SESSION GG1: FROM CHIPS TO CONCRETE
Chair: Marcel Ausloos
Wednesday, April 26, 2000
City (Argent.)

9:00 AM GG1.1
CAUSES AND PREVENTION OF CATASTROPHIC CHIP FAILURE. Andrea N. Grant and Robert F. Cook, University of Minnesota, Department of Chemical Engineering and Materials Science, Minneapolis, MN.

Almost never is the failure of an integrated circuit taken to mean the complete fracture of the silicon chip on which the circuits are built. Failures can be inherent (e.g., mis-processing, in which case the user never sees the chip), transient (e.g., radiation damage, in which case the user turns the machine off and on again to clear the soft error) or localized (e.g., electromigration damage, in which case the user perceives a degradation in machine performance). But, never catastrophic. Moreover, moves towards chip-scale packaging and greater temperature excursions during circuit operation lead to complete chip fracture as the possible dominant failure mechanism. While not as spectacular as an earthquake, the effects on transportation, telecommunications and commerce could be just as devastating. In this study, the stress on chips in small packages during thermal cycling is examined in the context of the mechanical damage generated in chips during processing and the likely fracture response of Si. In particular, sharp particle contact damage on the (100) and (110) surfaces of Si and the conditions for initiation of catastrophic cleavage fracture in chips in small polymeric packages are considered. Consideration is also given to cases in which the catastrophic cleavage of Si might be a good thing.

INFRASTRUCTURE AND ARCHITECTURAL SAFETY. Rudolph V. Manahaus, Sandia National Laboratories, Albuquerque, NM.

The mission of the Architectural Safety Symposia program at Sandia National Laboratories is to assure the performance of buildings, facilities, and other infrastructure systems under normal, abnormal, and malicious threats through educational outreach, efforts in the classroom, at conferences, and presentations such as this one. Public and professional awareness of the need to design and mitigate such threats is increased. Buildings, airports, utilities, and other kinds of infrastructure deteriorate over time, as evidenced most dramatically by our crumbling cities and aging buildings, bridges, and other facility systems. Natural disasters such as tornadoes, earthquakes, hurricanes, and flooding also stress the materials and structural elements of our built environment. In addition, criminals, vandals, and terrorists attack our federal buildings, dams, bridges, tunnels, and other public and private facilities. Engineers and architects are beginning to systematically consider these threats during the design, construction, and retrofit phases of buildings and infrastructures and are recommending advanced research in new materials and techniques. Existing building codes and standards do not adequately design to nor protect our infrastructure or the public from many of these emerging threats. The activities in Sandia’s Architectural Safety Symposium efforts take a risk management approach to enhancing the safety, security, and reliability of our constructed environment. The technologies and techniques developed during Sandia’s 50 years as the nation’s lead laboratory for nuclear weapons safety are now being applied to assessing and reducing the vulnerability of dams, to enhancing the safety and security of our staff in foreign embassies, and ensuring the reliability of other federal facilities. High consequence safety engineering and design brings together technological advancements, new material requirements, systems integration, and risk management to improve the safety, security, and reliability of our re-built environment.

CRITICAL MATERIALS ISSUES IN MODERN REACTOR SAFETY. Dana A. Power, Sandia National Laboratories, Albuquerque, NM.

Nuclear power currently supplies about 20% of the nation’s electrical needs. The nuclear power production industry is going through evolutions that will lead to greater efficiency and competitiveness. Many changes in the nuclear power industry are limited by materials. Materials issues can be especially troublesome as efforts are made to extend the operating licenses of nuclear power plants. Some of these critical materials issues are discussed in the paper including fuel cladding for extended fuel burnup, flaw distributions used in probabilistic fracture mechanics analysis of reactor pressure vessels, void swelling in irradiated austenitic stainless steels, problems of detecting and sizing flaws in steam generators, and issues of predicting flow accelerated corrosion. The paper will conclude with a discussion of the needs for better materials in future nuclear power plants.

SESSION GG2: FROM BATTLESHIPS TO CONFLAGRATIONS

2:00 PM *GG2.1
EXPLOSION ABOARD THE BATTLESHIP USS IOWA. Richard L. Schwebel.

