer of graphene, that from polar materials is strong enough to penetrate through a few layers of graphene. Such field penetration is substantially attenuated by 2D hexagonal boron nitride, which itself has polarization in its atomic bonds. Based on the control of transparency, modulated by the nature of materials as well as interlayer thickness, various types of single-crystalline materials across the periodic table can be epitaxially grown on 2D material-coated substrates. The epitaxial films can subsequently be released as free-standing membranes, which provides unique opportunities for the heterointegration of arbitrary single-crystalline thin films in functional applications.

Growth of Stable Metal-semiconductor Heterostructures Enabled through Monolayer Graphene

Patrick J. Strohbeen, Vivek Saraswat, Sebastian Manzo, Michael Arnold and Jason K. Kawasaki; University of Wisconsin-Madison, United States

Interdiffusion and interfacial reactions significantly limit the growth, processing, and operation conditions for devices based on functional transition metal / semiconductor interfaces. Conventional approaches require the use of thick (several nanometer) diffusion barriers, which are generally not epitaxial, and due to their finite thickness, are a significant perturbation to the idealized functional interface: for example, half metal / semiconductor interfaces for spintronics. Here, motivated by recent demonstrations of remote epitaxy of semiconductor/graphene/semiconductor heterostructures, we...
quantify the efficiency of monolayer graphene as a solid-state diffusion barrier in M/graphene/semiconductor heterostructures ($M = \text{Fe, Mn}$).

Through in-situ x-ray photoemission spectroscopy (XPS) we show suppression of the interfacial diffusion and reactivity in these systems by tracking core level shifts as a function of anneal temperature. In samples where $M = \text{Fe}$, we deposit 1nm of elemental Fe on Ge (001) substrates with and without monolayer graphene. The graphene is grown directly on the Ge (001) substrate by CVD to minimize the defects introduced by conventional layer transfer processes. For samples with no graphene barrier, we observe a complicated multi-component Fe 2p core level structure that evolves with increasing anneal temperature, indicative of significant Fe/Ge interfacial reactions. In contrast, for samples with a monolayer graphene barrier, the core level spectra do not change with temperature up to 300°C and there is no evidence for a reacted phase, suggesting that monolayer graphene is an excellent solid-state diffusion barrier. We will discuss similar experiments for $M = \text{Mn}$ and for different preparations of graphene on the semiconductor substrate, such as graphene layer transferred to Ge or GaAs.

Through these studies, we comment on the optimal synthesis and processing conditions for making graphene diffusion barriers.

SiC Remote Epitaxy—A New Paradigm for Stackable Electronics Rachael Myers-Ward1, Jeehwan Kim2, Matthew DeJarld1, Kuan Qiao2, Yunjo Kim2, S.P. Pavuny1 and Kurt D. Gaskill1; 1Naval Research Laboratory, United States; 2Massachusetts Institute of Technology, United States

Ideally, electronic heterostructures from dissimilar materials leads to enhanced functionality. Yet, experimentally forming these heterostructures is challenging due to lattice or thermal coefficient of expansion mismatch leading to defect formation or thermally driven atomic diffusion resulting in cross-doping and gradual junction transitions. These challenges may be overcome with the discovery of remote epitaxy and 2D layer transfer [1]. Here, SiC epitaxy is performed on epitaxial graphene as the electrostatic fields from the substrate penetrate the graphene and guide adatom registry. The film is easily peeled away since the graphene is not bonded to either the substrate or epilayer; the epilayer is then van der Waals bonded to a different material enabling new functionality. We will present experimental results on the remote epitaxy of SiC. There are three necessary steps to create remote epitaxy. The first is to grow epitaxial graphene on SiC, followed by transferring the graphene to a desired substrate (if different from SiC), and finally the growth of the remote epitaxial layer. If the remote epitaxy is to be SiC, which is the focus of this paper, the second step is not necessary. Epitaxial graphene (EG) was first synthesized on 4H- and 6H-SiC in a horizontal hot-wall CVD reactor between 1540 and 1580 °C in 10 slm of Ar and 100 mbar [2]. The growth temperature was dependent upon the offcut of the substrate, where substrates with higher offcuts require a lower growth temperature to ensure 1 ML of EG, which is desired to assist in SiC adatom registry during growth. SiC remote epitaxy was then performed on the EG using silane (2% in H2) and propane precursors, where the SiC polytype replicated the underlying substrate. In an effort to transfer the remote SiC epi/EG to another substrate such as SiO2/Si, a metallization step was performed. Thin Ti and/or Ni layers were initially deposited followed by a thicker high stress metal to create strain and aide in removing the remote SiC epi/EG from the SiC substrate [1]. Once transferred, the metal was removed via a metal etch.

In this work, we will discuss the important parameters needed for successful remote SiC epitaxy, such as graphene thickness, process flows, ramping conditions and remote epitaxy growth temperature. The epitaxial morphology characterized by SEM, Nomarski microscopy and Electron Detectio and graphene coverage and transfer evaluated by Raman spectroscopy will be presented.

Hybrid-Dimensional Heterostructures for Flexible Devices Gyu-Chul Yi; Seoul National University, Korea (the Republic of)

Contemporary human life relies heavily on mobile devices such as smart-phone, lap-top, or tablet PC which process tremendous amount of information every day. In near future, rapid development of information technology would eventually integrate the devices as a wearable and flexible form that will collect and process information ubiquitously. For the
fabrication of flexible and stretchable devices with high performance and reliability, monolithic integration of inorganic materials and devices in flexible form must be developed. We introduce hybrid dimensional heterostructures, composed of inorganic nanostructures grown directly on 2-dimensional (2-D) layered materials such as graphene and hexagonal boron nitride (h-BN), as one of the most promising materials for flexible device applications. The inorganic nanostructures in the hybrid nanomaterials exhibit excellent electrical and optical characteristics, including high carrier mobility, radiative recombination rate, and long-term stability. Meanwhile, 2-D layered materials, such as graphene, h-BN, chalcogenides and their hybrids, in the hybrid nanomaterials are flexible, stretchable, and mechanically strong, along with interesting and excellent physical properties. Here I report position- and morphology-controlled growths of ZnO and GaN nanostructures on graphene and h-BN using catalyst-free metal-organic vapor phase epitaxy and describe the methods to fabricate flexible light emitting diodes, transistors and pressure sensors.

8:30 AM S.EL02.03.12
One Dimensional GaN Based Nano-Optoelectronic Device Structures on Layered h-BN Grown by MOVPE Suresh Sundaram1,2,3, Xin Li3, Yacine Halfaya3, Taha Ayari3, Gilles Patriarche4, Christopher Bishop5, Saiful Alam3, Simon Gautier5, Paul L. Voss3,3, Jean Paul Salvestrini1,2,3 and Abdallah Ougazzaden4,3, 1Georgia Tech Lorraine, France; 2Georgia Institute of Technology, United States; 3CNRS UMI 2958 GT-CNRS, France; 4Université Paris-Saclay, France; 3Institut Lafayette, France

Recent advances in MOVPE enabled the high-quality growth of layered h-BN on sapphire substrates, and has resulted in the realization of series of 2D-3D III-nitride based device structures. This 2D layer also enables damage free mechanical lift-off which may drive future flexible and wearable industry with advanced high-efficient devices. Reliable wafer-scale 2D-2D heterostructure based devices have also been fabricated previously. Here we report, demonstration of MOVPE van der Waals epitaxial growth of GaN based nanostructures on 2D h-BN with a focus on large area van der Waals epitaxy and successful transfer to flexible platform. This approach to the growth of III-N nanostructures on h-BN avoids transfer processes and scaling issues seen with other 2D materials, since both the 1D (GaN nanorods) and 2D (h-BN) are grown at the wafer-scale and in one growth run. Further, this process is used to grow vertical core–shell p-GaN/InGaN/n-GaN nano-PIN device structures on wafer-scale 2D h-BN on sapphire and silicon substrates. Interesting results obtained on this futuristic process and mechanisms involved will be discussed.

Polar Quasi-2D Oxides via Epitaxy at Weakly-Coupled Interface Jian Shi; Rensselaer Polytechnic Institute, United States

When crystals approach 2D, their ferroelectric phase may be destabilized. How their temperature-dependent polarization behaves remains largely unknown. In this work, we attempt to answer this question using 2D pyroelectric oxides. We show that quasi-2D oxides down to a unit cell thickness can be epitaxially grown on perovskite substrate by the molten salt-assisted quasi-van der Waals epitaxy following a screw-dislocation driven mechanism. We experimentally demonstrate switchable in-plane photo-ferroelectricity and thickness-dependent pyroelectricity. Weakly-coupled interface allows us to reveal that electron-phonon renormalization leads to the observed dimensionality effect. Harnessing the dimensionality effect in pyroelectricity via novel epitaxy strategies could promote their applications in uncooled infrared cooling and thermal energy harvesting.

9:15 AM *S.EL02.03.14
Artificial Complex-Oxide Membrane Heterostructures Hyunseong Kum and Jeehwan Kim; Massachusetts Institute of Technology, United States

Complex-oxide materials exhibit a plethora of physical properties desirable for next-generation electronics, photonics, and quantum devices not present in other functional materials such as Si, III-V, and III-N. These properties may be present in bulk form or at a heterointerface, and may be created or enhanced by application of strain. However, to date, only epitaxial methods have been used to create various heterostructures with varying strain states. Unfortunately, epitaxial methods have strict limitations, requiring closely lattice mismatched and similar crystalline structure, which prevent unrestricted manipulation, integration, and utilization of these materials. Thus, the design space for heteroepitaxial systems is limited. Additionally, the range of strain that can be imparted by epitaxy is fixed by pseudomorphic conditions. Finally, epitaxial growth conditions, which typically occurs at high temperatures, preclude integration of materials that are less stable in such environments. This has been a consistent bottleneck preventing universal integration of dissimilar materials to date. To alleviate these restrictions, we present methods to produce freestanding complex-oxide membranes allowing artificial creation of complex-oxide heterostructures with vastly different crystalline structure, lattice, and orientation, such as perovskite, spinel, and garnet films. The first lift-off method, remote epitaxy, allows epitaxial seeding of the substrate
through monolayers of graphene, which can then be easily exfoliated due to the van der Waals nature of graphene. Using this method, we demonstrate freestanding single-crystalline perovskite SrTiO$_3$ (STO), spinel CoFe$_2$O$_4$ (CFO), and garnet Y$_3$Fe$_5$O$_{12}$ (YIG) membranes which can be freely bent and stacked to create artificial heterostructures. Although this method can be applied to a wide range of materials with ionicity of the atomic bonds, some complex-oxide materials, such as piezoelectric PMN-PT, are grown by sputtering, which damages the graphene due to the harsh plasma ambient. For these materials, we found that by choosing a substrate with a specific lattice mismatch, the epitaxial layer can be precisely separated from the substrate using a high stress Ni layer. The mechanism, upon careful TEM analysis, showed that a periodic array of edge dislocations as well as concentrated stress at the epilayer/substrate interface allows for atomically precise separation.

Finally, we demonstrate artificial heterostructures consisting of CFO/PMN-PT as a strain-mediated magnetoelectric composite, where due to the freestanding nature of the device, exhibited an order of magnitude higher magnetoelectric coupling response compared to films clamped to the substrate. Moreover, magnetostatic and magnetoelastic coupling was observed by stacking CFO/YIG membranes together, and more importantly, we found that it is possible to tune the Fermi-level of graphene by sandwiching it between YIG and CFO. We hope such demonstration of artificial 3D-3D and 2D-3D heterostructures will allow to significantly expand the possible permutations of materials and allow experimental realization of structures not possible by epitaxial means alone.

Emerging Epitaxy for Transferrable Flexible Optoelectronics—van der Waals and Remote Epitaxies
Young Joon Hong; Sejong University, Korea (the Republic of)

Technological fashion of electronics has recently changed from device miniaturization to flexible device and 3-dimensional heterogeneous integration. For the flexible devices, organic or polymeric materials have been generally used, but inorganic semiconductor is ultimately desirable in terms of high performance, long lifetime, and harsh environment tolerance. Nonetheless, the rigid, brittle characteristics of semiconductor has limited its utilization in the flexible device applications. Graphene-inserted growth is promising for tranferrable device fabrication because the surface of graphene has no dangling bonds. The van der Waals interfaces of overlayer/graphene/wafer enable mechanical exfoliation of overlayer from wafer via a facile sticky scotch tape technique.[1] Using the graphene interlayer, there are two epitaxy regimes, which are van der Waals remote epitaxies,[2,3] that can be classified by the role of graphene. In addition, the growth of wire or rod-shaped semiconductor crystallites is promising for deformable device applications because of the spatially separate geometry.[4] This talk introduces the aforementioned epitaxies for transferrable flexible optoelectronics. We begin discussing the role of graphene or underlying wafer how they dictate the epitaxial relation with overlayer. As the first section, the van der Waals epitaxy of InAs nanowires on graphene is presented. Then, as the second section, the remote epitaxy is introduced. Hydrothermal remote epitaxy of ZnO microrods and metal–organic vapor-phase remote epitaxy of GaN microrods are presented.[7–9] We also discuss the remote heteroepitaxy of ZnO on GaN and GaN on Al$_2$O$_3$ for lattice less-and far-mismatched remote epitaxy, respectively.[8,9] The transfer of GaN heterostructured microrods of $p$–$n$ junction with InGaN multiple quantum-wells is demonstrated for flexible microrod-light-emitting diode panel whose mechanical property is highly robust against crumpling/folding operations and repeated bending test.[9] Especially, we show the wafer recyclability for fabricating the deformable microrod-light-emitting diode panel over again on the same wafer in the remote epitaxy. We finally show how the principle of remote epitaxy, in which the limited thickness of graphene can penetrate the bonding feature of underlying wafer to the surface of graphene for epitaxial relationships, can be applied for site-selective growth.[10] The challenges and opportunities of epitaxies on/across graphene are discussed toward future flexible, transferrable displays technology.

References
Crystallographic defects, such as dislocation, are well known to strongly affect material’s physical properties. Electron-hole recombination mediated via dislocations (e.g. threading dislocation) is one of the predominant loss mechanisms for the sub-optimum performance in conventional semiconductors devices. However, how dislocation impacts its carrier dynamics in the ‘defects-tolerant’ halide perovskite is largely unknown. Stimulated by the successful pioneer work of remote homoepitaxy of semiconductor GaAs1, 2, researchers have also been achieved (remote heteroepitaxy) in the systems of AlN film on sapphire3, copper film on sapphire4, and ZnO film on GaN5. In our study, we synthesize epitaxial halide perovskite with controlled dislocation density via a remote heteroepitaxy approach using polar substrates (NaCl and CaF2) coated with graphene. Density functional theory calculations have revealed the structure and magnitude of the incompletely screened electrostatic potential from the polar substrates, supporting the remote epitaxy in the present case. The regulated film-substrate interactions have further reflected themselves in controlling the wavelengths of the ferroelastic domains. Molecular-dynamics simulations reveal the kinetic process during remote epitaxy. Comparing to the ionic epitaxy with high dislocation density (both misfit and threading), the film grown via remote shows much enhanced photoluminescence intensity and increased carrier lifetime. Our successful demonstration of remote epitaxy in halide perovskite provides an approach to develop free-standing halide perovskite film with reduced dislocation density. More importantly, dislocations and their impacts on carrier dynamics and device performance in halide perovskite have to be recognized and scrutinized.

Van der Waals (vdW) surfaces of 2D materials such as graphene and BN are attractive for growth of GaN and other III-nitride films and device structures. The weak inter-planar vdW bonding between 2D layers allows for easy mechanical separation of III-nitride films from the growth substrate for lift-off, transfer and integration on to arbitrary substrates. This approach of vdW lift-off is suitable for transfer of delicate single devices, like T-gate high electron mobility transistors (HEMT), as well as, wafer sized films. However, to obtain high performance devices, control over nucleation and epitaxy on 2D layers is necessary for high quality films. Additionally, to enable a simple transfer process strain and adhesion between the film and 2D layer must be balanced. In this paper, we describe the growth of high quality GaN and AlGaN/GaN HEMTs and large area membranes transferred to both flexible polymer substrates and a variety of rigid substrates. With access to GaN and AlGaN/GaN two dimensional electron gas (2DEG) membranes on flexible substrates, we investigate the effects of strain on basic materials properties from compressive to tensile. This is particularly powerful for probing the effects of strain on the electrical properties, like sheet carrier density and mobility, in the polarization induced AlGaN/GaN 2DEG. In transferred devices, we demonstrate exceptional transport properties with mobility \( \gtrsim 2,000 \text{ cm}^2/\text{Vs} \) and device performance with \( g_m \sim 300 \text{ mS/mm} \) and \( f_T \) and \( f_{\text{max}} > 34 \text{ GHz} \) and 75 GHz under strain while bending. Lastly, we will cover vdW and adhesive bonding to high and low thermal conductivity substrates and the effects on device performance and self-heating. This paper will highlight the great potential of vdW epitaxy and lift-off for transfer and integration of GaN on to various platforms.

**Free-Standing and Ultrathin Inorganic Light-Emitting Diode Array Fabricated on Graphene**

Youngbin Tchoe¹, Kunook Chung², Keundong Lee³, Janghyun Jo³, Kyungmin Chung⁴, Jerome K. Hyun⁴, Miyoung Kim³ and Gyu-Chul Yi³; ¹University of California, San Diego, United States; ²Ulsan National Institute of Science and Technology, Korea (the Republic of); ³Seoul National Univ, Korea (the Republic of); ⁴Ewha Womans University, Korea (the Republic of)

Inorganic micro light-emitting diode (micro-LED) arrays are emerging as one of the most promising light emitters for next-generation display technologies and ultrahigh-resolution optogenetic light source arrays. An inorganic micro-LED can exhibit all of the important characteristics of an organic LED, including fast response time and a high contrast ratio, but with significantly improved resolution, brightness, efficiency, and lifetime due to its increased carrier mobilities, radiative recombination rates, and long-term stability. In free-standing and ultrathin form, the applicability of micro-LEDs can be further expanded to include various wearable, medical, and implantable devices, which require conformal contact on human skin or organs with minimal discomfort and stress. By creating an array of free-standing inorganic microstructure devices that are orders of magnitude smaller than the bending radius, mechanical flexibility can be accommodated. However, the inherent rigidity of inorganic materials and difficulty separating inorganic thin films from their single crystal growth substrates represent substantial challenges to the fabrication of freestanding and ultrathin inorganic LEDs. To resolve this problem, growths of inorganic semiconductor nanostructures and thin films on graphene substrates have recently been proposed, since graphene has great scalability and extremely thin layered hexagonal lattice structure as an excellent substrate for GaN growth. Moreover, the inorganic semiconductors prepared on large-area graphene can be transferred easily to or grown on elastic substrates to mitigate the flexibility demand. Here, we suggest a method of fabricating ultrathin, high-resolution inorganic micro-LED arrays based on individually addressable GaN microdisk LED arrays grown on graphene dots. Here, we report on the fabrication and EL characteristics of free-standing and ultrathin, individually addressable GaN microdisk LED arrays grown on graphene dots. GaN microdisks were prepared by epitaxial lateral overgrowth on patterned graphene microdots on SiOx/Si substrates using MOVPE. After preparing the GaN microdisk arrays, \( p \)-GaN and InGaNGaN multiple quantum well, and \( n \)-GaN layers were heteroepitaxially grown on the surface of the GaN microdisks. Ultrathin layers composed of GaN microdisk LED arrays on graphene dot were prepared by coating a polyimide layer and lifting-off the entire layers from the substrate. Then, single-walled carbon nanotubes (SWCNTs)/Ni/Au and SWCNTs/Ti/Au multiple electrode lines were formed on the top and bottom surface of GaN microdisk arrays in an aligned manner and crossing each other. The electrical and optical characteristics of the individually addressable GaN microdisk array on graphene dots were investigated by measuring their current-voltage characteristics curves and EL characteristics at various bending conditions. We also confirmed that the ultrathin micro-LED array worked reliably under flexible conditions and continuous operation mode.

**Nucleation Control in van der Waals and Remote Epitaxy**

Jinkyoung Yoo; Los Alamos National Laboratory, United States
Hybrid structures composed of conventional semiconductors (3D materials) and atomically thin two-dimensional (2D) materials have offered opportunities of recyclable device manufacturing, novel functionalities based on carrier transfer and exciton transport, and understanding natures of van der Waals gap. However, nucleation of 3D materials on 2D materials has not been understood straightforwardly due to absence of surface dangling bonds on 2D material though interaction the overgrown layer and 2D layer as a substrate has been explained by van der Waals interaction. Recent observation performed by the presenter’s team revealed that surface energy landscape is a key for nucleation of 3D materials on 2D materials. Increase in surface energy on 2D layer enhances nucleation probability of 2D materials significantly.

In the presentation those will be discussed several key aspects of nucleation of 3D materials on 2D materials, such as a few strategies to enhance surface energy on 2D layer, insights of the nucleation strategy on remote epitaxy, and demonstration of devices based on 3D/2D heterostructures.

12:00 PM S.EL02.03.24

Van der Waals Epitaxy of Germanium on Multi-Layer Graphene/h-BN Stacks—Limitation of Screening Out-of-Plane Dipole Moment

Yeonhoo Kim, Seth Swarnadeep, Towfiq Ahmed, Junseok Jeong, Seokhoon Choi, Young Joon Hong, Ho Won Jang, Woo Seok Yang and Jinkyoung Yoo; Los Alamos National Laboratory, United States; University of Central Florida, United States; Sejong University, Korea (the Republic of); Seoul National University, Korea (the Republic of); Korea Electronics Technology Institute, Korea (the Republic of)

Growth of semiconducting materials on two-dimensional (2D) materials, such as graphene, hexagonal boron nitride (h-BN), and transition metal dichalcogenides, has opened up novel opportunities for controlled functionality, economical device production, and flexible hybrid device manufacturing. A key method of semiconductor growth on 2D materials is van der Waals (vdW) epitaxy. In vdW epitaxy, nucleation of semiconductors on 2D layers is the main bottleneck due to the absence of surface dangling bonds on 2D layers. Induced out-of-plane dipole moments on 2D layers has been introduced to solve the nucleation issue. As demonstrated in 2018, out-of-plane dipole moments can be generated at the interfaces between different 2D materials. However, the screening effects of multiple 2D layers on the out-of-plane dipole have not been thoroughly explored. An atomically thin 2D monolayer does not provide enough screening of potential fluctuation in a substrate. Moreover, stacking multi-layers of atomically thin 2D materials can be still transparent to the potential in a substrate.

We studied the screening effects of graphene multi-layers on out-of-plane dipole moment for nucleation of germanium (Ge) on graphene/h-BN stack. Graphene/h-BN stacking enhances the out-of-plane dipole moment ~1,000 times compared to that of graphene or h-BN alone. The enhanced out-of-plane dipole moment induces a remarkably higher nucleation probability of Ge on graphene/h-BN stack compared to that on graphene. Furthermore, we explored the limitation of stacked layers of multi-graphene/h-BN to elucidate the screening effect of out-of-plane dipole moment on Ge nucleation. VdW epitaxy studies and calculation of out-of-plane dipole moment on the surface of the top graphene layer along with a number of graphene layers stacked on h-BN were systematically conducted. Electron microscopy and thin film field effect transistor characterizations were performed to correlate structural and electrical properties of Ge grown on multi-layer graphene/h-BN. In addition, insight of semiconductor device manufacturing with multi-layers of 2D materials will be discussed.

Liquid Phase Epitaxy of Low-Dimensional Ferroelectric Complex Oxide

Jie Jiang, Lifu Zhang and Jian Shi; Rensselaer Polytechnic Institute, United States

The structural quality and homogeneity of the epitaxial film is critical for the performance of many electronic and optoelectronic devices. The epitaxial films are mainly grown by either vapor-phase epitaxy (VPE) or liquid-phase epitaxy (LPE). The VPE technique is capable to grow multilayer and quantum well structures with controlled deposition process down to atomic scale, so it is favored in industry and developed rapidly during the past decades. However, growth of oxides and nitrides via VPE suffers from defect-rich films containing secondary phases and numerous grain boundaries. LPE, a growth process where a film of crystalline material is deposited from a supersaturated solution onto a single-crystal substrate, yields much higher crystalline quality of epitaxial films than VPE. The supersaturation for LPE is extremely low thus enabling the growth near thermodynamic equilibrium. Therefore, epitaxial films via LPE exhibit many advantages like highest structural perfection, automatic controlled stoichiometry, homogeneous dopant incorporation, flat surfaces and possibility of upscaling and mass production.

In this study, we use a molten salt-assisted LPE technique to prepare a single crystalline epitaxial low-dimensional ferroelectric complex oxide, Dion-Jacobson quasi-2D layered oxide, on LaAlO₃ (LAO) substrates. We present an in-plane polarization switching in this quasi-2D oxide. We find that the epitaxy growth follows a screw-dislocation driven mechanism. X-ray diffraction analysis confirms the epitaxial flakes with high crystalline quality. Our microscopy and second harmonic
generation measurements show the presence of ferroelastic domains and lack of inversion symmetry, respectively, in the epitaxial film. Our quasi-2D oxide exhibits a switchable photovoltaic ferroelectric effect where the polarization is modified by above band gap megawatts nanosecond optical pumping. Our high quality of epitaxial quasi-2D oxide would renew attentions and provide a good insight of this traditional LPE technique. In this layered complex oxide, the coupling between the in-plane ferroelectricity and other physical properties, e.g. the switchable photo diode effect and the photon-induced domain switching, may enable versatile applications down to the atomic scale.

S.EL02.04.12
Radiofrequency-Transparent Electrode for Device Integration  Taehoon Kim, Gwangmook Kim and Wooyoung Shim; Yonsei University, Korea (the Republic of)

When an electromagnetic wave impinges on a conductor, most of the incident wave is reflected, which makes metals and transparent conducting oxides (TCOs), such as tin-doped indium oxide (ITO), opaque to visible light (429–750 THz) and far-infrared (FIR) (< 20 THz). This incompatibility between optical transparency and electrical conductivity is well-defined fundamental material properties, but this is often not easy to enhance both simultaneously. Opacity due to electrical conductivity is more pronounced in the lower frequency range. This fundamental incompatibility creates a barrier for the realization of enhanced user-interface and device integration. We present a design strategy for preparing megahertz-range transparent conductor and a concept towards ‘device-to-device integration’ enabled by electromagnetic wave transmittance. The approach to the properties of conductors is verified using a conducting polymer, Poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS), whose microstructure is effectively controlled by solution process. The use of a transparent conducting polymer as an electrode enables the fabrication of a fully functional touch-controlled display device and magnetic resonance imaging (MRI)-compatible biomedical monitoring device, which would open up a new paradigm for transparent conductors.

S.EL02.04.13
Sodium-Sparked Reduced Graphene Oxide Composite for Low-Temperature Sodium-Beta Alumina Batteries Dana Jin1, MinJung Kim1, Yoon-Cheol Park2, Keeyoung Jung2 and Wooyoung Shim1; 1Yonsei University, Korea (the Republic of); 2Research Institute of Industrial Science & Technology, Korea (the Republic of)

Among all the anode materials, Li and Na have the highest capacity and great potential to increase the energy density of batteries. Unfortunately, dendrite growth in metal anodes is one of the safety concerns in current battery devices. One approach to address this issue is to use molten or liquid-metal electrodes. This concept has been applied to sodium-beta alumina batteries (NBBs), which are based on a liquid-Na anode and $\beta''$–Al$_2$O$_3$ solid electrolyte. Consequently, NBBs, such as Na-metal halide (ZEBRA) batteries, are among the most promising technologies for large-scale renewable energy storage because of their high theoretical specific energy, high energy efficiency, and good cycle life.

Interestingly, in the initial stages of sodium-beta alumina batteries (NBBs) development, it was not anticipated that the low performance would rise from the Na/$\beta''$–Al$_2$O$_3$ interface. Liquid Na metal should be an ideal reversible electrode, provided that it can be maintained in contact with the whole operating area of the $\beta''$–Al$_2$O$_3$ throughout the discharging and charging of the cell. It was expected to be the least problematic component of the cell. In reality, liquid Na does not fully wet the surface of the $\beta''$–Al$_2$O$_3$. Although early observations revealed that incomplete wetting of the $\beta''$–Al$_2$O$_3$ surface by Na and consequent interfacial impedance problems were likely in NBBs, little was reported for numerous years. Ideally, full contact with liquid Na should be achieved, which provides a large active interface area and thus leads to high NBB performance at low temperatures.

We propose a simple approach to achieve unprecedented NBB performance with a capillary-induced wetting concept that significantly improves the Na wetting on $\beta''$–Al$_2$O$_3$. In this study, we adopted sparked reduced graphene oxide (rGO) loaded on the surface of the $\beta''$–Al$_2$O$_3$ as an ideal “wetting sheet,” compared with previous metal (Li or Na)-ion batteries where
Van der Waals (vdW) materials are composed of two-dimensional planes that are held together by weak interlayer interaction. VdW crystals have attracted increasing attention in the past couple of decades because of their significantly different properties from three-dimensional materials. However, it is a small class of materials, with fewer than 100 layered compounds catalogues in the Inorganic Crystal Structure Database (ICSD), including graphite, h-BN, transition metal dichalcogenides, metal halides, metal pnictides, and metal oxides. Here, we present a topochemical redox concept to prepare a new binary vdW materials by structure control from ternary parent compounds. The vdW crystals obtained had the same chemical composition as known three-dimensionally bonded compounds, but exhibited layer crystalline structures. In our vdW crystal design strategy, we synthesized LiFeAs and CaFe2As2 as parent compounds. We then selectively removed Li and Ca from parent materials by topochemical redox to obtain FeAs vdW crystals with various crystal structures. We confirmed crystal structure of FeAs vdW crystal by X-ray diffraction (XRD), transmission electron microscope (TEM), scanning transmission electron microscope (STEM) and X-ray photoemission spectroscopy (XPS) and measured electrical property and mechanical property to identify the difference FeAs vdW crystal with three-dimensional orthorhombic FeAs.

Patterned All-Graphene Surface Enables Position-Controlled Remote Heteroepitaxy of ZnO Microrods Junseok Jeong1,2, Daekwon Jin1,2 and Young Joon Hong1,2; 1Sejong University, Korea (the Republic of); 2Graphene Research Institute–Texas Photonics Center International Research Center (GRI–TPC IRC), Korea (the Republic of)

Heteroepitaxy of semiconductor on two-dimensional atomic layered materials (2d-ALMs) has been promising for fabricating transferrable and flexible devices, because the use of 2d-ALMs allows to easily exfoliate overlayer device from host substrate.[1,2] Recently, an emerging epitaxy has been reported, which is the so-called remote epitaxy.[3,4] The remote epitaxy enables to produce single crystalline overlayer on graphene layer because the crystallographic registrations of overlayer can be copied from a underlying single crystalline substrate across graphene layer.[4,5] In the remote epitaxy of microrods (MRs), graphene thickness that is the remote epitaxial gap is critical to determine growth density of MR overlayer because penetrated field strength given from substrate leading to nucleation–growth is attenuated as the graphene thickness increases.[4] This implies that as we use graphene interlayer with spatially different thicknesses can result in different growth regimes of i) remote epitaxy or ii) non-growth, depending on graphene thickness. We present how the remote epitaxy can be applied to selective-area growth using graphene pattern layer. Position-controlled remote heteroepitaxy was performed by hydrothermal growth of ZnO MRs on intaglio-patterned graphene (IPG)-coated c-plane GaN substrate. The IPG layer consists of two graphene parts of (I) perforated-hole-patterned multilayer graphene (MLG) that prevents the remote epitaxy, which act as a growth mask layer, and (II) single-layer graphene (SLG) penetrating the potential field from underlying GaN substrate to allow remote heteroepitaxy of ZnO through the hole aperture of mask layer, which is embedded between GaN and MLG mask layer. The hole-aperture SLG area yielded remote heteroepitaxial ZnO MRs, whereas MLG area inhibited growth. Diameter and spacing of ZnO MRs are controlled by changing the hole pattern parameters. Transmission electron microscopy revealed the remote heteroepitaxial relationship between ZnO and GaN across the SLG area. According to density-functional theory calculations, the orbitals of SLG transfer the charge from the underlying GaN to the SLG surface leading to remote epitaxy, but the thick MLG was not capable of charge transfer in a long range. The weak van der Waals adhesion of ZnO/IPG/GaN was applied to exfoliate the ZnO MRs overlayer by a thermal release tape-assisted exfoliation technique and to recycle the original substrate. Our results readily open an opportunity to utilize the remote epitaxy for transfer of arrayed epitaxial structures in the designed size and arrangement for device manufacturing.

Recent Progress of Remote Epitaxy of III-Nitride System

Wei Kong, Kuan Qiao, Yunpeng Liu, Chansoo Kim and Jeehwan Kim; Massachusetts Institute of Technology, United States

III-nitride materials including GaN, InN, AlN, and their ternary alloys have been one of the key materials to realize advanced electronic and optoelectronic devices, such as high electron mobility transistors, light emitting diodes and lasers. The device performance heavily depends on defect density of III-nitride materials. However, the lack of native substrates leads to the challenges in fabricating defect-free III-nitride materials, severely limiting the implementation of variety of new devices utilizing III-nitride materials. Additionally, the attachment of III-nitride thin film to its substrate poses challenges of heterointegration of III-nitrides with other material systems. Separation of III-nitride thin films from the substrate while maintaining the pristine material quality is highly favorable.

We have previously shown the synthesis of GaAs on two dimensional materials followed by the separation of GaAs epitaxial thin film from its substrate [1], by utilizing the process so-called “remote-epitaxy”. Such discovery reveals the possibilities towards the fabrication of defect-free semiconductor materials without the constriction of substrate availability. In this report, we demonstrate the remote-epitaxy process to fabricate thin film GaN [2], as well as its ternary InGaN. The remote-epitaxial materials have been characterized by X-ray diffraction, atomic force microscopy and transmission electron microscopy, rendering device grade material quality. Additionally, the thin film III-nitrides can be peeled off from the substrates, and subsequently bonded to a foreign material surface, including Si and SiO2. Based on GaN/Si heterostructure, III-nitride based photonic/phononic cavity is demonstrated. This work has demonstrated a promising path for the integration of III-nitride with an arbitrary material system.

New materials and device integration demands motivate the ability to lift off and transfer epitaxial material. We use a Van der Waals-bonded 2D boron nitride (BN)-on-sapphire template to grow GaN by MOCVD then subsequently separate the GaN using a stress-induced lift-off method. This method has potential for wafer-scale heterogenous integration since large crack-free areas can be separated and the bottom epi-layer surface has sub-nanometer roughness. In this method a tensilely-stressed Ni layer deposited on the GaN acts to separate the epi-layer at the 2D BN interface allowing us to lift off whole wafer-sized GaN layers which are crack-free. Although large crack-free areas of GaN can be separated, the residual compressive strain in the GaN can cause cracks if the strain is inhomogeneously relaxed as the layer is transferred to the new substrate. By varying the stress and thickness of the Ni layer we can homogeneously relax some of the GaN strain upon separation and reduce the resulting crack density. We report on our development of this process including modeling and measurement of the GaN strain by Raman spectroscopy throughout the process.

Remote Epitaxy of ZnO Microrod Arrays across Graphene Junseok Jeong1,2 and Young Joon Hong1,2; 1Sejong University, Korea (the Republic of); 2Graphene Research Institute–Texas Photonics Center International Research Center (GRI–TPC IRC), Korea (the Republic of)

Two-dimensional atomic materials are emerging as epitaxial substrates for transferrable and flexible device application.[1] Graphene has excellent properties for the use as a substrate, such as high electrical conductivity, excellent mechanical strength, and optical transparency.[2,3] Nevertheless, since the difficulties of producing single crystalline thin film and crystallographically aligned nano/microstructures on graphene, due to the use of poly-domain graphene, there remains a challenge to utilize the graphene as a substantially epitaxial substrate. This obstacle can be overcome by the remote epitaxy.[4] The remote epitaxy enables to grow single crystalline overlayer on graphene regardless of the graphene domain because crystallographic registration can be dictated from underlying substrate through graphene. Here, we demonstrate remote homoepitaxy of ZnO microrods (MRs) on different crystal planes of apolar a-plane and polar c-plane ZnO substrates across graphene using hydrothermal growth method. Despite of the presence of poly-domain graphene intermediate layer, the ZnO MRs were epitaxially grown on a-plane and c-plane ZnO substrates, which were found to be homogeneous in-plane orientation over the entire surface of graphene-coated ZnO substrates. Such homoepitaxial relationship across graphene between ZnO MR and substrate was revealed through transmission electron microscopic and selected area electron diffraction analyses. The density-functional theory calculations suggested that the charge redistribution occurring near graphene induces the electric dipole formation, so the attracted adatoms lead to nucleation-growth of the remote-epitaxial overlayer. Because of a strong potential field caused by long-range charge transfer given from the substrate, even the use of bi-layer and tri-layer graphene resulted in the remote-epitaxial ZnO MRs. The effect of substrate crystal planes is also theoretically and empirically demonstrated. The ability of the graphene, which can be released from the host substrate without covalent bonds, was adapted to transfer the overlayer MR arrays. After the delamination, the host substrate was reused by repeating the process of remote epitaxy over again. This unconventional epitaxy technique offers an opportunity of the producing well aligned, transferrable and flexible epitelaxial nano/microstructure arrays templates for epitaxial electronics and optoelectronics applications and regenerating the substrate for cost-saving device manufacturing.

Remote Epitaxy of III-V Semiconductors on CVD-Graphene for Wafer Re-Usability and Flexible Electronics Kuangye Lu, Hyunseok Kim, Sanghoon Bae, Sangho Lee and Jeehwan Kim; Massachusetts Institute of Technology, United States

III-V compound semiconductors offer outstanding electronic and photonic properties that outperform silicon, but the cost of III-V wafers is extremely expensive. Although reusing original wafers can effectively minimize the cost of wafers, current techniques for wafer recycling add significant costs in fabrication, nullifying the cost savings by reusing the wafer. Remote epitaxy is a newly discovered method that enables single-crystal growth of III-V semiconductor thin films and easy exfoliation of the grown film, thus promising for reusing wafers multiple times. It requires an atomically thin spacer layer, such as graphene, to be present on top of III-V substrates, which allows enough field penetration from substrates through the graphene layer to make epitaxial III-V thin films grown on it maintain single-crystallinity. In addition, the graphene layer
provides weak bonding at the III-V/graphene interface, and thus thin films grown on top of graphene can be easily exfoliated, leading to a cost-effective way of wafer reuse and flexible thin film production. However, previous methods of transferring graphene onto III-V wafers, which use polymethyl methacrylate (PMMA) or metal stressor layers to transfer graphene grown on foreign substrates like copper or SiC, introduce defects and damages on graphene and/or substrates during the transfer process. Remote epitaxial films grown on the damaged graphene/substrate suffer from lower crystal quality and imperfect exfoliation, which undermines wafer reusability and device performance.

Here we report the CVD growth of amorphous graphene on III-V wafers at low temperature that enabled improved quality of remote epitaxial films and their perfect exfoliation. By introducing toluene as a carbon source which cracks at a relative low temperature for graphene growth, we show fully covered amorphous graphene on AlGaAs/GaAs substrates despite arsenic’s low decomposition temperature. The surface of graphene-coated AlGaAs/GaAs substrate remains smooth with a RMS roughness of around 3Å. We also demonstrate 100% coverage of single-crystalline GaAs thin films grown on amorphous graphene, with the film’s quality significantly improved compared to the case of transferred graphene. In addition, roughness of the substrate’s surface remains the same after exfoliation of grown GaAs film, and the growth and exfoliation were successfully repeated multiple times, proving the feasibility for wafer recycling. Through this low temperature CVD growth approach and remote epitaxy, we successfully demonstrate wafer-scale flexible thin film exfoliation and recycling of substrates, which will lead to new opportunities in III-V thin film-based electronics and novel heterostructures with reduced cost.

**GaN on 2D BN for Stress-Induced Lift-off** Eric Blanton$^{1,2}$, Timothy Prusnick$^{1,2}$ and Michael Snure$^{1}$; $^{1}$Air Force Research Laboratory, United States; $^{2}$KBR, United States

New materials and device integration demands motivate the ability to lift off and transfer epitaxial material. We use a Van der Waals-bonded 2D boron nitride (BN)-on-sapphire template to grow GaN by MOCVD then subsequently separate the GaN using a stress-induced lift-off method. This method has potential for wafer-scale heterogenous integration since large crack-free areas can be separated and the bottom epi-layer surface has sub-nanometer roughness. In this method a tensilely-stressed Ni layer deposited on the GaN acts to separate the epi-layer at the 2D BN interface allowing us to lift off whole wafer-sized GaN layers which are crack-free. Although large crack-free areas of GaN can be separated, the residual compressive strain in the GaN can cause cracks if the strain is inhomogeneously relaxed as the layer is transferred to the new substrate. By varying the stress and thickness of the Ni layer we can homogeneously relax some of the GaN strain upon separation and reduce the resulting crack density. We report on our development of this process including modeling and measurement of the GaN strain by Raman spectroscopy throughout the process.

**Enhanced Heavy Metals Removal Using a New Bucky-Paper Membrane Containing MWCNTs and Two Biopolymers—Chitosan and Carrageenan** Sara S. Alnasser, Afnan Alharbi, Ahmad alshahrani, Mohammed Alsuaibani, Bandar Alotai and Mihdar almihdar; KACST, Saudi Arabia

Due to the current global water crisis, wastewater treatment requires considerable attention and development. Dissolved heavy metals in water trigger serious alerts and can have lethal effects on various components of the environment including water resources, soil, plants, animals, and can also be threatening the health of human beings. In this study, we addressed the issue by introducing novel bucky-paper membranes that were fabricated using a combination of biopolymers (i.e., chitosan and carrageenan) and multi-walled carbon nanotubes (MWCNTs). Three dispersions of MWCNTs with chitosan, carrageenan, and chitosan-carrageenan with 0.1% v/w were prepared using vacuum filtration. The removal of six heavy metals (i.e., cobalt, nickel, copper, cadmium, barium, and lead) was investigated in this study. The water permeability and the removal of heavy metals were evaluated using a dead-end (DE) filtration system. Heavy metals removal was studied at pH 7 and under a range of varying applied pressures (1 to 6 bar). At an applied pressure of 1 bar, the removal of lead and copper by the MWCNTs/carrageenan membrane reached 99% and 88%, respectively. However, MWCNTs/carrageenan membrane was
found to be fragile. Nevertheless, adding chitosan to carrageenan had significantly improved the mechanical strength of the membrane while sustain the excellent removal properties of the heavy metals. That is, MWCNT/chitosan-carrageenan membrane significantly exceeds MWCNTs/carrageenan membrane in tensile strength, tensile strain and young’s modules by 400%, 17%, and 6%, respectively. On the other hand, the MWCNTs/chitosan membrane showed a high water permeate flux that reached up to 200 L/h.m². Also, the electrical conductivity of all membranes varied from 37 S/CM to 57 S/CM. Additional characterization techniques on the three membranes were conducted in this study as well.

Radiofrequency-Transparent Electrode for Device Integration Taehoon Kim, Gwangmook Kim and Wooyoung Shim; Yonsei University, Korea (the Republic of)

When an electromagnetic wave impinges on a conductor, most of the incident wave is reflected, which makes metals and transparent conducting oxides (TCOs), such as tin-doped indium oxide (ITO), opaque to visible light (429–750 THz) and far-infrared (FIR) (< 20 THz). This incompatibility between optical transparency and electrical conductivity is well-defined fundamental material properties, but this is often not easy to enhance both simultaneously. Opacity due to electrical conductivity is more pronounced in the lower frequency range. This fundamental incompatibility creates a barrier for the realization of enhanced user-interface and device integration. We present a design strategy for preparing megahertz-range transparent conductor and a concept towards ‘device-to-device integration’ enabled by electromagnetic wave transmittance. The approach to the properties of conductors is verified using a conducting polymer, Poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS), whose microstructure is effectively controlled by solution process. The use of a transparent conducting polymer as an electrode enables the fabrication of a fully functional touch-controlled display device and magnetic resonance imaging (MRI)-compatible biomedical monitoring device, which would open up a new paradigm for transparent conductors.

S.EL02.04.13
Sodium-Sparked Reduced Graphene Oxide Composite for Low-Temperature Sodium-Beta Alumina Batteries Dana Jin1, MinJung Kim1, Yoon-Cheol Park2, Keeyoung Jung2 and Wooyoung Shim1; 1Yonsei University, Korea (the Republic of); 2Research Institute of Industrial Science & Technology, Korea (the Republic of)

Among all the anode materials, Li and Na have the highest capacity and great potential to increase the energy density of batteries. Unfortunately, dendrite growth in metal anodes is one of the safety concerns in current battery devices. One approach to address this issue is to use molten or liquid-metal electrodes. This concept has been applied to sodium-beta alumina batteries (NBBs), which are based on a liquid-Na anode and $\beta''$–Al$_2$O$_3$ solid electrolyte. Consequently, NBBs, such as Na-metal halide (ZEBRA) batteries, are among the most promising technologies for large-scale renewable energy storage because of their high theoretical specific energy, high energy efficiency, and good cycle life.

Interestingly, in the initial stages of sodium-beta alumina batteries (NBBs) development, it was not anticipated that the low performance would rise from the Na/$\beta''$–Al$_2$O$_3$ interface. Liquid Na metal should be an ideal reversible electrode, provided that it can be maintained in contact with the whole operating area of the $\beta''$–Al$_2$O$_3$ throughout the discharging and charging of the cell. It was expected to be the least problematic component of the cell. In reality, liquid Na does not fully wet the surface of the $\beta''$–Al$_2$O$_3$. Although early observations revealed that incomplete wetting of the $\beta''$–Al$_2$O$_3$ surface by Na and consequent interfacial impedance problems were likely in NBBs, little was reported for numerous years. Ideally, full contact with liquid Na should be achieved, which provides a large active interface area and thus leads to high NBB performance at low temperatures.

We propose a simple approach to achieve unprecedented NBB performance with a capillary-induced wetting concept that significantly improves the Na wetting on $\beta''$–Al$_2$O$_3$. In this study, we adopted sparked reduced graphene oxide (rGO) loaded on the surface of the $\beta''$–Al$_2$O$_3$ as an ideal “wetting sheet,” compared with previous metal (Li or Na)-ion batteries where sparked rGO layers have been used for such metal reservoirs as an anode. The sparked rGO layers with nanogaps exhibited complete liquid-Na wetting, regardless of the surface energy between the liquid Na and graphene oxide, which originated from the capillary force in the gaps (see the figures). This indicated (i) that the Na nucleation and growth were sufficiently rapid to form liquid Na when the battery was charged and (ii) that the area of the Na$^+$ passway at the Na (anode)/$\beta''$–Al$_2$O$_3$ (electrolyte) interface was maximized when the battery was discharged. Thus, a high state-of-charge for potential state-of-art low-temperature NBBs was obtained. This cell-stacking architecture is simple and scalable and addresses the fundamental limitations of NBBs by allowing Na wetting at low temperatures.

FeAs van der Waals Crystal Jongbum Won1, Hyesoo Kim1, Eunsil Lee2, Jongyoung Kim2 and Wooyoung Shim1; 1Yonsei University, Korea (the Republic of); 2Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of)

Van der Waals (vdW) materials are composed of two-dimensional planes that are held together by weak interlayer interaction. VdW crystals have attracted increasing attention in the past couple of decades because of their significantly different properties from three-dimensional materials. However, it is a small class of materials, with fewer than 100 layered compounds catalogues in the Inorganic Crystal Structure Database (ICSD), including graphite, h-BN, transition metal dichalcogenides, metal halides, metal pnictides, and metal oxides. Here, we present a topochemical redox concept to prepare a new binary vdW materials by structure control from ternary parent compounds. The vdW crystals obtained had the same chemical composition as known three-dimensionally bonded compounds, but exhibited layered crystal structures. In our vdW crystal design strategy, we synthesized LiFeAs and CaFe2As2 as parent compounds. We then selectively removed Li and Ca from parent materials by topochemical redox to obtain FeAs vdW crystals with various crystal structures. We confirmed crystal structure of FeAs vdW crystal by X-ray diffraction (XRD), transmission electron microscope (TEM), scanning transmission electron microscope (STEM) and X-ray photoemission spectroscopy (XPS) and measured electrical property and mechanical property to identify the difference FeAs vdW crystal with three-dimensional orthorhombic FeAs.

S.EL02.04.19
Patterned All-Graphene Surface Enables Position-Controlled Remote Heteroepitaxy of ZnO Microrods Junseok Jeong1,2, Daekwon Jin1,2 and Young Joon Hong1,2; 1Sejong University, Korea (the Republic of); 2Graphene Research Institute–Texas Photonics Center International Research Center (GRI–TPC IRC), Korea (the Republic of)

Heteroepitaxy of semiconductor on two-dimensional atomic layered materials (2d-ALMs) has been promising for fabricating transferrable and flexible devices, because the use of 2d-ALMs allows to easily exfoliate overlayer device from host substrate.[1,2] Recently, an emerging epitaxy has been reported, which is the so-called remote epitaxy.[3,4] The remote epitaxy enables to produce single crystalline overlayer on graphene layer because the crystallographic registrations of overlayer can be copied from a underlying single crystalline substrate across graphene layer.[4,5] In the remote epitaxy of microrods (MRs), graphene thickness that is the remote epitaxial gap is critical to determine growth density of MR overlayer because penetrated field strength given from substrate leading to nucleation–growth is attenuated as the graphene thickness increases.[4] This implies that as we use graphene interlayer with spatially different thicknesses can result in different growth regimes of i) remote epitaxy or ii) non-growth, depending on graphene thickness.

We present how the remote epitaxy can be applied to selective-area growth using graphene pattern layer. Position-controlled remote heteroepitaxy was performed by hydrothermal growth of ZnO MRs on intaglio-patterned graphene (IPG)-coated c-plane GaN substrate. The IPG layer consists of two graphene parts of (I) perforated-hole-patterned multilayer graphene (MLG) that prevents the remote epitaxy, which act as a growth mask layer, and (II) single-layer graphene (SLG) penetrating the potential field from underlying GaN substrate to allow remote heteroepitaxy of ZnO through the hole aperture of mask layer, which is embedded between GaN and MLG mask layer.

The hole-aperture SLG area yielded remote heteroepitaxial ZnO MRs, whereas MLG area inhibited growth. Diameter and spacing of ZnO MRs are controlled by changing the hole pattern parameters. Transmission electron microscopy revealed the remote heteroepitaxial relationship between ZnO and GaN across the SLG area. According to density-functional theory calculations, the orbitals of SLG transfer the charge from the underlying GaN to the SLG surface leading to remote epitaxy, but the thick MLG was not capable of charge transfer in a long range. The weak van der Waals adhesion of ZnO/IPG/GaN was applied to exfoliate the ZnO MRs overlayer by a thermal release tape-assisted exfoliation technique and to recycle the original substrate. Our results readily open an opportunity to utilize the remote epitaxy for transfer of arrayed epitaxial structures in the designed size and arrangement for device manufacturing.

III-V compound semiconductors offer outstanding electronic and photonic properties that outperform silicon, but the cost of III-V wafers is extremely expensive. Although reusing original wafers can effectively minimize the cost of wafers, current techniques for wafer recycling add significant costs in fabrication, nullifying the cost savings by reusing the wafer. Remote epitaxy is a newly discovered method that enables single-crystal growth of III-V semiconductor thin films and easy exfoliation of the grown film, thus promising for reusing wafers multiple times. It requires an atomically thin spacer layer, such as graphene, to be present on top of III-V substrates, which allows enough field penetration from substrates through the graphene layer to make epitaxial III-V thin films grown on it maintain single-crystallinity. In addition, the graphene layer provides weak bonding at the III-V/graphene interface, and thus thin films grown on top of graphene can be easily exfoliated, leading to a cost-effective way of wafer reuse and flexible thin film production. However, previous methods of transferring graphene onto III-V wafers, which use polymethyl methacrylate (PMMA) or metal stressor layers to transfer graphene grown on foreign substrates like copper or SiC, introduce defects and damages on graphene and/or substrates during the transfer process. Remote epitaxial films grown on the damaged graphene/substrate suffer from lower crystal quality and imperfect exfoliation, which undermines wafer reusability and device performance.

Here we report the CVD growth of amorphous graphene on III-V wafers at low temperature that enabled improved quality of remote epitaxial films and their perfect exfoliation. By introducing toluene as a carbon source which cracks at a relative low temperature for graphene growth, we show fully covered amorphous graphene on AlGaAs/GaAs substrates despite arsenic’s low decomposition temperature. The surface of graphene-coated AlGaAs/GaAs substrate remains smooth with a RMS roughness of around 3Å. We also demonstrate 100% coverage of single-crystalline GaAs thin films grown on amorphous graphene, with the film’s quality significantly improved compared to the case of transferred graphene. In addition, roughness of the substrate’s surface remains the same after exfoliation of grown GaAs film, and the growth and exfoliation were successfully repeated multiple times, proving the feasibility for wafer recycling. Through this low temperature CVD growth approach and remote epitaxy, we successfully demonstrate wafer-scale flexible thin film exfoliation and recycling of substrates, which will lead to new opportunities in III-V thin film-based electronics and novel heterostructures with reduced cost.

We investigate nanoparticle film structures as components for daytime radiative cooling, using a generalized effective medium theory which is capable of recovering the Maxwell-Garnett, Bruggeman, and Coherent Potential mixing formulas. We show that, in all cases, nanoparticle fill fraction is a degree of freedom which can be used to improve free space coupling and spectrally tune the emissivity and absorptivity curves so as to optimize radiative emission within the atmospheric transmission window (8 – 14 μm). Based on this theory, we design different radiative cooling structures from composites of SiO2 and Si3N4 nanoparticle films, which were chosen as the example emissive materials because of their strong absorption peaks within the atmospheric transmission window. Our results show that two-layer nanoparticle films of these materials outperform all thin-film analogs and are sufficient to achieve cooling performances comparable to leading reports in literature. Further research will explore how the low thermal conductivity of nanoparticle films could be used to further enhance daytime radiative cooling performance. This research supports the idea that simple nanoparticle films couple provide a viable method for designing radiative cooling structures, provided scalable methods are identified for nanoparticle fabrication.

The history of coloration has been proceeded by trials and development of many technologies for selectively splitting the light. Structural coloration, among them, has grown up as a potential candidate alternating traditional pigments/dyes coloration since their great durability, sustainable production, and fine color tuning by controlling materials and dimension. As this property, structural color facilitates the creation of security features for anti-counterfeiting. However, conventionally, most of them have used metal/dielectric materials to make a resonating system at a specific wavelength and polarization condition which demands complex fabrication processes such as e-beam lithography or ion beam lithography technology. Even though this system can be suitable to an ultra-high definition structural color display, it is limited to only a few
millimeter scales or less. To apply into a realistic application such as banknote, luxury products, or customer goods, it is necessary to make it over centimeter scale with a flexible medium.

In this work, to break through these significant flexibility/scalability limitations, we developed polarization distinguishable covert display with ultrathin porous nanocolumns (PNCs) on a metal film by glancing angle deposition (GLAD) method. Particularly, the unique property of this covert display showed powerful functions which provide a hurdle to the inadvertent viewing of stored optical information without compromising their aesthetic. This structure with lossy PNCs on a metal film makes a non-trivial phase shift at the interfaces causing short reflection path and finally shows strong resonance [1]. Furthermore, the PNCs fabricated with GLAD produce anisotropic media and has different effective complex refractive index causing different resonating condition depending on polarization direction [2]. Using this concept, we designed polarization distinguishable color filters with a variety of materials and dimensions with rigorous coupling wave analysis (RCWA) method. In this process, we obtained an enlarged color range occupying over 80% of standard RGB area. In this color response, some showed a small color difference ($\Delta E$), the other showed a large color difference following polarization angle. Additionally, we confirmed this result is originated from human eye’s spectral responses according to between tristimulus value and reflectance spectra having a single minimum. Using these results, we designed optical data label (i.e., QR code) which shows inadvertent viewing in the naked eye (under unpolarized light), on the other hand, this label can be selectively detected by polarized light. For practical application, we designed this label into daily consumer goods with the color matching between labels and products to avoid compromising aesthetics of products and successfully demonstrated onto wine bottleneck, food packaging with confirming the authentication process. As a multi-functional color display, we demonstrated a colorimetric detection. Due to the low complex refractive index of porous medium, PNCs are sensitive to subtle external environment change. Consequently, PNCs reveal a sensitive color change according to background refractive index or additional layer thickness change. Using this unique property, we presented colorimetric detection with external change for volatile organic compounds (VOCs) and humidity.

**Hybrid Monolithic Plasmonic Materials for Nonlinear Absorption from the Visible to the NIR**

Stephane Parola¹, Carole Vaillant¹, Denis Chateau¹, Anthony Desert¹, Frederic Lerouge¹, Frederic Chaput¹, Sylvain David¹, Olivier Maury¹, Chantal Andraud¹, Gerard Berginc², Mikael Lindgren³, Hampus Lunden⁴ and Cesar Lopes⁴; ¹ENS Lyon, France; ²THALES, France; ³NTNU, Norway; ⁴FOI, Sweden

Hybrid materials are commonly used for wide range of optical applications (sensors, filters, imaging, photocatalysis…). The use of interactions between emitting or absorbing systems and plasmonic nanostructures have also been an intensive field of research due to the possibility to tune and optimize the optical responses using the local electromagnetic field. The synthesis of gold nanostructures combining high yield, purity, large scale and plasmon resonance spreading from the visible to the NIR wavelengths was developped.[2,3] These nanostructures were functionalized in order to allow their homogeneous incorporation in transparent hybrid silica matrices using the sol-gel process.[4,5] Co-dispersion of the metallic structures with nonlinear dyes was successfully achieved.[6] The role of the concentration, shape and size of the metal nanoparticles on the optical response was evaluated. The respective impact on the nonlinear optical response of the dyes will be discussed both in the visible and the near infrared wavelengths.

**New Ligands and Approaches to RSA Materials**

Emigdio Turner¹, Sebastian Vittardi¹, Ryan O'Donnell² and Jeffrey Rack¹; ¹The University of New Mexico, United States; ²U.S. Army Research Laboratory, United States

Reverse Saturable Absorption (RSA) is a nonlinear optical effect in which the excited state of a molecule or material exhibits greater absorptivity than its corresponding ground state. Traditional approaches to optimize this effect in transition metal compounds and materials are to employ extended aromatic rings to enhance absorption at longer wavelengths and to increase the excited state lifetime. In contrast, we have created a new class of chelating ligands comprising phosphorous and sulfur donor atoms. These types of ligands impart beneficial non-emissive properties to transition metal complexes. Complexes of Ir containing these new P,S ligands with derivatives of phenylpyridine will be prepared. In addition to standard characterization techniques (absorption spectroscopy, electrochemistry, NMR spectroscopy, crystallography, etc), these complexes will be interrogated by transient absorption spectroscopy from the femtosecond to the millisecond time scale. These data will determine the excited state spectra and RSA response as a function of wavelength. These data and others will be presented.

**Sensitized Photon Upconversion in Metal Organic Frameworks—The Role of 3D Structure**

Stefan Illic, Jennifer Rowe and Amanda J. Morris; Virginia Polytechnic Institute and State University, United States

Metal-organic frameworks (MOFs) are a diverse class of highly ordered and tunable nanoscale materials that are increasingly employed in several solar energy conversion schemes. Investigation of light-harvesting and energy transfer processes within the three-dimensional framework of such nanoscopic materials results in more efficient design of biomimetic chromophore arrays for artificial photosynthesis. Here we present the synthesis and photophysical investigation of three anthracenic MOFs. The MOFs were synthesized by following a one-pot solvothermal synthetic protocol, and the powders were structurally characterized with the help of X-ray powdered diffraction (PXRD) patterns and scanning electron microscopy (SEM) images. Steady-state and time-resolved spectroscopic techniques aided in exploring the photophysical behavior in MOFs as a function...
of 3D structure. Upon surface functionalization of a sensitizing palladium porphyrin, excitation of the composite with green light resulted in upconverted emission. The role of the 3D incorporation of the anthracenes and resultant spacing of the anthracene units dictates the efficiency of the upconversion process.

Controlling Nonlinear Generation via Multipolar Interference Ekaterina Poutrina1,2 and Augustine Urbas1; 1Air Force Research Laboratory, United States; 2UES, Inc., United States

Probing the nonlinear response in light-matter interactions offers the advantage of lifting some fundamental limitations existing within the scope of linear operations. One of the most striking examples is the ability of breaking the reciprocity of light transmission. Transmission through a medium characterized by a symmetric, time-independent, and linear permittivity tensor stays the same when reversing the excitation direction, or interchanging the source and the detector. While serving as an innate foundation in any optical design, it presents a fundamental challenge for applications requiring a non-reciprocal directionality of light propagation.

Here, we show that the option of non-reciprocity in the directionality and the efficiency of nonlinear generation is inherently incorporated in the response of nanoelements exhibiting magnetic dipolar (or higher-order multipolar) Mie resonance(s) in their linear response. In particular, we show that nonlinear generation from a nanoelement, where it regularly occurs nearly isotropically in all directions (due to the lack of phase matching constraints within nanoscale interaction volumes), can be made both unidirectional and non-reciprocal, such that the generation occurs predominantly in a single direction which, additionally, remains unchanged with respect to a fixed laboratory coordinate system when reversing the direction of the fundamental beam(s). In contrast with the previous studies, the proposed approach does not require asymmetry in either the geometry or the material composition of the nanoelement. Rather, it relies on the multiplicative nature of the nonlinear response which, in turn, allows a simultaneous change in phase of both the electric and the magnetic, nonlinearly induced, dipolar modes, when switching the phase of a single (either electric or magnetic) vector of the fundamental field.

Furthermore, the interference can occur between various pathways within the electric and magnetic (nonlinearly produced) dipolar modes. As a result, non-reciprocity in terms of just a change in the efficiency of nonlinear generation when reversing the direction of any subset of the fundamental beams is inherent to and expected in the nonlinear response of most nanoelements, even the symmetric ones, and for most of the nonlinear processes. Targeted engineering of the relative strengths of various pathways within each (nonlinearly produced) multipolar mode may then allow an interferometric cancellation of the generated field for a given nonlinear process, for certain respective directions of the fundamental beams.

Reliance on multipolar interference in the suggested approach inherently assumes the manifestation of the described phenomena on the nanoscale, through the response of subwavelength-scale elements. These nanoelements can thus be used as building blocks to construct a metasurface or a medium with similar unique features in its nonlinear response. As an example, we present a metasurface operating as a one-way nonlinear mirror, where the image is formed by a process of difference frequency generation on one and the same side of the metasurface independently of the object location.

Both non-reciprocal directionality and inhibition of the nonlinear response require, however, a careful engineering of the respective strengths of various pathways within each (electric or magnetic) type of the nonlinearly produced multipolar partial wave. As such, these phenomena are not expected to manifest in natural nonlinear materials, even those possessing natural magnetic dipolar transitions. They, however, can be achieved via a tailored design of the effective magneto-electric nonlinear polarizabilities of a nanoelement.

High-Energy Nonreciprocal Directional Dichroism in a Chiral Magnet Janice Musfeldt1, Michael O. Yokosuk1, Heung-Sik Kim2, Scott Crooker3, Sang-Wook Cheong4, Kristjan Haule4 and David Vanderbilt4; 1University of Tennessee, United
Nonreciprocal directional dichroism is an unusual light-matter interaction that gives rise to diode-like behavior in low symmetry materials. The chiral varieties are particularly scarce due to the requirements for strong spin-orbit coupling, broken time reversal symmetry, and a chiral axis. We bring together magneto-optical spectroscopy and first principles calculations to reveal high energy, broad band nonreciprocal directional dichroism in Ni$_2$TeO$_6$ with special focus on behavior in the metamagnetic phase above 52 T. In addition to demonstrating this effect in the magnetochiral configuration, we explore the transverse magnetochiral orientation in which applied field and light propagation are orthogonal to the chiral axis and by so doing, uncover an additional configuration with a nonreciprocal response in the visible part of the spectrum. In a significant conceptual advance, we use first-principles methods to analyze how the Ni$^{2+}$ $d$-to-$d$ on-site excitations develop magnetoelectric character and present a microscopic model that unlocks the door to theory-driven discovery of chiral magnets with nonreciprocal properties.

8:10 PM *S.EL04.03.07
Hot-Electron Dynamics in Quantum Dots Manipulated by Spin-Exchange Auger Interactions Victor I. Klimov; Los Alamos National Laboratory, United States

Colloidal semiconductor quantum dots (QDs) are attractive materials for realizing highly flexible, solution-processable optical gain media with readily tunable operational wavelengths [1, 2]. However, QDs are difficult to use in lasing due to extremely short optical gain lifetimes limited by nonradiative multiband Auger recombination [3]. In particular, this is a serious obstacle for realizing cw optically and electrically pumped lasing devices. Recently, we have explored several approaches for mitigating the problem of Auger decay by taking advantage of a new generation of core/multi-shell QDs with a radially graded composition that allow for considerable (nearly complete) suppression of Auger recombination [4, 5]. Using these specially engineered QDs, we have been able to realize optical gain with direct-current electrical pumping [4], which has been a long-standing goal in the field of colloidal nanostructures. Further, we have applied these dots to practically demonstrated the viability of a ‘zero-threshold optical gain’ concept using not neutral but negatively charged particles wherein the pre-existing electrons block either partially or completely ground-state absorption [5, 6]. Such charged QDs are optical-gain-ready without excitation, which allows us to reduce the lasing threshold to record-low values that are well below a fundamental single-exciton-per-dot limit [6]. Most recently, we have developed QD devices that operate as both an electroluminescent (EL) structure and a distributed feedback optically pumped laser [7]. By carefully engineering a refractive-index profile across the device stack, we have been able to demonstrate low-threshold lasing even with a very thin EL-active region, which comprises only three monolayers of the QDs. All of these recent developments demonstrate a considerable promise of colloidal QDs for implementing solution-processable optically and electrically pumped lasers operating across a wide range of wavelengths.

8:30 PM *S.EL04.03.01
Strong Coupling and Induced Transparency with Single Quantum Dots and Plasmons—Towards Ultrafast All-Optical Nonlinearities at the Nanoscale Matthew Pelton; University of Maryland-Baltimore County, United States

Achieving room-temperature quantum-mechanical strong coupling, or vacuum Rabi splitting, between a single emitter and a plasmon resonance has been a longstanding goal. Recently, two peaks have been observed in the scattering spectra of plasmonic metal nanostructures coupled to single molecules and single quantum dots, and this was taken as evidence of strong coupling. However, a two-peak scattering structure can also arise at intermediate coupling strengths, below the strong-coupling threshold, due to Fano-like interference between the plasmon and emitter dipole. We unambiguously distinguish between intermediate and strong coupling by measuring both the scattering spectra and the photoluminescence spectra of coupled plasmon-emitter structures. Specifically, we couple single colloidal quantum dots to a plasmon resonator by placing them in the gap between a gold nanoparticle and a silver film. We observe weak, intermediate,
and strong coupling in these hybrid metal-semiconductor structures at room temperature, depending on the detailed nanoscale structure of the metal nanoparticle. These structures have the potential to provide ultrafast, low-power optical nonlinearities on the nanoscale. Both induced transparency and strong coupling can be canceled by absorbing a photon in the quantum dot, leading to a strong change in extinction at the quantum dot transition frequency. Since only a single photon must be absorbed by the QD for this to happen, the energy needed for modulation has the potential to be extremely low, and the structure has the potential to enable all-optical information processing, possibly including neuromorphic computation and quantum information processing. One limitation to the practical application of these structures, however, is the random nature of their assembly and the resulting low yield of structures exhibiting the desired transparency or strong coupling. One approach we have taken to this low yield is to replace the metal nanoparticle with a metal scanning-probe tip. In this way, we are able to achieve reversible, controllable strong coupling to several individual quantum dots, one at a time. Our current efforts are focused on developing bottom-up techniques of chemical synthesis and assembly for the high-yield production of strongly-coupled metal-semiconductor hybrid nanostructures.

8:50 PM BREAK

8:55 PM *S.EL04.03.05 Nanoparticle Materials for Photonics Jake Fontana; Naval Research Laboratory, United States

In this talk, we will describe a materials self-assembly approach to controllably weld gold nanorods end-to-end, forming much higher aspect ratio dimers in macroscale quantities, linking the nanorods using unfocused femtosecond light. Electrostatic-based molecular assembly controls the discrete selection of end-to-end dimer assemblies, preventing larger structures. Large, high-quality yields of welded dimers can be produced by illuminating these dimer suspensions at their capacitively coupled plasmon resonance wavelength using femtosecond light pulses. In-situ absorbance measurements demonstrate an isosbestic point which results from the conversion of single nanorods to capacitively coupled plasmon dimers, indicative of direct population conversion. We will discuss the underlying physical mechanisms for the welding process as well as the optical properties of the newly formed high aspect ratio dimers.

9:15 PM SESSION Q&A WRAP UP

5:00 AM S.EL04.01.01 A Comparison of the Photophysical Properties of Pt(II) and Au(I) Substituted Fluorene-Benzothiazole Chromophores and their Impact on Nonlinear Optical Performance Tod Grusenmeyer1, Alexis T. Phillips1, Joseph J. Mihaly2, Christopher L. McCleese1, David J. Stewart1, Thomas G. Gray2, Thomas M. Cooper1 and Joy E. Haley1; 1Air Force Research Laboratory, United States; 2Case Western Reserve University, United States

Our research group has a long history of developing chromophores that exhibit non-linear absorption. Substantial progress was made to this end with the synthesis of two-photon chromophores substituted with transition metals. The inclusion of the metal center facilitates the formation of triplet excited-states in the two-photon chromophore. If this leads to a triplet state with strong excited-state absorption at wavelengths where two-photon absorption is active, the nonlinear optical performance of the chromophore is enhanced. The champion molecule from these initial studies was found to be bis(phenylethynyl)bis(tributylphosphine)platinum (II) bearing two alkynyl-benzothiazolylfluorene ligands. Recently, Au(I) analogs of this complex containing fluorene-benzothiazole and alkynyl-fluorene-benzothiazole ligands have be synthesized with differing ancillary ligands attached to the Au(I) center. Varying the ancillary ligand on Au(I) from a phosphine to a N-heterocyclic carbene alters the photophysical properties of the chromophoric ligand. UV-vis, steady-state and time-resolved luminescence, and transient absorption results will be discussed. This talk will compare the photophysical properties and their impact on the nonlinear performance of the original platinum (II) alkynyl-fluorene-benzothiazole complex and the Au(I) fluorene-diphenylamine and Au(I) alkynyl-fluorene-diphenylamine complexes.
Hybrid Monolithic Plasmonic Materials for Nonlinear Absorption from the Visible to the NIR

Triplet Excited State Derived Excimer Formation in a Solid State Matrix
1Air Force Research Laboratory, United States; 2General Dynamics Information Technology, United States; 3Southwestern Ohio Council for Higher Education, United States

It is well known in the literature that for a two photon nonlinear absorbing dye to be the most effective, high concentrations are needed. The problem is that most photophysical studies are done at low concentration and in a solution. These low concentration studies are important for understanding inherent materials properties but it is also important to understand what happens in a material at high concentration. In addition to this, efforts have been made to study the effects of incorporating a dye into a solid matrix environment to better understand the constraints this environment has to a given material. Here we present the results of a study of a two photon absorbing platinum dye, E1-BTF, incorporated into various hosts including PMMA, epoxy, polyurethane, and sol gel. Similar results were found in all hosts that a triplet excited state derived excimer forms at the highest concentrations. This is due to close packing of the E1-BTF molecule where both static and dynamic quenching may occur. The host material defined the highest achievable concentrations for each polymer host. We will report on the overall photophysical properties of E1-BTF in these polymer hosts.
Optical modes can couple to sufficiently strongly absorbing vibrational transitions to create new polaritonic states in the mid-infrared. Transient infrared spectroscopy of these new states reveals rich spectra that report on coherences between and population of both the polaritons and so-called reservoirs of uncoupled modes. Our previous work, focusing on one-dimensional, pump-probe spectroscopy has shown that cavity-coupled vibrations have potential for photonic devices and can exhibit modified relaxation dynamics compared to uncoupled systems. Here, we present new results from two dimensional infrared spectroscopy (2D IR) and pump filtering experiments that give deeper insight into the spectroscopic responses of the vibrationally excited polaritonic system. We report on the spectroscopic polaritonic signatures in cavity-coupled systems and the influence of the homogeneous linewidth of the vibrational mode on the population dynamics of coupled systems.

Is DBP an Unwanted Guest in Lead-Halide Perovskite Sensitized Upconversion? Alexander S. Bieber, Zachary VanOrman, Sarah Wieghold and Lea Nienhaus; Florida State University, United States

Infrared-to-visible upconversion (UC) bears the potential to surpass the Shockley Queisser limit for single junction photovoltaics. Here, bulk-perovskite sensitized UC has been shown to be a promising approach in which free electrons and holes can be injected into the triplet state of the upconverting semiconductor. In these UC systems, a bulk-perovskite thin film is employed as the absorber layer and rubrene, a p-type tetraphenyl derivative of tetracene, is used as the annihilator layer. To boost the UC quantum yield, the rubrene layer is usually doped with dibenzotetraphenylperiflanthene (DBP) in a commonly used host-guest/annihilator-emitter approach. DBP is used to harvest the singlet excited state from rubrene through a Förster resonance energy transfer, which prevents rubrene from undergoing the reverse process of singlet fission. To understand and optimize the role of DBP in the upconversion devices, we fabricate bilayer devices consisting of a lead halide perovskite sensitizer followed by a layer of rubrene/DBP with varying concentrations of DBP. Steady state and time resolved spectroscopy are then used to study the energy transfer processes in the bilayer devices. As expected, an increase in the DBP concentration results in the reduction of the rubrene emission, indicating a higher transfer efficiency. In addition, we observe an increase in the upconverted light emission when the rubrene/DBP ratio is varied. However, the time-resolved dynamics indicate that DBP may not merely be a guest in the system, but rather directly influences the observed upconversion dynamics and the device performance. These insights provide a path to further optimize and improve the efficiencies of bulk-perovskite sensitized UC devices.

Cavity-Modified Non-Linear Optical Response and Chemical Reaction Kinetics Blake S. Simpkins1, Wonmi Ahn2, Igor Vurgaftman2, Adam Dunkelberger1, Andrea Grafton1 and Jeffrey C. Owratisky; 1U.S. Naval Research Laboratory, United States; 2Excet, United States; 3Naval Research Laboratory, United States

Quantum emitters placed in resonant optical cavities have shown modified spontaneous emission rates and frequency when they are coupled in the weak coupling regime. In the so-called strong coupling regime, however, the coupled oscillators, i.e., emitters and optical modes, exchange energies inextricably, creating new hybrid states called polaritons. Recently, this half-light half-matter quasi-state has been demonstrated in a system where molecular vibrations are coherently coupled to optical cavity modes. In this talk, we will focus on non-linear transient response probed in the ultrafast regime, cavity-modified saturable absorption, and cavity-modified chemical reactivity. Specifically, we find excited-state spectra that reveal coherences between populations of both cavity polaritons and so-called dark states and explore the influence of the homogeneous linewidth of the vibrational modes. Our recently published results[1] show that the saturation fluence (typically, an intrinsic parameter of a material) can be tailored via cavity coupling and exhibits a counterintuitive scaling with system parameters (cavity length and molecular concentration). Lastly, we monitor transmission spectra of the Fabry-Pérot microcavity filled with species that participate in a simple addition reaction. Both reactants and products have strong molecular vibrations that couple to the optical cavity modes, resulting in quantifiable vacuum Rabi splittings. We examine the reaction rates in and out of the cavity to expose the influence of vibrational strong coupling on reaction kinetics. Our results will extend the potential of cavity-modified material properties, which will have important implications for ultrafast optical devices and chemical synthesis and catalysis.

2020 MRS Virtual Spring/Fall Meeting, November 27-December 4, 2020, Spring Abstracts Final Program 2/3/21
New Ligands and Approaches to RSA Materials Emigdio Turner¹, Sebastian Vittardi¹, Ryan O'Donnell² and Jeffrey Rack¹; ¹The University of New Mexico, United States; ²U.S. Army Research Laboratory, United States

Reverse Saturable Absorption (RSA) is a nonlinear optical effect in which the excited state of a molecule or material exhibits greater absorptivity than its corresponding ground state. Traditional approaches to optimize this effect in transition metal compounds and materials are to employ extended aromatic rings to enhance absorption at longer wavelengths and to increase the excited state lifetime. In contrast, we have created a new class of chelating ligands comprising phosphorous and sulfur donor atoms. These types of ligands impart beneficial non-emissive properties to transition metal complexes. Complexes of Ir containing these new P,S ligands with derivatives of phenylpyridine will be prepared. In addition to standard characterization techniques (absorption spectroscopy, electrochemistry, NMR spectroscopy, crystallography, etc), these complexes will be interrogated by transient absorption spectroscopy from the femtosecond to the millisecond time scale. These data will determine the excited state spectra and RSA response as a function of wavelength. These data and others will be presented.

Sensitized Photon Upconversion in Metal Organic Frameworks—The Role of 3D Structure Stefan Illic, Jennifer Rowe and Amanda J. Morris; Virginia Polytechnic Institute and State University, United States

Metal-organic frameworks (MOFs) are a diverse class of highly ordered and tunable nanoscale materials that are increasingly employed in several solar energy conversion schemes. Investigation of light-harvesting and energy transfer processes within the three-dimensional framework of such nanoscopic materials results in more efficient design of biomimetic chromophore arrays for artificial photosynthesis. Here we present the synthesis and photophysical investigation of three anthracenic MOFs. The MOFs were synthesized by following a one-pot solvothermal synthetic protocol, and the powders were structurally characterized with the help of X-ray powdered diffraction (PXRD) patterns and scanning electron microscopy (SEM) images. Steady-state and time-resolved spectroscopic techniques aided in exploring the photophysical behavior in MOFs as a function of 3D structure. Upon surface functionalization of a sensitizing palladium porphyrin, excitation of the composite with green light resulted in upconverted emission. The role of the 3D incorporation of the anthracenes and resultant spacing of the anthracene units dictates the efficiency of the upconversion process.

Controlling Nonlinear Generation via Multipolar Interference Ekaterina Poutrina¹,² and Augustine Urbas¹; ¹Air Force Research Laboratory, United States; ²UES, Inc., United States

Probing the nonlinear response in light-matter interactions offers the advantage of lifting some fundamental limitations existing within the scope of linear operations. One of the most striking examples is the ability of breaking the reciprocity of light transmission. Transmission through a medium characterized by a symmetric, time-independent, and linear permittivity tensor stays the same when reversing the excitation direction, or interchanging the source and the detector. While serving as an innate foundation in any optical design, it presents a fundamental challenge for applications requiring a non-reciprocal directionality of light propagation.

Here, we show that the option of non-reciprocity in the directionality and the efficiency of nonlinear generation is inherently incorporated in the response of nanoelements exhibiting magnetic dipolar (or higher-order multipolar) Mie resonance(s) in their linear response. In particular, we show that nonlinear generation from a nanoelement, where it regularly occurs nearly isotropically in all directions (due to the lack of phase matching constraints within nanoscale interaction volumes), can be made both unidirectional and non-reciprocal, such that the generation occurs predominantly in a single direction which,
Additionally, *remains unchanged* with respect to a fixed laboratory coordinate system when reversing the direction of the fundamental beam(s). In contrast with the previous studies, the proposed approach does not require asymmetry in either the geometry or the material composition of the nanoelement. Rather, it relies on the multiplicative nature of the nonlinear response which, in turn, allows a *simultaneous* change in phase of *both* the electric and the magnetic, *nonlinearly induced*, dipolar modes, when switching the phase of a single (either electric or magnetic) vector of the fundamental field. Furthermore, the interference can occur between various pathways *within* the electric and magnetic (nonlinearly produced) dipolar modes. As a result, non-reciprocity in terms of just a change in the *efficiency* of nonlinear generation when reversing the direction of any subset of the fundamental beams is inherent to and expected in the nonlinear response of most nanoelements, even the symmetric ones, and for most of the nonlinear processes. Targeted engineering of the relative strengths of various pathways within each (nonlinearly produced) multipolar mode may then allow an interferometric cancellation of the generated field for a given nonlinear process, for certain respective directions of the fundamental beams.

Reliance on multipolar interference in the suggested approach inherently assumes the manifestation of the described phenomena on the nanoscale, through the response of subwavelength-scale elements. These nanoelements can thus be used as building blocks to construct a metasurface or a medium with similar unique features in its nonlinear response. As an example, we present a metasurface operating as a one-way nonlinear mirror, where the image is formed by a process of difference frequency generation on one and the same side of the metasurface independently of the object location.

Both non-reciprocal directionality and inhibition of the nonlinear response require, however, a careful engineering of the respective strengths of various pathways *within* each (electric or magnetic) type of the nonlinearly produced multipolar partial wave. As such, these phenomena are not expected to manifest in natural nonlinear materials, even those possessing natural magnetic dipolar transitions. They, however, can be achieved via a tailored design of the effective magneto-electric nonlinear polarizabilities of a nanoelement.

**First-Principles Simulation of Nonreciprocal Directional Dichroism in Correlated Materials**

Heung-Sik Kim¹, Michael O. Yokosuk²,², Kiman Park³, Janice L. Musfeldt³, Michael O. Yokosuk¹, Heung-Sik Kim², Scott Crooker³, Sang-Wook Cheong³, Kristjan Haule⁴ and David Vanderbilt⁴; ¹University of Tennessee, Knoxville, United States; ²Kangwon National University, Korea (the Republic of); ³Pacific Northwest National Laboratory, United States; ⁴Los Alamos National Laboratory, United States

Computation of response functions, based on linear response theory and first-principles electronic structure methods, has been extensively utilized for analyses and predictions of various functional materials such as ferroelectrics, piezoelectrics, and multiferroics. For the study of strongly correlated materials, however, methods based on standard density functional theory need substantial improvement; because of the need of incorporating the so-called two-particle vertex correction in evaluating response functions, which is computationally demanding, an extensive study of functional and correlated materials has remained a challenging task. To mitigate this difficulty and facilitate investigations of correlated functional materials, we propose a new theoretical method to compute linear response functions of strongly correlated Mott insulators. Our approach starts from the strongly correlated atomic regime, unlike other first-principles-based methods, which circumvents evaluating vertex correction terms and enables computationally cheap evaluation of material properties in Mott systems. As an example, we present our simulation results of nonreciprocal directional dichroism in Ni₃TeO₆, which is a wide-gap Mott insulator, showing a promising agreement with experimental observations.

Strong Coupling and Induced Transparency with Single Quantum Dots and Plasmons—Towards Ultrafast All-Optical Nonlinearities at the Nanoscale Matthew Pelton; University of Maryland-Baltimore County, United States

Achieving room-temperature quantum-mechanical strong coupling, or vacuum Rabi splitting, between a single emitter and a plasmonic resonance has been a longstanding goal. Recently, two peaks have been observed in the scattering spectra of plasmonic metal nanostructures coupled to single molecules and single quantum dots, and this was taken as evidence of strong coupling. However, a two-peak scattering structure can also arise at intermediate coupling strengths, below the strong-coupling threshold, due to Fano-like interference between the plasmon and emitter dipole. We unambiguously distinguish between intermediate and strong coupling by measuring both the scattering spectra and the photoluminescence spectra of coupled plasmon-emitter structures. Specifically, we couple single colloidal quantum dots to a plasmon resonator by placing them in the gap between a gold nanoparticle and a silver film. We observe weak, intermediate, and strong coupling in these hybrid metal-semiconductor structures at room temperature, depending on the detailed nanoscale structure of the metal nanoparticle. These structures have the potential to provide ultrafast, low-power optical nonlinearities on the nanoscale. Both induced transparency and strong coupling can be canceled by absorbing a photon in the quantum dot, leading to a strong change in extinction at the quantum dot transition frequency. Since only a single photon must be absorbed by the QD for this to happen, the energy needed for modulation has the potential to be extremely low, and the structure has the potential to enable all-optical information processing, possibly including neuromorphic computation and quantum information processing. One limitation to the practical application of these structures, however, is the random nature of their assembly and the resulting low yield of structures exhibiting the desired transparency or strong coupling. One approach we have taken to this low yield is to replace the metal nanoparticle with a metal scanning-probe tip. In this way, we are able to achieve reversible, controllable strong coupling to several individual quantum dots, one at a time. Our current efforts are focused on developing bottom-up techniques of chemical synthesis and assembly for the high-yield production of strongly-coupled metal-semiconductor hybrid nanostructures.

Nanoparticle Materials for Photonics Jake Fontana; Naval Research Laboratory, United States

In this talk, we will describe a materials self-assembly approach to controllably weld gold nanorods end-to-end, forming much higher aspect ratio dimers in macroscale quantities, linking the nanorods using unfocused femtosecond light. Electrostatic-based molecular assembly controls the discrete selection of end-to-end dimer assemblies, preventing larger structures. Large, high-quality yields of welded dimers can be produced by illuminating these dimer suspensions at their capacitively coupled plasmon resonance wavelength using femtosecond light pulses. In-situ absorbance measurements demonstrate an isosbestic point which results from the conversion of single nanorods to capacitively coupled plasmon dimers, indicative of direct population conversion. We will discuss the underlying physical mechanisms for the welding process as well as the optical properties of the newly formed high aspect ratio dimers.

Hot-Electron Dynamics in Quantum Dots Manipulated by Spin-Exchange Auger Interactions Victor I. Klimov; Los Alamos National Laboratory, United States

Colloidal semiconductor quantum dots (QDs) are attractive materials for realizing highly flexible, solution-processable optical gain media with readily tunable operational wavelengths [1, 2]. However, QDs are difficult to use in lasing due to extremely short optical gain lifetimes limited by nonradiative multicarrier Auger recombination [3]. This, in particular, is a serious obstacle for realizing cw optically and electrically pumped lasing devices. Recently, we have explored several
approaches for mitigating the problem of Auger decay by taking advantage of a new generation of core/multi-shell QDs with a radially graded composition that allow for considerable (nearly complete) suppression of Auger recombination [4, 5]. Using these specially engineered QDs, we have been able to realize optical gain with direct-current electrical pumping [4], which has been a long-standing goal in the field of colloidal nanostructures. Further, we have applied these dots to practically demonstrated the viability of a ‘zero-threshold optical gain’ concept using not neutral but negatively charged particles wherein the pre-existing electrons block either partially or completely ground-state absorption [5, 6]. Such charged QDs are optical-gain-ready without excitation, which allows us to reduce the lasing threshold to record-low values that are well below a fundamental single-exciton-per-dot limit [6]. Most recently, we have developed QD devices that operate as both an electroluminescent (EL) structure and a distributed feedback optically pumped laser [7]. By carefully engineering a refractive-index profile across the device stack, we have been able to demonstrate low-threshold lasing even with a very thin EL-active region, which comprises only three monolayers of the QDs. All of these recent developments demonstrate a considerable promise of colloidal QDs for implementing solution-processable optically and electrically pumped lasers operating across a wide range of wavelengths.