An open breach explosion in a 16-inch gun aboard the battleship USS IOWA killed 47 crew members on April 19, 1989. An investigation by the US Navy concluded that the explosion could not have been an accident, but that it was probably the result of an intentional act by a member of the ship’s crew. The Navy investigators supported these conclusions with evidence of foreign materials on the rotating band of the projectile. They associated these foreign materials with residues of an improvised chemical ignition device, and believed that the device was initiated by an intentional breach into the breech of the gun. Committees of both the House and Senate held hearings on the Navy’s investigation and questioned their conclusions. An outgrowth of those hearings, the Senate Armed Services Committee asked Sandia National Laboratories to conduct an independent investigation of the explosion and the Navy’s conclusions. The Sandia investigation determined that the foreign materials identified by the Navy were common to several areas of battleship turrets and 16-inch projectiles. This included residues of calcium chloride, various glycol and ion fibers. Furthermore, some of these same residues were found on regions of the projectile protected from the explosion. Sandia concluded that there was no explicit evidence that a chemical ignition device was present in the breech of the gun. The independent investigation also revealed that a high-speed overram of the propellant could initiate an explosion by a previously unknown mechanism. This mechanism was related to the crushing of propellant pellets and the emission of burning particles from projectile surfaces. Full-scale experiments using a 16-inch configuration demonstrated that explosions would result with various probabilities depending on the overram speed. It was concluded that the explosion aboard the USS IOWA could have resulted from an inadvertent high speed overram of the propellant, perhaps associated with confusion and inexperience of crewmen in the center gun room. Some ‘lessons learned’ from this investigation have been identified and will be discussed.

WEAPONS MATERIALS. Georges Michelet, Xavier Garage, FN Herstal, Herstal, BELGIUM.
Since many years, firearm’s design has been based on extensive use of traditional metallic materials. Regarding operating conditions severity, it was a comfortable position. In the last fifteen years, user's requirements were growing (weight budget, cost reduction, etc.) and designers had to consider potential use of new materials. During P90 sub-machine-gun design, introduction of reinforced fiber composites like polyethylene fibre XRF induced design methodology reconsideration. It was the first use of a material having highly temperature sensitive mechanical characteristics. As environmental temperature became a key factor, failure modes analysis and performance assessment methods needed to be reviewed. Those changes brought use of new scientific tools during design stage like structural dynamic analysis (experimental and finite elements computation); fatigue computation; mechanical simulation, etc. Testing programs and methods were also adapted in order to put in evidence the environment effects on product performance. Thanks to this design process reengineering, performance goals have been achieved and user's safety was preserved.

**FORENSICS OF FIRE-EXPLODED MATERIALS.** Remi Gérald, University of Michigan, Ann Arbor, MI; David W. Pettit, Stryker Consultants, East Syracuse, NY.

The determination of causes of fire damage to buildings and other large-scale structures often requires detailed materials analysis and characterization of individual fire-exposed components, ranging from massive structural members to the smallest constituents of electrical/electronic packages. Fire investigation includes not only examination of functional performance but also environmental exposure. Post-mortem reports of burning fires have often implicated fluorescent lighting systems as a possible fire cause, especially the ballast components in which the transformer assembly steps up the 110-120V line to around 200V for efficient but heat-producing operation. We have investigated dozens of fires in which blame has been initially associated with ballast components, but have found only one unusual case in which ballast performance was causative. Forensic examination, laboratory control experiments, and thermodynamic and kinetic analyses have demonstrated the growth of copper sulfide whiskers on copper transformer wires provides unambiguous evidence in cases in which ballasts are blameworthy. We hope our findings will also be useful in other lines of research.

**TOWARDS THE UNDERSTANDING OF THE THERMAL DEGRADATION OF COMMERCIALLY AVAILABLE FIRE-RESISTANT CABLE.** Catherine Henri, A. Buhlert, R. Cloots, Department of Inorganic and Structural Chemistry, University of Liege, BELGIUM; B. Gilbert, Department of Analytical Chemistry, University of Liege, BELGIUM; A. Bernard, Department of Geochemistry, University of Brussels, BELGIUM; G. Beyer, Kabweker Epen, Epen, BELGIUM.

Recent studies related to the processing of commercially available fire-resistant cables have been concerned by the effects of addition of zinc borate and alumina hydrate to the polymer matrix in order to achieve good flame-retardant properties. We report here on microscopic investigations on such cables submitted to different heat treatments. This allows us to get information about the structural modifications and some understanding on the degradation of the electrical properties. We conclude with a short proposal to improve its efficiency.

**STATISTICS OF AVALANCHE AS FAILURE PRECURSORS.** Stéphane Roux, Centre de Recherche CNRS/Saint-Gobain, Aubervilliers, FRANCE.

We consider the development of damage in quasibrittle heterogeneous materials, up to the occurrence of failure. Various statistical models have been developed in this context, from one-dimensional or mean field models such as the fiber bundle model which can be solved analytically, to higher dimensionality models which can be studied numerically. Generally these models give rise to unstable breakdown events called "avalanches". The height of the avalanche may display a size distribution which gives some information on the variability of the global failure of the system. In particular, avalanche sizes are power-law distributed with a universal exponent, up to a maximum avalanche size which diverges as the global failure point is approached. Such a behavior is formally reminiscent of critical phenomena where global failure plays the role of the critical point. This scenario is discussed in relation with the concept of self-organized criticality. Enlarging the scope of the models, such a statistics of avalanches can be applied to a wide variety of "pinning" phenomena, and traced back to the statistics of microscopic driving force fluctuations. In this framework, two different features can account for the algebraic form of avalanches: one is the statistical distribution of the driving force itself, and the second is the time correlations which are present in the driving force signal. Extensions to crack propagation and other failure models are discussed. Other related models of thermally activated damage, which exhibits precursor signs to global failure, will also be discussed.

**HUMIDITY-INDUCED COHESION EFFECTS IN GRANULAR MEDIA.** Nathalie Froyssé, Luc Petit, Laboratoire de Physique de la Matière Condensée, Nice, FRANCE.

Despite the significance and the frequency of humidity effects on granular materials, the knowledge of these effects rests mainly on phenomenological and most of the time only qualitative observations. We have performed experiments under accurately controlled humidity conditions in order to quantify such moisture-induced effects. We report the measurements of the maximal stability angle and the repose angle of a pile made of small glass beads, as a function of the relative vapor pressure, up to close to saturation. The influence of the wetting properties of the interstitial liquid on the grains was investigated; the comparison of the results obtained with water and heptane shows that the wetting properties have a strong influence on the cohesion of the non-saturated granular medium. Several experiments have been undertaken in order to obtain information on the liquid bridges that form between grains and give rise to cohesion of the granular medium. Our aim is to understand the close connection that exists through interparticle forces, between microscopic properties such as wetting properties and surface roughness of the grains, and global scale properties of the pile, as its stability and flowability.

**EXPERIMENTAL STUDY OF INSTABILITY OF LARGE STRAIN FLOW IN DENSE GRANULAR MATERIAL.** Vitalii Nesterenko, Dept. of Mechanical and Aerospace Engineering, UC San Diego, CA; Richard Kloppe, Donald Shockey, Donald Curran and Thomas Cooper, SRI International, CA.

Large strain flow of dense granular materials created by fracture (catastrophic failure of initially solid ceramic is very important for ballistic performance of ceramic armor, penetration into dense rocks and concrete. There is a need for well characterized 2-D and 3-D experiments with dynamic flow of such materials to compare with existing theories and with the results of numerical modeling. Cavity expansion experiments (Kloppe, Shockey et al., 1996) and collapse tube experiments - Thick Walled Cylinder (TWC) method (Nesterenko, Meyers et al., 1996) provide data with controlled low and initial stress patterns under high dynamic pressure waves, in initial and developed stages of penetration process correspondingly. This presentation is focused on the results obtained with the help of thick-walled TWC method. In the experiments global hoop stress increases in the range 0-1.5GPa, and strain rates above 10^4/s. Shear localization was a primary mechanism accommodating large strains. Morphology of shear band was very different ranged from sharp crack-like to relatively broad areas with large local shear strains accompanied by comminution. Number of localized shear bands does not depend strongly on overall hoop strain in experiments. Comparison of experimental results with results of numerical simulations based on FRAGIMID model (Curran et al. 1993, 1998) and the possibility to convert TWC approach into truly 3-D method by introducing a highly tapered geometry of experiment with large angle of the central rod will be discussed.