Exciton-Polaritons in a Tunable Microcavity with 2D-Peroxides Based on Free-Standing Thin Films Karolina Lempicka1, Magdalena Furman1, Marcin Muszynski1, Mateusz Krol1, Adam Wincukiewicz1, Rafal Mazur2, Maria Kaminska1, Wiktor Piecek1, Pawel W. Majewski2, Jacek Szczynko1 and Barbara Pietka1; 1University of Warsaw, Poland; 2Institute of Applied Physics, Military University of Technology, Poland; 3Faculty of Chemistry, University of Warsaw, Poland

Recently, interest in organic-inorganic perovskites has increased due to their application in photovoltaics, photonics and optoelectronics. They have also been used as a strong light emitters in the microcavities, due to the possibility of obtaining strong light-matter coupling regime, and the occurrence of coherent macroscopic effects, such as Bose-Einstein condensation of exciton-polaritons. Compared with multi quantum wells heterostructures produced by epitaxial growth of inorganic semiconductors, 2D perovskites displays stronger dielectric confinement in the inorganic layers, whereas excitons in such materials are characterized by a higher binding energy and exhibits strong nonlinearities. It indicates that the devices based on polaritons in 2D perovskite layers can work stable at room temperature. In our work we present a novel construction of a tunable planar dielectric cavity containing free standing layers of 2D-perovskite. Perovskites are deposited on thin films obtained from solution P2611:NMP.

The realization of such microcavity is innovative due to specific and unique technique of preparing emitter from thin films of layered perovskite-type semiconductor (C6H5(CH2)2NH3)2PbI4. The frame of free-standing films from polyimide solution were deposited by spin-coating technique on silica substrate. After heating, obtained structure served as matrix to deposit 2D-layered perovskite. Fabrication of ultrathin polyimide films allows to isolate lots of arbitrary materials from the substrate. Obtained thin film of perovskite were placed between dielectric mirrors controlled through piezo positioners, which allowed to shift photonic mode over the range of 100 meV. Such 2D perovskites can be considered as spontaneous realizations of a quantum well, in which organic material is sandwiched between organic cations acting as a potential barrier. The advantage of an emitter based 2D perovskites strongly coupled to the cavity field is its enhanced emission rate. Moreover, the regime of exciton-polaritons condensate compared to typical lasers is the ability to obtain laser action without the need to create population inversion. The additional advantage of our tuneable structure is the possibility to adjust the emission wavelength. A strong coupling regime between the perovskite exciton and the confined photon mode is evidenced at room temperature from angular-resolved reflectivity and photoluminescence experiments. The observed exciton-photon coupling strength is of $\Omega \sim 110$ meV.

The scientific meaning of this work is concentrated on the realization of new approach to obtain efficient, thin layer of organic-inorganic materials in a microcavity and developing a room-temperature devices for the observation of strong light-matter coupling and lasing phenomena.

Effects of Disorder on Two-Photon Absorption in Chalcogenide Glass

Nikita Dutta\textsuperscript{1}, Juliana M. Almeida\textsuperscript{2}, Cleber Mendonça\textsuperscript{2} and Craig B. Arnold\textsuperscript{1}; \textsuperscript{1}Princeton University, United States; \textsuperscript{2}University of São Paulo, Brazil

Chalcogenide glasses (ChGs) have long been of interest to the photonics community for their unique properties like high refractive index, photo-induced phase changes, and high optical nonlinearities. The latter are essential for all-optical systems but can be difficult to tailor due to a lack of understanding of their complex origins. Here we use open-aperture Z-scan to compare the two-photon absorption (2PA) spectra of arsenic (III) sulfide ChG samples with different levels of local bonding disorder. We find that the difference between the 2PA coefficients of the samples depends on the ratio of the photon energy to the band gap energy, giving rise to two distinct regions in the spectra. We then explain these observations using an effective mass model that links the 2PA coefficient of a glass to its level of structural disorder. Our results offer a generalized structure-property relation for semiconducting glasses that can be used to enhance optical nonlinearities for photonic applications.

Exploring I\textsubscript{I}-II-IV-VI\textsubscript{4}-Type Materials beyond Cu\textsubscript{2}BaSnS\textsubscript{4} for Energy Applications

Garrett C. McKeown Wessler, Jon-Paul Sun, Tianlin Wang, Tong Zhu, Volker Blum and David B. Mitzi; Duke University, United States

Recently, Cu\textsubscript{2}BaSnS\textsubscript{4} (CBTS) and its mixed-chalcogen analog Cu\textsubscript{2}BaSn(S,Se)\textsubscript{4} (CBTSSe) have emerged as promising new semiconductors for photovoltaic (PV) and photoelectrochemical (PEC) applications. This potential is due to CBTS and CBTSSe having high absorption coefficients, abundant and non-toxic elemental makeups, and reduced tendency for antisite disorder between cations.\textsuperscript{[1,2]} Beyond CBTS and CBTSSe, various other compounds within the I\textsubscript{I}-II-IV-VI\textsubscript{4} (I = Li, Ag, Cu; II = Ba, Sr, Eu, Pb; IV = Si, Ge, Sn; VI = S, Se) family have drawn attention for applications in thermoelectrics (e.g. Ag\textsubscript{2}BaS\textsubscript{3}Se\textsubscript{4}), nonlinear optics (Li\textsubscript{2}BaSnS\textsubscript{2}Se), and solar energy conversion (Cu\textsubscript{2}SrSnSe\textsubscript{4}).\textsuperscript{[3-5]} Therefore, it is useful to explore the larger I\textsubscript{I}-II-IV-VI\textsubscript{4} space beyond CBTS for promising semiconductors. This talk will explore several new compounds within this space. Cu\textsubscript{2}BaGeSe\textsubscript{4} (CBGSe) has been shown theoretically and experimentally to have favorable solar-energy conversion prospects\textsuperscript{[6]} and the material properties of this compound can be tuned through cationic alloying (namely Sn for Ge) similar to substituting Se for S in CBTSSe.\textsuperscript{[7]} Close examination of the crystal structures of CBGSe and the fully-Sn substituted Cu\textsubscript{2}BaSnSe\textsubscript{4} reveals related structural moieties upon which the lattices are built. This has led to the design and discovery of three new semiconductors Ag\textsubscript{2}SrSiS\textsubscript{4}, Ag\textsubscript{2}SrGeS\textsubscript{4}, and Ag\textsubscript{2}SrSnS\textsubscript{4}. These compounds have band gaps within relevant ranges for single- and multi-junction PV as well as PEC applications. Future work will investigate further the properties of these compounds and hypothetical related semiconductors for solar-energy conversion applications.

Strong Coupling of Light and Matter Observed in a Tunable Microcavity with 2D-Perovskites at Room Temperature

Magdalena Furman\textsuperscript{1}, Marcin Muszynski\textsuperscript{1}, Karolina Lempicka\textsuperscript{2}, Mateusz Krol\textsuperscript{1}, Adam Wincukiewicz\textsuperscript{1}, Rafal Mazur\textsuperscript{1}, Maria Kaminska\textsuperscript{1}, Wiktor Piec\textsuperscript{1}, Jacek Szczytzy\textsuperscript{1} and Barbara Pietka\textsuperscript{1}; \textsuperscript{1}Faculty of Physics, University of Warsaw, Poland; \textsuperscript{2}Military University of Technology, Poland

In recent years hybrid-organic-inorganic perovskites have become a very promising materials for photonic applications and optical devices. Special attention is given to the two-dimensional (2D) perovskites. In the two-dimensional crystalline form...
these materials behave as a self-organized multiple quantum-well heterostructures. Compared to analogous semiconductor heterostructures 2D-layered perovskites displays stronger dielectric confinement in the inorganic layers, whereas excitonic resonances in such materials are characterized by a high binding energy and large oscillator strengths which leads to a great stability even at room temperatures, as well as exhibit strong non-linearities.

We report the realization of a tunable planar dielectric microcavities containing a 2D-layered perovskite-type semiconductor, CH$_3$NH$_3$PbI$_3$, showing the strong-coupling regime at both room and liquid helium temperatures. 2D-layered perovskite structure was synthesized from the organic solution which was deposited by spin-coating on a dielectric mirror.

The tunable cavity was constructed of two dielectric mirrors. The distance between the mirrors was controlled through piezo positioners. It allow, at the same time, for the realization of high fineness open micro-cavities (high Q) with tunable photonic mode and to avoid deterioration of perovskite crystals caused by the growth of the upper mirror. A strong coupling regime between the perovskite exciton and the confined photon mode is evidenced at room and liquid-helium temperatures from angular-resolved reflectivity and photoluminescence experiments. The observed exciton-photon coupling strength is of W~110 meV and photonic mode can be tuned over the range of 100 meV.

The scientific significance of this work is based on the realization of a room-temperature new material platform allowing for the observation of phenomena previously carried out at cryogenic temperatures.

(Si)GeSn Semiconductors for Integrated MIR Opto-Electronics Simone Assali¹, Alain Dijkstra², Anis Attiaoui¹, Mahmoud Atalla¹, Aashish Kumar¹, Samik Mukherjee³ and Oussama Moutanabbir³; ¹Ecole Polytechnique de Montreal, Canada; ²Technische Universiteit Eindhoven, Netherlands

Sn-containing group IV semiconductors (Si)GeSn represent a versatile platform to implement a variety of Si-compatible photonic, optoelectronic, and photovoltaic devices. This class of semiconductors provides two degrees of freedom, strain and composition, to tailor the band structure and lattice parameter thus enabling a variety of heterostructures and low-dimensional
systems on a Si substrate. In this presentation, we will discuss the recent progress in controlling and understanding the opto-electronic properties of metastable (Si)GeSn semiconductors. The relevance of these semiconductors for Si-compatible mid-infrared optoelectronics will be discussed from both materials and device perspectives. The growth of the (Si)GeSn multi-layer heterostructure with Sn contents up to ~20at.% is currently performed using a chemical vapor deposition (CVD) reactor on a Silicon wafer. By reducing the growth temperature, the Sn content in the alloy is increased, while preserving a high degree of crystal purity for the heterostructure in the topmost Sn-rich layer.[2,3] Atom probe tomography (APT) measurements will be discussed to address the abruptness of the interfaces in the GeSn multi-layer heterostructure and the uniform composition in the 18 at.% GeSn layer grown on top.[2] Positron annihilation lifetime spectroscopy (PAS) and depth-profiled Doppler broadening measurements will be discussed to enrich the understanding of point defects in these semiconductors. Based on these analyses, we found that divacancies are the predominant type of point defects in GeSn with composition in the 6.5-13 at.% range.[4]

Photoluminescence (PL) emission studies will be presented and discussed. In a GeSn layer with a Sn content of 18 at.% the room temperature PL emission was found to be centered at 0.36 eV (i.e. 3.5 μm wavelength).[2] However, the compressive in-plane strain (-1.3 %) in these GeSn layers reduces the directness of the alloy, leading to a higher energy gap value. By releasing the strain down to -0.2% in the 18 at.% Sn layer using a fully-underetched micro-disk geometry, a 50 meV red-shift of the PL emission energy down to 0.31 eV (i.e. 4.0 μm wavelength) is obtained. Moreover, the strained and relaxed PL emission and absorption measurements ranging from 300K down to 4K will be shown.[5] These observations will be discussed in the light of photocurrent measurements and photodetectors operating at MIR wavelengths.

S.E.L06.11.02
Epitaxial Growth of Atomically-Sharp GeSn/Ge/GeSn Tensile Strained (≥1.5 %) Quantum Well on Si
Simone Assali, Aashish Kumar, Jérôme Nicolas, Samik Mukherjee, Anis Attiaoui, Patrick Del Vecchio and Oussama Moutanabbir; Ecole Polytechnique de Montreal, Canada

In a full-group IV integrated semiconductor platform for tensile-strained Ge the direct-band gap can be obtained when the Ge is grown on a lattice-mismatched Ge0.87Sn0.13 substrate. With this approach the main challenge is to increase the incorporation of Sn in Ge above the ~1 at.% equilibrium composition. Major developments were recently achieved in the epitaxial growth of random GeSn alloys with composition above 16 at.%. A biaxial tensile strain in a Ge layer up to ~1.5% was demonstrated when growing on a Ge0.88Sn0.12 substrate.[2-3] However, despite the large amount of tensile strain in Ge, no information is available on the abruptness of the Ge-GeSn interface and on the possibility of the subsequent GeSn growth on top. Here, we discuss the epitaxial growth of a tensile-strained GeSn/Ge/GeSn (s-Ge) QW heterostructure with sharp interfaces and in-plane biaxial strain above 1.5 % grown on lattice-mismatched Ge0.86Sn0.14.[4] The sharpness of the Ge/GeSn heterostructure interfaces will be addressed using TEM-EELS and atom probe tomography (APT) measurements. A coherent s-Ge epitaxy with a tunable layer thickness in the sub-20 nm range is achieved. The pseudomorphic nature of the s-Ge layer will be discussed by combining cross-sectional STEM measurements and XRD-RSM measurements performed at a synchrotron radiation facility. The s-Ge QW platform is a new versatile platform to investigate light-hole (LH) spin-based qubits and 2D high hole mobility electronics. Under tensile in-plane biaxial strain, LH occupies the top of the valence band and the LH-HH splitting can exceed 100s meV. Moreover, when the tensile in-plane biaxial strain approaches 2 % only LH are confined in the QW, thus minimizing LH-HH interactions

S.E.L06.11.04
Homogeneous Cooling Dynamics in Laser Enhanced-Direct Print Additive Manufacturing of Circular Optical Fiber Interconnects
Roger B. Tipton¹, Dianhao Hou¹, Thomas Weller² and Venkat Bhethanabotla¹; ¹University of South Florida, United States; ²Oregon State University, United States

Integrated photonics have many compelling advantages for computing and communication applications, including high-speed
and extremely wide bandwidth operations. When fused deposition printing (FDM) a PMMA plastic optical fiber on a surface the bottom of the fiber is flat due to non-uniform cooling and the force of gravity on the fiber during solidification. Here we show that by embedding the fiber in a urethane optical cladding material, the fiber cools homogeneously and retains its round ship which is optimum for light transmission. This homogeneous cooling allows the use of a flexible, low cost additive and subtractive assembly method called laser enhanced-direct print additive manufacturing (LE-DPAM) to produce plastic optical fiber interconnects for photonic systems we have enabled higher transmission rates, lower power requirements, improve signal integrity and timing, less heat generation, and improve security of communication signals.

Eldred Lee1,2, Zhehui Wang2, Michael James2, Eric Fossum1, Kaitlin Anagnost1 and Jifeng Liu1; 1Dartmouth College, United States; 2Los Alamos National Laboratory, United States

Since the discovery of X-rays, the continuous expansion of X-ray technology has transformed our society. However, the capability gap for hard X-ray detectors in the 10-100 keV range is problematic. Even though scintillator-based methods are widely used, they are limited by their decay time response, light yield, and spatial resolution, which may prevent them from being effective in the next generation of light source facilities, the generic platform of imaging sensor technology, and quantum image computing.

One class of X-ray detection primarily focuses structured photocathode designs that rely on external photoemission and collecting electrons converted from photons using an external electric field. This research only demonstrated up to 5% photon-to-electron conversion efficiency (electron generation) at 7.5keV incident photon energy, which is still commendable as this value has been roaming around the 1-1.5% area for external photoemission for a few decades [1, 2]. However, we believe that there is a potential to significantly increase this 5% electron generation even beyond 7.5keV incident photon energy via X-ray photon emission from high-Z materials.

Here, we present the Monte Carlo simulation results and analyses via Monte Carlo N-Particle Software (MCNP) that demonstrate a tremendous potential of revolutionizing the advancement of X-ray imaging with a two-layer design that consists of a high-Z semiconductor material on top of a Si layer. The high-Z layer is called photon attenuation layer (PAL), and the Si layer the electron detection layer (EDL). PAL-EDL latticed multi-pixel X-ray detector can also lead to low inter-pixel scattering with significant electron and photoelectron generation. The underlying principle of this design is photon energy down conversion, where the top high-Z PAL leads to an effective X-ray photon energy attenuation down to a few keV and allows Si to absorb them with a much higher absorption coefficient. This approach is distinct from scintillators in that the attenuated photons remain in X-ray spectral regime instead of visible regime. For instance, with PbTe, CdTe or CZT PAL and the Si EDL, we have observed >22% electron generation at 10keV X-ray photon energy and >2.8% electron generation at 40 keV incident photon energy with minimum inter-pixel scattering effects. The average electron energy lies between a few hundred eV and a couple keV.

At 30-40keV, we observed that adding a high-Z PAL on top of Si EDL can lead up to 13x higher electron generation than the typical Si direct-detection method seen in commercial products such as photomultipliers. Furthermore, because MCNP does not include the “avalanche gain” process in Si, the observed efficiencies may be underestimated. The MCNP results will be coupled with models that take the avalanche gain process into consideration (e.g. TCAD). In addition, this high-Z PAL-Si EDL configuration can be integrated to regular backside illumination (BSI) CMOS image sensor or quanta image sensor-based devices, paving the way towards a billion-pixel X-ray camera design for wide field-of-view applications in light sources [3].

Study of Space Charge Limited Conduction Mechanism and Effect of In Situ Annealing on the Trap Distribution in
GaAsSb Nanowires

Mehul K. Parakh, Sean Johnson, Rabin Pokharel, Priyanka Ramaswamy, Surya Nalamati, Jia Li and Shanthi Iyer; North Carolina A&T State University, United States

This work presents the first observation of space charge limited conduction (SCLC) mechanism in intrinsic GaAsSb nanowires (NWs) grown by Ga-assisted molecular beam epitaxy and the effect of post-growth in-situ annealing in an ultra-high vacuum on trap concentration and its energy distribution in the NWs. Current-voltage (I-V) measurements on single NW (using conductive atomic force microscopy) and ensemble NWs (using two probe method) exhibited linear behavior at lower bias transitioning to a power-law behavior at higher bias, where the dominance of injected carriers over thermally generated charge carriers was observed. Temperature-dependent I-V analysis (I-V-T) on as-grown ensemble NW device in SCLC region yielded a trap concentration of $10^{16}$ cm$^{-3}$ distributed over a wide energy distribution in the bandgap as opposed to the reduced trap concentration of $7 \times 10^{14}$ cm$^{-3}$ in in-situ annealed NW ensemble confined to a narrower energy distribution of 0.12 eV located below the band edge, suggesting that annealing in ultra-high vacuum is an effective approach for the annihilation of the traps. The trap energy level in in-situ annealed NWs is speculated to be originating from Ga vacancy, and GaSb anti-site defect level during growth. Observations of increased PL intensity with reduced full-width half maxima at 4K and lower LO mode in corresponding Raman spectra for in-situ annealed NWs compared to as-grown NWs further attest to the annihilation of traps on in-situ annealing. Further, AFM current mapping also exhibited a considerable increase in several conducting NWs in in-situ compared to as-grown NWs. Hence, I-V-T analysis of the SCLC mechanism has been demonstrated to be a simple approach to obtain information on growth induced traps in the NWs.

S.EL06.11.08

James Pan$^{1,2}$; $^1$Advanced Enterprise and License Company, United States; $^2$Northrop Grumman Electronic Systems, United States

Photon-generated carriers may substantially improve the output current, and reduce series resistance of CMOSFETs. Photonic devices, such as Multiple Quantum Well Lasers, Quantum Dots Lasers, Vertical Cavity Surface-Emitting Lasers (VCSEL), Light Emitting Diodes (LEDs) have been reported for various applications. With modulation doped laser junctions, and bandgap engineered tunneling mechanisms, ultra-low resistivity and laser diode forward voltage can be achieved. These laser diodes can be fabricated in the drain region of a MOSFET. A photon sensor, such as avalanche photo diode (APD), can be included in the channel / well regions. The laser, APD, and MOSFET are fabricated as one integral transistor. When the MOSFET is turned off, the laser is also turned off. The laser is switched on only when a gate voltage and a drain voltage are applied to the MOSFET. Light emitted from the laser is absorbed by the APD. Light current produced by the built-in photon sensors or APD reduces series resistance and may substantially improve the output current and switching speed.

Indium Tin Oxide (ITO) is commonly used in Charge Coupled Devices (CCD) receiving front illumination. The gate electrode material can be replaced with ITO, which is transparent for specific light spectrums. The new Photonic CMOS transistor, including nonlinear optical films and multiple photon sensors (for various light spectrums) can be used for CCD (with ITO) or CMOS image products (without ITO) for front or back illumination.

When external light is absorbed in the depleted channel and well regions (where the multiple photon sensors or APDs are located) of a Photonic MOSFET, light electrons are generated. These light electrons produce a drain current, which turns on the built-in laser in the drain region. The result is not only a light current, but also a new beam of a laser light are generated. Much higher resolution may be achieved with multiplexing of the light signals and specially designed ROIC (Read Out Integrated Circuit), which may also include Photonic CMOSFETs.

Nonlinear Optics have been reported for various products and applications. The nonlinear crystal films change the input light signal and produces an output light signal of a different frequency or color. In the new Photonic CMOS transistor, in addition to the built-in laser in the drain, there are multiple avalanche photo diodes in the channel / well regions, nonlinear crystal films below the APDs, and a reflector (metal or multiple indices total reflection film stack) in the bottom of the device. The APDs are designed to absorb lights from various bands of spectrums. When light passes through the Photonic CMOS Transistor, some APD films absorb lights of specific frequencies, and other APD films absorb the reflected light of different frequencies through the nonlinear crystal layers. This feature enhances the absorption rate and external quantum efficiency of the Photonic MOSFET, and may significantly improves the quality and resolution of the images from the CCD or CMOS.
imaging devices.

In this paper we will discuss Photonic MOSFET drain current (IDS) vs. spectral characteristics of nonlinear optical films. With the nonlinear optical films, it is possible to substantially improve the CMOS performance according to these data. Dark current density and resolution using a Photonic CMOS image sensor vs. traditional CMOS image sensor are analyzed. The advantages of a Photonic CMOS image sensor are lower dark current, and higher light sensitivity, due to the built-in lasing device and multiple photon sensing films, and nonlinear optical features.

Information regarding incident light spectrums vs. Ion / Ioff ratio for a Photonic CMOS image sensor will be presented. Comparison of the speeds of CMOS image sensors with and without the built-in nonlinear optics films will be discussed.

We will also introduce various types of crystals of nonlinear optics suitable for the Photonic CMOS image sensing applications.

Comparison between Silicon and Silicon Nitride Platform for Nonvolatile Phase Change Photonic In-Memory Computing Xuan Li1, Nathan Youngblood2, Zengguang Cheng1 and Harish Bhaskaran1; 1University of Oxford, United Kingdom; 2University of Pittsburgh, United States

Demands for applying silicon photonics to high-performance computing systems have grown significantly in recent years due to the breakdown of Dennard scaling and information transfer bottlenecks in the conventional von Neumann architecture. Data processing on photonic platforms is a promising approach because of the potential advantages over electrical approaches where large bandwidth, high efficiency, ultrafast modulation speed, and low crosstalk are crucial. Critical photonic components, such as lasers, modulators, switches, filters, multiplexers, photodetectors, and memory cells, have been developed on different material platforms, such as silicon nitride (SiN), GeSi, III-V semiconductors, and others, with silicon on insulator (SOI) being the dominant platform. Owing to its compatibility with mature CMOS processes and integration with electrical devices, fabless and large scale silicon photonic integrated circuits (PICs) are available and thus offer a promising route to future commercialization.

Recently fully integrated photonic memory devices have been demonstrated on silicon nitride and silicon. This approach not only enables photonic data storage on-chip, but also shows multilevel storage, improved SNR, and reduced switching energy over available optical storage technology. Previous work on silicon nitride waveguides demonstrated both multilevel storage (> 32 levels) and computation in a fully optical framework. This was despite the fact that silicon nitride does not benefit from a high refractive index contrast (~2/1.5 in Si3N4/SiO2 vs 3.5/1.5 in Si/SiO2) or the ability to integrate active photonics (such as modulators and photodetectors) directly in the waveguide. Silicon-On-Insulator (SOI), on the other hand, has both these advantages, leading to smaller footprint devices and easy integration with high-speed, CMOS-based electronics. In spite of rapid advances of demonstrations in this field on both silicon and silicon nitride platforms, a clear pathway towards choosing between the two has been lacking.

Here, we systematically evaluate and compare the computation performance of phase change photonics on a silicon platform and a silicon nitride platform. Our experimental results show that whilst Silicon platforms are superior to Silicon Nitride in terms of potential for integration, modulation speed, and device footprint, it requires trade-offs in terms of energy efficiency. We then successfully demonstrate single-pulse modulation using phase-change optical memory (PCOM) on silicon photonic waveguides and demonstrate efficient programming, memory retention, and readout of > 4 bits of data per cell. This decreased the device footprint compared with silicon nitride photonics and reduced both the energy and time required for reaching arbitrary memory levels. We have characterized the reliability of this approach and outlined a comparison with other state-of-the-art programming methods. The use of silicon demonstrates a major step toward making phase-change photonic memory a viable and integrable technology. Our results have potential applications like deep learning based on vector-matrix multiplication and neuromorphic computing. Our approach paves the way for the in-memory computing on the silicon photonic platform.

TEM and EDX Analyses of Thermally Improved Phase-Change Memory by Optimized Encapsulation Layer Gauthier Lefèvre1, Anna-Lisa Serra2, Olga Cueto2, Niccolo Castellani2, Guillaume Bourgeois2, Nicolas Bernier2, Marie Claire Cyrille2, Mathieu Bernard2, Virginie Beugin2, Christophe Vallée1, Sylvain David1, Christelle Charpin2, Etienne Nowak2 and Gabriele Navarro2; 1LTM-CNRS, France; 2CEA-LETI, France
Phase-Change Memory (PCM) is a promising candidate for next generation of non-volatile memory [1]. PCM operations rely on the reversible phase transition between the amorphous and the crystalline phase, which occurs upon current-induced joule heating. Therefore, the reliability of the programming operation depends also on the thermal efficiency of the device [2]. Heat retention is thus essential in PCM and in complete contradiction with usual conception of electronic devices where thermal dissipation is a key point.

In this context, optimized thermal encapsulation in Ge-rich Ge-Sb-Te based PCM devices enables programming current reduction and improved data retention [3]. Indeed, an SiC encapsulation layer provides a more uniform heating of the active volume of the PCM cell, with respect to a standard SiN layer. Thanks to TEM and EDX analyses performed on state-of-the-art PCM heater-based devices, we demonstrate the higher uniformity of the heating process in the PCM cell during the programming operation achieved by optimized SiC encapsulation. Moreover, nano-diffraction patterns analysis highlights the crystalline morphology of the programmed active volume and of the surrounding material. Finally, we show the agreement between experimental data and TCAD simulations.

S.EL09.07.04 Structural Transitions and Switching Effect in Nanoscaled Ge2Sb2Te5 Films Modified by Bismuth Impurity Nurlan Almassov1, Andrei Sazonov2, Sanzhar Dyussembayev3, Oleg Prikhodko4, Nazim Guseinov4, Zhandos Tolepov4 and Sergei Kozukhin5; 1Nazarbayev University, Kazakhstan; 2University of Waterloo, Canada; 3University of Waterloo, Canada; 4Kazatomprom, Kazakhstan; 4Al-Farabi Kazakh National University, Kazakhstan; 5Kurnakov Institute of General and Inorganic Chemistry, Russian Academy of Sciences, Russian Federation

The design of non-volatile memory cells based on phase change materials (PCM) is the subject of many studies. And one of the most promising materials are the films of Ge2Sb2Te5 chalcogenide glassy semiconductor (CGS). The operation of memory cell is based on a reversible glass-crystal phase transition, which occurs when a current pulse passes through the film's nano-volume. The embedding of metal impurity in the films can improve the property of memory cells. However, the features of phase transition in the metal-modified Ge2Sb2Te5 films are poorly understood. This work presents the results of the study of the structure observed in nanoscale films of Ge2Sb2Te5 modified by Bi (Ge2Sb2Te5<Bi>). By the method of HR-TEM imaging it was found that the structure of Ge2Sb2Te5<Bi> films presents the amorphous matrix with isolated crystalline nanoregions (nanoclusters) of metallic bismuth with average size ~ 8 nm. Local atomic structure of the films was studied by Raman spectroscopy. It was found that under the laser irradiation there is the structure transition of nanoscale Ge2Sb2Te5 films from amorphous into polycrystalline hexagonal stable state through metastable polycrystalline cubic phase. In contrast, in the Ge2Sb2Te5<Bi> films the transition from amorphous to polycrystalline hexagonal stable state under the laser irradiation occurs without intermediate metastable cubic phase.

S.EL09.07.05 Analysis of the Limitation of the JMAK Equation for Crystallization of GST Based Phase Change Materials (PCMs) Kazimierz J. Plucinski; Military University of Technology, Poland

An investigation into the relationship between crystal fraction and electrical conductivity for GST materials was performed. Transition from amorphous to conduction state for homogeneous nucleation of conductive crystallites in the resistive amorphous layer and limitation of the JMAK equation to modeling this transition is analyzed. In particular, the analysis relate to the validity of the model in terms of time-temperature description of crystallization and dependencies between minimum amount of crystal during nucleation and percolative threshold

S.EL12.05.01 Multi-level Tactile Ferroelectric Field Effect Transistor Sensing Memory Kyuho Lee and Cheolmin Park; Yonsei University, Korea (the Republic of)
A tactile memory, which can sense and memorize the external stimuli, has been reported up to date with great potential in emerging wearable electronics. To realize bi-functional systems for sensing and memorizing, two device platforms integrated with tactile sensor and memory have drawbacks from physically bulky systems as well as increase of circuit resistance from wire connection, giving rise to low sensing sensitivity. In particular, a binary memory with bi-level state of ON/OFF has limitation in storing multi-level sensing information that requires multiple memory array. A multi-level memory-based single device platform without the integration is, therefore, on demand.

Herein, we demonstrate a non-volatile multi-level tactile memory based on a single ferroelectric-gate field-effect transistor (Fe-FET) allowing for intelligent electronic skins (e-skins), which can sense, memorize, and then retrieve the tactile information. Pressure-sensitive top-gate shape formation can precisely sense and memorize the external pressure stimuli by making an underlying ferroelectric film polarized according to the size of the contact area between top-gate and ferroelectric film, giving rise to variation of gate voltage supply. Our tactile 1-transistor memory exhibits high sensitivity of >90 kPa⁻¹ at low pressure stimuli of <1.5 kPa, and shows good reliability in multiple programming and erasing up to 50 cycles and long-term stability even with bending radius of 6 mm. Tactile memory arrays showing precise spatial positioning of external stimuli with non-volatile multi-level sensing, memorizing, and then retrieving after one week have broad applications suitable for wearable human-interactive electronics.

Effect of Sintering Temperature/Particle Size on Structural, Magnetic and Transport Properties of Polycrystalline Nd₀.₅Ca₀.₅MnO₃: Manganites
Dharmendra Raghav¹, Harikrishna Singh² and Ghanshyam D. Varma¹; ¹Indian Institute of Technology Roorkee, India; ²C.S.I.R. N.P.L., India

Nanosized materials, such as nanoparticles, nanowires, nanotubes, and nanocomposites are currently the focus of intense investigations due both to the physics they involve and to their potential for revolutionary technological applications. The applications are expected to be in a wide variety of diverse areas, such as logic circuits, magneto-electronic devices, magnetic data storage, medicine, and biotechnology. The phenomena and properties behind these applications are unique to nanodimensions, such as quantum confinement effects and enhanced surface to volume ratio. So, we have investigated the effect of particle size/sintering temperature on structural, magnetic and transport properties in Nd₀.₅Ca₀.₅MnO₃ system. Different size materials have been synthesized using Sol-gel method and sintered at 900, 1100 and 1300 degree Centigrade to get the samples of different particle sizes. Phase purity of the samples has been confirmed by Rietveld refinement of the powder X-Ray diffraction (XRD) data, which authenticates orthorhombic structure with Pnma space group. All three lattice constants (a, b and c), bond lengths and bond angles decrease with increasing particle size. The magnetization measurements (H@500 Oe) as a function of temperature exhibit paramagnetic (PM) to ferromagnetic (FM) transition and also brings out that (i) the divergence between the zero field cooled (ZFC) and field cooled cooling (FCC) magnetization decreases with increasing particle size, (ii) all samples show charge ordering at 250 K, (iii) the sharp drop of ZFC magnetization for all samples. At low temperatures a glassy behaviour is visible at higher particle size. The isothermal magnetization loops confirm the increase in the FM component at higher particle size at low temperature (20 K). The temperature dependent resistivity of all samples have been measured without magnetic field and resistivity measurements show no insulator to metal transition at lower sintering temperature but at higher sintering temperature the metal to insulator transition has been found. The data of resistivity have been fitted by using variable range hopping model (VRH). Characteristic temperature (T₀), localization length (1/α) and average hopping distance (R) have been calculated by using this model. X-ray photoemission spectra of Mn2p and Mn2s core-level confirm dual valence state of Mn (Mn³⁺ and Mn⁵⁺), which is responsible for the magnetic behaviour of NCMO system. The correlation between the transport and observed magnetic properties of sintered NCMO samples will be described and discussed in paper.

S.EL.12.05.14
Domain Size Effects on Piezoelectricity in Lead-Free Ferroelectric Single Crystals
Bo Wang¹, J.J. Wang¹, Fei Li¹; and Long-Qing Chen¹; ¹Pennsylvania State University, University Park, United States; ²Xi’an Jiaotong University, China

Domain size is known to play a critical role in electromechanical properties of domain-engineered ferroelectric single crystals. For lead-based relaxor-PbTiO₃ crystals, nanosized polar regions are believed to be the origin of giant piezoelectricity. For lead-free systems such as [111]-poled tetragonal ferroelectric BaTiO₃ crystals, enhanced piezoelectricity has been reported by reducing the domain size from hundreds to several microns. These examples lead to a long-standing belief that the smaller the domain size, the higher the piezoelectricity. Our recent study reveals an alternative route to improve piezoelectricity by increasing the size of domains through AC poling in relaxor-PbTiO₃. In this poster, we will discuss the general domain size effect on piezoelectricity in prototypical non-lead perovskites in tetragonal, orthorhombic, and rhombohedral ferroelectric phases, such as BaTiO₃, K₀.₅Na₀.₅NbO₃, and BiFeO₃, by examining the effective piezoelectric
coefficients of engineered domain structures using a combination of thermodynamic analysis and phase-field simulations. We find that the domain size effect on piezoelectricity depends on the symmetry of the ferroelectric phase. The size effect becomes significant when the domain is reduced to a critical size (~ sub-100 nm) which depends on the proximity to a ferroelectric-ferroelectric phase transition and on the width of domain walls. Moreover, the domain size effect has a strong anisotropy, giving rise to opposite trends for different piezoelectric tensor components as well as varying along different probing directions. By separating the contributions from domains and domain walls, we reveal that the size effect is majorly originated from the modification of thermodynamic states of domains due to the presence of domain walls. We also reveal that the domain size effect on piezoelectricity can be understood as a competition between the domain size effects on the dielectric permittivity and on the polarization rotation. The former is related to the flattening of free energy landscapes, while the latter is due to the built-in fields between domain walls. Besides, we predict a convenient way of controlling the domain size by poling via an alternating electric field. This work offers a thermodynamic-based understanding of the domain size effect and brings new insights into the fundamental knowledge of the processing-microstructure-property relationship in piezoelectric single crystals.

PEALD and Band Alignment of AlF3 on Polycrystalline Diamond Robert D. Mecham, Daniel C. Messina, Jesse Brown and Robert J. Nemanich; Arizona State University, United States

Metal-fluoride thin films have previously been investigated as gate insulators in MISFETs (CaF2/Au/Diamond) and this work expands upon that investigation. AlF3 is an ultra-wide-bandgap (10.8 eV) material with a low dielectric constant (2.2). These properties indicate that AlF3 may be a suitable insulator for high power high frequency devices. AlF3 films have been deposited on hydrogen terminated boron-doped polycrystalline diamond in a plasma enhanced atomic layer deposition (PEALD) process. PEALD is an emerging energy enhanced ALD technique that utilizes plasma radicals to drive surface reactions rather than thermal energy. PEALD allows for lower impurities, increased growth rates, improved stoichiometry, and lower deposition temperatures. The reactants used were trimethylaluminum, pyridine-hydrogen fluoride, and a hydrogen plasma. In-situ X-ray photoelectron spectroscopy was used to determine the band alignment of AlF3 films on polycrystalline diamond. The valence band maxima are measured at 9.15 eV and 0.05 eV for AlF3 and diamond, respectively. A type II staggered gap is formed with a conduction band offset of 3.77 eV and a valence band offset of 9.1 eV. The results indicate that AlF3 should be appropriate as a dielectric on p-type diamond.

This research supported by the NSF under grant DMR-1710551.

S.EL15.08.03
Investigations of Ultrawide Bandgap (AlIn)2O3 Alloy for AlInN / GaN Devices Xiaoli Liu and Chee-Keong Tan; Clarkson University, United States

Recent progress in wide band gap semiconductor based power electronics technology sparked humongous interest in the development of the semiconductor materials. With the aim of further reducing the cost, size, compactness while improving energy efficiency and performance of electrical systems, semiconductor materials of larger energy bandgap have been highly sought after. Recent studies show that ternary AlInN material grown lattice-matched with GaN provides access of energy bandgap of ~4.5 eV, allowing theoretically higher Baliga figure of merit than GaN-based devices and similar to that of β-Ga2O3 based devices. However, it also poses some difficulty in controlling the field effect since insulating material with larger energy bandgap is required to create conducting channel and block electron leakage from devices. Finding an insulator material with energy bandgap larger than 4.5 eV that can be grown on AlInN material is thus important towards realizing the AlInN / GaN field effect transistor based devices. Most recently, AlInO material has been proposed as a viable material that can serve as the insulator through thermal oxidation of the AlInN material. While the AlInO material is expected to exhibit chemical formula of (Al1-xInx)2O3, it is unclear if the AlInO material is thermodynamically stable and the information of AlInO material is extremely limited to date. Understanding the material properties of AlInO material from the viewpoint of structural and electronic properties is therefore critical for AlInN / GaN devices.

In this work, (Al1-xInx)2O3 alloys covering complete In compositions are investigated using Density Functional Theory (DFT) calculations. Two different phases of AlInO alloys will be investigated: corundum and hexagonal. The effect of In atoms on the electronic properties of AlInO alloys is investigated. For structural properties, lattice constants and equilibrium volume of (Al1-xInx)2O3 alloys are analyzed. Moreover, band alignment between AlInO and AlInN is studied, exploring possible heterojunction lineups in various orientations.

For DFT calculation, supercell approach is implemented in which a 60-atom AlInN crystal is constructed. The In composition is varied through the number of Al atoms being replaced in the crystal structure. DFT calculations were carried out using commercial package MedeA-VASP software. Band structure calculations were performed by using projector augmented wave (PAW) method, with the use of semilocal generalized gradient approximation (GGA-PBE) functional to
treat the exchange correlation potential in the system. Other computational details such as the k-spacing and cutoff energy have been optimized to ensure reasonable DFT results. Surface supercells for both AlInO and AlInN alloys were also created in order to calculate the band alignment, and the parameters are set to be similar to bulk DFT calculations. Our DFT-calculated band structures of AlInO alloys indicate the possibility of direct bandgap property crossing over to indirect bandgap property when In-content is larger than 20%. Preliminary analysis of the DFT-calculated band structures show that the energy bandgap of Al2O3 reduces significantly when In content is added into the alloy. The energy bandgap of AlInN with 20%-In is less than 5eV. The results are expected since In atoms are much larger than the Al atoms, and significant bowing occurs in atomic size mismatch condition. Further studies on density of states are required to understand the contribution of each orbital in the bandgap reduction. Note that Al2O3 and In2O3 have bandgap of ~8.8eV and ~3eV, respectively. Adding In in Al2O3 also results in significant reduction of lattice constants, but lattice matching condition with AlInN is possible with proper tuning of In-content. From the formation energy analysis, it is also expected that more than 20% In will result in phase separation in the InAlN alloys. Details on AlInN alloys will be further discussed.

S.E.L15.08.09
Morphological and Electrical Study of Ga2O3-Ti Nanofilms Processed by Co-Sputtering Lucia Ivonne Juarez Amador1, Karen A. Neri2, Laura Hill-Pastor3, Miguel Galvan Arellano1, Mario Zambrano-Serrano1, Jose Alberto Andracca2, Gabriel Romero-Paredes3 and Ramon Peña-Sierra1; 1CINVESTAV-IPN, Mexico; 2Instituto Politécnico Nacional, Mexico; 3Centro de Investigacion en Dispositivos Semiconductores, BUAP, Mexico

In this work an experimental study to characterize titanium (Ti) doped amorphous-Gallium Oxide (Ga2O3) nano-films (a-Ga2O3:Ti) produced by magnetron sputtering at 300K is reported. The nano-films were deposited by the co-sputtering process using Ti and Gallium oxide (Ga2O3) targets with a two magnetron system; the films were deposited over glass substrates covered with a 20 nm of non-doped buffer Ga2O3 layer grown by the same process. The Ga2O3 concentration was changed by varying the RF-power of the Ga2O3 magnetron at 75 or 150 W, while the DC-power for the Ti target was set at 80W. Due to the non-equilibrium character of the sputtering technique the grown films can be considered as a distribution of Ti clusters embedded into an a-Ga2O3 matrix when the growth process is done at low temperatures, therefore post-grown annealing processes can be used to adjust the film properties fixing appropriately the annealing conditions, temperature or atmosphere composition. The annealing temperatures were 400, 450, 500 and 550 °C by periods of 10 min, in a high purity N2 atmosphere. When the samples were annealed at lower temperatures the resistivity of the films were varied from 5.74x10^4 to 134.63 Ω-cm, electron concentration from 10^22 to 10^16 cm^-3 and mobility of 0.475 to 6.689 cm^2/V-s. by annealing the samples at 550°C electrical insulating nano-films were produced by the complete oxidation of the Ti clusters. The relatively low mobility of the doped nano-films suggests the Ti dopant produces carrier dispersion suggesting the presence of Ti deep levels in the material. According to the X-ray diffraction analysis the Ti clusters in a-Ga2O3 matrix helps in reducing the required temperature to transform amorphous films to β-Ga2O3 at ~400 °C. The required temperature to produce the phase change was confirmed by SEM studies producing octahedral shape nanocrystallites with sizes from ~5 to 50 nm.

S.E.L15.08.10
Diamond P-I-N Diodes for Receiver Protectors Mohammad Faizan Ahmad1, Harshad Surdi1, Franz A. Koeck1, Robert J. Nemanich1, Stephen M. Goodnick1, Trevor J. Thornton1 and Josephine Chang2; 1Arizona State University, United States; 2Northrop Grumman Mission Systems, United States

The intrinsic properties of diamond are attractive for use in high power receiver protector (RP) systems such as those required at the input of radar systems. At low input power, the RP device presents a low capacitance and high resistance so that it adds negligible insertion loss to the desired signals. However, at high input power levels the RP turns on with a resistance much smaller than the 50 Ω characteristic impedance and the majority of the input power is reflected away from the receiver input. P-I-N diodes made of Si and GaAs used in today’s conventional RP systems have limitations at high-power. The wide bandgap of diamond coupled with its higher thermal conductivity give it a superior RF power handling capability that can protect sensitive RF front-end components from high power incident signals. Vertical diamond P-I-N diodes were fabricated with an n+-i-p++ structure consisting of: a heavily phosphorus-doped n-type diamond layer with a doping concentration >1x10^19 cm^-3 and a thickness of approximately 300 nm; an intrinsic diamond layer of thickness approximately 0.5 μm; and a heavily boron-doped diamond <111> substrate with doping concentration of 5x10^20 cm^-3 and a thickness of 300 μm. The sample was patterned by photolithography and Ti/Pt/Au contacts were deposited on both top and bottom surfaces of the diode. The PIN test structures consist of a total of 144 diodes with diameters of 50 μm, 100 μm, 200 μm, and 400 μm. A SiO2 hard mask of thickness 2 μm was deposited on the diamond surface prior to the isolation etch step. Reactive ion etching was used to define electrically isolated mesa regions etched to a depth of ~600 nm. The SiO2 etching was carried out using fluorine RIE with 25 sccm of CHF3 and Ar at a chamber pressure of 30 mTorr at 200
W. Diamond etching was done in the chamber with 38 sccm of O2 and 2 sccm of SF6 at a chamber pressure of 15 mTorr at 300 W.

The electrical characteristics of the P-I-N diodes were measured using DC and RF probe stations. The diodes show significant forward current starting at around 10 V. The lowest specific on-resistivity at high forward bias was measured using the DC probe station and found to be 4.5x10^{-4} \Omega \cdot cm^2. The capacitance of the diodes at zero bias was extracted from small-signal S-parameter measurements in the frequency range 0.1 – 10 GHz and found to be 7.6 nF/cm^2. Taken together these values suggest a figure of merit, FOM = R_{on}C_{off} = 6.81 ps corresponding to a frequency of 23.37 GHz.

A 200 µm diameter PIN diode was attached to a coplanar waveguide (CPW) for RF small-signal measurements as follows. The p-type substrate of the diode was soldered onto the ground plane of the ground-signal-ground strip-line of the CPW while the n-type top contact was wire bonded to the signal line. The diode was DC biased with a bias-T connected to the input of the CPW. S-parameters were measured at no bias and 12 V of forward bias, over a frequency range of 0.5 to 5 GHz at 10 dBm power. S_{11} and S_{21} were found to be -15 dB and -0.4 dB respectively with no bias at 500 MHz, confirming negligible insertion loss with no forward bias applied. At 12 V of forward bias, S_{11} and S_{21} were found to be -2.5 dB and -13 dB respectively at the same frequency, confirming that up to 95% of the input power is reflected by the forward biased PIN diode. With further optimization of the diode growth and fabrication it will be possible to reduce the on-resistance and the associated R_{on}C_{off} figure of merit with the goal of achieving PIN diodes that provide > 30 dB isolation for high power receiver protection applications.

This research is supported by a contract from Northrop Grumman Corporation. One of us (Mohammad Faizan Ahmad) acknowledges support from NSF contract ECCS-1542160.

Defect Structure and Distribution of Electrons in Ga2O3 and IGZO Stack Yong-Seok Lee, Min-Ju Choi, Yonghee Lee, Ho Won Jang and Young-Woon Kim; Seoul National University, Korea (the Republic of)

Epitaxial Ga2O3 film was grown on the Al2O3 substrate using magnetron sputtering. Because of the lattice mismatch between Ga2O3 and substrate, epitaxial films reveal mosaic domain structure with high number density of interfacial dislocations. Interfacial Domain size has an average diameter of ~ 40 nm. On the top of the Ga2O3, without additional treatment, semiconducting indium gallium zinc oxide (IGZO) was stacked to obtain the oxide/semiconductor structure. An external electron beam control system for SEM and TEM was designed and built in house to acquire position specific physical properties – direct measurement for the electron density and luminescence characteristics from the optical energy states. External control system was successfully adopted to Electron Beam-Induced Current Imaging (EBIC) to visualize 2-dimensional distribution of electrons at the interface, which can be indirect indication of preferred electron conduction paths. Cathodoluminescence in TEM was also adopted to identify the 2-dimensional distribution of optical bandgap. Defects, originated from the interface, works as dead centers of luminescence, not wavelengths shifters as can be typically seen from the partial dislocation in GaN/InGaN lighting emitting diode structure.

Exploring the Role of Defects Produced by Ion Irradiation on Near and Sub-Surface GaN Thomas W. Pfeifer\textsuperscript{1}, Ethan A. Scott\textsuperscript{2,1}, David Olson\textsuperscript{1}, Patrick E. Hopkins\textsuperscript{1}, Khalid Hattar\textsuperscript{2} and Stuart Van Deusen\textsuperscript{2}; \textsuperscript{1}University of Virginia, United States; \textsuperscript{2}Sandia National Laboratories, United States

The wide band gap and high thermal conductivity of gallium nitride semiconductors makes them ideal for high power and high frequency applications. These properties however are dependent upon the order and impurity concentration of the crystalline structure. In this study, we use Time Domain Thermoreflectance (TDTR) to investigate the role of defects on the thermal performance of GaN semiconductors. He atoms were implanted into GaN, with dosing concentrations varying between 1x10^{13} and 1x10^{19} cm^{-2} and implantation energies at both 400eV and 400keV. TDTR is a pump-probe technique that measures the change in thermoreflectance on the surface of a sample as a function of pump-probe delay time from picoseconds to nanoseconds; this change in thermoreflectance is related to both the temporal temperature decay from impulse heating driven by the sub-picosecond pump pulse and the frequency-dependent temperature rise induced from the modulated pump pulse train. Thus, TDTR is well suited to measure both the thermal conductance across near surface interfaces along with thermal property changes of buried damaged regions from the ion irradiation. Our TDTR apparatus includes an 800nm 80MHz femtosecond pulsed laser, the pump is modulated at 8.4MHz, and all samples included an aluminum transducer deposited on the surface. Ions implanted at low powers localize near the surface of the GaN, and their effect can be observed when measuring the Aluminum-GaN thermal boundary conductance. Ions implanted at higher powers penetrate to a depth greatly exceeded the thermal penetration depth of the TDTR measurement technique. Here, the role of defects due to the passage of the ions is observed and measured. We believe the results and trends observed in this study are not limited to GaN, and a deeper understanding of the effects of doping on thermal properties could assist in cooling of doped semiconductor
Crystal Defects in GaN and Diamond Transistor Structures

Aris Christou; University of Maryland, United States

The state-of-the-art power switching devices made from SiC and GaN semiconductors contain a high density of crystal defects. Most of these defects are present in starting wafers and some are generated during device processing. There is little conclusive evidence so far on the exact role that the crystal defects play on device performance, manufacturing yield, and more importantly, long-term field-reliability especially when devices are operating under extreme stressful environments. This paper provides a review of the current state-of-the-art of Diamond and GaN power semiconductor material technology, and the potential impact crystal defects may have on power switching electronics. UWBG Nitride materials suffer from both extended and point defects, each of which will challenge the material’s application in both vertical and lateral power devices. The extended defects include vertical threading dislocations of both edge and screw type. The latter defects have been shown to be correlated to leakage in vertical two terminal device structures while the influence of the former is still undetermined and remains a critical research issue. Channel surfaces in vertical three terminal devices will also degrade due to vertical threading dislocations. These extended defects occur in all epitaxial layers grown on c-plane substrates (the predominant and largest area substrate type) and are the result of the lack of a high quality substrate bulk material as well as substrate surface. Diamond faces the challenge of achieving n-type doping. We report our results on delta doped channels in diamond CVD epitaxial layers and the achievement of delta doped field effect transistors. Finally, our recent experiments of proton and gamma radiation effects show that diamond transistors transfer characteristics do degrade as a result of radiation induced defects.

Investigating F-Doped MZO as the Emitter in CdTe Solar Cells

Manoj K. Jamarkattel, Adam Phillips, Jacob Gibbs, Kamala Khanal Subedi, Fadhil K. Alfadhili, Randy J. Ellingson and Michael Heben; University of Toledo, United States

Recently, incorporation of Mg_xZn_{1-x}O (MZO) as the emitter in CdSeTe solar cells has resulted in improved open circuit voltage and efficiency. However, the MZO layer appears to be sensitive to subsequent device processing, possibly due to unoptimized conduction band alignment or insufficient doping in the MZO layer. Unfortunately, the carrier concentration in the MZO is dominated by oxygen vacancies, which is difficult to control. Here we investigate how doping MZO films with F affect the CdSeTe properties. We deposit the MZO:F in two ways. The first method is by depositing an MZO/MgF stack followed by high temperature anneal, while the second method will be cosputtering ZnO, MgO, and MgF. Our preliminary results on the bilayer stack show that, peak PL intensity and bulk carrier lifetime of MZO:F/CdTe device increased after annealing. There is evidence of intermixing of the MZO and MgF after annealing, suggesting that the Fermi level of the MZO is closer to the conduction band at the film interface. If this is the case, band bending in the CdTe layer will be enhanced, leading to reduced interface recombination. Further investigation into the cause of these results will be presented, as will the results obtained when a cosputtered MZO:F emitter is used. The findings of this study may lead to higher efficient CdTe devices.

Broadband Thermal Beaming Using Multiple Epsilon Near Zero Materials Jin Xu and Aaswath P. Raman; University of California, Los Angeles, United States

Controlling the propagation, absorption and emission of light has been a topic of fundamental interest in contemporary photonics research. In the context of controlling the emission of light from thermal sources, a central challenge is that of angular selectivity. Over the past two decades, a range of photonic strategies, including using surface phonon-polariton modes, have enabled anomalous angular ‘beaming’ of thermal radiation, albeit only at narrow ranges of wavelengths. However, thermal radiation is inherently a broadband phenomenon. We currently lack the ability to constrain broad-spectrum thermal emission over a narrow range of angles of incidence, but consistently over a broad range of wavelengths. This form of broadband thermal beaming would be a fundamentally enabling capability for a range of applications, including infrared imaging and camouflage, thermophotovoltaics and radiative cooling.

Here, we employ multiple epsilon-near-zero (ENZ) materials in a layered configuration to realize a broadband angularly selective thermal emitter. ENZ materials can fulfill high absorption and emission of incident light at wavelengths where the epsilon is near zero. Aluminum oxide (Al2O3), Silicon monoxide (SiO) and Silica (SiO2) are all polariton materials with different ENZ wavelength. When combining them on top of each other into a multilayer thin film structure, we can obtain broadband near-blackbody emission from 7 to 11µm at a certain range of angles of incidence in the p polarization. We demonstrate this broadband angularly selective thermal emitter through theory, simulations, and an experimentally fabricated structure.

By employing transfer matrix method, we analytically solve the dispersion relation of this multilayer thin film structure and able to observe the EM field using the simulation tool. Following that, experimental results are compared with the analytical models with excellent agreement. The ENZ multilayer stack was coated on a Φ=100mm wafer via electrical beam evaporation method on CHA MARK 40. First, a 100nm Aluminum layer was deposited on the silicon wafer and then with 200nm Al2O3, 300nm SiO and 100nm SiO2 on top of each other. Then the sample was characterized by a Fourier-transform infrared spectroscopy (FTIR)-Jacob 6100. The strongest emission occurs at an AOI around θ = 70° and can be tuned from 65°to 80° by just varying the thickness of the layers. Outside of this AOI range the multilayer film is highly reflective which allows a switch between emission and reflection mode by changing the AOI. The materials used and structure designed in our research are cheap and easy to fabricate and fully compatible with wafer-scale manufacturing. Overall, this thin film based ENZ approach opens a path towards broadband thermal beaming and angular selectivity at low cost, at large scale and with simple structures.

Cool White Polymer Coatings Based on Hollow Glass Microspheres for Radiative Cooling Xiao Nie1, Youngjae Yoo2, Hasitha Hewakuruppu1, Ziqi Yu1, Jonathan Sullivan1, Anirudh Krishna1 and Jaeho Lee1; 1University of California, Irvine, United States; 2Korea Research Institute of Chemical Technology, Korea (the Republic of)

While selective emitters can lead to significant radiative cooling by reflecting sunlight and emitting heat to the surroundings, current materials solutions such as multilayer structures or metallic reflectors are inadequate for large-scale radiative cooling
Comparison of Simulated and Measured Light Emission Spectra from Solid State Incandescent Light Emitting Devices

Yue Kuo¹, Abhinav Shukla¹ and Tyler W. Kuo²; ¹Texas A&M University, United States; ²The University of Texas at Austin, United States

The warm white light emission phenomena from a single solid state incandescent light emitting device (SSI-LED) was reported by Kuo's group (1,2). This device is composed of a very large number of nano-resistors formed from the breakdown of a MOS capacitor with a nm-thick high-k gate dielectric on a p-type Si wafer. Light is emitted during the passage of the current through the nano-resistors, i.e., following the Planck's law on blackbody emission. The light emission phenomena can last for more than 20,000 hours under the continuous operation condition in air without a passivation layer (3). The emitted light can be narrowed down to a narrow wavelength width near 850 nm (4), which is a potential light source in an on-chip optical interconnect system.

In this paper, the light emission phenomena over a SSI-LED has been simulated. The emission spectra from the thermal excitation of the nano-resistor at different temperatures with and without inclusion of an ITO or a-Si thin film filter are simulated and compared with that measured from the actual device. The device size effect on the distribution of nano-resistors and therefore the distribution of light dots is estimated and compared with that of the actual device, which will be correlated to the measured current density of the device.

Atmospheric Pressure Plasma Synthesis and Aerodynamic Focusing of Silicon Nanoparticles for Additive Manufacturing
Alexander Ho and Rebecca J. Anthony; Michigan State University, United States

The use of nonthermal plasmas has emerged as an effective method for the synthesis of high-quality nanoparticles. Extensive study of nonthermal plasma reactors under low pressure conditions has been conducted which has yielded systems capable of producing nanoparticles with size tunable properties. Miniaturization to a microscale reactor allows for effective operation of a RF nonthermal plasma reactor at atmospheric pressure. The reduced scale of the reactor also provides the opportunity for combining nanoparticle synthesis and deposition into a single system for manufacturing with nanoparticles.

Presented here is our work on the additive manufacturing of silicon nanoparticles synthesized at atmospheric pressure with a nonthermal plasma. The plasma was generated with a 13.56 MHz RF power supply inside a glass capillary tube between two external ring electrodes. A silane precursor gas together with an argon background gas were flown to the reactor for the synthesis of silicon nanoparticles. The reactor was attached to a motorized system responsible for controlled deposition of the nanoparticles in predetermined geometries. TEM and XRD has shown that control between crystalline and amorphous particles can be achieved by controlling the applied power. Control over the nanoparticle size has also been demonstrated by varying the overall gas flow rate to the reactor. In efforts to increase the capability of this system for manufacturing processes we have investigated methods to control the deposition resolution. Spreading of the particles after exiting the reactor leads to wide linewidths which can limit the performance of this tool for manufacturing. Manipulation of the gas flow with aerodynamic lenses allows for reduced expansion of the particles and improved resolution. With this method we have been able to reduce the spot size to 1.3 times the size of the reactor tube outlet diameter.

11:55 AM S.EL05.02.04
Direct Optical Lithography of Transparent Metal Oxide Nanomaterials for Optical and Optoelectronic Applications
Jia-Ahn Pan¹, Yuanyuan Wang¹,² and Dmitri V. Talapin¹; ¹University of Chicago, United States; ²Nanjing University, China

Colloidal nanoparticles have been established as a diverse class of material with many interesting and useful properties. However, their practical application often requires some form of patterning procedure such as photolithography, ink-jet printing and nanoimprint lithography. Direct optical lithography of functional inorganic nanomaterials (DOLFIN) is a solution-processed additive patterning technique that utilizes a photosensitive colloidal nanomaterial ink. Here we engineer ligand-colloid interactions to be optically sensitive, allowing us to achieve micron-resolution patterning of metal oxide nanomaterials. Using this approach, we demonstrate the facile lithography of thick (>500 nm) metal oxide structures, which have a high-refractive index (n > 1.8) and are highly transparent. As a proof of concept, we manufacture diffractive optical elements (e.g. gratings) to show that significant phase modulation of light is attainable. Unlike polymer-based optical elements, our optical devices are more robust and can tolerate high temperatures due to its primarily inorganic content. We
also show the patterning of conductive colloidal oxide nanomaterials (e.g. ITO), which facilitates its implementation as a transparent conductive electrode. These advances aim to facilitate the integration of colloidal nanomaterials in real-world applications.

12:00 PM S.EL05.02.03
Polymer Blend Lithography—Bioinspired Scalable Fabrication of Disordered Photonic Nanostructures for Biosensing Radwanul H. Siddique1,2, Vinayak Narasimhan1, Shailabh Kumar1 and Hyuck Choo1,2; 1California Institute of Technology, United States; 2Samsung Advanced Institute of Technology, Korea (the Republic of)

 Millions of years of evolution in the biological world has developed a plethora of micro- and nanoscopic photonic structures that are frequently superior to synthetic analogs. These biophotonic materials show interesting novel and tunable unforeseen properties with deliberately introduced disorder in their respective geometries and compositions. Over the last decade, photonic materials with tailored -i.e. with deliberately introduced- structural disorder have also attracted considerable interest in various optical applications due to their extended spectral and angular range of effectiveness. Most bio-inspired nanostructured devices or optical metamaterials designed to date have been demonstrated at small-scales using expensive top-down techniques. However, biological structure formation in nature utilizes several bottom-up self-assembly approaches for manufacturing hierarchical mesoscopic nanostructures (100 – 550 nm) with immense diversity. Despite recent efforts aimed at increasing top-down fabrication writing speed, alternative routes based on self-assemblies still possess major advantages for industrial implementation of disordered structures as they allow rapid processing over large areas (>cm²). In this communication, we show that up-scalable polymer blend lithography technique can be used as a versatile platform for fabricating 2D planar, disordered nanostructures that can be exploited in both top-down and bottom-up strategies. Polymer blend lithography utilizes the polymer-phase separation process following nature’s way of forming nanostructures. The tailored disorder is achieved here by adjusting the process parameters (polymer blend composition and deposition conditions), enabling us to tune the morphology and the spatial distribution of the nanostructures produced, and in turn their light management properties.

First, we use our approach to pattern a resist etching mask, employed for transferring disordered nanopillars by dry etching (top-down route) onto a Fabry-Perot-resonator-based intraocular pressure (IOP) sensor for glaucoma management. The nanostructure integration onto the IOP sensor led to a 2.5-fold improvement in readout angle allowing easy handheld monitoring and in a one-month in vivo study conducted in rabbits, showed a 3-fold reduction in IOP error and 12-fold reduction in tissue encapsulation and inflammation, compared to an IOP sensor without nanostructures. Second, we demonstrate that similar structures can serve as a template in a bottom-up configuration, whereby aluminum thin film is directly deposited into the disordered nanoholes to form scalable plasmonic metasurfaces. These metasurfaces generate hybrid multipolar lossless plasmonic modes resulting in a broadband fluorescence-enhancement factor above 1000 for visible wavelengths with respect to glass chips commonly used in bioassays. Using the metasurface and a multiplexing technique involving three visible wavelengths, we successfully detected three biomarkers, insulin, vascular endothelial growth factor, and thrombin relevant to diabetes, ocular and cardiovascular diseases, respectively, in a single 10-μL droplet containing only 1 femtomole of each biomarker.

Reuse of Si Substrates for Selective-Area Epitaxy of Large-Area III-V Nanowire Array-Based Flexible Infrared Photodetectors

Alireza Abrand, Mohadeseh A. Baboli, Thomas S. Wilhelm and Parsian K. Mohseni; Rochester Institute of Technology, United States

During the last decade, III-V semiconductor nanowires (NWs) have received great research interest due to their promising potential for next-generation electronic, optoelectronic, and photonic devices. One of the main challenges for epitaxially-grown III-V NWs, however, is their high manufacturing cost, which can be divided to two individual categories: (1) the cost of starting III-V substrates, and (2) the cost of pre-epitaxy fabrication associated with substrate patterning. Large-scale integration of III-V NW-based technologies requires novel nanofabrication strategies that mitigate both cost streams. Wafer costs can be substantially reduced simply through growth of III-V NWs on foreign substrates such as silicon or graphene, instead of on bulk III-V wafers. One strategy for simultaneously reducing fabrication complexity and pre-growth processing costs is to reuse Si substrates with existing predefined growth masks for selective-area epitaxy (SAE) of III-V NW arrays.

Here, we present wafer-scale, bottom-up SAE growth of InAs NW arrays and fabrication of flexible NW-based infrared (IR) photodetectors realized through delamination of embedded NW arrays and reuse of Si substrates with predefined growth masks. Silicon (111) substrates are patterned by conventional photolithography to obtain pores with 0.5 µm diameters and 1 µm pitch in SiO2 growth masks of 55 nm thickness. Next, InAs NW arrays are grown via the SAE approach using metalorganic chemical vapor deposition (MOCVD). Trimethyl-indium (TMIn) and arsine (AsH3) were used as precursor gases for the supply of In and As growth species, respectively, at a set-point growth temperature of 700 °C. A two-step growth technique is introduced, whereby a separate nucleation step using a TMIn flow rate of 16 μmol/min precedes a NW growth step at a TMIn flow rate of 0.77 μmol/min. This procedure is necessary for optimization of pore occupation toward a global NW yield of >85%, with NW aspect ratios of ~15. The InAs NW arrays are embedded in various polymer membranes and mechanically delaminated from their growth substrates, then bonded to carrier substrates for subsequent device fabrication. The polymer-embedded NW array exfoliation process leaves NW bases with heights of ~50 nm below the fracture plane attached to the growth surface. Consequently, five different substrates restoration processes are investigated prior to substrate-reuse. It is observed that the best results for re-growth of daughter generation InAs NW arrays on reused Si substrates can be realized when no additional wet etching, chemical treatment, or mechanical polishing steps are introduced between subsequent re-growth runs, as the remaining NW bases serve as SAE growth sites. Direct re-growth on reused Si substrates results in vertical extension of existing NW bases and growth of InAs NWs with aspect ratios >80 under the same growth conditions as the primary run with comparable global NW yield. For fabrication of flexible IR photodetectors using both primary and subsequent generation InAs NW arrays, a unique process flow is reported, which enables NW transfer yields of ~100% and preserves the original position and orientation of as-grown NWs. This work demonstrates that multiple generations of InAs NW-based devices can be fabricated through reuse of a single, templated Si substrate, without introduction of intermediate substrate restoration processes such as wet etching or chemical mechanical polishing. This approach can serve as an effective strategy toward growth and fabrication of large-area, high-efficiency, low-cost, flexible, and wearable device applications in III-V nanoelectronics, optoelectronics, and photovoltaics.

Transdimensional Photonic Lattices of High-Index Nanoantennas and Layered Materials

Fatih Ince, Viktoriia Babicheva and Soham Saha; University of New Mexico, United States

Planar optical elements with efficient light control at the nanoscale can be designed based on transdimensional photonic lattices that operate in the translational regime between two and three dimensions. Such transdimensional lattices include 3D-engineered nanoantennas supporting multipole Mie resonances and arranged in the 2D arrays to harness collective effects in the nanostructure [1]. Optical antennas made out of van der Waals material with naturally-occurring hyperbolic dispersion is
a promising alternative to plasmonic and high-refractive-index dielectric structures in the practical realization of nanoscale photonic elements. The antenna made out of hexagonal boron nitride (hBN) possesses different multipole resonances enabled by the supporting high-k modes and their reflection from the antenna boundaries. The full range of the resonances is demonstrated for the hBN cuboid antenna, a decrease of reflection from the array, and highly directional resonant scattering from antennas pairs. We show that transdimensional lattices consisting of resonant hBN antennas in the engineered periodic arrays have great potential to serve as functional elements in ultra-thin optical components and photonic devices. We show that a periodic array of particles with a large imaginary part of their permittivity (LIPP) can support well-defined modes localized within the particle, with the spectral position of the modes mainly defined by the array period. It has been known for a long time that a non-zero imaginary part of the permittivity enables propagating surface modes at the interface of materials with positive permittivities, known as Zenneck modes. Recently, it has been demonstrated that transition metal dichalcogenides (TMDC) layers support different kinds of propagating Zenneck waves defined by the layer thickness and interfaces with air and substrate [2]. Here, we show that localized Zenneck modes are possible on subwavelength particles and that the particles can serve as antennas for direction light scattering, reflection suppression, and Kerker-effect applications. To illustrate a possibility to control light, we show that simultaneous excitation of the several particle multipole resonances (electric dipole and quadrupole) allows for achieving significant reflection suppression and observation of the generalized lattice Kerker effect [3]. Materials with LIPP are common in nature, including TMDCs and lossy metals, titanium, chromium, and others.

Large-Scale Thermoregulatory Material Inspired by Cephalopods

Mohsin Ali Badshah1, Erica M. Leung1, Christopher Moore2, Panyiming Liu1, Marlon Pinedo1 and Alon Gorodetsky1,1,1,1; 1University of California, Irvine, United States; 2Chapman University, United States

Low-cost, large-area thermal management is desirable for the operation of many modern technologies including smart clothing, electronic circuits, building environments, and outdoor equipment to control heat flow. Inspired by the space blanket and the dynamic skin of cephalopods, we have demonstrated a large-area, highly uniform, low-cost nanostructured material with tunable thermoregulatory and infrared properties. We have implemented scalable nanofabrication processes to achieve a material with an area > 500 cm², a > 40 % change in infrared transmittance and reflectance, and a dynamic environmental setpoint temperature window of ~ 8 °C. Due to characteristics of scalability and associated figures of merit, our material affords new scientific and technological opportunities not only for adaptive optics and thermoregulation but also for any platform that would benefit from dynamic control of infrared radiation and heat.
Effect of Defective Microstructure on the Reflective Structural Color of Self-Assembled Colloidal Crystals

Tianyu Liu, Bryan VanSaders, Sharon C. Glotzer and Michael J. Solomon; University of Michigan–Ann Arbor, United States

We report the relationship between measures of the crystal quality of self-assembled colloidal crystal films and the intensity of their structural color. Structural color arises from geometric diffraction; it has potential applications in optical materials. To study the connection between crystal film quality and structural color intensity, we investigate the peak intensity of the reflection spectrum as a function of defect density, film thickness and impurity concentration using a combined experimental and computational approach. Polystyrene microspheres are self-assembled into defect-laden colloidal crystals via solvent evaporation. Colloidal crystal growth via sedimentation is simulated with molecular dynamics and the reflection spectrum of simulated crystals is calculated using the finite-difference time-domain method. We examine the impact of several commonly observed defect types (vacancies, stacking fault tetrahedra, planar faults, and microcracks) on structural color peak intensity. We find that the reduction in peak intensity scales with increased defect density; stacking fault tetrahedra have a particularly detrimental effect. The thickness profiles are characterized by cross-sectional scanning electron microscopy and profilometry. The reflective spectral response of the colloidal crystals is measured with a white light spectrophotometer. Our results show that reflectance of structural color increases as a function of the crystal thickness, until a plateau is reached at thicknesses greater than about 10 μm. The plateau reflection is 83.2% ± 2.8%; this value is significantly less than the 100% reactivity predicted for a fully crystalline material; the difference is caused by defects present in the experimental crystal structures. Finally, we manipulate the defect structures of colloidal crystals by introducing differently sized particles that function as impurities. As the concentration of the impurity is increased, the measured intensity of structural color reflection decreases by amounts that we correlate with the observed microstructure. These findings can guide the design of optical materials which tune the intensity of structural color.

Mechanochemical Conversion Kinetics of Red Phosphorus to Black Phosphorus for Optoelectronic Applications

Samuel V. Pedersen, Florent Muramutsa, Joshua D. Wood, Chad Husko, David Estrada and Brian Jaques; Boise State University, United States; Center for Advanced Energy Studies, United States; Wood Technical Consulting, United States; Iris Light Technologies, United States

With the promise of novel optoelectronic devices using black phosphorus (BP), there is a need for a large-scale synthesis method for BP compatible with on-chip integration. Herein, we attain large scale mechanochemical conversion of red phosphorus (RP) to black phosphorus (BP) via high energy ball milling. During the milling process, the collisions of hardened steel media rapidly compress amorphous RP into crystalline, orthorhombic BP flakes, with a conversion yield >95% for up to 5 g of bulk BP powder. Commercial scale-up of BP production can be extrapolated by empirically derived conversion kinetics from lab scale, high energy ball mills. RP’s milling conversion kinetics, as monitored via ex situ XRD, shows a sigmoidal behavior best described by the Avrami rate model. For <60% conversion, BP is rapidly formed at the expense of RP following an autocatalytic behavior with induction times proportional to the milling intensity. At ≥60% conversion, milling conversion rate suddenly decreases, indicative of a growth mechanism change with presumably a higher activation energy, thereby requiring higher impact energies for complete conversion. Further, by comparing the specific milling dose, namely, the energy input required for the phase transformation to reach completion, versus the conversion progress, we can determine the optimum milling conditions. We therefore ascertain the BP specific milling dose (50 kJ/g) and minimum impact energy (25 mJ/impact), both necessary to scale up production and minimize the power consumed in a tumbler milling vessel. Finally, the as-synthesized BP powder exfoliates more readily than single crystal BP sources in solution, as revealed by concentrations obtained from UV-Vis absorption under the same exfoliation conditions. The milled, converted BP solution is roughly 6-fold the concentration of the single crystal solution. High energy ball milling is demonstrated as a large scale, viable synthesis route for BP.
nanotextures that reduce visible reflectance to < 1% [1,2], or nanoholes that improve light trapping in photovoltaics at carrier selective rear contacts [3]. Nevertheless a greater latitude for optical property engineering would be possible using self-assembled BCP patterns at length scales commensurate with visible wavelengths of light in order to exploit optical diffraction and resonance effects. This is prohibited by exponentially slower ordering kinetics in the ultrahigh higher molecular weight BCPs (> 1000 kg/mol) required for this scaling. Here we report dramatically accelerated ordering afforded by blending in very low molecular weight (~3 kg/mol) homopolymer plasticizers. These formulations enable a 10× reduction in the time required to achieve ordered nanopatterns with periods > 200 nm. Subsequent reactive ion etching demonstrates that these nanopatterns are readily transferrable to other materials. Exemplar applications such as structural colors made possible using these self-assembled patterns will be described.

Physically Assisted Chemical Assembly for Large-Area, Reproducible Near-Field Response Regina Ragan; University of California, Irvine, United States

Single molecule (SM) detection represents the ultimate limit of chemical detection. Over the years, many experimental techniques have emerged with this capacity. Yet, SM detection and imaging methods require large, reproducible spectral datasets in order to benefit from chemometric methods. We will present a scalable chemical assembly platform for plasmonic and metamaterial architectures that yield reproducible optical response. For example, surface enhanced Raman scattering spectroscopy (SERS), with extensive applications in biosensing, is demonstrated to be particularly promising because Raman active molecules can be identified without recognition elements and is capable of SM detection. Yet quantification at ultralow analyte concentrations requiring detection of SM events remains an ongoing challenge, with the few existing methods requiring carefully developed calibration curves that must be redeveloped for each analyte molecule. We will present work where we demonstrate that using 2-dimensional physically activated chemical (2PAC) self-assembly, we can achieve reproducible enhancement factors of 10⁹ over 1 cm². 2PAC crosslinks nanoparticles into discrete assemblies with a small molecule linker, where the crosslinking reaction is driven by electrohydrodynamic flow at on a substrate surface. The hotspots observed in a 2PAC fabricated assembly have gap spacing is 0.9 nm, corresponding to the length of the chemical crosslinker. Large area SERS maps are acquired from these 2PAC assembled surfaces from analyte dissolved in water and even complex biological media.

One of the most important applications of contemporary machine learning, i.e., image analysis, has remained relatively untouched by the SERS community. We will show that a combination of large area and reproducible SERS substrates with a CNN model is used to address the long standing challenge in SERS: quantification of sub-nanomolar analyte concentrations. A convolutional neural network (CNN) model when applied to bundles of reliable SERS spectra yields a robust, facile method for concentration quantification down to 10 fM using SM detection events. The demonstrated limit of blank (LOB) is 1 fM for Rhodamine 800, with a limit of quantification (LOQ) of 10 fM. Furthermore, the model’s predicted concentrations have an average r² value of 0.958 over 6 orders of magnitude as determined by k-folds cross validation. A key advantage of the analysis is its compatibility with transfer learning, the use of large datasets to train a model and then generalize this pretrained model to new molecules quickly with significantly smaller datasets. The uniformity of enhancement factor is essential for our approach, as large variance in the dataset not only increases the variance in predictions, but also requires more data for convergence and prevents a transfer learning approach. Generalization of the CNN model to other analytes using transfer learning is demonstrated with methylene blue. Transfer learning achieves good results with as few as 50 8x8 pixel maps. Thus entire datasets are acquired quickly, requiring just 5.3 minutes of total laser exposure time per concentration to train a robust model that is much faster and more scalable than required for building SM concentration regression models. This demonstrates a proof of concept for hyperspectral CNN image analysis of SERS, which could be broadly applicable within SERS, especially in the biological setting where classification of images could improve analysis of bacteria that are already imaged with SERS. We will also present results showing this approach is able to differentiate susceptible and resistant bacterial strains for rapid antimicrobial susceptibility tests.

9:45 AM S.EL05.05.07
Multi-Layered Nanoparticle Coatings with Tunable Refractive Index and Surface Roughness Deposited with Aerosol Impact Driven Assembly (AIDA)  
Peter Firth$^{1,2}$, Zachary C. Holman$^{2,1}$ and Shannon Poges$^{1,2}$;  
$^1$Swift Coat, United States;  
$^2$Arizona State University, United States

The next generation of functional coatings will likely be composed of nanomaterials. At the laboratory scale nanomaterial-based coatings have shown the potential to improve performance and enable completely new functionality in applications like thermal barrier coatings on high-temperature parts, active layers in electronic devices, anti-reflective coatings for PV modules, or biocompatible coatings for medical applications. In all cases, these coatings should be able to be formed over large areas at commercial production rates and have a uniform and controllable thickness, and their constituent particles should retain their nano-properties.

Present nanomaterial films developed in laboratories are often unable to be reproduced on a commercial scale; the manufacturing methods are inherently nanomaterial, substrate, and application specific. This specificity results in manufacturing processes that are expensive or offer limited utility. We propose an advanced nanomaterial film manufacturing technology based on Aerosol Impact Driven Assembly (AIDA) that overcomes these deficiencies.

AIDA begins by aerosolizing a nanomaterial using any desired technique, from atomizing a nanoparticle-laden solution to feeding nanoparticle-precursor gas into a plasma. The aerosolized material is fed into the AIDA system, which consists of two chambers separated by a slit-shaped nozzle, with the bottom chamber held under vacuum (< 1 Torr). The nanomaterial is accelerated to a velocity of several hundred meters/second as it and the aerosol background gas are forced through the nozzle, resulting in the formation of a curtain of nanoparticles directed into the downstream chamber. A substrate is passed through the curtain, and the nanomaterial collides with and adheres to the substrate, forming a thin coating.

AIDA’s unique approach to film formation enables independent control over nearly every aspect of the coating’s morphology. As a dry spray technique, there are no inherent limitations on the thickness. Coatings ranging in thickness from a sub-monolayer to >1mm have been produced with dynamic deposition rates as high as 6 mm-m/min. By adjusting the particle impact velocity, the porosity of the coating can be controlled between 5% and 95%. This enables control over film properties like the refractive index, heat transfer coefficient, and dielectric constant. By changing the angle of impaction, the surface roughness of the film can be tuned between 0 nm and >100 nm allowing engineers to tune the effective surface energy of the coating. Combining this intimate control of film morphology with the wide range of nanomaterials compatible with AIDA allows engineers to produce complex, multi-layered, multi-component, and multi-functional films using a single platform.

As a case study, we will showcase an AIDA system capable of depositing on 14”x24” substrates that uses an in-situ non-thermal plasma reactor to synthesize metal-oxide nanoparticles (SiO$_2$, TiO$_2$, and ZnO) and produce a multi-layered coating that is simultaneously highly photocatalytic (self-cleaning) and anti-reflective for use in PV module glass. The composition of each layer will be tuned to maximize the photocatalytic self-cleaning effect. The thickness and refractive index of each layer will be precisely tuned to optimize its anti-reflective properties and provide a 3% transmittance gain compared to uncoated glass. The surface roughness of each layer will be tuned to promote adhesion and provide the desired water contact angle on the top surface to enhance self-cleaning.

Effectively Transparent Contacts for Photovoltaic Devices  
Rebecca Saive$^{1,2,3}$;  
$^1$University of Twente, Netherlands;  
$^2$California Institute of Technology, United States;  
$^3$ETC Solar, Netherlands

Effectively transparent contacts (ETCs) constitute the only front contact technology to date overcoming the inherent trade-off between grid conductivity and transparency[1]. When applied to solar cells relative efficiency improvements of 4-10% can be achieved. ETCs consist of triangular cross-section microscale silver grids that redirect incoming light towards the absorber material of the photovoltaic (PV) device instead of reflecting it back to the light source. Key features of this technology are the mesoscale structure size leading to ray-optical near-field interaction and low sheet resistivity [2] in combination with a novel fabrication method allowing for mirror-like optical properties. Here, the design of ETCs, their physical and visual [3] properties, application in different solar cell technologies and the principle of residue-free imprint lithography will be presented. Commercialization of the ETC technology is underway and executed by the award-winning Caltech and UTwente.
5:30 AM S.EL05.01.02
A Triple-Mode mid-IR Modulator for All-Surface Large-Scale Heat Management Po-Chun Hsu; Duke University, United States

Radiative heat management is a promising approach for thermoregulation because it is ubiquitous, rapid, lightweight, and energy-efficient. The sensitivity and spectral tunability also make thermal radiation particularly powerful in many energy applications, such as rooftop radiative cooling, solar thermal heating, wearable thermal management, and so on. As the radiative heat management concept becomes more and more prevalent and influential, it also calls for more functions integrated into one single device. In this talk, I will introduce a triple-mode mid-infrared modulator that can switch among transmission, reflection, and emission states. The device is composed of an elastomer/metal thin film with a rationally designed coupling relationship between mechanical and optical properties. The fabrication is highly scalable and does not need any photolithography. By controlling the biaxial strain of the elastomer/metal film, the device can switch among the three modes with unprecedented performance of emittance contrast $|\Delta \varepsilon| = 0.44$, transmittance contrast $|\Delta \tau| = 0.48$, and reflectance contrast $|\Delta \rho| = 0.38$, and these modulation remains stable after 100 cycles. Being able to switch among three modes means the device can perform heating and cooling on objects with all kinds of surface emissivities, no matter it is perfect thermal emitter such as the human body or poor emitters such as metals. We also performed semi-empirical structure optimization to serve as the future pattern design guideline. It provides a new paradigm in the cross-disciplining area of soft and shape-changing photonic materials.

Comparison of Simulated and Measured Light Emission Spectra from Solid State Incandescent Light Emitting Devices Yue Kuo¹, Abhinav Shukla¹ and Tyler W. Kuo²; ¹Texas A&M University, United States; ²The University of Texas at Austin, United States

The warm white light emission phenomena from a single solid state incandescent light emitting device (SSI-LED) was reported by Kuo's group (1,2). This device is composed of a very large number of nano-resistors formed from the breakdown of a MOS capacitor with a nm-thick high-k gate dielectric on a p-type Si wafer. Light is emitted during the passage of the current through the nano-resistors, i.e., following the Planck's law on blackbody emission. The light emission phenomena can last for more than 20,000 hours under the continuous operation condition in air without a passivation layer (3). The emitted light can be narrowed down to a narrow wavelength width near 850 nm (4), which is a potential light source in an on-chip optical interconnect system.

In this paper, the light emission phenomena over a SSI-LED has been simulated. The emission spectra from the thermal excitation of the nano-resistor at different temperatures with and without inclusion of an ITO or a-Si thin film filter are simulated and compared with that measured from the actual device. The device size effect on the distribution of nano-resistors and therefore the distribution of light dots is estimated and compared with that of the actual device, which will be correlated to the measured current density of the device.

Switchable Smart Radiative Heating and Cooling BuildingEnvelope Po-Chun Hsu; Duke University, United States

2020 MRS Virtual Spring/Fall Meeting, November 27-December 4, 2020, Spring Abstracts Final Program 2/3/21
Solar thermal energy has been one of the major energy sources to realize zero energy buildings for a sustainable future. The high efficiency and low cost make it particularly attractive to reduce the energy consumption for hot water and space heating. On the other hand, the radiative cooling uses the rest of the sky, i.e. the outer space, as the cold source to generate cooling that can offset the usage of refrigeration and space cooling. Both technologies show rapid and promising improvement in the past decade, which calls for new engineering and design principles to further maximize the energy saving for buildings. In this talk, I will introduce a smart building envelope that can switch between solar heating and radiative cooling, so it can be applied to buildings at various climate zones (spatial variation) under different weather and forms of energy demand (temporal variation). The dual-function material which possesses both heating and cooling property is switched mechanically between ~600 W/m² of solar heating and ~100 W/m² of radiative cooling in less than one minute. This high performance is the outcome of heat transport analysis and engineering. We demonstrate this smart heat managing building envelope can be adopted in all 16 climate zones in the US and produce in more energy-saving on a yearly basis.

6:30 AM S.EL05.01.07
Cool White Polymer Coatings Based on Hollow Glass Microspheres for Radiative Cooling  \textit{Xiao Nie}¹, \textit{Youngjae Yoo}², Hasitha Hewakuruppu¹, Ziqi Yu¹, Jonathan Sullivan¹, Anirudh Krishna¹ and Jaeho Lee¹; ¹University of California, Irvine, United States; ²Korea Research Institute of Chemical Technology, Korea (the Republic of)

While selective emitters can lead to significant radiative cooling by reflecting sunlight and emitting heat to the surroundings, current materials solutions such as multilayer structures or metallic reflectors are inadequate for large-scale radiative cooling systems that require lightweight, flexible and low-cost materials. Commonly used coatings for scalable applications, including commercial pigment-embedded white paints, suffer from strong ultraviolet absorption from embedded high-refractive-index (n~2.5) TiO₂ particles and a low near-infrared reflectivity. The strong ultraviolet absorption induces severe photocatalytic degradation for the organic binder components in TiO₂-based paints. Integrating low refractive index particles such as SiO₂ microspheres can be used to avoid high ultraviolet absorption because the extinction coefficient of SiO₂ remains approximately zero throughout the ultraviolet/visible/near-infrared spectrums. Here we create a lightweight, flexible and scalable polymer coating by integrating controlled volume concentrations of hollow glass microspheres within a polydimethylsiloxane (PDMS) matrix since PDMS is a commonly used low-cost polymer with little solar absorption and easy accessibility. We utilize hollow SiO₂ microspheres instead of solid microspheres as they provide a higher interfaces-to-volume ratio and a much smaller density. Our size analysis shows that the diameter of the hollow glass microspheres ranges from 2 µm to over 40 µm and the shell thickness are roughly 0.05 times the diameter (0.1 µm to 2 µm). The prepared polymer coating offers a maximum mass density of 681 kg/m³ and the corresponding areal density of 0.885 kg/m². The polymer coating also shows excellent flexibility and scalability which is beneficial for large-scale applications. As the volume concentration of hollow glass microspheres increases from 0 to 70%, the average reflectivity in the visible spectrum accordingly increases from 0.06 to 0.92 while the emissivity in the mid-infrared remains above 0.85. We use computations based on rigorous coupled-wave analysis to explain the role of hollow glass microspheres in increasing the solar reflectivity. The high solar reflectivity is attributed to the strong backscattering of sunlight enabled by refractive index difference between PDMS matrix (n~1.4) and SiO₂ shell (n~1.45), as well as between SiO₂ shell and air void (n~1) inside the microsphere. Our computation based on the Finite-difference time-domain method shows that hollow glass microspheres with a hierarchical arrangement of diameters are more efficient in scattering the sunlight and thus the polymer coating composed of large numbers of such hierarchical systems randomly distributed in a PDMS matrix can provide high solar reflectivity. The high mid-infrared emissivity is attributed to multiple extinction peaks of PDMS in the mid-infrared wavelength caused by different vibrational modes of its molecular structures. Our outdoor temperature measurement shows that the polymer coating on a concrete surface can lead to a temperature reduction of 25°C during the day, which is also 9°C below ambient temperature when conduction and convection are limited. Our building energy analysis shows the potential impact of the polymer coating on common buildings in Phoenix and estimates annual cooling energy savings of 6-38 MJ/m². The demonstrated ultraviolet-resistant property shows that the polymer coating exhibits great reliability and thus outperforms commercially available white paints. The selectively reflective polymer coating material based on hollow glass microspheres presents optimal material solutions for large-scale radiative cooling applications in buildings.

Broadband Thermal Beaming Using Multiple Epsilon Near Zero Materials  \textit{Jin Xu} and Aaswath P. Raman; University of California, Los Angeles, United States

Controlling the propagation, absorption and emission of light has been a topic of fundamental interest in contemporary photonics research. In the context of controlling the emission of light from thermal sources, a central challenge is that of angular selectivity. Over the past two decades, a range of photonic strategies, including using surface phonon-polariton modes, have enabled anomalous angular ‘beaming’ of thermal radiation, albeit only at narrow ranges of wavelengths.
However, thermal radiation is inherently a broadband phenomenon. We currently lack the ability to constrain broad-spectrum thermal emission over a narrow range of angles of incidence, but consistently over a broad range of wavelengths. This form of broadband thermal beaming would be a fundamentally enabling capability for a range of applications, including infrared imaging and camouflage, thermophotovoltaics and radiative cooling.