**DEM APPLICATION TO MIXING AND SEGREGATION MODEL IN INDUSTRIAL BLENDING SYSTEM.** Kenji Yamane, Taiho Pharmaceutical Co., Ltd, Quality Control Dept, Tokushima, JAPAN.

To predict the motion of powders and grains is important in pharmaceutical industries. Many pharmaceutical engineers have studied granular flows related to powder mixing. In this study, DEM (Discrete Element Method) approach is presented as an industrial application to investigate the behavior of granular flows. The granular motion in a rotating cylinder was focused on the basic study of DEM for industrial application. Rotating cylinder is a fundamental system for commercial blenders widely used in many industrial processes. In addition, segregation of particles in an industrial blender is very interesting phenomenon. Not only industrial engineers but also physicists study this segregation mechanism. DEM simulation showed...
radial segregation of two different size particles in a rotating cylinder. From the viewpoint of calculated granular temperature, radial segregation analysis was analyzed. Particle migration in axial direction, which is the source for axial segregation, was also shown by DEM simulation.

9:45 AM *GG3.5/B7.5* HOW SANDCASTLES FALL. THE CRITICAL ANGLE OF WET SANDPILES. Thomas G. Mason, Denis Ertas, Thomas C. Halsey, Exxon Research and Engineering, Annandale, NJ; Alex J. Levine, University of Pennsylvania, Dept. of Physics, Philadelphia, PA.

Capillary forces induced by small quantities of liquid significantly affect the stability of sandpiles, which makes possible the construction of sandcastles at all. We determine the maximum angle of stability of sandpiles as a function of liquid content, theoretically and experimentally. This angle becomes system size dependent in the presence of cohesive forces, as is well known in soil mechanics. The increase in the liquid content is associated with an increase in the size of the bridge formed by the surface roughness of the particles, as well as by the surface tension of the added fluid, and exhibits three regimes as a function of the added-fluid volume. Theoretical results are in good agreement with experimental observations, which include confocal microscopy of the fluid-filled particle contact regions.

10:30 AM *GG3.6/B7.6* NEW METHODS FOR SNOW AVALANCHE RISK MANAGEMENT AND FORECASTING. P. Bartelt, Swiss Federal Institute for Snow and Avalanche Research. FLUMEN, Davos Dorf, SWITZERLAND.

The Swiss Federal Institute for Snow and Avalanche Research is responsible for developing technical and organizational measures to prevent avalanche disasters. The institute is divided into two basic sections. The first is the operational avalanche warning service. This unit not only determines the avalanche danger on a day-to-day basis, but is also responsible for developing information transfer tools that can be used by avalanche professionals at the local level. The second unit is a research group that studies physics of snow and avalanches. As part of this research, avalanche dynamics models have been developed that track the motion of flowing and powder snow avalanches. These models are used by local communities to prepare hazard maps that delimit land into red (high danger), blue (medium danger) and white (no danger) zones. Numerical models have also been developed to track the development of the snowpack over time. In this presentation we will give a brief overview of the institute and talk about new methodologies (numerical models, forecasting models) that are being applied to prevent catastrophic avalanche disasters.

11:00 AM *GG3.7/B7.7* WETTING-TIME EFFECTS IN GRANULAR MEDIA. P. Schiffer, R. Alberti, A-L. Barnabasi, Dep. of Physics, University of Notre Dame, Notre Dame, IN; P. Tegzes, T. Vicsek, Department of Biological Physics, Eotvos University, HUNGARY.

While most studies of granular media focus on the properties of dry materials in which the intergranular forces are purely repulsive, the addition of a thin layer of a wetting fluid adds an attractive force to the system, leading to a new dimension to the understanding of physics. The physics of such a wet granular system is relatively unexplored, and there is no basic understanding of how interstitial liquid affects the granular properties. This problem is of great scientific interest and practical importance since granular materials relevant to many industrial applications often contain significant liquid between the grains. We investigate the effect of interstitial liquid on the physical properties of granular media both theoretically and experimentally by measuring the angle of repose as a function of the liquid content in a spherical granular medium. We find that large changes in the physical properties of granular materials can be induced by even a nanometer-scale layer of liquid micrometer-size grains. The liquid-induced adsorptive forces lead to three distinct regimes in the observed behavior as the liquid content is increased: a granular regime in which the grains move individually, a correlated regime in which the grains move in correlated clusters, and a plastic regime in which the grains flow coherently. The qualitative properties of the different regimes can be understood within the framework of two different proposed theories: the surface stability theory of Albert et al. and the bulk stability theory of Halsey and Levine.