Here, we employ multiple epsilon-near-zero (ENZ) materials in a layered configuration to realize a broadband angularly selective thermal emitter. ENZ materials can fulfill high absorption and emission of incident light at wavelengths where the epsilon is near zero. Aluminum oxide (Al2O3), Silicon monoxide (SiO) and Silica (SiO2) are all polariton materials with different ENZ wavelength. When combining them on top of each other into a multilayer thin film structure, we can obtain broadband near-blackbody emission from 7 to 11µm at a certain range of angles of incidence in the p polarization. We demonstrate this broadband angularly selective thermal emitter through theory, simulations, and an experimentally fabricated structure.

By employing transfer matrix method, we analytically solve the dispersion relation of this multilayer thin film structure and able to observe the EM field using the simulation tool. Following that, experimental results are compared with the analytical models with excellent agreement. The ENZ multilayer stack was coated on a Φ=100mm wafer via electrical beam evaporation method on CHA MARK 40. First, a 100nm Aluminum layer was deposited on the silicon wafer and then with 200nm Al2O3, 300nm SiO and 100nm SiO2 on top of each other. Then the sample was characterized by a Fourier-transform infrared spectroscopy (FTIR)-Jacob 6100. The strongest emission occurs at an AOI around θ = 70° and can be tuned from 65°to 80° by just varying the thickness of the layers. Outside of this AOI range the multilayer film is highly reflective which allows a switch between emission and reflection mode by changing the AOI. The materials used and structure designed in our research are cheap and easy to fabricate and fully compatible with wafer-scale manufacturing. Overall, this thin film based ENZ approach opens a path towards broadband thermal beaming and angular selectivity at low cost, at large scale and with simple structures.

Scalable Fabrication of Radiative Cooling Paint Yuan Yang and Jyotirmoy Mandal; Columbia University, United States

Radiative cooling is an attractive method to save energy usage for terrestrial entities, such as buildings and vehicles. To achieve efficient radiative cooling, high solar reflectance and high thermal emittance are needed. In this talk I will present out recent results on developing porous polymer paint for achieving high-performance radiative cooling. Strong sunlight reflectance at the polymer/air interface leads to solar reflectance of 96-99.6% and thermal emittance of 0.97. Sub-ambient cooling of 6 oC is achieved under strong sunlight. Such paint can also be prepared in scalable fashion and applied by wide range of surface with irregular shapes. Moreover, we have achieved dynamic switching inside by wetting/dewetting the porous film by liquid. A bilayer design is also developed for colored cooling paint, which shows 10-30% higher reflectance in the infrared part of solar spectrum.

R2R-UV Nanoimprinting for Large-Area Fabrication of Freeform Micro-Optical Components Barbara Stadlober, Stephan Rutloff, Johannes Götz, Dieter Nees, Ladislav Kuna, Ursula Palfinger, Anja Haase, Martin Smolka, Jan Hesse, Claude Leiner and Christian Sommer; Joanneum Research, Austria

Recently, R2R-UV nanoimprinting has proven to be very useful and unrivalled for the large-area fabrication of high-resolution, hierarchical structures at reasonable throughput deployed for mechanically flexible and lightweight functional surfaces in bionic applications like drag-reducing films or transparent conductive electrodes [1], [2].
Here we report on the deployment of our UV-Nanoimprinting pilot line for the manufacturing and upscaling of optical components in lighting and microfluidic applications. This pilot line covers all steps needed for upscaling, namely design & simulation, origination via maskless laser lithography, tooling via Step & Repeat UV-NIL and large area replication via R2R UV-nanoimprinting.

One key prerequisite for the versatile deployment of UV-nanoimprinting is the adjustability of the imprint resin towards the targeted application scenario. It should be tuneable in terms of elasticity and surface tension to account for easy demoulding and for low (water-repellent) as well as high (water-wicking) energy surfaces and it should have low enough viscosity to allow for large-area coating. Special requirements for the channel forming resin in microfluidics are a sufficiently high surface energy to allow for a fast and long distance filling of analytes, the ability to be bio-functionalized and low cytotoxicity. For optical polymer components, the tuneability of the refractive index is important as well. Another key aspect is the seamless tiling of master structures via Step & Repeat UV nanoimprinting on PET sheets to form large-area flexible imprint stamps for readily mounting around the imprint roller.

On this base, we R2R-fabricated complex freeform microoptical element (FFMOE) designs with small height on polymer films that enable a tailored redirection of light from discrete LED sources. These films enabled the generation of ultra-thin direct-lit luminaires with very homogeneous irradiance over a defined area shape [3]. FFMOE-covered films were also applied for light management in wall-wash luminaires. Finally, we used FFMOEs to improve the outcoupling of the chemiluminescence signal in \textit{in-vitro} diagnostic chips for the detection of diverse pathogens. The biosensor signal was increased by a factor of ~1.7 as tested in a portable read-out device of a commercial chip testing platform.

Polymer Blend Lithography—Bioinspired Scalable Fabrication of Disordered Photonic Nanostructures for Biosensing
Radwanul H. Siddique$^1\text{,2}$, Vinayak Narasimhan$^1$, Shailabh Kumar$^1$ and Hyuck Choo$^1\text{,2}$; $^1$California Institute of Technology, United States; $^2$Samsung Advanced Institute of Technology, Korea (the Republic of)

Millions of years of evolution in the biological world has developed a plethora of micro- and nanoscopic photonic structures that are frequently superior to synthetic analogs. These biophotonic materials show interesting novel and tunable unforeseen properties with deliberately introduced disorder in their respective geometries and compositions$^1$. Over the last decade, photonic materials with tailored -i.e. with deliberately introduced- structural disorder have also attracted considerable interest in various optical applications due to their extended spectral and angular range of effectiveness$^2$. Most bio-inspired nanostructured devices or optical metamaterials designed to date have been demonstrated at small-scales using expensive top-down techniques. However, biological structure formation in nature utilizes several bottom-up self-assembly approaches for manufacturing hierarchical mesoscopic nanostructures (100 – 550 nm) with immense diversity. Despite recent efforts aimed at increasing top-down fabrication writing speed, alternative routes based on self-assembly still possess major advantages for industrial implementation of disordered structures as they allow rapid processing over large areas (>cm$^2$).

In this communication, we show that up-scalable polymer blend lithography technique can be used as a versatile platform for fabricating 2D planar, disordered nanostructures that can be exploited in both top-down and bottom-up strategies. Polymer blend lithography utilizes the polymer-phase separation process following nature’s way of forming nanostructures. The tailored disorder is achieved here by adjusting the process parameters (polymer blend composition and deposition conditions), enabling us to tune the morphology and the spatial distribution of the nanostructures produced, and in turn their light management properties.

First, we use our approach to pattern a resist etching mask, employed for transferring disordered nanopillars by dry etching (top-down route) onto a Fabry-Perot-resonator-based intraocular pressure (IOP) sensor for glaucoma management$^3$. The nanostructure integration onto the IOP sensor led to a 2.5-fold improvement in readout angle allowing easy handheld monitoring and in a one-month in vivo study conducted in rabbits, showed a 3-fold reduction in IOP error and 12-fold reduction in tissue encapsulation and inflammation, compared to an IOP sensor without nanostructures. Second, we demonstrate that similar structures can serve as a template in a bottom-up configuration, whereby aluminum thin film is directly deposited into the disordered nanoholes to form scalable plasmonic metasurfaces$^4$. These metasurfaces generate hybrid multipolar lossless plasmonic modes resulting in a broadband fluorescence-enhancement factor above 1000 for visible wavelengths with respect to glass chips commonly used in bioassays. Using the metasurface and a multiplexing technique involving three visible wavelengths, we successfully detected three biomarkers, insulin, vascular endothelial growth factor, and thrombin relevant to diabetes, ocular and cardiovascular diseases, respectively, in a single 10-μL droplet containing only
1 femtomole of each biomarker.

Direct Optical Lithography of Transparent Metal Oxide Nanomaterials for Optical and Optoelectronic Applications Jia-Ahn Pan1, Yuanyuan Wang1,2 and Dmitri V. Talapin1; 1University of Chicago, United States; 2Nanjing University, China

Colloidal nanoparticles have been established as a diverse class of material with many interesting and useful properties. However, their practical application often requires some form of patterning procedure such as photolithography, ink-jet printing and nanoimprint lithography. Direct optical lithography of functional inorganic nanomaterials (DOLFIN) is a solution-processed additive patterning technique that utilizes a photosensitive colloidal nanomaterial ink. Here we engineer ligand-colloid interactions to be optically sensitive, allowing us to achieve micron-resolution patterning of metal oxide nanomaterials. Using this approach, we demonstrate the facile lithography of thick (>500 nm) metal oxide structures, which have a high-refractive index (n > 1.8) and are highly transparent. As a proof of concept, we manufacture diffractive optical elements (e.g. gratings) to show that significant phase modulation of light is attainable. Unlike polymer-based optical elements, our optical devices are more robust and can tolerate high temperatures due to its primarily inorganic content. We also show the patterning of conductive colloidal oxide nanomaterials (e.g. ITO), which facilitates its implementation as a transparent conductive electrode. These advances aim to facilitate the integration of colloidal nanomaterials in real-world applications.

Atmospheric Pressure Plasma Synthesis and Aerodynamic Focusing of Silicon Nanoparticles for Additive Manufacturing Alexander Ho and Rebecca J. Anthony; Michigan State University, United States

The use of nonthermal plasmas has emerged as an effective method for the synthesis of high-quality nanoparticles. Extensive study of nonthermal plasma reactors under low pressure conditions has been conducted which has yielded systems capable of producing nanoparticles with size tunable properties. Miniaturization to a microscale reactor allows for effective operation of a RF nonthermal plasma reactor at atmospheric pressure. The reduced scale of the reactor also provides the opportunity for combining nanoparticle synthesis and deposition into a single system for manufacturing with nanoparticles. Presented here is our work on the additive manufacturing of silicon nanoparticles synthesized at atmospheric pressure with a nonthermal plasma. The plasma was generated with a 13.56 MHz RF power supply inside a glass capillary tube between two external ring electrodes. A silane precursor gas together with an argon background gas were flown to the reactor for the synthesis of silicon nanoparticles. The reactor was attached to a motorized system responsible for controlled deposition of the nanoparticles in predetermined geometries. TEM and XRD has shown that control between crystalline and amorphous particles can be achieved by controlling the applied power. Control over the nanoparticle size has also been demonstrated by varying the overall gas flow rate to the reactor. In efforts to increase the capability of this system for manufacturing processes we have investigated methods to control the deposition resolution. Spreading of the particles after exiting the reactor leads to wide linewidths which can limit the performance of this tool for manufacturing. Manipulation of the gas flow with aerodynamic lenses allows for reduced expansion of the particles and improved resolution. With this method we have been
able to reduce the spot size to 1.3 times the size of the reactor tube outlet diameter.

Additive Manufacturing of 3D Microscale Gradient Refractive Index Polymer Optics in Porous Silicon Paul V. Braun; University of Illinois at Urbana Champaign, United States

Here we present Subsurface Controllable Refractive Index via laser Beam Exposure (SCRIBE), a novel lithographic approach to fabricate polymer optical elements with arbitrary 3D index profiles at precise locations within a mesoporous silicon scaffold. We achieve a broad index range at 633 nm of 1.55 to 2.01 by adjusting the laser exposure. We demonstrate a microscale doublet objective that focuses visible light to $750 \pm 20 \mu m$ and a smallest-on-record 15-μm diameter spherical Luneburg (gradient index) lens. Finally, we realize integrated photonic devices that use 3D waveguides to couple light vertically from the surface to a horizontally oriented subsurface all-pass microring ($Q = 10,000$). These demonstrations present a new paradigm for lithographically-aligned 3D fabrication of polymer micro-optics and photonic systems.

Advances in Additive Manufacturing and Architected Materials for Micro and Nanoscale 3D Structures Christopher M. Spadaccini; Lawrence Livermore National Laboratory, United States

Material properties are governed by the chemical composition and spatial arrangement of constituent elements at multiple length-scales. This fundamentally limits material properties with respect to each other creating trade-offs when selecting materials for specific applications. For example, strength and density are inherently linked so that, in general, the more dense the material, the stronger it is in bulk form. We are combining inverse design methods such as topology optimization, with advanced additive micro- and nanomanufacturing techniques to create new material systems with previously unachievable property combinations – architected mechanical metamaterials. The performance of these materials is fundamentally controlled by geometry at multiple length-scales, from the nano- to the macroscale, rather than chemical composition alone. We have demonstrated designer properties of these mechanical metamaterials in polymers, metals, ceramics and combinations thereof. Properties include ultra-stiff lightweight materials, negative stiffness, and negative thermal expansion to name a few, as well as functional properties such electrical, optical, and even chemical responses. Recently, we have also demonstrated metamaterials which respond to external stimuli; namely magnetic fields. We have primarily utilized our custom developed additive properties of these mechanical metamaterials in polymers, metals, ceramics and combinations thereof. Properties include ultra-stiff lightweight materials, negative stiffness, and negative thermal expansion to name a few, as well as functional properties such electrical, optical, and even chemical responses. Recently, we have also demonstrated metamaterials which respond to external stimuli; namely magnetic fields. We have primarily utilized our custom developed additive micro- and nano-additive manufacturing techniques to create these structures and materials. These include projection microstereolithography (PuSL), direct ink writing (DIW), and electrophoretic deposition (EPD). I will also touch on new advanced concepts such as volumetric additive manufacturing (VAM), computed axial lithography (CAL), parallel two-photon polymerization, and diode-based additive manufacturing (DiAM) as well as new materials including graphene aerogel and nanoporous gold.

Lawrence Livermore National Laboratory is operated by Lawrence Livermore National Security, LLC, for the U.S. Department of Energy, National Nuclear Security Administration under Contract DE-AC52-07NA27344.

5:00 AM *S.EL05.04.01
Plasmonic Material Platforms for Tunable Nanophotonic Devices Alexandra Boltasseva, Deesa Shah, Soham Saha and Vladimir Shalaev; Purdue University, United States

In the field of tunable optics, transparent conducting oxides (TCOs) have heralded a new generation of all-optical switches. The extraordinary enhancement of reflection modulation by epsilon-near-zero materials has paved the way for lithography-free all-optical switches in the telecommunication regime. We have demonstrated reflection modulation of up to 40% with optical pump-powers in the millijoules/cm² range, utilizing planar films of aluminum-doped zinc oxide [1]. Furthermore, we have demonstrated the addition and subtraction of the optically induced nonlinearities utilizing simultaneous intraband and
interband pumping, performing operations in the sub-picosecond timescale [2]. We have also demonstrated low power optical switching with cadmium oxide in the mid-infrared regime, where the free-carrier-induced changes in the refractive index can achieve reflection modulation up to 135% with pump-powers as low as 1.3 mJ/cm². Finally, we have brought together low-loss dielectrics such as undoped ZnO and metals such as titanium nitride in hybrid metal-dielectric resonators to demonstrate broadband optical switching in the near-infrared wavelengths, achieving reflection modulation over 50% with relaxation times in the order of 2 picoseconds [3].

Transdimensional materials (TDMs) are yet another material platform gaining traction for dynamically tunable nanophotonic devices. The optical responses of atomically thin plasmonic films can be engineered by precise control of their structural and compositional parameters. This unique tailorability establishes TDMs as an attractive material for the design of tailorable and dynamically switchable metasurfaces [4]. Transition metal nitrides (TMNs) are ideal materials to investigate the tailorable properties of plasmonic films with thicknesses of just a few monolayers. The optical and electrical properties of smooth, epitaxial, TiN ranging from 2 to 10 nm have been characterized by ellipsometry and Hall measurements [5]. Although the metallicity decreases in smaller thicknesses, the thinnest film (2 nm) still retains a carrier density of 10²²cm⁻³ and is plasmonic at visible wavelengths. We have also explored the role of oxidation, and strain through first principles density functional (DFT) calculations, providing a way to tailor the optical response [6]. Gate dependent Hall measurements on a 1 nm film also reveals extreme tunability of the carrier concentration (up to 8.5%).

TCOs and TMNs have been reported as promising material platforms for actively tunablenanophotonic devices. While our results have long established TCOs as a major player for ultrafast, switchable metasurfaces, our progress in developing tunable atomically thin TiN demonstrates the potential for tunable plasmonics based on TDMs.

**Transdimensional Photonic Lattices of High-Index Nanoantennas and Layered Materials**

Fatih Ince, Viktoriia Babicheva and Soham Saha; University of New Mexico, United States

Planar optical elements with efficient light control at the nanoscale can be designed based on transdimensional photonic lattices that operate in the translational regime between two and three dimensions. Such transdimensional lattices include 3D-engineered nanoantennas supporting multipole Mie resonances and arranged in the 2D arrays to harness collective effects in the nanostructure [1]. Optical antennas made out of van der Waals material with naturally-occurring hyperbolic dispersion is a promising alternative to plasmonic and high-refractive-index dielectric structures in the practical realization of nanoscale photonic elements. The antenna made out of hexagonal boron nitride (hBN) possesses different multipole resonances enabled by the supporting high-k modes and their reflection from the antenna boundaries. The full range of the resonances is demonstrated for the hBN cubic antenna, a decrease of reflection from the array, and highly directional resonant scattering from antennas pairs. We show that transdimensional lattices consisting of resonant hBN antennas in the engineered periodic arrays have great potential to serve as functional elements in ultra-thin optical components and photonic devices.

We show that a periodic array of particles with a large imaginary part of their permittivity (LIPP) can support well-defined modes localized within the particle, with the spectral position of the modes mainly defined by the array period. It has been known for a long time that a non-zero imaginary part of the permittivity enables propagating surface modes at the interface of materials with positive permittivities, known as Zenneck modes. Recently, it has been demonstrated that transition metal dichalcogenides (TMDC) layers support different kinds of propagating Zenneck waves defined by the layer thickness and interfaces with air and substrate [2]. Here, we show that localized Zenneck modes are possible on subwavelength particles and that the particles can serve as antennas for direction light scattering, reflection suppression, and Kerker-effect applications. To illustrate a possibility to control light, we show that simultaneous excitation of the several particle multipole resonances (electric dipole and quadrupole) allows for achieving significant reflection suppression and observation of the generalized lattice Kerker effect [3]. Materials with LIPP are common in nature, including TMDCs and lossy metals, titanium, chromium, and others.
Acknowledgment. This material is based upon work supported by the Air Force Office of Scientific Research under Grant No. FA9550-19-1-0032.

Flat Optics—From Metasurfaces to New Cameras Federico Capasso; Harvard University, United States

Metasurfaces enable arbitrary control of the wavefront of light by locally manipulating amplitude, phase and polarization.\textsuperscript{1,2} I will present advances in components (metalenses and structurally birefringent phase plates) that have enabled the realization of high-performance polarization sensitive cameras and depth cameras. Recent developments have enabled the practical realization of optical elements in which the polarization of light may vary spatially.\textsuperscript{3} We recently presented an extension of Fourier optics—matrix Fourier optics—for understanding these devices and apply it to the design and realization of metasurface gratings implementing arbitrary, parallel polarization analysis.\textsuperscript{4} We show how these gratings enable a compact, full-Stokes polarization camera without standard polarization optics. Our single-shot polarization camera requires no moving parts, specially patterned pixels, or conventional polarization optics and may enable the widespread adoption of polarization imaging in machine vision, remote sensing, and other areas.\textsuperscript{5} We also have demonstrated a compact depth sensor that is inspired by the jumping spider.\textsuperscript{5} It combines novel metalenses, which modifies the phase of incident light at a subwavelength scale, with efficient computations to measure depth from image defocus. The sensor uses a metalens to split the light that passes through an aperture, and concurrently form two differently-defocused images at distinct regions of a single planar photosensor. We have demonstrated a system that deploys a 3mm-diameter metalens to measure depth over a 10cm distance range, using fewer than 700 floating point operations per output pixel, at video rates.\textsuperscript{5} Compared with previous passive depth sensors, our metalens depth sensor is compact, single-shot and requires a small amount of computation. This integration of nano-photonics and efficient computation brings artificial depth sensing closer to being feasible on millimeter-scale, micro-Watts platforms such as microrobots and micro-sensor networks.

Nanoprinting-Enabled Scalable Metasurfaces for Hyperlens, Metalens and Metahologram in the Visible Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Metamaterials consist of subwavelength structured units have demonstrated many promising applications in optics and photonics. However, practical applications of metamaterials have been prohibited by low productivity of conventional fabrication methods. Electron beam lithography has been widely used to realize metamaterials which operate in the visible because necessary critical dimension of the unit structure is smaller than the diffraction limit of typical photolithography. Most metamaterials have been demonstrated by electron beam lithography whereas it is not suitable for practical uses due to high cost and ridiculously low throughput. Here, we demonstrate large scale metamaterials operating in the visible based on nanoprintprint lithography (NIL) which allows rapid replication of nanostructures. An efficient and convenient new imaging device made of a wafer-scale array of spherical hyperlenses are demonstrated based on NIL. Hyperlens is a metamaterial based imaging device whose super-resolving power comes from the hyperbolic dispersion relation in anisotropic media, which enables the sub-diffraction-limited objects to be resolved in the far-field \cite{1}. However, hyperlens suffered from the extreme difficulties in fabrication process and objects placement which restrict the practical uses of the hyperlens devices. To overcome this limitations, direct pattern transfer techniques using NIL is applied as implementing large-scale hyperlens arrays is desirable \cite{2}. We demonstrate 4-inch wafer-scale array of hyperlenses using NIL and it is integrated into a conventional microscopy system for imaging hippocampal neurons with resolution down to 151 nm, much smaller than the diffraction limit of conventional imaging systems \cite{3}. We also demonstrate one-step fabrication method based on NIL to realize dielectric metasurfaces \cite{4,5}. Despite many advantages of conventional NIL, it is still inefficient to fabricate dielectric metasurfaces because conventional NIL requires
secondary operations such as thin film deposition and etching, which reduce productivity, substrate compatibility and cost competitiveness of NIL. To overcome the limitations, we develop nanoparticle composite (NPC) that consists of high-index nanoparticle inclusions in UV-curable resin. The refractive index of the NPC can be controlled by the volume fraction of the inclusion. Since the transferred pattern by the NPC can itself work as metasurfaces due to sufficiently high refractive index of the NPC, dielectric metasurfaces can be realized by a single step of NIL without any secondary operations. Experimental demonstration of metahologram and metalens verify the feasibility of our method, thereby we believe our approach provides a promising opportunity to manufacture metamaterials for practical uses.

Scalable Nanophotonic Methods to Identify Pathogens and Their Interactions Jennifer A. Dionne; Stanford University, United States

Bacterial infections such as pneumonia, staphylococcus, and streptococcus do not often make headlines, yet they are responsible for more deaths than AIDS and many cancers and rank among the most expensive medical conditions to treat. Bacterial identification and antibiotic susceptibility testing can span days, even in state-of-the-art laboratories using the most advanced technologies, delaying the use of targeted antibiotics and accelerating the spread of infectious disease. Here, we present development of scalable, clinically-compatible nanophotonic imaging tools for bacterial pathogen identification, their antibiotic susceptibility, and their interactions with immune cells. First, we combine Raman spectroscopy and deep learning to accurately classify bacteria by both species and antibiotic resistance in a single step. We design a convolutional neural network (CNN) for spectral data and train it to identify 30 of the most common bacterial strains from single-cell Raman spectra, achieving antibiotic treatment identification accuracies exceeding 99% and species identification accuracies similar to leading mass spectrometry identification techniques. Our combined Raman-CNN system represents a proof-of-concept for rapid, culture-free identification of bacterial isolates and antibiotic resistance. Then, we introduce a new class of in vivo optical probes to monitor the forces between pathogens and immune cells with high spatial and temporal resolution. Our design is based on upconverting nanoparticles that, when excited in the near-infrared, emit light of a different color and intensity in response to nano- to-microNewton forces. The nanoparticles are sub-30nm in size, do not bleach or photobleach, and can enable deep tissue imaging with minimal tissue autofluorescence. We present the design, synthesis, and characterization of these nanoparticles both in vitro and in vivo; both chronic and acute cytotoxicity assays are used to confirm biocompatibility. Long-term, our Raman-CNN platform and optical-force sensors could enable several advances for personalized medicine and mitigation of infectious disease, allowing patients to receive the appropriate drug at the appropriate dosage and for the appropriate duration.

Reuse of Si Substrates for Selective-Area Epitaxy of Large-Area III-V Nanowire Array-Based Flexible Infrared Photodetectors Alireza Abrand, Mohadeseh A. Baboli, Thomas S. Wilhelm and Parsian K. Mohseni; Rochester Institute of Technology, United States

During the last decade, III-V semiconductor nanowires (NWs) have received great research interest due to their promising potential for next-generation electronic, optoelectronic, and photonic devices. One of the main challenges for epitaxially-grown III-V NWs, however, is their high manufacturing cost, which can be divided to two individual categories: (1) the cost of starting III-V substrates, and (2) the cost of pre-epitaxy fabrication associated with substrate patterning. Large-scale integration of III-V NW-based technologies requires novel nanofabrication strategies that mitigate both cost streams. Wafer costs can be substantially reduced simply through growth of III-V NWs on foreign substrates such as silicon or graphene, instead of on bulk III-V wafers. One strategy for simultaneously reducing fabrication complexity and pre-growth processing costs is to reuse Si substrates with existing predefined growth masks for selective-area epitaxy (SAE) of III-V NW arrays. Here, we present wafer-scale, bottom-up SAE growth of InAs NW arrays and fabrication of flexible NW-based infrared (IR) photodetectors realized through delamination of embedded NW arrays and reuse of Si substrates with predefined growth masks. Silicon (111) substrates are patterned by conventional photolithography to obtain pores with 0.5 µm diameters and 1 µm pitch in SiO2 growth masks of 55 nm thickness. Next, InAs NW arrays are grown via the SAE approach using
metalorganic chemical vapor deposition (MOCVD). Trimethyl-indium (TMIn) and arsine (AsH3) were used as precursor gases for the supply of In and As growth species, respectively, at a set-point growth temperature of 700 °C. A two-step growth technique is introduced, whereby a separate nucleation step using a TMIn flow rate of 16 μmol/min precedes a NW growth step at a TMIn flow rate of 0.77 μmol/min. This procedure is necessary for optimization of pore occupation toward a global NW yield of >85%, with NW aspect ratios of ~15. The InAs NW arrays are embedded in various polymer membranes and mechanically delaminated from their growth substrates, then bonded to carrier substrates for subsequent device fabrication. The polymer-embedded NW array exfoliation process leaves NW bases with heights of ~50 nm below the fracture plane attached to the growth surface. Consequently, five different substrates restoration processes are investigated prior to substrate-reuse. It is observed that the best results for re-growth of daughter generation InAs NW arrays on reused Si substrates can be realized when no additional wet etching, chemical treatment, or mechanical polishing steps are introduced between subsequent re-growth runs, as the remaining NW bases serve as SAE growth sites. Direct re-growth on reused Si substrates results in vertical extension of existing NW bases and growth of InAs NWs with aspect ratios >80 under the same growth conditions as the primary run with comparable global NW yield. For fabrication of flexible IR photodetectors using both primary and subsequent generation InAs NW arrays, a unique process flow is reported, which enables NW transfer yields of ~100% and preserves the original position and orientation of as-grown NWs. This work demonstrates that multiple generations of InAs NW-based devices can be fabricated through reuse of a single, templated Si substrate, without introduction of intermediate substrate restoration processes such as wet etching or chemical mechanical polishing. This approach can serve as an effective strategy toward growth and fabrication of large-area, high-efficiency, low-cost, flexible, and wearable device applications in III-V nanoelectronics, optoelectronics, and photovoltaics.

Large-Scale Thermoregulatory Material Inspired by Cephalopods Mohsin Ali Badshah1, Erica M. Leung1, Christopher Moore2, Panyiming Liu1, Marlon Pinedo1 and Alon Gorodetsky1,1; 1University of California, Irvine, United States; 2Chapman University, United States

Low-cost, large-area thermal management is desirable for the operation of many modern technologies including smart clothing, electronic circuits, building environments, and outdoor equipment to control heat flow. Inspired by the space blanket and the dynamic skin of cephalopods, we have demonstrated a large-area, highly uniform, low-cost nanostructured material with tunable thermoregulatory and infrared properties. We have implemented scalable nanofabrication processes to achieve a material with an area > 500 cm², a > 40 % change in infrared transmittance and reflectance, and a dynamic environmental setpoint temperature window of ~ 8 °C. Due to characteristics of scalability and associated figures of merit, our material affords new scientific and technological opportunities not only for adaptive optics and thermoregulation but also for any platform that would benefit from dynamic control of infrared radiation and heat.

Effect of Defective Microstructure on the Reflective Structural Color of Self-Assembled Colloidal Crystals Tianyu Liu, Bryan VanSaders, Sharon C. Glotzer and Michael J. Solomon; University of Michigan–Ann Arbor, United States

We report the relationship between measures of the crystal quality of self-assembled colloidal crystal films and the intensity of their structural color. Structural color arises from geometric diffraction; it has potential applications in optical materials because it is more resistant to environmental degradation than coloration mechanisms that are of chemical origin. Structural color can be produced from self-assembled films of colloidal particles. To study the connection between crystal film quality and structural color intensity, we investigate the peak intensity and peak width of structural color reflection spectra as a function of defect density, film thickness and impurity concentration using a combined experimental and computational approach. Polystyrene microspheres are self-assembled into defect-laden colloidal crystals via solvent evaporation. Colloidal crystal growth via sedimentation is simulated with molecular dynamics and the reflection spectrum of simulated crystals is calculated using the finite-difference time-domain method. We examine the impact of several commonly observed defect types (vacancies, stacking fault tetrahedra, planar faults, and microcracks) on structural color peak intensity. We find that the
reduction in peak intensity scales with increased defect density; stacking fault tetrahedra have a particularly detrimental effect. The thickness profiles are characterized by cross-sectional scanning electron microscopy and profilometry. The reflective spectral response of the colloidal crystals is measured with a white light spectrophotometer. Our results show that reflectance of structural color increases as a function of the crystal thickness, until a plateau is reached at thicknesses greater than about 10 μm. The plateau reflection is 83.2% ± 2.8%; this value is significantly less than the 100% reflectivity predicted for a fully crystalline material; the difference is caused by defects present in the experimental crystal structures. Finally, we manipulate the defect structures of colloidal crystals by introducing differently sized particles that function as impurities. As the concentration of the impurity is increased, the measured intensity of structural color reflection decreases by amounts that we correlate with the observed microstructure. These findings can guide the design of optical materials which tune the intensity of structural color.

Processes for Hyper-Scaling Electronic and Photonic Device Manufacturing Michael A. Filler; Georgia Institute of Technology, United States

This talk will overview our work toward two general-purpose nanomanufacturing processes for the hyper-scaling of semiconductor nanowire-based electronic and photonic devices: SCALES and Geode. The SCALES process (Selective CoAxial Lithography via Etching of Surfaces) leverages chemical differences between compositionally distinct nanowire segments to yield polymer surface masks with nanoscale precision. The Geode process utilizes an unconventional substrate – the interior surface of hollow silica microcapsules lined with the metal nanoparticles that seed nanowire growth – to increase the throughput of nanowire production by orders-of-magnitude. These processes are part of an emerging platform for the massively scalable fabrication and deployment of high-performance semiconductor materials and devices for applications in electronics and photonics.

Scalable Self-Assembly of Nanoparticles into 3D Hierarchal Microspheres Shanying Cui, Xin Guan, Christopher Roper and Adam Gross; HRL Laboratories, United States

Sprayable coatings for frequency-selective reflectors or absorbers in the visible and infrared are enabled by heterogeneous and hierarchal microspheres, such as high index contrast core-shell structures or spherical Bragg stacks. However, such nano-to micron-scale architecture can be difficult to achieve for a wide array of visible and infrared transparent materials. In this talk, we describe a fast, scalable, and material-agnostic process to make heterogeneous structures for omnidirectional IR reflection and scattering. We apply our self-assembly method to multiple nanoparticle compositions (SiO2, TiO2, LiYF4, InP, PbSe) and nanoparticle shapes (spheres, pyramids, hexagonal prisms), yielding smooth and uniform microspheres 10-100 micrometers in diameter. The microspheres have a high nanoparticle packing density and do not contain any IR-active organic ligands or binders. Next, we show control of the microsphere internal structure by co-assembling two materials, yielding structures ranging from core-shell to a periodic mixture. Diffuse reflectance measurements of the assembled microspheres show that MWIR scattering is enhanced for materials with differing refractive indexes (Δn > 1). Our process is capable of making scattering microspheres at a rate of >0.1 grams / minute, thereby leveraging existing nanoparticle capabilities and unique properties and scaling them into macroscale coatings (m² surfaces) for optical and photonics applications.

Mechanochemical Conversion Kinetics of Red Phosphorus to Black Phosphorus for Optoelectronic Applications Samuel V. Pedersen1,2, Florent Muramutsa1, Joshua D. Wood1, Chad Husko1, David Estrada1,2 and Brian Jaques1,2; 1Boise State University, United States; 2Center for Advanced Energy Studies, United States; 3Wood Technical Consulting, United States; 4Iris Light Technologies, United States

With the promise of novel optoelectronic devices using black phosphorus (BP), there is a need for a large-scale synthesis method for BP compatible with on-chip integration. Herein, we attain large scale mechanochemical conversion of red phosphorus (RP) to black phosphorus (BP) via high energy ball milling. During the milling process, the collisions of hardened steel media rapidly compress amorphous RP into crystalline, orthorhombic BP flakes, with a conversion yield >95% for up to 5 g of bulk BP powder. Commercial scale-up of BP production can be extrapolated by empirically derived conversion kinetics from lab scale, high energy ball mills. BP’s milling conversion kinetics, as monitored via ex situ XRD,
shows a sigmoidal behavior best described by the Avrami rate model. For <60% conversion, BP is rapidly formed at the expense of RP following an autocatalytic behavior with induction times proportional to the milling intensity. At ≥60% conversion, milling conversion rate suddenly decreases, indicative of a growth mechanism change with presumably a higher activation energy, thereby requiring higher impact energies for complete conversion. Further, by comparing the specific milling dose, namely, the energy input required for the phase transformation to reach completion, versus the conversion progress, we can determine the optimum milling conditions. We therefore ascertain the BP specific milling dose (50 kJ/g) and minimum impact energy (25 mJ/impact), both necessary to scale up production and minimize the power consumed in a tumbler milling vessel. Finally, the as-synthesized BP powder exfoliates more readily than single crystal BP sources in solution, as revealed by concentrations obtained from UV-Vis absorption under the same exfoliation conditions. The milled, converted BP solution is roughly 6-fold the concentration of the single crystal solution. High energy ball milling is demonstrated as a large scale, viable synthesis route for BP.

Plasmonic Devices Based on Collapsible Nanofingers **Wei Wu**; University of Southern California, United States

Nano-gap structure has attracted great scientific interests. For example, plasmonic nanostructures with nano-gaps concentrate light to a small volume, which can lead to many potential applications. While it is theoretically predicted that the optimal plasmonic hot spot is a gap of less than 1 nanometer between two metallic particles, there is still no manufacturing technology to reliably fabricate it with high-precision and controllability at practical cost. In this work, we present a novel fabrication technique that combines both top-down and bottom-up process to produce large-area nanogap structures with atomic-precision gap size control. First, two layers of photoresist and one liftoff layer were spin-coated on substrates, then Nanoimprint (NIL)[1], Reactive Ion Etching (RIE) and Metal Deposition were utilized to achieve desired metal patterns. Afterwards, uncovered areas were etched by RIE to form high aspect ratio nanofingers and Atomic Layer Deposition was used to grow selected thin dielectric layer outside nanofingers. After dripping ethanol onto samples, high aspect ratio nanofingers would be driven to collapse by capillary force during ethanol evaporation. By manipulating nanofinger heights and dielectric thicknesses, gap size down to 0.8 nm can be precisely defined after finger collapsing and such structure can be utilized as an ideal platform to study the rich sciences of plasmon and quantum effect. For example, we experimentally demonstrated that tunneling barrier height across the gap can be adjusted by using appropriate gap spacer materials and gap sizes.[2] As a result, plasmonic enhancement can be strongly affected since the electron tunneling mechanism is the most essential part in determining the plasmonic enhancement factor. It was found that as the tunneling barrier height is decreased, the enhancement of electron tunneling manifests itself in a wider optimal gap, a redshift of the plasmon frequency with increasing gap size was also observed when the gaps narrowed to sub-5 nm range[2]. Moreover, many photonic applications have been studied and implemented intensively based on our controllable nanogap structures. Those include plasmonic enhanced fluorescence, single-molecule label-free sensing by SERS[3] and plasmonic enhanced photocatalysis.

Multi-Layered Nanoparticle Coatings with Tunable Refractive Index and Surface Roughness Deposited with Aerosol Impact Driven Assembly (AIDA) **Peter Firth**1,2, Zachary C. Holman2,1 and Shannon Poges1,2; 1Swift Coat, United States; 2Arizona State University, United States

The next generation of functional coatings will likely be composed of nanomaterials. At the laboratory scale nanomaterial-based coatings have shown the potential to improve performance and enable completely new functionality in applications like thermal barrier coatings on high-temperature parts, active layers in electronic devices, anti-reflective coatings for PV modules, or biocompatible coatings for medical applications. In all cases, these coatings should be able to be formed over large areas at commercial production rates and have a uniform and controllable thickness, and their constituent particles should retain their nano-properties. Present nanomaterial films developed in laboratories are often unable to be reproduced on a commercial scale; the manufacturing methods are inherently nanomaterial, substrate, and application specific. This specificity results in manufacturing processes that are expensive or offer limited utility. We propose an advanced nanomaterial film manufacturing technology based on Aerosol Impact Driven Assembly (AIDA) that overcomes these deficiencies. AIDA begins by aerosolizing a nanomaterial using any desired technique, from atomizing a nanoparticle-laden solution to feeding nanoparticle-precursor gas into a plasma. The aerosolized material is fed into the AIDA system, which consists of
two chambers separated by a slit-shaped nozzle, with the bottom chamber held under vacuum (< 1 Torr). The nanomaterial is accelerated to a velocity of several hundred meters/second as it and the aerosol background gas are forced through the nozzle, resulting in the formation of a curtain of nanoparticles directed into the downstream chamber. A substrate is passed through the curtain, and the nanomaterial collides with and adheres to the substrate, forming a thin coating. AIDA’s unique approach to film formation enables independent control over nearly every aspect of the coating’s morphology. As a dry spray technique, there are no inherent limitations on the thickness. Coatings ranging in thickness from a sub-monolayer to >1mm have been produced with dynamic deposition rates as high as 6 mm-m/min. By adjusting the particle impact velocity, the porosity of the coating can be controlled between 5% and 95%. This enables control over film properties like the refractive index, heat transfer coefficient, and dielectric constant. By changing the angle of impaction, the surface roughness of the film can be tuned between 0 nm and >100 nm allowing engineers to tune the effective surface energy of the coating. Combining this intimate control of film morphology with the wide range of nanomaterials compatible with AIDA allows engineers to produce complex, multi-layered, multi-component, and multi-functional films using a single platform.

As a case study, we will showcase an AIDA system capable of depositing on 14”x24” substrates that uses an in-situ non-thermal plasma reactor to synthesize metal-oxide nanoparticles (SiO$_2$, TiO$_2$, and ZnO) and produce a multi-layered coating that is simultaneously highly photocatalytic (self-cleaning) and anti-reflective for use in PV module glass. The composition of each layer will be tuned to maximize the photocatalytic self-cleaning effect. The thickness and refractive index of each layer will be precisely tuned to optimize its anti-reflective properties and provide a 3% transmittance gain compared to uncoated glass. The surface roughness of each layer will be tuned to promote adhesion and provide the desired water contact angle on the top surface to enhance self-cleaning.

7:15 AM S.EL05.05.08
Physically Assisted Chemical Assembly for Large-Area, Reproducible Near-Field Response Regina Ragan; University of California, Irvine, United States

Single molecule (SM) detection represents the ultimate limit of chemical detection. Over the years, many experimental techniques have emerged with this capacity. Yet, SM detection and imaging methods require large, reproducible spectral datasets in order to benefit from chemometric methods. We will present a scalable chemical assembly platform for plasmonic and metamaterial architectures that yield reproducible optical response. For example, surface enhanced Raman scattering spectroscopy (SERS), with extensive applications in biosensing, is demonstrated to be particularly promising because Raman active molecules can be identified without recognition elements and is capable of SM detection. Yet quantification at ultralow analyte concentrations requiring detection of SM events remains an ongoing challenge, with the few existing methods requiring carefully developed calibration curves that must be redeveloped for each analyte molecule. We will present work where we demonstrate that using 2-dimensional physically activated chemical (2PAC) self-assembly, we can achieve reproducible enhancement factors of 10$^9$ over 1 cm$^2$. 2PAC crosslinks nanoparticles into discrete assemblies with a small molecule linker, where the crosslinking reaction is driven by electrohydrodynamic flow at on a substrate surface. The hotspots observed in a 2PAC fabricated assembly have gap spacing is 0.9 nm, corresponding to the length of the chemical crosslinker. Large area SERS maps are acquired from these 2PAC assembled surfaces from analyte dissolved in water and even complex biological media.

One of the most important applications of contemporary machine learning, i.e., image analysis, has remained relatively untouched by the SERS community. We will show that a combination of large area and reproducible SERS substrates with a CNN model is used to address the long standing challenge in SERS: quantification of sub-nanomolar analyte concentrations. A convolutional neural network (CNN) model when applied to bundles of reliable SERS spectra yields a robust, facile method for concentration quantification down to 10 fM using SM detection events. The demonstrated limit of blank (LOB) is 1 fM for Rhodamine 800, with a limit of quantification (LOQ) of 10 fM. Furthermore, the model’s predicted concentrations have an average $r^2$ value of 0.958 over 6 orders of magnitude as determined by k-folds cross validation. A key advantage of the analysis is its compatibility with transfer learning, the use of large datasets to train a model and then generalize this pretrained model to new molecules quickly with significantly smaller datasets. The uniformity of enhancement factor is essential for our approach, as large variance in the dataset not only increases the variance in predictions, but also requires more data for convergence and prevents a transfer learning approach. Generalization of the CNN model to other analytes using transfer learning is demonstrated with methylene blue. Transfer learning achieves good results with as few as 50 8x8 pixel maps. Thus entire datasets are acquired quickly, requiring just 5.3 minutes of total laser exposure time per concentration to train a robust model that is much faster and more scalable than required for building SM concentration regression models. This demonstrates a proof of concept for hyperspectral CNN image analysis of SERS, which could be broadly applicable within SERS, especially in the biological setting where classification of images could improve analysis of bacteria that are already imaged with SERS. We will also present results showing this approach is able to differentiate susceptible and
resistant bacterial strains for rapid antimicrobial susceptibility tests.

Periodic Self-Assembled Nanopatterns with Spacings Approaching Visible Wavelengths Using Block Copolymer/Homopolymer Blends
Gregory S. Doerk, Ruipeng Li, Masafumi Fukuto and Kevin Yager; Brookhaven National Laboratory, United States

Bottom up self-assembly of block copolymers (BCPs) offers a scalable, economical alternative to lithography for producing large area, highly uniform nanopatterns required for engineering materials with tailored light-matter interactions. At their typical scales (~20-50 nm feature spacing), thin film BCP nanopatterns may be used to generate deep subwavelength like nanotextures that reduce visible reflectance to < 1% [1,2], or nanoholes that improve light trapping in photovoltaics at carrier selective rear contacts [3]. Nevertheless a greater latitude for optical property engineering would be possible using self-assembled BCP patterns at length scales commensurate with visible wavelengths of light in order to exploit optical diffraction and resonance effects. This is prohibited by exponentially slower ordering kinetics in the ultrahigh higher molecular weight BCPs (> 1000 kg/mol) required for this scaling. Here we report dramatically accelerated ordering afforded by blending in very low molecular weight (~3 kg/mol) homopolymer plasticizers. These formulations enable a 10× reduction in the time required to achieve ordered nanopatterns with periods > 200 nm. Subsequent reactive ion etching demonstrates that these nanopatterns are readily transferrable to other materials. Exemplar applications such as structural colors made possible using these self-assembled patterns will be described.

Random Nanoparticle Films for Efficient Radiative Emission and Daytime Cooling Based on a Generalized Effective Medium Theory
Parker Wray, Magel Su and Harry A. Atwater; California Institute of Technology, United States

We investigate nanoparticle film structures as components for daytime radiative cooling, using a generalized effective medium theory which is capable of recovering the Maxwell-Garnett, Bruggeman, and Coherent Potential mixing formulas. We show that, in all cases, nanoparticle fill fraction is a degree of freedom which can be used to improve free space coupling and spectrally tune the emissivity and absorptivity curves so as to optimize radiative emission within the atmospheric transmission window (8 – 14 μm). Based on this theory, we design different radiative cooling structures from composites of SiO2 and Si3N4 nanoparticle films, which were chosen as the example emissive materials because of their strong absorption peaks within the atmospheric transmission window. Our results show that two-layer nanoparticle films of these materials outperform all thin-film analogs and are sufficient to achieve cooling performances comparable to leading reports in literature. Further research will explore how the low thermal conductivity of nanoparticle films could be used to further enhance daytime radiative cooling performance. This research supports the idea that simple nanoparticle films couple provide a viable method for designing radiative cooling structures, provided scalable methods are identified for nanoparticle fabrication.

Scalable, Multi-Functional Covert Polarization Display with Colorimetric Detection
Joo Hwan Ko, Young Jin Yoo and Young Min Song; Gwangju Institute of Science and Engineering, Korea (the Republic of)
The history of coloration has been proceeded by trials and development of many technologies for selectively splitting the light. Structural coloration, among them, has grown up as a potential candidate alternating traditional pigments/dyes coloration since their great durability, sustainable production, and fine color tuning by controlling materials and dimension. As this property, structural color facilitates the creation of security features for anti-counterfeiting. However, conventionally, most of them have used metal/dielectric materials to make a resonating system at a specific wavelength and polarization condition which demands complex fabrication processes such as e-beam lithography or ion beam lithography technology. Even though this system can be suitable to an ultra-high definition structural color display, it is limited to only a few millimeter scales or less. To apply into a realistic application such as banknote, luxury products, or customer goods, it is necessary to make it over centimeter scale with a flexible medium.

In this work, to break through these significant flexibility/scalability limitations, we developed polarization distinguishable covert display with ultrathin porous nanocolumns (PNCs) on a metal film by glancing angle deposition (GLAD) method. Particularly, the unique property of this covert display showed powerful functions which provide a hurdle to the inadvertent viewing of stored optical information without compromising their aesthetic. This structure with lossy PNCs on a metal film makes a non-trivial phase shift at the interfaces causing short reflection path and finally shows strong resonance [1]. Furthermore, the PNCs fabricated with GLAD produce anisotropic media and has different effective complex refractive index causing different resonating condition depending on polarization direction [2]. Using this concept, we designed polarization distinguishable color filters with a variety of materials and dimensions with rigorous coupling wave analysis (RCWA) method. In this process, we obtained an enlarged color range occupying over 80% of standard RGB area. In this color response, some showed a small color difference ($\Delta E$), the other showed a large color difference following polarization angle. Additionally, we confirmed this result is originated from human eye’s spectral responses according to between tristimulus value and reflectance spectra having a single minimum. Using these results, we designed optical data label (i.e., QR code) which shows inadvertent viewing in the naked eye (under unpolarized light), on the other hand, this label can be selectively detected by polarized light. For practical application, we designed this label into daily consumer goods with the color matching between labels and products to avoid compromising aesthetics of products and successfully demonstrated onto wine bottleneck, food packaging with confirming the authentication process. As a multi-functional color display, we demonstrated a colorimetric detection. Due to the low complex refractive index of porous medium, PNCs are sensitive to subtle external environment change. Consequently, PNCs reveal a sensitive color change according to background refractive index or additional layer thickness change. Using this unique property, we presented colorimetric detection with external change for volatile organic compounds (VOCs) and humidity.

2D Layered Semiconductors as Optical Gain Materials for On-Chip Photonic Applications  Cun-Zheng Ning1,2, Zhen Wang1, Hao Sun1 and Qiyao Zhang1; 1Tsinghua University, China; 2Arizona State University, United States

One of very important requirements for nanolasers intended for future photonic chips is the energy consumption. The amount of total energy input to a laser required to a large extent is determined by the critical value of carrier density, at which optical gain occurs. In conventional semiconductors, optical gain is based on electron-hole plasma and it occurs at the so-called transparency density, which is near and above the Mott density, typically on the order of 10^{12} per square centimeter. In 2D materials, the orders of magnitude larger exciton binding energy make it possible to have optical gain based on various excitonic species such as excitons, trions, bi-excitons etc. Such optical gain can occur at density levels several orders of magnitude smaller, well below the Mott density. In this talk, we will discuss possibilities of such optical gain in 2D materials that could occur at extremely low injection levels. As an example, we will discuss our recent experimental results [1] on trion gain in a gated 2D MoTe2 structure that occurs at the density level ~5 orders of magnitude smaller than the Mott density.

Utilizing Geometry and Topology for Enabling Integrated Chiral Photonics  Ritesh Agarwal; University of Pennsylvania, United States

With ever-increasing demand for faster speeds, copper interconnects that ferry vast amounts of data in computing devices are expected to significantly lag behind the requirements, thereby creating a bottleneck for moving data rapidly. Optical interconnects provide a promising alternative, allowing much faster speeds and larger bandwidths between different components, on or off chip. Three most critical interconnect components are light sources, waveguides and detectors. Currently, optical communication is performed by a combination of these devices where the information is encoded in photon number and frequency (intensity and bandwidth). However, no information is encoded in intrinsic properties of photons, i.e., photon spin and also possibly the orbital angular momentum modes of the light beam. Analogous to the idea of spintronics, where the spin degree of freedom of electrons are utilized to encode and transmit information, similar enhancements in the data processing capabilities of the optical interconnect systems can be obtained if information can be encoded in photon spin. Photons, have two fundamental spin polarizations reflected in their polarization state, i.e., right and left circular polarization. To fully utilize more degrees of freedom of light to enhance the data processing capabilities of network systems, it is required that new light sources, detectors and waveguides be designed and fabricated that can produce, transmit and detect light with complex polarizations. We will discuss some recent developments in our laboratory towards the development of topological waveguides that can route photonic signals based on photon spin and also photodetectors that are sensitive to circular polarization (photon spin). Either by protecting or breaking certain symmetries in (meta)materials, new photonic materials and devices will be discussed that can enable a new generation of photonic devices that can encode, transmit and sense information encoded in spin and angular momentum modes of light that are promising for the development of integrated chiral photonic systems with extremely large data processing capabilities.

7:55 PM *S.EL06.10.01
Diffractive Optical Neural Networks Designed by Deep Learning  Aydogan Ozcan and Deniz Mengu; University of California, Los Angeles, United States

We introduce a physical mechanism to perform machine learning by demonstrating a Diffractive Deep Neural Network (D^2NN) architecture that can all-optically implement various functions following the deep learning-based design of passive layers that work collectively. We created 3D-printed diffractive networks that implement classification of handwritten digits as well as the function of an imaging lens, spectral filters and wavelength demultiplexers at terahertz spectrum. This passive diffractive network can perform, at the speed of light, various complex
functions that computer-based neural networks can implement, and will find applications in all-optical image analysis, feature detection and object classification, also enabling new camera designs and optical components that perform unique tasks using diffractive neural networks designed by deep learning.

8:15 PM S.EL06.01.07
An Efficient Opto-Electronic III-V Nanowire Based Implementation of the Insect Brain Central Complex  
David Winge¹, Heiner Linke¹, Magnus Borgstrom³, Barbara Webb², Stanley Heinze¹ and Anders Mikkelsen¹; ¹Lund University, Sweden; ²University of Edinburgh, United Kingdom

Insects are capable of amazing tasks, such as traveling across hundreds of kilometers of unfamiliar terrain to pinpoint a specific breeding ground, with a brain that contains 100 000x fewer neurons than our own brains, using merely a few drops of nectar as energy supply. At each moment during navigation, the insect has to decide whether to turn right, left or go straight. Integrating sensory inputs, internal states, and previous experience, it computes its current and intended headings, compares the two, and initiates steering. A brain region called the central complex (CX) is essential for these tasks. Recently a biologically constrained computational model of the CX has been generated that can carry out these computations to generate homing behavior [1]. This computational model has been shown to carry out homing tasks using speed and heading information of limited precision, with considerable noise in the circuit. Containing less than 100 neurons, it can serve as a model system to understand the functionality and prove the efficiency of novel hardware solutions.

To realize this CX model we propose and theoretically model a network circuit based on existing III-V nanowire (NW) optoelectronic components that are optically connected through a shared waveguide structure. The neural weights of the mutual interconnections are achieved by controlling the far-field light emission patterns and by strategic placement of the nano-components. As a result, there is no need for physical connecting wires between the network nodes. Each node in this network is capable of both receiving, evaluating and sending optical signals, while power consumption is minimized by using high efficiency concepts from NW based photovoltaics and quantum dot emitters [2-6]. We show that the modeled coupling efficiencies and activation functions well suffice to facilitate excellent navigation in the insect neuron model [1]. As the efficiencies and electrical performance of the NW devices are known, we can estimate the energy consumption per operation and find that this should be at least as low as in biological processes [7] and beyond standard hardware implementations.

Our detailed simulations of the fundamental device component, which will act as a basic sigmoid neural node throughout the network, show how it performs the tasks of receiving light inputs, evaluating them and emitting a light output. We model it as an electrical circuit which is parametrized and solved by a standard SPICE solver (Ngspice). We describe the subcomponents using an Ebers-Moll model and the Shockley diode equation, respectively, where the relevant properties were calculated using a drift-diffusion model with thermionic boundary conditions in COMSOL. A NW phototransistor was optimized to give enough gain to broadcast the signal to the next layer using a realistic non-radiative Shockley-Read-Hall recombination lifetime for NWs of 1.34 ns [8] as well as Lorenz-Mie scattering theory. Extensive finite difference time domain (FDTD) simulations (Lumerical), were made for the central part of the CX model which consists of eight fully interconnected components. They were placed in a shared asymmetric waveguide which was optimized for the target wavelength. As the neurons of this layer are interconnected, input-output isolation is non-trivial, and the FDTD model was used to optimize the network in this respect. The gain of the fundamental device ensures both cascadeability and proper fan-out without the need of critical biasing [9], and the analog architecture carries a built-in robustness to noise [1].

Optical Signal Processing Using Dielectric Metasurfaces  
Jinghui Yang, Wenqi Zhu, Lu Chen, Cheng Zhang, Henri J. Lezec and Amit Agrawal; National Institute of Standards and Technology, United States

Optical analog computing provide solutions with fast and power-efficient performance for big-data applications. Recently investigated metamaterials and metasurfaces demonstrate potentials in mathematical operations over wavelength-scale footprint. We extend the functionality of using nonlocal dielectric metasurface to perform spatial differentiation equation for
imaging processing. The study pave the way towards ultrathin devices for optical signal processing.

8:23 PM *S.EL06.09.01
SiGe/Si-Based Electro-Optic Platform for Microwave-Optical Transduction Jason S. Orcutt; IBM T. J. Watson Research Center, United States

Superconducting qubit quantum computers offer new capabilities for quantum information processing, but require < 50 mK environments and near complete isolation from outside noise sources. To enable quantum information to be exchanged with these systems outside of cryogenic conditions by means of higher energy photons, many approaches towards microwave-optical transduction are being explored by the research community. Three-wave mixing in linear electro-optic materials is a particularly appealing approach due to the inherent simplicity and elimination of excess noise sources that are introduced by intermediate states present in many alternative technologies. However, material microwave and optical loss rates have limited conversion efficiency below 50% in demonstrations to date. Here, I present IBM’s work towards integrating low loss SiGe/Si optical resonators with the low loss Nb-on-Si microwave resonators that have been developed for superconducting qubits. An effective linear electro-optic coefficient for coupling the microwave and optical fields by three wave mixing is induced by strongly biasing the microwave resonators to leverage the DC Kerr effect in Si and SiGe. For 1 MHz-rate transducers, the resulting microwave-optical coupling strength is calculated to be sufficient to reach the peak conversion efficiency condition. Demonstrating microwave-optical transduction in this platform is then dependent on achieving low defectivity fabrication of the proposed SiGe/Si optical waveguides. I will present a study of this materials problem and an analysis of the overall optimal transducer design.

This work was funded by LPS/ARO under CQTS program, contract number W911NF-18-1-0022.

A New Paradigm for Scalable Quantum Optical Circuits—On-Chip Single Photon Source Arrays Integrated with Optically Resonant Metastructure Based Light Manipulating Units Anupam Madhukar1, Jiefei Zhang1, Swarnabha Chattaraj1 and Siyuan Lu2; 1University of Southern California, United States; 2IBM T.J. Watson Research Center, United States

Manipulation of single photons generated deterministically from pre-specified sources on-chip to create multiphoton entangled states remains a major goal to be reached in photonic quantum information processing platforms. Notable advances have been made in single photon source performance and demonstrations of photon interference and entanglement based largely upon finding suitable single photon source from an otherwise random ensemble. The lack of scalable on-chip architectures stands as a major obstacle to realizing compact quantum information technologies.

In this talk I will present our proposition [1,2] and continuing efforts [3,4] to realize such a photonic chip built upon a unique class of spatially-ordered arrays of surface-curvature driven mesa-top single quantum dots (MTSQDs) [1,3]. These AlGaAs/InGaAs MTSQDs exhibit spectral uniformity as low as 1.8nm across 5×8 arrays, exhibit pairs of as-grown QDs having emission energy within 200μeV, and single photon purity > 99%. Following a planarization overlayer growth, these buried single photon sources (SPS) provide the essential platform for subsequent lithographic fabrication of emitted photon light manipulating units (LMUs). The LMUs exploit either the well-developed photonic 2D crystal approach or a new approach we introduced [1,2] based upon Mie-like resonances in interacting subwavelength-sized dielectric building block (DBB) based metastructures. The in-plane single Mie-like resonance of the metamaterial (the LMU) provides all the needed basic photon manipulation functions to create controlled on-chip interference and entanglement [4]: enhancement of the SPS emission rate (Purcell enhancement), directional emission (local antenna), state-preserving propagation, path bifurcation (beam-splitting), and beam combining. Findings of our combined theoretical analysis, numerical simulations, and experimental studies of such SPS-LMU primitives — the essential building unit for quantum optical circuits — will be presented. The emphasis is on the holistic approach to proof-of-principle demonstration of the needed on-chip multifunctional system with its built-in trade-offs rather than the best of any individual light manipulation function.

The work is supported by the US Army Research Office (W911NF1910025) and the Air Force Office of Scientific Research (FA9550-17-1-0353).
In recent years, InAs quantum dot lasers have proven themselves resilient against crystalline defects that form during heteroepitaxial growth of III-Vs on silicon. The three-dimensional confinement and reduced in-plane diffusion lengths of carriers in quantum dots relative to quantum wells are the source of this resiliency, but alone these characteristics are not sufficient for demonstrating commercially reliable performance for lasers on silicon. Quantum dot active regions must be utilized together with highly optimized III-V/Si buffers to reduce the dislocation density to achieve acceptable device reliability.

In this talk, recent advances in GaAs/Si templates will be highlighted along with the resulting enhancements in laser reliability. Over the last three years, we have produced InAs quantum dot lasers on GaAs/Si templates with dislocation densities ranging from $3 \times 10^8$ cm$^{-2}$ down to $< 7 \times 10^6$ cm$^{-2}$ by optimizing thermal cycling procedures and strained filter layers. As the material has improved, the extrapolated mean-time-to-failure has increased several orders of magnitude to $>10,000,000$ h at 35°C and $>50,000$ h at 60°C.

In addition to improving laser reliability, the improvements in material quality have virtually closed the performance gap relative to native substrate lasers before aging. At dislocation densities of $7 \times 10^6$ cm$^{-2}$, low threshold, high power, and high efficiency lasers are readily achievable with continuous wave operation above 100°C. These improvements justified more advanced laser implementations and investigations into the dynamic performance of quantum dot lasers on silicon. The unique atom-like density of states of quantum dots has historically enabled unique properties such as an insensitivity to optical feedback, highly engineerable gain bandwidth, and ultrafast gain recovery; these properties unique to quantum dots have enabled Fabry-Perot lasers with complete insensitivity to optical feedback, high performance mode-locked lasers operating at 20 GHz with 64 channels capable of 4.1 Tbps transmission below the forward error correction (FEC) limit, and 100 GHz colliding pulse mode-locked lasers capable of 0.9 Tbps transmission below the FEC limit. Achieving each of these results required a high degree of optimization in the epi design and materials growth to obtain uniform distributions of high-quality quantum dots, which will be emphasized in the talk.

Further improving performance and, in particular, demonstrating commercially viable reliability at elevated temperatures $>60^\circ$C will require additional efforts to reduce the dislocation density in the laser active region. Our efforts to push the threading dislocation density $< 2 \times 10^6$ cm$^{-2}$ while also reducing the buffer thickness will be discussed in addition to efforts to address misfit dislocations that have been observed in the laser active region. Given the much larger cross-section of material that interacts with a misfit dislocation relative to a thread, it is believed that addressing these defects is critical to reaching the goal of native substrate level device reliability on a silicon substrate.

9:07 PM S.EL06.07.03
Mid-Infrared Emission and Absorption From GeSn/Ge Core-Shell Nanowires with Nanophotonic Light Extraction
Siying Peng, Michael Braun, Andrew C. Meng, Zhengrong Shang, Alberto Salleo and Paul McIntyre; Stanford University, United States

Mid-infrared light sources are key components for future chemical sensing, on-chip optical interconnect and LIDAR technologies. GeSn alloys can be synthesized under silicon CMOS compatible conditions. Therefore, GeSn can open pathways for miniaturization of mid-infrared devices such as on-chip molecular sensors, optical interconnects and thermal cloaking devices. Most importantly, direct band gap GeSn is a promising material for on chip integration of light emitters. Previous research on GeSn films has shown mid-infrared lasing at increasing temperatures, initially (in 2015) at less than 90K and, in more recent reports, at or near room temperature. It has also been shown that GeSn nanowires with high-Sn content exhibit strong direct-gap photoluminescence at room temperature. Compared to GeSn thin films, GeSn nanowires are less constrained to lattice match with misfitting (e.g. Ge, Si) substrates and therefore may achieve higher Sn contents without strain and defects that promote non-radiative recombination. Additionally, unlike in a planar GeSn film where the emission angle is limited to $< 13^\circ$ by its high refractive index (n=4), GeSn nanowires provide a platform to design the optical density of states for highly efficient light extraction directly from the light emitting material. GeSn nanowires may also constitute a superior medium for absorption and generation of photocarriers.

We demonstrate room temperature mid-infrared photodetection using resonantly absorbing GeSn/Ge core/shell nanowire photonic crystals. We have synthesized GeSn/Ge core/shell single crystal nanowires with 4% Sn that exhibit strong direct-
bandgap photoluminescence at room temperature. The vertical nanowire photodetection device consists of arrays of nanowires in-filled with PMMA insulating layer, an ITO top contact and an aluminum bottom contact. Using full wave FDTD simulations, we optimize Mie resonances of individual nanowires (300 nm in diameter) at the desired bandgap wavelength. We further engineer the absorption with nanowires arranged in photonic crystal arrays. To synthesize the nanowire device, gold catalysts were patterned on Ge [111] substrate and then two step VLS growth was performed to synthesize Ge core and GeSn shell. We performed photocurrent characterization with an FTIR spectrometer at room temperature. The photocurrent spectrum of Ge nanowire photonic crystals indicates a four-fold enhancement due to resonant absorption, with the photocurrent spectrum tunable by varying the photonic crystal geometry. For emission, we designed, synthesized and characterized mid-infrared emission of GeSn/Ge core-shell nanowires with 9-12% Sn. Full wave FDTD simulations reveal that the geometry of GeSn/Ge nanowires can be tuned to be resonantly scattering at the direct band gap energy. To further enhance light extraction, we use FDTD simulations to optimize GeSn/Ge nanowires in photonic crystal arrays to maximize the density of photonic states above the light line within the emission spectrum. The light emitting device consists of a similar device structure to that which is useful for photodetection. Room temperature photoluminescence characterization reveals both direct- and indirect-gap emissions in the mid-infrared, while electroluminescence characterization at 200 mA/cm reveals direct bandgap emission at both 2000 nm and 2300 nm. Optimization of nanophotonic light extraction efficiency will be discussed.

SESSION S.EL06.13: Live Panel Discussion: Intelligent Photonics

Sorger3 and Paul R. Prucnal2; 1Queen's University, Canada; 2Princeton University, United States; 3George Washington University, United States

Artificial Intelligence (AI) is transforming our lives in the same way as the advent of the Internet and cellular phones has done. AI is revolutionizing the healthcare industry with complex medical data analysis, actualizing self-driving cars, and beating humans at strategy games such as Go. However, it takes thousands of CPUs and GPUs, and many weeks to train the neural networks in AI hardware. Traditional CPUs, GPUs, and neuromorphic (i.e., brain-inspired) electronics such as the IBM TrueNorth and Google TPU, may find it a challenge to train the neural networks of the future.

Neuromorphic photonics has experienced a recent surge of interest over the last few years, promising orders of magnitude improvements in both speed and energy efficiency over digital electronics using: artificial neural networks, spiking neural networks, and reservoir computing. By combining the high bandwidth and efficiency of photonic devices with the adaptive, parallelism and complexity attained by methods similar to those seen in the brain, photonic processors have the potential to be at least ten thousand times faster than state-of-the-art electronic processors while consuming less energy/computation.

We will provide an overview of neuromorphic photonic systems and their application to optimization and machine learning problems. We will discuss the physical advantages of photonic processing systems and describe underlying device models that allow practical systems to be constructed. We also describe several real-world applications for control and deep learning inference. Lastly, we will discuss scalability in the context of designing a full-scale neuromorphic photonic processing system, considering aspects such as signal integrity, noise, and hardware fabrication platforms. This talk is intended for a wide audience and hopes to teach how theory, research, and device concepts from neuromorphic photonics could be applied in practical machine learning systems.

Ferroelectric Phase Shifters in Silicon Photonics for Novel Types of Optical Computing Jean Fompeyrine, Felix Eltes, Stefan Abel and Bert Offrein; IBM Research Zurich, Switzerland

Integrated photonic circuits efficiently combine multiple optical functions on a single physical platform, such as guiding, modulating, splitting, or detection of light. The integration of these functions removes barriers for designing and realizing large optical circuits, as present when using discrete components like bulky lenses or mirrors in tabletop optical networks.
With the rise of silicon photonics, integrated photonic circuits (PICs) are becoming increasingly large and highly functional, eventually allowing unprecedented concepts of photonic computing. Examples are integrated photonic quantum processors, microwave photonic filters and processors, and optical accelerators to train and execute neural networks.

An important building block in integrated optical circuits is an efficient link between the optical and electrical domain. Well-known examples of such links are integrated high-speed modulators to convert electrical signals into optical signals at very high-speed, and low-power tuning elements to compensate for variations in the device operation temperature and for device-to-device variations during fabrication. To enable such electro-optic links, the two most widely used physical effects are the plasma-dispersion effect and Joule heating. Although these effects are attractive to use due to their compatibility with standard photonic fabrication processes, their performance in integrated devices is intrinsically limited by high insertion losses and high-power dissipation.

Over the past decade, we established an alternative electro-optic switching technology by embedding a Pockels material into silicon-based photonic devices [1]. We reached this goal by developing a process to fabricate ferroelectric barium-titanate (BTO) thin films on silicon substrates using advanced epitaxial deposition techniques and by developing a BTO process technology [2]. We correlated the electro-optical properties of the thin films with their structural properties such as porosity and crystalline symmetry to show guidelines for improving the functional properties. By realizing integrated hybrid BTO/silicon devices, we demonstrated record-high, in-device Pockels coefficients of >900 pm/V. The Pockels effect in BTO-based photonic devices indeed enables extremely fast data modulation at rates beyond >40 Gbps and ultra-low-power electro-optic tuning of silicon and silicon-nitride waveguides. We also show ways of how to integrate and use BTO in plasmonic slot waveguide structures for very compact optical devices. With the development of a wafer-level integration scheme of single-crystalline BTO layers to a 200 mm process [3], we could demonstrate a viable path to combine the BTO-technology with existing fabrication routes.

With major breakthroughs in the past years, BTO has emerged as a strong candidate for a novel generation of electro-optic devices. Major achievements of the BTO technology will be covered in the presentation, ranging from important materials aspects, device development, integration concepts, and novel applications in the area of quantum computing, high-speed communication, and neuromorphic optical computing.

Manipulating Integrated Quantum Systems Using Classical Silicon Carbide Devices Christopher Anderson1, Alexandre Bourassa1, Kevin Miao1 and David Awschalom1,2; 1University of Chicago, United States; 2Argonne National Laboratory, United States

The neutral divacancy (VV0) in silicon carbide (SiC) exhibits robust spin coherence and a high-quality near-infrared spin-photon interface in a material compatible with mature fabrication techniques. Here, we make use of this scalable semiconductor host and design electronic devices to manipulate embedded isolated quantum systems. Specifically, we create and isolate single spin defects in a commercial p-i-n diode [1]. This simple integration enables engineering of the defect’s charge environment and drastically reduces electric field noise. Surprisingly, the use of electrical gating mitigates spectral diffusion and achieves near-lifetime limited optical linewidths. Furthermore, by exploiting field confinement of the junction,
we show that the optical transitions can be gate-tuned by nearly a terahertz, revealing a spectral tuning range extending over 40,000 optical linewidths. This geometry may allow for spectral multiplexing of many quantum channels, and also provides a method for using electric fields combined with optical excitation for deterministic charge state control.

Applying gigahertz ac electric fields to SiC devices produces coherent interference in the form of Landau-Zener-Stückelberg fringes, arising from interactions between microwave and optical photons [2], even in the absence of a microwave resonator. We demonstrate lifetime-limited optical coherence and clock-like spin transitions with increased robustness against magnetic noise. Electrical driving of excited-state electron orbitals offers advantages over spin-based coupling and points towards new types of hybrid quantum systems. These results reveal new opportunities for electrical manipulation of spin-based quantum systems in scalable SiC electronic devices.

Novel Semiconductor Structures for Single Photon Emission and Detection Anna Fontcuberta i Morral; École Polytechnique Fédérale de Lausanne, Switzerland

Semiconductor materials play a pivotal role in photonic technology. They can be used as tailored photon emitters and detectors. Combined with plasmonic structures and photonic design, their efficiency and functionality is further extended. In this talk we show how compound semiconductor nanostructures such as nanowires and nanoscale membranes (nanofins) can be used for both single photon emission and detection [1,[2]]. We will explore what kind of heterostructures are optimal for these applications. We will also elucidate how photon detection can be optimized by the nanowire geometry and the combination with plasmonic structures [2,[3]]. Finally, we will also explore materials with a lower production and environmental cost and how to fabricate them at a similar functionality than compound semiconductors. We will show how GeSn thin films and nanostructures have the potential to become the leading material in mid-infrared photodetection.

3:25 PM *S.EL06.03.01
Quantum Neural Network—Connecting Quantum and Brain with Optics Yoshihisa Yamamoto1,2; 1Stanford University, United States; 2NTT Research, Inc., United States

Combinatorial optimization problems are ubiquitous in our modern life. Classical examples include lead optimization in drug and biocatalyst discovery, resource optimization in wireless communications, logistics and scheduling, sparse coding for compressed sensing, deep machine learning in artificial intelligence and fintech. These optimization problems can be mapped to either Ising model, XY model or k-SAT problem, which is a main reason why various Ising, XY and SAT solvers have been proposed and implemented in the recent years.

We have focused on the network of optical parametric oscillators to construct coherent Ising machines, XY machines and SAT solvers. An optical parametric oscillator (OPO) operates as a quantum analog device at below oscillation threshold and also functions as a classical digital device at above oscillation threshold. We need not only quantum computational resources, such as quantum correlation and quantum suppression of chaos, but also classical computational resources, such as spontaneous symmetry breaking and exponential amplitude amplification, to build an efficient optimizer. An OPO is almost a unique choice of device to realize such quantum and classical computational resources simultaneously at room temperatures.

A study on quantum state engineering in an OPO with measurement-feedback control was dated back to 1980s [1,2]. A
PPLN waveguide OPO device was identified as a stable and efficient generator for squeezed vacuum state pulses at communication wavelengths in 1990s [3]. An idea of using the pitchfork bifurcation and spontaneous symmetry breaking at OPO threshold as an irreversible decision making process was proposed in 2013 [4] and experimentally implemented [5,6]. A scalable architecture based on measurement-feedback coupling scheme was subsequently demonstrated [7,8]. Those devices already demonstrated competitive performance against modern heuristics [9] and quantum annealers [10]. In this talk, we will discuss the principles of quantum-classical crossover and future prospects of quantum neural network.

through an engineered hybrid Ge$_2$Sb$_2$Se$_4$Te$_1$-silicon Mach Zehnder modulator photonic memory with thermoelectrical programmability. The network can effortlessly perform inference tasks with high accuracy at the speed-of-light.

Machine-learning tasks performed by neural networks demonstrated useful capabilities for producing reliable, and repeatable intelligent decisions. Integrated photonics, leveraging both component miniaturization and the wave-nature of the signals, can potentially outperform electronics architectures when performing inference tasks. However, the missing photon-photon force challenges non-volatile photonic device-functionality required for efficient neural networks. Here we present a novel concept and its optimization of multi-level non-volatile photonic memories based on an ultra-compact (<4µm) hybrid phase-change-material Ge$_2$Sb$_2$Se$_4$Te$_1$-silicon Mach Zehnder modulator, with low insertion losses (3dB), to serve as node in a photonic neural network (NN). An optimized electro-thermal switching mechanism is engineered, causing phase transitions in the GSST, induced by heating by tungsten contacts, which allows weight updating functionality of the network. We show that a 5 V pulse-train (<1µs, 20 pulses) applied to a serpentine contact produces crystallization and a single pulse of longer duration (2µs) amorphization, used to set the analog synaptic weights of a neuron. Emulating an opportunely trained 100 x 100 fully connected multilayered perceptron NN with these weighting functionalities embedded as photonic memory, shows a 92% inference accuracy and robustness towards noise when performing predictions of unseen data. Exploiting the low delay interconnectivity of photonic integrated chips and the non-volatile transitions of PCM, an all-optical (AO) trained NN, that effortlessly performs dot-product functionality can be achieved, enabling intelligent computing functionality at the time-of-flight of the photon.

The written portion of the material corresponds to discrete states of the weighting function, and assuming a stable writing resolution of about 500 nm, same achieved by optical writing, the total amount of available quantized resolution is given by 8 distinct states (3-bit), which can be further improved by extending the device length by multiple of $L_π$. Additionally, this is a reversible process, which allows to update the weights after any execution times. Interestingly, this solution is not hindered by insertion losses, which are negligible due to the rather low absorption coefficient of GSST at 1550 nm, and the total losses (~3dB) are mainly caused by the balancing mechanism (in this first analysis straightforwardly obtained achieved by placing a gold contact on the balancing arm). As an interim conclusion, this novel PCM MZM features by a micrometer-compact (<4µm) footprint and low insertion losses (3dB), enabling the implementation of a deep NN which comprises multiple nodes.

As preliminary study, we estimated the functionality of the proposed perceptron as main unit of the NN, by emulating its behavior in a 3-layer fully connected NN implemented in the Google Tensorflow tool and, as an initial example, for the MNIST data set. Nonlinear activation functions (here considered as electro-optic) are placed between two consecutive layers on each input connection. The network is trained both without and with noise of the weights and NLAF. Our hypothesis, confirmed by preliminary studies on the network is that, when we allow for a certain amount of noise during the training, the model during the inference stage, becomes more robust and the network can perform inference with up to 92% accuracy showing robustness towards noise.

Mie Resonant Dielectric Metastructure Based Optical Circuits Integrated with Quantum Dot Single Photon Source for on-Chip Scalable Quantum Information Processing

Swarnabha Chattaraj$^1$, Jiefei Zhang$^1$, Siyuan Lu$^2$ and Anupam Madhukar$^1$; $^1$University of Southern California, United States; $^2$IBM Thomas J. Watson Research Center, United States

Realization of on-chip scalable optical quantum information processing (QIP) systems requires optical circuits built around arrays of single photon sources (SPSs) to manipulate the emitted photons and enable interference between photons from distinct SPSs resulting in entanglement. Towards such a goal we have reported a new class of on-chip single quantum dot arrays - grown on lithographically fabricated mesas designed to exploit the attendant surface stress gradient driven adatom migration during MBE growth thus termed mesa-top single quantum dots (MTSQDs) [1]. These MTSQDs, we have demonstrated, are ~99% pure SPSs [2] that are readily integrable with on-chip light manipulating units (LMUs) that provide the needed multiple functions of enhancing the emission rate of the SPS and the directionality of the photon emission in the horizontal direction, on-chip propagation, splitting and recombining to enable on-chip interference towards entanglement. So far attempts towards creating such LMUs (mostly resonant cavity and waveguide) have been based on photonic crystal membrane structures and exploit departure from Bragg scattering to provide localized photon modes for individual cavity or waveguides thus facing the challenge of strict mode-matching between these components. In contrast, in this talk we present an approach to realizing all the required light manipulating functions based on metastructures made of subwavelength size dielectric building blocks (DBBs) where a common collective Mie resonance of the interacting DBBs is exploited to provide all the needed light manipulating functions simultaneously [3, 4, 5]. These Mie resonances are fundamentally different from
Bragg scattering as they are typically broad in spectrum, with a typical Q~100- that alleviates the strict requirements of spectral and spatial matching between the network components and with the SPS emission mode. Moreover, Mie resonances are less sensitive to effect of fabrication disorders that introduce aperiodicity in the array. Furthermore, the spectral broad nature of the Mie resonances allows controlled interference between the electric and magnetic modes resulting in directionality of photon emission and propagation without strong field localization—an effect that is unique to this class of LMUs. Importantly, providing all the needed light manipulating functions using the same collective Mie mode circumvents issue of mode mismatch between the components of the optical circuit including the SPS, and thus allows design and realization of large-scale circuits.

Aimed at the above noted objective of on-chip nanophotonic systems, in this talk we will present finite element method (FEM)-based design and simulation of the response of an MTSQD-DBB integrated optical circuit that exploits the dominant collective magnetic and electric dipole mode to provide the MTSQD emission rate enhancement (Purcell effect) ~5 as well as emission directionality (the nanoantenna effect), lossless on-chip propagation, beam-splitting, and beam-combining [4, 5]. We show that such structures enable on-chip interference of photons resulting in path entanglement between the two MTSQD SPSs at large distances.

Finally, we will present FEM simulations of direct coupling of two SPSs via an intermediate lossless collective Mie mode over on-chip distances much longer than the wavelength. We show that such coupling can result in a super-radiant state involving on-chip SPSs at a distance resulting in a ~2 fold enhanced decay rate [5]. This emergent super-radiant state in such SPS-SPS coupled system is maximally entangled, and thus may act as a potential resource for on chip QIP.

Ferroelectric Phase Shifters in Silicon Photonics for Novel Types of Optical Computing Jean Fompeyrine, Felix Eltes, Stefan Abel and Bert Offrein; IBM Research Zurich, Switzerland

Integrated photonic circuits efficiently combine multiple optical functions on a single physical platform, such as guiding, modulating, splitting, or detection of light. The integration of these functions removes barriers for designing and realizing large optical circuits, as present when using discrete components like bulky lenses or mirrors in tabletop optical networks. With the rise of silicon photonics, integrated photonic circuits (PICs) are becoming increasingly large and highly functional, eventually allowing unprecedented concepts of photonic computing. Examples are integrated photonic quantum processors, microwave photonic filters and processors, and optical accelerators to train and execute neural networks.

An important building block in integrated optical circuits is an efficient link between the optical and electrical domain. Well-known examples of such links are integrated high-speed modulators to convert electrical signals into optical signals at very high-speed, and low-power tuning elements to compensate for variations in the device operation temperature and for device-to-device variations during fabrication. To enable such electro-optic links, the two most widely used physical effects are the plasma-dispersion effect and Joule heating. Although these effects are attractive to use due to their compatibility with standard photonic fabrication processes, their performance in integrated devices is intrinsically limited by high insertion losses and high-power dissipation.

Over the past decade, we established an alternative electro-optic switching technology by embedding a Pockels material into silicon-based photonic devices [1]. We reached this goal by developing a process to fabricate ferroelectric barium-titanate (BTO) thin films on silicon substrates using advanced epitaxial deposition techniques and by developing a BTO process technology [2]. We correlated the electro-optical properties of the thin films with their structural properties such as porosity and crystalline symmetry to show guidelines for improving the functional properties. By realizing integrated hybrid BTO/silicon devices, we demonstrated record-high, in-device Pockels coefficients of >900 pm/V. The Pockels effect in BTO-based photonic devices indeed enables extremely fast data modulation at rates beyond >40 Gbps and ultra-low-power electro-optic tuning of silicon and silicon-nitride waveguides. We also show ways of how to integrate and use BTO in plasmonic slot waveguide structures for very compact optical devices. With the development of a wafer-level integration scheme of single-crystalline BTO layers to a 200 mm process [3], we could demonstrate a viable path to combine the BTO-technology with existing fabrication routes.
With major breakthroughs in the past years, BTO has emerged as a strong candidate for a novel generation of electro-optic devices. Major achievements of the BTO technology will be covered in the presentation, ranging from important materials aspects, device development, integration concepts, and novel applications in the area of quantum computing, high-speed communication, and neuromorphic optical computing.

7:00 AM S.EL06.01.06
Data-Driven Design for Optical Analog Computing Wenjin Xue and Owen Miller; Yale University, United States

In this work, we find precision layered-material optical designs that can perform state-of-the-art edge detection among compact-form-factor approaches, offering high efficiency and large angular bandwidth / numerical aperture. We identify these designs by two approaches: first, adjoint-based “inverse design” of the layered structures, for rapid optimization of many parameters, and second, by training the structures on software-based edge-detection algorithms that can be “learned” into the hardware itself. Optical computing platforms based on such layered media offer simpler integration and more compact form factors than structured or free-space alternatives. We identify the benefits and tradeoffs of ideal material properties—metal/dielectric, lossy/lossless—within these optimal designs, and discuss its generalization beyond edge detection to more general optical analog computing.

7:15 AM S.EL06.01.07
An Efficient Opto-Electronic III-V Nanowire Based Implementation of the Insect Brain Central Complex David Winge1, Heiner Linke1, Magnus Borgstrom1, Barbara Webb2, Stanley Heinze1 and Anders Mikkelsen1; 1Lund University, Sweden; 2University of Edinburgh, United Kingdom

Insects are capable of amazing tasks, such as traveling across hundreds of kilometers of unfamiliar terrain to pinpoint a specific breeding ground, with a brain that contains 100 000x fewer neurons than our own brains, using merely a few drops of nectar as energy supply. At each moment during navigation, the insect has to decide whether to turn right, left or go straight. Integrating sensory inputs, internal states, and previous experience, it computes its current and intended headings, compares the two, and initiates steering. A brain region called the central complex (CX) is essential for these tasks. Recently a biologically constrained computational model of the CX has been generated that can carry out these computations to generate homing behavior [1]. This computational model has been shown to carry out homing tasks using speed and heading information of limited precision, with considerable noise in the circuit. Containing less than 100 neurons, it can serve as a model system to understand the functionality and prove the efficiency of novel hardware solutions.

To realize this CX model we propose and theoretically model a network circuit based on existing III-V nanowire (NW) optoelectronic components that are optically connected through a shared waveguide structure. The neural weights of the mutual interconnections are achieved by controlling the far-field light emission patterns and by strategic placement of the nanocomponents. As a result, there is no need for physical connecting wires between the network nodes. Each node in this network is capable of both receiving, evaluating and sending optical signals, while power consumption is minimized by using high efficiency concepts from NW based photovoltaics and quantum dot emitters [2-6]. We show that the modeled coupling efficiencies and activation functions work well to facilitate excellent navigation in the insect neuron model [1]. As the efficiencies and electrical performance of the NW devices are known, we can estimate the energy consumption per operation and find that this should be at least as low as in biological processes [7] and beyond standard hardware implementations.

Our detailed simulations of the fundamental device component, which will act as a basic sigmoid neural node throughout the network, show how it performs the tasks of receiving light inputs, evaluating them and emitting a light output. We model it as an electrical circuit which is parametrized and solved by a standard SPICE solver (Ngspice). We describe the subcomponents using an Ebers-Moll model and the Shockley diode equation, respectively, where the relevant properties were calculated using a drift-diffusion model with thermionic boundary conditions in COMSOL. A NW phototransistor was optimized to give enough gain to broadcast the signal to the next layer using a realistic non-radiative Shockley-Read-Hall recombination lifetime for NWs of 1.34 ns [8] as well as Lorenz-Mie scattering theory. Extensive finite difference time domain (FDTD) simulations (Lumerical), were made for the central part of the CX model which consists of eight fully interconnected...
components. They were placed in a shared asymmetric waveguide which was optimized for the target wavelength. As the neurons of this layer are interconnected, input-output isolation is non-trivial, and the FDTD model was used to optimize the network in this respect. The gain of the fundamental device ensures both cascadeability and proper fan-out without the need of critical biasing [9], and the analog architecture carries a built-in robustness to noise [1].

Spectrally Controllable Lasers for Information Processing Based on Nanophotonic Networks Dhruv Saxena1, Alexis Arnaudon1, Oscar Cipolato1, Michele Gaio1, Sophia Yaliraki1, Dario Pisignano2, Andrea Camposeo2, Mauricio Barahona1 and Riccardo Sapienza1; 1Imperial College London, United Kingdom; 2NEST, Istituto Nanoscienze-CNR, Italy

Nanophotonic networks, where light flows in a mesh of interconnected optical waveguides, can serve as an unconventional lasing cavity, supporting resonant modes that are formed by light propagation and interference across many network links. In this talk, I will discuss our recent efforts to make spectrally controllable lasers with nanostructured sub-wavelength networks [1]. The networks are made from polymer nanofibers that are doped with a laser dye and can lase over a wide range of frequencies, corresponding to many network modes. Interestingly, we can exploit mode competition in the network laser for spectral control and signal processing. For example, we can experimentally single-out a lasing frequency out of the spectral haystack by selectively illuminating a very small subset of the network links. This result is also predicted by a graph description of Maxwell’s equations, and a steady-state ab initio laser theory (netSALT) which is used to model the network laser. In particular, netSALT enables the design of the network topology for lasing and identification of the most important edges in the network that are necessary for sustaining a particular mode.

We demonstrate lifetime-limited optical coherence and clock-like spin transitions with increased robustness against magnetic noise. Electrical driving of excited-state electron orbitals offers advantages over spin-based coupling and points towards new types of hybrid quantum systems. These results reveal new opportunities for electrical manipulation of spin-based quantum systems in scalable SiC electronic devices.