11:30 AM *GG3.8/B7.8* TRANSPORT THROUGH PARTICULATE MATERIALS LIKE CONCRETE. Piet Stroeven, Faculty of Civil Engineering and Geoscience, Delft University of Technology, Delft, THE NETHERLANDS.

Cementitious composites are based on a particular skeleton of a wide range of particle sizes, from the sub-millimeter to the decimeter range. Ideally, the open space between such particles is filled up by a cementitious binder, which is in the mixing stage a hurray of particles dispersed in water. Size of the [blended] cement particles can range from 1 to 100 µm, or more. Due to size segregation of the binder particles at the aggregate surfaces at the initial (fresh) state, a so-called interfacial transition zone (ITZ) is formed around the aggregate particles. Consequently, the grading of the cement particles (i.e., particle size distribution function) is a function of the distance to the aggregate particle's surface. A relatively porous ITZ is resulting, a feature maintained in the hardened state. Ingress of harmful substances in hardened concrete (as fluid) is promoted by the relatively high porosity in the ITZ, i.e., the presence of dense aggregate particles increases the path length, but the low density matrix is the favorable route. Currently, computer simulation studies are underway to study the character (such as the continuity) of the porosity in the interphase (as a function of water to cement ratio, cement fineness, etc.). But even when technological measures are taken to reduce the density (such as high performance concrete), the substances have to circumvent the particles. This paper will therefore focus on the common problem in transport phenomena in a granular material like concrete, i.e., the tortuosity in the transport route. An analytical solution based on stochastic notions will be presented. A similar solution could be used in aggregated matter of dense particles where the matrix is absent, like in sand, or sandy soils. It is interesting to note further, that the presented solution also describes the fracture surface generation of brittle fracture, which is controlled by the relative weakness of the ITZ. Hence, this solution can be on the basis of fracture mechanical estimates of strength properties.

SESSION GG4: FROM ENGINES TO ASTEROIDS

1:30 PM *GG4.1* STRUCTURAL FAILURE BY FATIGUE. PROBLEMS IN GAS TURBINE ENGINES AND CARCAGINE PROSTHESSES. Robert O. Ritchie, Department of Materials Science and Mineral Engineering, University of California, Berkeley, CA.

It is estimated that over 80% of all structural failures can be traced to mechanical fatigue, invariably in association with cyclic plasticity, sliding or physical contact (fretting or rolling contact fatigue), environmentally- assisted damage (corrosion fatigue), or elevated temperatures (creep-fatigue). Many of these fail so, as aircraft crashes or medical implant fractures, incur enormous financial costs and can involve significant loss of life. Indeed, the annual cost of such fatigue failures has been estimated to be between one and two billion dollars. From this presentation, we focus on the role of cyclic fatigue in two quite diverse safety-critical applications, namely, the premature failure of metallic engine components, e.g., blades and disks, in gas turbines in military aircraft due to high-cycle fatigue, and the mechanical fracture of ceramic heart valve prostheses implanted in the human body. Specifically, we will examine how such fatigue failures can be analyzed, from a materials (microstructure), mechanical (fracture mechanics) and chemical (corrosion) standpoint, and how a rational basis for prediction development can be developed to minimize the risk of further failures.

2:00 PM *GG4.2* DAMAGE AND FAILURE IN COMPLEX MICROSTRUCTURES. Elisabeth Bouchez, SRSIM, CEA-Saclay, Gif-sur-Yvette, FRANCE.