Tailoring of Defect Centers in 3C-SiC for Potential Application in Quantum Information In Situ During Sublimation Epitaxial Growth Peter J. Wellmann and Michael Schöler; University of Erlangen, Germany

In recent years, vacancy related defect centers in SiC have been identified as optically active, high potential candidates for the application in devices in the field of quantum information. Often such defect centers have been created by means of ion or electron beam implantation followed by subsequent annealing. As a result, these materials remain defective from a structural point of view with deteriorate electronic properties. In this work we present a process to generate and tailor vacancy defect centers in-situ during sublimation epitaxial growth of 3C-SiC with preserved electronic properties. (i) By adaption of the growth rate we were able to tailor the concentration of the carbon vacancy defect VcVsi, VcCsi and Vc at the discrete optical transition energies between 1.138 eV, 1.233 eV and 1.278 eV, respectively. (ii) Using extreme annealing conditions, we observed the generation of the nitrogen vacancy defect (NcVsi)- at an optical transition energy of 0.884 eV. In our presentation we will introduce the processing of the special 3C-SiC layers, identify their structural properties using Raman spectroscopy and discuss the optical active defect centers by means of low temperature photoluminescence measurements.

Quantum Neural Network—Connecting Quantum and Brain with Optics Yoshihisa Yamamoto1,2; 1Stanford University, United States; 2NTT Research, Inc., United States

Combinatorial optimization problems are ubiquitous in our modern life. Classical examples include lead optimization in drug and biocatalyst discovery, resource optimization in wireless communications, logistics and scheduling, sparse coding for compressed sensing, deep machine learning in artificial intelligence and fintech. These optimization problems can be mapped to either Ising model, XY model or k-SAT problem, which is a main reason why various Ising, XY and SAT solvers have been proposed and implemented in the recent years.

We have focused on the network of optical parametric oscillators to construct coherent Ising machines, XY machines and SAT solvers. An optical parametric oscillator (OPO) operates as a quantum analog device at below oscillation threshold and also functions as a classical digital device at above oscillation threshold. We need not only quantum computational resources, such as quantum correlation and quantum suppression of chaos, but also classical computational resources, such as spontaneous symmetry breaking and exponential amplitude amplification, to build an efficient optimizer. An OPO is almost a unique choice of device to realize such quantum and classical computational resources simultaneously at room temperatures.
A study on quantum state engineering in an OPO with measurement-feedback control was dated back to 1980s [1,2]. A PPLN waveguide OPO device was identified as a stable and efficient generator for squeezed vacuum state pulses at communication wavelengths in 1990s [3]. An idea of using the pitchfork bifurcation and spontaneous symmetry breaking at OPO threshold as an irreversible decision making process was proposed in 2013 [4] and experimentally implemented [5,6]. A scalable architecture based on measurement-feedback coupling scheme was subsequently demonstrated [7,8]. Those devices already demonstrated competitive performance against modern heuristics [9] and quantum annealers [10]. In this talk, we will discuss the principles of quantum-classical crossover and future prospects of quantum neural network.

Quantum Mechanical Simulation and Modelling of Semiconductor Nanowires Quantum-Dots for Quantum Cryptography Application Vihar P. Georgiev, Hamilton Carrillo-Nunez, Amretashis Sengupta and Asen Asenov; University of Glasgow, United Kingdom

Physical unclonable functions (PUF) are considered as one of the most promising methods for hardware authentication. PUFs are typically compact devices providing a response when challenged that is linked to uncontrollable stochastic processes and physics variability that occur during hardware manufacturing. As a result, it is practically impossible to produce two identical devices, which is highly desirable for applications in cybersecurity. For example, an important source of statistical variability in semiconductor nano-electronics, which has a huge impact on the electrical characteristics of each device, is the random dopant distribution (RDD) within the structure. The stochastic nature of the RDD profile for each device leads to a unique electrical output for each device. Indeed, this is the main idea and strength behind PUFs based on quantum dots that can be fabricated using standard CMOS technology and processes. In addition, as the dimensions of the modern transistors range from a few to tens of nanometers, there is a unique opportunity to use quantum mechanical effects, such as confinement and tunneling, as another layer of security based on quantum effects. One possible device structure that can be fabricated using the standard CMOS process and that can be implemented in current electrical circuits is a quantum-dot-in-wire device, which is considered in this work. The dot device relies on tunneling of electrons through a barrier and for this reason it can be considered a device that provides a quantum fingerprint.

Our work shows quantum mechanical simulations of quantum-dots (QDs) embedded within Si and III-V nanowires. To capture the effect of statistical sources of variability, we simulated more than 100 automatically unique nanowire devices with differing numbers and positions of dopants, not only in the quantum dot but also at the source and the drain regions also. Our results reveal that the specific number of dopants and their positions give rise to unique current-voltage characteristics, providing unique signatures for use as the basis of physical unclonable functions (PUFs). Hence, unique current-voltage characteristics can be defined as quantum fingerprints and applied to problems in cybersecurity, such as authentication and identification. Here we have also established a link between the RDD position, the transmission spectra, current spectrum and local density of states. Our work captures the complex nature of the quantum effects in such ultra-small-scaled devices and it can be used for investigating quantum mechanical effects in not only the dot but also in conventional transistors. Moreover, adoption of hardware security devices for authentication is on the rise. The technology proposed here delivers a practical means to extract fingerprints from quantum confined systems that could provide robust security to current electronics.

Large-Scale Coherent Ising Machine for Solving Combinatorial Optimization Problems Hiroki Takesue; NTT Basic Research Laboratories, Japan

In recent years, Ising model solvers based on artificial spin systems have been studied intensively. A coherent Ising machine (CIM) is one of such systems in which the binary phase state of degenerate optical parametric oscillators (DOPO) is used to
represent an Ising spin. By using long-distance (typically 1 km) fiber cavity that contains a phase sensitive amplifier based on the 2nd or 3rd order nonlinear optical effect, we can generate thousands of time-multiplexed DOPO pulses. The “spin-spin” interaction is implemented by using a measurement-feedback scheme, with which we can effectively realize all-to-all connection among thousands of DOPO pulses. The networked DOPO pulses are most likely to oscillate at a phase configuration that best stabilize the whole network, which gives the solution to the given Ising problems. In this talk, I will describe the large-scale CIM developed by NTT, which could find solution to maximum cut problem of 2000-node graphs faster than a conventional digital computer.

Quantum Electrodynamical Density Functional Theory for Light-Matter Coupling of Molecules in Lossy Cavities
Derek Wang¹, Tomas Neuman¹, Johannes Flick¹,² and Prineha Narang¹; ¹Harvard University, United States; ²Flatiron Institute, United States

Light-matter coupling can e.g. influence chemical reactivity of molecules or modify transfer of energy through matter via formation of hybrid light-matter polaritonic states [1]. To elucidate the microscopic nature of such effects, we extend quantum electrodynamical density functional theory (QEDFT)--a first-principles, non-perturbative methodology for describing interactions between quantized light and matter [2]--by fully accounting for photonic losses in realistic optical cavities. We demonstrate that our method successfully addresses situations where the photonic losses dominate the dynamics of the excitations and show that the first-principles approach correctly predicts spectral response of such weakly coupled systems. We further apply the method to describe the cavity-induced interaction among electronic excited states, opening up new pathways in strongly-coupled molecular systems.

This work was supported by the DOE ‘Photonics at Thermodynamic Limits’ Energy Frontier Research Center under grant DE-SC0019140. DW is an NSF Graduate Research Fellow.

6:30 AM S.E.L06.03.07
Chromatic and Panchromatic Nonlinear Optoelectronic CMOSFETs for CMOS Image Sensors, Laser Multiplexing, Computing and Communication
James Pan¹,²; ¹Advanced Enterprise and License Company, United States; ²Northrop Grumman Corporation, United States

A Photonic CMOS Field Effect Transistor includes an ultra low-resistance, high quantum efficiency laser fabricated in the MOSFET drain region, and multiple photon sensors or Avalanche Photo Diodes (APD) in the channel / well regions. The MOSFET, laser, and APD's are fabricated as one integral transistor. When a voltage is applied to the gate and a voltage is applied to the drain, both MOSFET and laser are turned on. Light emitted from the laser is absorbed by the APD to cause an avalanche breakdown. The high breakdown current flows into the drain to be a high output current. When the MOSFET is off, both laser and APD are switched off. Very low resistance and forward voltage lasers (VF near 0V) have been reported. With modulation doped junctions, bandgap engineered tunneling mechanisms, and low temperature selective epitaxy process (III-V or II-VI direct bandgap semiconductors on Silicon), these very low resistance lasers or LEDs are suitable for being fabricated in the drain of the Photonic CMOSFETs.

The Photonic CMOSFETs not only generates an internal laser light, but also can be used as an external light sensor. The internal and external lights may be of the same or various different frequencies. In the former case, it is defined as Chromatic Photonic CMOS. In the latter case, it is defined as Panchromatic Photonic CMOS. The photon sensor, or avalanche photo diode in the Chromatic Photonic CMOSFETs is designed to absorb lights from a specified range of light spectrum. Narrow bandgap semiconductors, or wide bandgap semiconductors can be used to build photon sensors in the Photonic CMOSFETs for photon absorption from infrared to ultraviolet ranges.

Three light signals are processed by a Photonic MOSFET. The first signal comes from the drain voltage. The second signal comes from the gate voltage. The third signal comes from the external light. Light emitted from the built-in laser in the drain region is modulated by the gate and drain voltages, and absorbed by a specific photon sensor in the channel / well region. The external light is absorbed by another photon sensor in the well region, and generates a different light current. All these three light signals are processed and multiplexed by the Photonic CMOS transistor.

Nonlinear optical films can be fabricated in the well region of a Photonic MOSFET.
The frequency or color of an input light signal is different from the output light due to multiple photon generations and absorptions in nonlinear optical films. The purpose of the nonlinear optical films is to increase the photon absorption rate and internal quantum efficiency of a Photonic MOSFET, and improve the laser multiplexing and communications. The nonlinear optical crystals can be fabricated on top of a total reflection layer (metal, or multiple refraction indices films), and below the CMOS channel region.

We will present information for device configurations of the Chromatic and Panchromatic Photonic CMOSFETs, and illustrate how light signals are modulated and multiplexed. We also include nonlinear optical crystals - and show the effects of such various nonlinear optics on the signal processing and light generation mechanisms. We will also provide evidence how the Chromatic Photonic CMOS technology may offer additional benefits for laser communication and more efficient signal processing systems.

Information regarding the Photonic CMOS output current (IDS) vs. input voltages (VGS and VDS) for various external and internal light spectrums will be presented. Techniques to optimize the internal quantum efficiency and photon absorption rate for various incident light frequencies will be illustrated. We will also present data for improved light sensitivity and changes in the output current due to the Photonic CMOS devices.

Finally, we will show the performance advantages of the Photonic CMOS for CMOS image sensor application - what are needed in the ROIC (Read Out Integrated Circuit) to process multiple multiplexed light signals.

2D Layered Semiconductors as Optical Gain Materials for On-Chip Photonic Applications Cun-Zheng Ning1,2, Zhen Wang1, Hao Sun1 and Qiyao Zhang1; 1Tsinghua University, China; 2Arizona State University, United States

One of very important requirements for nanolasers intended for future photonic chips is the energy consumption. The amount of total energy input to a laser required to a large extend is determined by the critical value of carrier density, at which optical gain occurs. In conventional semiconductors, optical gain is based on electron-hole plasma and it occurs at the so-called transparency density, which is near and above the Mott density, typically on the order of 1012 per square centimeter. In 2D materials, the orders of magnitude larger exciton binding energy make it possible to have optical gain based on various excitonic species such as excitons, trions, bi-excitons etc. Such optical gain can occur at density levels several orders of magnitude smaller, well below the Mott density. In this talk, we will discuss possibilities of such optical gain in 2D materials that could occur at extremely low injection levels. As an example, we will discuss our recent experimental results [1] on trion gain in a gated 2D MoTe2 structure that occurs at the density level ~5 orders of magnitude smaller than the Mott density.

Metal-Clad InP Cavities for Nanolasers on Si Preksha Tiwari1, Pengyan Wen1, Svenja Mauthe1, Noelia Vico Trivino1, Daniele Caimi1, Yannick Baumgartner1, Marilyne Sousa1, Markus Scherrer1, Chang-Won Lee2 and Kirsten Moselund1; 1IBM Research-Zurich (en dash), Switzerland; 2Hanbat National University, Korea (the Republic of)

Photonic integrated circuits offer high-speed data transmission and reduced energy per bit consumption. To meet the energy requirements for on-chip communication, a small form factor of the integrated III-V semiconductor emitters and detectors is crucial. Ding et al. suggest a laser volume of less than ~2(λ/n)3 to lower the energy to 10 fJ/bit.1 Scaling to these dimensions, however, is not possible for purely photonic devices, hence hybrid plasmonic-photonic cavities are being explored.2 Using template-assisted selective epitaxy (TASE), we can integrate high quality III-Vs epitaxially on Si, despite their lattice
and thermal mismatch. We have demonstrated InP microdisk lasers grown via TASE and are currently integrating InGaAs quantum wells for emission above the Si absorption edge. Moreover, we have used intensity measurements of scattered photoluminescence (PL) in Au waveguides on InP to confirm that PL couples to surface plasmons and is guided in this materials system.

In this work, we explore Au cladded III-V whispering gallery mode (WGM) cavities to further scale down the footprint of lasers. We design and fabricate InP cavities with resonances in the near-infrared using direct wafer bonding. InP is bonded on Si and (WGM) cavities with diameters from 100nm to 1000nm are dry etched subsequently. In a second step selected cavities are cladded with Au and the performance of purely photonic and metal-clad devices is compared. µ-PL spectroscopy is performed using a ps-pulsed supercontinuum laser at 750nm. A 100x objective is used to focus light on the sample from the top and collect the PL response. Measurements show evidence of lasing with resonant emission around 900 nm and a far field radiation pattern with fringes for cavities above 500 nm in diameter in both cases, with and without Au. For the Au cladded case, the threshold is higher. Indication of lasing is not observed for 400 nm wide purely photonic structures. However, for the cavities cladded with Au, a resonant peak emerges, indicating lasing at around 920 nm. Finite difference time domain simulations fit with our experimental observations and confirm a decrease in quality factor with decreasing diameter for the photonic cavities. Around 600 nm diameter, Q-factors become comparable to Au cladded cavities. When further reducing the cavity size, purely photonic cavities support no resonances anymore while cladded cavities do.

In summary, we observe evidence of lasing at room temperature for WGM cavities upon pulsed optical excitation. Preliminary results show that for smaller cavities one benefits from metal cladded designs and is able to scale down the emitter beyond the limit of purely photonic cavities. In a next step we will apply the same approach to InP cavities directly grown in silicon using TASE. This might further improve performance as the TASE growth results in atomically smooth sidewalls with reduced defect density.

**Novel Semiconductor Structures for Single Photon Emission and Detection**  
Anna Fontcuberta i Morral; Ecole Polytechnique Federale de Lausanne, Switzerland

Semiconductor materials play a pivotal role in photonic technology. They can be used as tailored photon emitters and detectors. Combined with plasmonic structures and photonic design, their efficiency and functionality is further extended. In this talk we show how compound semiconductor nanostructures such as nanowires and nanoscale membranes (nanofins) can be used for both single photon emission and detection [1],[2]. We will explore what kind of heterostructures are optimal for these applications. We will also elucidate how photon detection can be optimized by the nanowire geometry and the combination with plasmonic structures [2,[3]]. Finally, we will also explore materials with a lower production and environmental cost and how to fabricate them at a similar functionality than compound semiconductors. We will show how GeSn thin films and nanostructures have the potential to become the leading material in mid-infrared photodetection.

**A New Paradigm for Scalable Quantum Optical Circuits—On-Chip Single Photon Source Arrays Integrated with Optically Resonant Metastructure Based Light Manipulating Units**  
Anupam Madhukar1, Jiefei Zhang1, Swarnabha Chattarat1 and Siyuan Lu2; 1University of Southern California, United States; 2IBM T.J. Watson Research Center, United States

Manipulation of single photons generated deterministically from pre-specified sources on-chip to create multiphoton entangled states remains a major goal to be reached in photonic quantum information processing platforms. Notable advances have been made in single photon source performance and demonstrations of photon interference and entanglement based largely upon finding suitable single photon source from an otherwise random ensemble. The lack of scalable on-chip architectures stands as a major obstacle to realizing compact quantum information technologies.

In this talk I will present our proposition [1,2] and continuing efforts [3,4] to realize such a photonic chip built upon a unique class of spatially-ordered arrays of surface-curvature driven mesa-top single quantum dots (MTSQDs) [1,3]. These AlGaAs/InGaAs MTSQDs exhibit spectral uniformity as low as 1.8nm across 5×8 arrays, exhibit pairs of as-grown QDs having emission energy within 200μeV, and single photon purity > 99%. Following a planarization overlayer growth, these buried single photon sources (SPS) provide the essential platform for subsequent lithographic fabrication of emitted photon light manipulating units (LMUs). The LMUs exploit either the well-developed photonic 2D crystal approach or a new approach we introduced [1,2] based upon Mie-like resonances in interacting subwavelength-sized dielectric building block (DBB) based metastructures. The in-plane single Mie-like resonance of the metastructure (the LMU) provides all the needed basic photon manipulation functions to create controlled on-chip interference and entanglement [4]: enhancement of the SPS emission rate (Purcell enhancement), directional emission (local antenna), state-preserving propagation, path bifurcation (beam-splitting), and beam combining. Findings of our combined theoretical analysis, numerical simulations, and experimental studies of such SPS-LMU primitives — the essential building unit for quantum optical circuits — will be presented. The emphasis is on the holistic approach to proof-of-principle demonstration of the needed on-chip multifunctional system with its built-in trade-offs rather than the best of any individual light manipulation function.

The work is supported by the US Army Research Office (W911NF1910025) and the Air Force Office of Scientific Research (FA9550-17-1-0353).

2020 MRS Virtual Spring/Fall Meeting, November 27-December 4, 2020, Spring Abstracts Final Program 2/3/21
Advances in Quantum Dot Single Photon Sources

Yasuhiko Arakawa; The University of Tokyo, Japan

Since the first proposal of the semiconductor quantum dot in 1982[1], the quantum dots have been intensively investigated for both fundamental solid state physics and device applications. Advances of self-assembling crystal growth technology of quantum dots enabled realization of high performance semiconductor lasers[2] and quantum information devices such as single photon sources. Moreover, implementing a single quantum dot in an optical nanocavity provides a new platform for solid-state cavity quantum electrodynamics (cavity-QED)[3].

In this talk, we first discuss recent progress in growth and physics of GaN quantum dots for single photon sources (SPSs) at a ultraviolet wavelength, including a position controlled nanowire quantum dot with a giant biexciton binding energy over 60meV and high temperature operation up to 350 K[4,5]. Secondly, for implementation of SPSs onto silicon-based photonic integrated circuits, we also discuss a transfer printing method that integrates quantum dot SPSs into a silicon waveguide, demonstrating InAs/GaAs quantum dot SPSs with high waveguide coupling efficiencies, as well as the integration of two SPSs into a waveguide[6].

Keynote: Light-Matter Interaction in Two-Dimensional Semiconductors

Vinod Menon; City College and Graduate Center of CUNY, United States

Owing to their large oscillator strength and strong exciton binding energy, two-dimensional (2D) transition metal dichalcogenides (TMDs) have emerged as an attractive material platform for studying strong light-matter coupling and associated phenomena. Following up on our previous work on strong light-matter coupling in 2D TMDs [1, 2], here we will present results on enhancing the nonlinear interaction between the quasiparticles (exciton-polaritons). This is achieved using excited states of excitons (Rydberg states) which have larger Bohr radii. We will also present our recent results on controlling the valley pseudospin via the pseudomagnetic fields in optical cavities and our work on realizing an electrically pumped polariton LED [3]. Finally, we will first present our work on realizing single photon emitters (SPEs) in hexagonal boron nitride (hBN), a van der Waals material, via strain engineering [4] and coupling of these SPEs to high Q silicon nitride microresonators [5].

References
Mid-infrared light sources are key components for future chemical sensing, on-chip optical interconnect and LIDAR technologies. GeSn alloys can be synthesized under silicon CMOS compatible conditions. Therefore, GeSn can open pathways for miniaturization of mid-infrared devices such as on-chip molecular sensors, optical interconnects and thermal cloaking devices. Most importantly, direct band gap GeSn is a promising material for on chip integration of light emitters. Previous research on GeSn films has shown mid-infrared lasing at increasing temperatures, initially (in 2015) at less than 90K and, in more recent reports, at or near room temperature. It has also been shown that GeSn nanowires with high-Sn content exhibit strong direct-gap photoluminescence at room temperature. Compared to GeSn thin films, GeSn nanowires are less constrained to lattice match with misfitting (e.g. Ge, Si) substrates and therefore may achieve higher Sn contents without strain and defects that promote non-radiative recombination. Additionally, unlike in a planar GeSn film where the emission angle is limited to $< 13^\circ$ by its high refractive index ($n>4$), GeSn nanowires provide a platform to design the optical density of states for highly efficient light extraction directly from the light emitting material. GeSn nanowires may also constitute a superior medium for absorption and generation of photocarriers.

We demonstrate room temperature mid-infrared photodetection using resonantly absorbing GeSn/Ge core/shell nanowire photonic crystals. We have synthesized GeSn/Ge core/shell single crystal nanowires with 4% Sn that exhibit strong direct-bandgap photoluminescence at room temperature. The vertical nanowire photodetection device consists of arrays of nanowires in-filled with PMMA insulating layer, an ITO top contact and an aluminum bottom contact. Using full wave FDTD simulations, we optimize Mie resonances of individual nanowires (300 nm in diameter) at the desired bandgap wavelength. We further engineer the absorption with nanowires arranged in photonic crystal arrays. To synthesize the nanowire device, gold catalysts were patterned on Ge [111] substrate and then two step VLS growth was performed to synthesize Ge core and GeSn shell. We performed photocurrent characterization with an FTIR spectrometer at room temperature. The photocurrent spectrum of Ge nanowire photonic crystals indicates a four-fold enhancement due to resonant absorption, with the photocurrent spectrum tunable by varying the photonic crystal geometry.

For emission, we designed, synthesized and characterized mid-infrared emission of GeSn/Ge coreshell nanowires with 9-12% Sn. Full wave FDTD simulations reveal that the geometry of GeSn/Ge nanowires can be tuned to be resonantly scattering at the direct band gap energy. To further enhance light extraction, we use FDTD simulations to optimize GeSn/Ge nanowires in photonic crystal arrays to maximize the density of photonic states above the light line within the emission spectrum. The light emitting device consists of a similar device structure to that which is useful for photodetection. Room temperature photoluminescence characterization reveals both direct- and indirect-gap emissions in the mid-infrared, while photoluminescence characterization at 200 mA/cm reveals direct bandgap emission at both 2000 nm and 2300 nm. Optimization of nanophotonic light extraction efficiency will be discussed.

III-V compound semiconductor nanowires have been successfully used for a precise and simultaneous control of lattice parameters and bandgap structures bringing to existence a variety of functional nanoscale heterostructures and low-dimensional systems. Extending this paradigm to group IV semiconductors will be a true breakthrough that will pave the way to creating an entirely new class of silicon-compatible clean energy conversion, optoelectronic, and photonic devices. With this perspective, germanium-tin (GeSn) and silicon-germanium-tin (SiGeSn) alloys have recently been the subject of extensive investigations as new vertical systems to independently engineer lattice parameter and bandgap energy and directness.[1-5] The ability to incorporate Sn atoms into silicon and germanium at concentrations about one order of magnitude higher than the equilibrium solubility is at the core of these emerging potential technologies. In this presentation, we will address the epitaxial growth and stability of these metastable nanowires with focus on Ge/GeSn core/shell nanowires with a sub-30 nm core. The reduced dimension of the Ge core was found to facilitate the growth of GeSn shell at a Sn content of $\sim$10at.%, about 10-fold higher than the equilibrium solubility. We will discuss the optical and electronic properties and present strategies to integrate these nanowires in fabrication of short wavelength infrared (SWIR) and mid-infrared (MIR) optoelectronic devices. Finally, by using a microfabricated strain engineering platform, we will show...
that tensile strain allows tuning of the optical properties of Ge/GeSn core/shell nanowires in the SWIR and MIR range, thus laying the groundwork to implement innovative optoelectronic devices.

SESSION S.EL06.08: III-V Photonic Materials and Devices
On Demand Abstracts Available for Viewing Starting On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
S-EL06

5:00 AM *S.EL06.08.01
Template-Assisted Selective Epitaxy for Integrated Photonics Svenja Mauthe, Preksha Tiwari, Markus Scherrer, Philipp Staudinger, Daniele Caimi, Marilyne Sousa, Yannick Baumgartner, Heinz Schmid, Kirsten Moselund and Noelia Vico Trivino; IBM Research-Zurich, Switzerland

High-density and high-efficiency small light sources will have a wide range of applications including sensing, spectroscopy, quantum computing, and optical communications. In this regard, the integration of III-V materials on silicon has been pursued for decades to combine the best of both semiconductor families: Silicon for electronics and photonics components such as passive waveguides, wavelength filters, modulators, and photodetectors along with III-V semiconductors as direct bandgap efficient light emitters. Several approaches have been investigated relying overall on either bonding III-Vs to a silicon wafer or direct growth.

The main challenge to be overcome in direct growth stems from the significant lattice and thermal mismatch between III-Vs and Si that leads to crystal defects. We have developed a novel growth method named template-assisted selective epitaxy (TASE) to cointegrate seamlessly different materials. The high crystal quality of TASE-grown III-Vs resulted in state-of-the-art electronic devices. TASE-grown materials fill and take the shape of a pre-defined hollow oxide template. Overall benefits of TASE include low defect density, absence of foreign catalyst (Au-free), and precise control of crystal composition, position, shape, and size.

For integrated photonics TASE offers several advantages that are not achievable with other integration schemes. As all the fabrication steps involve only Si – no III-V processing – the template can hence be fabricated in a Si photonic foundry on an SOI wafer. This way, based on the mature Si technology, we can create III-V nanostructures featuring arbitrary shapes, e.g., vertical or horizontal nanowires, rings, microdisks, or photonic crystals. It also enables in-plane co-integration with Si-based components. Dense co-integration of different III-Vs was implemented on the same chip by sequential growth runs. We have recently demonstrated microdisk lasers grown by TASE which compared favorably to similar structures fabricated by the mature wafer bonding approach. However, the true benefit of TASE comes from enabling a seamless integration with silicon. In this talk we shall focus on these aspects, and how this enables novel device architectures including hybrid III-V/silicon photonic crystal cavities and photodetectors.

This research was supported by the European Union H2020 ERC StG PLASMIC (Grant No. 678567), SiLAS (Grant No. 735008) and Swiss National Science Foundation SPILA (Grant No. CRSK-2_190806).

Self-Assisted Epitaxial Growth of GaAsSb Nanowires on Monolayer Graphene Surya Nalamati1, Priyanka Ramaswamy1, Kendall Dawkins1, Jeffrey Kronz2, Robert Lavelle2, David Snyder2, C. Lewis Reynolds3, Matthew Cabral3 and Shanthi Iyer1; 1North Carolina A&T State University, United States; 2The Pennsylvania State University, United States; 3North Carolina State University, United States
We report the successful growth of high-quality GaAs1–xSbx nanowires on monolayer graphene/SiO2/p-Si (111) using molecular beam epitaxy (MBE) for the application of a flexible near-infrared photodetector. A systematic and detailed study of NW growth parameters, namely, growth temperature, V/III beam equivalent pressure (BEP) ratio, and Ga shutter opening duration, has been carried out. Growth of vertical <111> oriented nanowires on graphene with 4 K photoluminescence emission in the range 1.24–1.38 eV has been achieved. The presence of a weak D mode in Raman spectra of NWs grown on graphene suggests that NW growth did not alter the intrinsic properties of the monolayer graphene. High-resolution transmission electron microscopy and a selective area diffraction pattern confirmed the zinc-blende crystal structure of the NWs. This study suggests that Sb as a surfactant plays a critical role in the surface engineering of the substrate, leading to the superior optical quality of NWs exhibiting a higher 4 K photoluminescence intensity and lower full width at half maxima (fwhm) with significant improvement in optical responsivity compared to NWs grown on Si substrate of similar Sb composition. Novel growth conditions for improvement of NW density and device performance will be discussed.

Toward Scalable III-V Nanowire Networks for IR Photodetection Nicholas P. Morgan1, Martin Friedl1, Didem Dede1, Alexander Dorodný2, Sabbir Khan3,4, Lucas Gúniat1, Akshay Balgarkashi1, Wonjong Kim1, Jean-Baptiste Leran1, Peter Krostrup3,4, Juerg Leuthold2 and Anna Fontcuberta i Morral1; 1EPFL, Switzerland; 2ETH Zürich, Switzerland; 3University of Copenhagen, Denmark; 4Microsoft Quantum Materials Lab, Denmark
InGaAs is an ideal material for near-infrared (IR) photodetection at telecommunications wavelengths, but its devices typically require the use of bulk III-V substrates which are costly and largely incompatible with CMOS processing.1 Nanowire-based photodetectors are a promising route to the integration of III-V materials with Si electronics and even offer a number of performance advantages over bulk devices.2 For example, the anisotropic geometry of nanowires allows for the possibility of polarization-resolved photodetection as well as fast carrier collection, making them suitable for fast and efficient multiplexed applications.3 Recently, arrays and networks of high-quality horizontal InAs and InGaAs nanowires have been demonstrated using selective area epitaxy on III-V substrates by growing them on top of GaAs nanomembrane buffers.4,5 Extension of this technique through monolithic integration of GaAs nanomembranes on Si (001) offers the opportunity to create scalable, high-performance IR photodetectors at a fraction of the cost of current InGaAs-based devices. This, however, requires a reliable method to grow defect-free GaAs nanomembranes on Si. In this work, we investigate the growth of GaAs nanomembranes on Si by molecular beam epitaxy. Specifically, we combine various defect reduction techniques, including v-groove trenches, aspect ratio trapping and migration enhanced epitaxy, and characterize the resulting nanostructures. We demonstrate highly faceted nanomembranes several micrometers in length that exhibit large defect-free regions, which may be suitable as a template for future horizontal InGaAs nanowires. Furthermore, we introduce a novel architecture for photoconductive detectors based on these templated nanowires using plasmonic enhancement. Through frequency domain finite element simulations, we demonstrate polarization-sensitive absorption of up to 20% in the nanowire active material and the ability to tune the absorption response by changing the dimensions of the array. Finally, we present related work on the fabrication and characterization of photodetectors based on InAs(1-x)Sb and InSb nanowire crosses and hashtags grown by the vapor-liquid-solid technique.6,7,8 These structures offer the possibility of polarization-resolved photodetection in the mid-IR. To the best of our knowledge, IR photodetectors based on nanowire crosses and/or hashtags have not been previously reported.

Epitaxial Quantum Dot Lasers on Silicon

Justin Norman¹, Chen Shang¹, Daehwan Jung², Jennifer Selvidge¹, Songtao Liu¹, Yating Wan¹, Zeyu Zhang¹, Mario Dumont¹, MJ Kennedy¹, Robert Herrick³, Kunal Mukherjee¹, Arthur Gossard¹ and John Bowers¹; ¹University of California, Santa Barbara, United States; ²Korea Institute of Science and Technology, Korea (the Republic of); ³Intel Corporation, United States

In recent years, InAs quantum dot lasers have proven themselves resilient against crystalline defects that form during heteroepitaxial growth of III-Vs on silicon. The three-dimensional confinement and reduced in-plane diffusion lengths of carriers in quantum dots relative to quantum wells are the source of this resiliency, but alone these characteristics are not sufficient for demonstrating commercially reliable performance for lasers on silicon. Quantum dot active regions must be utilized together with highly optimized III-V/Si buffers to reduce the dislocation density to achieve acceptable device reliability.

In this talk, recent advances in GaAs/Si templates will be highlighted along with the resulting enhancements in laser reliability. Over the last three years, we have produced InAs quantum dot lasers on GaAs/Si templates with dislocation densities ranging from $3 \times 10^8$ cm$^{-2}$ down to $< 7 \times 10^6$ cm$^{-2}$ by optimizing thermal cycling procedures and strained filter layers. As the material has improved, the extrapolated mean-time-to-failure has increased several orders of magnitude to >10,000,000 h at 35°C and >50,000 h at 60°C.

In addition to improving laser reliability, the improvements in material quality have virtually closed the performance gap relative to native substrate lasers before aging. At dislocation densities of $7 \times 10^6$ cm$^{-2}$, low threshold, high power, and high efficiency lasers are readily achievable with continuous wave operation above 100°C. These improvements justified more advanced laser implementations and investigations into the dynamic performance of quantum dot lasers on silicon. The unique atom-like density of states of quantum dots has historically enabled unique properties such as an insensitivity to optical feedback, highly engineerable gain bandwidth, and ultrafast gain recovery; these properties unique to quantum dots have enabled Fabry-Perot lasers with complete insensitivity to optical feedback, high performance mode-locked lasers operating at 20 GHz with 64 channels capable of 4.1 Tbps transmission below the forward error correction (FEC) limit, and 100 GHz colliding pulse mode-locked lasers capable of 0.9 Tbps transmission below the FEC limit. Achieving each of these results required a high degree of optimization in the epi design and materials growth to obtain uniform distributions of high-quality quantum dots, which will be emphasized in the talk.

Further improving performance and, in particular, demonstrating commercially viable reliability at elevated temperatures >60°C will require additional efforts to reduce the dislocation density in the laser active region. Our efforts to push the threading dislocation density $< 2 \times 10^6$ cm$^{-2}$ while also reducing the buffer thickness will be discussed in addition to efforts to address misfit dislocations that have been observed in the laser active region. Given the much larger cross-section of material that interacts with a misfit dislocation relative to a thread, it is believed that addressing these defects is critical to reaching the goal of native substrate level device reliability on a silicon substrate.

Optical Communication and Energy Conversion for Small-Footprint Edge Computing

Ning Li; IBM T.J. Watson Research Center, United States

Advancement in microelectronics technology enables autonomous edge computing platforms in the size of a dust mote, bringing efficient and low cost artificial intelligence computing close to end users. The key components of these edge computers include (i) communication devices to talk to nearby host computers and (ii) power sources to convert energy to on-chip electrical power. As RF communication and power converters suffer from low efficiency with reduced antenna size, optical devices can provide much higher efficiency in sub-centimeter footprint. As there is limited energy storage inside the small footprint of edge computers, we developed power-saving light-emitting-diodes (LEDs) with high efficiency at ultra-low current and voltage[1], by improving the quantum well design and increasing the radiative radiation rate at low injection current. The device exhibits close to unity internal quantum efficiency at a current density orders of magnitude lower than that for conventional LEDs. Wireless communication is demonstrated at these low power conditions. We also investigated dust-sized III-V photovoltaic (PV) cells grown on silicon and Silicon-on-insulator substrate[2], considering surface passivation and crystallographic defects. We demonstrated highest power density micro-PVs on silicon substrate. These silicon substrates with integrated III-V devices can be used as the substrate carrier for heterogeneous integration of various silicon chiplets using wafer-level-packaging.

**Beyond Nanowire Size Constraints: New Epitaxy Strategies Towards Metastable III-V Layers**

Philipp Staudinger¹, Svenja Mauthe¹, Nicolas Tappy², Anna Fontcuberta i Morral²,², Kirsten Moselund¹ and Heinz Schmid¹; ¹IBM Research Zurich, Switzerland; ²EPFL, Switzerland

Metastable crystal phases of conventional semiconductors comprise enormous potential for high-performance electro-optical devices, while at the same time benefitting from the chemical similarity to their stable counterparts which enables the reuse of established processing technology. AlAs, AlSb, AlP, GaP and Ge all possess indirect bandgaps in their thermodynamically stable cubic phase, whereas both theoretical calculations as well as first experimental reports suggest their band transition to be direct when their lattice periodicity is changed to the hexagonal wurtzite (WZ) or lonsdaleite (LD) symmetry [1, 2]. These findings recently triggered intense research interest for creating efficient light sources in the important amber-green wavelength regime of the visible spectrum where a lack of suitable emitting materials currently limits the performance of LEDs and semiconductor lasers [3]. Beyond that, direct bandgap Ge and SiGe compounds could even pave the way towards active group-IV optoelectronic devices. However, synthesizing these novel polytypes remains challenging and so far, has mainly been achieved in the form of thin nanowires, mostly by using Au catalysts and by compromising other important parameters such as crystal morphology or doping, hampering scientific and commercial exploitation.

In this work, we demonstrate new techniques to synthesize layers in their metastable WZ phase. InP is particularly suited for this task as both the stable cubic and the WZ phase exhibit a direct, but distinctive bandgap, which allows efficient optical analysis. We use MOCVD and selective area epitaxy to grow pure WZ nanowires and fins. We then show two extensions of this technique to obtain planar layers: The first one is based on confined epitaxy and enables growth on standard (001)-oriented substrates [4]. In a second, newly introduced approach we explore epitaxial layer overgrowth (ELO) on (111)A-oriented wafers. This allows to grow pure WZ layers on insulator exceeding areas of 100 μm², constituting a promising substrate for device fabrication. The material quality of the structures is determined by micro-photoluminescence (μ-PL), high-resolution scanning transmission electron microscopy (HR-STEM), atomic force microscopy (AFM), and cathodoluminescence (CL). We compare the investigated techniques, show their limitations and develop a general model to explain polymorphism in planar layers.

This work was supported by the EU H2020 program SiLAS (Grant Agreement No. 735008).

**SiGe/Si-Based Electro-Optic Platform for Microwave-Optical Transduction**

Jason S. Orcutt; IBM T. J. Watson Research Center, United States

Superconducting qubit quantum computers offer new capabilities for quantum information processing, but require < 50 mK environments and near complete isolation from outside noise sources. To enable quantum information to be exchanged with these systems outside of cryogenic conditions by means of higher energy photons, many approaches towards microwave-optical transduction are being explored by the research community. Three-wave mixing in linear electro-optic materials is a particularly appealing approach due to the inherent simplicity and elimination of excess noise sources that are introduced by intermediate states present in many alternative technologies. However, material microwave and optical loss rates have limited conversion efficiency below 50% in demonstrations to date. Here, I present IBM’s work towards integrating low loss SiGe/Si optical resonators with the low loss Nb-on-Si microwave resonators that have been developed for superconducting qubits. An
effective linear electro-optic coefficient for coupling the microwave and optical fields by three wave mixing is induced by strongly biasing the microwave resonators to leverage the DC Kerr effect in Si and SiGe. For 1 MHz-rate transducers, the resulting microwave-optical coupling strength is calculated to be sufficient to reach the peak conversion efficiency condition. Demonstrating microwave-optical transduction in this platform is then dependent on achieving low defectivity fabrication of the proposed SiGe/Si optical waveguides. I will present a study of this materials problem and an analysis of the overall optimal transducer design.

This work was funded by LPS/ARO under CQTS program, contract number W911NF-18-1-0022.

5:30 AM *S.EL06.09.02
Quantum Photonics with InAs Quantum Dots Marcelo Davanco; National Institute of Standards and Technology, United States

Photonic quantum technologies rely on the fact that photons can be endowed with long coherence times, can travel long distances at light-speed, and interact only weakly with the environment, thereby constituting near-ideal carriers of quantum information. Single-photon qubits are a core resource for many quantum technologies currently being developed for systems that, based on quantum mechanical effects, have great potential to perform communication, signal processing, computation and measurements with significantly superior security, efficiency and sensitivity [1–3]. In such applications, an ideal quantum light source would emit a pure, high-rate stream of highly indistinguishable single-photons produced on-demand. Single-photon sources based on single quantum emitters – such as quantum dots, organic molecules, point-defects in solids, etc. - have a great potential to fulfill all such requirements. Among the various types of single quantum emitters available in the solid-state, self-assembled InAs/GaAs quantum dots constitute the most promising material system to date [4], having been used to demonstrate triggered single-photon emission with indistinguishability close to that of spontaneous pair sources, and orders or magnitude higher generation rates [5, 6]. Such quantum dots consist of nanometer-scale islands of InAs that are grown epitaxially in a GaAs host, and are operated at cryogenic temperatures. Importantly, the ability to produce quantum dots within high index contrast GaAs nanophotonic geometries enables strong control of crucial quantum dot emission characteristics, such as the excited state decay rate and outcoupling into select spatial modes [5–7]. The former characteristic translates into control of the single-photon emission rate and, to some degree, coherence. The latter translates into efficient funneling of the single-photons into a useful, output optical spatial mode – e.g., a low-divergence Gaussian beam [7, 8] or a single optical fiber mode [9] -, which has a strong impact on the overall source efficiency. This talk will describe our progress in developing high efficiency single-photon sources based on self-assembled InAs/GaAs quantum dots in nanophotonic structures. In particular, because the availability of mature chip-scale photonic integration techniques provides compelling advantages towards scalable photonic quantum systems, our recent results on deterministic fabrication of heterogeneous integrated photonic devices with single quantum dot based sources of on-chip waveguide-coupled single-photons [10, 11] will be covered.

Superconducting Single Photon Detectors and Their Applications in Quantum/neuro Networks Sae Woo Nam; National Institute of Standards and Technology, United States

Single-photon detectors are increasingly becoming an essential tool for a wide range of applications in physics, chemistry, biology, communications, medicine, and remote sensing. In the area of computing, efficient single photon detection is important for quantum information processing with photons as well as recently proposed work for large-scale superconducting optoelectronic networks for neuromorphic computing. Ideally, a single photon detector generates a
measurable signal only when a single photon is absorbed. Furthermore, the ideal detector would have 100% detection efficiency, no false positive (dark counts), and transform-limited timing resolution. Recently, there has been tremendous progress in the development of superconducting nanowire single-photon detectors (SNSPDs or SSPDs) towards nearly ideal performance. The SNSPD is an alternative to conventional semiconductor avalanche photodiodes (APDs) especially for wavelengths in the near-infrared region of the spectrum. Since the first demonstration of single photon detection with a superconducting nanowire, there has been significant effort to package nanowire detectors into systems that could be used in real-world applications. I will review a few technological breakthroughs in SNSPD designs and performance, will briefly describe where advances in materials and material science could have immediate impact on the use of these detectors for computing.

6:30 AM S.EL06.09.04
Chromium Ions as High Fidelity Optically Addressable Spin Qubits in Commercial Silicon Carbide Berk Diler1, Samuel J. Whiteley1,1, Christopher Anderson1,1, Gary Wolfovicz1,2, Marie E. Wesson1, Edward Bielejec2, F. Joseph P. Heremans1,2 and David Awschalom1,1,2; 1The University of Chicago, United States; 2Argonne National Laboratory, United States

Optically active spin defects in wide bandgap semiconductors continue to attract attention as qubits in the solid state. The ground state spin sublevels of these defects can store and process information while the atom-like optical transitions can initialize and read out the spin. Introducing these defect centers reliably into the host material is critical for future device integration. To this end, we explore chromium ion creation through implantation and annealing in silicon carbide (SiC) [1], a technologically mature and CMOS compatible wafer scale host crystal. Chromium in the 4+ charge state (Cr4+) has an S = 1 ground state and an S = 0 excited state with a near-infrared (1070 nm) strain insensitive optical transition that has a high Debye-Waller factor of 75%, making it interesting for quantum communication through fiber optic networks. We find that the created Cr4+ ensemble has an order of magnitude narrower linewidth of the optical hole (31 MHz) compared to as grown samples. We use the Λ-like level structure as a spin-photon interface and study the transition rates to optimize for high fidelity spin initialization and readout of 79%. At cryogenic temperatures (15 K), we measure long ensemble spin coherence times of $T_2^*$ = 317 ns and a $T_2$ = 81 μs limited by the ensemble density and $T_1$ greater than 1 s. These results demonstrate Cr4+ in SiC as an attractive optically active spin-qubit for integration within quantum devices.

Diffractive Optical Neural Networks Designed by Deep Learning Aydogan Ozcan and Deniz Mengu; University of California, Los Angeles, United States

We introduce a physical mechanism to perform machine learning by demonstrating a Diffractive Deep Neural Network (D2NN) architecture that can all-optically implement various functions following the deep learning-based design of passive layers that work collectively. We created 3D-printed diffractive networks that implement classification of images of handwritten digits and fashion products as well as the function of an imaging lens, spectral filters and wavelength demultiplexers at terahertz spectrum. This passive diffractive network can perform, at the speed of light, various complex functions that computer-based neural networks can implement, and will find applications in all-optical image analysis, feature detection and object classification, also enabling new camera designs and optical components that perform unique tasks using diffractive neural networks designed by deep learning.

5:30 AM S.EL06.10.02
Broadband Diffractive Neural Networks Yi Luo, Deniz Mengu, Nezih T. Yardimci, Yair Rivenson, Muhammed Veli, Mona Jarrahi and Aydogan Ozcan; University of California, Los Angeles, United States
The success of deep learning has recently stimulated broad interest in optical neural networks due to their key advantages: (1) ease of parallelization and scalability, (2) low power and (3) high data processing speed. Merging wave optics with deep learning methods, Diffractive Deep Neural Networks (D^2NN) have been introduced as an optical neural network framework, which is based on the engineering of light-matter interaction occurring at successive diffractive layers that connect an input (e.g., an object to be classified) to an output plane through optical diffraction. During the design of a D^2NN, which is performed in a computer using deep learning methods, including e.g., error backpropagation and stochastic gradient descent, the phase and/or amplitude patterns of each diffractive layer of a network are jointly-optimized to solve a given computational task such as image classification. After its design, the resulting diffractive optical network is physically fabricated to perform all-optical inference at its output plane. Successful demonstrations of diffractive neural networks include all-optical object classification and ultra-compact imaging systems, involving 3D-printed diffractive layers that compute through the diffraction of terahertz (THz) radiation. In these previous works, the diffractive networks processed spatially and temporally coherent radiation, involving a monochromatic plane-wave illumination. Here we expand our D^2NN framework to simultaneously process a continuum of wavelengths, making it applicable to all-optical computing settings where broadband illumination is essential and/or advantageous. Using the native and/or engineered dispersion of materials, broadband diffractive optical neural networks simultaneously process all the target wavelengths within a desired band to compute a statistical or deterministic task that it is trained for. We experimentally confirmed the success of this framework by designing, 3D-printing and testing seven different diffractive networks that process an input THz pulse to perform a series of tunable, single passband and dual passband spectral filters, as well as spatially-controlled wavelength de-multiplexing. Using a THz Time-Domain Spectroscopy (TDS) system, we demonstrated a very good match between our experimental results and the corresponding numerical design for each fabricated broadband diffractive network. Leveraging deep learning-based optimization tools and material dispersion properties, this broadband diffractive network framework provides a powerful method to engineer light-matter interaction in 3D, opening up new avenues to design non-intuitive, task-specific optical components as well as all-optical classifiers and processors. The presented method is broadly applicable to various parts of the electromagnetic spectrum, including the visible band, and can be further strengthened by the additional degrees of freedom provided by engineered material systems including e.g., metamaterials. We believe broadband diffractive networks provide a unique framework to perform all-optical statistical inference for machine learning tasks as well as to design deterministic and task-specific optical components, broadly covering a non-intuitive and yet powerful design space.

5:45 AM S.EI06.10.03
Optical Signal Processing Using Dielectric Metasurfaces Jinghui Yang, Wenqi Zhu, Lu Chen, Cheng Zhang, Henri J. Lezec and Amit Agrawal; National Institute of Standards and Technology, United States

Optical analog computing provides solutions with fast and power-efficient performance for big-data applications. Recently investigated metamaterials and metasurfaces demonstrate potentials in mathematical operations over wavelength-scale footprint. We extend the functionality of using nonlocal dielectric metasurface to perform spatial differentiation equation for imaging processing. The study pave the way towards ultrathin devices for optical signal processing.

6:00 AM S.EI06.10.04
Flat Optics for Image Differentiation You Zhou1, Hanyu Zheng1, Ivan Kravchenko2 and Jason G. Valentine1; 1Vanderbilt University, United States; 2Oak Ridge National Laboratory, United States

Image processing has become a critical technology in a variety of science and engineering disciplines. While most image processing is performed digitally, optical analog processing has the advantages of being low-power and high-speed though it requires a large volume. Here, we demonstrate optical analog imaging processing using a flat optic for direct image differentiation allowing one to significantly shrink the required optical system size. We first demonstrate how the image differentiator can be combined with traditional imaging systems such as a commercial optical microscope and camera sensor for edge detection at a numerical aperture up to 0.32. Second, we demonstrate how the entire processing system can be realized as a monolithic compound flat optic by integrating the differentiator with a metasens. The compound nanophotonic system manifests the advantage of thin form factor optics as well as the ability to implement complex transfer functions and could open new opportunities in applications such as biological imaging and machine vision.

The differentiator consists of carefully designed silicon nanorods that can transform an image into its second-order derivative, taking the Laplacian of the incident field. The optical response is based on interference between direct transmission and a low-Q guided resonance allowing for transmission at large incident angles but none at normal incidence. Fourier imaging was carried out showing the required quadratic transfer function for an NA up to 0.32, which allows resolving edges at the scale of 4 microns. To showcase its practical application, we first demonstrate the device at a wavelength of 740 nm by integrating the differentiator with a commercial microscope. This allowed us to reveal high-contrast edge information.
when imaging biological cells, akin to phase contrast microscopy though with a considerably simpler system. Using scalable manufacturing techniques, not involving lithography, we also fabricated the nanoarray over a centimeter-scale wafer and demonstrate edge detection when placing the filter directly in front of an imaging sensor. Lastly, we have demonstrated the creation of a monolithic flat optic combining both a metalens and the differentiator for realizing a compact image processing system.

S.EL06.11.01
**Sn-containing group IV semiconductors (Si)GeSn represent a versatile platform to implement a variety of Si-compatible photonic, optoelectronic, and photovoltaic devices. This class of semiconductors provides two degrees of freedom, strain and composition, to tailor the band structure and lattice parameter thus enabling a variety of heterostructures and low-dimensional systems on a Si substrate. In this presentation, we will discuss the recent progress in controlling and understanding the optoelectronic properties of metastable (Si)GeSn semiconductors. The relevance of these semiconductors for Si-compatible mid-infrared optoelectronics will be discussed from both materials and device perspectives. The growth of the (Si)GeSn multilayer heterostructure with Sn contents up to ~20 at.% is currently performed using a chemical vapor deposition (CVD) reactor on a Silicon wafer. By reducing the growth temperature, the Sn content in the alloy is increased, while preserving a high degree of crystal purity for the heterostructure in the topmost Sn-rich layer.**

Atom probe tomography (APT) measurements will be discussed to address the abruptness of the interfaces in the GeSn multi-layer heterostructure and the uniform composition in the 18 at.% GeSn layer grown on top. Positron annihilation lifetime spectroscopy (PAS) and depth-profiled Doppler broadening measurements will be discussed to enrich the understanding of point defects in these semiconductors. Based on these analyses, we found that divacancies are the predominant type of point defects in GeSn with composition in the 6.5-13 at.% range.

Photoluminescence (PL) emission studies will be presented and discussed. In a GeSn layer with a Sn content of 18 at.% the room temperature PL emission was found to be centered at 0.36 eV (i.e. 3.5 μm wavelength). However, the compressive in-plane strain (-1.3 %) in these GeSn layers reduces the directness of the alloy, leading to a higher energy gap value. By releasing the strain down to -0.2% in the 18 at.% Sn layer using a fully-underetched micro-disk geometry, a 50 meV red-shift of the PL emission energy down to 0.31 eV (i.e. 4.0 μm wavelength) is obtained. Moreover, the strained and relaxed PL emission and absorption measurements ranging from 300K down to 4K will be shown. These observations will be discussed in the light of photocurrent measurements and photodetectors operating at MIR wavelengths.

S.EL06.11.02
**Epitaxial Growth of Atomically-Sharp GeSn/Ge/GeSn Tensile Strained (≥1.5 %) Quantum Well on Si** Simone Assali, Aashish Kumar, Jérôme Nicolas, Samik Mukherjee, Anis Attiaoui, Patrick Del Vecchio and Oussama Moutanabbir; Ecole Polytechnique de Montreal, Canada

In a full-group IV integrated semiconductor platform for tensile-strained Ge the direct-band gap can be obtained when the Ge is grown on a lattice-mismatched Ge0.87Sn0.13 substrate. With this approach the main challenge is to increase the incorporation of Sn in Ge above the ~1 at.% equilibrium composition. Major developments were recently achieved in the epitaxial growth
of random GeSn alloys with composition above 16 at.%. A biaxial tensile strain in a Ge layer up to ~1.5% was demonstrated when growing on a Ge$_{0.88}$Sn$_{0.12}$ substrate.[2-3] However, despite the large amount of tensile strain in Ge, no information is available on the abruptness of the Ge-GeSn interface and on the possibility of the subsequent GeSn growth on top. Here, we discuss the epitaxial growth of a tensile-strained GeSn/Ge/GeSn (s-Ge) QW heterostructure with sharp interfaces and in-plane biaxial strain above 1.5% grown on lattice-mismatched Ge$_{0.86}$Sn$_{0.14}$.[4] The sharpness of the Ge/GeSn heterostructure interfaces will be addressed using TEM-EELS and atom probe tomography (APT) measurements. A coherent s-Ge epitaxy with a tunable layer thickness in the sub-20 nm range is achieved. The pseudomorphic nature of the s-Ge layer will be discussed by combining cross-sectional STEM measurements and XRD-RSM measurements performed at a synchrotron radiation facility.

The s-Ge QW platform is a new versatile platform to investigate light-hole (LH) spin-based qubits and 2D high hole mobility electronics. Under tensile in-plane biaxial strain, LH occupies the top of the valence band and the LH-HH splitting can exceed 100s meV. Moreover, when the tensile in-plane biaxial strain approaches 2% only LH are confined in the QW, thus minimizing LH-HH interactions.

**S.E.L06.11.04**

**Homogeneous Cooling Dynamics in Laser Enhanced-Direct Print Additive Manufacturing of Circular Optical Fiber Interconnects**

Roger B. Tipton$^1$, Dianhao Hou$^1$, Thomas Weller$^2$ and Venkat Bhethanabotla$^1$; $^1$University of South Florida, United States; $^2$Oregon State University, United States

Integrated photonics have many compelling advantages for computing and communication applications, including high-speed and extremely wide bandwidth operations. When fused deposition printing (FDM) a PMMA plastic optical fiber on a surface the bottom of the fiber is flat due to non-uniform cooling and the force of gravity on the fiber during solidification. Here we show that by embedding the fiber in a urethane optical cladding material, the fiber cools homogeneously and retains its round ship which is optimum for light transmission. This homogeneous cooling allows the use of a flexible, low cost additive and subtractive assembly method called laser enhanced-direct print additive manufacturing (LE-DPAM) to produce plastic optical fiber interconnects for photonic systems we have enabled higher transmission rates, lower power requirements, improve signal integrity and timing, less heat generation, and improve security of communication signals.

**S.E.L06.11.05**

**Monte Carlo Simulation and Design of Novel High-Z Photon Attenuation Material-Si Two-Layer High-Energy X-Ray Detectors with Significantly Enhanced Efficiency**

Eldred Lee$^{1,2}$, Zhehui Wang$^2$, Michael James$^2$, Eric Fossum$^1$, Kaitlin Anagnost$^1$ and Jifeng Liu$^1$; $^1$Dartmouth College, United States; $^2$Los Alamos National Laboratory, United States

Since the discovery of X-rays, the continuous expansion of X-ray technology has transformed our society. However, the capability gap for hard X-ray detectors in the 10-100 keV range is problematic. Even though scintillator-based methods are widely used, they are limited by their decay time response, light yield, and spatial resolution, which may prevent them from being effective in the next generation of light source facilities, the generic platform of imaging sensor technology, and quantum image computing.

One class of X-ray detection primarily focuses structured photocathode designs that rely on external photomission and collecting electrons converted from photons using an external electric field. This research only demonstrated up to 5% photon-to-electron conversion efficiency (electron generation) at 7.5keV incident photon energy, which is still commendable as this value has been roaming around the 1-1.5% area for external photomission for a few decades [1, 2]. However, we believe that there is a potential to significantly increase this 5% electron generation even beyond 7.5keV incident photon energy via X-ray photon emission from high-Z materials.

Here, we present the Monte Carlo simulation results and analyses via Monte Carlo N-Particle Software (MCNP) that demonstrate a tremendous potential of revolutionizing the advancement of X-ray imaging with a two-layer design that consists of a high-Z semiconductor material on top of a Si layer. The high-Z layer is called photon attenuation layer (PAL), and the Si layer the electron detection layer (EDL). PAL-EDL latticed multi-pixel X-ray detector can also lead to low inter-pixel scattering with significant electron and photoelectron generation. The underlying principle of this design is photon energy down conversion, where the top high-Z PAL leads to an effective X-ray photon energy attenuation down to a few keV.
and allows Si to absorb them with a much higher absorption coefficient. This approach is distinct from scintillators in that the attenuated photons remain in X-ray spectral regime instead of visible regime. For instance, with PbTe, CdTe or CZT PAL and the Si EDL, we have observed >22% electron generation at 10keV X-ray photon energy and >2.8% electron generation at 40 keV incident photon energy with minimum inter-pixel scattering effects. The average electron energy lies between a few hundred eV and a couple keV.

At 30-40keV, we observed that adding a high-Z PAL on top of Si EDL can lead up to 13x higher electron generation than the typical Si direct-detection method seen in commercial products such as photomultipliers. Furthermore, because MCNP does not include the “avalanche gain” process in Si, the observed efficiencies may be underestimated. The MCNP results will be coupled with models that take the avalanche gain process into consideration (e.g. TCAD). In addition, this high-Z PAL-Si EDL configuration can be integrated to regular backside illumination (BSI) CMOS image sensor or quanta image sensor-based devices, paving the way towards a billion-pixel X-ray camera design for wide field-of-view applications in light sources [3].

Study of Space Charge Limited Conduction Mechanism and Effect of In Situ Annealing on the Trap Distribution in GaAsSb Nanowires
Mehul K. Parakh, Sean Johnson, Rabin Pokharel, Priyanka Ramaswamy, Surya Nalamati, Jia Li and Shanthi Iyer; North Carolina A&T State University, United States

This work presents the first observation of space charge limited conduction (SCLC) mechanism in intrinsic GaAsSb nanowires (NWs) grown by Ga-assisted molecular beam epitaxy and the effect of post-growth in-situ annealing in an ultra-high vacuum on trap concentration and its energy distribution in the NWs. Current-voltage (I-V) measurements on single NW (using conductive atomic force microscopy) and ensemble NWs (using two probe method) exhibited linear behavior at lower bias transitioning to a power-law behavior at higher bias, where the dominance of injected carriers over thermally generated charge carriers was observed. Temperature-dependent I-V analysis (I-V-T) on as-grown ensemble NW device in SCLC region yielded a trap concentration of $10^{16}$ cm$^{-3}$ distributed over a wide energy distribution in the bandgap as opposed to the reduced trap concentration of $7 \times 10^{14}$ cm$^{-3}$ in in-situ annealed NW ensemble confined to a narrower energy distribution of 0.12 eV located below the band edge, suggesting that annealing in ultra-high vacuum is an effective approach for the annihilation of the traps. The trap energy level in in-situ annealed NWs is speculated to be originating from Ga vacancy, and Ga$_{34}$Sb$_{34}$ anti-site defect level during growth. Observations of increased PL intensity with reduced full-width half maxima at 4K and lower LO mode in corresponding Raman spectra for in-situ annealed NWs compared to as-grown NWs further attest to the annihilation of traps on in-situ annealing. Further, AFM current mapping also exhibited a considerable increase in several conducting NWs in in-situ compared to as-grown NWs. Hence, I-V-T analysis of the SCLC mechanism has been demonstrated to be a simple approach to obtain information on growth induced traps in the NWs.

Photon-generated carriers may substantially improve the output current, and reduce series resistance of CMOSFETs. Photonic devices, such as Multiple Quantum Well Lasers, Quantum Dots Lasers, Vertical Cavity Surface-Emitting Lasers (VCSEL), Light Emitting Diodes (LEDs) have been reported for various applications. With modulation doped laser junctions, and bandgap engineered tunneling mechanisms, ultra-low resistivity and laser diode forward voltage can be achieved. These laser diodes can be fabricated in the drain region of a MOSFET. A photon sensor, such as avalanche photo diode (APD), can be included in the channel / well regions. The laser, APD, and MOSFET are fabricated as one integral
transistor. When the MOSFET is turned off, the laser is also turned off. The laser is switched on only when a gate voltage and a drain voltage are applied to the MOSFET. Light emitted from the laser is absorbed by the APD. Light current produced by the built-in photon sensors or APD reduces series resistance and may substantially improve the output current and switching speed.

Indium Tin Oxide (ITO) is commonly used in Charge Coupled Devices (CCD) receiving front illumination. The gate electrode material can be replaced with ITO, which is transparent for specific light spectrums. The new Photonic CMOS transistor, including nonlinear optical films and multiple photon sensors (for various light spectrums) can be used for CCD (with ITO) or CMOS image products (without ITO) for front or back illumination.

When external light is absorbed in the depleted channel and well regions (where the multiple photon sensors or APDs are located) of a Photonic MOSFET, light electrons are generated. These light electrons produce a drain current, which turns on the built-in laser in the drain region. The result is not only a light current, but also a new beam of a laser light are generated. Much higher resolution may be achieved with multiplexing of the light signals and specially designed ROIC (Read Out Integrated Circuit), which may also include Photonic CMOSFETs.

Nonlinear Optics have been reported for various products and applications. The nonlinear crystal films change the input light signal and produces an output light signal of a different frequency or color. In the new Photonic CMOS transistor, in addition to the built-in laser in the drain, there are multiple avalanche photo diodes in the channel / well regions, nonlinear crystal films below the APDs, and a reflector (metal or multiple indices total reflection film stack) in the bottom of the device. The APDs are designed to absorb lights from various bands of spectrums. When light passes through the Photonic CMOS Transistor, some APD films absorb lights of specific frequencies, and other APD films absorb the reflected light of different frequencies through the nonlinear crystal layers. This feature enhances the absorption rate and external quantum efficiency of the Photonic MOSFET, and may significantly improves the quality and resolution of the images from the CCD or CMOS imaging devices.

In this paper we will discuss Photonic MOSFET drain current (IDS) vs. spectral characteristics of nonlinear optical films. With the nonlinear optical films, it is possible to substantially improve the CMOS performance according to these data. Dark current density and resolution using a Photonic CMOS image sensor vs. traditional CMOS image sensor are analyzed. The advantages of a Photonic CMOS image sensor are lower dark current, and higher light sensitivity, due to the built-in lasing device and multiple photon sensing films, and nonlinear optical features.

Information regarding incident light spectrums vs. Ion / Ioff ratio for a Photonic CMOS image sensor will be presented. Comparison of the speeds of CMOS image sensors with and without the built-in nonlinear optics films will be discussed.

We will also introduce various types of crystals of nonlinear optics suitable for the Photonic CMOS image sensing applications.
New Approaches for Computing from Brain-Inspired Dynamics  
R. Stanley Williams; Texas A&M University, United States

With the saturation of Moore’s scaling of transistors, there has been an explosion in activity and creativity to find new modes of computation that will continue to scale exponentially with time even though transistor circuits only improve modestly. Much of the inspiration for new ways of computing comes from what little we understand about the brain. We actually don’t know how the brain computes, but many different possibilities have been proposed, e.g. multinary logic (ternary and higher), Neural Networks of all kinds, extensions of Hebbian learning via spike-timing dependent plasticity, Boltzmann/Ising machines, Hopfield networks, Bayesian inference and Markov Chains, to name a few. Actually, these possibilities are not necessarily mutually exclusive – the brain may use some combination of them or even use a higher order generalization that contains several of them, since many share mathematical similarities. How to express these computational modes in hardware is a significant challenge. Since the brain itself is a highly nonlinear dynamical system, an appropriate focus for research is nonlinear dynamical circuit theory. This is the realm of the Principle of Local Activity, which provides a basis for understanding and building new generations of neuron-like amplifiers and chaotic oscillators, and designing circuits that are biased at the Edge of Chaos, where complexity and emergent behavior are found. What new types of devices will be used to construct these circuits? Can we emulate or even surpass neural data processing and computation using new types of dynamical electronic-ionic-thermal devices that express similar behavior? Finally, what materials will we use to build these new devices and incorporate them into the existing commercial integrated circuit foundries? I will present a brief historical survey of brain-inspired computation that begins with research in neurophysiology and psychology in the 1920’s. I will show what constitutes the present state of the art, and actually how primitive that is compared to the human brain despite the hype surrounding present machine learning. I will describe some major opportunities that exist for new computing paradigms based on emerging hardware and electronic devices such as memristors, which have the potential for many orders of magnitude improvement in time to solution and energy consumption compared to purely digital systems. I will also highlight some of the most exciting research and the groups performing it in labs around the world.

Electronic Structure, Defect Chemistry and Element Doping in Phase-Change Vanadium Dioxide  
Baiyu Zhang and Xiaofeng Qian; Texas A&M University, United States

Vanadium dioxide, a strongly correlated electronic material, is known for its metal-insulator transition (MIT) accompanied by a structural phase transition. While the controversy in the phase transition mechanism makes VO₂ one of the most challenging subjects, recent years have witnessed a great effort in studying the MIT mechanism and modulation, and the potential of VO₂ in device applications, owing to the MIT temperature close to room temperature. Element doping is an effective approach to regulate MIT in VO₂. For example, W and Mo doping reduce MIT temperature of VO₂, while Ge doping has opposite effect. Here we present our first-principles study of VO₂ upon element doping. We will reveal the effect of the doping on atomistic and electronic structure of VO₂ as well as the corresponding defect chemistry in both insulating monoclinic phase and metallic tetragonal phase. Finally, we will discuss the implications of first-principles simulation results on the phase transition and future improvement of VO₂ based neuromorphic materials.

**Atomistic Models of Switching Mechanisms in ReRAM Devices** Alexander Shluger¹, Jonathon Cottom¹, Jack Strand¹ and Kamal Patel¹,²; ¹Univ College London, United Kingdom; ²A*STAR, Singapore

The mechanistic origins of memristive behaviour strongly depend on the chemical composition and morphology of materials comprising memristive devices and their interfaces. We use symmetric TiN/SiO2/TiN and asymmetric Au/Ti/a-SiO1.95/Mo stacks described in [1] and HfO2 based stacks [2] as model systems to discuss the mechanisms of electroforming and reset in resistive random access memory devices (ReRAM) using density functional theory (DFT) and atomistic modelling. The bulk system (far from the interface) is approximated as stoichiometric polycrystalline HfO2 or amorphous (a)-SiO2 and HfO2, whereas the oxide/TiN interface is considered explicitly and constructed using DFT simulations assuming different degrees of hydroxylation of oxide surface. Grain boundaries in polycrystalline HfO2 are shown to attract O vacancies and facilitate electroforming [2]. Structural degradation of amorphous oxide films is facilitated by electron injection and bias application. In particular, trapping of two extra electrons at intrinsic sites inside a-SiO2 film results in weakening of Si-O bonds and emergence of efficient bond breaking pathways for producing neutral O vacancies and interstitial Oi2- ions with low activation barriers (≈ 0.2 eV) [3]. These barriers are further reduced at the TiN/SiO2 interface and by the electric field, facilitating diffusion of Oi2- from the bulk towards the interface coupled to a lowering of the formation energies for the Oi2- as a function of the distance from the interface. The charge transition level for the Oi (0/2-) moves towards that of the TiN Fermi level as the Oi approaches the interface resulting in a transfer of the electrons to the TiN electrode at the interface. Once the interstitials arrive at the interface, there is an initial ‘oxidation’ of the interface via the formation of a TiO layer, preferably at Ti-interface sites [4]. The Ti-O bonds are strong with high barriers (> 1.2 eV) for dissociation and O migration along the surface. Once the interface Ti-sites are occupied, Oi are incorporated at or in the layers directly below the interface or diffuse inside TiN via grain boundaries. A significant amount of oxygen is emitted into gas [1,4]. Reset happens as a result of O trapped at the interface and inside the grain boundaries diffusing back into the oxide and recombining with O vacancies. Retention is facilitated by the high barrier to Ti-O bonds dissociation at the interface, which is reduced as the reset bias is applied. We discuss the role of interface structure in the mechanisms of oxygen trapping and release at the metal/oxide interfaces in resistive switching/reset processes.

**Surveying Metastable Phase Space for ‘Transformers’—Tuning Electron Correlation in M,V2O5 Materials to Realize Neuromorphic Functionality** Justin L. Andrews, Abhishek Parija, Joseph Handy and Sarbajit Banerjee; Texas A&M University, United States

Solid-state materials that exhibit electronic instabilities can be leveraged to emulate the spiking behavior characteristic of neuronal function; however, beyond VO2 and NbO2, the palette of materials that exhibit sharp electronic phase transitions above room temperature is sparse. The rational design of such materials is complicated by the complexity of neuronal dynamics which further requires independent control over the onset threshold and the conductance switching magnitude of their electronic transitions. Thereby, synthetic approaches that enable precise control over the extent and strength of electron correlation within a given system are greatly desirable. Given the complexity of the problem, the chosen chemical system should exhibit electronic behavior spanning extremes between highly-correlated and itinerant domains. Ternary vanadium oxides (M,V2O5) represent such a system due to the availability of multiple accessible redox states and a variety of low-dimensional structural motifs that can accommodate the intercalation of a variety of ions spanning the breadth of the periodic table, offering vast compositional tunability. We have reported a number of electronic phase transitions in this mixed-valence (xd/yd) M,V2O5 system, including voltage-driven lone pair-mediated metal-insulator transitions in the quasi-1D β-Pb0.33V2O5, temperature-driven metal-insulator transitions in the layered δ-K0.5V2O5, and pronounced semiconductor-semiconductor transitions in δ-Ag0.88V2O5. More recently, we have observed colossal (six orders of magnitude) metal-
insulator transitions in β′-CuxV2O5 and have shown these electronic transitions to be driven by polaron oscillations that are
mediated by copper diffusion between two adjacent crystallographic sites. However, moving beyond elucidation of the
mechanisms underpinning these observed transitions into intuitive materials design requires a robust and modular synthetic
approach. We have recently pioneered the use of topochemistry to synthesize metastable polymorphs of V2O5. These
polymorphs exhibit distinctive vanadium-oxygen bonding motifs that in turn give rise to varying extents of d-band
dispersion. We have used these metastable V2O5 materials as inorganic equivalents of ‘synthons’ in subsequent intercalation
reactions to independently control the intercalated ion (‘M’), its stoichiometry (‘x’), and how it is situated within the desired
V2O5 framework (layered or quasi-1D tunnel structure). Using this approach we have targeted and synthesized metastable
binary and ternary vanadium oxide materials that have found use as photocatalysts, multivalent ion cathode materials, and as
materials for neuromorphic computing. Ultimately, we have demonstrated a chemical system, denoted as [M(H2O)n]xV2O5,
where M, its degree of hydration, its stoichiometry, and the vanadium-oxygen connectivity are each independently tunable,
establishing ternary vanadium oxides a promising system for the rational engineering of electronic instabilities.

Indirect Observation of Domain-by-Domain Transition through Electrical Characterization of BVO2 Adelaide
Bradicich, Aliya J. Yano, Heidi Clarke, Erick Braham, Sarbajit Banerjee and Patrick Shamberger; Texas A&M University,
United States
Exploration of new computing architectures is underway in order to meet the challenge of advancing computing past the
limitation of the impending end to the further downsizing of transistors. Neuromorphic computing architectures are being
developed in order to push the constraints of conventional computing by mimicking certain behaviors of the brain. However,
using conventional materials, many different elements are needed in order to simulate the most basic of functions.
Consequently, the development of novel functional materials to replace materials used in conventional networks is necessary
to enable efficiency. Vanadium dioxide is of interest for neuromorphic applications due to its temperature-controlled metalinsulator transition (MIT) from an insulating monoclinic phase to a metallic rutile phase. It has been shown that vanadium
dioxide devices are well-suited to applications in neuromorphic computing because of their ability to mimic neuronal
behavior. In order to control various aspects of the phase transition, such as transition temperature, hysteresis, and change in
resistivity, it is common practice to dope the VO2. However, this also can introduce intrinsic defects into the material that can
result in a length-scale dependent variability in properties. Consequently, a comprehensive study of the behavior of doped
VO2 on a device level is critical for moving forward in the development of neuromorphic devices.
In this study, it is demonstrated that doping VO2 with interstitial boron results in the formation of multiple domains.
Temperature-controlled optical microscopy confirms their presence, which causes the MIT in a single particle to occur in
discrete steps over a small range of temperatures. Within that temperature range, there exist stable phase fractions of fully
transitioned material. This behavior is not immediately evident through the characterization of a B-VO2 device, in which the
phase transition is triggered by Joule heating due to application of current or voltage across the material. When the device is
switched by application of a voltage sweep, the decreasing resistance from M1 to R results in sudden, self-propagating
heating to above the TMIT, accelerating the transition of the material. In this case, the phase transition appears to occur
suddenly and abruptly as in undoped VO2. However, when the MIT is triggered by application of a current sweep, the
decreasing resistance results in a self-limiting heating. This slows down heating of the device, allowing an indirect
observation of the more gradual transition of the material as seen in optical microscopy. Analysis of the current sweeps
shows small discrete changes in the measured resistance, corresponding to the discrete transition of a domain. This study
provides insight into the number of domains present in the material, as well as information on the relationship between the
dopant concentration and the number of domains formed. Through the different electrical characterization methods, it
illustrates a history-dependent coexistence of the two phases of B-VO2.

contains all of them, since many share mathematical similarities. How to express these computational approaches in an electronic circuit is a significant challenge. Since the brain itself is a highly nonlinear dynamical system, an appropriate area to investigate is nonlinear dynamical circuit theory. This is the realm of the Principle of Local Activity, which provides a basis for inventing and building new generations of two-terminal oscillators and amplifiers that emulate the integrate and fire dynamics of neurons to produce action potentials for signal processing and axon-like active transmission lines. Combining such devices will enable the design of circuits that are biased at the Edge of Chaos, where the emergence of complex patterns and behavior in a homogeneous medium are found. What new types of devices will be used to construct these circuits? Can we emulate neural computation using new electronic-ionic-thermal devices that exhibit dynamical behavior? These could be based on properties such as negative differential resistance and/or capacitance that arise from thermally activated transport, Mott transitions, molecular redox chemistry, electro-mechanical response in soft matter, and/or multi-ferroelectric characteristics. Finally, how do we find the materials that we will use to build these new devices and measure their properties? There are known materials that have the right type of electronic properties, but they often have disadvantages such requiring exotic elements or a phase transition temperature that is too low or too high compared to normal operating conditions. Can we intentionally design materials that will operate in the Goldilocks zone for a brain-inspired computing machine – or must we test everything that we can fabricate combinatorially? What properties should we try to optimize, e.g. transition temperatures, hysteresis loop widths, conductance and capacitance changes, or magnitude of negative differential resistance? What are the ways of using the properties we do understand to invent the new materials we need? This is a rapidly growing research field that requires coordinated efforts across a broad range of materials expertise from fundamental chemistry to circuit design and fabrication.

7:00 AM S.EL07.02.05
Efficient Parallel Training of a Crossbar Array Using Organic Redox Transistors Yiyang Li1,2, T. Patrick Xiao1, Armantas Melianas3, Erik Isele1, Christofer Bennet1, Sapan Agarwal1, Alberto Salleo3, Elliot J. Fuller1 and A. Alec Talin1; 1Sandia National Laboratories, United States; 2University of Michigan, United States; 3Stanford University, United States

In-memory computing using crossbar arrays of non-volatile memory has the potential to significantly decrease the energy consumption of both inference and training. While crossbar arrays for inference, or dot-product engines, using two-terminal memristors and three-terminal flash memory have been demonstrated to be more efficient than their digital counterparts, crossbar arrays for training have been much more challenging due to difficulties in matching materials properties with training algorithms. In particular, energy-efficient training arrays necessitate the ability to conduct an outer product update, where all the synaptic weights are simultaneously updated, a feat which has not been accomplished in two-terminal devices. We recently developed the three-terminal organic redox transistor based on PEDOT:PSS which is able to conduct binary outer product updates between neighboring conductance states, a crucial step towards energy-efficient training [1]. However, no training algorithm has been implemented.

In this work, we demonstrate for the first time how three-terminal redox transistors are able to train a perceptron network that is adapted to multiple tasks in parallel. We use a small crossbar array of nine synapses to simultaneously train an AND gate, an OR gate, and a NAND gate. We conduct nonbinary and continuous analogue weight updates by controlling the programming time along a given row and column, at micro-second time scales. We use crossbar simulation software (CrossSim) to replicate this training in simulation, and show strong agreement between simulation and experiment. Simulations further show that the ability to train small perceptron networks is enabled by linear and predictable weight updates as well as the low device-to-device variation of the redox transistors, and that two-terminal TaOx memristors will not be able to train this small network to complete accuracy. By showing experimental evidence of training, this work further validates the ability of CrossSim to predict how accurately and quickly analogue non-volatile memory are able to train an artificial neural network.

First Order Reversal Curve Distributions for Ferroelectric Materials as a Function of Temperature and Imprint

Susan E. Trolier-McKinstry, Kathleen Coleman and Betul Akkopru-Akgun; The Pennsylvania State University, United States

The Preisach model describes the hysteresis response of a ferroelectric material as being a composite of an ensemble of hysterons. The irreversible hysterons are used to estimate the stability of various states as a function of prior field history. This paper will describe the first order reversal curve distributions for lead zirconate titanate thin films as a function of a number of variables, including the levels of donor and acceptor doping, the level of imprint, and temperature from 10 – 300 K. Ultimately, data of this type are required to fully describe the number of discriminable states in a neuromorphic computing system.

Dynamically Evolving Metastability in an Atomic Hourglass—Temporal Control of the Metal-Insulator Transition of VO2 by a Mobile Dopant

Erick Braham, Diane Sellers, Ruben Villarreal, Timothy Brown, Theodore Alivio, Heidi Clarke, Luis De Jesus, Raymundo Arroyave, Patrick Shamberger and Sarbajit Banerjee; Texas A&M University, United States

Solid-solid phase transitions are often accompanied by massive changes in fundamental materials properties such as resistivity and optical transmittance. The relative stabilities of the phases involved in these transitions can be modulated through several means one of which being through doping or alloying which has been shown to create an immutable alteration of the transformation barriers. Reversible post synthetic modulation of a phase transition continues to be a challenge that, if allowed, would enable distinct potential for useful for neuromorphic computing, chronometry, and sensing. Metal—insulator transition materials are excellent candidates for neuromorphic computing of which VO2 is a canonical example. We demonstrate in VO2 mobile dopants that are weakly coupled to the lattice provide a means of imbuing an entirely reversible and dynamical modulation of the metal-insulator transition of VO2. Specifically, we demonstrate the remarkable time-dependent evolution of the relative phase stabilities of insulating monoclinic (M1) and metallic rutile (R) phases of VO2 in a completely reversible “hourglass” fashion as interstitial boron species relax from high-energy sites where they are situated upon a thermally induced phase transition. The relaxation process corresponds to a 50°C range of the transition temperature achieved within the same sample as a function of residence time and temperature. The diffusive boron dopant atoms provide a means of attaining a reconfigurable and readable time- and thermal history dependent response that derives from intrinsic material properties.

Atomistic Understanding of Memory Effect in Monolayer Memristors and Emerging Applications

Saban Hüs1, Ruijing Ge1, Po-An Chen2, Xiaohan Wu1, Jack Lee1, Meng-Hsueh Chiang2 and Deji Akinwande1; 1The University of Texas at Austin, United States; 2National Cheng Kung University, Taiwan

This talk will present the latest research progress on the atomic-level details of non-volatile resistance switching (NVRS) in 2D memory devices. In particular, we will focus on our scanning tunneling microscopy (STM) based imaging and transport studies, together with the first principle calculations on the common point defects of 2D materials. For this investigation, we employ the STM tip as the top electrode of vertical metal-insulator-metal (MIM) memory device and examine the defect sites in atomic resolution before and after resistive switching events. These studies provide one to one correlation between the structural and electronic properties of the heterogeneities and their role in the resistance switching mechanism. Through these studies, we seek to deduce which particular defect structures are most desirable for NVRS and utilize this information for emerging applications.

Control of Metal-Insulator Transition Character in VO2 through Chemical Doping

Patrick Shamberger, Heidi Clarke, Adelaide Bradicich, Aliya Yano, Diane Sellers, Erick Braham and Sarbajit Banerjee; Texas A&M University, United States

Chemical control of the coupled electronic-structural transformation in correlated oxide systems is a vigorously investigated area, due to fundamental interest in the role chemical dopants play in stabilizing different crystal structures and altering
electron band structure, as well as practical interest in being able to tune the critical transformation temperature and the degree of volatility of the transformation. Such an approach holds promise for tuning the properties of adaptive oxide phases to demonstrate novel functionality and emulate neuromorphic behaviors. While chemical doping has shown dramatic effects in changing the thermodynamic stability of different doped VO₂ phases, including increasing or depressing phase transformations by up to ~20 °C, and stabilizing phases that are not typically observed in undoped VO₂ upon simple heating and cooling, very little is known regarding the impact of chemical doping on transformation behavior in this system. Doping could potentially modify the behavior of the electronic-structural phase transformation by at least three mechanisms: 1) by altering the energy landscape of the system, including the magnitude of energy barriers limiting forward and reverse transformation, 2) by stabilizing intermediate phases, which may introduce alternative transformation paths, or 3) by introducing localized regions of strain surrounding chemical dopants, which could affect local thermodynamic equilibria heterogeneously throughout a sample. Importantly, all three of these effects could potentially impact either the energy barriers limiting incipient nucleation of a new daughter phase within a parent phase, or the mobility of heterophase boundaries, impacting the rate of growth of domains of a daughter phase. Clarifying changes in phase transformation mechanisms requires microscopic investigation of domain nucleation and growth in both undoped and doped systems. Resolving these questions can expose important underlying clues in understanding transformation mechanisms in both undoped and chemically doped systems, and can reveal new approaches to engineering metal-insulator transitions (MIT) with desired transformation behavior.

Here, we present representative illustrations of the effect of chemical dopants on altering phase transformation mechanisms and progression, drawn from select interstitial and substitutional doping schemes. We will illustrate 1) the use of dopants to simultaneously alter transformation equilibrium temperature and hysteresis, 2) the use of dopants to extend the width of the phase transformation, introducing extended regions of phase coexistence, as well as 3) the use of dopants to introduce relaxation effects, which can be used to dynamically tune the equilibrium transformation temperature of the system.

Strategies to Precisely Control Synaptic Weights for Neuromorphic Computing Arrays Jeehwan Kim; Massachusetts Institute of Technology, United States

Neuromorphic computing has recently emerged as a non-Von Neuman computing method. Because its analog switching ability to represent multiple synaptic weights by varying conductance in the vertical filaments formed in the switching medium, a resistive memory has been considered as an artificial synapse for suitable neuromorphic hardware platform. Conventional resistive memories typically utilize a defective amorphous solid as a switching medium for defect-mediated formation of conducting filaments. However, the imperfection of the switching medium also causes stochastic filament formation leading to spatial and temporal variation of the devices. Such variation of artificial synapses prevented community from obtaining large-scale artificial neural networks. In this talk, I will present new type of resistive memory that can more precisely confine the conducting paths so that uniform artificial synapses have been obtained leading to 100% yield 32x32 arrays with a great programmability. In this talk, I will discuss about our strategies to control the ionic conduction paths: one is to utilize threading dislocations as confinement paths of ionic conduction in SiGe epitaxially grown on a Si wafer and another is to alloy Ag active metal with silicidable metals to have additional controls in conduction channels. These result in low temporal/spatial variation, linear synaptic weight update, great endurance, and long retention time. Actual crossbar arrays were fabricated and I will present properties and programmability of our ANN arrays.
steep subthreshold slope and low operating voltage. The exploitation of the subthreshold FET characteristics, which naturally exhibit exponential relationships in their transfer functions, also allow to directly emulate the biophysics of neural systems.

On the other hand, the ability to alter the conductance levels in a controllable way makes Phase Change Memory devices particularly well-suited for synaptic realizations. The two key synaptic attributes of efficacy and plasticity can be efficiently realized using a unit comprising PCM devices and FETs.

In this presentation, we will show the disruptive properties of advanced NanoFETs for ultimate integration, reduction of energy consumption and enhanced performance, such as Nanowire FETs, Carbon Nanotube FETs, Tunnel FETs, Negative capacitance FETs, Hybrid Devices, combined with novel materials such as III-V, Ge, 2D/TMDs, Heterostructures, Phase Change, Nanofilament, Ferroelectric, Semimetal.

These innovative materials could be used for boosting NanoFETs electrical properties and/or developing new generation of memory devices, for instance Storage Class Memories, for near-memory computing where FET processing units are placed in close proximity to the memory unit for increased system performance. They can also be used for In-Memory Computing, for which the computation is performed in place by exploiting the physical attributes of memory devices organized as a computational memory unit [1-5].

S.EL07.05.01 Polaron Oscillation and Cation Shuttling Underpin the Metal-Insulator Transition of β'-Cu₅V₂O₅ Joseph Handy, Justin L. Andrews and Abhishek Parija; Texas A&M University, United States

Silicon circuitry has been the mainstay of the semiconductor industry for several decades but is fundamentally constrained by the Fermi-Dirac electron distribution of electron energies, which establishes an immutable limit to the steepness of switching characteristics that can be achieved within a device. As such, electrostatically-modulated transistors inevitably give rise to much wasteful power consumption, requiring large swaths of logic circuitry on a chip to be left inoperative at any given time. Much attention has therefore focused on the design of materials exhibiting a pronounced switching of electrical conductance with minimal energy dissipation in response to small external stimuli. Electron-correlated transition metal oxides exhibiting pronounced metal-to-insulator transitions are excellent candidates for energy efficient computation and further provide a means of emulating the spiking behavior of biological neural circuitry. Amongst the rare palette of materials exhibiting pronounced metal—insulator transitions, β'-Cu₅V₂O₅ stands out for its tunability of the transformation temperature and, as we demonstrate here, a pronounced nonlinear response to applied temperature, voltage, and current in relation to Cu stoichiometry. We have shown that polaron oscillation, underpinned by the real-space shuttling of Cu-ions between two adjoining split-site positions within a 1D tunnel defined by VO₅ square pyramids and VO₆ octahedra underpins the metal-insulator transition of this material. Our work combines high-resolution structure refinement from variable-temperature single-crystal and powder X-ray diffraction; variable-temperature extended X-ray absorption fine structure spectroscopy (EXAFS) studies of local structure; angle-integrated photoemission spectroscopy, resonant inelastic X-ray scattering (RIXS), and hard X-ray photoemission spectroscopy (HAXPES) studies of electronic structure; density functional theory (DFT)
modeling of electronic structure; and single-nanowire measurements of transport phenomena. The results provide unprecedented mechanistic insight into the close interplay between crystal structure distortions and emergence of electron correlation which gives rise to the metal—insulator transition of a strongly correlated system. The utilization of cation diffusion and polaron shuttling demonstrates a means of using ionic vectors in conjunction with subtle structural distortions to obtain highly nonlinear and memristive conductance switching as required for neuromorphic computing and sensing.

**Phase-Change Materials—Empowered by an Unconventional Bonding Mechanism** Matthias Wuttig; RWTH Aachen University, Germany

Phase-change materials (PCMs) have demonstrated a wide range of potential applications ranging from electronic memories to photonic devices. These applications are enabled by the unconventional portfolio of properties that characterizes crystalline PCMs. Here, I address the origin of these unusual properties and how they are related to the application potential of these materials. Evidence will be presented that the properties are related to an unconventional bonding mechanism. Employing a novel map, which separates solids according to the number of electrons transferred and shared between adjacent atoms, it is shown that PCMs occupy a well-defined region. Depicting physical properties such as the optical dielectric constant as the third dimension in the map reveals systematic property trends. Such trends can be utilized to unravel the origins of the unconventional materials properties or alternatively, as a means to optimize them.

**9:30 AM **
**Atomistic Simulations of Phase-Change Materials** Riccardo Mazzarello; RWTH Aachen University, Germany

Phase-change materials (PCMs) are used in optical devices and electronic non-volatile memories, and are promising candidates for neuro-inspired computing applications. These technologies exploit the ability of PCMs to switch rapidly between amorphous and crystalline states with pronounced optical and electrical contrast. In this tutorial an overview is given of recent computational work on PCMs based on density functional theory and machine-learning potentials. It will be shown that simulations have enabled the elucidation of fundamental links between structure and dynamics. Such links have shed light on technologically relevant properties of PCMs, including the ultrafast crystallization at high temperature, the behaviour of the liquid phase in the deep undercooling regime and the relaxation of the amorphous state.

**11:00 AM **
Integrated Phase-Change Photonic Devices and Systems Wolfram Pernice; University of Münster, Germany

Driven by the rapid rise of silicon photonics, optical signaling is moving from the realm of long-distance communications to chip-to-chip, and even on-chip domains. If on-chip signaling becomes optical, we should consider what more we might do with light than just communicate. We might, for example, set goals for the storing and processing of information directly in the optical domain. Doing this might enable us to supplement, or even surpass, the performance of electronic processors, by exploiting the ultrahigh bandwidth and wavelength division multiplexing capabilities offered by optics. Here, I show how, by using an integrated photonics platform that embeds chalcogenide phase-change materials into standard silicon photonics circuits, we can achieve some of these goals. Specifically, I show that a phase-change integrated photonics platform can deliver binary and multilevel memory, arithmetic and logic processing, as well as synaptic and neuronal mimics for use in neuromorphic, or brain-like, computing -- all working directly in the optical domain.

Electronic Properties of Phase Change Compounds in the Liquid State—Effective Charges for Electromigration and Semiconductor-Metal Transition from First Principles Matteo Cobelli1, Mario Galante2, Daniele Dragoni1, Stefano Sanvito2 and Marco Bernasconi1; 1Università di Milano-Bicocca, Italy; 2Trinity College, Ireland

In the reset process of phase change memories, the active material is brought rapidly above the melting temperature by Joule heating. Atomic migration in the liquid state due to the high electric field can lead to alloy demixing and eventually to device failure. The electromigration force \( F \) responsible for ionic migration is proportional to the electric field via the effective charge \( Z^* \) (\( F = Z^* E \)). Information on the effective charges is thus of great relevance for the electrothermal modeling of the device. However, experimental estimates of the effective charges in the liquid state suffer from large uncertainties. A possible route to estimate \( Z^* \) relies, in fact, on the modeling of the concentration profile of the different species in highly cycled memory cells which, however, depends on several mostly unknown parameters that have to be plug into phenomenological transport equations [1].

In this work, we show that a direct first principles calculation of the effective charges in metallic liquids is possible by computing the atomic forces in the presence of both an electric field and an electronic current within the Non-Equilibrium Green Function scheme implemented in the code Smeagol [2]. We will present results on the calculation of the effective charges, including the wind force, for the GeTe and Sb2Te5 phase change compounds in the liquid state.

Another feature of the liquid state that affects device operations is the opening of an electronic gap upon cooling from the melting point to the glass transition temperature during reset. The temperature at which the metallic liquid turns into a semiconductor is another important parameter for the electrothermal modeling of the device. By means of density functional molecular dynamics and the use of a hybrid exchange and correlation functional, we have estimated the temperature of gap opening in the supercooled liquid phase of GeTe and Ge2Sb2Te5 compounds.

5:15 PM S.EL09.02.02
Phase Change Materials by Design—The Power and Potential of Maps Matthias Wuttig; RWTH Aachen University, Germany

It has been a long-time dream of mankind to design materials with tailored properties. In recent years, the focus of our work has been the design of phase change materials for applications in data storage. In this application, the remarkable property portfolio of phase change materials (PCMs) is employed, which includes the ability to rapidly switch between the amorphous and crystalline state. Surprisingly, in PCMs both states differ significantly in their properties. This material combination
makes them very attractive for data storage applications in rewriteable optical data storage, where the pronounced difference of optical properties between the amorphous and crystalline state is employed. This unconventional class of materials is also the basis of a storage concept to replace flash memory. Today’s talk will discuss the unique material properties, which characterize phase change materials. In particular, it will be shown that only a well-defined group of materials utilizes a unique bonding mechanism (‘Bond No. 6’), which can explain many of the characteristic features of crystalline phase change materials. Different pieces of evidence for the existence of this novel bonding mechanism, which we have coined metavalent bonding, will be presented. In particular, we will present a novel map, which separates the known strong bonding mechanisms of metallic, ionic and covalent bonding, which provides further evidence that metavalent bonding is a novel and fundamental bonding mechanism. This insight is subsequently employed to design phase change materials as well as thermolectric materials.

5:25 PM S.EL09.05.14

In Situ Study of Vacancy Disordering in Crystalline Phase-Change Materials under Electron Beam Irradiation
Xudong Wang1, Tingting Jiang1, Jiangjing Wang1 and Wei Zhang1,2; 1Center for Advancing Materials Performance from the Nanoscale, State Key Laboratory for Mechanical Behavior of Materials, Xi’an Jiaotong University, China; 2Xi’an Jiaotong University Suzhou Institute, China

Fast and reversible phase transitions in chalcogenide phase-change materials (PCMs) play a key role in next-generation memory and computing chips. The Ge-Sb-Te compounds, such as Ge2Sb2Te5 and GeSb2Te4, are under active investigations, not only because they serve as the key element in commercial products, but also because they provide a rich platform for fundamental research in materials science.

Disorder-driven metal insulator transition has been reported in crystalline Ge-Sb-Te phase-change materials (PCMs), where the high concentration and statistical distribution of atomic vacancies were identified as the key factor in shaping the localization properties of electrons and, thus, the electrical transport. Vacancy ordering has been consistently observed in crystalline Ge-Sb-Te thin films upon thermal annealing, triggering a structural transition from a cubic rocksalt structure to a layered hexagonal structure and an insulating to metallic transition.

In this work, we demonstrate an opposite vacancy disordering process upon extensive electron beam irradiation, which drives the reverse transition from the stable hexagonal phase to the metastable cubic phase. The combined in situ transmission electron microscopy experiments and density functional theory nudged elastic band calculations reveal three transition stages, including (I) the vacancy diffusion in the hexagonal phase, (II) the change in atomic stacking, and (III) the vanishing of vacancy-rich planes. The driving force of the vacancy disordering process is attributed to the kinetic knock-on collision effects of the high-energy focused electron beams, which prevail over the heating effects.

Our electron irradiation experiment not only provides an alternative approach to tune the vacancy distribution that is crucial for the disorder-driven metal-insulator transition of GST crystals, but also makes an instruction for the TEM measurement of structural details of a particular solid-state phase of PCMs that the three critical TEM parameters, namely, accelerating voltage, beam intensity and recording time, should be reduced as much as possible to avoid structural transitions during the measurement.

5:35 PM S.EL09.06.01

Reconfigurable Infrared Flat Optics with Novel Phase Change Materials
Christopher M. Roberts1, Yifei Zhang2, Mikhail Shalaginov2, Paul Robinson1, Paul Miller1, Kevin Tibbetts1, Sean Gorsky1, Vladimir Liberman1, Carlos A. Rios Ocampo2, Tian Gu2, Myungkoo Kang3, Anupama Yadav3, Kathleen Richardson3, Juejun Hu2 and Jeffrey Chou1; 1MIT Lincoln Laboratory, United States; 2Massachusetts Institute of Technology, United States; 3University of Central Florida, United States

Previously, we have reported on a novel class of chalcogenide phase change materials, based on Ge-Sb-Se-Te (GSST) alloys, with excellent infrared transparency from 1.5 to > 15 micron wavelengths. Increasing Se substitution leads to a progressive lowering of extinction coefficient. A material in this family with a particular useful stoichiometry, Ge2Sb2Se4Te1 (GSS4T1), possesses broadband transparency through the infrared range while maintaining a large index contrast between its amorphous and crystalline phases. Defining a figure of merit as Δn/k (where n,k are the real, imaginary parts of the refractive index), our materials shows >100x figure of merit (FOM) improvement over conventional GST throughout the infrared range.

In this talk, we describe novel applications enabled by reversible switching of low loss GSS4T1 material. In the first application, we exploit the exceptional FOM of the Se-doped PCM to realize a nonvolatile photonic switch with
unprecedented high performance. Our device, based on a racetrack SiN resonator with a PCM gate, exhibits a large switching contrast ratio of 42 dB and a low insertion loss of < 0.5 dB, far outperforming previous nonvolatile switches as well as devices based on the classical GST-225 material with a similar configuration.

Additional novel applications are enabled by our development of wafer-scale pixelated electrical switchable PCM devices. The pixelated devices are fabricated in a CMOS-compatible clean room on 8 inch wafers utilizing a full Si-based fabrication tool set. Devices of various pixel sizes, from 1 to 30 micron have been fabricated. Additionally, fabrication of more complicated sub-pixel metasurfaces was demonstrated. Electrical switching measurement is obtained by applying electrical pulse trains through a programmable voltage generator into the gate of a high powered transistor. Microsecond switching of 30-micron and 1-micron pixels in a wafer-scale device has been demonstrated. Current devices have demonstrated over 1,000 switching cycles and further durability improvements are underway.

As an application of pixelated electrical device, we have demonstrated a concept of compact infrared reflection spectrometer with no moving parts. Here, we leverage the ability to obtain gradually changing reflection signature of the pixel with voltage between fully-converted crystalline and amorphous phases. This wavelength shift is essentially a nonlinear filter which can be used to reconstruct an input spectrum. Since the reflection response of the pixel states is pre-determined, a spectral response of the scene can be extracted once the pixel spectrum is fully characterized with a known calibrated spectral source. We have carried out such characterization utilizing a supercontinuum laser in the short-wave infrared part of the spectrum and the results of spectral signature extraction for three different incident spectral scenarios.

**Effects of Spatial Confinement on Phase-Change Materials** Ann-Katrin U. Michel and David J. Norris; ETH Zürich, Switzerland

Phase-change materials (PCMs) allow for an ultrafast and reversible transition between their amorphous (a) and crystalline (c) state. This structural transition results in a pronounced change in their optical and electrical properties. The strong resistivity contrast of several orders of magnitude has been employed in electronic and neuromorphic memories, while the unity-scale refractive index change $\Delta n = |n_a - n_c|$ has been applied in rewritable optical-data-storage memories. Additionally, $\Delta n$ is the subject of research in various photonic applications.[1]

For tunable photonics, PCMs are very desirable, but expensive and laborious to produce. Thus, colloidal PCMs that can be easily synthesized could provide broader access to this material class and allow for deposition on a variety of substrates, including prepatterned holes and vertical interconnect accesses. However, due to the size reduction from GeTe thin films to small nanoparticles (NPs), new effects can arise. Examples are the occurrence of localized surface plasmon resonances in c-GeTe NPs,[2] and size dependence of the crystallization temperature $T_c$.[3] Thickness dependent temperature scaling was also reported for very thin sputtered PCM films, and related to their bonding characteristics.[4] Recent results indicate that the spatial confinement of PCMs into small NPs results in an increase of the optical band gap $E_g$, while maintaining the pronounced contrast between the band gaps for a- and c-PCMs $E_{g,a}$ and $E_{g,c}$ respectively.[5]

Insights into small-size PCM NPs can promote the application of these materials in different fields, and add value to fundamental scientific questions, especially regarding the current debate on the chemical bonding in PCMs.[6] Despite the bottom-up synthesis of PCM NPs, structural confinement can be realized by sub-wavelength patterning. While laser pulses do not allow for switching on such small length scales, tip-induced crystallization can lead to features below 100 nm. The resulting so-called metasurfaces feature extremely strong field confinement and nearly $2\pi$ phase shift.[7]

Crystallization Properties of Nano Amorphized Areas in Epitaxial Epitaxial GST on Si (111) by TEM

In Situ Characterizations

Antonio M. Mio\(^1\), Giuseppe D'Arrigo\(^1\), Jos Boschker\(^2\), Alessandro Meli\(^1\), Stefano Cecchi\(^2\), Eugenio Zallo\(^2\), Antonella Scicutto\(^1\), Marzia Buscema\(^1\), Elena Bruno\(^3\), Raffaella Calarco\(^2\) and Emanuele Rimini\(^1\); \(^1\)CNR-IMM, Italy; \(^2\)Paul-Drude-Institut für Festkörperelektronik, Germany; \(^3\)Dipartimento di Fisica e Astronomia Ettore Majorana, Università degli Studi di Catania, Italy

The crystallization behavior of amorphous nano-regions (20-100 nm in diameter) embedded in a textured epitaxial Ge\(_2\)Sb\(_2\)Te\(_5\) 25 nm thick film grown on Si (111) substrate has been investigated in situ by TEM analysis. The amorphous regions were obtained by irradiation with 30 keV Ge\(^+\) at a fluence of 1.5x10\(^{14}\) ions/cm\(^2\) of masked samples. The adopted configuration simulates the GST structure of a device in the RESET state, it is then of relevance for understanding their data retention characteristics. The in situ TEM analysis indicates that the amorphous to crystal transition is characterized by an initial growth velocity of 3.6 pm/s at 75°C, probably related to the external partially damaged area. For the previous annealed sample, a velocity of about 2.6 pm/s was observed at 90°C and a growth speed of 170 pm/s at 110°C for the 50nm and 100nm diameter amorphous spots. The 20 nm diameter amorphous spots recrystallize after the annealing at 90°C. The transition is governed only by crystallization (nucleation is absent) of the atoms located at the boundary of the amorphous dot with the surrounding crystalline regions. In some case a preferential growth along surfaces normal to the [110] and to the [121] directions has been found. The crystallographic characterization of the regrowth crystal indicates a good matching with the zone axis of the surrounding material although the crystalline seed Si (111) at the bottom interface is missing for the damage.

Pulsed Laser Deposited Sb\(_2\)Te\(_3\), GaSb and Ge –Rich GST Thin Films and Heterostructures for Memory Devices

Daniel T. Yimam, Jamo Momand and Bart J. Kooi; Zernike Institute for Advanced Materials, University of Groningen, Netherlands

Future Electronic Smart Systems (ESS) require energy efficient storage and fast processing of large amount of data. Phase-Change Materials, exhibiting large electrical and optical contrast between two phases also allowing multiple intermediate states, are highly desired for this application, because in principle they also have the ability to store and process data at the same physical place (Wuttig et al. Nat. Mater. 2007). Despite progresses which have been made to achieve the full potential of Ge\(_2\)Sb\(_2\)Te\(_5\) based PCM devices, several reliability issues still hinder the realization of ultimate performance. Void formation due to density change upon switching, low crystallization temperature for automotive applications, and resistance drift over time are among the few. GaSb is considered as a promising candidate for future phase change random access memory (PCRAM) devices because of its fast crystallization, high crystallization temperature, and lack of density change upon switching at a specific composition of Ga\(_{30}\)Sb\(_{70}\) (Putero et al. APL Materials. 2013). Pulsed Laser Deposition (PLD) has become one of the most popular thin film deposition technique. Some of the reasons for this popularity are the flexibility, processing speed, and the wide range of materials that can be deposited. In this work we discuss PLD of single and alternating layers of Sb\(_2\)Te\(_3\), GaSb, and Ge-rich GST thin films on various substrates. Amorphous, polycrystalline, and textured heterostructures of Sb\(_2\)Te\(_3\)/GaSb and Sb\(_2\)Te\(_3\)/Ge-rich GST are deposited. Reflection high-energy electron diffraction (RHEED) is used as in-situ growth monitoring tool during deposition to achieve desired film quality. Moreover, deposited films are characterized by Scanning Transmission Electron Microscope (S/TEM) for composition and quality analysis before producing single cell vehicles for electrical device testing.

6:25 PM *S.EL09.05.01

Phase Change Memory from Fundamental Research to Industrial Development

Zhitang Song; Chinese Academy of Sciences, China

Phase change random access memory (PCRAM) has been successfully applied in the computer storage architecture, as storage class memory, to bridge the performance gap between DRAM and Flash-based solid-state drive due to its good scalability, 3D-integration ability, fast operation speed and compatible with CMOS technology. A good understanding of phase change mechanism is of great help to design new phase change materials with fast operation speed, low power consumption and long-lifetime. In this presentation, we firstly review the development of PCRAM and different understandings on phase change mechanisms in recent years, and then propose a new view on the mechanism, which is based on the octahedral structure motifs and vacancies. Octahedral structure motifs are the based units during phase transition. Robust octahedra and plenty of vacancies in both amorphous and crystalline phase, respectively avoiding large atomic...
rearrangement and providing necessary space, are of crucial to achieve the nanosecond or even sub-nanosecond operation of PCRAM. Based on this mechanism, we introduce Sc-based robust octahedra in Sb2Te3 phase change materials, called Sc-Sb-Te, and achieve 700 ps operation speed. Recently, the concentration of dopants has also been optimized by correlative atom probe tomography and transmission electron microscopy investigations. Focusing on phase change materials and PCRAM for decades, we have successfully developed 128Mb embedded PCRAM chips, which can meet the requirements of most embedded systems.

6:40 PM S.EL09.04.06
Effect of Optical Illumination on Resistance Drift in Ge2Sb2Te5 Line Cells Raihan Sayeed Khan, Helena Silva and Ali Gokirmak; University of Connecticut, United States

The large resistivity contrast between the highly resistive amorphous phase and low resistive crystalline phase of phase change memory (PCM) provides opportunities for multi bit per cell memory and neuromorphic applications. However, the drift of resistance of amorphous phase limits the potential of PCM as multiple intermediate states can overlap over time. Although resistance drift is generally attributed to structural relaxation [1], we have observed significant resistance drift in Ge2Sb2Te5 line cells at cryogenic temperatures and also being affected by optical illumination, indicating charge trapping [2]. A detailed understanding of the mechanisms behind resistance drift may allow for mitigating techniques. In this work, we study the effect of optical illumination between 125 K and 300 K and also the effect of different optical illumination conditions on the drift coefficient.

Thermal Properties of Carbon Nitride Toward Use as an Electrode in Phase Change Memory Devices Kiumars Aryana1, John Gaskins1, Joyeeta Nag2, John Read2, David Olson1, Michael Grobis2 and Patrick E. Hopkins1; 1University of Virginia, United States; 2Western Digital Corporation, United States

In phase change memory cells, the majority of heat is lost through the electrodes during the programming process that leads to significant drops in the performance of the memory device. In this investigation, we report on the thermal properties of thin film carbon nitride with modest electrical resistivity of 5-10 mW cm, low thermal conductivity of 1.47W/m/K, and low interfacial thermal conductance between carbon nitride and phase change material for length scales below 40 nm. The thermally insulating property of carbon nitride makes it a suitable thermal barrier, allowing for less heat loss during Joule heating within the memory unit. We compare carbon nitride thermal properties against commonly used electrodes and insulators such as tungsten and silicon nitride, respectively, to demonstrate the promise of carbon nitride as a potential material candidate for electrode applications in phase change memory devices.

Density Functional Simulations of the Atomic Structure and Dynamics of Phase Change Materials Jaakko Akola1,2, Janne Kalikka2 and Robert Jones3; 1Norwegian University of Science and Technology, Norway; 2Tampere University, Finland; 3Forschungszentrum Juelich, Germany

Crystallization of phase change materials has been studied by extensive density functional/molecular dynamics simulations (DF/MD). Four crystallization simulations of amorphous Ge2Sb2Te5(460 atoms) have been completed at 600 K with simulation times up to 8.2 ns.1,2 A sample with a history of order crystallizes completely in 1.2 ns, but ordering in others takes
more time and is less complete. The amorphous starting structures without memory display phases (<1 ns) with subcritical nuclei (10–50 atoms) ranging from nearly cubical blocks to string-like configurations of ABAB squares and AB bonds extending across the cell. Percolation initiates the rapid phase of crystallization and is coupled to the directional p-type bonding. The results emphasize the stochastic nature of crystallization and the importance of sufficiently large samples. This is particularly evident in describing the role of crystallites that can merge to form larger units or hinder complete crystallization by the formation of grain boundaries.

Amorphous Sb is known to crystallize extremely rapidly already at room temperature. Crystallization of Sb has been studied at 600 K using six DF/MD simulations with up to 882 atoms.\(^3\) Crystallization proceeded layer-by-layer in most cases and was extremely rapid (~36 m/s). As shown in Fig. 1, diffusion plays a minor role in the process as the crystallization proceeds from the crystalline rim, and the evolution of bond lengths and ring statistics supports the bond-interchange model of Sb-rich phase change materials.\(^4\)

We have also carried out extensive DF/MD simulations (over 500 atoms, up to 100 ps) of liquid bismuth at four temperatures between 573 - 1023 K.\(^5\) These simulations provided details of the dynamical structure factors, the dispersion of longitudinal and transverse collective modes, and related properties (power spectrum, viscosity, and sound velocity). Agreement with available inelastic x-ray and neutron scattering data and with previous simulations is generally very good. The results show that DF/MD dynamics simulations can give dynamical information of good quality without the use of fitting functions, even at long wavelengths.

Accurate and Efficient Deep Neural Network for High-Throughput-Simulation-Based Optimization of Chalcogenide Phase Change Materials Jie Liu\(^1,2\); \(^1\)Hunan University, China; \(^2\)University of Washington, United States

Chalcogenide phase change materials (PCM) are widely-used in optical data storage technologies. Also, they are promising to become the next-generation mainstream electronic non-volatile memory technology. These have been discussed and simulated in our prior work \[1-4\]. The operation of PCM-based devices hinge on the repeated rupture and formation of atomistic-scale chemical bonds to reversibly switch between crystalline and amorphous phases, which require atomistic-scale simulation methodology to achieve in-depth optimization. Nowadays, there are two categories of such methodologies -- density functional theory (DFT) and artificial neural network (ANN). DFT-based molecular dynamics (MD) is accurate but inefficient -- it is practically applicable to only hundreds of atoms. ANN-based MD is efficient but inaccurate -- its maximum error of atomic force prediction can be over 10 eV/Angstrom.

In our recent work \[5\], we present a method based on deep neural network (DNN) to model PCM, which is both accurate and efficient. The DNN-based MD has a computational complexity of O(N), where N is the number of atoms. So, DNN-based MD is orders of magnitude faster than DFT, whose computational complexity is around O(N\(^3\)). Furthermore, the maximum error of atomic force prediction of DNN-based MD is around 0.1 to 1 eV/Angstrom, which is much more accurate than ANN in the existing literature. In our another recent work \[6\], we present a transfer learning (TL) method, to handle the needs to simulate multiple combinations (different PCM stoichiometry, doping, etc.). Compared to the state-of-art methods in PCM literature, the proposed TL method can significantly reduce the amount of DFT data used to train the neural network, which is beneficial to enable high-throughput simulations.

Combining the accuracy and efficiency \[5\], and the trasferrability between different materials \[6\], we aim at establishing a general-purpose PCM optimization method based on high-throughput simulations.

The working principle of conventional phase change memory device is based on ultrafast reversible phase changes between crystalline and amorphous phases of Ge-Sb-Te (GST) materials. For information storage, phase change memory device uses a large contrast either in electrical resistance between the amorphous phase (high-resistance state) and crystalline phase (low-resistances state) or in optical reflectivity between the amorphous phase (low reflectivity state) and crystalline phase (high reflectivity phase). The erase of GST-based memory cell is achieved by applying a high intensity either electrical or laser pulses. These processes lead to the amorphization via melting and subsequent fast quenching of the phase change alloy. However, GST alloys are poor glass formers. Thus, rapid cooling rates are required to suppress the recrystallization of the alloys during the erase process. On another hand, the write process is accomplished by applying either electrical or optical pulses with low intensity. This results in an amorphous-to-crystalline phase transition. Due to intrinsic feature of GST alloys, a main challenge in material science is the optimization of memory writing times, which are limited by the crystallization kinetics of the alloys. In order to speed up the crystallisation rates, several strategies were proposed, including doping of GST materials, precrystallization of an amorphous matrix or using GST based superlattices. Being a nucleation-dominant material, the crystallization of GST alloy in a nanosized phase-change memory cell might however proceed at the crystalline interfaces. This contribution focuses on determination of crystallization dynamics in epitaxial Ge2Sb2Te5 (GST225) thin films on application relevant (nanosized) length and (nanosecond) time scales. We irradiate the thin films by a single UV laser pulse with a 20 ns pulse duration and with different laser fluences. First, we study the structural transitions in epitaxial GST225 thin films starting from the layered trigonal GST225 structures [1]. We compare the obtained results with the behaviour of GeTe-Sb2Te3 based superlattices (SLs) after the laser irradiation. In both cases, the results reveal the phase transition to the cubic GST225 structure. The cubic phase forms from a transient molten phase at the melt-crystalline interface upon cooling process and crystallizes with epitaxial relationship to the parent phase. Second, by introducing a method based on combination of high temporal and spatial resolution, we determine the crystallization rates of the cubic GST225 phase [2]. The rates are ranging from 0.4 m/s to 1.7 m/s. The values are well in agreement with the published experimental and theoretical data. Moreover, a variation of the laser fluence leads to different cooling rates, which result in different solidification rates and freezing of an amorphous state. Irradiation of amorphous GST225 phase by laser pulse with lower fluence leads to the re-crystallization of the phase and epitaxial formation of the cubic GST225 structure. Overall, our work shows an approach for the investigation of crystallisation kinetics in wide range of phase change materials on application relevant length and time scales. In addition, we demonstrate amorphization and crystallization of GST225 material by using UV laser with single pulse duration and wavelength only, where in the conventional amorphous-to-crystalline phase transitions the lasers with different pulse durations, number and wavelengths are usually applied.

Nanoscale Probing of Phase Transition Properties in Chalcogenides Using Embedded Heater-Thermometer Nicolas Wainstein, Gany Ankonina, Shahar Kvatinisky and Eilam Yalon; Technion - Israel Institute of Technology, Israel

Phase-change materials (PCM) are technologically attractive materials for non-volatile memory, neuromorphic computing, optoelectronics, and recently, radiofrequency (RF) applications. Chalcogenide PCMs present a dissimilar resistance between the crystalline (low-resistivity) and amorphous phase (high-resistivity). The phase transition is thermally activated, and its kinetics can span orders of magnitude in time, down to sub-nanosecond timescale. Hence, proper probing of the thermal actuation is required to understand the fundamental material properties of PCMs, particularly the physics of melt-quench processes in nanoscale devices, interface vs. bulk effects, drift, and threshold voltage phenomena. Research efforts have been made to characterize PCM using a microthermal stage (MTS) [1]. The MTS structure used either a top Pt heater for the thermal actuation of a lateral Ge2Sb2Te5 (GST) device or a Pt heater surrounding the GST. Thus, the MTS allowed for probing with thermal time scales on the order of microseconds or longer.

Four-terminal, in-line, indirectly heated phase-change switches (IPCS) have been proposed for high-performance RF
applications, thanks to their state-of-the-art figure-of-merit (FOM) = 1/(2\pi R_{ON}C_{OFF}) [2, 3]. A typical IPCS consists of two RF ports in-line with the PCM (i.e., the RF path), separated by a small gap, and two terminals for thermal actuation using an embedded heater. The heater runs transversely to the direction of the RF path, under the PCM. The heater and the RF path are separated by a thin electrically isolating film (e.g., SiN\(_4\)). GeTe has been so far the material of choice for RF applications due to its low resistivity in the crystalline phase and relatively large resistivity contrast with the amorphous state, but recently an Sb\(_2\)Te\(_3\) IPCS was demonstrated with similar FOM and improved energy efficiency [3].

In this study, we report on the use of IPCS device structure as a platform for electro-thermal characterization of phase transition properties of PCM in nanoscale films at nanosecond temporal resolution. The isolation between the heater and the PCM layer electrically decouples the heating pulse and PCM probing. Thus, the phase transition, as well as temperature-dependent properties up to temperatures of \sim 100 K, can be measured during heating pulse application with ns resolution. Furthermore, since the heater is buried underneath the PCM, our setup allows for 1) steady-state PCM temperature validation using scanning thermal microscopy (SThM) from the top surface, 2) separation between contribution of contact (interface) and bulk effects by varying overlap and underlap between the heater and the PCM contacts, and 3) test different materials of interest without significant change in the fabrication process. We use GeTe as a prototype material with known melting temperature, crystallization kinetics, and surface treatment for low ohmic contacts [4]. Measurements are carried out using RF probes for the heater and the PCM to reduce the overshoot and ringing of short-pulses and produce clean waveforms for nanosecond probing. The experimental results are compared to a detailed finite element electro-thermal model to extract key material properties. Overall, our platform can be used to uncover the intriguing kinetics of crystallization and amorphization in chalcogenides and other amorphous semiconductors.

As one of the most promising candidates for developing new neuromorphic architectures for non-von Neumann computing and information storage, Ge\(_2\)Sb\(_2\)Te\(_5\) (GST225) in photonic devices shows non-volatile, fast, and multi-step changes between the amorphous state and the meta-stable states. In order to search for other composition ratios with desired properties, e.g. large figure of merit, lower switching energy, etc., we have systematically investigated a broad composition range of the Ge-Sb-Te (GST) system. The GST combinatorial spread was fabricated by co-sputtering Ge, Sb and Te targets and was confirmed by wavelength dispersive spectroscopy that the composition variation across the Si wafer covers most part of the GST phase diagram. X-ray diffraction measurements (synchrotron radiation), Raman spectroscopy and resistance mapping clearly show evolution of the structure and phase-change temperature in the GST system. Refractive index and extinction coefficient were calculated at each composition spot using a scanning ellipsometer: some composition ratios were found to have a small extinction coefficient in the amorphous state, a high phase-change temperature, and a large figure of merit. Then, the nano-size photonic devices fabricated by these ratios were measured and showed good reversibility (more than 40000 cycles) and multi-level symmetric switching (at least 15 levels), suggesting that such compositions can be promising for photonic devices for neuromorphic control. Further, we confirm that compositions with promising properties are near the boundary between the Sb-Te and the Ge-Sb-Te phases, indicating that co-existence of the phases at microstructural level may be playing a role in giving rise to their properties. This work is funded by an ONR MURI (Award No. N00014-17-1-2661).

GeSbTe alloys, widely employed for phase change non volatile memory, are usually not suitable in embedded and automotive applications, because of the low crystallization temperature. Doping, in particular with Ge, has been shown to be a viable way to extend the thermal stability of GeSbTe alloys [1,2]. However, once an optimised composition has been selected, during device operation, the material stoichiometry may change, due to the atomic migration induced by the high temperature and/or by the electric field [3]. These variations may lead to programming and retention performance.
degradation or even to device failure. It is therefore crucial to understand the extent of the atomic migration and its impact on the stoichiometry, as well as on the crystallization properties. In order to decouple the effect of the atomic diffusion at high temperature from that of the field induced electromigration, we have irradiated crystalline Ge rich GeSbTe thin films by laser. The films were prepared by sputter deposition in the amorphous phase, and then converted into the crystalline structure by annealing at 400°C. The irradiation has been performed by using a Yb-YAG laser (515 nm) with 600 ns pulse, operating at different energy densities. By changing the energy density, complete or partial melting and quenching, with amorphization of the film, can be achieved. In this way we are able to study the thermal diffusion processes decoupled from the field induced electromigration. After melting and quenching, the atomic elements distribution has been studied by Transmission Electron Microscopy (TEM) and Electron Energy Loss Spectroscopy (EELS). We find that, even without the electric field, the melting gives rise to a prominent diffusion of Ge atoms. By employing finite elements computational analysis, a diffusion coefficient of Ge on the order of 5x10^{-5} cm² s⁻¹ in the molten phase has been estimated. After amorphization under different irradiation conditions, we have followed the crystallization upon thermal annealing by in-situ time resolved reflectivity measurement. Such a crystallization process, after the first melting and quenching, is expected to be different from the crystallization of the as deposited amorphous film, since the melting produces not only sub-critical crystalline nuclei, but also a modification of the stoichiometry. The study of the crystallization in such a “primed” material is very similar to the situation occurring in a real memory device after the first erasing step and therefore it is relevant for reliability evaluations.

Cw Laser Annealing Induces Stress Field During Phases Transition in Ge₂Sb₂Te₅ Layer Giuseppe D’Arrigo¹, Mario Scuderi¹, Antonio M. Mio¹, Gregory Favaro², Antonella Sciuto¹, Marzia Buscema¹, Alessandro Meli¹, Giovanni Li Destri³, Egidio Carria⁴, Domenico Mello⁵, Michele Calabretta⁵, Alessandro Sitta⁴, Julian Pries⁵ and Emanuele Rimini¹; ¹CNR-IMM, Italy; ²Anton Paar USA Inc., Switzerland; ³Università di Catania, Italy; ⁴STMicroelectronics, Italy; ⁵RWTH Aachen University, Germany

The mechanical properties, Hardness and Young module, of crystalline micrometer stripes of Ge₂Sb₂Te₅ and of the surrounding 2.2 μm thick amorphous film have been measured simultaneously. Crystallization was performed by a Continuous Wave laser irradiation process in the range 1.25-3.2 mW. The density changes between the amorphous and the crystalline phase cause a relevant stress in the processed material. Usually the stress is measured by the wafer curvature. This methodology doesn’t allow a detailed investigation of the local mechanical modifications when the two phases amorphous and crystalline are contiguous, as in an optical or electrical storage device. The use of micrometer patterned structures and nano-indentation measurements allow us to determine the mechanical behavior of the two contiguous GST phases. The measured values of the mechanical property are more dispersed for the crystallized material than those for the contiguous amorphous phase. The Young modulus and the hardness are 51±8 GPa and 2880±450 MPa for the crystallized and 33±4 GPa and 1989±300 MPa for the amorphous phase respectively. Microcracks are also seen, together with fracture lines. The occurrence of delamination at laser power densities above 1.70 mW indicates that for these crystallized thicknesses the maximum tensile strength in the amorphous and crystalline phases was reached and exceeded. The phase transition has also been investigated by several analytical tools (TEM, SEM, Raman and XRD diffraction). A simulation code was adopted to compute the temperature-time-space profile as a function of the laser power. These results were used to compare the measured crystallized thickness to that calculated.

Uncovering β-Relaxations in Amorphous Phase-Change Materials Shuai Wei¹, Si-Xu Peng², Yudong Cheng¹, Julian Pries¹, Hai-Bin Yu³ and Matthias Wuttig¹; ¹RWTH Aachen University, Germany; ³Huazhong University of Science and Technology, China

Relaxation processes are decisive for many relevant physical properties of amorphous materials. For amorphous phase-change materials (PCMs) employed in non-volatile memories, relaxation processes are, however, difficult to characterize due to the lack of bulk samples. Here, instead of bulk samples, we use powder mechanical spectroscopy for powder samples to detect the prominent excess wings – a characteristic feature of β-relaxations – in a series of amorphous PCMs at temperatures
below the glass transition. By contrast, β-relaxations are vanishingly small in amorphous chalcogenides of similar composition, which lack the characteristic features of phase-change materials. This conclusion is corroborated upon crossing the border from PCMs to non-PCMs, where β-relaxations drop significantly. Such a distinction implies that amorphous PCMs belong to a special kind of covalent glasses whose locally fast atomic motions are preserved even below the glass transitions. These findings also suggest a correlation between β-relaxation and crystallization kinetics of PCMs, which may have technological implications for phase-change memory functionalities.

Modeling Charge and Electro-Thermal Heat Transport in Phase Change Memory Cells Md Tashfıq Bin Kashem, Jake Scoggin, Ali Gokirmak and Helena Silva; University of Connecticut, United States

In order to model phase change memory (PCM) cells, dynamic materials models have to be coupled with charge and heat transport models [1]-[7]. Since PCM cells experience high temperatures, very large thermal gradients (~ 50 K/nm) and high current densities during their normal reset and set operations, thermoelectric contributions are significant for both charge and heat transport in these cells. Furthermore, some of the assumptions made for large scale thermoelectric devices do not hold under these extreme conditions.

Charge transport in PCM cells can be modeled using a drift-diffusion approximation. However, electronic material properties such as carrier concentrations, mobilities and diffusivities are not well characterized for phase change materials. In this study, we construct (i) a drift-diffusion model using thermoelectric characteristics of the material, measured in a large temperature range, and (ii) an electrothermal heat transport model that does not assume mild temperature gradients only. Our simulation results show that both Thomson heat (thermoelectric effects in the bulk materials) and Peltier heat (thermoelectric effects at the contact regions) play a significant role, and give rise to significantly asymmetric thermal profiles in symmetric PCM cells.

Reversible Electrochemical Phase Change in Monolayer to Bulk-Like MoTe2 by Ionic Liquid Gating Dante Zakhidov¹, Daniel A. Rehn²,³, Evan J. Reed¹ and Alberto Salleo¹; ¹Stanford University, United States; ²Los Alamos National Laboratory, United States

Transition metal dichalcogenides (TMDs) exist in various crystal structures with semiconducting, semi-metallic, and metallic properties. The dynamic control of these phases is of immediate interest for next generation electronics such as phase change memories and TMDs have the potential to outperform current phase-change materials such as GeSbTe on energy efficiency while also being fundamentally more scalable. Of the binary Mo and W-based TMDs, MoTe₂ is attractive for electronic applications because it has the lowest energy difference (40 meV) between the semiconducting (2H) and semi-metallic (1T') phases, allowing for MoTe₂ phase change by electrostatic doping.

Here we report phase change between the 2H and 1T' polymorphs of MoTe₂ in thicknesses ranging from the monolayer case to effective bulk (73nm) using an ionic liquid electrolyte at room temperature and in air. We find consistent evidence of a partially reversible 2H-1T’ transition using in-situ Raman spectroscopy where the phase change occurs in the top-most layers of the MoTe₂ flake. We empirically find that the transition voltage of the phase change increases with thickness which provides a direct avenue to transition-voltage control for phase change devices. We also show evidence of electrochemical activity during the gating process by observation of Te metal deposition. This finding suggests the formation of Te vacancies which have been reported to lower the energy difference between the 2H and 1T' phase, potentially aiding the phase change process. This provides another avenue for transition-voltage control through defect engineering but also emphasizes the need for better understanding of electrolyte gating and chalcogenide vacancy formation. Our discovery that the phase change can be achieved on the surface layer of bulk materials reveals that this electrochemical mechanism does not require isolation of a
single layer and the phase change effect may be more broadly applicable than previously thought. We will also discuss recent work on implementation of a solid state device with the use of ionic gels and porous dielectrics.

Beyond von–Neumann Computing—Engineering Artificial Synapses for In–Memory Computing Valeria Bragaglia, Benedikt Kersting, Prasad Jonnalagadda, Antonio La Porta, Daniel Jubin, Diana Dávila, Jason Giannopoulos, Manuel Le Gallo, Ghazi Syed, Folkert Horst, Jean Fompeyrine, Bert Offrein and Abu Sebastian; IBM Research-Zurich, Switzerland

The processing of an input dataset by a deep neural network, e.g. for classification tasks, is a series of vector-matrix multiplications (input data * synapse weight). The size and number of matrices that need to be processed are too large to be stored in a Static Random Access Memory (SRAM) unit. For this reason, data need to be shuffled constantly between memory and processing unit in a classical computing architecture, leading to inefficiency and performance mitigation. Dedicated neuromorphic computing hardware may help to overcome these issues and is a promising technology for the post–von Neumann computing era. Especially memristive devices are suitable for this dedicated hardware. A crossbar of memristive devices stores the synaptic weights in a physical matrix. The weight can be read non-destructively and updated e.g. during training. The matrix vector multiplication can be performed in-memory by coding the synaptic weight to the device conductance and the input data to the read voltage amplitude. Several memristive technologies are under study for the implementation of neuromorphic hardware, and they rely on diverse physical mechanisms and materials [1]. However, improvements in the device characteristics are required for optimal hardware acceleration in both performance precision and energy consumption. Examples of challenges are the minimization of inter and intra device asymmetricity, non-linearity and stochasticity, and the increase of the dynamic range.

In this talk I will present Phase Change Memories (PCM) and filamentary-based Oxide Resistive RAM (OxReRAM), the two most promising candidates to represent artificial synapses in neuromorphic hardware [2,3]. In PCM-based memristors, the conductance change relies on a phase transition in the material, while for filamentary-based OxReRAM, the synaptic weight depends on the rupture/formation of oxygen vacancies based conductive paths. Strength and challenges of the two classes of memristors will be discussed. For each technology, an innovative design and material stack concepts will be presented, demonstrating enhanced operational characteristics. The material-stack characterization by means of X-ray reflectivity and diffraction, Hall-measurements as well as the electrical characterization of the devices will be covered. A discussion on the ideal class of applications for a more efficient use of PCM- or OxReRAM-based synapses will follow.

Optical Properties and Photonic Applications of Monatomic Phase-Change Materials Zengguang Cheng, Samuel Humphrey, James Y. Tan, Tara Milne, Nikolaos Farmakidis, Eugene Soh, Seongdong Lim, Robert Taylor and Harish Bhaskaran; University of Oxford, United Kingdom

With the increasing demand of high-density storage and neuromorphic hardware driven by the rapidly growing of artificial intelligence, miniaturized phase-change memory device has been developed for energy-efficient data storage and computing[1]. Typical phase-change memory devices are based on complex compounds with precisely controlled stoichiometry. Therefore, monatomic phase-change materials using single element of antimony has been proposed as a promising candidate in ultra-small phase-change device without the need of compositional optimization[2]. On the other hand, the integration of phase-change materials with photonics has provided considerable opportunities of data storage[3], computing[4] and machine learning[5] in photonics, benefited from the fast speed, large bandwidth and low cross talking in optical domain[6] as well as the exceptional properties of phase-change materials[7]. Herein, we systematically studied the material properties, especially the optical properties, of thin-layer antimony films during the phase-changing process. With a huge contrast of optical constants between the amorphous and crystalline states, we demonstrated integrated non-volatile
photonic memories using monatomic phase-change materials, resulting in a unique platform for phase-change photonic applications.

Phase Change Material Volatile and Non-Volatile Memory in Photonic Neural Networks
Mario Miscuglio1, Robert E. Simpson2, Simon Wall3 and Volker J. Sorger4; 1George Washington University, United States; 2Singapore University of Technology and Design, Singapore; 3ICFO–The Institute of Photonic Sciences, Spain

Here we demonstrate heterogeneous integration of phase-change materials GST and GSST for memory functionality in silicon photonic circuits. Using these materials we show a) an electro-optic WRITE and optical READ as a dot-product multiplier that can be used as a non-volatile 'weight in photonic neural networks (NN), and b) an all-optical WRITE and optical READ performing the nonlinear activation function 'thresholding' of the NN.

An all-optical (AO) nonlinear (NL) material forms the ultimate basis for a new generation of photonic NNs. Here we show the response and integrate such material-based nonlinearity into a photonic perceptron. Besides passive weighting functionalities, which saves static power with respect to an implementation with EOMs, we will use a nonlinear activation function (NL AF, ‘threshold’ of NN) based on temporary optical response of GST when optically pumped. For the implementation of the optical nonlinearity, instead of an electro-optic mediated nonlinearity, as proposed by our group and others, we propose to integrate a thin film of GST in an all-optical thresholder in a pump-probe configuration. In this configuration there is no conversion between light and electronics until read out, that could be pushed at the very end of the network. Thus, the inference delay of this network is ps-short. This GST film acts as an optical intensity modulator of the weighted-addition on a second probe source. The optical transitions which modulates the nonlinear function are corroborated by a recent break-through in GST mediated optical nonlinearity which allows for optical modulation of light without requiring the material to recrystallize. This physical modulation mechanism relies on a femtosecond-short excitation, which directly detaches electrons from resonantly bonded states resulting in a non-equilibrium, immediate decrease in the dielectric function and the saturation of the imaginary part of the dielectric function at the same value as the amorphous-state. This femtosecond pulse induced change in the optical properties is not the same as those dictated by thermal process, used for the weighting functions, and hence does not result in the change in crystallinity. Without the complete depopulation of the resonantly bonded state, we can achieve up to 13% reversible modulation of the dielectric function, more than 10x larger than that observed in silicon photo-switches. This allows for a response time of about 100 fs of these all-optical NLAf (thresholds) for pure optical NNs. The neuron is then interconnected to others in a feedforward fully connected NN of L layers (multi-layered perceptron). The input signal is encoded in the laser intensity. Each layer consists of a logic block which performs pointwise matrix multiplication (i) and element-wise NLAf (ii). The weighed addition is performed using a similar approach seen in. In this case, the weights are not fixed thermally which requires a great expense of power budget and insulation strategies, but it is fixed using phase change materials, which have been optically written (in a similar fashion as a rewritable DVD) and kept at their respective state without any dissipation of static power. The NLAf is also performed using GST films in a pump-probe configuration; the optical pump, from free space, induces the temporary phase transition and the material alters its complex refractive index in a volatile way. The effective mode index of the waveguide, in which the probe signal travels, is altered as nonlinear function of the available power after the weighted addition.

Density Functional Simulations of the Atomic Structure and Dynamics of Phase Change Materials Jaakko Akola¹,², Janne Kalikka² and Robert Jones³; ¹Norwegian University of Science and Technology, Norway; ²Tampere University, Finland; ³Forschungszentrum Juelich, Germany

Crystallization of phase change materials has been studied by extensive density functional/molecular dynamics simulations (DF/MD). Four crystallization simulations of amorphous Ge₂Sb₂Te₅ (460 atoms) have been completed at 600 K with simulation times up to 8.2 ns.¹⁻² A sample with a history of order crystallizes completely in 1.2 ns, but ordering in others takes more time and is less complete. The amorphous starting structures without memory display phases (<1 ns) with subcritical nuclei (10–50 atoms) ranging from nearly cubical blocks to string-like configurations of ABAB squares and AB bonds extending across the cell. Percolation initiates the rapid phase of crystallization and is coupled to the directional p-type bonding. The results emphasize the stochastic nature of crystallization and the importance of sufficiently large samples. This is particularly evident in describing the role of crystallites that can merge to form larger units or hinder complete crystallization by the formation of grain boundaries.

Amorphous Sb is known to crystallize extremely rapidly already at room temperature. Crystallization of Sb has been studied at 600 K using six DF/MD simulations with up to 882 atoms.³ Crystallization proceeded layer-by-layer in most cases and was extremely rapid (∼36 m/s). As shown in Fig. 1, diffusion plays a minor role in the process as the crystallization proceeds from the crystalline rim, and the evolution of bond lengths and ring statistics supports the bond-interchange model of Sb-rich phase change materials.⁴

We have also carried out extensive DF/MD simulations (over 500 atoms, up to 100 ps) of liquid bismuth at four temperatures between 573 - 1023 K.⁵ These simulations provided details of the dynamical structure factors, the dispersion of longitudinal and transverse collective modes, and related properties (power spectrum, viscosity, and sound velocity). Agreement with available inelastic x-ray and neutron scattering data and with previous simulations is generally very good. The results show that DF/MD dynamics simulations can give dynamical information of good quality without the use of fitting functions, even at long wavelengths.

Phase Change Materials by Design—The Power and Potential of Maps Matthias Wuttig; RWTH Aachen University, Germany

It has been a long-time dream of mankind to design materials with tailored properties. In recent years, the focus of our work has been the design of phase change materials for applications in data storage. In this application, the remarkable property portfolio of phase change materials (PCMs) is employed, which includes the ability to rapidly switch between the amorphous and crystalline state. Surprisingly, in PCMs both states differ significantly in their properties. This material combination makes them very attractive for data storage applications in rewriteable optical data storage, where the pronounced difference of optical properties between the amorphous and crystalline state is employed. This unconventional class of materials is also the basis of a storage concept to replace flash memory. Today’s talk will discuss the unique material properties, which characterize phase change materials. In particular, it will be shown that only a well-defined group of materials utilizes a unique bonding mechanism (‘Bond No. 6’), which can explain many of the characteristic features of crystalline phase change materials. Different pieces of evidence for the existence of this novel bonding mechanism, which we have coined metavalent bonding, will be presented. In particular, we will present a novel map, which separates the known strong bonding mechanisms of metallic, ionic and covalent bonding, which provides further evidence that metavalent bonding is a novel and fundamental bonding mechanism. This insight is subsequently employed to design phase change materials as well as thermoelectric materials.

Accurate and Efficient Deep Neural Network for High-Throughput-Simulation-Based Optimization of Chalcogenide Phase Change Materials

Jie Liu1,2; 1Hunan University, China; 2University of Washington, United States

Chalcogenide phase change materials (PCM) are widely-used in optical data storage technologies. Also, they are promising to become the next-generation mainstream electronic non-volatile memory technology. These have been discussed and simulated in our prior work [1-4]. The operation of PCM-based devices hinge on the repeated rupture and formation of atomistic-scale chemical bonds to reversibly switch between crystalline and amorphous phases, which require atomistic-scale simulation methodology to achieve in-depth optimization. Nowadays, there are two categories of such methodologies -- density functional theory (DFT) and artificial neural network (ANN). DFT-based molecular dynamics (MD) is accurate but inefficient -- it is practically applicable to only hundreds of atoms. ANN-based MD is efficient but inaccurate -- its maximum error of atomic force prediction can be over 10 eV/Angstrom.

In our recent work [5], we present a method based on deep neural network (DNN) to model PCM, which is both accurate and efficient. The DNN-based MD has a computational complexity of O(N), where N is the number of atoms. So, DNN-based MD is orders of magnitude faster than DFT, whose computational complexity is around O(N^3). Furthermore, the maximum error of atomic force prediction of DNN-based MD is around 0.1 to 1 eV/Angstrom, which is much more accurate than ANN in the existing literature. In our another recent work [6], we present a transfer learning (TL) method, to handle the needs to simulate multiple combinations (different PCM stoichiometry, doping, etc.). Compared to the state-of-art methods in PCM literature, the proposed TL method can significantly reduce the amount of DFT data used to train the neural network, which is beneficial to enable high-throughput simulations.

Combining the accuracy and efficiency [5], and the trasferrability between different materials [6], we aim at establishing a general-purpose PCM optimization method based on high-throughput simulations.

Femtosecond X-Ray Diffraction Reveals a Liquid–Liquid Phase Transition in Phase-Change Materials

Peter Zalden1,2, Florian Quirin3, Mathias Schumacher3, Jan Siegel3, Shuai Wei4, Azize Koc3,4, Matthieu Nicoul3, Mariano Trigo5,7, Pererik Andreasson9, Henrik Enquist5, Michael J. Shu6, Toimmaso Pardini10, Mathieu Chollet4, Diling Zhu7, Henrik Lemke11,7, Ider Ronneberger4, Jürgen Larsson9, Aaron M. Lindenberg7,7,9, Henry E. Fischer12, Stefan Hau-Riege10, David A. Reis5,7, Riccardo Mazzarello4, Matthias Wuttig8,13 and Klaus Sokolowski-Tinten3; 1European XFEL, Germany; 2University of Hamburg, Germany; 3University of Duisburg-Essen, Germany; 4RWTH Aachen University, Germany; 5Instituto de Optica, Spain; 6Universität Potsdam, Germany; 7SLAC National Accelerator Laboratory, United States; 8Lund University, Sweden; 9Stanford University, United States; 10Lawrence Livermore National Laboratory, United States; 11Paul Scherrer Institute, Switzerland; 12Institut Laue-Langevin, France; 13Forschungszentrum Jülich GmbH, Germany

Phase-Change Materials (PCMs) are the active switching element in novel electronic memory devices. Their data storage is based on a crystallization and glass formation mechanism that offers (i) fast crystallization over a wide range of elevated temperatures and (ii) glass formation at ambient conditions. Fundamentally, these regimes are characterized by a low and high activation energy of viscosity, respectively. The transition between these regimes has been previously associated with a fragile-to-strong crossover[1] and/or with the glass transition[2], but its microscopic origin has been elusive - mostly due to the experimental limitation imposed by the fast crystallization of this disordered state. Recent measurements using femtosecond X-ray diffraction at an X-ray free electron laser (XFEL) resolved the atomic structure during this transition[3].

An optical laser pulse was employed to melt the PCM, whose structure was probed at different time delays after the excitation, i.e., during the quenching process. The resulting data show that the increase of kinetic activation energy coincides with the onset of a Peierls distortion in the PCMs Ag4In3Sb67Te26 (AIST) and Ge15Sb85. Based on the weak dependence of this onset temperature on the cooling-rate, we attribute this onset to a liquid-liquid phase transition. Ab-initio computer simulations confirm this trend in the atomic structure and provide further insight into the underlying mechanism: The distortion breaks the local symmetry, opens an electronic band gap and localizes charges, giving the bonds more covalent character, which is commonly associated with a decrease in the flexibility of bond angles. This insight reveals a relation between the structure and kinetics of PCMs. In this contribution, we will also discuss similar measurements on the most common PCM Ge2Sb2Te5 and contrast its behavior to a similar but distinct transition mechanism observed in supercooled liquid Ge.

6:30 AM *S.EL09.02.05
Liquid State Behavior of Favored PCM Formulations—The Role of the Metallicity C. Austen Angell1, Pierre Lucas2 and Shuai Wei3; 1Arizona State University, United States; 2University of Arizona, United States; 3RWTH Aachen University, Germany

The functioning of PCM materials in the context of involatile digital memory technology involves a complex interplay of liquid, glass and crystal phase behaviors. Here we focus attention on the peculiarities of the liquid state as judged by the temperatures at which transitions from metallic to semiconducting states occur, relative to melting points. In some cases like As2Se3 and As2Te3 this transition occurs far above the melting point. In others, like pure Te, it is observed to occur quite deep in the supercooled liquid state. Data are sparse for elements and binary compounds, but we can include other compositions by introduction of a metallicity parameter, MP, which is the inverse of the composition-averaged Pauling electronegativity, \( \chi \), i.e.,

\[
MP = \frac{1}{(x_1 \chi_{P1} + x_2 \chi_{P2} + \ldots + x_i \chi_{Pi})},
\]

When we plot the temperatures of at which the M-SC transition occurs (scaled by the melting points), against MP, we find, by extrapolation, that all of the preferred PCM compositions have their M-SC transitions at similar depth in the supercooled liquid state, where the crystallization rate is exceptionally high. The implications, and applications, of this finding will be discussed.

7:00 AM S.EL09.02.06
Reversible Electrochemical Phase Change in Monolayer to Bulk-Like MoTe2 by Ionic Liquid Gating Dante Zakhidov1, Daniel A. Rehn1,2, Evan J. Reed1 and Alberto Salleo1; 1Stanford University, United States; 2Los Alamos National Laboratory, United States

Transition metal dichalcogenides (TMDs) exist in various crystal structures with semiconducting, semi-metallic, and metallic properties. The dynamic control of these phases is of immediate interest for next generation electronics such as phase change memories and TMDs have the potential to outperform current phase-change materials such as GeSbTe on energy efficiency while also being fundamentally more scalable. Of the binary Mo and W-based TMDs, MoTe2 is attractive for electronic applications because it has the lowest energy difference (40 meV) between the semiconducting (2H) and semi-metallic (1T') phases, allowing for MoTe2 phase change by electrostatic doping.

Here we report phase change between the 2H and 1T' polymorphs of MoTe2 in thicknesses ranging from the monolayer case to effective bulk (73nm) using an ionic liquid electrolyte at room temperature and in air. We find consistent evidence of a partially reversible 2H-1T' transition using in-situ Raman spectroscopy where the phase change occurs in the top-most layers of the MoTe2 flake. We empirically find that the transition voltage of the phase change increases with thickness which provides a direct avenue to transition-voltage control for phase change devices. We also show evidence of electrochemical activity during the gating process by observation of Te metal deposition. This finding suggests the formation of Te vacancies which have been reported to lower the energy difference between the 2H and 1T' phase, potentially aiding the phase change process. This provides another avenue for transition-voltage control through defect engineering but also emphasizes the need for better understanding of electrolyte gating and chalcogenide vacancy formation. Our discovery that the phase change can be achieved on the surface layer of bulk materials reveals that this electrochemical mechanism does not require isolation of a single layer and the phase change effect may be more broadly applicable than previously thought. We will also discuss recent work on implementation of a solid state device with the use of ionic gels and porous dielectrics.
Towards the Investigation of Electronic Properties of Epitaxial Phase Change Materials

Fabrizio Arciprete1,2, Valeria Bragaglia1,2, Stefano Cecchi2, Eugenio Zallo2, Ernesto Placidi2,1, Daniele Dragoni5, Marco Bernasconi5, Jos Boschker2 and Raffaella Calarco6,2; 1University of Rome Tor Vergata, Italy; 2Paul-Drude-Institut für Festkörperelektronik, Germany; 3IBM Research-Zurich, Switzerland; 4Sapienza University of Rome, Italy; 5University of Milano-Bicocca, Italy; 6CNR-IMM, Italy

Phase Change Materials (PCMs) represent an important materials class from both a fundamental and technological point of view. Although much effort is still required to determine all the physical mechanisms underlying their complex physical properties, memory devices based on PCMs, which exploit the resistance contrast between the amorphous and crystalline phases, are already at the production stage. The ternary \((\text{GeTe})_m(\text{Sb}_2\text{Te}_3)_n\) alloys are the prototypical phase change materials commonly used for optical and memory devices in the composition \(\text{Ge}_2\text{Sb}_2\text{Te}_5\) (GST225). Among other fabrication methods, such as pulsed laser deposition and sputtering, which is the main technique used in industry, Molecular Beam Epitaxy (MBE) has recently gained in importance because of the advantage to obtain epitaxial quasi-single-crystalline PCM layers. This achievement has made it possible the investigation of material properties for which structural perfection is of crucial importance. For example, we have been able to demonstrate that highly ordered crystalline phases can be deposited by van der Waals (vdW) epitaxy, where adjacent building blocks are weakly bonded among them and to the substrate. Furthermore, epitaxial quasi single-crystalline GST, with ordered stacking of intrinsic vacancies, exhibits a large resistivity range that is promising for the realization of memory cells with large programming windows [1].

In this presentation we will first review our advances in the growth of epitaxial GST alloys by MBE on both Si and InAs substrates. We have carried out a growth engineering of single-crystalline GST to achieve unprecedented control over structural order, phase, and composition. The combined use of X-ray diffraction and Raman spectroscopy allowed us to draw a growth phase diagram for GST [2].

The capability to retain the stored information during the memory lifetime is a fundamental property of PCM, and any spontaneous evolution of the amorphous phase toward the more stable crystalline one is undesired. This is especially true when the device working temperature may be higher than the crystallization temperature, as in automotive applications. In this regards we will present our first results in the search of suitable PCM alloys with improved physical properties in terms of crystallization temperature and crystallization speed. In particular we will show our first crystallization study of Ge-rich GST, aiming to identify thermally stable PCMs with high crystallization temperature, and our first results on the investigation, by X-ray Photoemission Spectroscopy (XPS), of the electronic properties of both epitaxial GST and Ge-rich GST. XPS data will be correlated with X-ray diffraction and Raman characterization.

Pulsed Laser Deposited Sb2Te3, GaSb and Ge –Rich GST Thin Films and Heterostructures for Memory Devices

Daniel T. Yimam, Jamo Momand and Bart J. Kooi; Zernike Institute for Advanced Materials, University of Groningen, Netherlands

Future Electronic Smart Systems (ESS) require energy efficient storage and fast processing of large amount of data. Phase-Change Materials, exhibiting large electrical and optical contrast between two phases also allowing multiple intermediate states, are highly desired for this application, because in principle they also have the ability to store and process data at the same physical place(Wuttig et al. Nat. Mater. 2007). Despite progresses which have been made to achieve the full potential of Ge2Sb2Te5 based PCM devices, several reliability issues still hinder the realization of ultimate performance. Void formation due to density change upon switching, low crystallization temperature for automotive applications, and resistance drift over time are among the few. GaSb is considered as a promising candidate for future phase change random access memory (PCRAM) devices because of its fast crystallization, high crystallization temperature, and lack of density change upon switching at a specific composition of \(\text{Ga}_{30}\text{Sb}_{70}\) (Putero et al. APL Materials. 2013). Pulsed Laser Deposition (PLD) has
become one of the most popular thin film deposition technique. Some of the reasons for this popularity are the flexibility, processing speed, and the wide range of materials that can be deposited. In this work we discuss PLD of single and alternating layers of Sb$_2$Te$_3$, GaSb, and Ge-rich GST thin films on various substrates. Amorphous, polycrystalline, and textured heterostructures of Sb$_2$Te$_3$/GaSb and Sb$_2$Te$_3$/Ge-rich GST are deposited. Reflection high-energy electron diffraction (RHEED) is used as in-situ growth monitoring tool during deposition to achieve desired film quality. Moreover, deposited films are characterized by Scanning Transmission Electron Microscope (S/TEM) for composition and quality analysis before producing single cell vehicles for electrical device testing.

Interfacial Crystallization of Epitaxial Ge$_2$Sb$_2$Te$_5$ Phase Change Thin Films Andriy Lotnyk, Mario Behrens, Martin Ehrhardt and Bernd Rauschenbach; Leibniz Institute of Surface Engineering (IOM), Germany

The working principle of conventional phase change memory device is based on ultrafast reversible phase changes between crystalline and amorphous phases of Ge–Sb–Te (GST) materials. For information storage, phase change memory device uses a large contrast either in electrical resistance between the amorphous phase (high-resistance state) and crystalline phase (low-resistance state) or in optical reflectivity between the amorphous phase (low reflectivity state) and crystalline phase (high reflectivity phase). The erase of GST-based memory cell is achieved by applying a high intensity either electrical or laser pulses. These processes lead to the amorphization via melting and subsequent fast quenching of the phase change alloy. However, GST alloys are poor glass formers. Thus, rapid cooling rates are required to suppress the recrystallization of the alloys during the erase process. On another hand, the write process is accomplished by applying either electrical or optical pulses with low intensity. This results in an amorphous-to-crystalline phase transition. Due to intrinsic feature of GST alloys, a main challenge in material science is the optimization of memory writing times, which are limited by the crystallization kinetics of the alloys. In order to speed up the crystallisation rates, several strategies were proposed, including doping of GST materials, precrystallization of an amorphous matrix or using GST based superlattices. Being a nucleation-dominant material, the crystallization of GST alloy in a nanosized phase-change memory cell might however proceed at the crystalline interfaces.

This contribution focuses on determination of crystallization dynamics in epitaxial Ge$_2$Sb$_2$Te$_5$ (GST225) thin films on application relevant (nanosized) length and (nanosecond) time scales. We irradiate the thin films by a single UV laser pulse with a 20 ns pulse duration and with different laser fluences. First, we study the structural transitions in epitaxial GST225 thin films starting from the layered trigonal GST225 structures [1]. We compare the obtained results with the behaviour of GeTe-Sb$_2$Te$_3$ based superlattices (SLs) after the laser irradiation. In both cases, the results reveal the phase transition to the cubic GST225 structure. The cubic phase forms from a transient molten phase at the melt-crystalline interface upon cooling process and crystallizes with epitaxial relationship to the parent phase. Second, by introducing a method based on combination of high temporal and spatial resolution, we determine the crystallization rates of the cubic GST225 phase [2]. The rates are ranging from 0.4 m/s to 1.7 m/s. The values are well in agreement with the published experimental and theoretical data. Moreover, a variation of the laser fluence leads to different cooling rates, which result in different solidification rates and freezing of an amorphous state. Irradiation of amorphous GST225 phase by laser pulse with lower fluence leads to the re-crystallization of the phase and epitaxial formation of the cubic GST225 structure. Overall, our work shows an approach for the investigation of crystallisation kinetics in wide range of phase change materials on application relevant length and time scales. In addition, we demonstrate amorphization and crystallization of GST225 material by using UV laser with single pulse duration and wavelength only, where in the conventional amorphous-to-crystalline phase transitions the lasers with different pulse durations, number and wavelengths are usually applied.

5:30 AM S.EL09.04.02
Crystallization Properties of Nano Amorphized Areas in Epitaxial Epitaxial GST on Si (111) by TEM In Situ Characterizations Antonio M. Mio1, Giuseppe D’Arrigo1, Jos Boschker2, Alessandro Meli1, Stefano Cecchi2, Eugenio Zallo2, Antonella Sciuto1, Marzia Buscema1, Elena Bruno3, Raffaella Calarco2 and Emanuele Rimini1; 1CNR-IMM,
The crystallization behavior of amorphous nano-regions (20-100 nm in diameter) embedded in a textured epitaxial Ge$_2$Sb$_2$Te$_5$ (GST) 25 nm thick film grown on Si (111) substrate has been investigated in situ by TEM analysis. The amorphous regions were obtained by irradiation with 30 keV Ge$^+$ at a fluence of 1.5x$10^{14}$ ions/cm$^2$ of masked samples. The adopted configuration simulates the GST structure of a device in the RESET state, it is then of relevance for understanding their data retention characteristics. In situ TEM analysis indicates that the amorphous to crystal transition is characterized by an initial growth velocity of 3.6 pm/s at 75°C, probably related to the external partially damaged area. For the previous annealed sample, a velocity of about 2.6 pm/s was observed at 90°C and a growth speed of 170 pm/s at 110°C for the 50nm and 100nm diameter amorphous spots. The 20 nm diameter amorphous spots recrystallize after the annealing at 90°C. The transition is governed only by crystallization (nucleation is absent) of the atoms located at the boundary of the amorphous dot with the surrounding crystalline regions. In some case a preferential growth along surfaces normal to the [110] and to the [121] directions has been found. The crystallographic characterization of the regrowth crystal indicates a good matching with the zone axis of the surrounding material although the crystalline seed Si (111) at the bottom interface is missing for the damage.

5:45 AM S.EL09.04.03
Nanosecond Probing of Phase Transition Properties in Chalcogenides Using Embedded Heater-Thermometer Nicolas Wainstein, Guy Ankonina, Shahar Kvatinsky and Eilam Yalon; Technion - Israel Institute of Technology, Israel

Phase-change materials (PCM) are technologically attractive materials for non-volatile memory, neuromorphic computing, optoelectronics, and recently, radiofrequency (RF) applications. Chalcogenide PCMs present a dissimilar resistance between the crystalline (low-resistivity) and amorphous phase (high-resistivity). The phase transition is thermally activated, and its kinetics can span orders of magnitude in time, down to sub-nanosecond timescale. Hence, proper probing of the thermal actuation is required to understand the fundamental material properties of PCMs, particularly the physics of melt-quench processes in nanoscale devices, interface vs. bulk effects, drift, and threshold voltage phenomena. Research efforts have been made to characterize PCM using a microthermal stage (MTS) [1]. The MTS structure used either a top Pt heater for the thermal actuation of a lateral Ge$_2$Sb$_2$Te$_5$ (GST) device or a Pt heater surrounding the GST. Thus, the MTS allowed for probing with thermal time scales on the order of microseconds or longer.

Four-terminal, in-line, indirectly heated phase-change switches (IPCS) have been proposed for high-performance RF applications, thanks to their state-of-the-art figure-of-merit (FOM)=$1/(2\pi R_{ON}C_{OFF})$ [2, 3]. A typical IPCS consists of two RF ports in-line with the PCM (i.e., the RF path), separated by a small gap, and two terminals for thermal actuation using an embedded heater. The heater runs transversely to the direction of the RF path, under the PCM. The heater and the RF path are separated by a thin electrically isolating film (e.g., Si$_3$N$_4$). GeTe has been so far the material of choice for RF applications due to its low resistivity in the crystalline phase and relatively large resistivity contrast with the amorphous state, but recently an Sb$_7$Te$_5$ IPCS was demonstrated with similar FOM and improved energy efficiency [3].

In this study, we report on the use of IPCS device structure as a platform for electro-thermal characterization of phase transition properties of PCM in nanoscale films at nanosecond temporal resolution. The isolation between the heater and the PCM layer electrically decouples the heating pulse and PCM probing. Thus, the phase transition, as well as temperature-dependent properties up to temperatures of $\sim$1100 K, can be measured during heating pulse application with ns resolution. Furthermore, since the heater is buried underneath the PCM, our setup allows for 1) steady-state PCM temperature validation using scanning thermal microscopy (SThM) from the top surface, 2) separation between contribution of contact (interface) and bulk effects by varying overlap and underlap between the heater and the PCM contacts, and 3) test different materials of interest without significant change in the fabrication process. We use GeTe as a prototype material with known melting temperature, crystallization kinetics, and surface treatment for low ohmic contacts [4]. Measurements are carried out using RF probes for the heater and the PCM to reduce the overshoot and ringing of short-pulses and produce clean waveforms for nanosecond probing. The experimental results are compared to a detailed finite element electro-thermal model to extract key material properties. Overall, our platform can be used to uncover the intriguing kinetics of crystallization and amorphization in chalcogenides and other amorphous semiconductors.

Uncovering β-Relaxations in Amorphous Phase-Change Materials Shuai Wei, Si-Xu Peng, Yudong Cheng, Julian

2020 MRS Virtual Spring/Fall Meeting, November 27-December 4, 2020, Spring Abstracts Final Program 2/3/21
Relaxation processes are decisive for many relevant physical properties of amorphous materials. For amorphous phase-change materials (PCMs) employed in non-volatile memories, relaxation processes are, however, difficult to characterize due to the lack of bulk samples. Here, instead of bulk samples, we use powder mechanical spectroscopy for powder samples to detect the prominent excess wings – a characteristic feature of β-relaxations – in a series of amorphous PCMs at temperatures below the glass transition. By contrast, β-relaxations are vanishingly small in amorphous chalcogenides of similar composition, which lack the characteristic features of phase-change materials. This conclusion is corroborated upon crossing the border from PCMs to non-PCMs, where β-relaxations drop significantly. Such a distinction implies that amorphous PCMs belong to a special kind of covalent glasses whose locally fast atomic motions are preserved even below the glass transitions. These findings also suggest a correlation between β-relaxation and crystallization kinetics of PCMs, which may have technological implications for phase-change memory functionalities.

6:15 AM S.EL09.04.05
Impact of High Electric Field on Resistance Drift in Amorphous Ge$_2$Sb$_2$Te$_5$ Phase Change Memory Line Cells at Low Temperatures ABM Hasan Talukder, Raihan Sayeed Khan, Helena Silva and Ali Gokirmak; University of Connecticut, United States

Phase change memory (PCM) technology utilizes the large resistivity contrast between the crystalline and amorphous phases of chalcogenide materials. However, the resistance of the amorphous phase deviates from its originally programmed value over time, which is commonly referred to as resistance drift. This resistance drift may lead to inaccurate read operations and thus poses a major challenge to the realization of multilevel cell (MLC) PCM.

We have performed electrical characterization of Ge$_2$Sb$_2$Te$_5$ (GST) line cells at low temperatures expecting to see very small or no drift since resistance drift has been understood to be caused by structural relaxation which is a thermally activated defect annihilation process [1]-[3]. However, we observed resistance drift at cryogenic temperatures with drift coefficients comparable to the room temperature value of ~0.1 [4]. Furthermore, we observed a significant acceleration in resistance drift with high electric field stress in 80 K - 200 K temperature range. Resistance of the cells stabilizes after the electrical stress allowing stable field and temperature-dependent electrical characterization.

These results suggest that charge traps and charge injection to these traps play a significant role in the resistance drift of amorphous phase change materials.

Effect of Optical Illumination on Resistance Drift in Ge$_2$Sb$_2$Te$_5$ Line Cells Raihan Sayeed Khan, Helena Silva and Ali Gokirmak; University of Connecticut, United States

The large resistivity contrast between the highly resistive amorphous phase and low resistive crystalline phase of phase change memory (PCM) provides opportunities for multi bit per cell memory and neuromorphic applications. However, the drift of resistance of amorphous phase limits the potential of PCM as multiple intermediate states can overlap over time. Although resistance drift is generally attributed to structural relaxation [1], we have observed significant resistance drift in Ge$_2$Sb$_2$Te$_5$ line cells at cryogenic temperatures and also being affected by optical illumination, indicating charge trapping [2]. A detailed understanding of the mechanisms behind resistance drift may allow for mitigating techniques. In this work, we
study the effect of optical illumination between 125 K and 300 K and also the effect of different optical illumination conditions on the drift coefficient.

Phase Change Memory from Fundamental Research to Industrial Development Zhitang Song; Chinese Academy of Sciences, China

Phase change random access memory (PCRAM) has been successfully applied in the computer storage architecture, as storage class memory, to bridge the performance gap between DRAM and Flash-based solid-state drive due to its good scalability, 3D-integration ability, fast operation speed and compatible with CMOS technology. A good understanding of phase change mechanism is of great help to design new phase change materials with fast operation speed, low power consumption and long-lifetime. In this presentation, we firstly review the development of PCRAM and different understandings on phase change mechanisms in recent years, and then propose a new view on the mechanism, which is based on the octahedral structure motifs and vacancies. Octahedral structure motifs are the based units during phase transition. Robust octahedra and plenty of vacancies in both amorphous and crystalline phase, respectively avoiding large atomic rearrangement and providing necessary space, are of crucial to achieve the nanosecond or even sub-nanosecond operation of PCRAM. Based on this mechanism, we introduce Sc-based robust octahedra in Sb$_2$Te$_3$ phase change materials, called Sc-Sb-Te, and achieve 700 ps operation speed. Recently, the concentration of dopants has also been optimized by correlative atom probe tomography and transmission electron microscopy investigations. Focusing on phase change materials and PCRAM for decades, we have successfully developed 128Mb embedded PCRAM chips, which can meet the requirements of most embedded systems.

5:15 AM *S.EL09.05.02
Amorphization and Crystallization of Ge Rich GeSbTe Thin Films for Embedded Memory Applications Stefania M. Privitera1, Corrado Bongiorno1, Veronique Sousa2, Gabriele Navarro2, Chiara Sabbione2, Marie Claire Cyrille2, Egidio Carria2 and Emanuele Rimini1; 1IMM-CNR, Italy; 2CEA-LETI, France; 3STMicroelectronics, Italy

GeSbTe alloys, widely employed for phase change non volatile memory, are usually not suitable in embedded and automotive applications, because of the low crystallization temperature. Doping, in particular with Ge, has been shown to be a viable way to extend the thermal stability of GeSbTe alloys [1,2]. However, once an optimised composition has been selected, during device operation, the material stoichiometry may change, due to the atomic migration induced by the high temperature and/or by the electric field [3]. These variations may lead to programming and retention performance degradation or even to device failure. It is therefore crucial to understand the extent of the atomic migration and its impact on the stoichiometry, as well as on the crystallization properties. In order to decouple the effect of the atomic diffusion at high temperature from that of the field induced electromigration, we have irradiated crystalline Ge rich GeSbTe thin films by laser. The films were prepared by sputter deposition in the amorphous phase, and then converted into the crystalline structure by annealing at 400°C. The irradiation has been performed by using a Yb-YAG laser (515 nm) with 600 ns pulse, operating at different energy densities. By changing the energy density, complete or partial melting and quenching, with amorphization of the film, can be achieved. In this way we are able to study the thermal diffusion processes decoupled from the field induced electromigration. After melting and quenching, the atomic elements distribution has been studied by Transmission Electron Microscopy (TEM) and Electron Energy Loss Spectroscopy (EELS). We find that, even without the electric field, the melting give rises to a prominent diffusion of Ge atoms. By employing finite elements computational analysis, a diffusion coefficient of Ge on the order of 5x10$^{-5}$ cm$^2$ s$^{-1}$ in the molten phase has been estimated.
After amorphization under different irradiation conditions, we have followed the crystallization upon thermal annealing by in-situ time resolved reflectivity measurement. Such a crystallization process, after the first melting and quenching, is expected to be different from the crystallization of the as deposited amorphous film, since the melting produces not only sub-critical crystalline nuclei, but also a modification of the stoichiometry. The study of the crystallization in such a “primed” material is very similar to the situation occurring in a real memory device after the first erasing step and therefore it is relevant for reliability evaluations.

5:30 AM S.EL09.05.03
Thermal Properties of Carbon Nitride Toward Use as an Electrode in Phase Change Memory Devices Kiumars Aryana1, John Gaskins1, Joycea Nag2, John Read2, David Olson1, Michael Grobis2 and Patrick E. Hopkins1; 1University of Virginia, United States; 2Western Digital Corporation, United States

In phase change memory cells, the majority of heat is lost through the electrodes during the programming process that leads to significant drops in the performance of the memory device. In this investigation, we report on the thermal properties of thin film carbon nitride with modest electrical resistivity of 5-10 mW cm, low thermal conductivity of 1.47W/m/K, and low interfacial thermal conductance between carbon nitride and phase change material for lengths less than 40 nm. The thermally insulating property of carbon nitride makes it a suitable thermal barrier, allowing for less heat loss during Joule heating within the memory unit. We compare carbon nitride thermal properties against commonly used electrodes and insulators such as tungsten and silicon nitride, respectively, to demonstrate the promise of carbon nitride as a potential material candidate for electrode applications in phase change memory devices.

5:45 AM S.EL09.05.04
The Effect of Metal Reactivity on Critical Interfaces in GeTe-Based Devices Kayla A. Cooley and Suzanne E. Mohney; The Pennsylvania State University, United States

Phase change materials (PCMs) are well-known for their crystalline-to-amorphous transitions that are both quick and reversible, offering a large contrast in electrical and optical properties of the two phases. Responsible for enabling the development of rewritable CD and DVD technology, this class of materials has greatly contributed to the development of modern data storage, entertainment, and computing; and due to so many contributions, research continues to point to applications in which chalcogenide PCMs provide novel solid-state devices. One such PCM, Germanium Telluride (GeTe), has been the focus of numerous studies to develop next generation non-volatile memory cells, photonic devices, and radio frequency (RF) switches.

The geometry of GeTe-based devices for radio frequency switches and non-volatile memory technologies often places GeTe thin films in contact with metal thin films. Despite the potential effect of metal/GeTe reactions on device performance, few studies have addressed the reactivity between elemental metals and GeTe or systematically approached the thermal stability of GeTe with metals. In response to this need, reactivity was determined by calculating ternary phase diagrams of metal-Ge-Te systems and performing transmission electron microscopy (TEM) both after metal deposition and after the samples were annealed for 12 h at 200 °C. GeTe is thermodynamically favored to react with many metals at room temperature. Nine of the 24 studied metals are not reactive with GeTe (Au, Ir, Mo, Os, Re, Ru, Ta, W, and Zn), while 15 metals have a thermodynamic driving force to react with GeTe at room temperature (Ag, Al, Cd, Co, Cu, Fe, Hf, Mn, Ni, Pd, Pt, Rh, Sc, Ti, and Y). Most of the unreactive metals, except Au and Zn, are not in thermodynamic equilibrium with GeTe at room temperature. These metals are refractory, and the lack of reactivity is ascribed to kinetic limitations.

Solid-state reactions between contact metals and GeTe produce an unexpected trend between metal work function and metal/GeTe contact resistance ($R_c$), which is actually the opposite to what is projected by the well-known Schottky-Mott Law. For a $p$-type semiconductor like GeTe, high work function metals, like Ni and Pt, would be expected to provide the lowest $R_c$ values. However, comparing all contact metals (Au, Ni, Mo, Sn, Ti, Pt, and Cr), Mo-based contacts (with a work function of only 4.60 eV) offered the lowest contact resistance. From cross-sectional TEM analysis, only Au- and Mo-based contacts did not react with GeTe. Thus, the work function of the contact metal of the reactive contacts is no longer the deciding factor in setting $R_c$, and we explore explanations for this trend in our ongoing work.
In order to model phase change memory (PCM) cells, dynamic materials models have to be coupled with charge and heat transport models [1]-[7]. Since PCM cells experience high temperatures, very large thermal gradients (~ 50 K/nm) and high current densities during their normal reset and set operations, thermoelectric contributions are significant for both charge and heat transport in these cells. Furthermore, some of the assumptions made for large scale thermoelectric devices do not hold under these extreme conditions.

Charge transport in PCM cells can be modeled using a drift-diffusion approximation. However, electronic material properties such as carrier concentrations, mobilities and diffusivities are not well characterized for phase change materials. In this study, we construct (i) a drift-diffusion model using thermoelectric characteristics of the material, measured in a large temperature range, and (ii) an electrothermal heat transport model that does not assume mild temperature gradients only. Our simulation results show that both Thomson heat (thermoelectric effects in the bulk materials) and Peltier heat (thermoelectric effects at the contact regions) play a significant role, and give rise to significantly asymmetric thermal profiles in symmetric PCM cells.

Acknowledgments: This work is partially supported by NSF under award DMR-1710468.

Contact Resistance Measurements of GST 225 to TiN Bottom Electrode
Guy M. Cohen and Amlan Majumdar; IBM T.J. Watson Research Center, United States

The contact resistance between TiN and GST 225 was measured using the transfer length method (TLM) and the end resistance method for the crystalline and amorphous phases of GST 225. We found a 3000x increase in contact resistance when GST 225 over the TiN electrodes changed from crystalline to amorphous. When considering common phase change material (PCM) memory cell geometries, our measurements suggests that the contact resistance is a large component of the change in the resistance when the device is switched between the crystalline and the amorphous phases. In other words, the increase of the device resistance when the device is reset is substantially due to the increase in the contact resistance and not solely due the change in the bulk resistance of the PCM.

Combinatorial Exploration of Phase Change Memory Materials with Enhanced Properties
Heshan Yu¹, Changming Wu², Xiaohang Zhang³, Apurva Mehta³, Ritesh Agarwal⁴, Mo Li⁵, Gilad Kuson⁵ and Ichiro Takeuchi¹; ¹University of Maryland, United States; ²University of Washington, United States; ³Stanford Synchrotron Radiation Lightsource, SLAC National Accelerator Laboratory, United States; ⁴University of Pennsylvania, United States; ⁵National Institute of Standards and Technology, United States

As one of the most promising candidates for developing new neuromorphic architectures for non-von Neumann computing and information storage, Ge₂Sb₂Te₅(GST225) in photonic devices shows non-volatile, fast, and multi-step changes between
the amorphous state and the meta-stable states. In order to search for other composition ratios with desired properties, e.g. large figure of merit, lower switching energy, etc., we have systematically investigated a broad composition range of the Ge-Sb-Te (GST) system. The GST combinatorial spread was fabricated by co-sputtering Ge, Sb and Te targets and was confirmed by wavelength dispersive spectroscopy that the composition variation across the Si wafer covers most part of the GST phase diagram. X-ray diffraction measurements (synchrotron radiation), Raman spectroscopy and resistance mapping clearly show evolution of the structure and phase-change temperature in the GST system. Refractive index and extinction coefficient were calculated at each composition spot using a scanning ellipsometer: some composition ratios were found to have a small extinction coefficient in the amorphous state, a high phase-change temperature, and a large figure of merit. Then, the nano-size photonic devices fabricated by these ratios were measured and showed good reversibility (more than 40000 cycles) and multi-level symmetric switching (at least 15 levels), suggesting that such compositions can be promising for photonic devices for neuromorphic control. Further, we confirm that compositions with promising properties are near the boundary between the Sb-Te and the Ge-Sb-Te phases, indicating that co-existence of the phases at microstructural level may be playing a role in giving rise to their properties. This work is funded by an ONR MURI (Award No. N00014-17-1-2661).

6:45 AM S.EL.09.05.09
Cw Laser Annealing Induces Stress Field During Phases Transition in GeSbTe Layer Giuseppe D’Arrigo1, Mario Scuderi1, Antonio M. Mio1, Gregory Favaro2, Antonella Sciuto1, Marzia Buscema1, Alessandro Meli1, Giovanni Li Destri3, Egidio Carria4, Domenico Mello5, Michele Calabretta4, Alessandro Sitta4, Julian Pries5, Matthias Wuttig5 and Emanuele Scuderi1; 1CNR-IMM, Italy; 2Anton Paar USA Inc., Switzerland; 3Università di Catania, Italy; 4STMicroelectronics, Italy; 5RWTH Aachen University, Germany

The mechanical properties, Hardness and Young module, of crystalline micrometer stripes of Ge:Sb:Te and of the surrounding 2.2 µm thick amorphous film have been measured simultaneously. Crystallization was performed by a Continuous Wave laser irradiation process in the range 1.25-3.2 mW. The density changes between the amorphous and the crystalline phase causes a relevant stress in the processed material. Usually the stress is measured by the wafer curvature. This methodology doesn’t allow a detailed investigation of the local mechanical modifications when the two phases amorphous and crystalline are contiguous, as in an optical or electrical storage device. The use of micrometer patterned structures and nano-indentation measurements allow us to determine the mechanical behavior of the two contiguous GST phases. The measured values of the mechanical property are more dispersed for the crystallized material than those for the contiguous amorphous phase. The Young module and the hardness are 51±8 GPa and 2880±450 MPa for the crystallized and 33±4 GPa and 1989±300 MPa for the amorphous phase respectively. Microcracks are also seen, together with fracture lines. The occurrence of delamination at laser power densities above 1.70 mW indicates that for these crystallized thicknesses the maximum tensile strength in the amorphous and crystalline phases was reached and exceeded. The phase transition has also been investigated by several analytical tools (TEM, SEM, Raman and XRD diffraction). A simulation code was adopted to compute the temperature-time-space profile as a function of the laser power. These results were used to compare the measured crystallized thickness to that calculated.

7:00 AM S.EL.09.05.10
Metal Incorporation in Germanium Telluride—A First Principles Study with Experimental Observations Kayla A. Cooley1, Nathan Kelibart1, James G. Champlain2, Laura B. Ruppalt2, Ismaila Dabo1 and Suzanne E. Mohney1; 1The Pennsylvania State University, United States; 2US Naval Research Laboratory, United States

Intentionally introducing impurity atoms into a semiconductor has been a common method for modifying material properties that are critical to many electronic and optoelectronic devices. For GeTe, a phase change material (PCM), there has been interest in using metal incorporation for this approach to materials engineering. GeTe thin films doped and/or alloyed with metals have been reported to exhibit improved device performance, like improved crystallization speed, thermal stability, and power consumption. However, these films have often been fabricated using non-equilibrium methods with high metal concentrations (>10 at. %). Since switching between the low-resistance crystalline and high-resistance amorphous states requires a heating cycle, the stability of metal-incorporated GeTe (GeTe:metal) films is critical to practical implementation of these materials in electronic devices. Understanding the effect of metal-incorporation in GeTe films provides valuable insights for engineering future PCM devices, both in terms of doping and discovery of ternary PCMs.

In this work, we present first principles calculations concerning the stability of GeTe doped with select metals (Cu, Fe, Mn, Mo, and Ti), as well as the effect of increasing dopant atom concentration (2-6 at.%) on the crystal structure and electronic properties of GeTe. From density-functional theory calculations of the formation energy of the ternary solid (GeTe doped with 2-6 at. % of Cu2+, Fe2+, Mn2+, Mo2+, and Ti2+), all metals favored substitution into the Ge site over the Te site. The formation energy of the GeTe:metal structure increases (or becomes less stable) with increasing metal incorporation for all
metals except Mn. Certain metals (Ti, Mo) clearly favor dopant atom clustering. In addition, different metal dopants have a varied distortion of the GeTe crystal structure and projected density of states. Computational results are compared to observed solubility trends in cross-sectional transmission electron microscopy (TEM) studies of metal/GeTe thin film systems (Cu, Mn, Mo, and Ti)\(^1\) and TEM, spectroscopic ellipsometry, and transport data from newly characterized co-sputtered GeTe:Fe films.

**Materials Gene Exploration and Modification for Phase-Change Memory Glass** Ming Xu and Xiangshui Miao; Huanzhong University of Science and Technology, China

Phase-change memory is the most promising candidate for the next generation memory technology. It utilizes the large property contrast between the amorphous and crystalline phases of phase change materials (PCMs), which switches to each other within nanoseconds. In the past decades, a lot of efforts have been devoted to explore how the structure defines the particular properties of PCMs, and it is discovered that the structure of the amorphous phase plays the key role in this case. For example, the fragility of the glass determines the crystallization speed (the programming speed in memory); the glass aging results in the resistance drift in the devices; the stability of the glass (data retention) is determined by the covalent bonds in this material. Since the amorphous phase is absent of long-range order and defects such as dislocation and grain boundary, the physical properties are usually determined by the short- and medium-range orders, and hence we call it the materials “gene” of glass.