Microstructure is known to be the key to toughening, and hence, to a good understanding of damage and fracture mechanisms at the microstructural scale should help design tough materials. In this range of length scales, which is strongly material dependent - one has to look at the material as a disordered medium, and many interesting phenomena have been identified by means of computer simulations. The importance of understanding of the scaling properties of cracks is shown through various experiments and numerical simulations. Some observations have been made in metal melts, alloys, and their morphology has been compared to the ones observed in molecular dynamics simulations on amorphous materials [glasses and ceramics]. This morphology fits the small length scales morphology of fracture surfaces, which may be the result of stress waves induced along the crack front by the microstructural heterogeneities. The large
long-term cost effectiveness for non-traditional technologies, and commercial barriers, which must be converted to opportunities, allowing for recognition by approving authorities. There exist largely unrecognized highly effective coating systems for decades-long infrastructure corrosion protection. Thermal spray technology, used with appropriate automation, can form corrosion/erosion resistant coatings, such as galvanically active zinc and aluminum-zinc alloys, and high-molecular weight polymer blends as low-VOC (volatile organic compounds) compliant barrier coatings. In addition, lead oxide/mustard vitrifying glasses can be thermally sprayed to mitigate against the severe environmental problems associated with conventional surface preparation methods. Advanced corrosion protection systems will be outlined and discussed with reference to civil and military infrastructure survivability. This work is supported by NSF’s MRSEC Program, No. DMR-9629257.

4:15 PM GG4.6
THE IDEALITY OF FRACTURE MODES AT VARIOUS LENGTH SCALES FROM CORROSION, DIELECTRIC BREAKDOWN TO EARTHQUAKES AND ASTEROID IMPACTS: Valery P. Kiehl, Institute of Solid State Physics, Chernogolovka, Moscow District, RUSSIA

The remarkable finding of this work is the universal correlation between the starting stresses (currents) for different stages of plastic flow and fracture at various length scales of observations (from atomic-scale internal friction, electromigration, etc. to macroscopic yield stress I), then from the starting stresses for the first microcrack nucleation (corrosion) up to macrocrack nucleation (dielectric breakdown), geotechnical and planet faults, etc., in single or polycrystalline, disordered, composite or polymer samples, films, superconductors and ceramics, meteoroids, etc. under various tests (from the corrosion up to shock stresses and asteroid impact) and environments. The universal scaling of stresses (stresses’ currents) allows to forecast the safety margins of material and points to the crucial role of deformation stress in mechanisms of plasticity and to the strict chain of deformation stages: atomic/microcrack dislocation motion/multiplication and full stop, cell and grain boundary origin, the first microcrack nucleation and microcrack coalescence into macrocracks (macrofracture) up to the planet faults. It is the change in dislocation cross-slip parameters versus deformation stress that explains the above scaling and deformation structures up to fracture: at low stresses and high temperatures, in extremely pure samples or at low stress rates the wavy or diffuse slip originates the so-called ductile mode of failure with rough rupture surfaces; at high deformation stresses and low temperatures, in impure/disordered (polymer) crystals, at high stress rates the straight slip lines promote the so-called brittle fracture mode: the smooth surfaces with atomically smooth cleavage steps, kinks, river patterns, vacancy clusters or microdimples, etc. 1. V.P. Kiehl, Mser. Sci. Engr., 1993, 164A. p. 356.

3:45 PM GG4.5
LONG-TERM CORROSION PROTECTION OF INFRASTRUCTURAL STEEL BY THERMAL SPRAY TECHNOLOGY—AN APPROACH WHOSE TIME HAS COME. Herbert Herman, SUNY Stony Brook, Dept of Materials Science and Center for Thermal Spray Research, Stony Brook, NY.

The repair and maintenance (R&M) of transportation-related infrastructural steel is one of the most compelling challenges facing industrialized nations. Governmental funding for infrastructure remediation will increase dramatically, but means through which R&M are to be implemented remain mired in political and technical indecision. This problem has now become urgent due to catastrophic failures and from an arising recognition that bridges and related components of the transport system are inextricably tied to societal economic systems. Similar challenges are faced by military organizations, where tremendously increased expenses and time are expended in maintenance. There is thus an almost feverish activity aimed at addressing R&M questions. Coupled with the deterioration of structural steel is the removal of rust and previously applied paint. Traditional grid blasting results in unacceptable environmental lead pollution hazards and, repair programs designed to avoid these problems are costly, leading to severe delays in the repair cycle. It is essential to establish Strategies for Reduced Maintenance. Effective programs are limited by institutional barriers which are difficult to overcome, but must involve education and clear demonstrations of...