We discovered in the our research that the local structure of PCMs could be described as “octahedral motifs”, which can be easily modified by adding different dopants. For example, the carbon, which forms tetrahedral clusters, can increases the stability of the glass to elongate the life of memory devices; the addition of Yi and Sc stabilizes the nuclei in the glass, remarkably accelerating the crystallization speed. The discovery of new PCMs enabled by the Materials Genome Engineering paves the way for the design of high-density phase change memory.

**7:30 AM S.EL09.05.12***

**Electron Beam Driven Phase Transitions in Phase-Change Materials and Phase Change Heterostructure** Jiangjing Wang\(^1\), Chun-Lin Jia\(^1,2\) and Wei Zhang\(^1\); Xi'an Jiaotong University, China; \(^2\)Forschungszentrum Jülich GmbH, Germany

Fast and reversible phase transitions in chalcogenide phase-change materials (PCMs), in particular, Ge-Sb-Te compounds, are not only of fundamental interests but also make PCMs based random access memory a leading candidate for nonvolatile memory, and even neuromorphic computing devices. For instance, a recently designed phase-change heterostructure (PCH), which consists of alternately stacked phase-change and confinement nanolayers to suppress the noise and drift, has attracted increasing attention. However, to RESET the memory cell, crystalline PCMs has to undergo phase transitions first to a liquid state and then to an amorphous state, corresponding to an abrupt change in electrical resistance. In this work, we demonstrate a progressive amorphization process in GeSb2Te4 thin films under electron beam irradiation on a transmission electron microscope (TEM). Melting is shown to be completely absent by the in situ TEM experiments. The progressive amorphization process resembles closely the cumulative crystallization process that accompanies a continuous change in electrical resistance. The same nonthermal amorphization process was also verified in the phase-change nanolayers of PCH. The displacement forces induced by knock-on collision effect of E-beams drives this nonthermal amorphization process, thus our work suggests that if displacement forces can be implemented properly, it should be possible to emulate symmetric neuronal dynamics by using PCMs.

**Electronic Properties of Phase Change Compounds in the Liquid State—Effective Charges for Electromigration and Semiconductor-Metal Transition from First Principles** Matteo Cobelli\(^1\), Mario Galante\(^2\), Daniele Dragoni\(^1\), Stefano Sanvito\(^2\) and Marco Bernasconi\(^2\); \(^1\)Università di Milano-Bicocca, Italy; \(^2\)Trinity College, Ireland

In the reset process of phase change memories, the active material is brought rapidly above the melting temperature by Joule heating. Atomic migration in the liquid state due to the high electric field can lead to alloy demixing and eventually to device failure. The electromigration force \(F\) responsible for ionic migration is proportional to the electric field via the effective charge \(Z^*\) (\(F = Z^* E\)). Information on the effective charges is thus of great relevance for the electrothermal modeling of the device. However, experimental estimates of the effective charges in the liquid state suffer from large uncertainties. A possible
route to estimate $Z^*$ relies, in fact, on the modeling of the concentration profile of the different species in highly cycled memory cells which, however, depends on several mostly unknown parameters that have to be plug into phenomenological transport equations [1].

In this work, we show that a direct first principles calculation of the effective charges in metallic liquids is possible by computing the atomic forces in the presence of both an electric field and an electronic current within the Non-Equilibrium Green Function scheme implemented in the code Smeagol [2]. We will present results on the calculation of the effective charges, including the wind force, for the GeTe and Sb$_2$Te$_3$ phase change compounds in the liquid state.

Another feature of the liquid state that affects device operations is the opening of an electronic gap upon cooling from the melting point to the glass transition temperature during reset. The temperature at which the metallic liquid turns into a semiconductor is another important parameter for the electrothermal modeling of the device. By means of density functional molecular dynamics and the use of a hybrid exchange and correlation functional, we have estimated the temperature of gap opening in the supercooled liquid phase of GeTe and Ge$_2$Sb$_2$Te$_5$ compounds.

In Situ Study of Vacancy Disordering in Crystalline Phase-Change Materials under Electron Beam Irradiation
Xudong Wang$^1$, Tingting Jiang$^1$, Jiangjing Wang$^1$ and Wei Zhang$^{1,2}$, $^1$Center for Advancing Materials Performance from the Nanoscale, State Key Laboratory for Mechanical Behavior of Materials, Xi’an Jiaotong University, China; $^2$Xi’an Jiaotong University Suzhou Institute, China

Fast and reversible phase transitions in chalcogenide phase-change materials (PCMs) play a key role in next-generation memory and computing chips. The Ge-Sb-Te compounds, such as Ge$_2$Sb$_2$Te$_5$ and GeSb$_2$Te$_4$, are under active investigations, not only because they serve as the key element in commercial products, but also because they provide a rich platform for fundamental research in materials science.

Disorder-driven metal insulator transition has been reported in crystalline Ge-Sb-Te phase-change materials (PCMs), where the high concentration and statistical distribution of atomic vacancies were identified as the key factor in shaping the localization properties of electrons and, thus, the electrical transport. Vacancy ordering has been consistently observed in crystalline Ge-Sb-Te thin films upon thermal annealing, triggering a structural transition from a cubic rocksalt structure to a layered hexagonal structure and an insulating to metallic transition.

In this work, we demonstrate an opposite vacancy disordering process upon extensive electron beam irradiation, which drives the reverse transition from the stable hexagonal phase to the metastable cubic phase. The combined in situ transmission electron microscopy experiments and density functional theory nudged elastic band calculations reveal three transition stages, including I) the vacancy diffusion in the hexagonal phase, II) the change in atomic stacking, and III) the vanishing of vacancy-rich planes. The driving force of the vacancy disordering process is attributed to the kinetic knock-on collision effects of the high-energy focused electron beams, which prevail over the heating effects.

Our electron irradiation experiment not only provides an alternative approach to tune the vacancy distribution that is crucial for the disorder-driven metal-insulator transition of GST crystals, but also makes an instruction for the TEM measurement of structural details of a particular solid-state phase of PCMs that the three critical TEM parameters, namely, accelerating voltage, beam intensity and recording time, should be reduced as much as possible to avoid structural transitions during the measurement.
Reconfigurable Infrared Flat Optics with Novel Phase Change Materials Christopher M. Roberts¹, Yifei Zhang², Mikhail Shalagainov², Paul Robinson¹, Paul Miller¹, Kevin Tibbetts¹, Sean Gorsky¹, Vladimir Liberman¹, Carlos A. Rios Ocampo², Tian Gu², Myungkoo Kang³, Anupama Yadav³, Kathleen Richardson³, Juejun Hu² and Jeffrey Chou¹; ¹MIT Lincoln Laboratory, United States; ²Massachusetts Institute of Technology, United States; ³University of Central Florida, United States

Previously, we have reported on a novel class of chalcogenide phase change materials, based on Ge-Sb-Se-Te (GSST) alloys, with excellent infrared transparency from 1.5 to > 15 micron wavelengths. Increasing Se substitution leads to a progressive lowering of extinction coefficient. A material in this family with a particular useful stoichiometry, Ge₂Sb₂Se₄Te₁ (GSS₄T₁), possesses broadband transparency through the infrared range while maintaining a large index contrast between its amorphous and crystalline phases. Defining a figure of merit as Δn/k (where n,k are the real, imaginary parts of the refractive index), our materials shows >100x figure of merit (FOM) improvement over conventional GST throughout the infrared range.

In this talk, we describe novel applications enabled by reversible switching of low loss GSS₄T₁ material. In the first application, we exploit the exceptional FOM of the Se-doped PCM to realize a nonvolatile photonic switch with unprecedented high performance. Our device, based on a racetrack SiN resonator with a PCM gate, exhibits a large switching contrast ratio of 42 dB and a low insertion loss of < 0.5 dB, far outperforming previous nonvolatile switches as well as devices based on the classical GST-225 material with a similar configuration.

Additional novel applications are enabled by our development of wafer-scale pixelated electrical switchable PCM devices. The pixelated devices are fabricated in a CMOS-compatible clean room on 8 inch wafers utilizing a full Si-based fabrication tool set. Devices of various pixel sizes, from 1 to 30 micron have been fabricated. Additionally, fabrication of more complicated sub-pixel metasurfaces was demonstrated. Electrical switching measurement is obtained by applying electrical pulse trains through a programmable voltage generator into the gate of a high powered transistor. Microsecond switching of 30-micron and 1-micron pixels in a wafer-scale device has been demonstrated. Current devices have demonstrated over 1,000 switching cycles and further durability improvements are underway.

As an application of pixelated electrical device, we have demonstrated a concept of compact infrared reflection spectrometer with no moving parts. Here, we leverage the ability to obtain gradually changing reflection signature of the pixel with voltage between fully-converted crystalline and amorphous phases. This wavelength shift is essentially a nonlinear filter which can be used to reconstruct an input spectrum. Since the reflection response of the pixel states is pre-determined, a spectral response of the scene can be extracted once the pixel spectrum is fully characterized with a known calibrated spectral source. We have carried out such characterization utilizing a supercontinuum laser in the short-wave infrared part of the spectrum and the results of spectral signature extraction for three different incident spectral scenarios.

Effects of Spatial Confinement on Phase-Change Materials Ann-Katrin U. Michel and David J. Norris; ETH Zürich, Switzerland

Phase-change materials (PCMs) allow for an ultrafast and reversible transition between their amorphous (a) and crystalline (c) state. This structural transition results in a pronounced change in their optical and electrical properties. The strong resistivity contrast of several orders of magnitude has been employed in electronic and neuromorphic memories, while the unity-scale refractive index change Δn = |n_c - n_a| has been applied in rewriteable optical-data-storage memories. Additionally, Δn is the subject of research in various photonic applications.¹ For tunable photonics, PCMs are very desirable, but expensive and laborious to produce. Thus, colloidal PCMs that can be easily synthesized could provide broader access to this material class and allow for deposition on a variety of substrates, including prepatterned holes and vertical interconnect accesses. However, due to the size reduction from GeTe thin films to small nanoparticles (NPs), new effects can arise. Examples are the occurrence of localized surface plasmon resonances in c-GeTe NPs,² and size dependence of the crystallization temperature T_c.³ Thickness dependent temperature scaling was also reported for very thin sputtered PCM films, and related to their bonding characteristics.⁴ Recent results indicate that the
spatial confinement of PCMs into small NPs results in an increase of the optical band gap $E_g$, while maintaining the pronounced contrast between the band gaps for a- and c-PCMs $E_{ga}$ and $E_{gc}$ respectively. 

Insights into small-size PCM NPs can promote the application of these materials in different fields, and add value to fundamental scientific questions, especially regarding the current debate on the unique chemical bonding in PCMs. Despite the bottom-up synthesis of PCM NPs, structural confinement can be realized by sub-wavelength patterning. While laser pulses do not allow for switching on such small length scales, tip-induced crystallization can lead to features below 100 nm. The resulting so-called metasurfaces feature extremely strong field confinement and nearly $2\pi$ phase shift.

Terahertz Spectroscopic Studies in Ge-Sb-Te Phase Change Materials Kotaro Makino; National Institute of Advanced Industrial Science and Technology, Japan

Phase change materials including Ge-Sb-Te (GST) alloys provide useful changes in the electronic and optical properties thanks to the reversible a structural phase transition between amorphous and crystalline phases. The phase change materials have been used for commercially-available optical and electrical memory technologies by exploiting the phase change property. In this context, GST is expected to be utilized also for terahertz (THz) wave engineering since the frequency of THz wave ranges between infrared light and radio wave. So far, we revealed that a THz pulse excitation is capable of structural control through unique nonlinear field-induced phenomena [1,2]. In addition, we performed a THz emission spectroscopy as well as a THz time-domain spectroscopy and found that these spectroscopic measurements can be used for evaluation of the film quality and electronic characteristics of the GST. Based on the result of THz time-domain spectroscopy, we propose that the reversible and nonvolatile changes in the THz properties of GST are promising for a variety of applications e.g. THz photonics and THz amplitude modulator [3].

Exploiting Phase Change Materials and Multi-Objective Optimization for Reconfigurable Multi-Functional Meta-Optics Sawyer D. Campbell, Yuahao Wu, Eric B. Whiting, Lei Kang, Pingjuan L. Werner and Douglas Werner; The Pennsylvania State University, United States

Phase change materials (PCMs) are an extremely attractive material platform for the realization of multi-functional and reconfigurable meta-optics. For example, PCMs can be exploited to synthesize metasurfaces and metamaterials to enable a variety of tunable devices such as beam-steerers, optical shutters, spectral filters, and adaptive focal length lenses [1]-[5]. However, the expanded degrees of design freedom that PCMs offer can make direct device design intractable for all but the most experienced engineers. This challenge is best overcome through the use of advanced inverse-design tools and state-of-the-art optimization algorithms. To this end, a number of successful meta-device inverse-design approaches have been demonstrated in the literature including those based on topology optimization, deep learning, and global optimization [6]. While each method has its pros and cons, one method stands out as an ideal candidate for reconfigurable meta-optic design: multi-objective optimization. In contrast to ubiquitous single-objective optimization algorithms, which require users to combine multiple goals into a single cost function usually via a weighted sum, true multi-objective optimization (MOO) algorithms allow designers to minimize multiple competing objectives simultaneously without the need for a priori information on how best to weight a single cost function [7], [8]. Thus, MOO algorithms are perfectly suited for reconfigurable meta-optic design as each independent functionality can be assigned a unique cost function and optimized. Moreover, MOO algorithms provide the user with a collection of designs called the Pareto set that can be analyzed to determine the inherent tradeoffs between competing design objectives. In our presentation, we will introduce an efficient multi-objective optimization enabled design framework for the generation of multi-functional unit cells based on phase
change materials. Additionally, several reconfigurable meta-optic design examples will be presented, and future research directions discussed.

All-Dielectric Varifocal Metalens for Aberration-Free Imaging

Mikhail Shalaginov1, Yifei Zhang1, Sensong An2, Myungkoo Kang1, Kathleen Richardson3, Hualiang Zhang2, Tian Gu1 and Juejun Hu1; 1Massachusetts Institute of Technology, United States; 2University of Massachusetts Lowell, United States; 3University of Central Florida, Orlando, United States

We present our results on design, fabrication and characterization of a tunable metalens based on optical phase change materials (O-PCMs). We first introduce a phase change meta-atom design concept enabling switching of metasurface devices between two arbitrary optical states. We then implement this principle to demonstrate a bifocal switchable metalens made of the low-loss non-volatile O-PCM Ge2Sb2Se4Te1 (GSST). The metalens can achieve large change in focal length, from 1.5 mm to 2 mm, which is caused by drastic change in meta-atoms refractive index. Additionally, the metalens exhibits focusing efficiencies above 20% in both amorphous and crystalline states. We further experimentally demonstrated aberration-free imaging using the lens and achieved diffraction-limited resolution in both states. This result represents the first experimental demonstration of a non-mechanical active metalens with diffraction-limited imaging capability.

Electrically Tunable Dielectric Metasurfaces Enabled by Optical Phase Change Materials

Yifei Zhang1, Junhao Liang1, Mikhail Shalaginov1, Bilal Azhar1, Jeffrey Chou2, Christopher M. Roberts2, Skylar Deckoff-Jones2, Clayton Fowler2, Carlos A. Rios Ocampo1, Sensong An1, Claudia Gonçalves1, Kathleen Richardson4, Hualiang Zhang2, Tian Gu1 and Juejun Hu1; 1Massachusetts Institute of Technology, United States; 2Lincoln Laboratory, Massachusetts Institute of Technology, United States; 3The University of Massachusetts Lowell, United States; 4University of Central Florida, Orlando, United States

The nonvolatile reconfiguration capability of optical phase change materials (O-PCMs) makes them highly attractive for tunable dielectric metasurfaces. However, conventional switching methods based on either laser pulsing or electrical-current triggered transition require raster-scanned writing and dedicated off-chip switching instruments, therefore incompatible with large-scale integration. Here we report the design, fabrication and characterization of a scalable electrical switching platform for tunable dielectric metasurfaces based on O-PCMs.

We first introduce Ge2Sb2Se4Te1 (GSST), a novel O-PCMs we developed recently that is specifically targeted for high-performance photonic applications. We demonstrate that GSST exhibits low-loss at both phases over a broad wavelength range, while still possessing a huge optical contrast ($\Delta n = 1.7$). Its improved amorphous phase stability also gives rise to a larger critical thickness for complete switching. Comparing to a critical thickness of only 100 nm or less for traditional PCMs such as Ge2Sb2Te5, GSST is a preferred material for providing desired phase coverage for metasurface applications. Geometrically optimized on-chip micro-heaters are implemented to achieve uniform temperature distribution within the metasurface region. This eliminates damage to the metasurface due to overheating. Devices of various heater dimensions, from 30 to 200 microns, have been fabricated. The fabricated devices are wire-bonded onto a custom printed circuit board.
carrier to enable *in-situ* device characterizations. We then implement the switching platform to demonstrate a tunable metasurface spectral filter. Multi-cycle bi-stable reversible switching is realized. Thanks to the huge optical contrast of GSST, the device provides a high reflectance modulation of 40%. In addition to bi-stable switching, broadband quasi-continuous resonance tuning over half an octave is also demonstrated. This is accomplished through controlling the fraction of crystallization of O-PCMs by varying pulse parameters.

We further demonstrate a nonvolatile beam deflection control method with a tunable metasurface reflectarray. The fabricated device deflects incident laser beam from +1 to 0 diffraction order upon phase transition, and it exhibits significant switching contrast between its two phases.

This result presents, to the best of our knowledge, the first experimental demonstration of a scalable switching platform for dielectric metasurfaces based on O-PCMs. We further demonstrate functional metasurface devices with bistable and quasi-continuous tuning capabilities. We believe that this platform will facilitate the development of numerous emerging applications capitalizing on its scalability and nonvolatile nature.

**S.EL09.07.01 Comparison between Silicon and Silicon Nitride Platform for Nonvolatile Phase Change Photonic In-Memory Computing**

Xuan Li¹, Nathan Youngblood², Zengguang Cheng¹ and Harish Bhaskaran¹; ¹University of Oxford, United Kingdom; ²University of Pittsburgh, United States

Demands for applying silicon photonics to high-performance computing systems have grown significantly in recent years due to the breakdown of Dennard scaling and information transfer bottlenecks in the conventional von Neumann architecture. Data processing on photonic platforms is a promising approach because of the potential advantages over electrical approaches where large bandwidth, high efficiency, ultrafast modulation speed, and low crosstalk are crucial. Critical photonic components, such as lasers, modulators, switches, filters, multiplexers, photodetectors, and memory cells, have been developed on different material platforms, such as silicon nitride (SiN), GeSi, III-V semiconductors, and others, with silicon on insulator (SOI) being the dominant platform. Owing to its compatibility with mature CMOS processes and integration with electrical devices, fabless and large scale silicon photonic integrated circuits (PICs) are available and thus offer a promising route to future commercialization.

Recently fully integrated photonic memory devices have been demonstrated on silicon nitride and silicon. This approach not only enables photonic data storage on-chip, but also shows multilevel storage, improved SNR, and reduced switching energy over available optical storage technology. Previous work on silicon nitride waveguides demonstrated both multilevel storage (> 32 levels) and computation in a fully optical framework. This was despite the fact that silicon nitride does not benefit from a high refractive index contrast (~2/1.5 in Si3N4/SiO2 vs 3.5/1.5 in Si/SiO2) or the ability to integrate active photonics (such as modulators and photodetectors) directly in the waveguide. Silicon-On-Insulator (SOI), on the other hand, has both these advantages, leading to smaller footprint devices and easy integration with high-speed, CMOS-based electronics. In spite of rapid advances of demonstrations in this field on both silicon and silicon nitride platforms, a clear pathway towards choosing between the two has been lacking.

Here, we systematically evaluate and compare the computation performance of phase change photonics on a silicon platform and a silicon nitride platform. Our experimental results show that whilst Silicon platforms are superior to Silicon Nitride in terms of potential for integration, modulation speed, and device footprint, it requires trade-offs in terms of energy efficiency.
We then successfully demonstrate single-pulse modulation using phase-change optical memory (PCOM) on silicon photonic waveguides and demonstrate efficient programming, memory retention, and readout of > 4 bits of data per cell. This decreased the device footprint compared with silicon nitride photonics and reduced both the energy and time required for reaching arbitrary memory levels. We have characterized the reliability of this approach and outlined a comparison with other state-of-the-art programming methods. The use of silicon demonstrates a major step toward making phase-change photonic memory a viable and integrable technology. Our results have potential applications like deep learning based on vector-matrix multiplication and neuromorphic computing. Our approach paves the way for the in-memory computing on the silicon photonic platform.

S.EL09.07.03
TEM and EDX Analyses of Thermally Improved Phase-Change Memory by Optimized Encapsulation Layer Gauthier Lefèvre1, Anna-Lisa Serra2, Olga Cueto2, Niccolo Castellani2, Guillaume Bourgeois2, Nicolas Bernier2, Marie Claire Cyrille2, Mathieu Bernard2, Virginie Beugin2, Christophe Vallée1, Sylvain David1, Christelle Charpin2, Etienne Nowak2 and Gabriele Navarro2; 1LTM-CNRS, France; 2CEA-LETI, France

Phase-Change Memory (PCM) is a promising candidate for next generation of non-volatile memory [1]. PCM operations rely on the reversible phase transition between the amorphous and the crystalline phase, which occurs upon current-induced joule heating. Therefore, the reliability of the programming operation depends also on the thermal efficiency of the device [2]. Heat retention is thus essential in PCM and in complete contradiction with usual conception of electronic devices where thermal dissipation is a key point.

In this context, optimized thermal encapsulation in Ge-rich Ge-Sb-Te based PCM devices enables programming current reduction and improved data retention [3]. Indeed, an SiC encapsulation layer provides a more uniform heating of the active volume of the PCM cell, with respect to a standard SiN layer. Thanks to TEM and EDX analyses performed on state-of-the-art PCM heater-based devices, we demonstrate the higher uniformity of the heating process in the PCM cell during the programming operation achieved by optimized SiC encapsulation. Moreover, nano-diffraction patterns analysis highlights the crystalline morphology of the programmed active volume and of the surrounding material. Finally, we show the agreement between experimental data and TCAD simulations.

S.EL09.07.04
Structural Transitions and Switching Effect in Nanoscaled Ge2Sb2Te5 Films Modified by Bismuth Impurity Nurlan Almassov1, Andrei Sazonov2, Sanzhar Dyussembayev3, Oleg Prikhodko4, Nazim Guseinov4, Zhandos Tolepov4 and Sergei Kozukhin2; 1Nazarbayev University, Kazakhstan; 2University of Waterloo, Canada; 3University of Waterloo, Canada; 4Kazatomprom, Kazakhstan; 5Al-Farabi Kazakh National University, Kazakhstan; 6Kurnakov Institute of General and Inorganic Chemistry, Russian Academy of Sciences, Russian Federation

The design of non-volatile memory cells based on phase change materials (PCM) is the subject of many studies. And one of the most promising materials are the films of Ge2Sb2Te5 chalcogenide glassy semiconductor (CGS). The operation of memory cell is based on a reversible glass-crystal phase transition, which occurs when a current pulse passes through the film's nano-volume. The embedding of metal impurity in the films can improve the property of memory cells. However, the features of phase transition in the metal-modified Ge2Sb2Te5 films are poorly understood. This work presents the results of the study of the structure observed in nanoscale films of Ge2Sb2Te5 modified by Bi (Ge2Sb2Te5–Bi). By the method of HR-TEM imaging it was found that the structure of Ge2Sb2Te5–Bi films presents the amorphous matrix with isolated crystalline nanoregions (nanoclusters) of metallic bismuth with average size ~ 8 nm. Local atomic structure of the films was studied by Raman spectroscopy. It was found that under the laser irradiation there is the structure transition of nanoscale Ge2Sb2Te5 films from amorphous into polycrystalline hexagonal stable state through metastable polycrystalline cubic phase. In contrast, in the Ge2Sb2Te5–Bi films the transition from amorphous to polycrystalline hexagonal stable state under the laser irradiation occurs without intermediate metastable cubic phase.

S.EL09.07.05
Analysis of the Limitation of the JMAK Equation for Crystallization of GST Based Phase Change Materials
An investigation into the relationship between crystal fraction and electrical conductivity for GST materials was performed. Transition from amorphous to conduction state for homogeneous nucleation of conductive crystallites in the resistive amorphous layer and limitation of the JMAK equation to modeling this transition is analyzed. In particular, the analysis relate to the validity of the model in terms of time-temperature description of crystallization and dependencies between minimum amount of crystal during nucleation and percolative threshold.

Controlling Electronic Signals Based on Domain Walls in Improper Ferroelectrics
Dennis Meier; Norwegian University of Science and Technology, Norway

Oxide materials exhibit a broad range of tunable phenomena, including magnetism, multiferroicity, and superconductivity. Oxide interfaces are particularly intriguing. Their low local symmetry combined with the sensitivity to electrostatics and strain leads to unusual physical properties beyond the bulk properties. Recently, ferroelectric domain walls have attracted attention as a novel type of oxide interface; the walls are spatially mobile and allow controlling electronic signals at the atomic scale, holding great potential as multifunctional 2D systems for future nanoelectronics.

In my talk, I will present unique features that occur at improper ferroelectric domain walls in hexagonal manganites and discuss how these walls can be used to emulate the behavior of key electronic components. For our studies, we choose the p-type semiconductor ErMnO₃ as it naturally develops all fundamental types of ferroelectric domain wall at room temperature, namely neutral (side-by-side) as well as negatively (tail-to-tail) and positively charged (head-to-head) wall configurations. The walls are explicitly robust and, hence, represent an ideal template onto which the desired electronic behavior can be imposed. I will show how the electronic properties can be optimized and controlled, and discuss the possibility to use such walls for designing 2D digital switches and half-wave rectifiers, bringing us one step closer to domain-wall based devices and networks for next-generation nanotechnology.

Ferroelectric and Magneto-Ionic Switching in Hafnia-Based Multiferroic Tunnel Junctions
Beatriz Noheda¹ ¹, Yingfen Wei¹, Sylvia Matzen², Cynthia Quinteros¹, Thomas Maroutian², Guillaume Agnus², Philippe Lecoeur², Pavan Nukala¹ and Mart Salverda¹; ¹University of Groningen, Netherlands; ² Universite Paris-Sud-Universite Paris-Saclay, France

Ferroelectric hafnia-based films show large electrical polarization at largely reduced dimensions. In addition they present low leakage as well as CMOS compatibility,[1] making them ideal candidates for memory and logic devices. Here we show that multiferroic tunnel junctions (MTJs) with ferroelectric Hf₀.₅Zr₀.₅O₂ barriers show both tunneling magnetoresistance effect (TMR) and tunneling electroresistance effect (TER), displaying four resistance states by magnetic and electric field switching.[2] Moreover, under electric field cycling of large enough magnitude, the TER can reach values as large as 10⁶%. Concomitant with this TER enhancement, the devices develop electrical control of spin polarization, with sign reversal of the TMR effect.[3] Currently, this intermediate state exists for a limited number of cycles and understanding the origin of these phenomena is key to improve its stability. Our study points to the magneto-ionic effect as the origin of the large TER and strong magneto-electric coupling, showing that ferroelectric polarization switching of the tunnel barrier is not the main contribution. The interplay between ferroelectric polarization and magneto-ionic coupling will be discussed.

Automated Experiment in Piezoresponse Force Microscopy—From FerroBOT to Active Learning
Sergei V. Kalinin, Rama Vasudevan, Maxim Ziatdinov, Kyle P. Kelley, Liam Collins and Stephen Jesse; Oak Ridge National Laboratory, United States
Piezoresponse force microscopy (PFM) has become the standard tool for imaging and spectroscopy of ferroelectric and multiferroic materials, providing wealth of information on domain structures and switching behaviors. However, until now PFM, similar to other scanning probe microscopy techniques, was based on the classical rectangular scans and predefined voltage patterns. In this presentation, I introduce our recent work on combining PFM with automated experimentation, exploring image-based feedback, non-rectangular and adaptable scans, and autonomous experiments. As one such example, we demonstrate a fundamentally new approach for exploring polarization dynamics of specific domain elements and topological structures in ferroelectric materials manipulation based on in-situ image-based feedback in PFM. This approach was demonstrated for probing highly pinned domain wall dynamics in polydomain PZT, one of the traditionally most difficult objects for PFM studies. We demonstrate the creation of frustrated phases with significantly enhanced electromechanical response prior to the onset of the wall motion and discuss future strategies for fabrication of predefined topological defects and exploration of their dynamic properties. We further illustrate the incorporation of non-rectangular scans and discuss the strategies for automated experimentation in PFM based on the Gaussian Process modelling. Finally, we explore the opportunities for exploring the fundamental physics of ferroelectric materials enabled by the combination of the automated PFM experiment and combinatorial synthesis.

This research is supported by the by the U.S. Department of Energy, Basic Energy Sciences, Materials Sciences and Engineering Division and the Center for Nanophase Materials Sciences, which is sponsored at Oak Ridge National Laboratory by the Scientific User Facilities Division, BES DOE.

1:15 PM *S.EL12.02.05
Emergent Phenomena at Oxide Interfaces with Strong Spin-Orbit Coupling [Jobu Matsuno; Osaka University, Japan]

We suggest that 5d electron systems are promising class of spintronic materials because of its strong spin-orbit coupling (SOC). A strong SOC inherent to 5d Ir oxides recently emerged as a new paradigm for oxide electronics. For example, we investigated novel physics of spin-orbital Mott insulators [1] and possible topological insulators [2] by tuning the electronic phases through superlattice technique. We also demonstrated a large spin Hall effect of IrO₃, one of the simplest 5d oxides, indicating that Ir oxides are promising class of spintronic materials [3]. In this talk, we focus on yet another topic on spintronics -- magnetic skyrmion as a topological spin texture. We have studied transport properties of bilayers consisting of m unit cells of ferromagnetic SrRuO₃ and 2 unit cells of SrIrO₃. We observed an anomaly in the Hall resistivity in addition to anomalous Hall effect (AHE); this is attributed to topological Hall effect (THE) [4]. The results suggest that magnetic skyrmions of 10–20 nm are generated by Dzyaloshinskii-Moriya interaction, which might be caused by both broken inversion symmetry at the interface and strong SOC of SrIrO₃. Even more surprising is that we can control both AHE and THE by electric field in the SrRuO₃-SrIrO₃ bilayers [5]. We observed the clear electric-field dependence only when SrIrO₃ is inserted between SrRuO₃ and a gate dielectric. The results established that strong SOC of nonmagnetic materials such as SrIrO₃ is essential in electrical tuning of these Hall effects.

We are also searching for spin-current transport properties at the interfaces consisting of magnetic oxides and nonmagnetic Ir oxides. We will report on the latest results on them. Through these studies on oxide interfaces containing Ir oxides, we may have a chance to approach a triple point for topology, correlation, and spin-orbit coupling.

1:30 PM *S.EL12.02.01
Dimensionality-Induced Change in Ferroelectric Topological Order in Oxide Superlattices [Megan E. Holtz¹, Elliot S. Padgett¹, Rachel Steinhardt², Charles M. Brooks², D.G. Schlom², David A. Muller¹,³ and Julia Mundy¹; ¹Harvard University, United States; ²Cornell University, United States; ³Kavli Institute at Cornell for Nanoscale Science, United States]

Topological defects can be formed at a phase transition where there is spontaneous symmetry breaking. These features play a central role in understanding phase transitions, ranging from superfluid ⁴He and high-temperature superconductors to cosmological systems. Certain hexagonal multiferroic materials also display topological defects including (charged) domain walls and ferroelectric vortices. In addition to serving as a model for their universality class, these sites can further host emergent phenomena including anomalous conduction and fractional electronic charges or quantized magnetic moments.
Here, we construct atomically-abrupt superlattices to study the ferroelectric order as a function of thickness. We observe controlled formation of charged ferroelectric domain walls. Electrostatic confinement of the walls and the associated vortices pushes the material from a $Z_6$ symmetry to a stripe phase with continuous $U(1)$ symmetry to a paraelectric phase with decreasing thickness. These materials also display unique topological features not observed in the bulk components. Together we demonstrate how dimensional confinement in artificial superlattices is a new probe for stabilizing new topologies in hexagonal ferroelectric systems.

1:45 PM DISCUSSION TIME

Structural Peculiarities of Epitaxial PMN-PT Thin Films Matjaz Spreitzer, U. Gabor, J. Belhadi, I. Rafalovskyi, N. Daneu, Aleksander Matavz, V. Bobnar, Z. Samardzija and J. Hlinka; Jožef Stefan Institute, Slovenia

Pb(Mg1/3Nb2/3)O3–PbTiO3 is a relaxor ferroelectric material that exhibits interesting dielectric and piezoelectric properties. Specifically, complex domain architectures are formed in compositions around the morphotropic phase boundary. The polar structure of thin films is additionally affected by the epitaxial strain. In order to understand the structure of these films, multiscale analysis is needed, considering limitations of individual analytical technique. It will be presented how a combination of high-resolution X-ray diffraction, selected area electron diffraction, atomic-resolution scanning transmission electron microscopy, polarized Raman scattering and wavelength-dispersive X-ray spectroscopy can be used to elucidate the structure of this material. Furthermore, it will be shown how macroscopic piezoelectric and dielectric measurements in different configurations can aid in understanding the film structural characteristics. Growth-related aspects will also be discussed, with emphasis on the challenges and peculiarities occurring in the growth of films with volatile components. Routes for the preparation of single-phase films with near-nominal stoichiometry will be presented, along with the specific defects that appear with off-stoichiometry. The role of the substrate on the phase purity and film quality will also be discussed. It will be shown why in some cases a rough interface is preferred.

SESSION S.EL12.07: Live Keynote II: Nanomagnetism/Magnetoelectrics

5:15 PM *S.EL12.04.02
Magnetoelectric Coupling by Piezoelectric Tensor Design Mark S. Rzchowski¹, J. Irwin¹, S. Lindemann¹, W. Maeng¹, J.J. Wang², V. Vaithyanathan¹, Jiamian Hu¹, Long-Qing Chen¹, D.G. Schlom³ and Chang-Beom Eom¹; ¹University of Wisconsin-Madison, United States; ²The Pennsylvania State University, United States; ³Cornell University, United States

Strain-coupled magnetoelectric (ME) phenomena in piezoelectric / ferromagnetic thin-film bilayers are a promising paradigm for sensors and information storage devices, where strain manipulates the magnetization of the ferromagnetic film. In-plane magnetization rotation with an electric field across the film thickness has been challenging due to the large reduction of in-plane piezoelectric strain by substrate clamping, and in two-terminal devices, the requirement of anisotropic in-plane strain. Here we show that these limitations can be overcome by designing the piezoelectric strain tensor using the boundary interaction between biased and unbiased piezoelectric. We fabricated 500 nm thick, (001) oriented [Pb(Mg1/3Nb2/3)O3]0.7-[PbTiO3]0.3 (PMN-PT) unclamped piezoelectric membranes with ferromagnetic Ni overlayers. Guided by analytical and numerical continuum elastic calculations, we designed and fabricated two-terminal devices exhibiting electric field-driven magnetization rotation. We develop a method that can apply designed strain patterns to many other materials systems to control properties such as superconductivity, band topology, conductivity, and optical response. We also discuss how these effects depend on the crystallographic orientation.

5:30 PM *S.EL12.04.03
Control of Ferromagnetic Skyrmions Using Ferroelectric Polarization Tae Won Noh; Seoul National University, Korea (the Republic of)

Ferromagnetic skyrmion is a topologically protected whirling spin texture in nanoscale. Due to its small size, topologically-protected stability, and solitonic nature together, it holds great promise for future spintronics applications. To translate these
compelling features into practical spintronic devices, we should face a key challenge in achieving effective control of
skyrmion properties, such as size, density, and thermodynamic stability. Recently, we reported the discovery of
ferroelectrically tunable skyrmions in ultrathin BaTiO3/SrRuO3 bilayer heterostructures. The ferroelectric proximity effect
occurring at the BaTiO3/SrRuO3 heterointerface can trigger a sizable Dzyaloshinskii-Moriya interaction. Thus the interaction
between two ferroic materials can stabilize robust skyrmions with diameters of several tens of nanometers.[1] Moreover, by
manipulating the ferroelectric polarization direction of the BaTiO3 layer, we could achieve local, switchable and nonvolatile
control of both skyrmion density and thermodynamic stability. Such a ferroelectrically tunable skyrmion system can work as a
new paradigm to simultaneously enhance the integratability and addressability of skyrmion-based functional devices.

5:45 PM *S.EL12.03.02
Challenges and Opportunities with X-Raying Novel Spin Textures Peter Fischer; Lawrence Berkeley National Lab,
United States

Spin textures are the foundation of properties and behavior of magnetic materials and drive the functionality of magnetic
devices. Topology and frustration that impact spin textures have recently attracted significant scientific interest and led to
intense research e.g. in magnetic skyrmions (Sk) and artificial spin ice systems (ASI) addressing a broad spectrum of
challenging scientific and technological questions, including stability, dynamics, nucleation, and transport. So far, Sk and
ASI have been treated foremost as two-dimensional spin textures, however, recent investigations have opened the door to a
conceptually next leap, which are three-dimensional nanoscale size magnetic spin textures (3D-spin-textures) e.g., chiral
bobbers, magnetic hopfions, and skyrmion tubes.

Advanced characterization tools that provide magnetic sensitivity to spin textures at high spatial resolution, ultimately at
buried interfaces and in all three dimensions [1], and at high temporal resolution to capture the spin dynamics across scales,
are therefore of large scientific interest.

Magnetic soft X-ray spectro-microscopies [2] provide unique characterization opportunities to study the statics and dynamics
of spin textures in magnetic materials combining X-ray magnetic circular dichroism (X-MCD) as element specific,
quantifiable magnetic contrast mechanism with spatial and temporal resolutions down to fundamental magnetic length, time,
and energy scales.

Current developments of x-ray sources aim to increase dramatically the coherence of x-rays opening the path to new
techniques, such as ptychography [3] or x-ray photo-correlation spectroscopy (XPCS) [4] that allow unprecedented studies of
nanoscale heterogeneity, complexity, and fluctuations.

I will review recent achievements and future opportunities with magnetic x-ray spectro-microscopies. Examples will include
static properties and dynamic behavior of various magnetic skyrmion [5,6] textures with potential application to novel
magnetic logic and storage devices, as well as results from an XPCS study at LCLS with a novel 2-pulse scheme that allowed
to discover an unexpected and drastic change of the correlation times in nanoscale spin fluctuations near phase boundaries,
i.e., in the skyrmion phase, and near the boundary with the stripe phase of a multilayered Fe/Gd system [4].

Finally, I will present a study on ferromagnetic liquid droplets, which could establish a complete paradigm shift in magnetic
materials, that combine characteristics of liquid, such as reconfigurability and short range spatial and temporal correlations
with ferromagnetism, which so far has been confined to condensed matter [7].

Observation, Manipulation and Understanding of Coupled Multiferroic Domains in Single-Phase
Magnetoelectrics Tsuyoshi Kimura; The University of Tokyo, Japan

Symmetry breaking ascribed to the evolution of an order parameter is one of the most important concepts in ferroic materials
such as ferromagnets and ferroelectrics, and bears “domain” structures. The domain switching by an external field is the key principle to exploit them for practical applications. In multiferroics, materials possessing multiple ferroic order parameters, the respective order parameters form domains and multiple types of domain states coexist. It is well-accepted that couplings between the multiple order parameters and domain states are essential for macroscopic magnetoelectric phenomena in multiferroics. However, there are few reports that directly compare responses of coexisting domain states to external fields and macroscopic magnetoelectric properties. In this presentation, we show selective observations of multiple magnetic order parameters and domain structures in some single-phase magnetoelectrics. This work has been done in collaboration with H. Ueda, R. Misawa, T. Katsuyoshi, J. K. H. Fischer, K. Kimura, Y. Tanaka, Y. Wakabayashi, T. Honda, J. S. White, M. Kenzelmann, A. B. Harris, N. Leo, and M. Fiebig.

Progress in Magnetoelectric Composites and Device Applications Shuxiang Dong, Zhaoqiang Chu, MohammadJavad PourhosseiniAsl and Zhonghui Yu; Peking University, China

Incorporating ferromagnetic, ferroelectric and ferroelastic orders inherently in a single-phase multiferroic material or manipulating one ferroic order with the others via interfacial coupling effects in multiferroic heterostructures has driven significant research activities aiming at the realization of their technological potential in the field of sensors, RF electronics, logic devices and memory etc. Magnetoelectric (ME) effect is essentially referred to as a change of electrical polarization (P) induced by external magnetic field (H) or a control of magnetization (M) via applied electric field (E). This report first introduces our recent progress in laminated ME composites consisting of a [011]-oriented Pb(Mg,Nb)O3-Pb(Ti,Zr)O3 (PMN-PZT) single-crystal fiber laminated with laser-treated amorphous FeBSi alloy (Metglas). High ME coupling coefficient around 10 kV/cm*Oe has been achieved. We will then review recent advances in multi-layered ME composites as well as their device applications including magnetic field/current sensors, dual-stimulus energy harvesters, ME memories, ME gyrators and tunable electronics. Some perspectives in terms of the future of magnetoelectric composites and devices will also be provided.

Neuromorphic Computing with Spintronic Oscillators Alice Mizrahi1,2,3, Tifenn Hirtzlin1, Matthew Daniels2,3, Nicolas Locatelli1, Akio Fukushima4, Hit Kubota4, Shinsi Yuasa4, M D. Stiles3, Julie Grollier1 and Damien Auerlioz2; 1Université Paris-Saclay, France; 2Université Paris Saclay, France; 3University of Maryland, United States; 4National Institute of Standards and Technology, United States; 5National Institute of Advanced Industrial Science and Technology (AIST), Japan

Artificial neural networks are performing tasks, such as image recognition and natural language processing, that offer great promises for artificial intelligence. However, these algorithms run on traditional computers and consume orders of magnitude more energy more than the brain does at the same task. One promising path to reduce the energy consumption is to build dedicated hardware to perform artificial intelligence. Spintronic devices are particularly interesting because they allow for complex functionality with low energy consumption and small size.

I will discuss the role of magnetic tunnel junctions as building blocks for artificial neural networks in hardware. These bistable nanodevices which magnetic state can be both read and written electrically. Their high endurance, reliability and CMOS-compatibility have made them flagship devices for novel forms of computing. While their main use is as non-volatile memories (MRAM), they can also exhibit rich non-linear dynamics which emulate the basic functionalities of neurons.

In particular, I will focus on the superparamagnetic regime of magnetic tunnel junctions and stochastic oscillators capable of harnessing the energy of thermal noise. While stochasticity is traditionally unwanted for computing, I will show how it can be leveraged to reduce energy consumption. I will draw an analogy between stochastic magnetic tunnel junctions and stochastic spiking neurons, which emit randomly spaced voltage spikes. I will show how these devices can be assembled into an artificial neural network an perform computing. Such a system would be competitive with conventional electronics implementations, both in terms of area on chip and energy consumption.

These results open the path to low energy hardware implementation of neural networks, making it possible to perform cognitive tasks on chip.

Composite multiferroics, composed of a magnetostrictive ferromagnet and a piezoelectric ferroelectric, hold promise for magnetic field sensors and energy efficient beyond-CMOS logic by harnessing magnetoelectric transduction. Enhancing device performance requires highly magnetostrictive materials, however, relatively little attention has been given to engineering magnetostriction in thin films. One promising magnetostrictor system are the Fe1-xGax alloys yet in bulk, the magnetostriction coefficient of Fe1-xGax alloys versus gallium composition peaks near ~18% Ga due to a phase change from the disordered A2 phase to an ordered BCC phase (D03). Here we discuss a means to boost (by 200-300% relative to bulk) the magnetostriction of Fe1-xGax thin film alloys by extending the phase stability of the A2 phase to higher Ga compositions.

Transport-based magnetoelectric characterization of a Fe1-xGax-[Pb(Mg1/3Nb2/3)O3]0.7-[PbTiO3]0.3 (PMN-PT) composite multiferroic heterostructure shows are reversible 90 deg electrical switch of magnetic anisotropy and a room temperature converse magnetoelectric coefficient of 5.5×10⁻⁶ s m⁻¹.

7:00 PM *S.EL12.04.13
Active Control of Spin Waves in Multiferroic Heterostructures Sebastiaan van Dijken; Aalto University, Finland

Active manipulation of spin waves is essential for the development of magnon-based technologies. One route towards this goal exploits reprogrammable magnonic crystals. In such structures, a varying spatial modulation of magnetic properties using, for instance, electric currents [1] or optical pulses [2] controls the transmission of spin waves. Besides these dynamic approaches, field-induced toggling between ferromagnetic and antiferromagnetic states in magnetic stripe arrays has been shown to modify spin wave transport in a non-volatile way [3].

Multiferroic heterostructures comprising coupled ferromagnetic and ferroelectric layers offer an interesting alternative as programmable hybrids for magnonics. Attractive properties of multiferroic heterostructures include the imprinting of magnetic domain patterns, the creation of abrupt anisotropy boundaries, strong pinning of magnetic domain walls, and electric field control of magnetic anisotropy, magnetic switching, and magnetic domain wall motion [4-6].

Here, we demonstrate that multiferroic heterostructures provide a versatile platform for the emission of short-wavelength spin waves [7], the confinement of spin wave modes in structurally uniform films [8], and active manipulation of spin wave transmission [9]. The multiferroic heterostructures consist of a ferroelectric BaTiO3 substrate and a strain-coupled ferromagnetic film with a thickness of 20 – 50 nm. At room temperature, this material system comprises fully correlated stripe domains in the ferroelectric and ferromagnetic subsystems. Utilizing strong pinning of ferromagnetic domain walls onto ferroelectric boundaries, we demonstrate active manipulation of spin wave transmission from 0% to 100% by non-volatile reprogramming of the domain-wall spin structure in a magnetic field [9]. In addition to magnetic field control, we also present recent results on active manipulation of spin wave transmission using electric fields. This sought-after effect originates from local strain-induced changes of the magnetic anisotropy. We demonstrate that the transmission of spin waves can be fully turned on and off in certain frequency bands by the application of voltage pulses across the BaTiO3 substrate. The multiferroic heterostructures allow also for continuous tuning of the spin wave phase and amplitude, offering prospects for voltage-controlled magnonic logic.

Controlling Electronic Signals Based on Domain Walls in Improper Ferroelectrics

Dennis Meier; Norwegian University of Science and Technology, Norway

Oxide materials exhibit a broad range of tunable phenomena, including magnetism, multiferroicity, and superconductivity. Oxide interfaces are particularly intriguing. Their low local symmetry combined with the sensitivity to electrostatics and strain leads to unusual physical properties beyond the bulk properties. Recently, ferroelectric domain walls have attracted attention as a novel type of oxide interface; the walls are spatially mobile and allow controlling electronic signals at the atomic scale, holding great potential as multifunctional 2D systems for future nanoelectronics.

In my talk, I will present unique features that occur at improper ferroelectric domain walls in hexagonal manganites and discuss how these walls can be used to emulate the behavior of key electronic components. For our studies, we choose the p-type semiconductor ErMnO3 as it naturally develops all fundamental types of ferroelectric domain wall at room temperature, namely neutral (side-by-side) as well as negatively (tail-to-tail) and positively charged (head-to-head) wall configurations. The walls are explicitly robust and, hence, represent an ideal template onto which the desired electronic behavior can be imposed. I will show how the electronic properties can be optimized and controlled, and discuss the possibility to use such walls for designing 2D digital switches and half-wave rectifiers, bringing us one step closer to domain-wall based devices and networks for next-generation nanotechnology.

Automated Experiment in Piezoresponse Force Microscopy—From FerroBOT to Active Learning

Sergei V. Kalinin, Rama Vasudevan, Maxim Ziatdinov, Kyle P. Kelley, Liam Collins and Stephen Jesse; Oak Ridge National Laboratory, United States

Piezoresponse force microscopy (PFM) has become the standard tool for imaging and spectroscopy of ferroelectric and multiferroic materials, providing wealth of information on domain structures and switching behaviors. However, until now PFM, similar to other scanning probe microscopy techniques, was based on the classical rectangular scans and predefined voltage patterns. In this presentation, I introduce our recent work on combining PFM with automated experimentation, exploring image-based feedback, non-rectangular and adaptable scans, and autonomous experiments. As one such example, we demonstrate a fundamentally new approach for exploring polarization dynamics of specific domain elements and topological structures in ferroelectric materials manipulation based on in-situ image-based feedback in PFM. This approach was demonstrated for probing highly pinned domain wall dynamics in polydomain PZT, one of the traditionally most difficult objects for PFM studies. We demonstrate the creation of frustrated phases with significantly enhanced electromechanical response prior to the onset of the wall motion and discuss future strategies for fabrication of predefined topological defects and exploration of their dynamic properties. We further illustrate the incorporation of non-rectangular scans and discuss the strategies for automated experimentation in PFM based on the Gaussian Process modelling. Finally, we explore the opportunities for exploring the fundamental physics of ferroelectric materials enabled by the combination of the automated PFM experiment and combinatorial synthesis.

This research is supported by the by the U.S. Department of Energy, Basic Energy Sciences, Materials Sciences and Engineering Division and the Center for Nanophase Materials Sciences, which is sponsored at Oak Ridge National Laboratory by the Scientific User Facilities Division, BES DOE.

Polar Metals Revisited

Pankaj K. Sharma1,2; 1The University of New South Wales, Australia; 2ARC Centre of Excellence in Future Low-Energy Electronics Technologies, University of New South Wales, Australia

Ferroelectricity has often been associated with and observed in materials that are insulating or semiconducting rather than metallic because conduction electrons in metals screen out the static internal fields arising from a long-range dipolar order. In the 1960s, Anderson and Blount proposed materials with these seemingly incompatible characteristics, i.e., metals with a polar axis termed ferroelectric metals. Since then, ferroelectric metals were merely a theoretical construct until recent experimental observations suggesting otherwise. Despite the progress, electrically switchable intrinsic electric polarization, together with the direct observation of ferroelectric domains, has not yet been realized in a bulk crystalline metal, although incomplete screening by mobile conduction charges should, in principle, be possible.

Here, we provide evidence that native metallicity and ferroelectricity coexist in bulk crystalline van der Waals WTe2. We
show that, despite being a Weyl semimetal, WTe$_2$ has switchable spontaneous polarization and a natural ferroelectric domain structure at room temperature. This new class of materials has tantalizing potential for functional nanoelectronics applications.

6:15 AM S.EL12.01.04
Superior Polarization Retention through Engineered Domain Wall Pinning Dawei Zhang$^{1}$, Daniel Sando$^{1,1}$, Pankaj K. Sharma$^{1,1}$, Xuan Cheng$^{2}$, Fan Ji$^{1,1}$, Vivasha Govinden$^{1,1}$, Matthew Weyland$^{2,2}$, Valanoor Nagarajan$^{1,1}$ and Jan Seidel$^{1,1}$; $^{1}$UNSW, Australia; $^{2}$Monash University, Australia

In the quest towards commercialization of ferroelectric-based non-volatile nanoelectronic devices, the realization of robust polarization retention is of great significance. However, ferroelectric materials always suffer from polarization relaxation during the time, typically happening within from days to a few weeks, which leads to a final retention loss for the data storage. In this work, by exploiting the domain wall pinning through designer-defect engineering in epitaxial BiFeO$_3$ films, we have demonstrated an ultra-long polarization with virtually no degradation in switched nanoscale domains for periods longer than two years. This already represents a more than 4000 % improvement over the best values hitherto reported and is believed to have an ongoing retention. Transmission electron microscopy (TEM) with atomic resolution reveals that nanoscale defect pockets pervade the entire film thickness homogeneously. These defects act as highly efficient domain wall pinning centres, resulting in the superb retention. This is also corroborated by scanning probe microscopy-based dynamic switching measurements as the results show a remarkably increased activation field for domain wall movement, originating from the defect-engineered domain wall pinning. Our findings demonstrate that defects can be exploited in a positive manner to solve reliability issues in ferroelectric films used in functional devices.

Memory Window Improvement of HZO-Based FeFETs with HfO$_2$ Interlayers Zhouchangwan Yu, Fei Huang, Yoshio Nishi, Simon S. Wong and Paul McIntyre; Stanford University, United States

Since the discovery of ferroelectricity in HfO$_2$ thin films that either doped or alloyed with other metal oxide components, HfO$_2$ based ferroelectric field-effect transistors (FeFETs) have gained increasing interest as a candidate emerging memory due to their ability to scale to very small device dimensions, and their CMOS compatibility. For a FeFET with metal-
ferroelectric-insulator-semiconductor (MFIS) gate stack, the insulator layer interposed between the ferroelectric and the semiconductor channel plays an important role to achieve a wide memory window (MW) and good endurance and retention. In this work, we experimentally demonstrate FeFETs with very large MW of 3.3 V by utilization of HfO₂ interlayers both on top of and under the ferroelectric Hf₀.₅Zr₀.₅O₂ (HZO) layer.

Based on the studies of metal-ferroelectric-metal (MFM) capacitors and MFIS gate stacks with ferroelectric HZO of 10 nm, the thicknesses of top and bottom HfO₂ interlayers are optimized to be 2 nm and 1 nm, respectively, in order to achieve maximum MW and minimum polarization "wake-up" effect. The MFIS without HfO₂ interlayers shows MW of 2.0 V, while the MFIS with HfO₂ interlayers shows MW greater than 3.0 V. The thickness of bottom HfO₂ layer of 2 nm is required to improve the MW, and the possible effect is that it forms a thin continuous film that facilitate the later ALD growth of HZO, which may benefit the orthorhombic phase formation.

It has been reported that FeFETs with 20 nm thick HfO₂ layer have a MW of 2.9 V, switched by +5 V and -5 V pulses on the gate.[i] By utilizing HfO₂ interlayers, our FeFETs has only 13 nm of HZO of HfO₂ layers in total, and exhibit a wider MW of 3.3 V, switched by +4 V and -4 V. In addition, our FeFET devices display good retention at 85°C and maintain a MW of 1.8 V extrapolated for 10 years. As for write disturb, the devices can withstand disturbas in a V₆ₕ/2 scheme up to the tested 10⁶ cycles without degradation of Iₜₚ/Iₚᵣ ratio.

7:45 AM S.E.L12.01.13
Strain-Induced Ferroelectricity in Freestanding SrTiO₃ Membranes Ruijuan Xu¹, Jiawei Huang², Edward Barnard¹, Seung Sae Hong¹, Ed Wong¹, Varun Harbola¹, Prastuti Singh¹, Bai Yang Wang¹, Shi Liu² and Harold Y. Hwang¹; ¹Stanford University, United States; ²Westlake University, China; ³Lawrence Berkeley National Laboratory, United States

SrTiO₃ is known to exhibit quantum paraelectricity in which quantum fluctuations suppress ferroelectric ordering at low temperature¹. Despite the intrinsic paraelectric nature of SrTiO₃, it is possible to stabilize ferroelectricity via a variety of means such as substrate-induced strain tuning², cation substitution³, ¹⁸O isotope substitution⁴, and defect engineering⁵, etc. In particular, the epitaxial strain applied via lattice mismatch in thin film heterostructures can significantly enhance the ferroelectric transition temperature Tc and even stabilize ferroelectricity at room temperature. However, since a given substrate provides a fixed and discrete lattice parameter that lacks mechanical flexibility, this approach is limited in the ability to dynamically control the strain state in a widely accessible range. In order to tune strain in a dynamic and continuous fashion, here we utilize freestanding SrTiO₃ crystalline membranes to extend the lattice control of ferroelectric ordering in such materials⁶. By dissolving a water-soluble epitaxial buffer layer, we can release SrTiO₃ films from substrates, and transfer the resulting freestanding membranes onto flexible polymer substrates that can be stretched to induce various strain states. Using optical second harmonic generation microscopy, we probe the ferroelectric phase transition as a function of strain wherein we observe Tc is significantly enhanced by strain. Upon applying 1.5% uniaxial strain, we observe robust room-temperature ferroelectricity with the notable feature of 180° ferroelectric domains using piezoresponse force microscopy. First-principle calculations and molecular dynamics simulations further reveal the structural nature at each given strain state and the order-disorder character of the phase transition in strained SrTiO₃ membranes. Overall, our work provides new insights regarding strain induced phenomena in oxide membranes and also demonstrates a new approach to dynamically control ferroelectric ordering in SrTiO₃.

Modeling Morphotropic Phase Boundary in Lead Zirconate Titanate as a Frustrated State

Ying Shi Teh and Kaushik Bhattacharya; California Institute of Technology, United States

The microstructure of lead zirconate titanate (PZT) at its morphotropic phase boundary (MPB) has attracted much interest due to its exceptional dielectric and ferroelectric properties. One long-held hypothesis is that a monoclinic phase exists at the narrow composition regime near the MPB of PZT to bridge the transition between rhombohedral and tetragonal phases. However till today, there remains no agreement regarding the specific monoclinic structure. Motivated by the disordering in the chemical composition of a solid solution, we propose an extension of the random field Ising model with dipolar state that includes long-range dipole-dipole interactions to study MPB in PZT. A Monte Carlo approach is then adopted to obtain low-energy configurations of the model. The method is formulated to suit the GPU architecture, hence allowing to solve large-scale cases that better capture composition disordering and domain pattern. Our model predicts a sharp transition from rhombohedral phase to tetragonal phase as the composition of lead titanate in PZT is increased. At the MPB, it shows a frustrated state mixed with domains of both rhombohedral and tetragonal phases. The average domain size undergoes a sudden dip while the domain walls no longer follow the low-order crystallographic directions at this region. These findings are consistent with experimental observations. Overall this model presents a picture of the competition between composition disordering and long-range interactions, and clarifies the structural inhomogeneity at the MPB.

Ferroelectric and Magneto-Ionic Switching in Hafnia-Based Multiferroic Tunnel Junctions

Beatriz Noheda1,1, Yingfen Wei1, Sylvia Matzen2, Cynthia Quinteros1, Thomas Maroutian2, Guillaume Agnus2, Philippe Lecoeur2, Pavan Nukala1 and Mart Salverda1; 1University of Groningen, Netherlands; 2 Universite Paris-Sud-Universite Paris-Saclay, France

Ferroelectric hafnia-based films show large electrical polarization at largely reduced dimensions. In addition they present low leakage as well as CMOS compatibility,[1] making them ideal candidates for memory and logic devices. Here we show that multiferroic tunnel junctions (MTJs) with ferroelectric Hf0.5Zr0.5O2 barriers show both tunneling magnetoresistance effect (TMR) and tunneling electroresistance effect (TER), displaying four resistance states by magnetic and electric field switching.[2] Moreover, under electric field cycling of large enough magnitude, the TER can reach values as large as 106%. Concomitant with this TER enhancement, the devices develop electrical control of spin polarization, with sign reversal of the TMR effect.[3] Currently, this intermediate state exists for a limited number of cycles and understanding the origin of these phenomena is key to improve its stability. Our study points to the magneto-ionic effect as the origin of the large TMR and strong magneto-electric coupling, showing that ferroelectric polarization switching of the tunnel barrier is not the main contribution. The interplay between ferroelectric polarization and magneto-ionic coupling will be discussed.

Control of Transport Properties of Hybrid Molybdenum Disulfide (MoS2)—Ferroelectric Devices via Domain Engineering

Alexey Lipatov1, Tao Li2, Nataliia Vorobeva1, Alexander Sinitskii1 and Alexei Gruverman1; 1University of Nebraska–Lincoln, United States; 2 Xi’an Jiaotong University, China

We introduce a concept of programmable ferroelectric devices comprised of two-dimensional (2D) and ferroelectric (FE) materials. It enables precise modulation of the in-plane conductivity of a 2D channel material through nanoengineering of FE domains with out-of-plane polarization. The functionality of these new devices has been demonstrated using field-effect transistors (FETs) fabricated with monolayer molybdenum disulfide (MoS2) channels on the Pb(Zr,Ti)O3 substrates. Using piezoresponse force microscopy, we show that local switching of FE polarization by a conductive probe can be used to tune the conductivity of the MoS2 channel. Specifically, patterning of the nanoscale domains with downward polarization creates
conductive paths in a resistive MoS$_2$ channel so that the conductivity of an FET is determined by the number and length of the paths connecting source and drain electrodes. In addition to the device programmability, we demonstrate the device ON/OFF cyclic endurance by successive writing and erasing of conductive paths in a MoS$_2$ channel. These findings may inspire the development of advanced energy-efficient programmable synaptic devices based on combination of 2D and FE materials.

9:00 AM S.EL12.01.18
Nanoscale Structural Ripples and Flexoelectric Effects in Free-Standing Single-Crystal Complex Oxide Ferroelectric Materials
Saidur R. Bakaul$^1$, Jaegyu Kim$^2$, Seunghun Hong$^2$, Mathew Cherukara$^1$, Tao Zhou$^1$, Liliana Stan$^1$, Claudio Serra$^3$, Sayeef Salahuddin$^1$, Amanda Petford-Long$^1$, Dillon D. Fong$^1$ and Martin V. Holt$^1$; $^1$Argonne National Laboratory, United States; $^2$Korea Advanced Institute of Science and Technology, Korea (the Republic of); $^3$University of California, Berkeley, United States

Recent studies have reported that freestanding epitaxial complex oxide thin films [1, 2] exhibit physical properties significantly different from original, as-grown films. For instance, the collapse of crystalline order has been reported in ultrathin, freestanding SrTiO$_3$ layers, induced by the electron-volt-level energy of bond breaking that is released from the interfacial layer during the transfer process. How such an energy landscape and bond rearrangement in one layer would necessarily affect other layers of a single crystal complex oxide thin film, i.e., in a three-dimensional object, is poorly understood. Unlike 2D materials such as graphene, complex oxides have strong interlayer bonds, which allows for long-range, three-dimensional mechanical energy propagation. The interfacial bond energy in typical complex oxide heterostructures is quite high and therefore, atomistic changes at the interface will alter the properties of all the layers, resulting in a very different mechanical and electrostatic energy landscape in the entirety of the material.

In this work, [3] we present the effect of interfacial bond-breaking on the structural and ferroelectric (FE) properties of epitaxially-grown PbZr$_{0.2}$Ti$_{0.8}$O$_3$ (PZT) thin films at mesoscopic length scale. PZT film grown on La$_{0.7}$Sr$_{0.3}$MO$_3$ (LSMO) buffered STO substrate is released by breaking the bond at the LSMO-PZT interface using a layer transfer technique. Utilizing the synchrotron X-ray nanoprobe technique we reveal that the bond-breaking results in nanoscale structural ripples in atomic planes of the FE material. The ripples are formed due to the lack of mechanical boundaries in all three dimensions. We estimate that such ripples can create a strong local strain gradient and flexoelectric field that is comparable to the coercive field of the FE film. In-situ piezo force microscopy and electronic transport measurements show that the flexoelectric effect generated from such ripples in atomic planes strongly blocks the FE domain wall motion and reduces the velocity by several orders magnitude. We will present and discuss the effect of these ripples on the energy landscape that controls domain wall motion and polarization reversal behavior.

Dimensionality-Induced Change in Ferroelectric Topological Order in Oxide Superlattices
Megan E. Holtz$^1$, Elliot S. Padgett$^1$, Rachel Steinhardt$^2$, Charles M. Brooks$^2$, D.G. Schlom$^2$, David A. Muller$^{1,3}$ and Julia Mundy$^1$; $^1$Harvard University, United States; $^2$Cornell University, United States; $^3$Kavli Institute at Cornell for Nanoscale Science, United States

Topological defects can be formed at a phase transition where there is spontaneous symmetry breaking. These features play a central role in understanding phase transitions, ranging from superfluid $^4$He and high-temperature superconductors to cosmological systems. Certain hexagonal multiferroic materials also display topological defects including (charged) domain walls and ferroelectric vortices. In addition to serving as a model for their universality class, these sites can further host emergent phenomena including anomalous conduction and fractional electronic charges or quantized magnetic moments.
Here, we construct atomically-abrupt superlattices to study the ferroelectric order as a function of thickness. We observe controlled formation of charged ferroelectric domain walls. Electrostatic confinement of the walls and the associated vortices pushes the material from a $Z_2$ symmetry to a stripe phase with continuous $U(1)$ symmetry to a paraelectric phase with decreasing thickness. These materials also display unique topological features not observed in the bulk components. Together we demonstrate how dimensional confinement in artificial superlattices is a new probe for stabilizing new topologies in hexagonal ferroelectric systems.

DFT Models of Negative Capacitance in Hafnium/Zirconium Oxide Polymorphs Kisung Chae1,2, Kyeongjae Cho2 and Andrew C. Kummel1; 1University of California, San Diego, United States; 2The University of Texas at Dallas, United States

Ferroelectric (FE) hafnium/zirconium oxide (HZO) thin films have shown many advantages in next-generation device applications such as negative capacitance gate oxides and FE random access memory (FERAM) or multi-state memory. In addition, spontaneous formation of atomically sharp phase and domain boundaries is prevalently observed in the HZO thin films due to structural similarity of the various polymorphs based on fluorite parent structure. Here, density functional theory (DFT) is employed to show that the FE o-phase could be stabilized by significant in-plane tension formed during the thermal annealing process, in which the as-deposited amorphous phase is crystallized into the more dense crystalline phases. The in-plane tension being the stabilization mechanism is in agreement with experiments but in contrast to some of the previous calculations which argued that in-plane compression is responsible for the stabilization of the o-phase. Furthermore, DFT is employed to model stacks of FE and paraelectric (PE) phases to provide an atomic model of negative capacitance. It is shown that the unfavorable interaction of the PE phase with the field from vertically polarized FE phase induce polarization rotation, phase change and domain wall formation consistent with negative capacitance. Furthermore, the rotation of polarization initiates at the PE/FE interface and propagates into the FE layer, while mixed FE phases with the vertical/rotated polarizations show shallow energy minima, and are further stabilized by applying an external electric field. Validation of negative capacitance in atomic models will further enable atomic models of stacks with high $k$ value and their switching behavior in response of external electric fields, mechanical strain, and defects.

Reconfiguring Functional Oxides in Atomically Controlled Thin Films Gertjan Koster; University of Twente, Netherlands

Consumer electronics and electronics is driven by low cost, reliable performance and low energy consumption. To truly enable innovations, new solutions have to be found in new materials. Oxides show multiple functional properties and therefor offer multiple solutions in one material. Moreover, the reconfiguring functionality of materials by using epitaxy or self-assembly etc. (e.g., non-magnetic to ferromagnetic, dielectric to piezoelectric properties or insulating to metallic) has been demonstrated. The success of reconfiguring many of these oxides critically depends on the atomically controlled thin film deposition techniques such as pulsed laser deposition but till now typically laboratory scale single crystalline wafers have been used. Important progress has been made in terms of plasma scanning techniques on large wafers and compatibility with technical materials (Si). However, fundamental knowledge of a scanning plasma and the composition of the thin films, which is essential in obtaining reliable reconfigured functional properties, is lacking.

In this presentation I will discuss examples of manipulation of magnetic properties in thin films and the possibility of reconfigurable functionality, also on technical wafers such as Si. We showed how to manipulate magnetic and electronic anisotropic properties in manganite heterostructures by engineering the oxygen network on the unit-cell level. In addition, the critical temperature of the metal-to-insulator transition as well as the magnetic transition temperature in RENiO$_3$ can be tuned by choosing spacer layers with different amounts of octahedral tilts in a superlattice configuration.

6:15 AM *S.EL12.02.05
Emergent Phenomena at Oxide Interfaces with Strong Spin-Orbit Coupling Jobu Matsuno; Osaka University, Japan

We suggest that 5$d$ electron systems are promising class of spintronic materials because of its strong spin-orbit coupling (SOC). A strong SOC inherent to 5$d$ Ir oxides recently emerged as a new paradigm for oxide electronics. For example, we investigated novel physics of spin-orbital Mott insulators [1] and possible topological insulators [2] by tuning the electronic phases through superlattice technique. We also demonstrated a large spin Hall effect of IrO$_2$, one of the simplest 5$d$ oxides, indicating that Ir oxides are promising class of spintronic materials [3].

In this talk, we focus on yet another topic on spintronics – magnetic skyrmion as a topological spin texture. We have studied...
transport properties of bilayers consisting of \( m \) unit cells of ferromagnetic SrRuO\(_3\) and 2 unit cells of SrIrO\(_3\). We observed an anomaly in the Hall resistivity in addition to anomalous Hall effect (AHE); this is attributed to topological Hall effect (THE) [4]. The results suggest that magnetic skyrmions of 10–20 nm are generated by Dzyaloshinskii-Moriya interaction, which might be caused by both broken inversion symmetry at the interface and strong SOC of SrIrO\(_3\). Even more surprising is that we can control both AHE and THE by electric field in the SrRuO\(_3\)-SrIrO\(_3\) bilayers [5]. We observed the clear electric-field dependence only when SrIrO\(_3\) is inserted between SrRuO\(_3\) and a gate dielectric. The results established that strong SOC of nonmagnetic materials such as SrIrO\(_3\) is essential in electrical tuning of these Hall effects.
We are also searching for spin-current transport properties at the interfaces consisting of magnetic oxides and nonmagnetic Ir oxides. We will report on the latest results on them. Through these studies on oxide interfaces containing Ir oxides, we may have a chance to approach a triple point for topology, correlation, and spin-orbit coupling.

Challenges and Opportunities with X-Raying Novel Spin Textures Peter Fischer; Lawrence Berkeley National Lab, United States

Spin textures are the foundation of properties and behavior of magnetic materials and drive the functionality of magnetic devices. Topology and frustration that impact spin textures have recently attracted significant scientific interest and led to intense research e.g. in magnetic skyrmions (Sk) and artificial spin ice systems (ASI) addressing a broad spectrum of challenging scientific and technological questions, including stability, dynamics, nucleation, and transport. So far, SK and ASI have been treated foremost as two-dimensional spin textures, however, recent investigations have opened the door to a conceptually next leap, which are three-dimensional nanoscale size magnetic spin textures (3D-spin-textures) e.g., chiral bobbers, magnetic hopfions, and skyrmion tubes.
Advanced characterization tools that provide magnetic sensitivity to spin textures at high spatial resolution, ultimately at buried interfaces and in all three dimensions [1], and at high temporal resolution to capture the spin dynamics across scales, are therefore of large scientific interest.
Magnetic soft X-ray spectro-microscopies [2] provide unique characterization opportunities to study the statics and dynamics of spin textures in magnetic materials combining X-ray magnetic circular dichroism (X-MCD) as element specific, quantifiable magnetic contrast mechanism with spatial and temporal resolutions down to fundamental magnetic length, time, and energy scales.

Current developments of x-ray sources aim to increase dramatically the coherence of x-rays opening the path to new techniques, such as ptychography [3] or x-ray photo-correlation spectroscopy (XPCS) [4] that allow unprecedented studies of nanoscale heterogeneity, complexity, and fluctuations.
I will review recent achievements and future opportunities with magnetic x-ray spectro-microscopies. Examples will include static properties and dynamic behavior of various magnetic skyrmion [5,6] textures with potential application to novel magnetic logic and storage devices, as well as results from an XPCS study at LCLS with a novel 2-pulse scheme that allowed to discover an unexpected and drastic change of the correlation times in nanoscale spin fluctuations near phase boundaries, i.e., in the skyrmion phase, and near the boundary with the stripe phase of a multilayered Fe/Gd system [4].
Finally, I will present a study on ferromagnetic liquid droplets, which could establish a complete paradigm shift in magnetic materials, that combine characteristics of liquid, such as reconfigurability and short range spatial and temporal correlations with ferromagnetism, which so far has been confined to condensed matter [7].

Neuromorphic Computing with Spintronic Oscillators

Alice Mizrahi1,2,3, Tifenn Hirtzlin1, Matthew Daniels2,3, Nicolas Locatelli1, Akio Fukushima4, Hit Kubota4, Shinshi Yuasa4, M D. Stiles5, Julie Grollier1 and Damien Auerlloz1; 1Université Paris-Saclay, France; 2University of Maryland, United States; 3National Institute of Standards and Technology, United States; 4National Institute of Advanced Industrial Science and Technology (AIST), Japan

Artificial neural networks are performing tasks, such as image recognition and natural language processing, that offer great promises for artificial intelligence. However, these algorithms run on traditional computers and consume orders of magnitude more energy more than the brain does at the same task. One promising path to reduce the energy consumption is to build dedicated hardware to perform artificial intelligence. Spintronics devices are particularly interesting because they allow for complex functionality with low energy consumption and small size.

I will discuss the role of magnetic tunnel junctions as building blocks for artificial neural networks in hardware. These bistable nanodevices which magnetic state can be both read and written electrically. Their high endurance, reliability and CMOS-compatibility have made them flagship devices for novel forms of computing. While their main use is as non-volatile memories (MRAM), they can also exhibit rich non-linear dynamics which emulate the basic functionalities of neurons.

In particular, I will focus on the superparamagnetic regime of magnetic tunnel junctions. Here, they behave as stochastic oscillators capable of harnessing the energy of thermal noise. While stochasticity is traditionally unwanted for computing, I will show how it can be leveraged to reduce energy consumption. I will draw an analogy between stochastic magnetic tunnel junctions and stochastic spiking neurons, which emit randomly spaced voltage spikes. I will show how these devices can be assembled into an artificial neural network an perform computing. Such a system would be competitive with conventional electronics implementations, both in terms of area on chip and energy consumption.

These results open the path to low energy hardware implementation of neural networks, making it possible to perform cognitive tasks on chip.

Field-Free Spin-Orbit Torque Perpendicular Magnetization Reversal Enabled by Interfacial Dzyaloshinskii-Moriya Interaction

Minyi Dai and Jiamian Hu; University of Wisconsin-Madison, United States

Perpendicular magnetization reversal through spin orbit torque (SOT) is of great recent interest due to its potential application in spin-orbit torque magnetoresistive random access memory (SOT-MRAM). Typically, a simultaneous application of in-plane bias magnetic field is required to break in-plane symmetry, which would cause crosstalk between neighboring memory units and thus impedes the development of high-density SOT-MRAM. Here, we propose a new approach to realize field-free SOT-mediated perpendicular magnetization reversal using micromagnetic simulations implemented in both our in-house package and MuMax3. Using realistic materials parameters from documented experimental measurements, our simulations suggest that such reversal can occur in a MgO/CoFeB/Pt multilayer stack when the disk size of CoFeB, the strength of Dyzaloshinskii-Moriya interaction at the CoFeB/Pt interface, and the magnitude of the driving in-plane current are all controlled within intermediate range. The kinetic mechanism of such new approach is presented and also understood by analogy to classical nucleation and growth theory.

Fabrication and Characterization of Layer-by-Layer Assembly of Spin Crossover Thin Films

Kayleigh A. McElveen1, Guanhua Hao1, Prescott Evans1, Peter Dowben1, Andrew Yost2,3 and Rebecca Lai1; 1University of Nebraska-Lincoln, United States; 2Oklahoma State University, United States
Iron (II) complexes have a ligand field energy and exchange-interaction energy that are within a few eV; therefore, the spin crossover (SCO) from low spin (LS) to high spin (HS) can be controlled using an external stimuli—temperature, pressure, light, etc. Similar to other bistable materials, iron (II) SCO complexes could find applications in technologies such as quantum logic operators and memory storage devices. However, most research on SCO complexes is performed on powder samples, which are incompatible with the industry’s needs for thin films with thickness control. In this study, we aim at developing a layer-by-layer assembly method to fabricate iron (II) SCO thin films. This thin film fabrication method has several advantages, including the precise control of film thickness by simply adjusting the number of layers. Prior to thin film fabrication, \([\text{Fe(pyrazine)}\{\text{M(CN)}_4\}] \) (M = Pt or Pd) bulk powders were synthesized so that their SCO properties could be used as a reference for their thin film counterparts. The SCO behavior of the Pt and Pd powders was confirmed with a vibrating sample magnetometer (VSM), and both powders displayed abrupt, room temperature hysteresis with widths of 45 K centered around 300 K. The abrupt spin transition is indicative of strong cooperativity between the metal centers. Rietveld analysis of x-ray diffraction (XRD) data further confirmed that the Pt and Pd powders were crystalline, showing nearly identical diffraction patterns in space group P4/m. Next, we employed the layer-by-layer solution deposition method to fabricate \([\text{Fe(pyrazine)}\{\text{M(CN)}_4\}] \) (M = Pt or Pd) thin films on gold substrates. The resultant Pt and Pd thin films were analyzed using x-ray absorption spectroscopy (XAS) to demonstrate the differences in spin state ratios during heating and cooling cycles. A 25-layer Pd thin film was determined to have a thickness of 0.760 ± 0.04 μm using a scanning electron microscope (SEM). The SCO behavior of the Pd thin film was analyzed using a superconducting quantum interference device (SQUID), and the results suggest the presence of an incomplete spin transition with some evidence of hysteresis. Based on the results from comparing the SCO behavior of thin films with varying number of layers (i.e., film thickness), the SCO behavior appears to improve with film thickness. This alludes to the fact that by increasing the number of layers to beyond 25, this method can potentially be used to fabricate thin films with optimal SCO behavior. When compared to the bulk powder results, the hysteresis loop of the thin film was not abrupt and the spin transition was incomplete, but the general shape was similar and both loops were centered around room temperature. Although further optimization is required to improve the quality of the films, our initial results have demonstrated the use of this simple solution-phase deposition method in the fabrication of SCO thin films.

SESSION S.EL12.04: Multiferroic and Magnetoelectric Materials

5:00 AM *S.EL12.04.02
Magnetoelectric Coupling by Piezoelectric Tensor Design Mark S. Rzchowski1, J. Irwin1, S. Lindemann1, W. Maeng1, J.J. Wang2, V. Vaithyanathan1, Jiamian Hu1, Long-Qing Chen2, D.G. Schlom3 and Chang-Beom Eom1; 1University of Wisconsin-Madison, United States; 2The Pennsylvania State University, United States; 3Cornell University, United States

Strain-coupled magnetoelectric (ME) phenomena in piezoelectric / ferromagnetic thin-film bilayers are a promising paradigm for sensors and information storage devices, where strain manipulates the magnetization of the ferromagnetic film. In-plane magnetization rotation with an electric field across the film thickness has been challenging due to the large reduction of in-plane piezoelectric strain by substrate clamping, and in two-terminal devices, the requirement of anisotropic in-plane strain. Here we show that these limitations can be overcome by designing the piezoelectric strain tensor using the boundary interaction between biased and unbiased piezoelectric. We fabricated 500 nm thick, (001) oriented \([\text{Pb(Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3]\)0.7-\([\text{PbTiO}_3]\)0.3 (PMN-PT) unclamped piezoelectric membranes with ferromagnetic Ni overlayers. Guided by analytical and numerical continuum elastic calculations, we designed and fabricated two-terminal devices exhibiting electric field-driven magnetization rotation. We develop a method that can apply designed strain patterns to many other materials systems to control properties such as superconductivity, band topology, conductivity, and optical response. We also discuss how these effects depend on the crystallographic orientation.

5:30 AM *S.EL12.04.03
Control of Ferromagnetic Skyrmions Using Ferroelectric Polarization Tae Won Noh, Seoul National University, Korea (the Republic of)

Ferromagnetic skyrmion is a topologically protected whirling spin texture in nanoscale. Due to its small size, topologically-
protected stability, and solitonic nature together, it holds great promise for future spintronics applications. To translate these compelling features into practical spintronic devices, we should face a key challenge in achieving effective control of skyrmion properties, such as size, density, and thermodynamic stability. Recently, we reported the discovery of ferroelectrically tunable skyrmions in ultrathin BaTiO3/SrRuO3 bilayer heterostructures. The ferroelectric proximity effect occurring at the BaTiO3/SrRuO3 heterointerface can trigger a sizable Dzyaloshinskii-Moriya interaction. Thus the interaction between two ferroic materials can stabilize robust skyrmions with diameters of several tens of nanometers.[1] Moreover, by manipulating the ferroelectric polarization direction of the BaTiO3 layer, we could achieve local, switchable and nonvolatile control of both skyrmion density and thermodynamic stability. Such a ferroelectrically tunable skyrmion system can work as a new paradigm to simultaneously enhance the integratability and addressability of skyrmion-based functional devices.

**Enhanced Magnetostriction in FeGa Epitaxial Thin Films**

*John T. Heron*1, Peter Meisenheimer1, Rachel Steinhardt2, Shihao Zhuang3, Suk Hyun Sung3, Mark Nowakowski2, Steve Novakov3, Bhagwati Prasad4, Chris Zollner2, Zhe Wang2, Natalie Dawley2, Allen Hunter1, Sasikanth Manipatruni2, Dmitri Nikonov3, Ian Young3, Long Qing Chen4, Jeffrey Bokor4, Ramamoorthy Ramesh4, Robert Hovden1, Jiamian Hu3 and D.G. Schlom2; 1University of Michigan, United States; 2Cornell University, United States; 3University of Wisconsin–Madison, United States; 4University of California, Berkeley, United States; 5Intel Corporation, United States; 6The Pennsylvania State University, United States

Composite multiferroics, composed of a magnetostrictive ferromagnet and a piezoelectric ferroelectric, hold promise for magnetic field sensors and energy efficient beyond-CMOS logic by harnessing magnetoelectric transduction. Enhancing device performance requires highly magnetostrictive materials, however, relatively little attention has been given to engineering magnetostriction in thin films. One promising magnetostrictor system are the Fe$_{1-x}$Ga$_x$ alloys yet in bulk, the magnetostriction coefficient of Fe$_{1-x}$Ga$_x$ alloys versus gallium composition peaks near ~18% Ga due to a phase change from the disordered A2 phase to an ordered BCC phase (D0$_{22}$). Here we discuss a means to boost (by 200-300% relative to bulk) the magnetostriction of Fe$_{1-x}$Ga$_x$ thin film alloys by extending the phase stability of the A2 phase to higher Ga compositions. Transport-based magnetoelectric characterization of a Fe$_{1-x}$Ga$_x$-[Pb(Mg$_{1/3}$Nb$_{2/3}$)O$_3$]$_{0.7-}[PbTiO_3]_{0.3}$ (PMN-PT) composite multiferroic heterostructure shows are reversible 90 deg electrical switch of magnetic anisotropy and a room temperature converse magnetoelectric coefficient of 5.5×10$^{-6}$ s m$^{-1}$.

**Deterministic and Robust Magnetic Rotation with an Electric Field in a Concave Triangular Nanomagnet**

*Ren-Ci Peng*1, Long-Qing Chen1, Ziyou Zhou1 and Ming Liu1; 1Xi’an Jiaotong University, China; 2The Pennsylvania State University, United States

Deterministic magnetic switching driven by electric fields rather than power-dissipating currents on the nanoscale is fundamentally challenging yet promising for applications to energy-efficient and high-density spintronic devices. Here, we demonstrate an electric-field-controlled deterministic, robust and reversible 120° rotation of ‘Y’-like magnetic state in a patterned nanoscale multiferroic heterostructure consisting of a concave triangular nanomagnet on the Pb(Mg$_{1/3}$Nb$_{2/3}$)O$_3$-PbTiO$_3$ film. The nanomagnet is juxtaposed with an overlying antiferromagnetic layer to acquire an exchange bias from their interface. Using phase-field simulations, we find that the rotation of ‘Y’-like magnetic state is controlled by a synergistic effect of strain-mediated electric-field-induced uniaxial magnetoelastic anisotropy, magnetic in-plane shape anisotropy of the concave-triangle-shaped nanomagnet, and an interfacial exchange-bias field. It is also shown that deterministic magnetic state switching can be accomplished by a pulsed strain, the duration of which can span from a few seconds or longer down to a few nanoseconds, providing great design flexibility. We also discussed the dynamics of electric-field-driven switching of ‘Y’-like magnetic state as well as the influence of lateral size, thickness and shape variation (i.e. concave radius) of the nanomagnet on the critical strain for the switching. These results offer a new and technologically viable route to designing nanomagnet-based nonvolatile spin memories with high density and low power.

**Progress in Magnetoelectric Composites and Device Applications**

*Shuxiang Dong, Zhaoqiang Chu, MohammadJavad PourhosseiniAsl and Zhonghui Yu; Peking University, China*

Incorporating ferromagnetic, ferroelectric and ferroelastic orders inherently in a single-phase multiferroic material or manipulating one ferroic order with the others via interfacial coupling effects in multiferroic heterostructures has driven significant research activities aiming at the realization of their technological potential in the field of sensors, RF electronics,
logic devices and memory etc. Magnetoelectric (ME) effect is essentially referred to as a change of electrical polarization (P) induced by external magnetic field (H) or a control of magnetization (M) via applied electric field (E). This report first introduces our recent progress in laminated ME composites consisting of a [011]-oriented Pb(Mg,Nb)O₃-Pb(Ti,Zr)O₃ (PMN-PZT) single-crystal fiber laminated with laser-treated amorphous FeBSi alloy (Metglas). High ME coupling coefficient around 10 kV/cm*Oe has been achieved. We will then review recent advances in multi-layered ME composites as well as their device applications including magnetic field/current sensors, dual-stimulus energy harvesters, ME memories, ME gyrotrons and tunable electronics. Some perspectives in terms of the future of magnetoelectric composites and devices will also be provided.

7:15 AM S.EL12.04.09

Synthesis of Multiferroic Nanoparticles and Their 3D Printed Silicon Elastomer Polymer Composites Felicia Horne¹, Soodabeh Azadehranjbar², Zahra Ahmadi², Archit Dhingra², Peter Dowben², Jeffrey Shield², Naga S. Korivi¹ and Vijaya K. Rangari¹; ¹Tuskegee University, United States; ²University of Nebraska, United States

There is great interest in composites of polymers and multiferroic nanoparticles for advanced electronic applications. There has been very little work done in the rapid prototyping of such composites. We report the fabrication of composites of silicone elastomer, and barium titanate/iron oxide nanoparticles. Multiferroic nanoparticles of Barium titanate/iron oxide were synthesized using sonochemical reaction of iron acetate, urea, barium titanate nanoparticles in a solvent. This results in iron oxide nanoparticles formed on and near the barium titanate nanoparticles. A subsequent sintering process improves the crystalline nature of the iron oxide. The barium titanate/iron oxide nanoparticles are combined with a moldable silicone elastomer (Dowsil MS-4007) at 5% weight ratio and loaded onto an extrusion head of a commercial 3D printer. Printing on a base maintained at 100°C results in the formation of solid nanocomposite layers. Observations will be presented from characterization of these layers by electrical and magnetic studies, microscopy, mechanical and thermal studies.

7:25 AM *S.EL12.04.11

Observation, Manipulation and Understanding of Coupled Multiferroic Domains in Single-Phase Magnetoelectrics Tsuyoshi Kimura; The University of Tokyo, Japan

Symmetry breaking ascribed to the evolution of an order parameter is one of the most important concepts in ferroic materials such as ferromagnets and ferroelectrics, and bears “domain” structures. The domain switching by an external field is the key principle to exploit them for practical applications. In multiferroics, materials possessing multiple ferroic order parameters, the respective order parameters form domains and multiple types of domain states coexist. It is well-accepted that couplings between the multiple order parameters and domain states are essential for macroscopic magnetoelectric phenomena in multiferroics. However, there are few reports that directly compare responses of coexisting domain states to external fields and macroscopic magnetoelectric properties. In this presentation, we show selective observations of multiple magnetic order parameters and domain structures in some single-phase magnetoelectrics. This work has been done in collaboration with H. Ueda, R. Misawa, T. Katsuyoshi, J. K. H. Fischer, K. Kimura, Y. Tanaka, Y. Wakabayashi, T. Honda, J. S. White, M. Kenzelmann, A. B. Harris, N. Leo, and M. Fiebig.

7:55 AM S.EL12.04.12

Electrical and Magnetic Properties of Thin Single Crystal Cr₂O₃ Films Nguyen M. Vu¹, Xiangpeng Luo¹, Steve Novakov¹, Wencai Jin², Johanna Nordlander³, Peter Meisenheimer¹, Morgan Trassin³, Liuyan Zhao¹ and John T. Heron¹; ¹University of Michigan, United States; ²Auburn University, United States; ³ETH Zürich, Switzerland

Magnetoelectric materials have been of great interest due to their potential for low-power spintronic devices via the electric field switching of magnetization. Antiferromagnet Cr₂O₃ is one of a very few room temperature magnetoelectrics and possesses unique properties such as uncompensated surface spins and perpendicular magnetic anisotropy. [1] Since the first demonstration of the electric field control of exchange bias in bulk single crystal Cr₂O₃ heterostructures [2], intense effort has focused the demonstration of magnetoelectric switching using Cr₂O₃ thin films at room temperature. [3,4] The existence of twin domains in thin films grown on metallic electrodes, however, leads to high leakage current and dielectric breakdown fields that can only be circumvented by growing rather thick films (250-500 nm). [4,5] By using an isostructural epitaxial oxide electrode, V₂O₅, recent studies have shown the reduction and even possible elimination of twin domains in Cr₂O₃ films. [3] Dielectric and magnetoelectric switching studies of 200 nm thick films show bulk like performance, however, for next generation logic and memory the films must be scaled down. [6]

Here we present an investigation of the electrical endurance and magnetic properties of very thin (30-60 nm) single crystal Cr₂O₃ films grown by pulsed laser deposition onto V₂O₅ buffered (0001) oriented Al₂O₃ substrates. Our results show that 60 nm single crystal thin film has bulk-like resistivity (10¹² cm) and significantly improved breakdown voltage (150-300...
MV/m). Using magnetometry, we investigate exchange bias of thin film Cr$_2$O$_3$/ferromagnet heterostructure. The blocking temperature is found to be at 285 K which is higher compared to twinned films with similar or greater thickness in literature. Further, Second Harmonic Generation confirms bulk magnetoelectric order of our single crystal thin film at room temperature. These results indicate the importance of crystallinity to realize bulk like properties in very thin films at room temperature.

8:10 AM *S.EL12.04.13
Active Control of Spin Waves in Multiferroic Heterostructures Sebastiaan van Dijken; Aalto University, Finland

Active manipulation of spin waves is essential for the development of magnon-based technologies. One route towards this goal exploits reprogrammable magnonic crystals. In such structures, a varying spatial modulation of magnetic properties using, for instance, electric currents [1] or optical pulses [2] controls the transmission of spin waves. Besides these dynamic approaches, field-induced toggling between ferromagnetic and antiferromagnetic states in magnetic stripe arrays has been shown to modify spin wave transport in a non-volatile way [3].

Multiferroic heterostructures comprising coupled ferromagnetic and ferroelectric layers offer an interesting alternative as programmable hybrids for magnonics. Attractive properties of multiferroic heterostructures include the imprinting of magnetic domain patterns, the creation of abrupt anisotropy boundaries, strong pinning of magnetic domain walls, and electric field control of magnetic anisotropy, magnetic switching, and magnetic domain wall motion [4-6].

Here, we demonstrate that multiferroic heterostructures provide a versatile platform for the emission of short-wavelength spin waves [7], the confinement of spin wave modes in structurally uniform films [8], and active manipulation of spin wave transmission [9]. The multiferroic heterostructures consist of a ferroelectric BaTiO$_3$ substrate and a strain-coupled ferromagnetic film with a thickness of 20 – 50 nm. At room temperature, this material system comprises fully correlated stripe domains in the ferroelectric and ferromagnetic subsystems. Utilizing strong pinning of ferromagnetic domain walls onto ferroelectric boundaries, we demonstrate active manipulation of spin wave transmission from 0% to 100% by non-volatile reprogramming of the domain-wall spin structure in a magnetic field [9]. In addition to magnetic field control, we also present recent results on active manipulation of spin wave transmission using electric fields. This sought-after effect originates from local strain-induced changes of the magnetic anisotropy. We demonstrate that the transmission of spin waves can be fully turned on and off in certain frequency bands by the application of voltage pulses across the BaTiO$_3$ substrate.

The multiferroic heterostructures allow also for continuous tuning of the spin wave phase and amplitude, offering prospects for voltage-controlled magnonic logic.

S.EL12.05.01
Multi-level Tactile Ferroelectric Field Effect Transistor Sensing Memory 

Kyuho Lee and Cheolmin Park; Yonsei University, Korea (the Republic of)

A tactile memory, which can sense and memorize the external stimuli, has been reported up to date with great potential in emerging wearable electronics. To realize bi-functional systems for sensing and memorizing, two device platforms integrated with tactile sensor and memory have drawbacks from physically bulky systems as well as increase of circuit resistance from wire connection, giving rise to low sensing sensitivity. In particular, a binary memory with bi-level state of ON/OFF has limitation in storing multi-level sensing information that requires multiple memory array. A multi-level memory-based single device platform without the integration is, therefore, on demand.

Herein, we demonstrate a non-volatile multi-level tactile memory based on a single ferroelectric-gate field-effect transistor (Fe-FET) allowing for intelligent electronic skins (e-skins), which can sense, memorize, and then retrieve the tactile information. Pressure-sensitive top-gate shape formation can precisely sense and memorize the external pressure stimuli by making an underlying ferroelectric film polarized according to the size of the contact area between top-gate and ferroelectric film, giving rise to variation of gate voltage supply. Our tactile 1-transistor memory exhibits high sensitivity of >90 kPa⁻¹ at low pressure stimuli of <1.5 kPa, and shows good reliability in multiple programming and erasing up to 50 cycles and long-term stability even with bending radius of 6 mm. Tactile memory arrays showing precise spatial positioning of external stimuli with non-volatile multi-level sensing, memorizing, and then retrieving after one week have broad applications suitable for wearable human-interactive electronics.

Effect of Sintering Temperature/Particle Size on Structural, Magnetic and Transport Properties of Polycrystalline 

Nd₀.₅Ca₀.₅MnO₃ Manganites 

Dharmendra Raghav¹, Harikrishna Singh² and Ghanshyam D. Varma¹; ¹Indian Institute of Technology Roorkee, India; ²C.S.I.R. N.P.L., India

Nanosized materials, such as nanoparticles, nanowires, nanotubes, and nanocomposites are currently the focus of intense investigations due both to the physics they involve and to their potential for revolutionary technological applications. The applications are expected to be in a wide variety of diverse areas, such as logic circuits, magneto-electronic devices, magnetic data storage, medicine, and biotechnology. The phenomena and properties behind these applications are unique to nanodimensions, such as quantum confinement effects and enhanced surface to volume ratio. So, we have investigated the effect of particle size/sintering temperature on structural, magnetic and transport properties in Nd₀.₅Ca₀.₅MnO₃ system. Different size materials have been synthesized using Sol-gel method and sintered at 900 , 1100 and 1300 degree Centigrade to get the samples of different particle sizes. Phase pureness of the samples has been confirmed by Rietveld refinement of the powder X-Ray diffraction (XRD) data, which authenticates orthorhombic structure with Pnma space group. All three lattice constants (a, b and c), bond lengths and bond angles decrease with increasing particle size. The magnetization measurements (H@500 Oe) as a function of temperature exhibit paramagnetic (PM) to ferromagnetic (FM) transition and also brings out that (i) the divergence between the zero field cooled (ZFC) and field cooled cooling (FCC) magnetization decreases with increasing particle size, (ii) all samples show charge ordering at 250 K, (iii) the sharp drop of ZFC magnetization for all samples. At low temperatures a glassy behaviour is visible at higher particle size. The isothermal magnetization loops confirm the increase in the FM component at higher particle size at low temperature (20 K). The temperature dependent resistivity of all samples have been measured without magnetic field and resistivity measurements show no insulator to metal transition at lower sintering temperature but at higher sintering temperature the metal to insulator transition has been found. The data of resistivity have been fitted by using variable range hopping model (VRH). Characteristic temperature (Tc), localization length (1/α) and average hopping distance (R) have been calculated by using this model. X-ray photoemission spectra of Mn2p and Mn2s core-level confirm dual valence state of Mn (Mn³⁺ and Mn⁴⁺), which is responsible for the magnetic behaviour of NCMO system. The correlation between the transport and observed magnetic properties of sintered NCMO samples will be described and discussed in paper.

Domain Size Effects on Piezoelectricity in Lead-Free Ferroelectric Single Crystals 

Bo Wang¹, J.J. Wang¹, Fei Li²,¹ and Long-Qing Chen¹; ¹Pennsylvania State University, University Park, United States; ²Xi’an Jiaotong University, China

Domain size is known to play a critical role in electromechanical properties of domain-engineered ferroelectric single
For lead-based relaxor-PbTiO$_3$ crystals, nanosized polar regions are believed to be the origin of giant piezoelectricity. For lead-free systems such as [111]-poled tetragonal ferroelectric BaTiO$_3$ crystals, enhanced piezoelectricity has been reported by reducing the domain size from hundreds to several microns. These examples lead to a long-standing belief that the smaller the domain size, the higher the piezoelectricity. Our recent study reveals an alternative route to improve piezoelectricity by increasing the size of domains through AC poling in relaxor-PbTiO$_3$. In this poster, we will discuss the general domain size effect on piezoelectricity in prototypical non-lead perovskites in tetragonal, orthorhombic, and rhombohedral ferroelectric phases, such as BaTiO$_3$, K$_{0.5}$Na$_{0.5}$NbO$_3$, and BiFeO$_3$, by examining the effective piezoelectric coefficients of engineered domain structures using a combination of thermodynamic analysis and phase-field simulations. We find that the domain size effect on piezoelectricity depends on the symmetry of the ferroelectric phase. The size effect becomes significant when the domain is reduced to a critical size (~ sub-100 nm) which depends on the proximity to a ferroelectric-ferroelectric phase transition and on the width of domain walls. Moreover, the domain size effect has a strong anisotropy, giving rise to opposite trends for different piezoelectric tensor components as well as varying along different probing directions. By separating the contributions from domains and domain walls, we reveal that the size effect is majorly originated from the modification of thermodynamic states of domains due to the presence of domain walls. We also reveal that the domain size effect on piezoelectricity can be understood as a competition between the domain size effects on the dielectric permittivity and on the polarization rotation. The former is related to the flattening of free energy landscapes, while the latter is due to the built-in fields between domain walls. Besides, we predict a convenient way of controlling the domain size by poling via an alternating electric field. This work offers a thermodynamic-based understanding of the domain size effect and brings new insights into the fundamental knowledge of the processing-microstructure-property relationship in piezoelectric single crystals.

**Bio-Inspired Organic Artificial Nerves for Peripheral Nerve Emulation**
Tae-Woo Lee$^1$, Zhenan Bao$^2$, Yeongjun Lee$^1$, Jin Young Oh$^2$, Yeongin Kim$^2$, Alex Chortos$^2$, Wentao Xu$^1$ and Dae-Gyo Seo$^1$; $^1$Seoul National University, Korea (the Republic of); $^2$Stanford University, United States

Biological nerves have evolved toward functionalities to efficiently process complex information in real-time. Unlike biological nerve system, von Neumann based computing system performs in centralized and sequential form which has
difficulty in event driven and parallel operation. In this regard, there has been many efforts to adopt the superior characteristic of biological nervous system and the concept of neuromorphic electronics have emerged. As the synaptic behavior can be implemented through single artificial synaptic device, it can emulate the functions of biological sensory and motor neurons when combined with sensors and actuators. Making the artificial nervous system desirable for soft robotics and neuroprosthetics have been widely investigated.

Here, artificial nervous systems were developed by using organic electronics to emulating peripheral nervous system. Pressure sensors (artificial mechanoreceptors), organic ring oscillators (artificial nerve fibers), and synaptic transistors were integrated to emulate the biological sensory nerve system. By forming hybrid reflex arc which connects artificial sensory nerve and biological motor nerves the applicability for neural prostheses was verified and the biological motor nerves were actuated depending on external pressure information. In addition, by integrating a stretchable artificial synapse, and a polymer actuator (an artificial muscle), stretchable artificial sensorimotor nervous system was developed. The optogenetics was emulated by contracting the artificial muscle with light stimulation. In parallel, the system distinguished the alphabet Morse code which showed the potential as an optical wireless communication method for human-machine interface. Furthermore, by integrating a triboelectric sensor for an artificial auditory system, artificial auditory system was emulated. We modulated morphology of organic semiconductors of the artificial synapses to implement the specific recover time of biological synapse facilitation. Our organic artificial nerve systems suggest promising strategy for bioinspired electronics, soft robotics, and neuroprosthetics.

The Mixed Conductivity in Highly-Ordered Polypyrrole Hybrid Materials Myung-Han Yoon, Ji Hwan Kim, Zubair Ahmad and Jaesuk Lee; Gwangju Institute of Science and Technology, Korea (the Republic of)

In this research, we report the effect of crystallinity on the mixed conductivity of highly-ordered polypyrrole film. Polypyrrol-4,4'-biphenyldisulfonic acid (poly(Py:BPDSA:Py)) hybrid was synthesized by oxidative polymerization after connecting two pyrrole monomers with various stoichiometric ratios of BPDSA in the aqueous solution. The structural and electrical/electrochemical analysis revealed that the increase in BPDSA content enlarges the crystallite size from 18.9 to 52.1 nm, the ratio of crystalline to amorphous domains by 6 times, the electrical conductivity from 174 to 406 S/cm, and the volumetric capacitance from 85 to 672 C/cm³, while the doping concentration extracted from Hall measurement and electrochemical analysis remains unchanged. On the other hand, the resultant poly(Py:BPDSA:Py)-based organic electrochemical transistors (OECTs) showed the maximum value of transconductance (0.5 mS) at the intermediate composition of BPDSA, which can be attributed to the retardation of ion movement in highly crystalline polymeric film. The repeated OECT operation revealed the stable current on-off ratio over 2 x10² without the significant loss in transconductance. All these results suggest that the mixed conductivity of poly(Py:BPDSA:Py) can be strategically modulated by engineering the crystallite size.

Nanocrystalline Organic Semiconductor Photocatalysts—A Dominance of Oxygen Reduction Reactions Eric D. Glowacki1,2; 1Linkoping University, Sweden; 2Warsaw University of Technology, Poland

Semiconductor-based catalysts can convert solar energy into chemical fuels such as hydrogen, hydrogen peroxide, or hydrocarbons produced via carbon dioxide reduction. Long overlooked due to stability concerns, some organic semiconductors have recently emerged as promising electrocatalysts and photocatalysts for operation in aqueous environments. Our attention has focused on nanocrystalline pigment-type organic semiconductors, which stand out due to stability and performance. Generally, we have found a high selectivity of organic semiconductors for oxygen reduction reactions, by both one-electron and two-electron pathways. The products of these reactions are superoxide or hydrogen peroxide. We find this occurs on numerous organic semiconductors and conducting polymers in a pH range from 1 to 12. The large pH stability window is remarkable when compared with inorganic counterparts. We have found that while photogenerated electrons reduce oxygen, the fate of the holes represents a complex picture. When the nanocrystalline semiconductor is used as a photocathode and efficient p-type transport is available, photogenerated holes can easily be extracted to an external circuit. If this is not possible or inefficient, the hole will either oxidize electron-donors in solution or precipitate autooxidation reactions of the semiconductor itself. The factors affecting this photocorrosion effect will be discussed, as well as principles leading to stabilization of the semiconductor catalyst. The possibilities of solar energy conversion into the high-energy molecule H₂O₂ enabling carbon-neutral energy storage in liquid form, in contrast to gaseous H₂, will be covered. Organic semiconductors have potential to become a powerful class of intrinsic catalysts, tunable by molecular design.

**Patterning Organic and Hybrid Semiconductor Microstructures for Electronics and Optoelectronics**  
Aram Amassian; North Carolina State University, United States

The transport properties and device performance of organic semiconductors is determined by the microstructure and morphology of polycrystalline thin films, including grain size, domain orientation and grain boundaries. For device applications, such as field-effect transistors, controlling the domain orientation and grain boundaries is particularly important as this mediates charge transport in the channel of the device. More generally, the opportunity to fabricate single crystal domains to match the device architecture would be a very promising pathway to unlock the intrinsic properties of organic and hybrid semiconductors. This presentation will discuss recent efforts to reduce and even eliminate grain boundaries in solution-processed organic and hybrid semiconductor films, with such applications as high performance field-effect transistors, photodetectors and light emitting devices envisioned. Approaches based on patterning the microstructure of thin films post-deposition or in situ will be discussed, as well as additive manufacturing-based coating and printing methods of delivering materials with single crystal-like properties at designated locations.

**Gating Semiconducting Polymers with Ionic Conductors**  
Michael L. Chabinyc; University of California, Santa Barbara, United States

Electrical doping of semiconducting polymers requires introduction of counter ions to maintain electroneutrality. These counter ions can modify electronic charge transport by changing the microstructure of the semiconductor and by electrostatic interactions between the charge carriers and their counter ion. We will discuss our recent work using single ion conducting polymers, known as polymeric ionic liquids, as the dielectric in transistors with semiconducting polymers. Polymeric ionic liquids (PILs) have tethered ionic functional groups on their backbone with an untethered counter ion leading to single ion conductivity. By appropriate molecular design of the PIL, the operation of polymer transistors can be switched from an electrical double layer mechanism to electrochemical doping of the bulk. The behavior of transistors with PIL gates reveals the differences in the electrical conductivity at the surface and bulk of semiconducting polymers at high charge carrier concentrations. The role of the infiltration of ions on the electronic density of states of semiconducting polymers can also be determined by measurements of the thermopower of electrochemical transistors. Our results show that electrochemical doping leads to a broadening of the DOS and helps to rationalize recent models for charge transport in semiconducting polymers at high carrier densities.

**Charge Transport and Thermoelectric Properties of High Mobility Conjugated Polymers**  
Henning Sirringhaus; Cambridge University, United Kingdom

Over recent years several new classes of conjugated polymers have shown promise as materials for polymer field-effect transistors with high field-effect mobilities. Many of the recently discovered high mobility polymers, in particular donor-acceptor copolymers, owe their excellent charge transport properties to a low degree of energetic disorder associated with a well-defined backbone conformation with small variations in torsion angles. In this presentation we will present our current understanding of the transport physics of these materials and focus in particular on the relationship between molecular structure, thin film processing and charge transport and thermoelectric properties of these materials. We will discuss new approaches for the doping of these polymers and for understanding their thermoelectric physics.

**ElectroNanopatterning and Template Arraying of Organic Semi-Conducting Polymers**  
Rigoberto C. Advincula; Case Western Reserve University, United States

The fabrication and manipulation of organic semiconductors as thin-film devices have met the challenge of combine structure-property relationships in practical devices even up to the nanoscale. This talk will focus on the use of pi-conjugated...
polymer precursors for electro-patterning nano-resolution patterns using conducting or current-sending AFM. The method involves the rational approach of preparing organic pi-conjugated polymers capable of crosslinking and also electrochemical activity. The interest is on light-emitting diode (LED) devices and photovoltaic (PV) devices. By using the precursor polymers, electrochemical methods capable of depositing as insoluble films or patterns enable patterning and multilayer formation. Application of a bias-voltage from an AFM tip is used for electronanopatterning but also junction-tunneling allows for signal voltage-current measurement – making them useful for memory devices or sensing. We will also describe the use of colloidal nanosphere lithography in producing arrays of conducting polymers with I-V behavior as probed by conducting SPM methods. These techniques demonstrate the ability to bring materials properties from bulk behavior up to the nanoscale.

Graphene-Templated Growth of Organic Semiconductors for Organic Electronics Kilwon Cho, Nguyen Ngan Nguyen and Hyo Chan Lee; Pohang University of Science and Technology, Korea (the Republic of)

High-performance organic electronic devices require organic semiconductor (OSC) thin films to possess desired microstructures. An effective approach is the use of graphene as a template for controlling growth behavior of OSC crystals. Unlike on ordinary substrates, the growth modes of OSCs on graphene are not only determined by the graphitic surface structure but also electronic characteristics of graphene. In this talk, I will discuss how OSC molecules assemble on graphene surface under the influence of graphene’s doping effect. Also, I will discuss a result that the OSC films grown on a graphene template under an optimized condition provide favorable vertical and lateral transport pathways for charge carriers and excitons in organic transistor and photovoltaic devices.

High Efficiency Actuators from Cellulose Acetate-Polyaniline Based Bilayer Najathulla Bhagavathi Chalil, Mudrika Khandelwal and Atul Deshpande; Indian Institute of Technology Hyderabad, India

Polyaniline is a well known conducting polymer preferred owing to facile synthesis and various oxidation states. Polyaniline, on application of a potential bias attracts oppositely charged ions causing volume expansion. This reversible expansion is exploited to prepare bilayer actuator with cellulose acetate electrospun mat as the substrate. A stable deflection of over 1 mm was observed at 1 V. Effect of amount and properties of polyaniline on deflection is studied along with energy conversion efficiency. This electro-chemical actuator can have potential applications in biomimetic soft robotics.

6:00 AM *S.EL13.01.06
Engineering Uniform Nanorod Arrays Optimized for Light Energy Harvesting Stephanie Lee; Stevens Institute of Technology, United States

Organic photovoltaics typically comprise two components in the photoactive layer – an electron donor and an electron acceptor – to overcome large excitonic binding energies in these Van der Waals systems. With typical exciton diffusion lengths in organic semiconductors on the order of 10 – 100 nm, the ideal structure of OPV photoactive layers comprises interdigitated crystalline domains of the electron donor and acceptor on the hundreds of nanometers lengths scale. Here, we present a novel strategy to form single-crystalline organic semiconductor nanoparticle arrays in situ during solution-phase deposition, with the size, orientation and spacing determined by nanostructured scaffolds at the substrate interface. Specifically, nanoporous scaffolds are introduced to the surface of device platforms that confine organic semiconductor nucleation at the air-solution-surface interface during a continuous dip coating process. These nuclei preferentially orient with their fast growth direction aligned parallel to the long axis of the pores. Subsequent crystallization proceeds beyond the scaffold to form uniform arrays of high-density, vertical nanorods with large exposed surface area. X-ray diffraction analysis has revealed that the vertical nanorods are oriented with the π-stack direction perpendicular to the substrate surface, the optimal orientation for light absorption and charge transport in organic solar cells and other devices with a sandwich electrode configuration. The height, diameter, and spacing of these nanorods are further tunable by varying the scaffold geometry and deposition conditions. Critically, this generalizable method to form uniform nanoparticle arrays is compatible with continuous processing methods that will enable the large-scale manufacturing of such materials.

A high-resolution microscopic gate-modulation imaging (μ-GMI) technique is recently developed to visualize spatial distribution of accumulated charges in operating organic field-effect transistors (OFETs) [1-4]. This technique utilizes high dynamic-range CMOS area-image sensor, which allows us to detect very slight change (up to 0.01%) of local optical absorption intensity in the channel semiconductor layers. The highly-sensitive and diffraction-limit μ-GMI becomes possible by taking advantage of the difference image sensing between at gate-on and gate-off states that are alternately biased. We successfully demonstrated that the technique is extremely useful for the microscope observations of channel charge and field distribution for studying carrier transport physics in OFETs [1,2], as well as for the rapid and collective inspection of thin-film transistor arrays [3,4].

Here we focus on the μ-GMI observations for model OFETs composed of high quality pentacene single-crystal channels that are fabricated by physical vapor transport technique and are attached on perfluorinated Cytop insulating layer coated on semitransparent substrates. We show that anomalously large GM signals appear through the whole channel region, when the drain voltage, which is comparable to the applied gate voltage, is biased (i.e., saturation regime): The observed GM signal intensity reaches as high as ~1x10^{-2}, which is in contrast to the much weaker GM signals (~1x10^{-4}), as observed without the application of drain voltage. Peculiar feature is that the GM signal is considerably enhanced around the pinch-off point where the carriers should be depleted. We point out that the observation should be associated with the unexpectedly inhomogeneous distribution of positive and negative local GM signals in polycrystalline pentacene TFTs [1]. We discuss the origin of these “undefinable” operating channel states in terms of the electric-field effect on charged molecules in intrinsic organic semiconductors, on the bases of further experimental results on the polarization-dependent analyses of GM spectra as well as the effect of the use of trap-free perfluorinated insulator interfaces.

In this research, we report the effect of crystallinity on the mixed conductivity of highly-ordered polypyrrole film. **Single-Layered Organic Photovoltaics with Double Cascading Charge Transport Pathways—17.78% Efficiencies**

Thomas P. Russell1,2, Feng Liu3, Mei Zhang3, Lei Zhu4, Guanqing Zhou1, Tianyu Hou5, Chaquan Qiu1, Qin Hu1, Bryon Larson2, Wei Fang3, Zaifei Ma5, Zheng Tang1, Haiming Zhu1 and Yongming Zhang1; 1University of Massachusetts Amherst, United States; 2Lawrence Berkeley National Laboratory, United States; 3Shanghai Jiao Tong University, China; 4National Renewable Energy Laboratory, United States; 5State Key Laboratory of Fluorinated Functional Membrane Materials, China; 6Donghua University, China; 7Zhejiang University, China

The chemical structure of donors (Ds) and acceptors (As) has been a limitation to the achievable power conversion efficiencies (PCEs) of bulk heterojunction (BHJ) active layers of binary D-A mixtures in organic photovoltaics. While new syntheses can be used to generate Ds and As, a holistic strategy that simultaneously improves open circuit voltage, short circuit current, and fill factor is necessary and has been pursued using different approaches in organic photovoltaics (OPVs) to PCEs. This holistic approach, though, has been elusive, due to morphological constraints and the inherent electronic structures of the components, leading to performance trade-offs. Ideally, both the morphology and electronic structure would lead to a maximization of light absorption, enhancement of exciton splitting, and ease of carrier extraction. Adding a third component has been done, resulting enhancement of either the morphology or electronic structure leading to PCE improvement, but only incremental, at best. However, using quaternary D-A blends, double cascading energy level alignment in BHJ organic photovoltaic active layers are realized, enabling efficient carrier splitting and transport, without perturbing the desired BHJ morphology. This has led to record-breaking PCEs of 17.78% where, by electronic structure and morphology optimization, simultaneous improvements of the open-circuit voltage, short-circuit current and fill factor are realized. This strategy opens numerous avenues to optimize light absorption, carrier transport, and charge transfer state energy levels by the chemical constitution of the components. The chemical structures of the Ds and As offer control over electronic structure and charge transfer state energy levels, enabling manipulation of hole-transfer rates, carrier transport, and non-radiative recombination losses.

*5:30 AM* **S.EL13.02/S.EL14.03.04**

**Interplay of Phase Diagrams, Processing and Stability of Non-Fullerene Organic Solar Cells**

Harald Ade; North Carolina State University, United States

Organic solar cells (OSCs) are considered one of the most promising cost-effective options for utilizing solar energy in high energy/weight or semi-transparent applications. Recently, the OSC field has been revolutionized by the development of novel non-fullerene small molecular acceptors with efficiencies now reaching >16%. The device stability and mechanical durability of non-fullerene OPVs have received less attention and developing devices with both high performance and long-term stability remains challenging, particularly if the material choice is restricted by roll-to-roll and benign solvent processing requirements and desirable ductility requirements. Yet, morphological and mechanical stability is a prerequisite for OPV commercialization. Here, we report our current understanding of the phase behavior of OPV mixtures and the relation of phase behavior to performance, processing needs (e.g., kinetic quenches), and morphological stability via meta-stability or vitrification. Characterization methods range from SIMS and DSC measurements to delineate phase diagrams and miscibility to soft x-ray scattering and WAXS to determine critical morphology parameters and molecule packing. A large range of miscibility (from hyper-miscibility to strong hypo-miscibility) is observed, including complex temperature dependence that can be a mixture of upper- and lower critical solution temperature behavior for both the binodal and the liquidus. The
measurements presented should help to create molecular structure-function relationships that would allow some predictive guidance on how desired phase behavior and vitrification properties can be targeted by specific chemical design. They also allow to predict how unstable binary systems can be stabilized with the correct ternary compound.

6:00 AM *S.EL13.02/S.EL14.03.05
Structure, Transport and Charging in Organic Mixed Ionic/Electronic Conductors Jonathan Rivnay; Northwestern University, United States

Organic mixed ionic/electronic conductors have gained considerable interest in bioelectronics, power electronics, circuits and neuromorphic computing. These organic, often polymer-based, semiconductors rely on a combination of ionic transport, electronic transport, and high volumetric charge storage capacity. Despite recent progress and a rapidly expanding library of new materials, the understanding of stability and transport/coupling of ionic and electronic carriers remain largely unexplored. We highlight recent synthetic and processing approaches used to tailor electrochemical device properties and stability, as well as new opportunities enabled by such advances. Our understanding of critical processes in electrochemical devices further requires us to study these materials in device-relevant conditions, fully considering the effects of ions and solvent on microstructure and transport. To this end, we report on recent efforts towards structure-property relations in high performance organic mixed conductors using ex-situ, in-situ, and operando scattering and spectroscopic techniques.

6:30 AM *S.EL13.02/S.EL14.03.06
Real-Time Investigation of Crystallization Pathways of Organo-Metal-Halide Perovskites Solar by In Situ X-Ray Scattering Michael F. Toney; SLAC National Accelerator Laboratory, United States

Perovskite solar cells (PSCs) have gained tremendous attention as potential materials for photovoltaics due to their high efficiencies approaching the best silicon solar cells and their compatibility with low-cost low-temperature fabrication methods (such as solution processing). Many solution-processing approaches have been adopted to manipulate perovskite formation including anti-solvent processing, inert-gas jet treatment, and additive-assisted processing. Some of these approaches allow room-temperature processing of perovskite thin films, while other approaches require post-deposition annealing. Perovskite film formation is complex, involving the formation of intermediates and/or metastable phases that strongly affect the final perovskite film microstructure. Therefore, understanding the mechanism of perovskite formation and the crystallization pathways is key for more facile control of perovskite formation. An effective way to understand the mechanisms of perovskite formation is using real-time X-ray scattering. Here, we use time-resolved x-ray scattering to investigate the perovskite formation of MAPbI3-based perovskites and mixed cation (Cs, FA)PbI3 perovskites in-situ during spin coating and the subsequent post-deposition treatments with different processing approaches such as additive-assisted processing, anti-solvent processing and N2-gas jet treatment.

Time-resolved monitoring of the perovskite thin film processing reveals the formation of intermediate phases on the route of perovskite formation, whereas perovskite formation is dominated by a sol-gel process. For MAPbI3-based perovskites processed with the MASCN additive, we show that the nature of the intermediate precursor phases and their formation/dissociation dynamics have an impact on the extent of nucleation and growth of perovskite phase affecting the microstructure of the perovskite film. Our findings reveal that the combination of two precursors (MASCN-precursor and DMSO-precursor) with fast and slow transformation rates contributes to the formation of micron-sized perovskite crystals, through seeding nuclei combined with the slow growth of the perovskite phase. For Cs-FA-containing perovskites, we show how the competition between the non-perovskite and perovskite phases formation are affected by the processing treatments. We find that dropping anti-solvent induces immediate crystallization from the bulk wet film, whereas applying N2-gas works by depleting volatiles from the top-surface leading to interface-induced crystallization that occurs after reaching supersaturation, while both treatments result in dominant crystallization of non-perovskite hexagonal phase with the formation of seeds of perovskite phase. When neither treatment is applied, the as-cast film is mostly amorphous with little non-perovskite phase formation. We further show how the initial structure of the as-cast precursor film impacts the perovskite formation during the subsequent annealing treatment.

Our work highlights the importance of real-time investigation of perovskite film formation which can aid in establishing processing-microstructure-functionality relationships and help to provide a fundamental understanding of the mechanisms of perovskite formation.

Making Plastics Learn—High-Performance Polymer-Based Artificial Synapses are Mixed Protonic and Electronic Devices
Alberto Salleo; Stanford University, United States

The brain can perform massively parallel information processing while consuming only ~1-100 fJ per synaptic event. I will describe a novel electrochemical neuromorphic device (ENODe) that switches at record-low energy (<0.1 fJ projected, <10 pJ measured) as well as voltage (<1 mV, measured), and displays a large number of distinct, non-volatile conductance states within a ~1 V operating range. The tunable resistance behaves very linearly, allowing blind updates in a neural network when operated with the proper access device. ENODes also display outstanding endurance achieving over $10^9$ switching events with very little degradation. I will describe our recent efforts at scaling and materials selection, allowing us to reach 20 ns write pulses and operation at high temperature (up to 120°C). These properties are very promising in terms of the ability to integrate with Si electronics to demonstrate online learning and inference. ENODes are electrochemical devices where gated proton drift induces changes in the electronic states of a semiconductor channel. The peculiarities of the physics of these devices will be discussed along with their consequences on device design and performance.

Enhancement-Mode PEDOT:PSS Organic Electrochemical Transistors Using Amine-Based Molecular De-Dopants
Scott T. Keene1, Tom van der Pol2, Dante Zakhidov1, Christ Weijtens2, Rene A. Janssen2, Alberto Salleo1 and Yoeri van de Burgt2; 1Stanford University, United States; 2Technische Universiteit Eindhoven, Netherlands

The recent emphasis of point-of-care diagnostics and preventative health monitoring has led to increasing interest in electronic devices aimed at noninvasive continuous health monitoring. Organic electronic materials are well suited for bioelectronics applications because of their biocompatibility and low Young’s modulus which is comparable to that of human tissue. In particular, organic electrochemical transistors (OECTs) show promise due to their ability to convert ionic signals, which are typically found in biological systems, to electronic outputs with high gain. Furthermore, the low operating voltages (<1 V) are ideal for biological samples due to the sensitivity of cells/proteins to an applied bias. As a result, OECTs have been implemented for biosensing, ion delivery, and neural recording.

The majority of OECTs are based on the commercially available conductive polymer blend PEDOT:PSS because of its high electronic and ionic mobilities. However, PEDOT chains in PEDOT:PSS are heavily doped due to the negative charge of sulfonate anions on the PSS units, and thus OECTs must operate in depletion mode. Thus, OECTs require significant voltages (+0.8 V vs Ag/AgCl) to hold the OECT in its off state, leading to increased power consumption and device instability caused by parasitic reactions with ambient oxygen. In this work, we mitigate these inherent problems with PEDOT:PSS by introducing small molecule amine de-dopants in solution which can reduce PEDOT chains. With these additives, we effectively de-dope PEDOT:PSS to achieve electronic characteristics similar to an intrinsic semiconductor. The resulting de-doped PEDOT:PSS is used to fabricate highly stable OECTs that operate in enhancement mode while preserving the exceptional electronic and ionic transport ($\mu_h \sim 2 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$, $C^* \sim 40 \text{ F cm}^{-2}$).

This presentation describes the chemical interactions between the PEDOT:PSS and amine de-dopant molecules to understand the relationship between the film microstructure and resulting electronic structure and transport properties. We demonstrate the relationship between de-dopant concentration and OECT performance, showing a tradeoff in mobilities and transconductance with increasing de-dopant concentration. Then, we use cyclic voltammetry and ultraviolet photoemission spectroscopy to probe the electronic structure of PEDOT, showing a deeper highest-occupied molecular-orbital (HOMO) level is responsible for the shift in OECT threshold voltage. Furthermore, we investigate microstructure of the de-doped PEDOT:PSS films using grazing incidence x-ray scattering measurements (GISAXS/GIWAXS), Raman spectroscopy, and atomic force microscopy to rationalize the difference in performance across the studied amines. Finally, we develop design criteria for selecting de-doping additives to further improve the stability and performance of enhancement-mode PEDOT:PSS OECTs for low-power wearable and implantable electronic devices.

5:45 AM *S.EL13.03.04
Bio-Inspired Organic Artificial Nerves for Peripheral Nerve Emulation
Tae-Woo Lee1, Zhenan Bao2, Yeongjun Lee1, Jin
Biological nerves have evolved toward functionalities to efficiently process complex information in real-time. Unlike biological nerve system, von Neumann based computing system performs in centralized and sequential form which has difficulty in event driven and parallel operation. In this regard, there has been many efforts to adopt the superior characteristic of biological nervous system and the concept of neuromorphic electronics have emerged. As the synaptic behavior can be implemented through single artificial synaptic device, it can emulate the functions of biological sensory and motor neurons when combined with sensors and actuators. Making the artificial nervous system desirable for soft robotics and neuroprosthetics have been widely investigated.

Here, artificial nervous systems were developed by using organic electronics to emulating peripheral nervous system. Pressure sensors (artificial mechanoreceptors), organic ring oscillators (artificial nerve fibers), and synaptic transistors were integrated to emulate the biological sensory nerve system. By forming hybrid reflex arc which connects artificial sensory nerve and biological motor nerves the applicability for neural prostheses was verified and the biological motor nerves were actuated depending on external pressure information. In addition, by integrating a stretchable artificial synapse, and a polymer actuator (an artificial muscle), stretchable artificial sensorimotor nervous system was developed. The optogenetics was emulated by contracting the artificial muscle with light stimulation. In parallel, the system distinguished the alphabet Morse code which showed the potential as an optical wireless communication method for human-machine interface. Furthermore, by integrating a triboelectric sensor for an artificial auditory system, artificial auditory system was emulated. We modulated morphology of organic semiconductors of the artificial synapses to implement the specific recover time of biological synapse facilitation. Our organic artificial nerve systems suggest promising strategy for bioinspired electronics, soft robotics, and neuroprosthetics.

6:15 AM *S.EL13.03.05
Charge Transport and Thermoelectric Properties of High Mobility Conjugated Polymers Henning Sirringhaus; Cambridge University, United Kingdom

Over recent years several new classes of conjugated polymers have shown promise as materials for polymer field-effect transistors with high field-effect mobilities. Many of the recently discovered high mobility polymers, in particular donor-acceptor copolymers, owe their excellent charge transport properties to a low degree of energetic disorder associated with a well-defined backbone conformation with small variations in torsion angles. In this presentation we will present our current understanding of the transport physics of these materials and focus in particular on the relationship between molecular structure, thin film processing and charge transport and thermoelectric properties of these materials. We will discuss new approaches for the doping of these polymers and for understanding their thermoelectric physics.

6:45 AM S.EL13.03.06
Influence of Contact Resistance on the Thermal Operation Stability of Conjugated Polymer Transistors Dung T. Tran, Xuyi Luo and Jianguo Mei; Purdue University, United States

The performance drop of organic field-effect transistors (OFETs) at high temperature is usually attributed to unstable and disrupted charge transport in the channel. However, the impact of charge injection process is overlooked and rarely discussed. Here, we proved that the contact resistance has a significant influence on the behavior of the OFETs at high temperature. Two different device structures with different contact resistance, bottom-contact-bottom-gate (BCBG) and top-contact-bottom-gate (TCBG), of an Isoindigo-based polymer, were characterized from room temperature to 220°C in air. The BCBG device witnessed a substantial threshold (VT) shifting, dropping on-current and unstable output curve at temperatures above 180°C. Conversely, the TCBG devices can maintain close-to-ideal VT, high mobility, stable output curves and high on/off ratio of 10^6 at 220°C. The contact resistance of the BCBG devices, estimated using the gated-transmission line method, is much higher than that of the TCBG devices in the whole range of measured temperature. More importantly, at fixed gate voltage, the ratio of contact to channel resistance (RC/RC) of BCBG devices increases with increasing temperature that makes them heavily contact-limited at elevated temperature. The TCBG devices, on the other hand, show no sign of being contact-limited even at 220°C. This study indicated the importance of charge injection and device architecture on designing thermal resistant OFETs as well as fundamental understanding of the charge transport in conjugated polymers in extreme conditions.

7:00 AM S.EL13.03.08
Ultraflexible Organic Single Crystal Electronics through Cooperative Structural Transitions Ying Diao; University of Illinois at Urbana-Champaign, United States
Electronic materials require flexibility in order to accomplish conformal integration on nonplanar dynamic surfaces such as skins, internal organs, and textiles for wearable and implantable devices. Mechanical flexibility of electronic materials has been achieved by geometrical engineering of hard materials or by molecular design of intrinsically deformable π-conjugated polymers. The latter approach is further amenable to large-scale, low-cost solution processing. However, high intrinsic deformability of π-conjugated polymers is attained at the expense of reduced crystallinity and/or conjugation length, either by the synthetic approach to introduce dynamic bonds or through nanoconfinement to enhance chain dynamics. On the other hand, exceptional molecular ordering is the primary requirement for disorder-free charge transport. Towards this end, single crystals or long-range ordered crystalline films of organic semiconductors have been pursued, achieving charge carrier mobility above 10 cm²V⁻¹s⁻¹ for both small molecules and polymers. Despite their promising performances, single crystals or crystalline films are not tolerant to mechanical deformation. It has been revealed that strain allows a shift toward non-equilibrium packing within the elastic deformation regime (the strain window limited up to about ±2%); strain above this limit leads to brittle fractures.

How to render molecular crystals highly deformable to reconcile the conflict of mechanical flexibility and exceptional molecular ordering? An intriguing strategy offered by biological systems is the contractile tail of bacteriophage T4 virus—its tail is comprised of a protein crystal capable of undergoing strain-induced cooperative structural transition to reach a staggering 60% contraction, thereby injecting DNA into the bacteria host. A similar strategy has been applied to synthetic materials, whose atomic/molecular cooperativity enables strain accommodation mechanisms such as shape memory effect (recovery of mechanically deformed shape by thermally induced phase transition), superelasticity (mechanically induced reversible shape change through stable-to-metastable phase transition) and ferroelasticity (mechanical shape reconfiguration through deformation twinning and detwining). On the contrary, mechanically deformable molecular crystals realized through cooperative structural transition are rare and has not been reported for electronic materials and applications.

We discover that mechanically-induced cooperative structural transitions can serve as a stress-releasing mechanism when mechanical deformation surpasses the intrinsic elastic limit. Upon mechanical shearing or bending, synchronized molecular rotation and/or displacement give rise to cooperative structural transitions, i.e. superelastic polymorph transition and ferroelastic deformation twinning in organic semiconductor single crystals. Through this mechanism, organic semiconductor single crystals can tolerate an unprecedented 13% strain while maintaining >70% of the unstrained charge carrier mobility. Moreover, thermomechanical cooperative structural transitions further enable shape memory effect, paving ways to designing ultraflexible single crystal electronic devices that can memorize shape and function at once.

7:30 AM S.EL.13.03.09
Capturing the Stress-strain Behavior of Polymer Thin Films and Using the Knowledge Gained to Achieve High-Performance Stretchable Electronics Runqiao Song¹, Narup Balar¹, Salma Siddika¹, Harry Schrickx¹, Jeremy James Rech², Wei You² and Brendan T. O’Connor¹; ¹North Carolina State University, United States; ²University of North Carolina at Chapel Hill, United States

Polymer semiconductors are promising materials for stretchable electronics owing to the opportunity to achieve intrinsically stretchable films. In stretchable devices, the films are expected to repeatedly deform under cyclic strain while being operationally stable. While there have been a number of successful demonstrations, the physical origin of the deformation behavior remains elusive. This is in part due to the difficulty in probing the stress-strain behavior of the semiconductor film owing to its thin nature and in-plane cyclic loading. Here, we employ a novel method to probe the stress-strain behavior of polymer semiconductor films under large cyclic strains. This is achieved by laminating the films onto a thin elastomer substrate and testing the composite behavior in a dynamic mechanical analyzer (DMA). The elastomer provides support to handle the film but is thin enough that the semiconductor of interest can be probed. The DMA provides a highly sensitive tool to extract detailed mechanical behavior of the composite with fine control of the sample temperature and strain rate. We use this film laminated on elastomer (FLOTEx) method to study a range of conjugated polymers and compare the results to the thermomechanical relaxation of the polymers. We find that the viscoelastic characteristics of the polymer not only impact film deformation in tension but also contraction upon strain removal. We find that many DA polymers have stress-strain behavior characteristic of cold-drawing at room temperature and are unstable under cyclic strain loading. However, we show that stretchability can be improved by varying the molecular structure of the polymer to modify viscoelastic behavior, demonstrated by exploring structural variants of P3BT-FAZ. Furthermore, we show that the polymer semiconductor elastomer composites have features consistent with Mullins’ effect that is commonly observed in elastomer composites. These features include strain-softening after the first strain cycle, stress-strain behavior that tracks with a virgin sample upon greater extensions, and a permanent set that changes with applied strain. This behavior is exploited to demonstrate high-performance stretchable field-effect transistors that are stable over a 40% cyclic strain.
Secondary Thermal Relaxations of Polymer Semiconductors and Impact on Flexible and Stretchable Devices

Semiconducting polymers are attractive materials for flexible and stretchable electronics owing to favorable mechanical properties. These properties are afforded by the viscoelastic nature of the polymers, which directly impact the mechanical and thermodynamic stability of the film. Recently, dynamic mechanical analysis (DMA) have been shown to be a sensitive probe to capture thermal relaxations in conjugated polymers. This is particularly useful to study recently developed donor-acceptor (DA) type copolymers that have been shown to have complex thermomechanical characteristics without a clear glass transition. In addition, DMA probes thermal transitions under the effect of direct mechanical loads, thus, provides a complete picture of thermomechanical properties of the polymer including thermal relaxations, storage and loss moduli, stress relaxation, etc. In this talk, we report on the origin of the thermal relaxations in the representative DA polymer PBnDT-FTAZ. This is done through an analysis of the DA polymer with systematic changes to the molecular structure. We then extend this analysis to a broad set of high performance DA polymers showing the common origin of the relaxation behavior associated with side-chains, localized backbone motion, and chain slippage. We then show that these transitions have a significant impact on film toughness demonstrating that localized relaxation largely associated with polymer side-chains dictate the ductile to brittle transition of the film. Finally, we take the information gained by the thermomechanical behavior of the polymers to demonstrate high performance stretchable organic field effect transistors, and morphologically stable high efficiency organic solar cells.

Influence of Acceptor Type and Polymer Molecular Weight on the Mechanical Properties of Polymer Solar Cells

The mechanical robustness of polymer solar cells (PSCs) is of great importance to ensure the long-term stability and enable their use as power-generators in flexible and stretchable electronics. Here, we present a comparative study of the mechanical properties of small-molecule acceptor (SMA)-based, polymer acceptors (PA)-based, and fullerene-based PSCs. We chose ITIC, P(NDI2OD-T2), and PCBM as three representative acceptor materials and blended them with the same polymer donor. To understand the difference between the mechanical properties of SMA-based and PA-based PSCs, we control the number-average molecular weight ($M_n$) of P(NDI2OD-T2) from 15 to 163 kg mol$^{-1}$ in all-PSCs. The high $M_n$ PA-based-PSCs exhibited a high strain at fracture of 31.1%, which is 9- and 28-fold higher than those of SMA-PSCs and PCBM-PSCs, respectively. The superior mechanical robustness of all-PSCs is attributed to using a PA above the critical molecular weight ($M_c$), which produces tie molecules and polymer entanglements that dissipate substantial mechanical strain energy with large plastic deformation. The connectivity between the crystalline domains generated by PA tie chains leads to high charge mobilities and photovoltaics performances of all-PSCs. Also, this feature explains very high donor:acceptor composition tolerance of all-PSCs in the photovoltaic and mechanical performances. Therefore, our work highlights the importance of incorporating high $M_n$ PAs above the $M_c$ for producing the PSCs with excellent mechanical robustness and device performance.

High-Performance Solution-Processed Two-Dimensional p- and n-Type Organic Single-Crystal Transistors and CMOS Circuits

Electronic devices in the future sustainable societies require maximum function with minimum amount of constituent materials and energy cost for production. Electronic functions are often originated from two-dimensional material properties so that device components of large area and small thickness saves material consumption. The fundamental electronic functions such as switching “zero” and “one” in the digit of information are governed only by a nanometer-scale thin layer at the very surface of the semiconductor material due to the very short penetration length of electric field. Future ten-meter scale large-area display also needs to be more “two-dimensional” to save materials and save energies to carry and equip on billboards.

This presentation focuses on recently developed ultrathin organic semiconductor single crystalline films that is suitable for large-area production with low energy consumption; the films is easily formed to large area from solution at relatively low temperature at 80 degrees centigrade. Extremely thin crystal films are controllably grown to a few molecular layers with the thickness of only 10 nm, so that material cost can be only 0.01 Euro per cm2. The talk begins with material chemistry of...
designing the semiconductor molecules that causes very high carrier mobility more than 10 cm2/Vs for p-type and 3-5 cm2/Vs for n-type organic single-crystal transistors. Furthermore, Recent development of key technologies for printed integrated circuits which can provide future low-cost platforms for RFID tags and sensing circuitries. Finally, a technology for large-area light-weight display sheets will be demonstrated.

Such prospect bears increasing reality because of recent research innovations in the field of material chemistry, charge transport physics, and solution processes of printable organic semiconductors. With excellent chemical and thermal stability in recently developed new materials, we are developing simple integrated devices based on CMOS using p-type and n-type printed organic FETs. Particularly important are new processing technologies for continuous growth of the organic single-crystalline semiconductor “wafers” from solution and for lithographical patterning of semiconductors and metal electrodes. Successful rectification and identification are demonstrated at 13.56 MHz with printed organic CMOS circuits.

Interfacial Drawing—Roll-to-Roll Coating of Semiconducting Polymer and Barrier Films onto Plastic Foils and Textiles

Rory Runser1, Samuel E. Root2,1, Derick Ober1, Kartik Choudhary1, Alexander Chen1, Charles Dhong3,1, Armando D. Urbina1 and Darren J. Lipomi1; 1University of California, San Diego, United States; 2Harvard University, United States; 3University of Delaware, United States

This paper demonstrates that a thin polymeric film (10-80 nm) can be continuously drawn from the meniscus of a nonpolar polymer solution at an air-water-fluoropolymer interface using a roll-to-roll process: “interfacial drawing.” With this process, it is possible to control the thickness of the film by manipulating the concentration of the solution, along with the drawing velocity of the receiving substrate. We demonstrate the formation of thin films >1 m in length, and 1000 cm2 in area, using our custom-designed apparatus. Interfacial drawing has three characteristics which compare favorably to other methods of forming and depositing polymeric thin films. First, the films are solidified prior to deposition, which means that they can be used to uniformly coat nonplanar, rough, or porous substrates. Second, these films can be stacked into multilayered architectures without risk of redissolving the layer beneath. Third, for some materials, the process yields films with superior mechanical compliance for applications such as wearable or flexible devices, compared to films produced by spin-coating. We demonstrate the utility of interfacial drawing by forming thin films of various semiconducting polymers, including the active layers of all-polymer bulk heterojunction solar cells as well as barrier coatings. As part of these demonstrations, we show how floating polymeric films can be transferred easily to diverse substrates, including those with rough and irregular surfaces, such as textiles and fabrics.

5:15 AM S.EL13.04.03

Modelling Grain Development in Crystalline Thin Films Produced by Meniscus-Guided Coating

Ke Zhang, Tomasz Marszalek, Wojciech Pisula and Jasper Michels; Max Planck Institute, Germany

Meniscus-guided coating (MGC) represents a range of scalable methods for controlled solution-deposition of functional materials, such as organic semiconductors, polymers, perovskites and metal-organic frameworks. MGC is of special interest to the fabrication of thin film devices that rely on an active layer with a high unidirectional charge carrier mobility. During MGC a substrate is translated under a coating head, slot or blade which deposits the solution from a steady-state liquid meniscus. The thickness of the dry film may decrease or increase with the coating speed, depending on whether deposition takes place in an evaporation-controlled or hydrodynamic (Landau-Levich) regime. The occurrence of these regimes has been reproduced and explained by models based on lubrication theory. In contrast to film thickness, so far little theoretical attention has been given to the effect of process parameters on the actual thin-film crystalline morphology, which is of critical influence to device performance. In this contribution we present our first effort to accounts for this. We develop a model that explains how substrate translation and solvent evaporation determine crystalline morphology in terms of the size, dispersity and shape anisotropy of spherulitic domains. The model reproduces the experimentally observed transition from macroscopically aligned structures, via stretched grains to isotropically impinged domains upon increasing the coating speed. Our calculations provide a framework that relates morphological characteristics to the deposition regime in MGC.
Patterning Organic and Hybrid Semiconductor Microstructures for Electronics and Optoelectronics
Aram Amassian; North Carolina State University, United States

The transport properties and device performance of organic semiconductors is determined by the microstructure and morphology of polycrystalline thin films, including grain size, domain orientation and grain boundaries. For device applications, such as field-effect transistors, controlling the domain orientation and grain boundaries is particularly important as this mediates charge transport in the channel of the device. More generally, the opportunity to fabricate single crystal domains to match the device architecture would be a very promising pathway to unlock the intrinsic properties of organic and hybrid semiconductors. This presentation will discuss recent efforts to reduce and even eliminate grain boundaries in solution-processed organic and hybrid semiconductor films, with such applications as high performance field-effect transistors, photodetectors and light emitting devices envisioned. Approaches based on patterning the microstructure of thin films post-deposition or in situ will be discussed, as well as additive manufacturing-based coating and printing methods of delivering materials with single crystal-like properties at designated locations.

Quantifying Effects of Molecular Interfaces on Device Dynamics via Resonant Soft X-Rays
Brian A. Collins; Washington State University, United States

With printable single-junction organic solar cell efficiencies reaching 16%, the economic viability of a >20% efficient, printable, and non-toxic panel is more achievable than ever before. To realize such a device near its limiting performance, however, a much more quantitative and granular model of how molecular ordering affects charge generation is required. The development of resonant soft X-ray scattering (RSoXS) has considerably aided nanostructure characterization yet is still rather undeveloped. I will discuss using new analytical models of RSoXS going beyond the simplistic 2-phase assumptions and that quantify the device donor-acceptor interfaces toward characterizing interfacial molecular orientation. We have, furthermore, developed an in-situ photophysical measurement suite, including time-delayed collection field. This suite and new device analysis quantifies the full excited state population dynamics on the exact same devices within which we measure the nanostructure. This has resulted in unprecedentedly quantitative structure-property relationships in model systems that reveal the effect of the mixed amorphous interface. With this new capability, functional relationships that dictate device performance from interfacial aggregation, mixing, and molecular orientation can be used to tailor molecular architecture and device processing that achieves the promise of truly competitive large scale solar harvesting.

Hybrid Materials Design for Wearables, Prosthetics and Robotics Systems
Benjamin C. Tee; National University of Singapore, Singapore

We are increasingly living in a hyper-connected environment where humans, smart devices and robots live in synergy together. The continued development of soft organic devices\(^1\) for bio-integrable and even neuro-integrable sensory systems will augment human abilities and drive new applications as health diagnostics, surgery and predictive analytics. In my talk, I will discuss materials design and strain engineering techniques to develop electronic intelligent materials with stretchability, sensitivity and robust mechanical properties, such as self-healing\(^2,3\). In addition, I will also discuss our recent progress in developing new scalable electronic skin platform technologies\(^4\) for systems capable of far greater perception and intelligence. It is envisioned that such electronic skins can be useful in future distributed conformable electronic skins\(^5\), neuro-prosthetic devices and wearable exo-suits in the increasingly digital and augmented human era.

**Nanocrystalline Organic Semiconductor Photocatalysts—A Dominance of Oxygen Reduction Reactions** Eric D. Glowacki1,2; 1Linkoping University, Sweden; 2Warsaw University of Technology, Poland

Semiconductor-based catalysts can convert solar energy into chemical fuels such as hydrogen, hydrogen peroxide, or hydrocarbons produced via carbon dioxide reduction. Long overlooked due to stability concerns, some organic semiconductors have recently emerged as promising electrocatalysts and photocatalysts for operation in aqueous environments. Our attention has focused on nanocrystalline pigment-type organic semiconductors, which stand out due to stability and performance. Generally, we have found a high selectivity of organic semiconductors for oxygen reduction reactions, by both one-electron and two-electron pathways. The products of these reactions are superoxide or hydrogen peroxide. We find this occurs on numerous organic semiconductors and conducting polymers in a pH range from 1 to 12. The large pH stability window is remarkable when compared with inorganic counterparts. We have found that while photogenerated electrons reduce oxygen, the fate of the holes represents a complex picture. When the nanocrystalline semiconductor is used as a photocathode and efficient p-type transport is available, photogenerated holes can easily be extracted to an external circuit. If this is not possible or inefficient, the hole will either oxidize electron-donors in solution or precipitate autooxidation reactions of the semiconductor itself. The factors affecting this photocorrosion effect will be discussed, as well as principles leading to stabilization of the semiconductor catalyst. The possibilities of solar energy conversion into the high-energy molecule H₂O₂ enabling carbon-neutral energy storage in liquid form, in contrast to gaseous H₂, will be covered. Organic semiconductors have potential to become a powerful class of intrinsic catalysts, tunable by molecular design.

6:30 AM *S.EL13.05.05*

**Structure-Property Relationships for Mixed Conductors in Organic Bioelectronics** Sahika Inal; King Abdullah University of Science and Technology, Saudi Arabia

In this talk, I will present an electronic platform based on an n-type conjugated polymer for detecting glucose as well as generating power from bodily fluids. We employ the n-type semiconducting material in an accumulation mode organic electrochemical transistor (OECT). The polymer is engineered to have specific interactions with the enzyme. This micron-scale device detects glucose without the need of a mediator and shows excellent sensitivity and selectivity over five orders of magnitude wide detection range. When integrated into an enzymatic biofuel cell, the same polymer serves as the anode, converting the glucose metabolism in an aqueous medium into power. The mediator-free glucose-oxygen fuel cell outperforms other reported systems at physiological glucose concentrations. This is the first-time use of n-type polymer in an energy generation device with the capability to operate in human fluids. Such polymers open up an avenue for the development of self-powered microscale sensors that run on metabolites produced by the body. These devices can be fabricated on flexible substrates, paving the way for implantable self-powered metabolite sensing.

**Plasticizing Small Molecule and Polymeric Semiconductors by Molecular Design** Antonio Facchetti1,2; 1Northwestern University, United States; 2Flextera Inc., United States

In this presentation we report the development of novel semiconductors for mechanically flexible and more ductile transistors and circuits. Particularly, we show that “ultra-soft” polymers comprising naphthalenediimides (NDI) units co-polymerized with “rigid” and “flexible” organic units can change how charge transport is affected by mechanical stress, demonstrating...
that polymer backbone composition is more important than film degree of texturing. This strategy enables to reduce the elastic modulus of the semiconducting film by >2-4x while retaining charge transport characteristics. In addition, new polycrystalline molecular semiconductor films based on perylenediimide molecules are plasticized by using an innovative polymer additive design strategy enabling polymer localization at the fragile grain boundaries. This approach preserves charge transport characteristics in a TFT architecture as well as greatly enhances film bendability and charge transport stability upon multiple bending (> 1000 x vs < 10 for the pristine molecular film).

Understanding the Processing Variables under Meniscus-Line-Guided Coating Ming Chen and Paddy K. L. Chan; University of Hong Kong, Hong Kong

Solution processable meniscus-line-guided (MGC) coating is an excellent candidate to realize highly crystallized organic semiconductor thin films in the fabrication of organic field effect transistors (OFETs). The basic processing parameters, including shearing speed (v), concentration (c), solvent boiling point (T_b) and deposition temperature (T), are pivotal to achieve fine control over the crystallinity of the deposited organic thin films and therefore, understanding of the interconnections between these parameters are highly desired. Here, we examine the effects of different fabrication factors on the crystal deposition rate systematically under MGC approach. The active layer material in current study is the 2,7-Dioctyl[1]benzothieno[3,2-b][1]benzothiophene (C8-BTBT) organic semiconductor. It is verified that v and c are connected to crystal deposition rate by means of mass conservation. The crystal deposition rate is further related to T and latent heat (L, proportional to T_b) in the Arrhenius form. Furthermore, the optimum organic thin film (roughness R_q < 0.25 nm and average mobility μ_ave = 5.88 cm^2 V^-1 s^-1) is achieved under a mass transfer rate of 6 × 10^{-11} kg s^-1 to 15 × 10^{-11} kg s^-1. Our findings provide valuable information in understanding the crystal growth under the MGC method, which is believed to be one of the highest potential approaches for the mass production of OFETs.

S.EL13.07.05
The Fabrication of the Organic Field-Effect Transistor Device at the Atomic Force Microscopy Probe Shui Hong Siddhartha Dai and Paddy K. L. Chan; The University of Hong Kong, Hong Kong

Sample surface potential measurement is one of the important topics for material research. The state-of-art surface measure technologies are Kelvin Probe Force Microscope (KPFM) and Electrostatic Force Microscope (EFM). Although those technologies can measure the surface of the sample in nanoscale, the equipment, in general, is sensitive to the environment due to the measurement noise and require extra amplifiers to improve the signal-to-noise ratio. This research aims at functionalizing the AFM probes by integrating an OFET onto the tip for localized electrical signal amplification. The OFET-AFM tip structure includes the source, drain, organic semiconductor and dielectric coating. The patterning of the source and drain electrodes are developed by the Focused Ion Beam (FIB). The meniscus-guided solution-processing method is employed to grow ultrathin (~30 nm) C10-DNTT crystal which will be transferred to the electrodes by the FIB milling method. We believe the ultrathin organic semiconductor crystal allows the contact resistance between electrodes and semiconductors to be low enough (~100 Ωcm) for decent transistor operation. Furthermore, the FIB milling can minimize the thermal damage, which is caused by the thermal evaporation of metal to the organic semiconductor during the fabrication process. As a result, building up a small scale (channel length less than 2 micrometer) OFET device at the AFM tip becomes possible. The Parylene coating (~500 nm) serves as the dielectric layer of the OFET and allows the OFET-AFM probe to measure the voltage signal from the sample surface. The surface potential of the probe will act as the gate bias of the OFET, thus to control the channel current of the device. We believe the OFET-AFM probe can open up a new direction in small scale biomedical applications.

Phototransistors Based on a Lightly Doped P3HT Thomas H. Debesay and Sam-Shajing Sun; Norfolk State University, United States
Organic/Polymeric Semiconductor (OSC) based devices have been under extensive study for the past three decades due to their intrinsic potential advantages such as lightweight, flexible, biocompatible, low toxicity, abundant material availability, low cost of processing, etc. A phototransistor incorporates the properties and functions of a transistor and photodetector. In this study, a phototransistor based on a donor/acceptor (D/A) pair (photo-doping) was studied and demonstrated. Unlike in organic photovoltaics (OPV) where 1:1 proportion by mass of the donor:acceptor is typically utilized to make up the active layer, that ratio appears to be too high for phototransistor applications. It has been reported that the D/A 1:1 concentration leads to a low overall phototransistor device performance, lack of I-V curve saturation (kink effect), and other undesired bipolar transistor behaviors. By systematically adjusting the materials doping concentrations and ratios, as well as device fabrication techniques, we were able to demonstrate a much-improved performance of a p-type phototransistor. Specifically, a high-performance OFET phototransistor was achieved via a very small amount of Phenyl-C71-butyric acid methyl ester (PCBM) doped into a Poly(3-hexylthiophene) (P3HT) host. With this work, a greater understanding behind the optimization of D/A based phototransistors is advanced.

Application of Fluorescent Molecules as Non-Invasive Sensors for Opto-Electronic Characterization on Nanometer Length Scales Thomas Ferschke1, Alexander Hofmann2, Wolfgang Brütting2 and Jens Pflaum1,*, 1University of Würzburg, Germany; 2University of Augsburg, Germany; *Bavarian Center for Applied Energy Research (ZAE Bayern), Germany

The non-invasive, in operando characterization of opto-electronic properties of organic semiconductors is of special interest as it enables information on microscopic processes governing the performance of a device and sheds light on its real lifecycle.

In this contribution we present a new approach to cope with this challenge by utilizing fluorescent Tetraphenylidibenzoperiflanthene (DBP) molecules as optically addressable sensors, deterministically positioned at very low concentration within archetypical N,N′-di-(1-naphthyl)-N,N′-diphenyl-(1,1′-biphenyl)-4,4′-diamine/Tris(8-hydroxyquinolato)aluminium (NPB/Alq3) organic light-emitting diodes (OLEDs) as model system. Observing variations in fluorescence intensity of the optically excited DBP sensor molecules during device operation allows for a correlation with the charge carrier distribution within a dynamic range of four orders of magnitude in current density (10^{-4} – 10^{0} mA/cm^2) under forward bias [1]. Due to the deliberate incorporation of the molecular probes at a well-defined depth within the OLED stack as well as utilization of a μ-photoluminescence technique this information is gathered with nanometer length scale resolution. The resolution is determined by opto-electronic processes like Langevin capture of injected charge carriers and Förster type resonant energy transfer and can be estimated to around 15 nm. Under reverse bias condition the molecular sensing method proves sensitive to uncompensated dipoles at the NPB/Alq3 heterointerface, which results from the preferential orientation of the molecular Alq3 dipoles during layer deposition [2]. The optical data is substantiated by complementary macroscopic impedance measurements performed on identical devices. In conjunction with the impedance measurement, drift-diffusion simulations [3] of the OLED stack characteristics are carried out to further corroborate the correlation between the observed photoluminescence changes and the opto-electronic device properties. The broad variety of molecular host-guest systems, renders this approach a universal tool for analyzing not only opto-electronic phenomena in many different organic electronic device structures but, for example, also in biological soft matter systems.

Ultra-Thin Laminated Organic Field-Effect Transistors (OFETs) Based Flexible Devices Zhenfei He and Paddy K. L. Chan; The University of Hong Kong, Hong Kong

Organic field-effect transistors (OFETs) based flexible electronic devices are the key players of the next generation wearable electronics. The conventional fabrication processes of flexible OFETs usually require layer by layer deposition which requires thermal and chemical compatibility among different layers. Fabrication errors induced in each layer will accumulate and eventually affect the overall performance of device. Here, we introduce a lamination method to fabricate ultra-thin flexible OFETs from separately prepared layers. Compared with the vacuum sublimated method where thin film Dinaphtho[2,3-b:2′,3′-f]thieno[3,2-b]thiophene (DNTT) is directly deposited onto the PEN substrate, the proposed method allows us to modify the growth mode of the DNTT by regulating the surface energy of the substrate, thus high crystallinity DNTT can be potentially obtained. Furthermore, the transferred gold electrodes onto the PMMA which can not only avoid
the thermal damage of the organic semiconductors, but also serve as the encapsulation layer for the OFET operation. We will show how to align the DNTT layer with the electrodes and top gate vertically under the microscope by lamination. Another major advantage of our lamination method is one can repeatedly using them onto different devices by delamination. The ultimate effective mobility of the flexible OFETs is targeting at 1.5 cm²V⁻¹s⁻¹. Last but not least, the proposed method allows us to fabricate individual layers at the same time which in principle would also boost up the production efficiency. The ultra-flexible OFETs can achieve a bending radius of 2 mm or less without significant degradation in electrical performance.

Epitaxial Growth of Vertical Organic Single-Crystalline Heterojunctions on Graphene Zixuan Guo, Enrique D. Gomez and Alejandro L. Briseno; The Pennsylvania State University, United States

Model heterojunctions have the potential to elucidate fundamental mechanisms for charge transfer at these interfaces. We demonstrate the epitaxial growth of single-crystalline p-n junctions on a graphene substrate using two organic small molecules: Zinc phthalocyanine (ZnPc) as a donor-type material (p-type), and 3,4,9,10-perylenetetracarboxylic dianhydride (PTCDA) as an acceptor-type material (n-type). The morphology of a p-n junction was demonstrated to vary upon deposition sequence, as an epitaxial PTCDA layer grown on top of ZnPc exhibits a nanopillar structure, while a ZnPc layer grown on PTCDA shows a bulk, island-like structure. The epitaxy mechanism follows a “point-on-line” rule where organic crystalline layers grow on top of each other by sensing and registering the spacings and periodicities of the lattice plane it grows on, which leads to different molecular packing motifs and resultant different morphologies. Preliminary grazing incidence wide-angle X-ray scattering (GIWAX) and high-resolution TEM studies show that both types of p-n junctions are highly orientated and molecules have a preferred face-on packing motif. This work together with conducting AFM results that show diode characteristics of p-n junctions in the dark suggest that graphene-templated p-n junctions can favor vertical charge carrier transport, and thus be suitable for use in organic photovoltaics (OPV). From this study, we can better understand the packing/orientation of molecules in vertically aligned nanostructures and how the geometrical arrangement, and resultant morphology, will affect the electronic properties and photovoltaic device design.

S.E.L13.07.15
Electron and Hole Mobility in Graphene and Glassy Carbon-Based Transistors Trevor Hunt and Sammuel Kassegne; San Diego State University, United States

Transistors have many uses for electrical systems including acting as a gate switch and enhancing signals. However most transistors are not compatible with biological systems due to the metallic materials they are made up of. For these instances, organic transistors made with carbon based materials are used. For my research I have been working on a similar carbon based FET (field effect transistor) using Glassy Carbon (GC) and Graphene (GR). With these two materials I hope to fabricate a transistor that will be compatible in biological systems as well as have high thermal and electrical properties as compared to conventional FET transistors. This type of transistor could be used to enhance electrochemical signals in vivo to act as a highly sensitive biosensor.

To test the properties of these combined materials, the electron mobility and resistivity was experimentally determined using the Hall Effect method along with Hall Bar type devices. Three devices were tested for the electron mobility; one fabricated with Graphene on top of Glassy Carbon and the other two were made with just a single layer of Glassy Carbon or Graphene respectively. A device made of gold was also tested as an experimental control. The transistors are characterized by determining the Transconductance, this is an electrical characteristic of transistors relating an output current with a given source voltage through the device. In order to determine the Transconductance of the transistor devices, numerous designs will be fabricated to test different sizes and design types. This will also be done with different material types (GR/GC, GC, and GR) similar to the mobility testing to have comparable results. Preliminary results from the Hall Experiments showed that the Graphene had the highest mobility and Glassy Carbon the lowest. The combination device (GR/GC) had a measured mobility between the two controls. These results show that the stacked material (GR/GC) has properties that lie between the two, which is typical of compound materials.

Novel A-D-A Type Compatibilizer for Thermally Stable Blend Morphology of Organic Solar Cells Seungjin Lee¹, Geou Kim¹, Nguyen Thanh Luan², Han Young Woo² and Bumjoon Kim¹; ¹KAIST, Korea (the Republic of); ²Korea University, Korea (the Republic of)

One of the biggest issues within BHJ light-harvesting films is macro-phase separation in domains of the donor and acceptor materials leading to severe PCE drop. To alleviate this problem, incorporating compatibilizer has been one solution by increasing adhesion between the phases, reducing the interfacial tension, and stabilizing morphology. In this study, a novel
Substitution of C atoms in a polymer backbone by N atoms allows for the facile tuning of the energy levels as well as the backbone conformation and packing structures of conjugated polymers. Herein, we report a series of three polymer acceptors (PAs) with N atoms introduced at different positions of the backbone, and investigate how these N atoms affect the device performances of all-polymer solar cells (all-PSCs). The three PAs, namely, P(NDI2DT-BTT), P(NDI2DT-PTT), and P(NDI2DT-BTTz), are composed of naphthalenediimide (NDI) and benzothiadiazole (BT)-based derivative (dithiophene-BT (BT), dithiophene-thiadiazolepyridine (PTT), and dithiazole-BT (BTThz)) units. The PTT and BTThz units are synthesized by replacing the C atoms in BT and thiophene, respectively, with N atoms, which effectively tune the optical, electrochemical, and charge-transporting properties of the corresponding PAs. The all-PSCs using PBDB-T as a polymer donor and P(NDI2DT-PTT) as the PA exhibit a significantly enhanced power conversion efficiency (PCE) of 6.95%, whereas the all-PSCs based on the other PAs show relatively lower PCEs (6.02% for PBDB-T:P(NDI2DT-BTT) and 1.43% for PBDB-T:P(NDI2DT-BTTz)). The high PCE of the PBDB-T:P(NDI2DT-PTT) device is due to superior charge transfer and charge dissociation, resulting from the closely-matched energy levels between PBDB-T and P(NDI2DT-PTT), as well as the more favorable BHJ morphology with improved miscibility. Importantly, the P(NDI2DT-PTT)-based all-PSC device shows improved air stability compared to the P(NDI2DT-BTT)-based device, which is most likely due to a decreased lowest unoccupied molecular orbital level of the PA. Our findings suggest that incorporation of N atoms into the PAs is an effective strategy for improving the efficiency and stability of all-PSCs.

Morphology Dependence of the Triplet Excited State in Platinum Containing Polyfluorene Copolymers Nikol Lambeva1, Moritz Riede2 and Donal D. Bradley2,1; 1University of Oxford, United Kingdom; 2King Abdullah University of Science and Technology, Saudi Arabia

Understanding the structure-property relationship of organic semiconducting polymers is critical for their future development for technological applications. To this end, studying suitable model systems is needed to expand our knowledge of how to modify the chemical structure of materials to get the desirable performance necessary for commercialization. The triplet states play a vital role in the optoelectronic properties of organic semiconductors with direct consequences for their use in devices. It is, thus, vital to have a deep understanding of the formation, transport and harvesting of triplet excitons in such materials. We report a photophysical study of a series of copolymers containing the light emitting polymer 9,9-dioclyfluorene (PFO). These comprise varying amounts (0.5, 1, 2.5 and 5%) of cyclometallated PyTPAPt(acac) complex or the corresponding organic PyTPA ligand embedded into the backbone of the PFO. Interest in such compounds stems from the large enhancement in spin-orbit coupling induced by the heavy platinum atoms making triplet emission partially allowed. Additionally, the morphological diversity of PFO allows to study the effect of film morphology on the photophysics. We investigate the temperature dependence of the photoluminescence in the range between 5K and 300K as well as the room temperature electroluminescence. Strong emission quenching with increasing platinum content is observed in both the glassy and β phases of the fluorene moiety with phosphorescence only observed at low temperature. The phosphorescence is ascribed to fluorene triplet emission from its energy and linewidth. We explore how trapping at defects and bimolecular recombination affect the emission efficiency. Analysis of photoluminescence measurements at different
excitation intensities indicates triplet-triplet annihilation leading to emission losses while phosphorescence temperature dependent intensity measurements demonstrate a distribution of trap sites for the triplet excited state. Finally, at higher platinum contents triplet emission from both the planar β phase and disordered glassy phase of PFO is observed despite fluorescence arising only from the β phase. We explore this phenomenon in the context of energy transfer between the different excited state energy levels.

S.EL13.07.21
Chain Conformation Control of a Polyfluorene-Based Copolymer for Improved OLED Performance Bingjun Wang, Moritz Riedel and Donal D. Bradley; University of Oxford, United Kingdom; King Abdullah University of Science and Technology, Saudi Arabia

Poly(9,9-di-n-octylfluorenyl-2,7-diyi), also known as PFO, is one of the most well-studied light emission polymers which can exhibit different microstructures depending on processing methods and conditions. One microstructure that attracts much attention is the β phase, in which the intermonomer torsion angle is ~180°, resulting in a planar-zigzag chain conformation. Researchers have shown that with a very small amount of β phase in PFO (~1.3%), the luminance and external quantum efficiency (EQE) of OLEDs can triple. In this work, we report on the generation of β phase in a 10% benzothiadiazole-containing PFO-based copolymer, poly[(9,9-di-n-octylfluorenyl-2,7-diyi)-co-\(\text{1,4-benzo-}\{2,1',3\}-\text{thiadiazole}\)] (ADS233YE), and the improvements in OLED performance that ensue.

The β phase was induced into ADS233YE thin films by either solvent vapour annealing or dipping the sample in a solvent/non-solvent mixture. The existence of β phase was confirmed by absorption spectra, and both photoluminescence (PL) spectra and photoluminescence quantum efficiencies (PLQE) of pristine and β phase-containing samples were measured and compared. ADS233YE OLEDs with β phase were found to perform better than without, including luminance (at 10 V, 5000 cd m\(^{-2}\) to 5700 cd m\(^{-2}\), i.e. 14% increase), EQE (peak value, 1.09% to 1.93%, i.e. 77% increase), luminance efficiency (peak value, 3.96 cd A\(^{-1}\) to 6.26 cd A\(^{-1}\), i.e. 58% increase), and luminous power efficiency (peak value, 2.20 lm W\(^{-1}\) to 3.69 lm W\(^{-1}\), i.e. 68% increase). Possible reasons for these enhancements include a lower ionisation potential in β phase-containing samples due to an extension of the conjugation length, more balanced hole and electron mobility caused by the self-doping effect of β phase chain segments, and more efficient energy transfer from fluorene to benzothiadiazole moieties, mediated by the β phase, all of which are currently being investigated.

Our study shows that controlling chain conformation by inducing β phase into a PFO-based copolymer can be a simple but effective way to boost OLED performance. It will be interesting to see if this approach can be generalised to other PFO-derivatives and even other polymer families, providing us with new options to optimise OLED devices.

Impact of Non-Halogenated Solvent Additives and Slot-Die Coating Processing on Perylene Diimide Based Active Layers Morphology Francesco Tintori, Audrey Laventure and Gregory C. Welch; University of Calgary, Canada

Perylene diimide (PDI) derivatives are organic semiconductor that, among others, have been identified as one of the best classes of non-fullerene acceptors (NFAs) for organic photovoltaic (OPV) devices, with the best power conversion efficiency surpassing 10%. Recently, our group has developed a series of N-annulated PDI dimers, that have demonstrated excellent processability from all types of solvents, including environmentally friendly 2-Me-THF and 2-Me-anisole, and can achieve respectable performances in OPV devices. The synthetic methods required to produce some of these have proven to be scalable and efficient, making them excellent candidates for the up-scaling of green printed electronic devices. We had previously identified one of said PDI dimers, with ethyl-hexyl side chains on the pyrrolic position, to be a suitable NFA for green solvent and air processed OPV.

This presentation will first discuss the rather unique self-assembly properties of this specific PDI NFA under the influence of processing solvent additives such as 1,8-diiodooctane (DIO), which can cause the crystallization of the molecular material in a polymeric matrix. This phenomenon was studied, and the aggregation effect was controlled under specific conditions using the benchmark polymer P3HT. To further investigate these findings and probe the phenomenon impact on a higher performing, and potentially scalable system, we identified a suitable medium band-gap benzodithiophene-quinoxaline polymer. The presentation will then focus on our effort to understand this system and translate it to scalable processing. First, diphenyl ether (DPE) was selected as a non-halogenated counterpart to DIO to make our system completely halogen-free, and
effect of DPE on the PDI molecular material was studied. Then, a comparison of spin-coated and slot-die coated active layer films was made looking at film properties, morphology evolution and OPV device performance. We identified dependencies between these parameters and the selected coating method and worked with slot-die coating to obtain superior OPV results. The results obtained demonstrated that solvent additives might play an additional beneficial role in the device fabrication of printed organic active layers, highlighting the need of further exploration of additives with dual or even multiple functions to optimize the processing involved in green printed electronics. \[^{[5]}\]

\textbf{Scalable Fabrication of High Mobility Monolayer OFETs Using Floating Film Transfer} Thomas M. Steckmann, Masrur Morshed Nahid, Abay Gadisa and Harald Ade; North Carolina State University, United States

Traditionally, the fabrication of ultrathin organic field-effect transistors (OFETs) is limited by both poor electrical performance in devices with fewer than 2-5 molecular layers and poor scalability of these methods. Here, we employ a floating film transfer method which uses the spontaneous spreading of polymer solutions over the surface of a green solvent to fabricate floating large area, highly uniform monolayer films which can be transferred to an arbitrary substrate for use in organic electronic devices. This method enables achieving high charge carrier mobility in material-efficient ultrathin films, which is comparable with values achieved in spin-cast thick film.

\textbf{Screening of Organic Solar Cell Materials Using Contactless Photoconductivity Measurements} Supriya Pillai\(^{1}\), Chao Wang\(^{2}\), Chris McNeill\(^{2}\), Mats Anderson\(^{2}\) and Nikos Kondidakis\(^{1}\); \(^{1}\)Macquarie University, Australia; \(^{2}\)Monash University, Australia; \(^{2}\)Flinders University, Australia

Introduction: The photovoltaic market is growing and although Silicon solar cells is considered to be the dominant technology, there is significant interest in research and development of other low-cost novel technologies. Organic Solar Cells (OSCs) has a niche market that require lightweight and flexible structures however their application is still limited because of low efficiencies and stability issues when compared to their inorganic counterparts. OSCs can clearly be a low cost technology, but to be able to take it to commercialisation, there is a need to develop new and efficient materials that are both stable and scalable. One of the great advantages of organic solar cells is the myriad of combinations of polymer materials that can be easily synthesised to form donor-acceptor blends, but the key is the performance in a device architecture.

Background: Currently, the organic blends need to be tested through trial and error and by fabricating the full devices which needs time and effort. In this work, we use the contactless technique of Time resolved microwave conductivity (TRMC) that can be used as a powerful diagnostic characterisation tool to screen and select the most promising materials and organic blend ratio before it goes into the device fabrication stage. It uses a pump-probe technique to measure the transient change in the microwave reflectivity of a sample inside a microwave cavity in the dark and when pumped with light, usually a laser pulse. The relative change in the absorbed microwave power from the dark signal to the excited signal is directly proportional to the photoconductance. Apart from being a contactless technique, it is also a non-intrusive photo-conductivity measurement technique that can measure dynamics of charge carrier generation and recombination and also study post-bleaching behaviour.

Method: To validate the TRMC as a screening tool, we identify a few blend materials from literature with known efficiencies and compare the TRMC figure of merit with the device efficiency results. The donor-acceptor blend samples for the TRMC are prepared by spin coating or blade coating on quartz substrates. To investigate the material properties better, photoconductivity decay analysis is also performed and photocarrier lifetimes are extracted. The ‘figure of merit’ for TRMC measurements used to evaluate the quality of the absorber material will be discussed and some preliminary results of screening a few polymer blends will be presented.
Conclusion: Our results so far show that there is a clear correlation between material quality and TRMC figure of merit and its extracted parameters. Hence TRMC characterisation can be used as a fast and high throughput technique to screen new polymer blends and predict device performance.

Understanding the Processing Variables under Meniscus-Line-Guided Coating
Ming Chen and Paddy K. L. Chan; University of Hong Kong, Hong Kong

Solution processable meniscus-line-guided (MGC) coating is an excellent candidate to realize highly crystallized organic semiconductor thin films in the fabrication of organic field effect transistors (OFETs). The basic processing parameters, including shearing speed ($v$), concentration ($c$), solvent boiling point ($T_b$) and deposition temperature ($T$), are pivotal to achieve fine control over the crystallinity of the deposited organic thin films and therefore, understanding of the interconnections between these parameters are highly desired. Here, we examine the effects of different fabrication factors on the crystal deposition rate systematically under MGC approach. The active layer material in current study is the $2,7$-Dioctyl[1]benzothieno[3,2-b][1]benzothiophene (C$_8$-BTBT) organic semiconductor. It is verified that $v$ and $c$ are connected to crystal deposition rate by means of mass conservation. The crystal deposition rate is further related to $T$ and latent heat ($L$, proportional to $T_b$) in the Arrhenius form. Furthermore, the optimum organic thin film (roughness $R_q < 0.25$ nm and average mobility $\mu_{ave} = 5.88$ cm$^2$ V$^{-1}$ s$^{-1}$) is achieved under a mass transfer rate of $6 \times 10^{-11}$ kg s$^{-1}$ to $15 \times 10^{-11}$ kg s$^{-1}$. Our findings provide valuable information in understanding the crystal growth under the MGC method, which is believed to be one of the highest potential approaches for the mass production of OFETs.

S.EL13.07.05
The Fabrication of the Organic Field-Effect Transistor Device at the Atomic Force Microscopy Probe
Shui Hong Siddhartha Dai and Paddy K. L. Chan; The University of Hong Kong, Hong Kong

Sample surface potential measurement is one of the important topics for material research. The state-of-art surface measure technologies are Kelvin Probe Force Microscope (KPFM) and Electrostatic Force Microscope (EFM). Although those technologies can measure the surface of the sample in nanoscale, the equipment, in general, is sensitive to the environment due to the measurement noise and require extra amplifiers to improve the signal-to-noise ratio. This research aims at functionalizing the AFM probes by integrating an OFET onto the tip for localized electrical signal amplification. The OFET-AFM tip structure includes the source, drain, organic semiconductor and dielectric coating. The patterning of the source and drain electrodes are developed by the Focused Ion Beam (FIB). The meniscus-guided solution-processing method is employed to grow ultrathin (~30 nm) C$_{10}$-DNTT crystal which will be transferred to the electrodes by the FIB milling method. We believe the ultrathin organic semiconductor crystal allows the contact resistance between electrodes and semiconductors to be low enough (< 100 $\Omega$cm) for decent transistor operation. Furthermore, the FIB milling can minimize the thermal damage, which is caused by the thermal evaporation of metal to the organic semiconductor during the fabrication process. As a result, building up a small scale (channel length less than 2 micrometer) OFET device at the AFM tip becomes possible. The Parylene coating (~500 nm) serves as the dielectric layer of the OFET and allows the OFET-AFM probe to measure the voltage signal from the sample surface. The surface potential of the probe will act as the gate bias of the OFET, thus to control the channel current of the device. We believe the OFET-AFM probe can open up a new direction in small scale biomedical applications.

Ultra-Thin Laminated Organic Field-Effect Transistors (OFETs) Based Flexible Devices Zhenfei He and Paddy K. L. Chan; The University of Hong Kong, Hong Kong

Organic field-effect transistors (OFETs) based flexible electronic devices are the key players of the next generation wearable electronics. The conventional fabrication processes of flexible OFETs usually require layer by layer deposition which requires thermal and chemical compatibility among different layers. Fabrication errors induced in each layer will accumulate and eventually affect the overall the performance of device. Here, we introduce a lamination method to fabricate ultra-thin flexible OFETs from separately prepared layers. Compared with the vacuum sublimated method where thin film Dinaphtho[2,3-b:2′,3′-f]thieno[3,2-b]thiophene (DNTT) is directly deposited onto the PEN substrate, the proposed method allows us to modify the growth mode of the DNTT by regulating the surface energy of the substrate, thus high crystallinity DNTT can be potentially obtained. Furthermore, the transferred gold electrodes onto the PMMA which can not only avoid the thermal damage of the organic semiconductors, but also serve as the encapsulation layer for the OFET operation. We will show how to align the DNTT layer with the electrodes and top gate vertically under the microscope by lamination. Another major advantage of our lamination method is one can repeatedly using them onto different devices by delamination. The ultimate effective mobility of the flexible OFETs is targeting at 1.5 cm²V⁻¹s⁻¹. Last but not least, the proposed method allows us to fabricate individual layers at the same time which in principle would also boost up the production efficiency. The ultra-flexible OFETs can achieve a bending radius of 2 mm or less without significant degradation in electrical performance.

Electron and Hole Mobility in Graphene and Glassy Carbon-Based Transistors Trevor Hunt and Sammuel Kassegne; San Diego State University, United States

Transistors have many uses for electrical systems including acting as a gate switch and enhancing signals. However most transistors are not compatible with biological systems due to the metallic materials they are made up of. For these instances, organic transistors made with carbon based materials are used. For my research I have been working on a similar carbon based FET (field effect transistor) using Glassy Carbon (GC) and Graphene (GR). With these two materials I hope to fabricate a transistor that will be compatible in biological systems as well as have high thermal and electrical properties as compared to conventional FET transistors. This type of transistor could be used to enhance electrochemical signals in vivo to act as a highly sensitive biosensor.

To test the properties of these combined materials, the electron mobility and resistivity was experimentally determined using the Hall Effect method along with Hall Bar type devices. Three devices were tested for the electron mobility; one fabricated with Graphene on top of Glassy Carbon and the other two were made with just a single layer of Glassy Carbon or Graphene respectively. A device made of gold was also tested as an experimental control.

The transistors are characterized by determining the Transconductance, this is an electrical characteristic of transistors relating an output current with a given source voltage through the device. In order to determine the Transconductance of the transistor devices, numerous designs will be fabricated to test different sizes and design types. This will also be done with different material types (GR/GC, GC, and GR) similar to the mobility testing to have comparable results.

Preliminary results from the Hall Experiments showed that the Graphene had the highest mobility and Glassy Carbon the lowest. The combination device (GR/GC) had a measured mobility between the two controls. These results show that the stacked material (GR/GC) has properties that lie between the two, which is typical of compound materials.

Chain Conformation Control of a Polyfluorene-Based Copolymer for Improved OLED Performance Bingjun Wang¹, Moritz Riede¹ and Donal D. Bradley¹,²; ¹University of Oxford, United Kingdom; ²King Abdullah University of Science and Technology, Saudi Arabia

Poly(9,9-di-n-octylfluoren-2,7-diyl), also known as PFO, is one of the most well-studied light emission polymers which can exhibit different microstructures depending on processing methods and conditions. One microstructure that attracts much attention is β-phase, in which the intermonomer torsion angle is ~180°, resulting in a planar-zigzag chain conformation. Researchers have shown that with a very small amount of β-phase in PFO (~1.3%), the luminance and external quantum efficiency (EQE) of OLEDs can triple\[11\]. In this work, we report on the generation of β-phase in a 10% benzothiadiazole-containing PFO-based copolymer, poly[(9,9-di-octylfluoren-2,7-diyl)-co-(1,4-benzo-{2,1′,3′}-thiadiazole)] (ADS233YE),
and the improvements in OLED performance that ensue.

The β-phase was induced into ADS233YE thin films by either solvent vapour annealing or dipping the sample in a solvent/non-solvent mixture. The existence of β-phase was confirmed by absorption spectra, and both photoluminescence (PL) spectra and photoluminescence quantum efficiencies (PLQE) of pristine and β-phase-containing samples were measured and compared. ADS233YE OLEDs with β-phase were found to perform better than without, including luminance (at 10 V, 5000 cd m⁻² to 5700 cd m⁻², i.e. 14% increase), EQE (peak value, 1.09% to 1.93%, i.e. 77% increase), luminance efficiency (peak value, 3.96 cd A⁻¹ to 6.26 cd A⁻¹, i.e. 58% increase), and luminous power efficiency (peak value, 2.20 lm W⁻¹ to 3.69 lm W⁻¹, i.e. 68% increase). Possible reasons for these enhancements include a lower ionisation potential in β-phase-containing samples due to an extension of the conjugation length, more balanced hole and electron mobility caused by the self-doping effect of β-phase chain segments, and more efficient energy transfer from fluorene to benzothiadiazole moieties, mediated by the β-phase, all of which are currently being investigated.

Our study shows that controlling chain conformation by inducing β-phase into a PFO-based copolymer can be a simple but effective way to boost OLED performance. It will be interesting to see if this approach can be generalised to other PFO-derivatives and even other polymer families, providing us with new options to optimise OLED devices.

Morphology Dependence of the Triplet Excited State in Platinum Containing Polyfluorene Copolymers

Understanding the structure-property relationship of organic semiconducting polymers is critical for their future development for technological applications. To this end, studying suitable model systems is needed to expand our knowledge of how to modify the chemical structure of materials to get the desirable performance necessary for commercialization. The triplet states play a vital role in the optoelectronic properties of organic semiconductors with direct consequences for their use in devices. It is, thus, vital to have a deep understanding of the formation, transport and harvesting of triplet excitons in such materials.

We report a photophysical study of a series of copolymers containing the light emitting polymer 9,9-diocetylfluorene (PFO). These comprise varying amounts (0.5, 1, 2.5 and 5%) of cyclometalated PyTPAPt(acac) complex or the corresponding organic PyTPA ligand embedded into the backbone of the PFO. Interest in such compounds stems from the large enhancement in spin-orbit coupling induced by the heavy platinum atoms making triplet emission partially allowed. Additionally, the morphological diversity of PFO allows to study the effect of film morphology on the photophysics. We investigate the temperature dependence of the photoluminescence in the range between 5K and 300K as well as the room temperature electroluminescence. Strong emission quenching with increasing platinum content is observed in both the glassy and β phases of the fluorene moiety with phosphorescence only observed at low temperature. The phosphorescence is ascribed to fluorene triplet emission from its energy and linewidth. We explore how trapping at defects and bimolecular recombination affect the emission efficiency. Analysis of photoluminescence measurements at different excitation intensities indicates triplet-triplet annihilation leading to emission losses while phosphorescence temperature dependent intensity measurements demonstrate a distribution of trap sites for the triplet excited state. Finally, at higher platinum contents triplet emission from both the planar β phase and disordered glassy phase of PFO is observed despite fluorescence arising only from the β phase. We explore this phenomenon in the context of energy transfer between the different excited state energy levels.
Perylene diimide (PDI) derivatives are organic semiconductor that, among others, have been identified as one of the best classes of non-fullerene acceptors (NFAs) for organic photovoltaic (OPV) devices, with the best power conversion efficiency surpassing 10%.[1] Recently, our group has developed a series of N-annulated PDI dimers, that have demonstrated excellent processability from all types of solvents, including environmentally friendly 2-Me-THF and 2-Me-anisole, and can achieve materials leading to severe PCE drop. To alleviate this problem, incorporating compatibilizer has been one solution by increasing adhesion between the phases, reducing the interfacial tension, and stabilizing morphology. In this study, a novel acceptor–donor–acceptor (A–D–A) triad type small molecule (SM), 5TRh-PCBM, which has an oligothiophene segment as the central core and fullerene-derivatives as the end groups, was synthesized. 5TRh-PCBM was added and evaluated into traditional fullerene-based blend (P3HT:PC61BM), and high-efficiency blend system (PTB7-Th:PC71BM) and (PBDB-T:PC71BM). Interestingly, with incorporating of 5TRh-PCBM, PCEs of PTB7-Th:PC71BM:5TRh-PCBM blends were 9.37%(1:1.5:0), 10.09%(1:1.5:0.125), and 9.72%(1:1.5:0.25). Furthermore, thermal stability of PTB7-Th:PC71BM:5TRh-PCBM (1:1.5:0.25) blend was improved retaining approximately 85% of its initial PCE at the annealing condition of 80°C for 120 hrs. Blend morphology was investigated through OM, GIWAXS, and RSoXS varying compatibilizer content ratio and annealing time. When 5TRh-PCBM was incorporated into each blend system, there were no apparent morphological transitions and macro-phase separation after thermal annealing. This thermally stable tolerance is likely due to the fullerene derivative end groups of 5TRh-PCBM as a binder which can prevent thermal diffusion of PC61BM (or PC71BM) and suppress its aggregation within each of the BHJ films. This compatibilization strategy demonstrated the useful guidelines of molecular engineering to achieve highly efficient and stable OSCs through controlling and stabilizing blend morphology.

Impact of Non-Halogenated Solvent Additives and Slot-Die Coating Processing on Perylene Diimide Based Active Layers Morphology Francesco Tintori, Audrey Laventure and Gregory C. Welch; University of Calgary, Canada

Perylene diimide (PDI) derivatives are organic semiconductor that, among others, have been identified as one of the best classes of non-fullerene acceptors (NFAs) for organic photovoltaic (OPV) devices, with the best power conversion efficiency surpassing 10%.[1] Recently, our group has developed a series of N-annulated PDI dimers, that have demonstrated excellent processability from all types of solvents, including environmentally friendly 2-Me-THF and 2-Me-anisole, and can achieve respectable performances in OPV devices.[2-4] The synthetic methods required to produce some of these have proven to be scalable and efficient, making them excellent candidates for the up-scaling of green printed electronic devices. We had previously identified one of said PDI dimers, with ethyl-hexyl side chains on the pyrrolic position, to be a suitable NFA for green solvent and air processed OPV.[5]

This presentation will first discuss the rather unique self-assembly properties of this specific PDI NFA under the influence of processing solvent additives such as 1,8-diiodooctane (DIO), which can cause the crystallization of the molecular material in a polymeric matrix. This phenomenon was studied, and the aggregation effect was controlled under specific conditions using the benchmark polymer P3HT.[4] To further investigate these findings and probe the phenomenon impact on a higher performing, and potentially scalable system, we identified a suitable medium band-gap benzodithiophene-quinoxaline polymer. The presentation will then focus on our effort to understand this system and translate it to scalable processing. First, diphenyl ether (DPE) was selected as a non-halogenated counterpart to DIO to make our system completely halogen-free, and effect of DPE on the PDI molecular material was studied. Then, a comparison of spin-coated and slot-die coated active layer films was made looking at film properties, morphology evolution and OPV device performance. We identified dependencies between these parameters and the selected coating method and worked with slot-die coating to obtain superior OPV results.
The results obtained demonstrated that solvent additives might play an additional beneficial role in the device fabrication of printed organic active layers, highlighting the need of further exploration of additives with dual or even multiple functions to optimize the processing involved in green printed electronics.[5]

Scalable Fabrication of High Mobility Monolayer OFETs Using Floating Film Transfer Thomas M. Steckmann, Masrur Morshed Nahid, Abay Gadisa and Harald Ade; North Carolina State University, United States

Traditionally, the fabrication of ultrathin organic field-effect transistors (OFETs) is limited by both poor electrical performance in devices with fewer than 2-5 molecular layers and poor scalability of these methods. Here, we employ a floating film transfer method which uses the spontaneous spreading of polymer solutions over the surface of a green solvent to fabricate floating large area, highly uniform monolayer films which can be transferred to an arbitrary substrate for use in organic electronic devices. This method enables achieving high charge carrier mobility in material-efficient ultrathin films, which is comparable with values achieved in spin-cast thick film.

Screening of Organic Solar Cell Materials Using Contactless Photoconductivity Measurements Supriya Pillai1, Chao Wang2, Chris McNeil1, Mats Anderson2 and Nikos Kopidakis1; 1Macquarie University, Australia; 2Monash University, Australia; 3Flinders University, Australia

Introduction: The photovoltaic market is growing and although Silicon solar cells is considered to be the dominant technology, there is significant interest in research and development of other low-cost novel technologies. Organic Solar Cells (OSCs) has a niche market that require lightweight and flexible structures however their application is still limited because of low efficiencies and stability issues when compared to their inorganic counterparts. OSCs can clearly be a low cost technology, but to be able to take it to commercialisation, there is a need to develop new and efficient materials that are both stable and scalable. One of the great advantages of organic solar cells is the myriad of combinations of polymer materials that can be easily synthesised to form donor-acceptor blends, but the key is the performance in a device architecture.

Background: Currently, the organic blends need to be tested through trial and error and by fabricating the full devices which needs time and effort. In this work, we use the contactless technique of Time resolved microwave conductivity (TRMC) that can be used as a powerful diagnostic characterisation tool to screen and select the most promising materials and organic blend ratio before it goes into the device fabrication stage. It uses a pump-probe technique to measure the transient change in the microwave reflectivity of a sample inside a microwave cavity in the dark and when pumped with light, usually a laser pulse. The relative change in the absorbed microwave power from the dark signal to the excited signal is directly proportional to the photoconductance. Apart from being a contactless technique, it is also a non-intrusive photo-conductivity measurement technique that can measure dynamics of charge carrier generation and recombination and also study post-bleaching behaviour.

Method : To validate the TRMC as a screening tool, we identify a few blend materials from literature with known efficiencies and compare the TRMC figure of merit with the device efficiency results. The donor-acceptor blend samples for the TRMC are prepared by spin coating or blade coating on quartz substrates. To investigate the material properties better, photoconductivity decay analysis is also performed and photocarrier lifetimes are extracted. The ‘figure of merit’ for TRMC measurements used to evaluate the quality of the absorber material will be discussed and some preliminary results of screening a few polymer blends will be presented.

Conclusion : Our results so far show that there is a clear correlation between material quality and TRMC figure of merit and its extracted parameters. Hence TRMC characterisation can be used as a fast and high throughput technique to screen new polymer blends and predict device performance.
Exploring Additive Effects on Charge Generation in a PM6:Y6 Organic Solar Cells

Awawd N. Alotaibi1, Xaiobo Zhou2, Brian A. Collins1,2 and Ma Wei2; 1Washington State University, United States; 2Xi’an Jiaotong University, China

Organic solar cells (OSCs) are promising as an alternative solar energy technology and their efficiencies are continuously increasing, with record power conversion efficiency at ~ 17%. The processes involved in charge generation and recombination in the bulk heterojunction active layer govern device performance. However, these processes are all entangled and hard to measure quantitatively, which limits progress in optimizing the ultimate performance. We use time delay collection field (TDCF) to disentangle and fully quantify each process occurring in the current record OSC system PM6:Y6 as a function of processing co-solvent, chloronapthalene, concentration. TDCF is an advanced charge extraction technique that can separate charge generation and recombination processes. We use this to measure generation current, recombination current, and extraction current all at the operating condition of the OSC devices, fully quantifying each loss process. A field dependence of charge generation indicates geminate recombination and our measurements show that the additive eliminates this loss process in PM6:Y6. We additionally vary the excitation wavelength to selectively excite the accepter and the donor molecules. Our initial result suggests that the excited Y6 acceptor generates relatively less charge than the PM6 donor. This new understanding of charge generation and recombination processes will help in design of new materials and optimization of device fabrication for high-performance, economical, and massively scalable solar power.

Towards In Situ Measurement of Nanostructure Dynamics During Ion Transport within a Conducting Polymer

Tamanna T. Khan1, Terry McAfee1,2, Thomas Ferron1 and Brian A. Collins1; 1Washington State University, United States; 2Lawrence Berkeley National Laboratory, United States

Ion transport in organic materials is attracting tremendous attention due to the possibilities in applications such as electrochemical transistors, bioelectronics, sensors, soft robotics, and printed electronics. Poly(3,4-ethylenedioxythiophene) doped with poly(styrenesulfonate) (PEDOT:PSS) shows promise as an ion transport material and has been integrated into biomedical applications while the nano-structure that enables this property is still unknown. Our previous study utilized Resonant Soft X-ray Scattering (RSoXS) which affords orders of magnitude higher contrast at an elemental absorption edge than electron or nonresonant X-ray techniques. There we showed the morphology consists of PEDOT-rich gel particles embedded within a PSS matrix and upon the addition of a co-solvent (Ethylene glycol) the PEDOT domains swell which was found to correlate with a reduction in ion flow. However, the measured nanostructures were dry and undoped, which do not directly demonstrate which domain facilitates ion flow. Here we will present our progress toward an in-situ RSoXS investigation of a PEDOT:PSS electrochemical transistor during ion transport. We will utilize an in-vacuum, microfluidic sample environment that is compatible with the newly developed RSoXS liquid-chamber at the Advanced Light Source. To achieve this goal, we modified the electrochemical device architecture and replaced the insulating ion barrier with no appreciable reduction in ion transport capabilities. Additionally, the fabrication of a miniaturized device on a micro-electromechanical system (MEMS) chip is under development. Understanding how the ions interact with the nano-structure to transduce an electric signal will enable these devices to potentially use in next generation medical devices.

Imaging the Spatial Distribution of Molecular Dopants in Organic Semiconductors at High Spatial Resolution Using Electron Microscopy

Gustav Persson, Sepideh Zokaei, Renée Kroon, Christian Muller and Eva M. Olsson; Chalmers University of Technology, Sweden

Electronic devices based on organic semiconductors have great potential for future applications in devices for energy harvesting and electronics due to low costs, mechanical flexibility and tunable properties. Molecular doping of organic semiconductors is fundamental in order to optimize their electronic properties in high performance devices such as photovoltaic cells, thermoelectrics or light emitting diodes. However, the spatial distribution of these dopants is not completely controlled. Previous studies have shown how density, distribution and diffusion of dopants can significantly affect electronic properties, disrupt the microstructure and decrease long term stability of the host polymer.

Electron microscopy has been used successfully in multiple studies characterizing organic semiconducting materials and extracting information with high spatial resolution. However, crucial information about the distribution of dopants and its
dependence of the structure of the surrounding material still remains to be investigated with high spatial resolution. This work addresses the fine scale distribution of molecular dopants in a polar polythiophene with oligoethylene glycol side chains. The microstructure of the system and the distribution of dopants will be correlated to electronic properties at different doping concentrations. Concepts on how to control the distribution of the dopants will be presented.

**Key Factors Study in Amphiphilic Block Copolymer-Oriented Porous SnO$_2$ Synthesis Process** Shanshan Yin$^1$, Peter Muller-Buschbaum$^{1,2}$ and Stephan V. Roth$^{1,4}$; $^1$Technische Universität München, Germany; $^2$Heinz Maier-Leibnitz Zentrum, Germany; $^3$KTH Royal Institute of Technology, Sweden; $^4$Deutsches Elektronen-Synchrotron DESY, Germany

SnO$_2$, as a crucial material in the field of energy storage, has always been the focus of scientific research. For organic-inorganic halide perovskite solar cells (PSCs) or dye-sensitized solar cells (DSSCs), SnO$_2$ affords high electron mobility and superior chemical stability amongst the various metal oxides. Moreover, as an alternative anode material for lithium-ion battery, it possesses a decent theoretical specific capacity of 1494 mAhg$^{-1}$. Compared with conventional bulk materials, mesoporous SnO$_2$ with high specific surface area affords more advantages when applied on either solar cells or lithium-ion batteries. By introducing the mesoporous structure, the recombination of injected electrons within the electron transport layer of the solar cell can be effectively inhibited. Furthermore, with this unique mesoporous structure, the structural collapse of lithium-ion battery anode provoked by significant volume expansion can also be effectively alleviated during the cycling process. In the present work, a novel amphiphilic block copolymer assisted sol-gel chemistry is used for the synthesis of porous SnO$_2$ nanostructure. Different kinds of solvent are used as a good solvent for both PS and PEO polymer chains, HCl is a selective poor solvent for PS chains and catalyst for the hydrolytic condensation reaction of SnO$_2$ precursor. With the progressive addition of HCl, the stretch of the hydrophobic PS chains is significantly restricted. As a result, different micelle structures of the block polymer are formed in the sol-gel solution, and the simultaneously hydrolysed SnO$_2$ nano-dot array is specifically confined in the PEO domains by hydrogen-bond interaction. With the evaporation of the solvent during spin-coating and annealing process, a distinct phase-separated SnO$_2$/PS-b-PEO composite thin film is obtained on the silicon substrate. For removing the organic polymer template, the composite thin film is calcined at 500 °C for two hours under ambient condition. The obtained nanostructure is visualized by scanning electron microscope (SEM). Crystallinity is characterized by X-ray diffraction (XRD). The buried structure within the thin film is investigated with grazing-incidence small-angle X-ray scattering (GISAXS) measurement.

**Near-IR Dual Luminescent Single Layer OLEDs** Sebastian Hammer$^1$, Thomas Ferschke$^1$, Gabriel Freiherr von Eyb$^1$ and Jens Pflaum$^{1,2}$; $^1$Julius-Maximillian-University Würzburg, Germany; $^2$The Bavarian Center for Applied Energy Research, Germany

Multi-color organic light emitting diodes (OLEDs) comprising just one active electro-optical material define the next vital step in the fast-developing field of photonic devices for optical data communication. Taking into account the spectral range of relevant transmission windows as well as the feasibility of coupling light to plasmonic nanostructures, an OLED device emitting at different wavelengths in the near infra-red (NIR) would be highly desirable. In this contribution we cope with these challenges by demonstrating a stable, dual luminescent OLED based on just one electro-optical active zinc phthalocyanine (ZnPc) layer [1]. ZnPc turns out to be a promising candidate for such single layer devices due to its different polymorphs [2] combined with specific emission characteristics, its photo-stability as well as luminescence in the long wavelength range between 800 and 900 nm which allows for efficient coupling to plasmonic excitations in metallic nanostructures [3]. Performing photoluminescence (PL) studies on ZnPc thin films over the full course of the phase transition between α- and β-polymorph, we are able to optically monitor the thermally induced structural changes and their impact on the respective emission over time. The Johnson-Mehl-Kolmogorov-Avrami model [4] can consistently describe the observed behavior of the transition kinetics derived by the distinct emission features of the involved α- and β-polymorphs. In combination with complementary structural studies and temperature dependent PL measurements from 4 K - 360 K this enables us to provide a comprehensive picture of the excited state emission and its correlation to the crystalline packing on molecular length.
scales. *Vice versa*, we exploit these morphology dependent emission characteristics to demonstrate a prototypical dual luminescent OLED comprising just one active layer of ZnPc. As will be shown, the emission properties can be spectrally tuned on demand between the excimer emission of the α-phase at 930 nm and the Frenkel emission of the β-phase at 780 nm by a suited thermal treatment. Considering the long-term stability of the adjusted spectral intensity distribution of the devices our work presents an approach towards simple organic photonic devices being of interest for future optical information technology.

**Time Resolved GIWAXS of PEDOT:PSS During Electrolyte Gating** Bryan D. Paulsen¹, Ruiheng Wu¹, Christopher J. Takacs², Joseph Strzalka², Qingteng Zhang³ and Jonathan Rivnay¹; ¹Northwestern University, United States; ²Stanford Synchrotron Radiation Lightsource, United States; ³Argonne National Laboratory, United States

Electrochemical control of electronic charge (electrolyte gating) has opened a broad array of applications for organic electronic materials including printed electronics, biosensors, neuromorphics, electrochromics, supercapacitors, and actuators to name a few. Structure-property relationships are critical for the advancement of these materials across application. Because electrolyte gating necessarily requires dynamic ion and solvent intercalation and expulsion during device operation, static structural measurements, including steady-state in situ and operando measurements, are critically limited. Understanding electrolyte gated organic materials requires understanding their dynamic structure, which in turn requires time-resolved in situ or operando techniques. Grazing incident wide angle X-ray scattering is a powerful tool to for accessing the microstructure of organic electronic materials. In particular, PEDOT:PSS is ubiquitous in organic electrolyte gated devices. Here the dynamic time-resolved operando GIWAXS of acid crystallized PEDOT:PSS films during aqueous electrolyte gating is reported. The majority of the structural transformation occurs over a narrow range of potential and the doping-dedoping structure dynamics are not symmetric, displaying very different time dependences. Coupling the time-resolved operando GIWAXS with time-resolved UV-vis-NIR reveals that the PEDOT:PSS structure depends not on the absolute charge density, but on the relative population dynamics of neutral, polaronic, and bipolaronic species. Even after the relative populations of charge species equilibrates, time-resolved GIWAXS shows continued long-lived structural relaxations. This complicated phenomena, which is inaccessible with steady-state ex situ, in situ, or operando methods, gives a concrete physical origin of the commonly observed asymmetry of electrolyte gated transistor turn on and turn off. Further it identifies the structural origin of the rate limiting physical processes to be targeted for rational materials design. Finally, this work represents the first report time-resolved X-ray scattering of an organic electronic material during electrochemical gating.

Single-Layered Organic Photovoltaics with Double Cascading Charge Transport Pathways—17.78% Efficiencies
Thomas P. Russell1,2, Feng Liu3, Mei Zhang4, Lei Zhu5, Guanqing Zhou6, Tianyu Hou7, Chaoqun Qiu8, Qin Hu1, Bryon Larson9, Wei Fang10, Zaifei Ma11, Zheng Tang12, Haiming Zhu13 and Yongming Zhang14; 1University of Massachusetts Amherst, United States; 2Lawrence Berkeley National Laboratory, United States; 3Shanghai Jiao Tong University, China; 4National Renewable Energy Laboratory, United States; 5State Key Laboratory of Fluorinated Functional Membrane Materials, China; 6Donghua University, China; 7Zhejiang University, China

The chemical structure of donors (Ds) and acceptors (As) has been a limitation to the achievable power conversion efficiencies (PCEs) of bulk heterojunction (BHJ) active layers of binary D-A mixtures in organic photovoltaics. While new syntheses can be used to generate Ds and As, a holistic strategy that simultaneously improves open circuit voltage, short circuit current, and fill factor is necessary and has been pursued using different approaches in organic photovoltaics (OPVs) to PCEs. This holistic approach, though, has been elusive, due to morphological constraints and the inherent electronic structures of the components, leading to performance trade-offs. Ideally, both the morphology and electronic structure would lead to a maximization of light absorption, enhancement of exciton splitting, and ease of carrier extraction. Adding a third component has been done, resulting enhancement of either the morphology or electronic structure leading to PCE improvement, but only incremental, at best. However, using quarternary D-A blends, double cascading energy level alignment in BHJ organic photovoltaic active layers are realized, enabling efficient carrier splitting and transport, without perturbing the desired BHJ morphology. This has led to record-breaking PCEs of 17.78% where, by electronic structure and morphology optimization, simultaneous improvements of the open-circuit voltage, short-circuit current and fill factor are realized. This strategy opens numerous avenues to optimize light absorption, carrier transport, and non-radiative recombination losses.

Interplay of Phase Diagrams, Processing and Stability of Non-Fullerene Organic Solar Cells
Harald Ade; North Carolina State University, United States

Organic solar cells (OSCs) are considered one of the most promising cost-effective options for utilizing solar energy in high energy/weight or semi-transparent applications. Recently, the OSC field has been revolutionized by the development of novel non-fullerene small molecular acceptors with efficiencies now reaching >16%. The device stability and mechanical durability of non-fullerene OPVs have received less attention and developing devices with both high performance and long-term stability remains challenging, particularly if the material choice is restricted by roll-to-roll and benign solvent processing requirements and desirable ductility requirements. Yet, morphological and mechanical stability is a prerequisite for OPV commercialization. Here, we report our current understanding of the phase behavior of OPV mixtures and the relation of phase behavior to performance, processing needs (e.g., kinetic quenches), and morphological stability via meta-stability or vitrification. Characterization methods range from SIMS and DSC measurements to delineate phase diagrams and miscibility to soft x-ray scattering and WAXS to determine critical morphology parameters and molecule packing. A large range of miscibility (from hyper-miscibility to strong hypo-miscibility) is observed, including complex temperature dependence that can be a mixture of upper- and lower critical solution temperature behavior for both the binodal and the liquidus. The measurements presented should help to create molecular structure-function relationships that would allow some predictive guidance on how desired phase behavior and vitrification properties can be targeted by specific chemical design. They also allow to predict how unstable binary systems can be stabilized with the correct ternary compound.

1:18 PM *S.EL14.01.04
In-situ Multimodal Measurements of Structure Formation in Solution Processed Semiconductors
Lee Richter; National Institute of Standards and Technology, United States
Solution processing of electrically active layers is a promising route to sustainable manufacturing of functional components on diverse substrates such as flexible foils and textiles. Typically, solution processing does not result in the thermodynamic equilibrium form; instead metastable, kinetically trapped structures dominate. This allows great flexibility in the ability to tailor film structure (and performance) by processing details. In general, ink formulation (solvent, additives), processing conditions (casting temperature), and post processing (thermal and solvent annealing) are empirically optimized. The transition to rational process design requires in-situ measurements to determine the complex trajectory of the system through phase separation and domain refinement. Photon-based techniques are ideally suited to this problem, yet no single measurement provides the required knowledge of composition, nano- and meso- scale structure. Lab-scale techniques, such as UV-vis or IR spectroscopy, ellipsometry, and photoluminescence are easily implemented and rapid, yet rely on phenomenological relationships between observable and structure. Synchrotron based grazing incidence X-ray scattering techniques (both wide angle diffraction and small angle scattering) are more rigorous in interpretation but can be limited in contrast. By performing multiple measurements on a single system, either simultaneously, or separately, detailed models for the kinetic evolution of film structure can be developed. Results will be presented from a number of studies of solution processing of organic semiconducting layers for both photovoltaic and transistor applications. Studies of both ink deposition, via blade coating and post processing (thermal and solvent vapor annealing) will highlight insights into phase separation, liquid-liquid vs liquid-solid, and kinetics, nucleation and vitrification, afforded by multimodal analysis for each highlighted system. The role of fundamental material properties: semi-crystallinity, liquid crystallinity, glass transition temperature, etc. as guides to ink processing will be developed.

**In Situ and In Operando Scattering Studies on Polymer Based Organic Solar Cells**

Peter Muller-Buschbaum; TU Munich, Germany

Organic solar cells are an interesting alternative to conventional silicon based solar cells as the feature new possibilities introduced by using a different class of materials namely polymers. Instead of expensive ultra-high vacuum technologies, fabrication can be done at room temperature, using wet chemical processing, and thereby enabling usage of methods such as roll-to-roll printing. As a consequence, the production of organic solar cells has the potential to become very cheap and easy. With in-situ grazing incidence small and wide angle X-ray scattering (GISAXS and GIWAXS) studies, we gain information on the kinetics of morphology formation of electrodes, blocking layers and active layers of the solar cells during processing. In terms of large scale usability, one of the major challenges for organic solar cells is to overcome their relatively short lifetime, as compared to their inorganic counterparts. To gain a deeper understanding of organic solar cell degradation with respect to changes in the active layer nano-morphology, we present an in-situ study on model polymer-fullerene solar cells during the first hours of operation. The in-operando study reveals information on both, its evolving current-voltage characteristics and active layer nano-morphology. For that purpose, GISAXS / GIWAXS measurements and current-voltage (IV) tracking of an operating solar cell are performed simultaneously to gain fundamental understanding. Starting from an optimized morphology of the active layers in terms of highest efficiencies for organic solar cells, depending on the system, a mixing or demixing process are identified to cause changes of the morphology. The altered morphology is less optimal for charge transport through the active layer due to poor percolation in a too fine morphology or poor splitting of excitons in a too coarse morphology.

**Real-Time Investigation of Crystallization Pathways of Organo-Metal-Halide Perovskites Solar by In Situ X-Ray Scattering**

Michael F. Toney; SLAC National Accelerator Laboratory, United States

Perovskite solar cells (PSCs) have gained tremendous attention as potential materials for photovoltaics due to their high efficiencies approaching the best silicon solar cells and their compatibility with low-cost low-temperature fabrication methods (such as solution processing). Many solution-processing approaches have been adopted to manipulate perovskite formation including anti-solvent processing, inert-gas jet treatment, and additive-assisted processing. Some of these approaches allow room-temperature processing of perovskite thin films, while other approaches require post-deposition annealing. Perovskite film formation is complex, involving the formation of intermediates and/or metastable phases that strongly affect the final perovskite film microstructure. Therefore, understanding the mechanism of perovskite formation and the crystallization pathways is key for more facile control of perovskite formation. An effective way to understand the mechanisms of perovskite formation is using real-time X-ray scattering. Here, we use time-resolved x-ray scattering to investigate the perovskite formation of MAPbI₃-based perovskites and mixed cation (Cs, FA)PbI₃ perovskites in-situ during spin coating and the subsequent post-deposition treatments with different processing approaches such as additive-assisted processing, anti-solvent processing and N₂-gas jet treatment.
Time-resolved monitoring of the perovskite thin film processing reveals the formation of intermediate phases on the route of perovskite formation, whereas perovskite formation is dominated by a sol-gel process. For MAPbI₃-based perovskites processed with the MASCN additive, we show that the nature of the intermediate precursor phases and their formation/dissociation dynamics have an impact on the extent of nucleation and growth of perovskite phase affecting the microstructure of the perovskite film. Our findings reveal that the combination of two precursors (MASCN-precursor and DMSO-precursor) with fast and slow transformation rates contributes to the formation of micron-sized perovskite crystals, through seeding nuclei combined with the slow growth of the perovskite phase. For Cs-FA-containing perovskites, we show how the competition between the non-perovskite and perovskite phases formation are affected by the processing treatments. We find that dropping anti-solvent induces immediate crystallization from the bulk wet film, whereas applying N₂-gas works by depleting volatiles from the top-surface leading to interface-induced crystallization that occurs after reaching supersaturation, while both treatments result in dominant crystallization of non-perovskite hexagonal phase with the formation of seeds of perovskite phase. When neither treatment is applied, the as-cast film is mostly amorphous with little non-perovskite phase formation. We further show how the initial structure of the as-cast precursor film impacts the perovskite formation during the subsequent annealing treatment.

Our work highlights the importance of real-time investigation of perovskite film formation which can aid in establishing processing-microstructure-functionality relationships and help to provide a fundamental understanding of the mechanisms of perovskite formation.

Advances in the Theoretical Description of Nonfullerene-Based Organic Solar Cells Jean-Luc Bredas¹²; ¹Georgia Institute of Technology, United States; ²The University of Arizona, United States

The field of organic photovoltaics is currently enjoying a major resurgence thanks to the development of increasingly performant combinations of polymer donors and nonfullerene-based acceptors. Power conversation efficiencies now approach the 18% mark in single-junction devices.

In this contribution, we will provide a theoretical description of of the factors that have enabled such advances, including:
- hybridization of the strongly absorbing local-exciton electronic states with the charge-transfer electronic states appearing at the donor-acceptor interfaces [1-2];
- minimization of the voltage losses through reduction of the nonradiative recombination pathways [3]; and
- extent of order in the nonfullerene acceptor domains [4-5].

This work is supported by the Office of Naval Research.

Pushing the Resolution Limits of Transmission Electron Microscopy for Imaging of Conjugated Polymers with Sub 4 Angstrom Resolution
Brooke Kuei, Ryan Fair and Enrique D. Gomez; The Pennsylvania State University, United States

Despite significant advances in transmission electron microscopes, the resolution limit of polymers remains limited by the electron dose the sample can handle. We thus propose that revealing the mechanisms for radiation damage can yield new methods for imaging at length scales not previously achievable. We have characterized the effect of beam damage on various conjugated polymers, including poly(3-hexylthiophene-2,5-diyl) (P3HT), poly(3-dodecylthiophene-2,5-diyl) (P3DDT), poly[N-9′-heptadecanyl-2,7-carbazole-alt-5,5-(4′,7′-di-2-thienyl-2′,1′,3′-benzothiadiazole)] (PCDTBT), and poly[[9-(1-octylmonyl)-9H-carbazole-2,7-diyl]-2,5-thiophenediyl-2,1,3-benzothiadiazole-4,7-diyl-2,5-thiophenediyl] and poly[[5,6-difluoro-2,1,3-benzothiadiazol-4,7-diyl]-alt-(3,3’’’-di(2-octyldodecyl)-2,2’;5’;2’’;5’’’;2’’’’-quaterthiophene-5,5’’’’-diyl)] (PFBT4T-2OD), via electron diffraction and low-loss electron energy-loss spectroscopy (EELS). We find that the critical dose for damage depends on dose rate, temperature and beam size. Altogether, our results suggest that a significant mechanism for beam damage in conjugated polymers is diffusion of secondary reactive species, such as free radicals. These new concepts in beam damage reveal strategies to push the resolution in the TEM, allowing us to image 3.6 Å π-π stacking in PFBT4T-2OD with high-resolution TEM (HRTEM) at cryogenic conditions, 4D STEM again at cryo temperatures, and HRTEM at room temperature using antioxidants to limit damage. We use high resolution information to reveal pathways for charge conduction, including the type of grain boundaries present, as well as the effect of liquid crystallinity on promoting orientational correlations between domains. Together with our work on predicting liquid crystalline order in conjugated polymers, we use microscopy to develop strategies for designing new molecules with long-range order and strong orientational correlations that lead to enhancement of macroscopic charge transport.

In Situ Transient Absorption Spectroscopy During the Formation of Organic Thin Films
Cathy Y. Wong; University of Oregon, United States

The electronic structure and exciton dynamics of the molecules and polymers that form the active layer in organic electronic devices can change dramatically during solution deposition. As solvent vaporizes, molecules aggregate and become electronically coupled, sometimes dramatically changing the exciton dynamics and thus the suitability of the material for electronic devices. The exciton dynamics of molecules in solution and in films of aggregates can be measured using transient absorption spectroscopy. However, the progression of exciton dynamics during film formation is unknown since measurements typically cannot be performed quickly enough to collect accurate transient absorption spectra of these species. The exciton dynamics of evolving material systems can be measured by increasing the speed of data collection. A novel implementation of transient absorption spectroscopy is introduced that can measure transient spectra with up to a 60 ps pump-probe time delay in one shot. The exciton dynamics of intermediate aggregation states are revealed during the formation of an organic film. The information gained using this technique can be used to modify environmental parameters during the film formation process to kinetically trap aggregates with exciton dynamics tailored for particular types of electronic devices.

Developing Models to Determine the Impacts of Synthetic Design and Processing on Organic Semiconductors
Chad Risko; University of Kentucky, United States

The potential to modulate material (opto)electronic properties through well-established synthetic chemistry methods has made organic semiconductors (OSC) a scientific playground. Limited knowledge among the relationships that connect chemical composition and molecular architecture, materials processing, and the solid-state packing arrangements that define the underlying physicochemical processes that determine OSC performance, however, renders OSC design to be highly Edisonian. We seek to address these connections to facilitate OSC design and deployment through the development and application of multiscale, theoretical materials chemistry approaches that build upon principles from organic and physical chemistry, condensed matter physics, and materials and polymer science. In this presentation, we will demonstrate how such approaches can reveal the striking influence that seemingly modest changes in chemical structure can have on the dynamics and solid-state packing of OSC active layers and resulting materials characteristics.
The materials discovery cycle contains many different components, including synthesis, characterization and data analysis and interpretation. In the past few decades, automatic synthesis pipelines have been established for many chemistry and materials systems. For characterization, many advanced techniques, such as X-ray scattering and NMR crystallography, have enabled the structure identification of various chemical, biological and materials systems, including polymers, inorganic materials, and proteins. These techniques have been developed and improved substantially over the past few decades, which brings high-throughput experimental discovery into reach. Meanwhile, these breakthroughs produce enormous data amounts. However, the process of understanding the structural features from data is still very labor-intensive. It requires many man-hours of work by highly specialized and trained scientific staff to interpret the data and identify the structure correctly. Recently, machine learning, a branch of artificial intelligence, has demonstrated the potential to tackle and accelerate the analysis of common techniques such as tomography, scattering, and spectroscopy.

Investigating MAPbI3 Thin-Film Formation During Spin Coating by In Situ Absorption and Photoluminescence Spectroscopy
Mihirsinh Chauhan1, Yu Zhong1, Konstantin Schötz1, Brijesh Trpathi2, Sven Huettner1, Anna Kohler1 and Fabian Panzer1; 1University of Bayreuth, Germany; 2Pandit Deendayal Petroleum University, India

Until today, the two-step processing method represents an attractive route for the thin film formation of halide perovskites. However, a fundamental understanding about the film formation dynamics in case of spin coating methylammonium iodide (MAI) on PbI2 has not been established yet. Here we apply in-situ optical spectroscopy during the two-step film formation of the model halide perovskite MAPbI3 via spin coating. We identify and analyze in detail the optical features that occur in photoluminescence and corresponding absorption spectra during processing. We find that the film formation takes place in five consecutive steps, including the formation of a MAPbI3 capping layer via an interface crystallization and the occurrence of an intense dissolution-recrystallization process. Consideration of confinement and self-absorption effects in the PL spectra, together with consideration of the corresponding absorption spectra allows to quantify the growth rate of the initial interface crystallization to be 12 nm/s. We find the main dissolution recrystallization process to happen with a rate of 445 nm/s, emphasizing its importance to the overall processing.

5:15 AM S.EL14.01.02
In-Situ Characterization of Organic Colloidal Composite Nanoparticles
Anderson M. de Campos and Tayebeh Ameri; University of Munich (LMU), Germany

The use of aqueous / alcohol-based nanoparticulate dispersions in printable optoelectronics offers a promising approach to control the donor: acceptor morphology on the nanoscale with the benefit of environmentally-friendly, solution-based fabrication. Appropriate nanoscale morphology of the donor: acceptor composite nanoparticles (NPs), such as Janus structure, is the prerequisite for a well-suited mesoscale morphology formation to ensure an efficient charge transport. The final nanostructure of a composite NP is determined by the competition between thermodynamics and kinetics during the particle formation. However, fine tuning and control of these variables require prior observations and in-situ measurements. In this presentation, we will discuss our achieved results on the in-situ analysis of the size growth and morphology evolution of the colloidal organic composite NPs by employing a stopped-flow apparatus equipped with various optical spectroscopic methods.

5:30 AM S.EL14.01.03
Developing Models to Determine the Impacts of Synthetic Design and Processing on Organic Semiconductors

6:00 AM S.EL14.01.04
In-situ Multimodal Measurements of Structure Formation in Solution Processed Semiconductors Lee Richter; National Institute of Standards and Technology, United States

Solution processing of electrically active layers is a promising route to sustainable manufacturing of functional components on diverse substrates such as flexible foils and textiles. Typically, solution processing does not result in the thermodynamic equilibrium form; instead metastable, kinetically trapped structures dominate. This allows great flexibility in the ability to tailor film structure (and performance) by processing details. In general, ink formulation (solvent, additives), processing conditions (casting temperature), and post processing (thermal and solvent annealing) are empirically optimized. The transition to rational process design requires in-situ measurements to determine the complex trajectory of the system through phase separation and domain refinement. Photon-based techniques are ideally suited to this problem, yet no single measurement provides the required knowledge of composition, nano- and meso- scale structure. Lab-scale techniques, such as UV-vis or IR spectroscopy, ellipsometry, and photoluminescence are easily implemented and rapid, yet rely on phenomenological relationships between observable and structure. Synchrotron based grazing incidence X-ray scattering techniques (both wide angle diffraction and small angle scattering) are more rigorous in interpretation but can be limited in contrast. By performing multiple measurements on a single system, either simultaneously, or separately, detailed models for the kinetic evolution of film structure can be developed. Results will be presented from a number of studies of solution processing of organic semiconducting layers for both photovoltaic and transistor applications. Studies of both ink deposition, via blade coating and post processing (thermal and solvent vapor annealing) will highlight insights into phase separation, liquid-liquid vs liquid-solid, and kinetics, nucleation and vitrification, afforded by multimodal analysis for each highlighted system. The role of fundamental material properties: semi-crystallinity, liquid crystallinity, glass transition temperature, etc. as guides to ink processing will be developed.

Resolving Structure Formation in Printed Thin Films Oliver Filonik1, Michael Buchhorn2, Christopher Greve2,1, Stephan Prüller1, Fabian Eller2, Adrian Ebert2 and Eva M. Herzig2; 1Technische Universität München, Germany; 2Universität Bayreuth, Germany

Structure formation is a complex interplay of physical interactions between the molecules of a system. In thin films structure formation can be triggered e.g. by the evaporation of the solvent or by heat treatments and is further influenced by a multitude of external parameters. Such external parameters can influence the nanostructure significantly and therefore alter the function of the involved materials. For some external parameters already small changes are sufficient to alter the final nanostructure within the thin film. If these are unidentified this results in poor reproducibility of the final thin film structure. For other external parameters the processing is rather stable. Often it is unclear what the physical reason for the sensitivity or stability towards the external parameters is. We want to show that time-resolved measurements, ideally on multi-length scales and with complementary methods will help to resolve fundamental structure formation processes in thin films. Comparing different material systems from printed organic photovoltaics to hybrid perovskite solar cells, I will point out the opportunities we have in interfering with the structure formation process to tune the material properties by external processing parameters.

6:45 AM S.EL14.01.06
In Situ Investigation of Sputter Deposition Electrodes on Different Layers of Non-Fullerene Organic Solar Cells Xinyu Jiang1, Simon J. Schaper1, Matthias Schwartzkopf2, Stephan V. Roth2,3 and Peter Muller-Buschbaum1,4; 1Technische Universität München, Germany; 2Deutsches Elektronen-Synchrotron DESY, Germany; 3KTH Royal Institute of Technology, Sweden; 4Heinz Maier-Leibnitz Zentrum, Germany

Bulk heterojunction (BHJ) polymer solar cells have gained significant improvements via both novel organic synthesis and easy fabrication methods. Especially the fabrication through solution allows for large scale deposition processes such as roll to roll printing. Furthermore, the application of conjugated polymers as functional layers makes organic solar cells an
attractive approach for a cost-effective solution to the current energy-shortage issue. Recently, the efficiencies of non-fullerene organic solar cells (OSCs) with small molecule acceptors rapidly increased to over 16%, which makes OSCs competitive to commercial available solid-state solar cells [1]. However, to make OPVs commercial competitive in the long term, overcoming degradation and achieving long device lifetime is of significant interest. The peeling-off of the electrode from the contact layer surface caused by aging stresses lead to an intrinsic degradation, which is one of the main reasons for the performance loss of OSCs [2]. Although thermal evaporation is a common method of fabricating the electrode due to its low cost, this technique brings several problems for the device such as soft contact between electrode and function layer interface. Another disadvantage is the inevitable high temperature during the fabrication process. Magnetron sputtering technique is a promising technique to solve these issues.

For understanding the mechanism of the metal cluster growth on the thin films with various morphologies, we introduce in-situ grazing incidence small angle X-ray scattering (GISAXS) is a technique to observe the morphology change during sputter process. In-situ GISAXS measurements during sputter deposition of Al nanolayers are conducted at the beamline P03 of DESY in Hamburg via using a DC magnetron sputter chamber. Active layers contain a P3DT4T:2OD donor with a small molecule acceptor EH-IDTBR blender dissolved in 1,2,4-trimethyl benzene and chlorobenzene respectively to obtain different morphology. Then 10 nm MoO3 blocking layers were deposited on their top surface, which usually acts as the electron blocking layer for the invert solar cell device. A 20 nm Al layer deposited on these four different layers through the sputtering technique. The morphology evolution during Al nanolayers growth observed in the out-of-plane cuts. The plane referred to is defined by the sample’s surface normal and the wave vector of the incident X-ray beam. All peaks of different thin films appear at lower effective thickness value. These peaks can be assigned to Al particles and clusters appearing during the sputtering process. It should be noted that the formation of Al layers with one layer MoO3 deposited on the active layer is slower than the active layer without deposition of MoO3. In addition, SEM and AFM images indicate that the morphology impact on Al growth significantly.

7:00 AM *S.EL14.01.07
Understanding and Controlling Aggregate Formation During Spin-Coating Anna Kohler, Fabian Panzer, Konstantin Schötz and Markus Reichenberger; University of Bayreuth, Germany

In this presentation, I shall discuss what we can learn from comparatively simple spectroscopic measurements regarding the formation of aggregates in polymers and oligomers when spin-coating. I will demonstrate that the aggregation process is preceded by a planarization of the polymer backbone, and that it can be described like a coil-globule transitions [1]. In particular, the nature of the resulting aggregates can be controlled through the substrate temperature [2,3] which changes the nucleation process. This is illustrated for a range of widely used polymers such as P3HT, PFO, PCDTBT, PCE11 and others.

7:30 AM S.EL14.01.09
The Critical Role of Materials’ Interaction in Realizing Organic Field-Effect Transistors via High-Dilution Blending with Insulating Polymers Indunil Angunawela, Masrur Morshed Nahid, Masoud Ghasemi, Aram Amassian, Harald Ade and Abay Gadisa; North Carolina State University, United States

A detailed understanding of the molecular and mesoscopic structure of a solution-processed organic, semiconducting thin film is still lacking, mostly due to the complicated film morphology. Recent progress, however, demonstrated the possibility of tuning the electronic properties of either short or long-range local molecular aggregates in films where high-performing semiconducting polymers are dispersed in a majority insulator and utilized in organic field effect transistors. Such a diluted blend matrix offers opportunities not only to reduce the cost associated with the semiconducting polymer significantly but also to systematically explore the fundamental molecular structure-function relationships. Herein, basic thermodynamic material interaction principles, in conjunction with detailed morphological studies, are invoked to understand the mesoscale
structures leading to more efficient charge transport in the ultrathin films applicable for transparent and flexible electronic applications. Exploring two high-performing polymers, PDPP3T and N2200, we report a drastic variance in the change in charge transport properties of these two polymers when dispersed in an insulator matrix, due to the large difference in thermodynamics, resulting differences in molecular interaction and dimension of their fibrillar morphology. This basic finding provides design guidelines for semiconductor: insulator blends to achieve long-range ordered polymers by selecting compatible blends, and hence, high mobility in organic transparent ultrathin films.

7:45 AM *S.EL14.01.10
In Situ and In Operando Scattering Studies on Polymer Based Organic Solar Cells  
Peter Muller-Buschbaum; TU Munich, Germany

Organic solar cells are an interesting alternative to conventional silicon based solar cells as the feature new possibilities introduced by using a different class of materials namely polymers. Instead of expensive ultra-high vacuum technologies, fabrication can be done at room temperature, using wet chemical processing, and thereby enabling usage of methods such as roll-to-roll printing. As a consequence, the production of organic solar cells has the potential to become very cheap and easy. With in-situ grazing incidence small and wide angle X-ray scattering (GISAXS and GIWAXS) studies, we gain information on the kinetics of morphology formation of electrodes, blocking layers and active layers of the solar cells during processing. In terms of large scale usability, one of the major challenges for organic solar cells is to overcome their relatively short lifetime, as compared to their inorganic counterparts. To gain a deeper understanding of organic solar cell degradation with respect to changes in the active layer nano-morphology, we present an in-situ study on model polymer-fullerene solar cells during the first hours of operation. The in-operando study reveals information on both, its evolving current-voltage characteristics and active layer nano-morphology. For that purpose, GISAXS / GIWAXS measurements and current-voltage (IV) tracking of an operating solar cell are performed simultaneously to gain fundamental understanding. Starting from an optimized morphology of the active layers in terms of highest efficiencies for organic solar cells, depending on the system, a mixing or demixing process are identified to cause changes of the morphology. The altered morphology is less optimal for charge transport through the active layer due to poor percolation in a too fine morphology or poor splitting of excitons in a too coarse morphology.

5:00 AM S.EL14.02.01
Microfluidic Printing of Two-Phase Polymer Semiconductor Systems for Enhanced Charge Transport and Solar Efficiency  
Antonio Facchetti1,2; 1Northwestern University, United States; 2Flexterra Inc., United States

The rational design of phase purity for two-phase conjugated polymer systems is challenging but crucial for organic/printed electronics. In this presentation we report a ‘mixed-flow design’ concept for printing two-phase conjugated polymer systems promoting phase purity for application in both bulk-heterojunction solar cells and thin-film transistors. The key aspect of this work lies in the mixed-flow design concept with the integration of both laminar and extensional flows using a unique designed microstructured shear blade. The fluid simulation is utilized as a tool for the flow pattern design to induce the shear, stretch and push-out effects to achieve optimal polymer chain conformation for phase purity. Experimentally, this mixed-flow strategy enhances semiconductor blend thin film crystallinity and increases phase purity with proper percolation. The improved morphology leads to higher short-circuit currents, enhanced fill factors, and significantly improved power conversion efficiency (PCE, enhanced by ~50% compared with conventional blade coating method) for printed all-polymer solar cells. In addition, this printing technique also enhances the performance of all-semiconductor polymer ambipolar transistors (mobility = + ~70%) as well as unipolar semiconductor polymer-insulating polymer transistors (mobility = + ~100%), suggesting the versatility of this methodology for various two-phase conjugated polymer systems.

5:15 AM S.EL14.02.03
Uncovering the Roles of the Donor-Acceptor Oligomer Chemistry and Solution Environment on the Conformation and Aggregation of Oligomers in Solution  
Chamikara D. Karunasena, Shi Li and Chad Risko; University of Kentucky, United States
The extrinsic properties of organic semiconductors (OSC) are deeply interconnected to their thin-film morphologies. To implement high performance and reproducible device fabrication guidelines and for synthetic regulation of the thin film morphologies, a rich understanding of the structure–processing–function relationships needs to be established. However, there currently exists limited insight to elucidate the physicochemical mechanisms that determine aggregation and self-assembly of OSC. Through molecular dynamics (MD) simulations, we aim to systematically understand how molecular design and processing chemistry impact the behavior of donor–acceptor (D–A) type oligomers in solution. In particular, we isolate the roles of the oligomer chemistry, oligomer concentration, and host solvent. Variations in these factors lead to a variety of rotational isomer preferences that, in turn, impacts the capacity of the oligomers to aggregate in solution. In total, the results provide molecular-scale foundations to allow for kinetic and thermodynamic control of OSC morphology development through solvent optimization.

Single-Layered Organic Photovoltaics with Double Cascading Charge Transport Pathways—17.78%

Efficiencies Thomas P. Russell1,2, Feng Liu3, Mei Zhang3, Lei Zhu3, Guanqing Zhou3, Tianyu Hou3, Chaoqun Qiu3, Qin Hu1, Bryon Larson4, Wei Fang5, Zaifei Ma6, Zheng Tang6, Haiming Zhu1 and Yongming Zhang3; 1University of Massachusetts Amherst, United States; 2Lawrence Berkeley National Laboratory, United States; 3Shanghai Jiao Tong University, China; 4National Renewable Energy Laboratory, United States; 5State Key Laboratory of Fluorinated Functional Membrane Materials, China; 6Donghua University, China; 7Zhejiang University, China

The chemical structure of donors (Ds) and acceptors (As) has been a limitation to the achievable power conversion efficiencies (PCEs) of bulk heterojunction (BHJ) active layers of binary D-A mixtures in organic photovoltaics. While new syntheses can be used to generate Ds and As, a holistic strategy that simultaneously improves open circuit voltage, short circuit current, and fill factor is necessary and has been pursued using different approaches in organic photovoltaics (OPVs) to PCEs. This holistic approach, though, has been elusive, due to morphological constraints and the inherent electronic structures of the components, leading to performance trade-offs. Ideally, both the morphology and electronic structure would lead to a maximization of light absorption, enhancement of exciton splitting, and ease of carrier extraction. Adding a third component has been done, resulting enhancement of either the morphology or electronic structure leading to PCE improvement, but only incremental, at best. However, using quaternary D-A blends, double cascading energy level alignment in BHJ organic photovoltaic active layers are realized, enabling efficient carrier splitting and transport, without perturbing the desired BHJ morphology. This has led to record-breaking PCEs of 17.78% where, by electronic structure and morphology optimization, simultaneous improvements of the open-circuit voltage, short-circuit current and fill factor are realized. This strategy opens numerous avenues to optimize light absorption, carrier transport, and charge transfer state energy levels by the chemical constitution of the components. The chemical structures of the Ds and As offer control over electronic structure and charge transfer state energy levels, enabling manipulation of hole-transfer rates, carrier transport, and non-radiative recombination losses.

5:30 AM *S.EL14.03/S.EL13.02.04
Interplay of Phase Diagrams, Processing and Stability of Non-Fullerene Organic Solar Cells Harald Ade; North Carolina State University, United States

Organic solar cells (OSCs) are considered one of the most promising cost-effective options for utilizing solar energy in high energy/weight or semi-transparent applications. Recently, the OSC field has been revolutionized by the development of novel non-fullerene small molecular acceptors with efficiencies now reaching >16%. The device stability and mechanical durability of non-fullerene OPVs have received less attention and developing devices with both high performance and long-term stability remains challenging, particularly if the material choice is restricted by roll-to-roll and benign solvent processing requirements and desirable ductility requirements. Yet, morphological and mechanical stability is a prerequisite for OPV
commercialization. Here, we report our current understanding of the phase behavior of OPV mixtures and the relation of
phase behavior to performance, processing needs (e.g., kinetic quenches), and morphological stability via meta-stability or
vitrification. Characterization methods range from SIMS and DSC measurements to delineate phase diagrams and miscibility
to soft x-ray scattering and WAXS to determine critical morphology parameters and molecule packing. A large range of
miscibility (from hyper-miscibility to strong hypo-miscibility) is observed, including complex temperature dependence that
can be a mixture of upper- and lower critical solution temperature behavior for both the binodal and the liquidus. The
measurements presented should help to create molecular structure-function relationships that would allow some predictive
guidance on how desired phase behavior and vitrification properties can be targeted by specific chemical design. They also
allow to predict how unstable binary systems can be stabilized with the correct ternary compound.

6:00 AM *S.EL14.03/S.EL13.02.05
Structure, Transport and Charging in Organic Mixed Ionic/Electronic Conductors Jonathan Rivnay; Northwestern
University, United States

Organic mixed ionic/electronic conductors have gained considerable interest in bioelectronics, power electronics, circuits and
neuromorphic computing. These organic, often polymer-based, semiconductors rely on a combination of ionic transport,
electronic transport, and high volumetric charge storage capacity. Despite recent progress and a rapidly expanding library of
new materials, the understanding of stability and transport/coupling of ionic and electronic carriers remain largely
unexplored. We highlight recent synthetic and processing approaches used to tailor electrochemical device properties and
stability, as well as new opportunities enabled by such advances. Our understanding of critical processes in electrochemical
deVICES further requires us to study these materials in device-relevant conditions, fully considering the effects of ions and
solvent on microstructure and transport. To this end, we report on recent efforts towards structure-property relations in high
performance organic mixed conductors using ex-situ, in-situ, and operando scattering and spectroscopic techniques.

6:30 AM *S.EL14.03/S.EL13.02.06
Real-Time Investigation of Crystallization Pathways of Organo-Metal-Halide Perovskites Solar by In Situ X-Ray
Scattering Michael F. Toney; SLAC National Accelerator Laboratory, United States

Perovskite solar cells (PSCs) have gained tremendous attention as potential materials for photovoltaics due to their high
efficiencies approaching the best silicon solar cells and their compatibility with low-cost low-temperature fabrication
methods (such as solution processing). Many solution-processing approaches have been adopted to manipulate perovskite
formation including anti-solvent processing, inert-gas jet treatment, and additive-assisted processing. Some of these
approaches allow room-temperature processing of perovskite thin films, while other approaches require post-deposition
annealing. Perovskite film formation is complex, involving the formation of intermediates and/or metastable phases that
strongly affect the final perovskite film microstructure. Therefore, understanding the mechanism of perovskite formation and
the crystallization pathways is key for more facile control of perovskite formation. An effective way to understand the
mechanisms of perovskite formation is using real-time X-ray scattering. Here, we use time-resolved x-ray scattering to
investigate the perovskite formation of MAPbI$_3$-based perovskites and mixed cation (Cs, FA)PbI$_3$ perovskites in-situ during
spin coating and the subsequent post-deposition treatments with different processing approaches such as additive-assisted
processing, anti-solvent processing and N$_2$-gas jet treatment.

Time-resolved monitoring of the perovskite thin film processing reveals the formation of intermediate phases on the route of
perovskite formation, whereas perovskite formation is dominated by a sol-gel process. For MAPbI$_3$-based perovskites
processed with the MASCN additive, we show that the nature of the intermediate precursor phases and their
formation/dissociation dynamics have an impact on the extent of nucleation and growth of perovskite phase affecting the
microstructure of the perovskite film. Our findings reveal that the combination of two precursors (MASCN-precursor and
DMSO-precursor) with fast and slow transformation rates contributes to the formation of micron-sized perovskite crystals,
through seeding nuclei combined with the slow growth of the perovskite phase. For Cs-FA-containing perovskites, we show
how the competition between the non-perovskite and perovskite phases formation are affected by the processing treatments.
We find that dropping anti-solvent induces immediate crystallization from the bulk wet film, whereas applying N$_2$-gas works
by depleting volatiles from the top-surface leading to interface-induced crystallization that occurs after reaching
supersaturation, while both treatments result in dominant crystallization of non-perovskite hexagonal phase with the
formation of seeds of perovskite phase. When neither treatment is applied, the as-cast film is mostly amorphous with little
non-perovskite phase formation. We further show how the initial structure of the as-cast precursor film impacts the
perovskite formation during the subsequent annealing treatment.

Our work highlights the importance of real-time investigation of perovskite film formation which can aid in establishing
processing-microstructure-functionality relationships and help to provide a fundamental understanding of the mechanisms of perovskite formation.

Multimodal Measurements for Organic Semiconductors—Comparing Real Space and Reciprocal Space Dean M. DeLongchamp, Subhrangsu Mukherjee and Andrew Herzing; National Institute of Standards and Technology, United States

Resonant soft X-ray scattering (RSoXS) has proven to be a powerful technique to measure the structure of organic semiconductor systems. A particularly common application is found in the determination of relative domain purity in organic solar cells (OSC). In polymer-fullerene systems, RSoXS has shown that higher average domain purity is generally correlated to OSC device performance. A simple interpretation of RSoXS purity measurements is complicated by the consideration that real morphologies may be composed of three or more phases, with mixed amorphous regions in addition to relatively pure, aggregated donor and acceptor domains. Scattering originating from orientational contrast is convoluted with phase purity information in OSC systems, further complicating analysis. A complete model that includes both molecular orientation and composition fluctuations is required.

Phase information is lost in RSoXS pattern collection, as it is in most radiation scattering experiments, and algorithmic reconstruction of the reciprocal-space pattern into a real-space model is not straightforward. Model development and forward pattern simulation with iterative comparison to experimentally collected data is the most common interpretation method. In RSoXS analysis these approaches are greatly accelerated by multimodal measurements that directly provide a real-space model of composition fluctuations. By applying atomic force microscopy (AFM) and transmission electron microscopy (TEM), we can construct real-space models for RSoXS interpretation that allow for the extraction of information that the RSoXS technique uniquely provides: the nanoscale molecular orientation. A mathematical and computational framework for forward-simulating RSoXS patterns from these real-space models will be demonstrated. Results from these approaches explain trends in device performance for both OSC and organic transistor devices.

5:30 AM S.EL14.04.02
Revealing Strain-Induced Conjugated Polymer Behaviors Using Soft X-Ray Scattering and Spectroscopy Wenkai Zhong1, Gregory Su1, Feng Liu2, Wanli Yang1 and Cheng Wang1; 1Lawrence Berkeley National Laboratory, United States; 2Shanghai Jiao Tong University, China

Conjugated polymers have generated great interest due to their potential in the fabrication of deformable logic circuits that can be integrated into portable/wearable electronics. Here, we developed a beamline setup that can be capable of probing the bulk- and surface-sensitive data of polymer thin films during tensile test using soft x-ray. The combination of experimental and simulated x-ray spectroscopies assists to uncover the fingerprint of molecular behaviors under strain-stress measurement. Furthermore, to establish the relationship of the molecular evolution and device performances, the charge transport properties of the static strained thin film are also evaluated. We expect this work can contribute to understand the molecular origins of mechanical behaviors associated with the resulting device performances.

5:45 AM S.EL14.04.03
Sharp Interfaces and Pure Domains Allow for Efficient Thick Organic Solar Cells for Roll-to-roll Production Obaid Alqahtani1,2, Victor Murcia1, Thomas Ferron1, Terry McAfee1,3, Safa Shoae4, Ardalan Armin5 and Brian A. Collins1; 1Washington State University, United States; 2Prince Sattam bin Abdulaziz University, Saudi Arabia; 3Advanced Light Source, Lawrence Berkeley National Laboratory, United States; 4University of Potsdam, Germany; 5Swansea University, United Kingdom

Organic solar cells (OSCs) shows continued progress as an alternative photovoltaic technology, now with power conversion efficiency record ~ 17% and rising. For successful industrialization of OSCs, a few challenges need to be overcome such as high performance with thick active layers. Intense research has shown that active-layer nanostructure governs performance in
Getting accurate performance predictions of organic semiconductors is crucial for the development of organic devices. Existing multi-scale analysis often relies on computationally expensive quantum-chemical calculations [1]. Machine learning approaches have been proposed to efficiently predict quantum-chemical quantities [2]. In this project, we present a multi-scale simulation for charge transport in an amorphous organic thin film of pentacene. The molecular structure of the pentacene film is obtained by Molecular Dynamics simulations. The transfer integrals between molecules are calculated with a novel approach that utilizes machine learning techniques. This method allows for efficient prediction of charge transport properties, enabling optimization of organic thin film devices for efficient energy conversion.

[1] Machine Learning for Predicting Charge Transfer Integrals in Organic Thin Films. Alessio Gagliardi and Michael Rinderle; Technical University Munich, Germany

Density Functional Theory (DFT) methods and passed to a kinetic Monte Carlo simulation to calculate charge carrier mobility. Since DFT simulations for every possible molecule orientation are not feasible we use machine learning using kernel ridge regression to predict the transfer integrals [3]. Critical steps to obtain a well trained, highly predictive model is the feature design, the prior information embedding and the structure of the training dataset. Several techniques will be discussed involving these three aspects of Machine Learning applied to organic semiconductor properties.

SESSION S.EL14.05: Materials Discovery

5:00 AM *S.EL14.05.04
Finding the Right Bricks for Molecular Legos—Data Mining Approaches to Organic Semiconductor Design Karsten Reuter, Christian Kunkel and Harald Oberhofer; Technische Universität München, Germany

Reflecting the general data revolution, knowledge-based methods are now also entering theoretical catalysis and energy related research with full might. Automatized workflows and the training of machine learning approaches with first-principles data generate predictive-quality insight into elementary processes and process energetics at undreamed-of pace. Computational screening and data mining allows to explore these data bases for promising materials and extract correlations like structure-property relationships. In this talk I will illustrate this general development on the basis of an in-house database of >64,000 organic molecular crystals for which charge-transport descriptors have been calculated from first principles [1]. Suitable clustering of this data leads for instance to engineered molecular crystals, in which promising scaffolds are functionalized with favorable side groups [2]. At the same time, smart visualization techniques like chemical space networks identify scaffolds with most room for optimization in hitherto least explored parts of materials space [3].

5:30 AM S.EL14.05.06
Quantum-Mechanical Investigation of Structure-Property Relationships in Organic Emitters for Efficient Thermally Activated Delayed Fluorescence Seyhan Salman1 and Veaceslav Coropceanu2; 1Clark Atlanta University, United States; 2Georgia Institute of Technology, United States

Thermally Activated Delayed Fluorescence (TADF) is one of the most promising mechanisms to realize high efficiency Organic Light Emitting Diodes (OLEDs) without the use of heavy transition metals and offers flexibility to fine-tune the electronic and optical properties of purely organic molecules. In TADF, nonemissive triplet excitons are harvested through a designed molecular emitter that undergoes efficient thermally activated reverse intersystem crossing (RISC) to a singlet manifold, which is followed by a radiative relaxation to the ground state. The rate of the RISC depends on the singlet-triplet energy gap, deltaE(ST), which needs to be minimized for an efficient TADF process. To minimize deltaE(ST), organic molecules with electron donor (D) and acceptor (A) groups are utilized, such that, the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) are localized on the donor and acceptor, respectively, giving spatially separated HOMOs and LUMOs, giving in a small deltaE(ST). While D-A molecules were the first examples of effective TADF materials, how this efficiency is achieved in devices is not understood. We use multiscale quantum-chemical methods to characterize the (opto)electronic properties of carbazole-based TADF emitters with known D-A groups. We benchmark our calculations with these systems. We will develop: (1) a comprehensive description, at the molecular level, of the fundamental photophysical processes of TADF emitters; (2) a modelling protocol that can accurately describe the electronic structure of such emitters; (3) structure-property relationships; and provide theoretical guidelines for the design of new materials and/or selection of existing materials with well-defined properties leading to devices with improved performances.
Improving Solution Processability of Benzodithiophene-Based Donor Polymer via Side Group Halogenation for Highly Efficient Organic Photovoltaics

Jin Su Park, Geonu Kim and Bumjoon J. Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

For the last few decades, bulk heterojunction (BHJ) organic photovoltaics (OPVs) have been considered as strong candidates for next generation power source for portable or wearable electronic devices with their versatile properties such as low-cost, large-area solution based fabrication, light weight, and flexibility. For general binary blend based OPVs, rational design of polymer donor for optimization of its physical and chemical properties is probably the most decisive step to improve the efficiency. In this sense, introduction of halogen atoms like fluorine and chlorine to either backbone or side chain of conjugated polymer is one of the most favored strategies. Halogen atoms have strong electronegativity values so that fluorinated or chlorinated polymers have downshifted HOMO and LUMO energy levels. This is particularly beneficial for donor polymers since downshifted HOMO can contribute to increase in open circuit voltage (VOC). Furthermore, small size fluorine atoms can induce molecular planarity to enhance the long-range ordering in the blend morphology, while large size chlorine atoms can reduce the unnecessary molecular aggregation. In other words, we can precisely control the blend morphology with fluorine and chlorine atoms. Herein, we demonstrated the positive effects of halogenation strategy to the OPV performance with three polymer donor series PBDT-X (X=H, F, and Cl). We could successfully achieve simultaneous control in the HOMO energy level and aggregation behavior of BDT-based polymer via introducing fluorine and chlorine atoms to side thienyl groups. Interestingly, PBDT-Cl showed a much enhanced processability and we could prepare super high $M_n$ of PBDT-Cl for device fabrication. The PCEs dramatically increased from 9.03% for PBDT-H:Y6 to 12.68% for PBDT-F:Y6 and 15.11% PBDT-Cl:Y6 based OPV devices. To our best knowledge, the PCE over 15% is comparably high with state-of-the-art highly efficient binary OPVs.

SESSION S.EL14.06: Advanced Characterization for Excited States

Advances in the Theoretical Description of Nonfullerene-Based Organic Solar Cells

Jean-Luc Bredas1,2; 1Georgia Institute of Technology, United States; 2The University of Arizona, United States

The field of organic photovoltaics is currently enjoying a major resurgence thanks to the development of increasingly performant combinations of polymer donors and nonfullerene-based acceptors. Power conversation efficiencies now approach the 18% mark in single-junction devices.

In this contribution, we will provide a theoretical description of of the factors that have enabled such advances, including:
- hybridization of the strongly absorbing local-exciton electronic states with the charge-transfer electronic states appearing at the donor-acceptor interfaces [1-2];
- minimization of the voltage losses through reduction of the nonradiative recombination pathways [3]; and
- extent of order in the nonfullerene acceptor domains [4-5].

This work is supported by the Office of Naval Research.

5:30 AM *S.EL14.06.04
In Situ Transient Absorption Spectroscopy During the Formation of Organic Thin Films Cathy Y. Wong; University of Oregon, United States

The electronic structure and exciton dynamics of the molecules and polymers that form the active layer in organic electronic devices can change dramatically during solution deposition. As solvent vaporizes, molecules aggregate and become electronically coupled, sometimes dramatically changing the exciton dynamics and thus the suitability of the material for electronic devices. The exciton dynamics of molecules in solution and in films of aggregates can be measured using transient absorption spectroscopy. However, the progression of exciton dynamics during film formation is unknown since measurements typically cannot be performed quickly enough to collect accurate transient absorption spectra of these species. The exciton dynamics of evolving material systems can be measured by increasing the speed of data collection. A novel implementation of transient absorption spectroscopy is introduced that can measure transient spectra with up to a 60 ps pump-probe time delay in one shot. The exciton dynamics of intermediate aggregation states are revealed during the formation of an organic film. The information gained using this technique can be used to modify environmental parameters during the film formation process to kinetically trap aggregates with exciton dynamics tailored for particular types of electronic devices.

6:00 AM S.EL14.06.05
Probing Self-Assembly of Intra-Molecular Singlet-Fission Materials David J. Jones; University of Melbourne, Australia

Multiple exciton generation (MEG) through singlet fission (SF) is a spin allowed process whereby a singlet excited state is split into two triplet excitons. Inclusion of SF chromophores into solar cells raises the maximum theoretical efficiency of a solar cell from the Shockley-Queisser limit of 33% to around 45% by effectively harvesting the energy from high energy photons.

We have been examining self-assembly of intra-molecular singlet fission materials as a pathway to control local energy landscapes and assist the dephasing of the correlated triplet pair [1,2]. Decoupling “isolated” triplet generation from the initially generated correlated triplet pair remains a significant issue as long lived “dephased” triplets allow for a higher chance of exciton harvesting. We have demonstrated high solid-state SF yield (170%) in solution processed intra-molecular SF materials, with isolated triplet lifetimes in the microseconds [2], using pi-pi-stacking to generate hexagonal columnar structures with the diketopyrrolopyrrole (TDPP) triplet host chromophores on the outside of the stacks. New transient EPR measurements indicate support for a S1→1(TT)→5(T-T)→ T3+T3 mechanism, that is a pathway to the quintet coupled triplet pair, then to the isolated triplets from the initially generated correlated triplet pair. In this presentation we will discuss the recent results from our structure property studies in the impact of self-assembly on SF yield and triplet lifetimes.

Exploring Additive Effects on Charge Generation in a PM6:Y6 Organic Solar Cells

Awwad N. Alotaibi1, Xaiobo Zhou2, Brian A. Collins1,2 and Ma Wei2; 1Washington State University, United States; 2Xi'an Jiaotong University, China

Organic solar cells (OSCs) are promising as an alternative solar energy technology and their efficiencies are continuously increasing, with record power conversion efficiency at ~ 17%. The processes involved in charge generation and recombination in the bulk heterojunction active layer govern device performance. However, these processes are all entangled and hard to measure quantitatively, which limits progress in optimizing the ultimate performance. We use time delay collection field (TDCF) to disentangle and fully quantify each process occurring in the current record OSC system PM6:Y6 as a function of processing co-solvent, chloronaphthalene, concentration. TDCF is an advanced charge extraction technique that can separate charge generation and recombination processes. We use this to measure generation current, recombination current, and extraction current all at the operating condition of the OSC devices, fully quantifying each loss process. A field dependence of charge generation indicates geminate recombination and our measurements show that the additive eliminates this loss process in PM6:Y6. We additionally vary the excitation wavelength to selectively excite the accepter and the donor molecules. Our initial result suggests that the excited Y6 acceptor generates relatively less charge than the PM6 donor. This new understanding of charge generation and recombination processes will help in design of new materials and optimization of device fabrication for high-performance, economical, and massively scalable solar power.

Towards In Situ Measurement of Nanostructure Dynamics During Ion Transport within a Conducting Polymer

Tamanna T. Khan1, Terry McAfee1,2, Thomas Ferron1 and Brian A. Collins1; 1Washington State University, United States; 2Lawrence Berkeley National Laboratory, United States

Ion transport in organic materials is attracting tremendous attention due to the possibilities in applications such as electrochemical transistors, bioelectronics, sensors, soft robotics, and printed electronics. Poly(3,4-ethylenedioxythiophene) doped with poly(styrenesulfonate) (PEDOT:PSS) shows promise as an ion transport material and has been integrated into biomedical applications while the nano-structure that enables this property is still unknown. Our previous study utilized Resonant Soft X-ray Scattering (RSoXS) which affords orders of magnitude higher contrast at an elemental absorption edge than electron or nonresonant X-ray techniques. There we showed the morphology consists of PEDOT-rich gel particles embedded within a PSS matrix and upon the addition of a co-solvent (Ethylene glycol) the PEDOT domains swell which was found to correlate with a reduction in ion flow. However, the measured nanostructures were dry and undoped, which do not directly demonstrate which domain facilitates ion flow. Here we will present our progress toward an in-situ RSoXS investigation of a PEDOT:PSS electrochemical transistor during ion transport. We will utilize an in-vacuum, microfluidic sample environment that is compatible with the newly developed RSoXS liquid-chamber at the Advanced Light Source. To achieve this goal, we modified the electrochemical device architecture and replaced the insulating ion barrier with no appreciable reduction in ion transport capabilities. Additionally, the fabrication of a miniaturized device on a micro-electromechanical system (MEMS) chip is under development. Understanding how the ions interact with the nano-structure to transduce an electric signal will enable these devices to potentially use in next generation medical devices.

Imaging the Spatial Distribution of Molecular Dopants in Organic Semiconductors at High Spatial Resolution Using Electron Microscopy

Gustav Persson, Sepideh Zokaei, Renée Kroon, Christian Muller and Eva M. Olsson; Chalmers University of Technology, Sweden

Electronic devices based on organic semiconductors have great potential for future applications in devices for energy harvesting and electronics due to low costs, mechanical flexibility and tunable properties. Molecular doping of organic semiconductors is fundamental in order to optimize their electronic properties in high performance devices such as photovoltaic cells, thermoelectrics or light emitting diodes. However, the spatial distribution of these dopants is not completely controlled.[1] Previous studies have shown how density, distribution and diffusion of dopants can significantly affect electronic properties, disrupt the microstructure[2] and decrease long term stability of the host polymer.[3]

Electron microscopy has been used successfully in multiple studies characterizing organic semiconducting materials and extracting information with high spatial resolution. However, crucial information about the distribution of dopants and its dependence of the structure of the surrounding material still remains to be investigated with high spatial resolution. This work addresses the fine scale distribution of molecular dopants in a polar polythiophene with oligoethylene glycol side chains.
chains. The microstructure of the system and the distribution of dopants will be correlated to electronic properties at different doping concentrations. Concepts on how to control the distribution of the dopants will be presented.

**Key Factors Study in Amphiphilic Block Copolymer-Oriented Porous SnO₂ Synthesis Process** Shanshan Yin¹, Peter Muller-Buschbaum¹,² and Stephan V. Roth¹,⁴; ¹Technische Universität München, Germany; ²Heinz Maier-Leibnitz Zentrum, Germany; ³KTH Royal Institute of Technology, Sweden; ⁴Deutsches Elektronen-Synchrotron DESY, Germany

SnO₂, as a crucial material in the field of energy storage, has always been the focus of scientific research. For organic-inorganic halide perovskite solar cells (PSCs) or dye-sensitized solar cells (DSSCs), SnO₂ affords high electron mobility and superior chemical stability amongst the various metal oxides. Moreover, as an alternative anode material for lithium-ion battery, it possesses a decent theoretical specific capacity of 1494 mAhg⁻¹. Compared with conventional bulk materials, mesoporous SnO₂ with high specific surface area affords more advantages when applied on either solar cells or lithium-ion batteries. By introducing the mesoporous structure, the recombination of injected electrons within the electron transport layer of the solar cell can be effectively inhibited. Furthermore, with this unique mesoporous structure, the structural collapse of lithium-ion battery anode provoked by significant volume expansion can also be effectively alleviated during the cycling process. In the present work, a novel amphiphilic block copolymer assisted sol-gel chemistry is used for the synthesis of porous SnO₂ nanostructure. Different kinds of solvent are used as a good solvent for both PS and PEO polymer chains, HCl is a selective poor solvent for PS chains and catalyst for the hydrolytic condensation reaction of SnO₂ precursor. With the progressive addition of HCl, the stretch of the hydrophobic PS chains is significantly restricted. As a result, different micelle structures of the block polymer are formed in the sol-gel solution, and the simultaneously hydrolysed SnO₂ nano-dot array is specifically confined in the PEO domains by hydrogen-bond interaction. With the evaporation of the solvent during spin-coating and annealing process, a distinct phase-separated SnO₂/PS-b-PEO composite thin film is obtained on the silicon substrate. For removing the organic polymer template, the composite thin film is calcined at 500 °C for two hours under ambient condition. The obtained nanostructure is visualized by scanning electron microscope (SEM). Crystallinity is characterized by X-ray diffraction (XRD). The buried structure within the thin film is investigated with grazing-incidence small-angle X-ray scattering (GISAXS) measurement.

**Near-IR Dual Luminescent Single Layer OLEDs** Sebastian Hammer¹, Thomas Ferschke¹, Gabriel Freiherr von Eyb¹ and Jens Pflaum¹,²; ¹Julius-Maximilian-University Würzburg, Germany; ²The Bavarian Center for Applied Energy Research, Germany

Multi-color organic light emitting diodes (OLEDs) comprising just one active electro-optical material define the next vital step in the fast-developing field of photonic devices for optical data communication. Taking into account the spectral range of relevant transmission windows as well as the feasibility of coupling light to plasmonic nanostructures, an OLED device emitting at different wavelengths in the near infra-red (NIR) would be highly desirable. In this contribution we cope with these challenges by demonstrating a stable, dual luminescent OLED based on just one electro-optical active zinc phthalocyanine (ZnPc) layer [1]. ZnPc turns out to be a promising candidate for such single layer devices due to its different polymorphs [2] combined with specific emission characteristics, its photo-stability as well as luminescence in the long wavelength range between 800 and 900 nm which allows for efficient coupling to plasmonic excitations in metallic nanostructures [3]. Performing photoluminescence (PL) studies on ZnPc thin films over the full course of the phase transition between α- and β-polymorph, we are able to optically monitor the thermally induced structural changes and their impact on the respective emission over time. The Johnson-Mehl-Kolmogorov-Avrami model [4] can consistently describe the observed behavior of the transition kinetics derived by the distinct emission features of the involved α- and β-polymorphs. In combination with complementary structural studies and temperature dependent PL measurements from 4 K - 360 K this enables us to provide a comprehensive picture of the excited state emission and its correlation to the crystalline packing on molecular length scales. *Vice versa*, we exploit these morphology dependent emission characteristics to demonstrate a prototypical dual luminescent OLED comprising just one active layer of ZnPc. As will be shown, the emission properties can be spectrally
tuned on demand between the excimer emission of the α-phase at 930 nm and the Frenkel emission of the β-phase at 780 nm by a suited thermal treatment. Considering the long-term stability of the adjusted spectral intensity distribution of the devices our work presents an approach towards simple organic photonic devices being of interest for future optical information technology.

S.EL14.07.10
Time Resolved GIWAXS of PEDOT:PSS During Electrolyte Gating Bryan D. Paulsen1, Ruiheng Wu1, Christopher J. Takacs2, Joseph Strzaika1, Qingteng Zhang1 and Jonathan Rivnay1; 1Northwestern University, United States; 2Stanford Synchrotron Radiation Lightsource, United States; 3Argonne National Laboratory, United States

Electrochemical control of electronic charge (electrolyte gating) has opened a broad array of applications for organic electronic materials including printed electronics, biosensors, neuromorphics, electrochromics, supercapacitors, and actuators to name a few. Structure-property relationships are critical for the advancement of these materials across application. Because electrolyte gating necessarily requires dynamic ion and solvent intercalation and expulsion during device operation, static structural measurements, including steady-state in situ and operando measurements, are critically limited. Understanding electrolyte gated organic materials requires understanding their dynamic structure, which in turn requires time-resolved in situ or operando techniques. Grazing incident wide angle X-ray scattering is a powerful tool to for accessing the microstructure of organic electronic materials. In particular, PEDOT:PSS is ubiquitous in organic electrolyte gated devices. Here the dynamic time-resolved operando GIWAXS of acid crystallized PEDOT:PSS films during aqueous electrolyte gating is reported. The majority of the structural transformation occurs over a narrow range of potential and the doping-dedoping structure dynamics are not symmetric, displaying very different time dependences. Coupling the time-resolved operando GIWAXS with time-resolved UV-vis-NIR reveals that the PEDOT:PSS structure depends not on the absolute charge density, but on the relative population dynamics of neutral, polaronic, and bipolaronic species. Even after the relative populations of charge species equilibrates, time-resolved GIWAXS shows continued long-lived structural relaxations. This complicated phenomena, which is inaccessible with steady-state ex situ, in situ, or operando methods, gives a concrete physical origin of the commonly observed asymmetry of electrolyte gated transistor turn on and turn off. Further it identifies the structural origin of the rate limiting physical processes to be targeted for rational materials design. Finally, this work represents the first report time-resolved X-ray scattering of an organic electronic material during electrochemical gating.

Toward Fundamental Limits of Ga2O3 Power Devices Huili G. Xing, Wenshen Li and Debdeep Jena; Cornell University, United States

Ga2O3, as a very wide bandgap semiconductor, promises a very high critical breakdown field. The theoretically estimated breakdown field is about 8 MV/cm, and the experimentally observed values are as high as 5.4 to 5.9 MV/cm to date. To take full advantage of the bandgap of Ga2O3, it is necessary to manage the electric field distribution in a Ga2O3 device to be as slow-changing as possible. In this talk, I will review various strategies and their underlying physical principles to manage the field distribution. With these strategies, record high figure-of-merits BV^2/Ron have been demonstrated in Ga2O3 Schottky barrier diodes and fin-transistors [1,2].

Ultra-Wide Bandgap 2D Materials—Challenges and New Approaches Joan M. Redwing1, Anushka Bansal1 and Zakaria Al Balushi2; 1The Pennsylvania State University, United States; 2University of California, Berkeley, United States

There is growing interest in wide and ultra-wide bandgap 2D materials such as hexagonal boron nitride (hBN) to serve as dielectric encapsulation layers for 2D heterostructures, as a host matrix for single photon emitters and as an integral part of III-nitride heterostructure devices. In the case of hBN, flakes and films have been formed by exfoliation of bulk crystals and CVD growth on metal substrates, respectively, but further advances are needed to realize wafer-scale single crystal films and expand the available range of wide bandgap 2D materials.

Our studies have focused on epitaxial growth of hBN and other 2D nitride layers by metalorganic chemical vapor deposition (MOCVD). High temperature epitaxial growth of hBN on c-plane sapphire was investigated using B2H6 and NH3 precursors to achieve high purity films. Gas phase pre-reactions between B2H6 and NH3 result in a significantly reduced growth rate for hBN at 1350°C and 50 Torr in a H2 carrier gas. Sequential precursor pulsing was used to minimize gas phase mixing and enable the growth of films with controlled thicknesses ranging from 5-100 nm. The hBN films on sapphire were subsequently used as templates for epitaxial growth of 2D transitional metal dichalcogenides such as MoS2 and WS2. We have also investigated novel methods to stabilize 2D forms of conventional III-nitride materials such as GaN. This process uses controlled intercalation and reaction of group III and V precursors within the interfacial region of quasi-free standing epitaxial graphene formed on SiC to form stable ultrathin GaNx films. The graphene capping layer provides thermodynamic stabilization of a unique R3m structure as identified by aberration-corrected scanning transmission electron microscopy. Density functional theory predicts a bandgap energy in the range of 4.79-4.89 eV for this structure which correlates well with experimental results from UV-visible reflectance and absorption measurements. The realization of few layer films of group III-nitrides would broaden the range of accessible bandgap energies of 2D materials providing new avenues for scientific exploration and electronic/optoelectronic device development.

11:25 AM *S.EL15.05.01
Dependence of Critical Electric Field on Semiconductor Bandgap—An Analytical Study Mark A. Hollis¹, Oleksiy Slobodyan², Jack Flicker², Jeremy Dickerson², Andrew Bender², Trevor Smith² and Robert J. Kaplar²; ¹MIT Lincoln Laboratory, United States; ²Sandia National Laboratories, United States
An accurate understanding of the critical electric breakdown field ($E_{\text{crit}}$) characterizing semiconductor materials is necessary for the design of power switches, power diodes, and RF power transistors. It is particularly important to understand the dependence of $E_{\text{crit}}$ on bandgap ($E_g$) as new ultrawide-bandgap materials are developed. Unfortunately, the reported dependencies of $E_{\text{crit}}$ on $E_g$ cover a surprisingly wide range in the literature. Moreover, while $E_{\text{crit}}$ is often assumed to be constant for a given material, it is more accurately a function of the device depletion-region width and doping. Further, there are wide discrepancies in the literature where $E_{\text{crit}}$ values for punch-through and non-punch-through structures are compared without regard for these differences. We report a new normalization procedure that enables an equivalent comparison of $E_{\text{crit}}$ values across materials, doping, and punch-through/non-punch-through device types. An extensive examination of many experimental avalanche-breakdown and ionization references reveals that the dependence $E_{\text{crit}} \sim E_g^{1.86}$ best fits the most reliable and newest data for both direct and indirect semiconductors over the range from $E_g = 0.66$ to 5.5 eV (comprising Ge, Si, InP, GaAs, 4H-SiC, GaN, and diamond). It may therefore be reasonable to use this $E_{\text{crit}} \sim E_g^{1.86}$ dependence as an approximate rule of thumb for predicting the critical electric fields of novel ultrawide-bandgap materials until precise measurements are made. Based on the $E_{\text{crit}} \sim E_g^{1.86}$ dependence, the relationship between specific on-resistance ($R_{\text{ON,sp}}$), breakdown voltage ($V_{\text{BD}}$), and $E_g$ for power switches over this bandgap range is best described by $R_{\text{ON,sp}} \sim V_{\text{BD}}^2 E_g^{-5.58}$ for both direct- and indirect-gap semiconductors.
